Small-incision cholecystectomy is a surgical procedure in which the gallbladder is removed through a small abdominal incision, as the name implies. If needed, the surgical incision is extended to remove larger gallbladder stones. Drains may or may not be used. The short length hospital stay has been identified as a major advantage of this type of procedure (Brunicardi, 2019; Cameron & Cameron, 2020; Goldman & Schafer, 2019). The procedure is controversial because it limits exposure to all involved biliary structures.

Choledochostomy

Choledochostomy is reserved for the patient with acute cholecystitis who may be too ill to undergo a surgical procedure. This procedure involves making an incision in the common duct, usually for removal of stones. After the stones have been evacuated, a tube is usually inserted into the duct for drainage of bile until edema subsides. This tube is connected to gravity drainage tubing; the patient is monitored closely, and a laparoscopic cholecystectomy is planned for a future date after acute inflammation has resolved.

Surgical Cholecystostomy

Cholecystostomy is performed when the patient's condition precludes more extensive surgery or when an acute inflammatory reaction is severe. The gallbladder is surgically opened, stones and the bile or the purulent drainage are removed, and a drainage tube is secured with a purse-string suture. The drainage tube is connected to a drainage system to prevent bile from leaking around the tube or escaping into the peritoneal cavity. After recovery from the acute episode, the patient may return for subsequent laparoscopic cholecystectomy. Despite its lower risk, surgical cholecystostomy has a high mortality rate (reported to be as high as 10% to 30%) because of the underlying infectious disease process (Brunicardi, 2019; Cameron & Cameron, 2020; Feldman et al., 2016; Goldman & Schafer, 2019).

Percutaneous Cholecystostomy

Percutaneous cholecystostomy has been used in the treatment and diagnosis of acute cholecystitis in patients who are poor risks for any surgical procedure or for general anesthesia. This at-risk population may include patients with sepsis or severe cardiac, renal, pulmonary, or liver failure (Goldman & Shafer, 2019; Roberts, Plotnik, Chick, et al., 2019). Under local anesthesia, a fine needle is inserted through the abdominal wall and liver edge into the gallbladder under

the guidance of ultrasound or computed tomography (CT). Bile is aspirated to ensure adequate placement of the needle, and a catheter is inserted into the gallbladder to decompress the biliary tract. Almost immediate relief of pain and resolution of signs and symptoms of sepsis and cholecystitis have been reported with this procedure. Antibiotic agents are given before, during, and after the procedure.

Endoscopic Ultrasound

Endoscopic ultrasound (EUS) is a guided gallbladder drainage procedure that is an effective treatment option with success rates comparable to percutaneous drainage (Goldman & Shafer, 2019). EUS is described in more detail later in the chapter.

Gerontologic Considerations

Surgical intervention for disease of the biliary tract is the most common operative procedure performed in the older adult. Cholesterol saturation of bile increases with age because of increased hepatic secretion of cholesterol and decreased bile acid synthesis.

Although the incidence of gallstones increases with age, the older patient may not exhibit the typical symptoms of fever, pain, chills, and jaundice. Symptoms of biliary tract disease in the older adult may be accompanied or preceded by those of septic shock, which include oliguria, hypotension, changes in mental status, tachycardia, and tachypnea.

Although surgery in the older adult presents a risk because of preexisting associated diseases, the mortality rate from serious complications of biliary tract disease itself is also high. The risk of death and complications is increased in the older patient who undergoes emergency surgery for life-threatening disease of the biliary tract. Despite the presence of chronic illness in many older patients, elective cholecystectomy is usually well tolerated and can be carried out with low risk if expert assessment and care are provided before, during, and after the surgical procedure (Rothrock, 2019).

The higher risk of complications and shorter length of hospital stay make it essential that older patients and their family members receive specific information about signs and symptoms of complications and measures to prevent them.

NURSING PROCESS

The Patient Undergoing Surgery for Gallbladder Disease

Assessment

The patient undergoing surgical treatment of gallbladder disease is often admitted to the hospital or same-day surgery unit on the morning of surgery. Preadmission testing is often completed a week or longer before admission. At that time, the nurse educates the patient about the need to avoid smoking, to enhance pulmonary recovery postoperatively, and to avoid respiratory complications. The need to avoid aspirin, nonsteroidal antiinflammtory drugs, and other agents (over-the-counter medications and herbal remedies) that can alter coagulation and other biochemical processes is also emphasized.

Assessment should focus on the patient's respiratory status. If a traditional surgical approach is planned, the high abdominal incision required during surgery may interfere with full respiratory excursion. The nurse notes a history of smoking, previous respiratory problems, shallow respirations, a persistent or ineffective cough, and the presence of adventitious breath sounds. Nutritional status is evaluated through a dietary history and a general examination performed at the time of preadmission testing. The nurse also reviews previously obtained laboratory results to obtain information about the patient's nutritional status.

Diagnosis

NURSING DIAGNOSES

Based on the assessment data, major postoperative nursing diagnoses may include the following:

- Acute pain and discomfort associated with surgical incision
- Impaired gas exchange associated with the high abdominal surgical incision (if traditional surgical cholecystectomy was performed)
- Impaired skin integrity associated with altered biliary drainage after surgical intervention (if a T-tube was inserted because of retained stones in the common bile duct or another drainage device was employed)
- Impaired nutritional status associated with inadequate bile secretion
- Lack of knowledge about self-care activities associated with incision care, dietary modifications (if needed), medications, and reportable signs or symptoms (e.g., fever, bleeding, vomiting)

COLLABORATIVE PROBLEMS/POTENTIAL COMPLICATIONS

Potential complications may include the following:

- Bleeding
- GI symptoms (may be related to biliary leak or injury to the bowel)

Planning and Goals

The goals for the patient include relief of pain, adequate ventilation, intact skin and improved biliary drainage, optimal nutritional intake, absence of complications, and understanding of self-care routines.

Nursing Interventions

After recovery from anesthesia, the patient is placed in the low Fowler position. Fluids may be administered IV, and nasogastric suction (a nasogastric tube was probably inserted immediately before surgery for a nonlaparoscopic procedure) may be instituted to relieve abdominal distention. Water and other fluids are given within hours after laparoscopic procedures. A soft diet is started after bowel sounds return, which is usually the next day if the laparoscopic approach is used.

RELIEVING PAIN

The location of the subcostal incision in nonlaparoscopic gallbladder surgery often causes the patient to avoid turning and moving, to splint the affected site, and to take shallow breaths to prevent pain. Because full expansion of the lungs and gradually increased activity are necessary to prevent postoperative complications, the nurse administers analgesic agents as prescribed to relieve the pain and to help the patient turn, cough, breathe deeply, and ambulate as indicated. The use of a pillow or abdominal binder over the incision may reduce pain during these maneuvers.

IMPROVING RESPIRATORY STATUS

Patients undergoing biliary tract surgery are especially prone to pulmonary complications, as are all patients with upper abdominal incisions. Therefore, the nurse reminds the patient to take deep breaths and cough every hour to expand the lungs fully and prevent atelectasis. The early and consistent use of incentive spirometry also helps improve respiratory function. Early ambulation prevents pulmonary complications as well as other complications, such as venous thromboembolism (VTE) formation. Pulmonary complications are more likely to occur in patients who are older, those with obesity, and those with preexisting pulmonary disease.

MAINTAINING SKIN INTEGRITY AND PROMOTING BILIARY DRAINAGE

In patients who have undergone a cholecystostomy or choledochostomy, the drainage tube must be connected immediately to a drainage receptacle. The nurse should fasten the tubing to the dressings or to the patient's gown, with enough leeway for the patient to move without dislodging or kinking the tube. Because a drainage system remains attached when the patient is ambulating, the drainage bag may be placed in a bathrobe pocket or fastened so that it is below the waist or common duct level. If drains are used, the nurse changes the dressings as required.

After these surgical procedures, the patient is observed for indications of infection, leakage of bile into the peritoneal cavity, and obstruction of bile drainage. If bile is not draining properly, an obstruction is probably causing bile to be forced back into the liver and bloodstream. Because jaundice may result, the nurse should assess the color of the sclerae. The nurse should note and report right upper quadrant abdominal pain, nausea and vomiting, bile drainage around any drainage tube, clay-colored stools, and a change in vital signs.

Bile may continue to drain from the drainage tract in considerable quantities for some time, necessitating frequent changes of the outer dressings and protection of the skin from irritation (bile is corrosive to the skin).

To prevent total loss of bile, the surgeon may want the drainage tube (T-tube) or collection receptacle elevated above the level of the abdomen so that the bile drains externally only if pressure develops in the duct system. Every 24 hours, the nurse measures the bile collected and records the amount, color, and character of the drainage. After several days of drainage, the T-tube may be clamped for 1 hour before and after each meal to deliver bile to the duodenum to aid in digestion (Brunicardi, 2019; Cameron & Cameron, 2020; Townsend et al., 2016). Within 7 days to 3 weeks, the drainage tube is removed (Brunicardi, 2019; Cameron & Cameron, 2020; Townsend et al., 2016). The patient who goes home with a drainage tube in place requires instruction and reassurance about the function and care of the T-tube (Rothrock, 2019).

In all patients with biliary drainage, the nurse (or the patient, if at home) observes the color of stools daily. Urine and stool specimens may be sent to the laboratory for examination for bile pigments. In this way, it is possible to determine whether the bile pigment is disappearing from the blood and is draining again into the duodenum. Maintaining a careful record of fluid intake and output is important.

IMPROVING NUTRITIONAL STATUS

The nurse encourages the patient to eat a diet that is low in fats and high in carbohydrates and proteins immediately after surgery. At the time of hospital discharge, there are usually no special dietary instructions other than to maintain a healthy diet and avoid excessive fats. Fat restriction usually is lifted in 4 to 6 weeks, when the biliary ducts dilate to accommodate the volume of bile once held by the gallbladder and when the ampulla of Vater again functions effectively. After this time, when the patient eats fat, adequate bile will be released into the GI tract to emulsify the fats and allow their digestion. This is in contrast to the condition before surgery, when fats may not have been digested completely or adequately and flatulence may have occurred. One purpose of gallbladder surgery is to allow a normal diet.

MONITORING AND MANAGING POTENTIAL COMPLICATIONS

Bleeding may occur as a result of inadvertent puncture or injury to a major blood vessel. Postoperatively, the nurse closely monitors vital signs and inspects the surgical incisions and any drains for bleeding. The nurse also assesses the patient for increased tenderness and rigidity of the abdomen. If these signs and symptoms occur, they are reported to the surgeon. The patient and family are instructed to report any change in the color of stools, because this may indicate complications. GI symptoms, although not common, may occur with manipulation of the intestines during surgery.

After laparoscopic cholecystectomy, the nurse assesses the patient for anorexia, vomiting, pain, abdominal distension, and temperature elevation. These may indicate infection or disruption of the GI tract and should be reported to the surgeon promptly. Because the patient is discharged soon after laparoscopic surgery, the patient and family are instructed verbally and in writing about the importance of reporting these symptoms promptly. Nurses should consider implementing the teach-back method when educating patients and families to ensure that they are able to describe what they have been taught in their own words or perform a task as instructed (see Chapter 3 for discussion of the teach-back method).

PROMOTING HOME, COMMUNITY-BASED CARE, AND TRANSITIONAL CARE

Educating Patients About Self-Care. The nurse educates the patient about the medications that are prescribed (vitamins, anticholinergic and antispasmodic agents) and their actions. The nurse also informs the patient and family about symptoms that should be reported to the primary provider, including jaundice, dark urine, pale-colored stools, pruritus, and signs of inflammation and infection such as pain or fever.

Some patients report one to three bowel movements a day, which is a result of a continual trickle of bile through the choledochoduodenal junction after cholecystectomy. Usually, such frequency diminishes over a period of a few weeks to several months.

Chart 44-2  **PATIENT EDUCATION**

Managing Self-Care After Laparoscopic Cholecystectomy

The nurse instructs the patient about pain management, activity and exercise, wound care, nutrition, and follow-up care as described below.

Managing Pain

- You may experience pain or discomfort from the gas used to inflate your abdominal area during surgery. Sitting upright in bed or a chair, walking, or using a heating pad may ease the discomfort.
- Take analgesic medications as needed and as prescribed. Report to your surgeon if pain is unrelieved even with analgesic use.

Resuming Activity

- Begin light exercise (walking) immediately.
- Take a shower or bath after 1 or 2 days.
- Drive a car after 3 or 4 days.
- Avoid lifting objects exceeding 5 lb after surgery, usually for 1 week.
- Resume sexual activity when desired.

Caring for the Wound

- Check puncture site daily for signs of infection.
- Wash puncture site with mild soap and water.
- Allow special adhesive strips on the puncture site to fall off. Do not pull them off.

Resuming Eating

- Resume your normal diet.
- If you had fat intolerance before surgery, gradually add fat back into your diet in small increments.

Managing Follow-Up Care

- Make an appointment with your surgeon for 7 to 10 days after discharge.
- Call your surgeon if you experience any signs or symptoms of infection at or around the puncture site: redness, tenderness, swelling, heat, or drainage.
- Call your surgeon if you experience a fever of 37.7°C (100°F) or more for 2 consecutive days.
- Call your surgeon if you develop nausea, vomiting, or abdominal pain.

If a patient is discharged from the hospital with a drainage tube still in place, the patient and family need education about its management. The nurse educates them in proper care of the drainage tube and the importance of reporting promptly any changes in the amount or characteristics of drainage. Assistance in securing the appropriate dressings reduces the patient's anxiety about going home with the drain or tube still in place. Chart 44-2 provides additional details about patient education for managing self-care after laparoscopic cholecystectomy.

Continuing and Transitional Care. With sufficient support at home, most patients recover quickly from a cholecystectomy. However, some patients may require a referral for transitional or home care. The hospital nurse can help ease the unpredictability of the postoperative and postdischarge experience for patients by providing relevant patient education, prompt pain relief, and an attentive approach to the nursing care (Rothrock, 2019). During home visits, the nurse assesses the patient's physical status, especially wound healing, and progress toward recovery. Assessing the patient for adequacy of pain relief and pulmonary exercises is also important. If the patient has a drainage system in place, the nurse assesses it for patency and appropriate management by the patient and family. Assessing for signs of infection and educating the patient about the signs and symptoms of infection are also important nursing interventions. The patient's understanding of the therapeutic regimen (medications, gradual return to normal activities) is assessed, and previous education is reinforced. The nurse emphasizes the importance of keeping follow-up appointments and reminds the patient and family of the importance of participating in health promotion activities and recommended health screening.

Evaluation

Expected patient outcomes may include:

1. Reports decrease in pain
   a. Splints abdominal incision to decrease pain
   b. Avoids foods that cause pain
   c. Uses postoperative analgesia as prescribed
2. Demonstrates appropriate respiratory function
   a. Achieves full respiratory excursion, with deep inspiration and expiration
   b. Coughs effectively, using pillow to splint abdominal incision
   c. Uses postoperative analgesia as prescribed
   d. Exercises as prescribed (e.g., turns, ambulates)
3. Exhibits normal skin integrity around biliary drainage site (if applicable)

a. Is free of fever; abdominal pain; change in vital signs; and presence of bile, foul-smelling drainage, or pus around drainage tube
b. Demonstrates correct management of drainage tube (if applicable)
c. Identifies signs and symptoms of biliary obstruction to be noted and reported
d. Has serum bilirubin level within normal range

4. Obtains relief from dietary intolerance
   a. Maintains adequate dietary intake and avoids foods that cause GI symptoms
   b. Reports decreased or absent nausea, vomiting, diarrhea, flatulence, and abdominal discomfort
5. Absence of complications
   a. Has normal vital signs (blood pressure, pulse, respiratory rate and pattern, and temperature)
   b. Reports absence of bleeding from GI tract and from biliary drainage tube or catheter (if present) and no evidence of bleeding in stool
   c. Reports return of appetite and no evidence of vomiting, abdominal distention, or pain
   d. Lists symptoms that should be reported to surgeon promptly and demonstrates an understanding of self-care, including wound care

DISORDERS OF THE PANCREAS

Pancreatitis (inflammation of the pancreas) is a serious disorder. The most basic classification system used to describe or categorize the various stages and forms of pancreatitis divides the disorder into acute and chronic forms. Acute pancreatitis can be a medical emergency associated with a high risk of life-threatening complications and mortality, whereas chronic pancreatitis often goes undetected because classic clinical and diagnostic findings are not always present in the early stages of the disease (Feldman et al., 2016; Papadakis & McPhee, 2020; Srinivasan & Friedman, 2018). By the time symptoms occur in chronic pancreatitis, approximately 90% of normal acinar cell function (exocrine function) has been lost (Feldman et al., 2016; Goldman & Shaffer, 2019; Papadakis & McPhee, 2020; Srinivasan & Friedman, 2018). Acute pancreatitis does not usually lead to chronic pancreatitis unless complications develop. However, chronic pancreatitis can be characterized by acute episodes.

Although the mechanisms causing pancreatic inflammation are unknown, pancreatitis is commonly described as autodigestion of the pancreas. It is believed that the pancreatic duct becomes temporarily obstructed, accompanied by hypersecretion of the exocrine enzymes of the pancreas.

These enzymes enter the bile duct, where they are activated and, together with bile, back up (reflux) into the pancreatic duct, causing pancreatitis.

Acute Pancreatitis 

Approximately 200,000 cases of acute pancreatitis occur in the United States each year, of which 80% are the result of cholelithiasis or sustained alcohol abuse (Faghih, Fan, & Singh, 2019; Olson, Perelman, & Birk, 2019). Acute pancreatitis ranges from a mild, self-limited disorder to a severe, rapidly fatal disease that does not respond to any treatment. These two main types of acute pancreatitis (mild and severe) are classified as interstitial edematous pancreatitis and necrotizing pancreatitis, respectively. Interstitial pancreatitis affects the majority of patients. It is characterized by a lack of pancreatic or peripancreatic parenchymal necrosis with diffuse enlargement of the gland due to inflammatory edema (Faghih et al., 2019; Olson et al., 2019). The edema and inflammation in interstitial pancreatitis is confined to the pancreas itself. Minimal organ dysfunction is present, and return to normal function usually occurs within 6 months. Although this is considered the milder form of pancreatitis, the patient is acutely ill and at risk for hypovolemic shock, fluid and electrolyte disturbances, and sepsis.

In the more severe form, necrotizing pancreatitis, there is tissue necrosis in either the pancreatic parenchyma or in the tissue surrounding the gland. This type can be sterile or infected; if the parenchyma is involved, this is a marker for more severe disease (Brunicardi, 2019; Faghih, et al., 2019; Olson et al., 2019). A more widespread and complete enzymatic digestion of the gland characterizes necrotizing pancreatitis. Enzymes damage the local blood vessels, and bleeding and thrombosis can occur. The tissue may become necrotic, with damage extending into the retroperitoneal tissues. Local complications include pancreatic cysts or abscesses and acute fluid collections in or near the pancreas. Patients who develop systemic complications with organ failure, such as pulmonary insufficiency with hypoxia, shock, kidney disease, and GI bleeding, are also characterized as having severe acute pancreatitis.

Gerontologic Considerations

Acute pancreatitis affects people of all ages, but the mortality rate associated with acute pancreatitis increases with age (Brunicardi, 2019; Faghih et al., 2019; Olson et al., 2019). In addition, the pattern of complications changes with age. Younger patients tend to develop local complications; the incidence

of multiple organ dysfunction syndrome (MODS) increases with age, possibly as a result of progressive decreases in physiologic function of major organs with increasing age. Close monitoring of major organ function (i.e., lungs, kidneys) is essential, and aggressive treatment is necessary to reduce mortality from acute pancreatitis in the older adult patient.

Pathophysiology

Self-digestion of the pancreas by its own proteolytic enzymes, principally trypsin, causes acute pancreatitis. These patients usually have had undiagnosed chronic pancreatitis before their first episode of acute pancreatitis. Gallstones enter the CBD and lodge at the ampulla of Vater, obstructing the flow of pancreatic juice or causing a reflux of bile from the CBD into the pancreatic duct, thus activating the powerful enzymes within the pancreas. Normally, these remain in an inactive form until the pancreatic secretions reach the lumen of the duodenum (Brunicardi, 2019; Faghih et al., 2019; Norris, 2019; Olson et al., 2019). Activation of the enzymes can lead to vasodilation, increased vascular permeability, necrosis, erosion, and hemorrhage (Brunicardi, 2019; Faghih et al., 2019; Norris, 2019; Olson et al., 2019; Townsend et al., 2016).

Other less common causes of pancreatitis include bacterial or viral infection, with pancreatitis occasionally developing as a complication of mumps viral infection. Spasm and edema of the ampulla of Vater, caused by duodenitis, can probably produce pancreatitis. Blunt abdominal trauma, peptic ulcer disease, ischemic vascular disease, hyperlipidemia, hypercalcemia, and the use of corticosteroids, thiazide diuretics, oral contraceptives, and other medications have also been associated with an increased incidence of pancreatitis. Acute pancreatitis may develop after surgery on or near the pancreas or after instrumentation of the pancreatic duct. In addition to alcohol consumption, use of tobacco products is a risk factor for the development of acute and chronic pancreatitis (Aune, Yahya, Norat, et al., 2019). Acute idiopathic pancreatitis accounts for up to 10% of the cases of acute pancreatitis. Some postulate that these cases may be related to occult microlithiasis (small stones in the bile) (Goodchild, Chouhan, & Johnson, 2019; Olson et al., 2019; Townsend et al., 2016). In addition, there is a small incidence of hereditary pancreatitis.

The mortality rate of patients with acute pancreatitis is 2% to 10% because of shock, anoxia, hypotension, or fluid and electrolyte imbalances. This mortality rate may also be related to the 10% to 30% of patients with severe acute disease characterized by pancreatic and peripancreatic necrosis (Goodchild et al., 2019; Olson et al., 2019; Townsend et al., 2016). Pancreatitis may result in complete recovery, may recur without permanent damage, or may progress to chronic pancreatitis. The patient who is admitted to the

hospital with a diagnosis of pancreatitis is acutely ill and needs expert nursing and medical care.

Clinical Manifestations

Severe abdominal pain is the major symptom of pancreatitis that causes the patient to seek medical care. Abdominal pain and tenderness and back pain result from irritation and edema of the inflamed pancreas. Increased tension on the pancreatic capsule and obstruction of the pancreatic ducts also contribute to the pain. Typically, the pain occurs in the midepigastrium. Pain is frequently acute in onset, occurring 24 to 48 hours after a very heavy meal or alcohol ingestion, and it may be diffuse and difficult to localize. It is generally more severe after meals and is unrelieved by antacids. Pain may be accompanied by abdominal distention; a poorly defined, palpable abdominal mass; decreased peristalsis; and vomiting that fails to relieve the pain or nausea.

The patient appears acutely ill. Abdominal guarding is present. A rigid or boardlike abdomen may develop, usually indicating peritonitis (Goodchild et al., 2019; Olson et al., 2019). Ecchymosis (bruising) in the flank or around the umbilicus may indicate severe pancreatitis. Nausea and vomiting are common in acute pancreatitis. The emesis is usually gastric in origin but may also be bile stained. Fever, jaundice, mental confusion, and agitation may also occur.

Hypotension is typical and reflects hypovolemia and shock caused by the loss of large amounts of protein-rich fluid into the tissues and peritoneal cavity. In addition to hypotension, the patient may develop tachycardia; cyanosis; and cold, clammy skin. Acute kidney injury is common.

Respiratory distress and hypoxia are common, and the patient may develop diffuse pulmonary infiltrates, dyspnea, tachypnea, and abnormal blood gas values. Myocardial depression, hypocalcemia, hyperglycemia, and disseminated intravascular coagulation may also occur with acute pancreatitis.

Assessment and Diagnostic Findings

The diagnosis of acute pancreatitis is based on the fulfillment of two out of the three following criteria: a history of upper abdominal pain, biochemical changes with serum amylase or lipase levels greater than three times the upper limit of normal, or typical findings on imaging (CT, magnetic resonance imaging [MRI] or ultrasonography). The presence of known risk factors is also helpful for diagnostic purposes (Feldman et al., 2016; Goodchild et al., 2019; Olson et al., 2019; Z.orniak, Beyer, & Mayerle, 2019). In most cases, serum amylase and lipase levels are elevated within 24 hours of the onset of the symptoms. Serum amylase usually returns to normal within 48 to 72 hours, but serum lipase levels may remain elevated for a longer period, often days longer than amylase. Urinary amylase levels also become elevated and remain

elevated longer than serum amylase levels. The white blood cell count is usually elevated; hypocalcemia is present in many patients and correlates well with the severity of pancreatitis. Transient hyperglycemia and glucosuria and elevated serum bilirubin levels occur in some patients with acute pancreatitis.

X-ray studies of the abdomen and chest may be obtained to differentiate pancreatitis from other disorders that can cause similar symptoms and to detect pleural effusions. Ultrasound studies, contrast-enhanced CT scans, and MRI scans are used to identify an increase in the diameter of the pancreas and to detect pancreatic cysts, abscesses, or pseudocysts.

Hematocrit and hemoglobin levels are used to monitor the patient for bleeding. Peritoneal fluid, obtained through paracentesis or peritoneal lavage, may contain increased levels of pancreatic enzymes. ERCP is rarely used in the diagnostic evaluation of acute pancreatitis, because the patient is acutely ill; however, it may be valuable in the treatment of gallstone pancreatitis.

The severity of acute pancreatitis is difficult to predict early in the course of the disease, but mortality can be predicted based on clinical and laboratory data (see Chart 44-3). According to the revised Atlanta Classification, there are three degrees of severity: (1) mild with the absence of organ failure and no local or systemic complications, (2) moderately severe with the presence of transient organ failure or local or systemic complications, and (3) severe acute pancreatitis characterized by persistent organ failure (>48 hours) (Banks, Bollen, Dervenis, et al., 2013; Z.orniak et al., 2019). Several risk stratification systems aim to predict persistent organ failure and complications. The Acute Physiology and Chronic Health Evaluation II (APACHE II), Ranson Criteria for Pancreatitis Mortality, and Bedside Index of Severity in Acute Pancreatitis (BISAP) are scoring systems that assess clinical and biochemical factors to determine the severity of acute pancreatitis. Laboratory values such as C-reactive protein, procalcitonin, and blood urea nitrogen (BUN) may also carry some predictive value (Z.orniak et al., 2019). Early prediction of the severity of acute pancreatitis is important for guiding early treatment, choosing the optimal level of care, and identifying patients who might benefit from transfer to a center that specializes in the care of this disease (Z.orniak et al., 2019).

Chart 44-3

The Ranson Criteria for Pancreatic Mortality

Criteria on Admission to Hospital

Age >55 years
White blood cells (WBCs) >16,000 mm^3
Serum glucose >200 mg/dL (>11.1 mmol/L)
Serum lactate dehydrogenase (LDH) >350 IU/L (>350 U/L)
Aspartate aminotransferase (AST) >250 IU/L

Criteria within 48 Hours of Hospital Admission

Fall in hematocrit >10% (>0.10)
Blood urea nitrogen (BUN) increase >5 mg/dL (>1.7 mmol/L)
Serum calcium <8 mg/dL (<2 mmol/L)
Base deficit >4 mEq/L (>4 mmol/L)
Fluid retention or sequestration >6 L
Partial pressure of oxygen (PO_2) <60 mm Hg
Two or fewer signs, 1% mortality; 3 or 4 signs, 15% mortality; 5 or 6 signs, 40% mortality; >6 signs, 100% mortality.

Note: The more risk factors a patient has, the greater the severity and likelihood of complications or death.

Adapted from Ranson, J. H., Rifkind, K. M., Roses, D. F., et al. (1974). Prognostic signs and the role of operative management in acute pancreatitis. *Surgery, Gynecology & Obstetrics*, *139*(1), 69–81.

Medical Management

Management of acute pancreatitis is directed toward relieving symptoms and preventing or treating complications. All oral intake is withheld to inhibit stimulation of the pancreas and its secretion of enzymes. Ongoing research has shown positive outcomes with the use of enteral feedings. The current recommendation is that, whenever possible, the enteral route should be used to meet nutritional needs in patients with pancreatitis. This strategy also has been found to prevent infectious complications safely and cost-effectively (McClave, 2019; Mueller, 2017; Olson et al., 2019; Ramanathan & Aadam, 2019; Townsend et al., 2016). Enteral feedings should be started early in the course of acute pancreatitis (Goodchild et al., 2019; McClave, 2019; Mueller, 2017; Olson et al., 2019; Ramanathan & Aadam, 2019). Parenteral nutrition has a role in the nutritional support of patients with severe acute pancreatitis, particularly in those who are unable to tolerate enteral nutrition (Goodchild et al., 2019; Mueller, 2017; Olson et al., 2019). Nasogastric suction may be used to relieve nausea and vomiting and to decrease painful abdominal distention and paralytic ileus (Brunicardi, 2019). Research data do not support the routine use of nasogastric tubes to remove gastric secretions in an effort to limit

pancreatic secretion. Though current literature discourages the use of acid-suppressive therapy, this practice is common for hospitalized patients. Histamine-2 (H_2) antagonists such as cimetidine may be prescribed to decrease pancreatic activity by inhibiting secretion of gastric acid. Proton pump inhibitors such as pantoprazole may be used for patients who do not tolerate H_2 antagonists or for whom this therapy is ineffective (Barbateskovic, Marker, Granholm, et al., 2019; Kavitt, Lipowska, Anyane-Yeboa, et al., 2019).

Pain Management

Adequate administration of analgesia is essential during the course of acute pancreatitis to provide sufficient pain relief and to minimize restlessness, which may stimulate pancreatic secretion further. Pain relief may require parenteral opioids such as morphine, fentanyl, or hydromorphone (Cameron & Cameron, 2020; Goodchild et al., 2019; Olson et al., 2019). The recommendation for pain management is the use of opioids, with assessment for their effectiveness, and altering therapy if pain is not controlled or is increased (Faghih et al., 2019; Goodchild et al., 2019; Olson et al., 2019). There is some evidence that implementing the World Health Organization (WHO) analgesia ladder provides a pragmatic approach to pain management in patients with pancreatitis (Z.orniak et al., 2019). This stepwise escalation from low potency to higher potency of nonsteroidal anti-inflammatory drugs (NSAIDs) alone or in combination with opioids may provide an effective method of pain management and lower the potential for opioid dependency (Z.orniak et al., 2019). NSAIDs must be avoided or used in caution in patients at risk for bleeding. GI paralysis and ileus are common problems in early acute pancreatitis that can be potentiated and aggravated with the use of high-dose opioids (Z.orniak et al., 2019). More research is needed to identify the best option for pain management in the patient with acute pancreatitis (Faghih et al., 2019). Until evidence-based recommendations are developed, guidelines for acute pain management in the perioperative setting should be followed (Rothrock, 2019). Antiemetic agents may be prescribed to prevent vomiting.

Intensive Care

Correction of fluid and blood loss and low albumin levels is necessary to maintain fluid volume and prevent acute kidney injury. The patient is usually acutely ill and is monitored in the intensive care unit, where hemodynamic monitoring and arterial blood gas monitoring are initiated. Antibiotic agents may be prescribed if infection is present. Prophylactic antibiotics are not recommended for patients with acute pancreatitis (Faghih et al., 2019; Goodchild, 2019; Olson et al., 2019). Insulin may be required if hyperglycemia occurs. Intensive insulin therapy (continuous infusion) in the critically ill

patient has undergone much study. The best practice recommendations, which have arisen from many investigations on this complex topic, include targeting a blood glucose level of 140 to 200 mg/dL if insulin therapy is required in critically ill medical and surgical patients. Additionally, clinicians are advised to avoid glucose targets <140 mg/dL because adverse effects are likely to increase with lower blood glucose targets (Horton, 2019).

Respiratory Care

Aggressive respiratory care is indicated because of the high risk of elevation of the diaphragm, pulmonary infiltrates and effusion, and atelectasis. Hypoxemia occurs in a significant number of patients with acute pancreatitis, even with normal x-ray findings. Respiratory care may range from close monitoring of arterial blood gases to the use of humidified oxygen to intubation and mechanical ventilation (see Chapter 19 for further discussion).

Biliary Drainage

Placement of biliary drains (for external drainage) and stents (indwelling tubes) in the pancreatic duct through endoscopy has been performed to reestablish drainage of the pancreas. This has resulted in decreased pain.

Surgical Intervention

Although the acutely ill patient is at high risk for surgical complications, surgery may be performed to assist in the diagnosis of pancreatitis (diagnostic laparotomy); to establish pancreatic drainage; or to resect or débride an infected, necrotic pancreas. The patient who undergoes pancreatic surgery may have multiple drains in place postoperatively, as well as a surgical incision that is left open for irrigation and repacking every 2 to 3 days to remove necrotic debris (see Fig. 44-6).

Postacute Management

Oral feedings that are low in fat and protein are initiated gradually. Caffeine and alcohol are eliminated from the diet. If the episode of pancreatitis occurred during treatment with thiazide diuretics, corticosteroids, or oral contraceptives, these medications are discontinued. Follow-up may include ultrasound, x-ray studies, or ERCP to determine whether the pancreatitis is resolving and to assess for abscesses and pseudocysts. ERCP may also be used to identify the cause of acute pancreatitis if it is in question and for endoscopic sphincterotomy and removal of gallstones from the common bile duct.

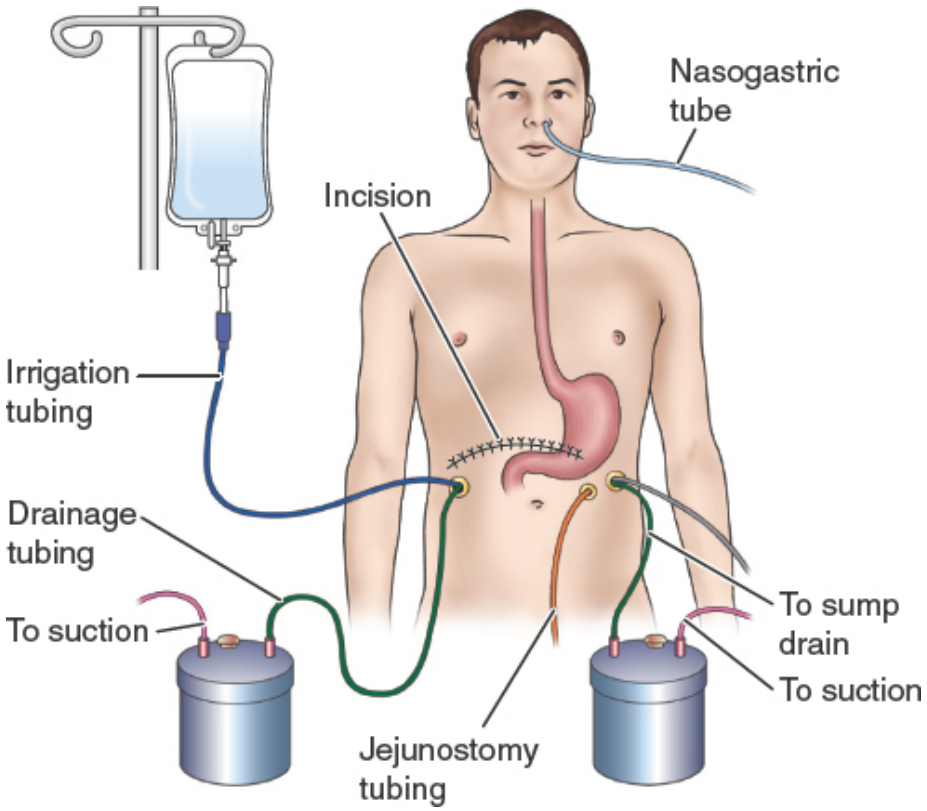

Figure 44-6 • Multiple sump tubes are used after pancreatic surgery. Triple-lumen tubes consist of ports that provide tubing for irrigation, air venting, and drainage.

Nursing Management

Relieving Pain and Discomfort

Because the pathologic process responsible for pain is autodigestion of the pancreas, the objectives of therapy are to relieve pain and decrease secretion of pancreatic enzymes. The pain of acute pancreatitis is often very severe, necessitating the liberal use of analgesic agents. The current recommendation for pain management in this population is parenteral opioids, including morphine, hydromorphone, or fentanyl via patient-controlled analgesia or bolus (Goodchild et al., 2019; Olson et al., 2019). In patients who are critically ill, a continuous infusion may be needed. Because most opioids stimulate spasm of the sphincter of Oddi to some degree, consensus has not been reached on the most effective agent. Ensuring patient comfort, regardless of the opioid prescribed, is the most essential aspect of care. The nurse frequently assesses the pain level and the effectiveness of the pharmacologic (and nonpharmacologic) interventions. Changes may be needed in the regimen for pain management based on the achievement of pain control. Pain assessment tools (see Chapter 9) are available for the nurse to ensure an accurate rating of pain. Nonpharmacologic interventions such as proper positioning, music,

distraction, and imagery may be effective in reducing pain when used along with medications.

Oral feedings are withheld to decrease the secretion of secretin. Parenteral fluids and electrolytes are prescribed to restore and maintain fluid balance. Nasogastric suction may be used to relieve nausea and vomiting or to treat abdominal distention and paralytic ileus. The nurse provides frequent oral hygiene and care to decrease discomfort from the nasogastric tube and relieve dryness of the mouth.

The patient who is acutely ill is maintained on bed rest to decrease the metabolic rate and reduce the secretion of pancreatic and gastric enzymes. If the patient experiences increasing severity of pain, the nurse reports this to the primary provider because the patient may be experiencing hemorrhage of the pancreas or the dose of analgesic medication may be inadequate.

The patient with acute pancreatitis is often confused or delirious because of severe pain, fluid and electrolyte disturbances, and hypoxia. Therefore, the nurse provides frequent and repeated but simple explanations about the need for withholding fluids, maintenance of gastric suction, and bed rest.

Improving Breathing Pattern

The nurse maintains the patient in a semi-Fowler position to decrease pressure on the diaphragm by a distended abdomen and to increase respiratory expansion. Frequent changes of position are necessary to prevent atelectasis and pooling of respiratory secretions. Pulmonary assessment, including monitoring of pulse oximetry or arterial blood gases, is essential to detect changes in respiratory status so that early treatment can be initiated. The nurse instructs the patient in techniques of coughing and deep breathing and in the use of incentive spirometry to improve respiratory function and assists the patient to perform these activities every hour.

Improving Nutritional Status

The nurse assesses the patient's nutritional status and notes factors that alter the patient's nutritional requirements (e.g., temperature elevation, surgery, drainage). Laboratory test results and daily weights are useful to monitor the nutritional status.

Enteral or parenteral nutrition may be prescribed. In addition to administering enteral or parenteral nutrition, the nurse monitors serum glucose levels every 4 to 6 hours. As the acute symptoms subside, oral feedings are gradually reintroduced. Between acute attacks, the patient receives a diet that is high in protein and low in fat (Goodchild et al., 2019; Olson et al., 2019). The patient should avoid heavy meals and alcoholic beverages.

Maintaining Skin Integrity

The patient is at risk for skin breakdown because of poor nutritional status, enforced bed rest, and restlessness, which may result in pressure injuries and breaks in tissue integrity. In addition, the patient who has undergone surgery may have multiple drains or an open surgical incision and is at risk for skin breakdown and infection. The wound, drainage sites, and skin are carefully assessed for signs of infection, inflammation, and breakdown. The nurse carries out wound care as prescribed and takes precautions to protect intact skin from contact with drainage. Consultation with a wound-ostomy-continence (WOC) nurse, a nurse specially educated in appropriate skin, wound, ostomy, and continence care is often helpful in identifying appropriate skin care devices and protocols. The patient must be turned every 2 hours; the use of specialty beds may be indicated to prevent skin breakdown.

Monitoring and Managing Potential Complications

Fluid and electrolyte disturbances are common complications because of nausea, vomiting, movement of fluid from the vascular compartment to the peritoneal cavity, diaphoresis, fever, and the use of gastric suction. The nurse assesses the patient's fluid and electrolyte status by noting skin turgor and moistness of mucous membranes. The nurse weighs the patient daily and carefully measures fluid intake and output, including urine output, nasogastric secretions, and diarrhea. In addition, it is important to assess for other factors that may affect fluid and electrolyte status, including increased body temperature and wound drainage. The patient is assessed for ascites, and abdominal girth is measured daily if ascites is suspected.

Fluids are administered IV and may be accompanied by infusion of blood or blood products to maintain the blood volume and to prevent or treat hypovolemic shock. Emergency medications must be readily available because of the risk of circulatory collapse and shock. The nurse promptly reports decreased blood pressure and reduced urine output, which indicate hypovolemia and shock or acute kidney injury. Low serum calcium and magnesium levels may occur and require prompt treatment.

Pancreatic necrosis is a major cause of morbidity and mortality in patients with acute pancreatitis because of resulting hemorrhage, septic shock, and MODS. The patient may undergo diagnostic procedures for confirmation of pancreatic necrosis. If the patient is found to have pancreatic necrosis with infection, this may require surgical, percutaneous or endoscopic débridement or insertion of multiple drains. Percutaneous or endoscopic catheter drainage is the first step of what is known as the "Step-Up Approach." Catheters are placed via the left or right retroperitoneal approach to drain the infection. Débridement, if required, may be performed through video-assisted retroperitoneal débridement. These interventions, coupled with appropriate, targeted antibiotic therapy, may be the only necessary treatment for some

patients (Paulino, Ramos, & Veloso Gomes, 2019; Rashid, Hussain, Jehanzeb, et al., 2019; Sion & Davis, 2019; Wolbrink, Kolwijck, Ten Oever, et al., 2019). These procedures are considered first-line approaches, with surgery reserved for patients for whom these interventions do not work. Prophylactic antibiotics are not indicated (Paulino et al., 2019; Sion & Davis, 2019; Wolbrink et al., 2019). The patient with pancreatic necrosis with or without infection is usually critically ill and requires expert medical and nursing management, including hemodynamic monitoring in the intensive care unit.

In addition to carefully monitoring vital signs and other signs and symptoms, the nurse is responsible for administering prescribed fluids, medications, and blood products; assisting with supportive management, such as the use of a ventilator; preventing additional complications; and providing physical and psychological care.

Shock and MODS may occur with acute pancreatitis. Hypovolemic shock may occur as a result of hypovolemia and sequestering of fluid in the peritoneal cavity. Hemorrhagic shock may occur with hemorrhagic pancreatitis. Septic shock may occur with bacterial infection of the pancreas. Cardiac dysfunction may occur as a result of fluid and electrolyte disturbances, acid–base imbalances, and release of toxic substances into the circulation.

The nurse closely monitors the patient for early signs of neurologic, cardiovascular, renal, and respiratory dysfunction and must be prepared to respond quickly to rapid changes in the patient's status, treatments, and therapies. In addition, it is important to inform the family about the patient's status and progress and to allow them to spend time with the patient. Management of shock and MODS is discussed in detail in Chapter 11.

Promoting Home, Community-Based, and Transitional Care

Educating Patients About Self-Care

After an episode of acute pancreatitis, the patient is often still weak and debilitated for weeks or months. A prolonged period may be needed to regain strength and return to the previous level of activity. Because of the severity of the acute illness, the patient may not recall education given during the acute phase. Patient education often needs to be repeated and reinforced. The nurse educates the patient about the factors implicated in the onset of acute pancreatitis and about the need to avoid high-fat foods, heavy meals, and alcohol. The patient and family should receive verbal and written instructions about signs and symptoms of acute pancreatitis and possible complications that should be reported promptly to the primary provider.

If acute pancreatitis is a result of biliary tract disease, such as gallstones and gallbladder disease, additional explanations are needed about required dietary

modifications. If the pancreatitis is a result of alcohol abuse, the nurse reinforces the need to avoid all alcohol.

Continuing and Transitional Care

A referral for home, community-based or transitional care is often indicated. This enables the nurse to assess the patient's physical and psychological status and adherence to the therapeutic regimen. The nurse also assesses the home situation and reinforces instructions about fluid and nutrition intake and avoidance of alcohol. Nurses should consider implementing the teach-back method when educating patients and families about this vital information (see Chapter 3 for a discussion of the teach-back method). After the acute attack has subsided, some patients may be inclined to return to their previous drinking habits. The nurse provides specific information about resources and support groups that may be of assistance in avoiding alcohol in the future. Referral to Alcoholics Anonymous as appropriate or other support groups is essential. See the accompanying plan of nursing care in Chart 44-4 for care of the patient with acute pancreatitis.

Chronic Pancreatitis

Chronic pancreatitis is an inflammatory disorder characterized by progressive destruction of the pancreas. As cells are replaced by fibrous tissue with repeated attacks of pancreatitis, pressure within the pancreas increases. The result is obstruction of the pancreatic and common bile ducts and the duodenum. In addition, there is atrophy of the epithelium of the ducts, inflammation, and destruction of the secreting cells of the pancreas.

Alcohol consumption in Western societies and malnutrition worldwide are the major causes of chronic pancreatitis. Patients diagnosed with chronic pancreatitis due to alcohol typically present between the ages of 40 and 60 years (Singh, 2019). Frequently, at that age, patients already report a long history of alcohol abuse. Excessive and prolonged consumption of alcohol accounts for approximately 70% to 80% of all cases of chronic pancreatitis (Papadakis & McPhee, 2020; Srinivasan & Friedman, 2018; Townsend et al., 2016). The incidence of pancreatitis is 50 times greater in people with alcoholism than in those who do not abuse alcohol. Long-term alcohol consumption causes hypersecretion of protein in pancreatic secretions, resulting in protein plugs and calculi within the pancreatic ducts. Alcohol also has a direct toxic effect on the cells of the pancreas. Damage to these cells is more likely to occur and to be more severe in patients whose diets are poor in protein content and either very high or very low in fat.

Smoking is another factor in the development of chronic pancreatitis. Because smoking and alcohol are often associated, it is difficult to separate the

effects of these two factors (Aune et al., 2019; Papadakis & McPhee, 2020; Singh, 2019).

Chart 44-4 PLAN OF NURSING CARE

Care of the Patient with Acute Pancreatitis

NURSING DIAGNOSIS: Acute pain associated with edema, distention of the pancreas, peritoneal irritation, and excess stimulation of pancreatic secretions
GOAL: Relief of pain

Nursing Interventions	Rationale	Expected Outcomes
1. Using a pain scale, assess pain level at baseline, before and after administration of analgesic medications.	1. Baseline assessment and control of pain are important because restlessness increases the body's metabolism, which stimulates the secretion of pancreatic and gastric enzymes.	• Patient rates pain using pain scale • Reports relief of pain, discomfort, and abdominal cramping • Moves and turns without increasing pain and discomfort • Rests comfortably and sleeps for increasing periods • Reports increased feelings of well-being and security with the health care team
2. Administer morphine, fentanyl, or hydromorphone frequently, as prescribed, to achieve level of pain acceptable to patient. Depending on pain severity, nonsteroidal anti-inflammatory drugs NSAIDs) may be considered alone or in combination with opioids.	2. Fentanyl and hydromorphone act by depressing the central nervous system and thereby increasing the patient's pain threshold.	
3. Maintain the patient NPO (nothing by mouth) as prescribed.	3. Pancreatic secretion is increased by food and fluid intake.	
4. Maintain the patient on bed rest.	4. Bed rest decreases body metabolism and thus reduces pancreatic and gastric secretions.	
5. Maintain continuous nasogastric drainage if paralytic ileus or nausea and vomiting, abdominal distention are present. a. Measure gastric secretions at specified intervals. b. Observe and record color and viscosity	5. Nasogastric suction relieves nausea, vomiting, and abdominal distention. Decompression of the intestines (if intestinal intubation is used) also assists in relieving	

of gastric secretions. c. Ensure that the nasogastric tube is patent to permit free drainage. 6. Report unrelieved pain or increasing intensity of pain. 7. Assist patient to assume positions of comfort; turn and reposition every 2 hours. 8. Use nonpharmacologic interventions for relieving pain (e.g., relaxation, focused breathing, diversion). 9. Listen to patient's expression of pain experience.	respiratory distress. 6. Pain may increase pancreatic enzymes and may also indicate pancreatic hemorrhage. 7. Frequent turning relieves pressure and assists in preventing pulmonary and vascular complications. 8. The use of nonpharmacologic methods will enhance the effects of analgesic medications. 9. Demonstration of caring can help to decrease anxiety.	

NURSING DIAGNOSIS: Discomfort associated with nasogastric tube
GOAL: Relief of discomfort associated with nasogastric intubation used to treat ileus, vomiting, and distention

Nursing Interventions	Rationale	Expected Outcomes
1. Use water-soluble lubricant around external nares. 2. Turn patient at intervals; avoid pressure or tension on nasogastric tube. 3. Provide oral hygiene and gargling solutions without alcohol. 4. Explain rationale for the use of nasogastric drainage.	1. Prevents irritation of nares. 2. Relieves pressure of tube on esophageal and gastric mucosa. 3. Relieves dryness and irritation of oropharynx. 4. Assists patient to cooperate with the drainage,	• Exhibits intact skin and tissue of nares at site of nasogastric tube insertion • Reports no pain or irritation of nares or oropharynx • Exhibits moist, clean mucous membranes of

	nasogastric tube, and suction.	mouth and nasopharynx • States that thirst is relieved by oral hygiene • Identifies rationale for nasogastric tube and suction
NURSING DIAGNOSIS: Impaired nutritional status associated with inadequate dietary intake, impaired pancreatic secretions, increased nutritional needs secondary to acute illness, and increased body temperature **GOAL:** Improvement in nutritional status		
Nursing Interventions	**Rationale**	**Expected Outcomes**
1. Assess current nutritional status and increased metabolic requirements. 2. Monitor serum glucose levels and administer insulin as prescribed. 3. Administer IV fluid and electrolytes, enteral or parenteral nutrition as prescribed. 4. Provide high-carbohydrate, low-protein, and low-fat diet when tolerated. 5. Instruct patient to eliminate alcohol, and refer to Alcoholics Anonymous, if indicated. 6. Counsel patient to avoid excessive use of	1. Alteration in pancreatic secretions interferes with normal digestive processes. Acute illness, infection, and fever increase metabolic needs. 2. Impairment of endocrine function of the pancreas leads to increased serum glucose levels. 3. Parenteral administration of fluids and electrolytes, and enteral or parenteral nutrients are essential to provide fluids, calories, electrolytes, and	• Maintains normal body weight • Demonstrates no additional weight loss • Maintains normal serum glucose levels • Reports decreasing episodes of vomiting and diarrhea • Reports return of normal stool characteristics and bowel pattern • Consumes foods high in carbohydrates, low in fat and protein

coffee and spicy foods. 7. Monitor daily weights.	nutrients when oral intake is prohibited. 4. These foods increase caloric intake without stimulating pancreatic secretions beyond the ability of the pancreas to respond. 5. Alcohol intake produces further damage to pancreas and precipitates attacks of acute pancreatitis. 6. Coffee and spicy foods increase pancreatic and gastric secretions. 7. This provides a baseline and a means to measure weight gain or weight loss.	• Explains rationale for high-carbohydrate, low-fat, low-protein diet • Eliminates alcohol from diet • Explains rationale for limiting coffee intake and avoiding spicy foods • Participates in Alcoholics Anonymous as appropriate or other counseling approach • Returns to and maintains desirable weight

NURSING DIAGNOSIS: Impaired breathing associated with splinting from severe pain, pulmonary infiltrates, pleural effusion, and atelectasis
GOAL: Improvement in respiratory function

Nursing Interventions	Rationale	Expected Outcomes
1. Assess respiratory status (rate, pattern, breath sounds), pulse oximetry, and arterial blood gases. 2. Maintain semi-Fowler position. 3. Instruct and encourage patient to take deep breaths and to cough every hour. 4. Assist patient to turn and change position every 2 hours. 5. Reduce the excessive metabolism of the body. a. Administer antibiotics as prescribed. b. Administer nasal oxygen as required for hypoxia. c. Use a hypothermia blanket if necessary.	1. Acute pancreatitis produces retroperitoneal edema, elevation of the diaphragm, pleural effusion, and inadequate lung ventilation. Intra-abdominal infection and labored breathing increase the body's metabolic demands, which further decreases pulmonary reserve and leads to respiratory failure. 2. Decreases pressure on diaphragm and allows greater lung expansion. 3. Taking deep breaths and coughing will clear the airways and reduce atelectasis. 4. Changing position frequently assists aeration and drainage of all lobes of the lungs. 5. Pancreatitis produces a severe peritoneal and retroperitoneal reaction that causes fever, tachycardia, and accelerated respirations. Supporting the patient with oxygen therapy decreases the workload of the respiratory system and the tissue utilization of oxygen. Reduction of fever and pulse rate	• Demonstrates normal respiratory rate and pattern and full lung expansion • Demonstrates normal breath sounds and absence of adventitious breath sounds • Demonstrates normal arterial blood gases and pulse oximetry • Maintains semi-Fowler position when in bed • Changes position in bed frequently • Coughs and takes deep breaths at least every hour • Demonstrates normal body temperature • Exhibits no signs or symptoms of respiratory

	decreases the metabolic demands on the body.	infection or impairment • Is alert and responsive to environment
COLLABORATIVE PROBLEM: Fluid and electrolyte disturbances, hypovolemia, shock **GOAL:** Improvement in fluid and electrolyte status, prevention of hypovolemia and shock		
Nursing Interventions	**Rationale**	**Expected Outcomes**
1. Assess fluid and electrolyte status (skin turgor, mucous membranes, urine output, vital signs, hemodynamic parameters). 2. Assess sources of fluid and electrolyte loss (vomiting, diarrhea, nasogastric drainage, excessive diaphoresis). 3. Combat shock if present. a. Administer corticosteroids as prescribed if patient does not respond to conventional treatment. b. Evaluate the amount of urinary output. Attempt to	1. The amount and type of fluid and electrolyte replacement are determined by the status of the blood pressure, the laboratory evaluations of serum electrolyte and blood urea nitrogen levels, the urinary volume, and the assessment of the patient's condition. 2. Electrolyte losses occur from nasogastric suctioning, severe diaphoresis, and emesis, and as a result of the patient being in a fasting state. 3. Extensive acute pancreatitis may cause peripheral vascular collapse and shock. Blood and plasma may be lost into the abdominal cavity; therefore, there is a decreased blood and plasma volume. The toxins from the bacteria of a necrotic pancreas may cause shock.	• Exhibits moist mucous membranes and normal skin turgor • Exhibits normal blood pressure without evidence of orthostatic hypotension • Excretes adequate urine volume • Exhibits normal, not excessive, thirst • Maintains normal pulse and respiratory rate • Remains alert and responsive • Exhibits normal arterial pressures and blood gases

maintain this at ≥0.5 mL/kg/hr and ≥400 mL/day.

4. Administer blood products, fluids, and electrolytes (sodium, potassium, chloride) as prescribed.

5. Administer plasma and blood products as prescribed.

6. Keep a supply of IV calcium gluconate or calcium chloride readily available.

7. Assess abdomen for ascites formation.
   a. Measure abdominal girth daily.
   b. Weigh patient daily.
   c. Assess abdomen for ascites (see Chapter 43, Fig. 43-6).

8. Monitor for manifestations of multiple organ dysfunction syndrome: neurologic, cardiovascular, renal, and respiratory dysfunction.

4. Patients with hemorrhagic pancreatitis lose large amounts of blood and plasma, which decreases effective circulation and blood volume.

5. Replacement with blood, plasma, or albumin assists in ensuring effective circulating blood volume.

6. Calcium may be prescribed to prevent or treat tetany, which may result from calcium losses into retroperitoneal (peripancreatic) exudate.

7. During acute pancreatitis, plasma may be lost into the abdominal cavity, which diminishes the blood volume.

8. All body systems may fail if pancreatitis is severe and treatment is ineffective.

- Exhibits normal electrolyte levels
- Exhibits no signs or symptoms of calcium deficit (e.g., tetany, carpopedal spasm)
- Exhibits no additional losses of fluids and electrolytes through vomiting, diarrhea, or diaphoresis
- Demonstrates no change in weight
- Demonstrates no increase in abdominal girth
- Demonstrates no fluid wave on palpation of the abdomen
- Demonstrates stable organ function without manifestations of failure

Clinical Manifestations

Chronic pancreatitis is characterized by recurring attacks of severe upper abdominal and back pain, accompanied by vomiting. Attacks are often so painful that opioids, even in large doses, do not provide relief. The risk of opioid dependence is increased in pancreatitis because of the chronic nature and severity of the pain. As the disease progresses, recurring attacks of pain are more severe, more frequent, and of longer duration. Some patients experience continuous severe pain, and others have dull, nagging constant pain. Periods of well-being sometimes follow the episodes of pain (Singh, 2019). In some patients, chronic pancreatitis is painless. The natural history of abdominal pain (character, timing, severity) is variable, and many studies have documented a decrease in pain ("burnout") over time in a majority of patients (Singh, 2019).

Weight loss is a major problem in chronic pancreatitis. More than 80% of patients experience significant weight loss, which is usually caused by decreased dietary intake secondary to anorexia or fear that eating will precipitate another attack (Kellerman & Rakel, 2018; Singh, 2019). Malabsorption occurs late in the disease, when as little as 10% of pancreatic function remains (Kellerman & Rakel, 2018; Singh, 2019). As a result, digestion, especially of proteins and fats, is impaired. The stools become frequent, frothy, and foul smelling because of impaired fat digestion, which results in stools with a high fat content referred to as **steatorrhea**. As the disease progresses, calcification of the gland may occur, and calcium stones may form within the ducts.

Assessment and Diagnostic Findings

A CT scan is the initial diagnostic test that should be performed for patients in whom there is a suspicion of chronic pancreatitis. The presence of either calcifications, pancreatic ductal changes, or both of these findings can substantiate the diagnosis of chronic pancreatitis (Singh, 2019). MRCP is considered for further evaluation, should the CT findings be equivocal in patients with known risk factors. Transabdominal ultrasonography is frequently used as a screening method for patients with abdominal symptoms. EUS and laparoscopic ultrasound are capable of detecting very small abnormalities in the pancreas. EUS is frequently used early in the evaluation of patients with pancreatic disease, and MRCP is increasingly being used in select patients who are candidates for the most invasive imaging method, ERCP. EUS evaluates for parenchymal and ductal abnormalities that are useful for diagnosis and staging (Singh, 2019). The staging of disease is important in the care of patients, and a combination of imaging methods is usually used to confirm the stage (Brunicardi, 2019; Singh, 2019). ERCP provides details

about the anatomy of the pancreas and the pancreatic and biliary ducts. It is also helpful in obtaining tissue for analysis and differentiating pancreatitis from other conditions, such as carcinoma (Singh, 2019).

A glucose tolerance test evaluates pancreatic islet cell function and provides necessary information for making decisions about surgical resection of the pancreas. An abnormal glucose tolerance test may indicate the presence of diabetes associated with pancreatitis. Acute exacerbations of chronic pancreatitis may result in increased serum amylase levels. Steatorrhea is best confirmed by laboratory analysis of fecal fat content (Kellerman & Rakel, 2018).

Medical Management

The management of chronic pancreatitis depends on its probable cause in each patient. Treatment is directed toward preventing and managing acute attacks, relieving pain and discomfort, and managing exocrine and endocrine insufficiency of pancreatitis (Singh, 2019; Papadakis & McPhee, 2020).

Nonsurgical Management

Nonsurgical approaches may be indicated for the patient who refuses surgery, is a poor surgical risk, or when the disease and symptoms do not warrant surgical intervention. Endoscopy to remove pancreatic duct stones, correct strictures with stenting, and drain cysts may be effective in select patients to manage pain and relieve obstruction via ERCP (Singh, 2019).

Management of abdominal pain and discomfort is similar to that of acute pancreatitis; however, the focus is usually on the use of nonopioid methods to manage pain and the implementation of the WHO's three-step ladder for the treatment of chronic pain. This involves initiating monotherapy and, if ineffective, instituting combination therapy with peripherally acting and centrally acting medications. Pain management in the early stages may respond to nonopioid analgesics, but if the pain becomes more constant or debilitating, introduction of opioid analgesics is appropriate. The abuse of opioids is possible in these patients, and may be more likely in patients with depression, higher pain intensity, and history of alcohol misuse or abuse (Singh, 2019). Adjunct means of pain modulation, such as use of antioxidants, antidepressants, and nonopioid agents as well as avoidance of smoking and alcohol, are recommended before starting opioids for pain control (Singh, 2019). Antioxidants assist in the relief of pain and in improving quality of life and are often given to patients with chronic pancreatitis (Jalal, Campbell, & Hopper, 2019; Singh, 2019). An EUS with guided placement of a celiac nerve block is a potential option for managing the chronic, unrelieved pain of this disease (Singh, 2019). Yoga and other mindfulness-based therapies may be effective nonpharmacologic methods for pain reduction and for relief of other

coexisting symptoms of chronic pancreatitis (Jalal et al., 2019). Persistent, unrelieved pain is often the most difficult aspect of management (Jalal et al., 2019; Singh, 2019). The primary provider, nurse, and dietitian emphasize to the patient and family the importance of avoiding alcohol and foods that have produced abdominal pain and discomfort in the past. The health care team stresses to the patient that no other treatment is likely to relieve pain if the patient continues to consume alcohol.

Diabetes resulting from dysfunction of the pancreatic islet cells is treated with diet, insulin, or oral antidiabetic agents. The hazard of severe hypoglycemia with alcohol consumption is stressed to the patient and family. Pancreatic enzyme replacement is indicated for the patient with malabsorption and steatorrhea.

Surgical Management

Chronic pancreatitis is not often managed by surgery. However, surgery may be indicated to relieve persistent abdominal pain and discomfort, restore drainage of pancreatic secretions, and reduce the frequency of acute attacks of pancreatitis and hospitalization (Brunicardi, 2019; Jalal et al., 2019; Singh, 2019). The type of surgery performed depends on the anatomic and functional abnormalities of the pancreas, including the location of disease within the pancreas, the presence of diabetes, exocrine insufficiency, biliary stenosis, and pseudocysts of the pancreas. Other considerations for surgery selection include the patient's likelihood for continued use of alcohol and the likelihood that the patient will be able to manage the endocrine or exocrine changes that are expected after surgery.

Pancreaticojejunostomy (also referred to as Roux-en-Y), with a side-to-side anastomosis or joining of the pancreatic duct to the jejunum, allows drainage of the pancreatic secretions into the jejunum. Pain relief occurs within 6 months in more than 85% of the patients who undergo this procedure, but pain returns in a substantial number of patients as the disease progresses (Brunicardi, 2019; Cameron & Cameron, 2020; Yeo, 2019).

Other surgical procedures may be performed for different degrees and types of underlying disorders. These procedures include revision of the sphincter of the ampulla of Vater, internal drainage of a pancreatic cyst into the stomach (see later discussion), insertion of a stent, and wide resection or removal of the pancreas. A Whipple's resection (pancreaticoduodenectomy) can be carried out to relieve the pain of chronic pancreatitis (see later discussion under Tumors of the Head of the Pancreas). In an effort to provide permanent pain relief and avoid endocrine and exocrine insufficiency that ensue with major resections of the pancreas, some procedures combine limited resection of the head of the pancreas with a pancreaticojejunostomy. These procedures, known as the Beger or Frey operations, remove most of the head of the pancreas except for a

shell of pancreatic tissue posteriorly (Brunicardi, 2019; Cameron & Cameron, 2020; Yeo, 2019).

When chronic pancreatitis develops as a result of gallbladder disease, surgery is performed to explore the common duct and remove the stones; usually, the gallbladder is removed at the same time. In addition, an attempt is made to improve the drainage of the CBD and the pancreatic duct by dividing the sphincter of Oddi, a muscle that is located at the ampulla of Vater (this surgical procedure is known as a sphincterotomy). A T-tube usually is placed in the common bile duct, requiring a drainage system to collect the bile postoperatively. Nursing care after such surgery is similar to that indicated after other biliary tract surgery.

Approximately two thirds of all patients with chronic pancreatitis can be managed with endoscopic or laparoscopic intervention (Jalal et al., 2019; Singh, 2019). Endoscopic and laparoscopic procedures such as distal pancreatectomy, longitudinal decompression of the pancreatic duct, nerve denervation, and stenting have been performed in patients with jaundice or recurrent inflammation and are being refined. Minimally invasive procedures to treat chronic pancreatitis may prove to be successful adjuncts in the management of this complex disorder (Jalal et al., 2019; Singh, 2019).

Patients who undergo surgery for chronic pancreatitis may experience weight gain and improved nutritional status; this may result from reduction in pain associated with eating rather than from correction of malabsorption. However, morbidity and mortality after these surgical procedures are high because of the poor physical condition of the patient before surgery and the frequent presence of cirrhosis. Even after undergoing these surgical procedures, the patient is likely to continue to have pain and impaired digestion secondary to pancreatitis.

Pancreatic Cysts

As a result of the local necrosis that occurs because of acute pancreatitis, collections of fluid may form close to the pancreas. These fluid collections become walled off by fibrous tissue and are called *pancreatic pseudocysts*. Pseudocysts are amylase-rich fluid collections contained within a wall of fibrous granulation tissue and develop within 4 to 6 weeks after an episode of acute pancreatitis. They are a result of pancreatic necrosis, which produces a pancreatic ductal leak into pancreatic tissue weakened by extravasating enzymes (Feldman et al., 2016; Goldman & Schafer, 2019). Pseudocysts are distinguished from true cysts by the characteristics of the lining of the walls of these anomalies. The lining of pseudocysts consists of fibrous granulation tissue, whereas true cysts have epithelium-lined walls (Bansal, Gupta, Singh, et al., 2019; Feldman et al., 2016; Goldman & Schafer, 2019; Papadakis &

McPhee, 2020). Pseudocysts are the most common type of pancreatic "cyst." Less common cysts occur as a result of congenital anomalies or secondary to chronic pancreatitis or trauma to the pancreas.

Diagnosis of pancreatic cysts and pseudocysts is made by ultrasound, CT scan, and ERCP. ERCP may be used to identify the anatomy of the pancreas and evaluate the patency of pancreatic drainage. Pancreatic pseudocysts may be of considerable size. When pancreatic pseudocysts enlarge, they impinge on and displace the adjacent stomach or the colon because of the location of pseudocysts behind the posterior peritoneum. Eventually, through pressure or secondary infection, they produce symptoms and require drainage.

Drainage into the GI tract or through the skin and abdominal wall may be established. In the latter instance, the drainage is likely to be profuse and destructive to tissue because of the enzyme contents. Hence, steps (including application of skin ointment) must be taken to protect the skin near the drainage site from excoriation. A suction apparatus may be used to continuously aspirate digestive secretions from the drainage tract so that skin contact with the digestive enzymes is avoided. Expert nursing attention is required to ensure that the suction tube does not become dislodged and suction is not interrupted. Consultation with a WOC nurse is indicated to identify appropriate strategies for maintaining drainage and protecting the skin.

Cancer of the Pancreas

Pancreatic cancer is the fourth leading cause of cancer death in men in the United States and the fifth leading cause of cancer death in women. It is very rare before the age of 45 years, and the majority of patients present in or beyond the sixth decade of life (Feldman et al., 2016; Papadakis & McPhee, 2020; Yeo, 2019). The incidence of pancreatic cancer increases with age, peaking in the seventh and eighth decades for both men and women (American Cancer Society [ACS], 2020). The frequency of pancreatic cancer has decreased slightly over the past 25 years among non-Caucasian men. There is a slight male preponderance; and in the United States, incidence is highest in African American males (ACS, 2020; Feldman et al., 2016). Exposure to industrial chemicals or toxins in the environment, and a diet high in fat, meat, or both are associated risk factors (ACS, 2020; Feldman et al., 2016; Papadakis & McPhee, 2020).

The risk of pancreatic cancer is greater in those with a history of increased pack years of cigarette smoking and in those with high alcohol intake. Diabetes, chronic pancreatitis, hereditary pancreatitis, and obesity are also associated with pancreatic cancer (Rawla, 2019; Yeo, 2019). The pancreas can also be the site of metastasis from other tumors.

Cancer may develop in the head, body, or tail of the pancreas; clinical manifestations vary depending on the site and whether functioning insulin-secreting pancreatic islet cells are involved. Approximately 70% of pancreatic cancers originate in the head of the pancreas and give rise to a distinctive clinical picture (Feldman et al., 2016; Rawla, 2019). Functioning islet cell tumors, whether benign (adenoma) or malignant (adenocarcinoma), are responsible for the syndrome of hyperinsulinism. The symptoms are typically nonspecific, and patients usually do not seek medical attention until late in the disease. Only about 7% of cases are diagnosed in early stages; 80% to 85% of patients have advanced, unresectable tumor when first detected. As a result, pancreatic carcinoma has only a 7% survival rate at 5 years regardless of the stage of disease at diagnosis or treatment (ACS, 2020; Rawla, 2019; Yeo, 2019).

Clinical Manifestations

Pain, jaundice, or both are present in more than 80% of patients and, along with weight loss, are considered classic signs of pancreatic carcinoma (Brunicardi, 2019; Feldman et al., 2016; Yeo, 2019). However, they often do not appear until the disease is far advanced. Other signs include rapid, profound, and progressive weight loss as well as vague upper or midabdominal pain or discomfort that is unrelated to any GI function and is often difficult to describe. Such discomfort radiates as a boring pain in the midback and is unrelated to posture or activity. It is often progressive and severe, requiring the use of opioids. It is often more severe at night and is accentuated when lying supine. Relief may be obtained by sitting up and leaning forward.

Malignant cells from pancreatic cancer are often shed into the peritoneal cavity, increasing the likelihood of metastasis. The formation of ascites is common. An important sign, if present, is the onset of symptoms of insulin deficiency: glucosuria, hyperglycemia, and abnormal glucose tolerance. Therefore, diabetes may be an early sign of carcinoma of the pancreas. Meals often aggravate epigastric pain, which usually occurs before the appearance of jaundice and pruritus.

Assessment and Diagnostic Findings

Spiral (helical) CT is more than 85% to 90% accurate in the diagnosis and staging of pancreatic cancer and currently is the most useful preoperative imaging technique. MRI/MRCP may also be used. EUS is useful in identifying small tumors and in performing fine-needle aspiration biopsy of the primary tumor or lymph nodes (Goldman & Schafer, 2019; Papadakis & McPhee, 2020). EUS can be superior to CT in localizing these small tumors, which can

produce dramatic symptoms despite their size (<1 cm) (Brunicardi, 2019). ERCP may also be used in the diagnosis of pancreatic carcinoma.

Cells obtained during ERCP are sent to the laboratory for analysis. GI x-ray findings may demonstrate deformities in adjacent organs caused by the impinging pancreatic mass.

A histologic diagnosis is not usually required in patients who are candidates for surgery. The tissue diagnosis is made at the time of the surgical procedure. Percutaneous fine-needle aspiration biopsy of the pancreas, which is used to diagnose pancreatic tumors, is also used to confirm the diagnosis in patients whose tumors are not resectable so that a palliative plan of care can be determined. This may eliminate the stress and postoperative pain of ineffective surgery. In this procedure, a needle is inserted through the anterior abdominal wall into the pancreatic mass, guided by CT, ultrasound, ERCP, or other imaging techniques. The aspirated material is examined for malignant cells. Although percutaneous biopsy is a valuable diagnostic tool, it has some potential drawbacks: a false-negative result if small tumors are missed and the risk of seeding of cancer cells along the needle track. Low-dose radiation to the site may be used before the biopsy to reduce this risk.

PTC is another procedure that may be performed to identify obstructions of the biliary tract by a pancreatic tumor. Several tumor markers (e.g., cancer antigen 19-9, carcinoembryonic antigen, DU-PAN-2) may be used in the diagnostic workup, but they are nonspecific for pancreatic carcinoma. These tumor markers are useful as indicators of disease progression.

Angiography, CT scans, and laparoscopy may be performed to determine whether the tumor can be removed surgically. Intraoperative ultrasonography has been used to determine whether there is metastatic disease to other organs.

Medical Management

If the tumor is resectable and localized (typically tumors in the head of the pancreas), the surgical procedure to remove it is usually extensive (see later discussion). However, total excision of the lesion often is not possible for two reasons: (1) extensive growth of tumor before diagnosis, and (2) probable widespread metastases (especially to the liver, lungs, and bones). More often, treatment is limited to palliative measures.

Although pancreatic tumors may be resistant to standard radiation therapy, the patient may be treated with radiation and chemotherapy (5-fluorouracil, leucovorin, and gemcitabine). Currently, gemcitabine is the standard of care for patients with metastatic pancreatic cancer and has been found to lengthen survival (ACS, 2020; Feldman et al., 2016). The targeted anticancer drug erlotinib has demonstrated a slight improvement in advanced pancreatic cancer survival when used in combination with gemcitabine (ACS, 2020; Brunicardi, 2019). Agents such as S-1 (an oral fluoropyrimidine), or the use of

nanoparticle albumin-bound paclitaxel with gemcitabine therapy, combined with radiation or surgery may also result in improved survival (ACS, 2020; Brunicardi, 2019; Kamisawa, Wood, Itoi, et al., 2016). Irinotecan, in combination with fluorouracil and leucovorin, was approved as treatment for metastatic pancreatic adenocarcinoma that has progressed following treatment with a gemcitabine-based therapy. 5-Fluorouracil or capecitabine, a similar but orally administered drug, are used as radiosensitizers during radiation therapy (Brunicardi, 2019). Single-agent gemcitabine may be used in patients who are not well enough to tolerate combination therapy (ACS, 2020; Brunicardi, 2019; O'Reilly, Fou, Hasler, et al., 2018).

If the patient undergoes surgery, intraoperative radiation therapy may be used to deliver a high dose of radiation to the tumor with minimal injury to other tissues; this may also be helpful in relief of pain. Interstitial implantation of radioactive sources has also been used, although the rate of complications is high. A large biliary stent inserted percutaneously or by endoscopy may be used to relieve jaundice (Brunicardi, 2019; O'Reilly et al., 2018).

Nursing Management

Pain management and attention to nutritional requirements are important nursing measures that improve the level of patient comfort. Skin care and nursing measures are directed toward relief of pain and discomfort associated with jaundice, anorexia, and profound weight loss. Specialty mattresses are beneficial and protect bony prominences from pressure. Pain associated with pancreatic cancer may be severe and may require liberal use of opioids; patient-controlled analgesia should be considered for the patient with severe, escalating pain.

There is growing evidence that symptoms frequently appear together in a phenomenon known as a symptom cluster. A symptom cluster is two (or more) symptoms occurring at the same time. The symptoms included in a cluster may have shared underlying mechanisms or outcomes, and pancreatic cancer is one of the diseases that appears to have associated symptom clusters. It may be beneficial to investigate these symptoms as a cluster, rather than individually (Miaskowski, Barsevick, Berger, et al., 2017).

Symptom clusters associated with pancreatic cancer have been identified in several studies and include affective, GI, gustatory, and discomfort-related symptoms (Burrell, Yeo, Smeltzer, et al., 2018a, 2018b). See the Nursing Research Profile in Chart 44-5.

Knowledge and awareness regarding symptom clusters is important to nursing care for patients with pancreatic cancer. Improving nursing assessments and interventions based upon this evidence may improve the quality of life and survival in patients with pancreatic cancer undergoing surgical resection for this disease (Burrell et al., 2018a, 2018b). Because of the

poor prognosis and likelihood of short survival, end-of-life preferences are discussed and honored. If appropriate, the nurse refers the patient to hospice care. See Chapters 12 and 13 for care of the patient with cancer and end-of-life care, respectively.

Promoting Home, Community-Based, and Transitional Care

Educating Patients About Self-Care

Specific education for the patient and family varies with the stage of disease and the treatment choices made by the patient. If the patient elects to receive chemotherapy, the nurse focuses on prevention of side effects and complications of the agents used. If surgery is performed to relieve obstruction and establish biliary drainage, education addresses management of the drainage system and monitoring for complications. The nurse educates the family about changes in the patient's status that should be reported to the primary provider.

Continuing and Transitional Care

A referral for home, community-based, or transitional care is indicated to help the patient and family deal with the physical problems and discomforts associated with pancreatic cancer and the psychological impact of the disease. The nurse assesses the patient's physical status, fluid and nutritional status, skin integrity, and the adequacy of pain management. The nurse educates the patient and family on strategies to prevent skin breakdown and relieve pain, pruritus, and anorexia. It is important to discuss and arrange palliative care (hospice services) as indicated in an effort to relieve patient discomfort, assist with care, and comply with the patient's end-of-life decisions and wishes.

Tumors of the Head of the Pancreas

Tumors of the head of the pancreas comprise 60% to 80% of all pancreatic tumors (Goldman & Schafer, 2019; Yeo, 2019). Tumors in this region of the pancreas obstruct the common bile duct where the duct passes through the head of the pancreas to join the pancreatic duct and empty at the ampulla of Vater into the duodenum. The tumors producing the obstruction may arise from the pancreas, the common bile duct, or the ampulla of Vater (Yeo, 2019).

Chart 44-5 NURSING RESEARCH PROFILE

Symptom Clusters in Patients with Pancreatic Cancer

Burrell, S. A., Yeo, T. P., Smeltzer, S. C., et al. (2018a). Symptom clusters in patients with pancreatic cancer undergoing surgical resection: Part I. *Oncology Nursing Forum*, *45*(4), e36–e52.

Purpose

The purpose of this study was to describe patient-reported symptoms and symptom clusters in patients with pancreatic cancer undergoing surgical resection.

Design

The study recruited 143 patients with stage II pancreatic cancer undergoing surgical resection alone or with subsequent adjuvant chemoradiation or chemotherapy to participate in a nested, longitudinal, exploratory study through convenient sampling techniques. The Functional Assessment in Cancer Therapy–Hepatobiliary questionnaire was used to assess 17 pancreatic cancer symptoms preoperatively and at 3, 6, and 9 months postoperatively. Exploratory and confirmatory factor analyses were used to identify symptom clusters.

Findings

Fatigue, trouble sleeping, poor appetite, trouble digesting food, and weight loss were consistently reported as the most prevalent and severe symptoms. Sixteen distinct symptom clusters were identified within 9 months of surgery. Four core symptom clusters persisted over time: affective, GI, gustatory, and discomfort.

Nursing Implications

The findings in this study may be used by nurses to provide anticipatory patient and family education and guidance as they begin and continue with their treatment.

Nurses and other health care providers will be knowledgeable about symptoms and symptom clusters in this population, which may guide assessments and interventions.

Clinical Manifestations

The obstructed flow of bile produces jaundice, clay-colored stools, and dark urine. Malabsorption of nutrients and fat-soluble vitamins may result if the

tumor obstructs the entry of bile to the GI tract. Abdominal discomfort or pain and pruritus may be noted, along with anorexia, weight loss, and malaise. If these signs and symptoms are present, cancer of the head of the pancreas is suspected.

The jaundice of this disease must be differentiated from that due to a biliary obstruction caused by a gallstone in the common duct. Jaundice caused by a gallstone is usually intermittent and occurs more commonly in women and in people with obesity and who have had previous symptoms of gallbladder disease.

Assessment and Diagnostic Findings

Diagnostic studies may include duodenography, angiography by hepatic or celiac artery catheterization, pancreatic scanning, PTC, ERCP, and percutaneous needle biopsy of the pancreas. Results of a biopsy of the pancreas may aid in the diagnosis.

Medical Management

Before extensive surgery can be performed, a period of preparation is necessary because the patient's nutritional status and physical condition are often quite compromised. Various liver and pancreatic function studies are performed. A diet high in protein along with pancreatic enzymes, which aid digestion, is often prescribed. Preoperative preparation includes adequate hydration, correction of prothrombin deficiency with vitamin K, and treatment of anemia to minimize postoperative complications. Enteral or parenteral nutrition and blood component therapy are frequently required.

A biliary drainage procedure may be performed, usually with a catheter via percutaneous access, to relieve the jaundice and, perhaps, to provide time for a thorough diagnostic evaluation. Total pancreatectomy (removal of the pancreas) may be performed if there is no evidence of direct extension of the tumor to adjacent tissues or regional lymph nodes. A pancreaticoduodenectomy (Whipple's procedure or resection) is used for potentially resectable cancer of the head of the pancreas (see Fig. 44-7) (Brunicardi, 2019; Yeo, 2019). This procedure involves removal of the gallbladder, a portion of the stomach, duodenum, proximal jejunum, head of the pancreas, and distal common bile duct. Reconstruction involves anastomosis of the remaining pancreas and stomach to the jejunum (Cameron & Cameron, 2020; Townsend et al., 2016; Yeo, 2019). A pylorus-preserving pancreaticojejunostomy (PPPD) may also be performed for tumors of the head of the pancreas and may reduce postgastrectomy symptoms and improve overall GI function (Yeo, 2019). The result of these procedures is removal of the tumor, allowing flow of bile into the jejunum. If the tumor cannot be

excised, the jaundice may be relieved by diverting the bile flow into the jejunum by anastomosing the jejunum to the gallbladder, a procedure known as **cholecystojejunostomy** (Brunicardi, 2019; Yeo, 2019).

The postoperative management of patients who have undergone a pancreatectomy or a pancreaticoduodenectomy is similar to the management of patients after extensive GI or biliary surgery. The patient's physical status is often suboptimal, increasing the risk of postoperative complications. Hemorrhage, vascular collapse, and hepatorenal failure remain the major postoperative complications. The mortality rate associated with these procedures has decreased because of advances in nutritional support and improved surgical techniques. A nasogastric tube with suction and parenteral nutrition allow the GI tract to rest while promoting adequate nutrition.

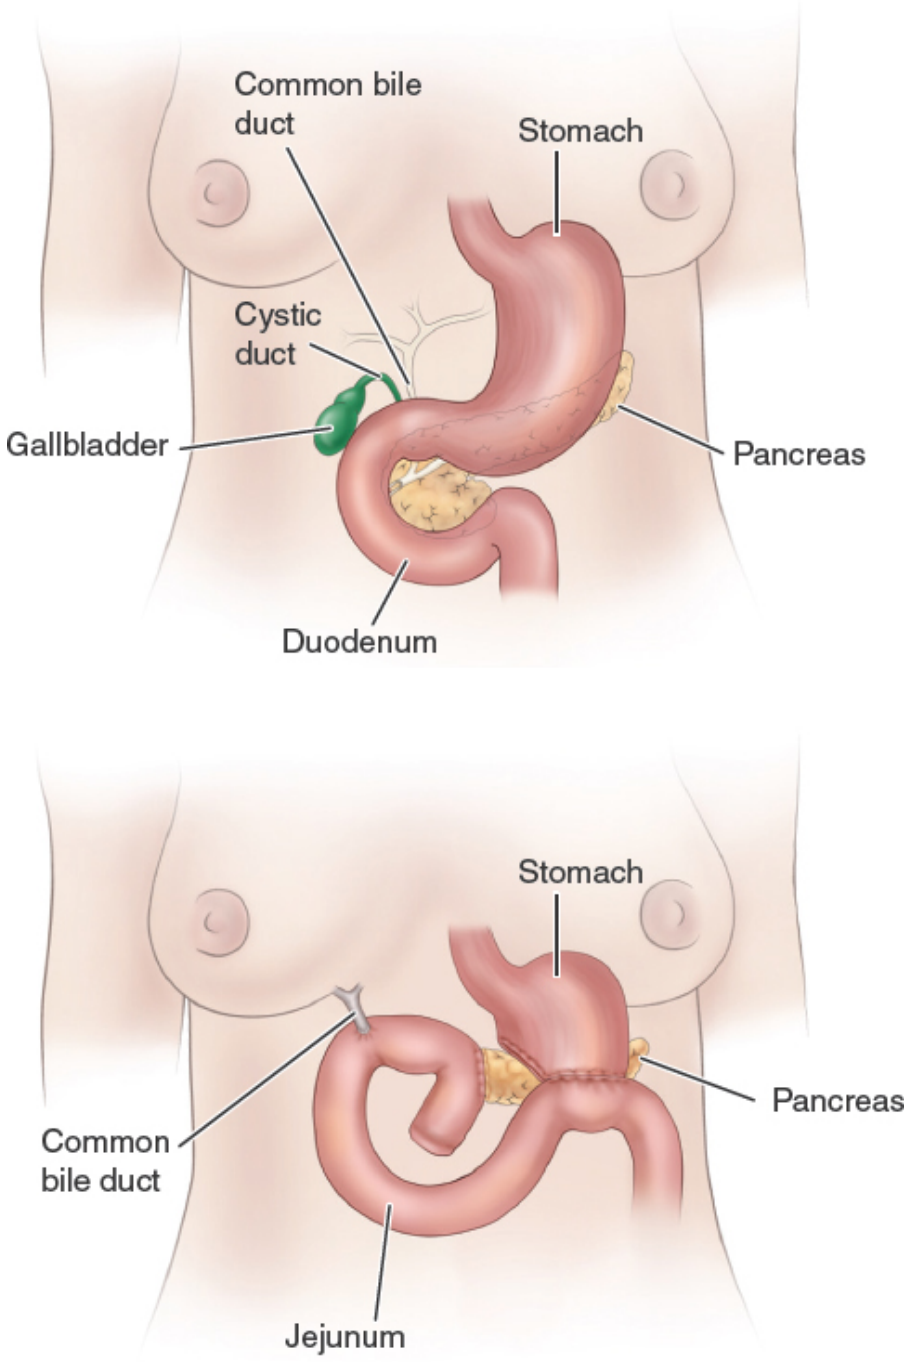

Figure 44-7 • Pancreatoduodenectomy (Whipple's procedure or resection). End result of resection of carcinoma of the head of the pancreas or the ampulla of Vater. The common duct is sutured to the side of the jejunum (choledochojejunostomy), and the remaining portion of the pancreas and the end of the stomach are sutured to the side of the jejunum.

Nursing Management

Preoperatively and postoperatively, nursing care is directed toward promoting patient comfort, preventing complications, and assisting the patient to return to and maintain as normal and comfortable a life as possible. The nurse closely monitors the patient in the intensive care unit after surgery; in the immediate postoperative period, multiple IV and arterial lines are used for fluid and blood replacement and hemodynamic monitoring, and a mechanical ventilator may be used. It is important to note and report changes in vital signs, arterial blood gases and pressures, pulse oximetry, laboratory values, and urine output. The nurse must also consider the patient's compromised nutritional status and risk of bleeding. Depending on the type of surgical procedure performed, malabsorption syndrome and diabetes are likely; the nurse must address these issues during acute and long-term patient care.

Although the patient's physiologic status is the focus of the health care team in the immediate postoperative period, the patient's psychological and emotional states must be considered, along with those of the family. The patient has undergone a major high-risk surgery and is critically ill; anxiety and depression may affect recovery. The immediate and long-term outcomes of this extensive surgical resection are uncertain, and the patient and family require emotional support and understanding in the critical and stressful preoperative and postoperative periods.

Promoting Home, Community-Based, and Transitional Care

Educating Patients About Self-Care

The patient who has undergone this extensive surgery requires careful and thorough preparation for self-care at home. The nurse educates the patient and family about strategies to relieve pain and discomfort, along with strategies to manage drains, if present, and to care for the surgical incision. The patient and family members may require education about the use of appropriate analgesic medications, parenteral nutrition, wound care, skin care, increasing activity, and management of drainage.

The nurse may need to educate the patient and family about the need for modifications in the diet because of malabsorption and hyperglycemia resulting from the surgery. It is important to educate the patient and family about the continuing need for pancreatic enzyme replacement, a low-fat diet, and vitamin supplementation. The nurse describes—verbally and in writing—the signs and symptoms of complications and educates the patient and family about indicators of complications that should be reported promptly.

Discharge of the patient to a long-term care or rehabilitation facility may be warranted after surgery as extensive as pancreatectomy or pancreaticoduodenectomy, particularly if the patient's preoperative status is not

optimal. Information about the education that has been provided is shared with the long-term care staff so that instructions can be clarified and reinforced. During the recovery or long-term phase of care, the patient and family receive further education about self-care in the home.

Continuing and Transitional Care

A referral for home, community-based, or transitional care may be indicated when the patient returns home. The nurse assesses the patient's physical and psychological status and the ability of the patient and family to manage needed care. The nurse provides needed physical care and monitors the adequacy of pain management. In addition, it is important to assess the patient's nutritional status and monitor the use of enteral or parenteral nutrition, if used. The nurse discusses the use of hospice services with the patient and family and makes a referral if indicated.

Pancreatic Islet Tumors

At least two types of tumors of the pancreatic islet cells are known: those that secrete insulin (insulinoma) and those in which insulin secretion is not increased (nonfunctioning islet cell cancer). All of these types of tumors combined are termed *neuroendocrine tumors* (NETs). Insulinomas produce hypersecretion of insulin and cause an excessive rate of glucose metabolism. The resulting hypoglycemia may produce symptoms of weakness, mental confusion, and seizures. These symptoms may be relieved almost immediately by oral or IV administration of glucose. The 5-hour glucose tolerance test is helpful to diagnose insulinoma and to distinguish a diagnosis of NET from other causes of hypoglycemia.

Surgical Management

If a tumor of the islet cells (a type of NET) has been diagnosed, surgical treatment with removal of the tumor is usually recommended (Brunicardi, 2019; Yeo, 2019). The tumors may be benign adenomas, or they may be malignant. Complete removal usually results in almost immediate relief of symptoms. In some patients, symptoms may be produced by simple hypertrophy of this tissue rather than a tumor of the islet cells. In such cases, a partial pancreatectomy (removal of the tail and part of the body of the pancreas) is performed.

Nursing Management

In preparing the patient for surgery, the nurse must be alert for symptoms of hypoglycemia and be ready to administer glucose as prescribed if symptoms occur. Postoperatively, the nursing management is the same as after other upper abdominal surgical procedures, with special emphasis on monitoring serum glucose levels. Patient education is determined by the extent of surgery and alterations in pancreatic function.

Hyperinsulinism

Hyperinsulinism is caused by overproduction of insulin by the pancreatic islets. Symptoms resemble those of excessive doses of insulin and are attributable to the same mechanism: an abnormal reduction in blood glucose levels. Clinically, it is characterized by episodes during which the patient experiences unusual hunger, nervousness, sweating, headache, and faintness; in severe cases, seizures and episodes of unconsciousness may occur. The findings at the time of surgery or at autopsy may indicate hyperplasia (overgrowth) of the islets of Langerhans or a benign or malignant tumor involving the islets that is capable of producing large amounts of insulin (see preceding discussion). Occasionally, tumors of nonpancreatic origin produce an insulinlike material that can cause severe hypoglycemia and may be responsible for seizures coinciding with blood glucose levels that are too low to sustain normal brain function (i.e., lower than 30 mg/dL [1.6 mmol/L]) (Goldman & Schafer, 2019; Kellerman & Rakel, 2018).

All of the symptoms that accompany spontaneous hypoglycemia are relieved by the oral or parenteral administration of glucose. Surgical removal of the hyperplastic or neoplastic tissue from the pancreas is the only successful method of treatment. About 15% of patients with spontaneous or functional hypoglycemia eventually develop diabetes.

Ulcerogenic Tumors

Some tumors of the islets of Langerhans are associated with hypersecretion of gastric acid that produces ulcers in the stomach, duodenum, and jejunum. This is referred to as **Zollinger-Ellison syndrome**. The hypersecretion is so excessive that even after partial gastric resection, enough acid is produced to cause further ulceration. If a marked tendency to develop gastric and duodenal ulcers is noted, an ulcerogenic tumor of the islets of Langerhans is considered (Brunicardi, 2019; Yeo, 2019). The clinical manifestations include nausea, vomiting, diarrhea, and burning discomfort or pain in the upper abdomen. The diagnostic test for this disorder includes measuring a blood gastrin level. Imaging tests may include CT scan or MRI, EUS or upper endoscopy.

Scintigraphy and positron emission tomography (PET)/CT are sensitive and specific tests for this disease (Brunicardi, 2019; Yeo, 2019).

These tumors, which may be benign or malignant, are treated by excision, if possible. Frequently, however, removal is not possible because of extension beyond the pancreas and because the tumors are often quite small and difficult to locate. Acid hypersecretion in patients with gastrinoma can be managed with proton pump inhibitors and this is often the first-line treatment intervention. Highly selective vagotomy may make management easier in some patients and should be considered in those with surgically untreatable or unresectable gastrinoma. Total gastrectomy for Zollinger-Ellison is not indicated (Brunicardi, 2019; Yeo, 2019). Embolization or radiofrequency ablation may also be used to control the tumor.

The many disorders of the biliary and pancreatic systems result in a host of clinical and biochemical abnormalities presented in detail in this chapter. The recognition and management of these illnesses pose a challenge to nurses. There is now much evidence about the prevention, diagnosis, and treatment of these disorders. However, there is still much to learn as the medical and nursing communities strive to provide optimum care to patients afflicted with biliary and pancreatic disorders.

CRITICAL THINKING EXERCISES

1 pq A 57-year-old man has been having symptoms over the past 2 months including burning discomfort or pain in his upper abdomen, nausea, and diarrhea. He thought that he had acid reflux with heartburn so he started an over-the-counter histamine antagonist. His appetite had decreased and he had lost several pounds. The patient's physician performed a complete physical examination and thinks that the patient may have Zollinger-Ellison syndrome. What laboratory testing might you anticipate? What diagnostic imaging will most likely be performed? What medication or medications may be prescribed? Since the patient continues to be symptomatic, surgery is recommended. What patient education can you provide to best prepare the patient for the surgical intervention and the postoperative care?

2 ebp A 58-year-old man presents to the emergency department with complaints of severe midepigastric pain. He is also nauseated and vomiting. His vital signs reveal hypotension and tachycardia and he is mildly febrile. His history is significant for alcohol abuse and hypertension. What laboratory and imaging studies do you expect to be performed? His CT scan revealed noninfected pancreatic necrosis. An evidence-based approach for managing pancreatic necrosis was implemented. Would surgery be included in this initial approach? What first-line intervention would you expect to be implemented in this case? What classification of pancreatitis is this patient experiencing? After 1 week in the hospital, the patient's fever is higher, he is having more abdominal pain and a repeat CT scan reveals multiple fluid collections and worsening edema consistent with infected pancreatic necrosis. What is the evidence for new therapies to effectively treat this patient?

3 ipc A 55-year-old woman has been experiencing upper abdominal pain for several weeks. She believes that she has gallbladder disease but is concerned because her mother died from pancreatic cancer. She visits her primary provider who prescribes diagnostic and laboratory studies. Which laboratory tests would you expect to be assessed? An MRI reveals a small mass at the head of the pancreas. What type of referrals might be appropriate for this patient? What members of the interprofessional health care team do you anticipate as being integral to the care of this patient?

45 Assessment and Management of Patients with Endocrine Disorders

LEARNING OUTCOMES

On completion of this chapter, the learner will be able to:

1. Describe the functions of each of the endocrine glands and their hormones.
2. Differentiate diagnostic studies and clinical manifestations for endocrine disorders.
3. Demonstrate knowledge of management strategies for endocrine disorders.
4. Explain nursing interventions in the care of patients with endocrine disorders.
5. Use the nursing process as a framework for care of the patient with an endocrine disorder.

NURSING CONCEPTS

Cellular Regulation
Family
Infection
Inflammation
Metabolism
Mobility
Nutrition
Stress

GLOSSARY

acromegaly: progressive enlargement of peripheral body parts resulting from excessive secretion of growth hormone

Addison's disease: chronic adrenocortical insufficiency due to inadequate adrenal cortex function

Addisonian crisis: acute adrenocortical insufficiency; characterized by hypotension, cyanosis, fever, nausea/vomiting, and signs of shock

adrenalectomy: surgical removal of one or both adrenal glands

adrenocorticotropic hormone (ACTH): hormone secreted by the anterior pituitary, essential for growth and development

androgens: male sex hormones

basal metabolic rate: chemical reactions occurring when the body is at rest

calcitonin: hormone secreted by the thyroid gland; participates in calcium regulation

Chvostek sign: spasm of the facial muscles produced by sharply tapping over the facial nerve in front of the parotid gland and anterior to the ear; suggestive of latent tetany in patients with hypocalcemia

corticosteroids: hormones produced by the adrenal cortex or their synthetic equivalents

Cushing's syndrome: group of symptoms produced by an oversecretion of adrenocorticotropic hormone; characterized by truncal obesity, "moon face," acne, abdominal striae, and hypertension

diabetes insipidus: condition in which abnormally large volumes of dilute urine are excreted as a result of deficient production of vasopressin

euthyroid: state of normal thyroid hormone production

exophthalmos: abnormal protrusion of one or both eyeballs

glucocorticoids: steroid hormones secreted by the adrenal cortex in response to adrenocorticotropic hormone; produce a rise of liver glycogen and blood glucose

goiter: enlargement of the thyroid gland

Graves disease: a form of hyperthyroidism; characterized by a diffuse goiter and exophthalmos

hormones: chemical transmitter substances produced in one organ or part of the body and carried by the bloodstream to other cells or organs on which they have a specific regulatory effect

mineralocorticoids: steroid hormones secreted by the adrenal cortex

myxedema: severe hypothyroidism; can be with or without coma

negative feedback: regulating mechanism in which an increase or decrease in the level of a substance decreases or increases the function of the organ producing the substance

pheochromocytoma: adrenal medulla tumor

syndrome of inappropriate antidiuretic hormone (SIADH): excessive secretion of antidiuretic hormone from the pituitary gland despite low serum osmolality level

thyroidectomy: surgical removal of all or part of the thyroid gland

thyroiditis: inflammation of the thyroid gland; may lead to chronic hypothyroidism or may resolve spontaneously

thyroid-stimulating hormone (TSH): released from the pituitary gland; causes stimulation of the thyroid, resulting in release of T_3 and T_4

thyroid storm: life-threatening condition of the thyroid due to untreated hyperthyroidism

thyrotoxicosis: condition produced by excessive endogenous or exogenous thyroid hormone

thyroxine (T_4): thyroid hormone; active iodine compound formed and stored in the thyroid; deiodinated in peripheral tissues to form triiodothyronine; maintains body metabolism in a steady state

triiodothyronine (T_3): thyroid hormone; formed and stored in the thyroid; released in smaller quantities, biologically more active, and with faster onset of action than T_4; widespread effect on cellular metabolism

Trousseau sign: carpopedal spasm induced when blood flow to the arm is occluded using a blood pressure cuff or tourniquet, causing ischemia to the distal nerves; suggestive sign for latent tetany in hypocalcemia

vasopressin: antidiuretic hormone secreted by the posterior pituitary

The endocrine system plays a vital role in orchestrating transportation of chemicals across cell membranes, growth and development, metabolism, fluid and electrolyte balance, acid–base balance, adaptation, and reproduction (Norris, 2019). This interconnected network of glands is closely linked with the nervous and immune systems, regulating the functions of multiple body organs. The hypothalamus is responsible for this interrelationship. The pituitary gland, because of its status as the master gland, plays an important role in the regulation of endocrine hormones; its primary function is to secrete hormones into the bloodstream, which in turn affects endocrine glands such as the thyroid. Disorders of the endocrine system are common and are manifested as hyper- and hypofunction.

Nursing interventions are essential in the management of patients with endocrine disorders. This chapter focuses on the anatomy and physiology of the endocrine system; the most common endocrine disorders of the pituitary, thyroid, parathyroid, and adrenal glands; clinical manifestations; diagnostic studies; medical management; and nursing interventions. The unique endocrine and exocrine functions of the pancreas, pancreatic function, and

associated pancreatic disorders are discussed in Chapter 44 and reproductive structures, including the ovaries and testes, are discussed in Chapters 50 and 53, respectively.

ASSESSMENT OF THE ENDOCRINE SYSTEM

Anatomic and Physiologic Overview

The endocrine system involves the release of chemical transmitter substances known as **hormones**. These substances regulate and integrate body functions by acting on local or distant target sites. Hormones are generally produced by the endocrine glands but may also be produced by specialized tissues such as those found in the gastrointestinal (GI) system, the kidney, and white blood cells. The GI mucosa produces hormones (e.g., gastrin, enterogastrone, secretin, cholecystokinin) that are important in the digestive process; the kidneys produce erythropoietin, a hormone that stimulates the bone marrow to produce red blood cells; and the white blood cells produce cytokines (hormonelike proteins) that actively participate in inflammatory and immune responses.

The endocrine system has a unique relationship with the immune and the nervous systems. Chemicals such as neurotransmitters (e.g., epinephrine) released by the nervous system can also function as hormones when needed. The immune system responds to the introduction of foreign agents by means of chemical messengers (cytokines), and is also subject to regulation by adrenal corticosteroid hormones (Norris, 2019).

Glands of the Endocrine System

The endocrine system is composed of the pituitary gland, thyroid gland, parathyroid glands, adrenal glands, pancreatic islets, ovaries, and testes. See Figure 45-1 for major hormonal secreting glands of the endocrine system. Most hormones secreted from endocrine glands are released directly into the bloodstream. However, exocrine glands, such as sweat glands, secrete their products through ducts onto epithelial surfaces or into the GI tract.

Function and Regulation of Hormones

Hormones help regulate organ function in concert with the nervous system. The rapid action by the nervous system is balanced by slower hormonal action. This dual regulatory system permits precise control of organ functions in response to changes within and outside the body.

The endocrine glands are composed of secretory cells arranged in minute clusters known as acini. A rich blood supply provides a vehicle for the hormones produced by the endocrine glands to enter the bloodstream rapidly.

The amount of circulating hormones depends on their unique function and the body's needs. In the healthy physiologic state, hormone concentration in the bloodstream is maintained at a relatively constant level. To prevent accumulation, these hormones must be inactivated continuously by a **negative feedback** system so that when the hormone concentration increases, further production of that hormone is inhibited. Conversely, when the hormone concentration decreases, the rate of production of that hormone increases.

Classification and Action of Hormones

Hormones are classified into four categories according to their structure: (1) amines and amino acids (e.g., epinephrine, norepinephrine, and thyroid hormones); (2) peptides, polypeptides, proteins, and glycoproteins (e.g., thyrotropin-releasing hormone [TRH], follicle-stimulating hormone [FSH], and growth hormone [GH]); (3) steroids (e.g., **corticosteroids**, which are hormones produced by the adrenal cortex or their synthetic equivalents); and (4) fatty acid derivatives (e.g., eicosanoid, retinoids) (Norris, 2019). Although most hormones released by endocrine glands can be transported to distant target sites for action, some hormones never enter the bloodstream because they act locally in the area where they are released; this is called *paracrine action* (e.g., the effect of sex hormones on the ovaries). Others may act on the actual cells from which they were released; this is called *autocrine action* (e.g., the effect of insulin from pancreatic beta cells on those cells) (Norris, 2019).

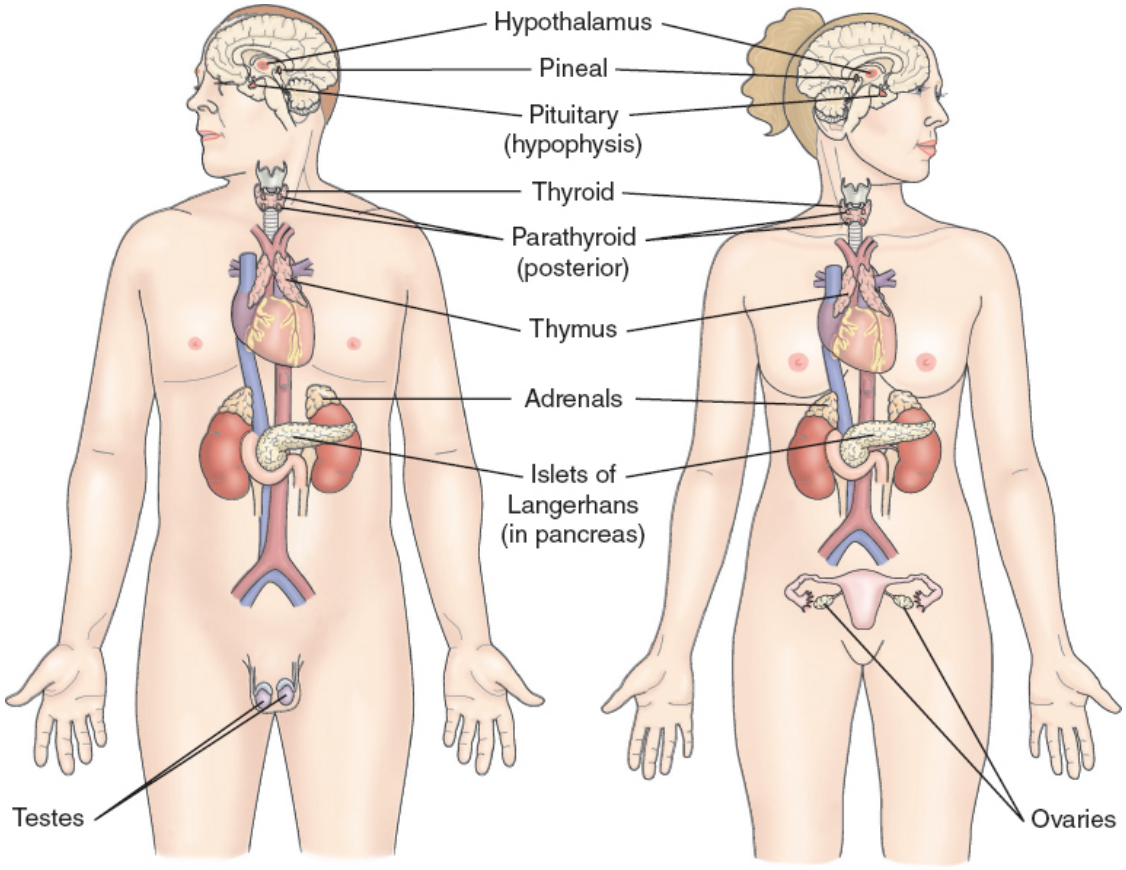

Figure 45-1 • Major hormone-secreting glands of the endocrine system.

Hormones can alter the function of the target tissue by interacting with chemical receptors located either on the cell membrane or in the interior of the cell. For example, *peptide* and *protein hormones* interact with receptor sites on the cell surface, resulting in stimulation of the intracellular enzyme adenyl cyclase. This causes increased production of cyclic 3′,5′-adenosine monophosphate (AMP). The cyclic AMP inside the cell alters enzyme activity. Thus, cyclic AMP is the "second messenger" that links the peptide hormone at the cell surface to a change in the intracellular environment. Some protein and peptide hormones also act by changing membrane permeability and act within seconds or minutes. The mechanism of action for *amine hormones* is similar to that for peptide hormones (Norris, 2019).

Steroid hormones, because of their smaller size and higher lipid solubility, penetrate cell membranes and interact with intracellular receptors. The steroid–receptor complex modifies cell metabolism and the formation of messenger ribonucleic acid (mRNA) from deoxyribonucleic acid (DNA). The mRNA then stimulates protein synthesis within the cell. Steroid hormones require several hours to exert their effects, because they exert their action by the modification of protein synthesis.

Assessment

The nursing assessment of the patient with endocrine dysfunction includes a health history and physical examination that evaluates the effects of endocrine disorders on the patient.

Health History

Although specific endocrine disorders are often accompanied by specific clinical symptoms, more general manifestations may also occur. A thorough health history and review of systems are necessary for diagnosis and management of these disorders. Patients should be asked if they have experienced changes in the following areas: energy level, tolerance to heat or cold, weight, thirst, frequency of urination, bowel function, body proportions, muscle mass, fat and fluid distribution, secondary sexual characteristics (e.g., loss or growth of hair), menstrual cycle, memory, concentration, sleep patterns, mood, vision, joint pain, and sexual dysfunction. Documentation is important regarding the severity of these changes, the length of time the patient has experienced these changes, the way in which these changes have affected the patient's ability to carry out activities of daily living, the effect of the changes on the patient's self-perception, and family history.

Physical Assessment

The physical examination should include vital signs; head-to-toe inspection; and palpation of skin, hair, and thyroid. Findings should be compared with previous findings, if available. Physical, psychological, and behavioral changes should be noted. Examples of changes in physical characteristics on examination may include appearance of facial hair in women, "moon face," "buffalo hump," **exophthalmos** (abnormal protrusion of one or both eyeballs), vision changes, edema, thinning of the skin, obesity of the trunk, thinness of the extremities, increased size of the feet and hands, edema, and hypo- or hyperreflexia. The patient may also exhibit changes in mood and behavior such as nervousness, lethargy, and fatigue (Jensen, 2019).

Diagnostic Evaluation

A variety of diagnostic studies are used to evaluate the endocrine system. The nurse educates the patient about the purpose of the prescribed studies, what to expect, and any possible side effects related to these examinations prior to testing. The nurse notes trends in results that provide information about disease progression as well as the patient's response to therapy.

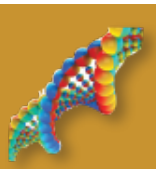
Blood Tests

Blood tests determine the levels of circulating hormones, the presence of autoantibodies, and the effect of a specific hormone on other substances (e.g., the effect of insulin on blood glucose levels). The serum levels of a specific hormone may provide information to determine the presence of hypo- or hyperfunction of the endocrine system and the site of dysfunction. An example of a specific hormone that is amenable to analyzing by blood testing is thyroid hormone (i.e., T_3 and T_4; see later discussion). Radioimmunoassay tests are frequently used to detect antigen levels which give additional information about hormone levels and levels of other substances (Fischbach & Fischbach, 2018).

Urine Tests

Urine tests are used to measure the amount of hormones or the end products of hormones excreted by the kidneys. One-time specimens or, in some disorders, 24-hour urine specimens are collected to measure hormones or their metabolites. For example, urinary levels of free catecholamines (norepinephrine, epinephrine, and dopamine) may be measured in patients with suspected **pheochromocytoma,** a tumor of the adrenal medulla. Several disadvantages related to urine tests that must be considered are that patients may be unable to urinate at scheduled intervals and that some medications or disease states may affect the test results (Norris, 2019).

Additional Diagnostic Studies



Stimulation tests are used to confirm hypofunction of an endocrine organ. The tests determine how an endocrine gland responds to the administration of stimulating hormones that are normally produced or released by the hypothalamus or pituitary gland. If the endocrine gland responds to this stimulation, the specific disorder may be in the hypothalamus or pituitary. Failure of the endocrine gland to respond to this stimulation helps identify the problem as being in the endocrine gland itself.

Suppression tests are used to detect hyperfunction of an endocrine organ. They determine if the organ is not responding to the negative feedback mechanisms that normally control secretion of hormones from the hypothalamus or pituitary gland. Suppression tests measure the effect of a given exogenous dose of the hormone on the endogenous secretion of the hormone or on the secretion of stimulation hormones from the hypothalamus or pituitary gland.

Imaging studies include radioactive scanning, magnetic resonance imaging (MRI), computed tomography (CT), ultrasonography, positron emission

tomography (PET), and dual-energy x-ray absorptiometry (DXA) (Norris, 2019).

Genetic screening is becoming more routine in the assessment of endocrine disorders (see Chart 45-1). DNA testing can be used for the identification of specific genes associated with endocrine disorders, selective targeting for drug development, and increased understanding of the function of the endocrine system. Genetic screening is used to determine the presence of a gene mutation that may predispose a person to a certain condition, the implications of which must be considered by the patient.

Chart 45-1  **GENETICS IN NURSING PRACTICE**

Metabolic and Endocrine Disorders

Metabolic and endocrine disorders that are influenced by genetic factors are complex and typically impact multiple body systems. Some examples of genetic metabolic and endocrine disorders include:

- Diabetes
- Disorders in amino acids (e.g., phenylketonuria, homocystinuria, maple syrup urine disease)
- Disorders of carbohydrate metabolism (e.g., galactosemia)
- Disorders of fatty acid oxidation (e.g., medium-chain acyl-CoA dehydrogenase deficiency)
- Disorders of glycogen storage (e.g., Pompe disease, Von Gierke disease, Danon disease, Cori disease, Anderson disease, McArdle disease)
- Disorders of lysosomal storage disease (e.g., Tay Sachs, Gaucher, Niemann-Pick, Fabry disease)
- Disorders of mucopolysaccharides (e.g., Hurler syndrome, Hunter disease, Morquio syndrome)
- Disorders in urea cycle (e.g., ornithine transcarbamylase deficiency)
- Hemochromatosis
- McCune–Albright syndrome
- Multiple endocrine neoplasia type I and type II

Nursing Assessments

Refer to Chapter 4, Chart 4-2: Genetics in Nursing Practice: Genetic Aspects of Health Assessment

Family History Assessment

- Assess family history for relatives with early-onset hepatic, pancreatic, or endocrine disease.
- Inquire about family members with diabetes and their ages at onset.
- Assess family history of other related genetic conditions such as cystic fibrosis, alpha$_1$-antitrypsin deficiency, and hemochromatosis.

Patient Assessment

- Assess for physical symptoms such as mucosal neuromas, hypertrophied lips, skeletal abnormalities, and marfanoid appearance.
- Assess for signs of arthritis and hemochromatosis (bronze pigmentation of the skin).
- Assess for history of seizures, sweet smell to urine, jaundice, lethargy, vomiting, dehydration, acidosis, neutropenia, hepatomegaly, high ammonia levels

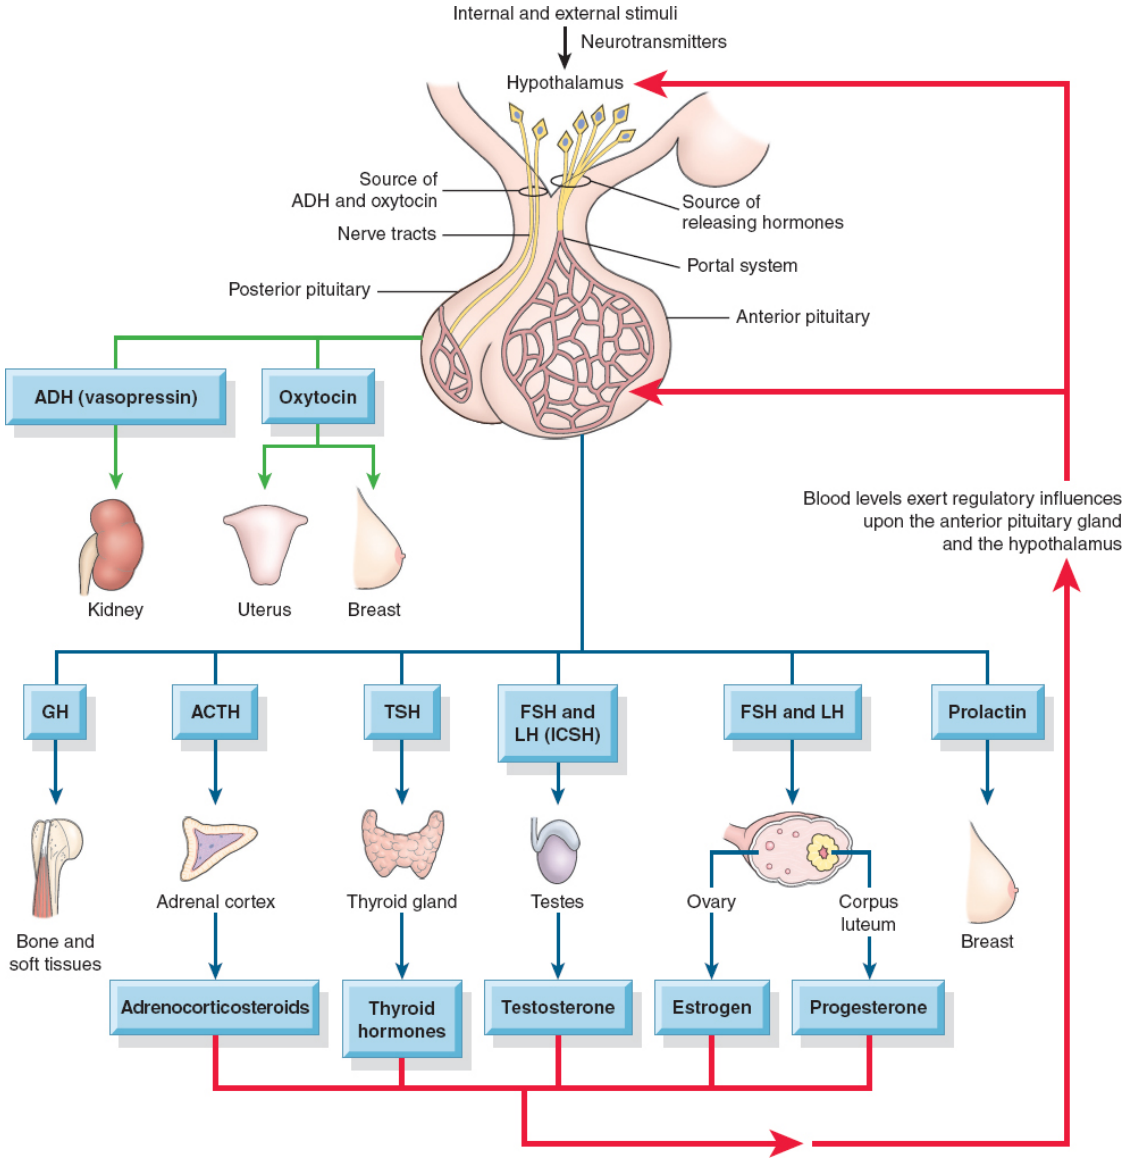

Figure 45-2 • The pituitary gland, the relationship of the brain to pituitary action, and the hormones secreted by the anterior and posterior pituitary lobes. ADH, antidiuretic hormone; GH, growth hormone; ACTH, adrenocorticotropic hormone; TSH, thyroid-stimulating hormone; FSH, follicle-stimulating hormone; LH, luteinizing hormone; ICSH, interstitial cell-stimulating hormone.

THE PITUITARY GLAND

Anatomic and Physiologic Overview

The pituitary gland, or hypophysis, is commonly referred to as the master gland because of the influence it has on secretion of hormones by other endocrine glands (see Fig. 45-2). The round structure, about 1.27 cm (1/2 inch) in diameter, is located on the inferior aspect of the brain and is divided into anterior and posterior lobes. The gland is controlled by the hypothalamus, which is an adjacent area of the brain that is connected to the pituitary by the pituitary stalk.

Anterior Pituitary

The major hormones of the anterior pituitary gland are FSH, luteinizing hormone (LH), prolactin (PRL), **adrenocorticotropic hormone (ACTH)**, **thyroid-stimulating hormone (TSH)**, and GH (also referred to as somatotropin). The secretion of these major hormones is controlled by releasing factors secreted by the hypothalamus. These releasing factors reach the anterior pituitary by way of the bloodstream in a special circulation called the *pituitary portal blood system.* Other hormones include melanocyte-stimulating hormone and beta-lipotropin; the function of lipotropin is poorly understood.

The hormones released by the anterior pituitary enter the general circulation and are transported to their target organs. The main function of TSH, ACTH, FSH, and LH is the release of hormones from other endocrine glands. Imbalanced ACTH secretion characterizes both Addison's disease (hypoproduction) and Cushing's syndrome (hyperproduction). PRL acts on the breast to stimulate milk production. Hormones that stimulate other organs and tissues are discussed in conjunction with their target organs.

GH, the most abundant anterior pituitary hormone, regulates growth in children and energy and metabolism in adults. GH increases protein synthesis in many tissues, increases the breakdown of fatty acids in adipose tissue, and increases blood glucose levels. Other hormones, such as thyroid hormone and insulin, are required for the GH system to function as well. Secretion of GH is increased by deep sleep, stress, exercise, fasting, malnutrition, hypoglycemia, trauma, hypovolemic shock, and sepsis, and is decreased in the presence of obesity, depression, and hypothyroidism (Norris, 2019).

Posterior Pituitary

The important hormones secreted by the posterior lobe of the pituitary gland are **vasopressin**, also referred to as antidiuretic hormone (ADH), and oxytocin. These hormones are synthesized in the hypothalamus and travel from the hypothalamus to the posterior pituitary gland for storage. Vasopressin controls the excretion of water by the kidney; its secretion is stimulated by an increase in the osmolality of the blood or by a decrease in blood pressure. Oxytocin

secretion is stimulated during pregnancy and at childbirth. Oxytocin also facilitates milk ejection during lactation and increases the force of uterine contractions during labor and delivery.

Pathophysiology

Abnormalities of pituitary function are caused by over- or undersecretion of any of the hormones produced or released by the gland. Abnormalities of the anterior and posterior portions of the gland may occur independently. Hypopituitarism, or hypofunction of the pituitary gland, can result from disease of the pituitary gland itself or disease of the hypothalamus; the outcome is essentially the same. Hypopituitarism can result from radiation therapy to the head and neck area. The total destruction of the pituitary gland by trauma, tumor, or vascular lesion removes all stimuli that are normally received by the thyroid, the gonads, and the adrenal glands. This leads to extreme weight loss, emaciation, atrophy of all endocrine glands and organs, hair loss, impotence, amenorrhea, hypometabolism, and hypoglycemia. Coma and death occur if the missing hormones are not replaced (Norris, 2019).

Anterior Pituitary

Oversecretion (hypersecretion) of the anterior pituitary gland most commonly involves ACTH or GH and results in **Cushing**'s **syndrome** (group of symptoms produced by an oversecretion of ACTH) or acromegaly, respectively. **Acromegaly**, a disorder caused by an excess of GH in adults, results in enlargement of peripheral body parts and soft tissue, after the fusion of the epiphyseal plates has occurred (Hickey & Silverstein, 2019), without an increase in height with an incidence of between 0.2 and 1.1 cases per 100,000 people (Lavrentaki, Paluzzi, Wass, et al., 2017). Although rare, oversecretion of GH in children before the fusion of epiphyseal growth plates result in pituitary gigantism; a person may grow to be 7 or even 8 feet tall. Conversely, insufficient secretion of GH during childhood can result in generalized limited growth and pituitary dwarfism. Undersecretion (hyposecretion) commonly involves all of the anterior pituitary hormones and is termed *panhypopituitarism*. In this condition, the thyroid gland, the adrenal cortex, and the gonads atrophy (shrink) because of loss of the tropic-stimulating hormones. Hypopituitarism may result from destruction of the anterior lobe of the pituitary gland (Norris, 2019).

Posterior Pituitary

The most common disorder related to posterior lobe dysfunction is **diabetes insipidus** (DI), a condition in which abnormally large volumes of dilute urine are excreted as a result of deficient production of vasopressin. DI may occur following surgical treatment of a brain tumor, secondary to nonsurgical brain tumors, traumatic brain injury, infections of the nervous system, post hypophysectomy (removal of the pituitary), failure of renal tubules to respond to ADH, and the use of specific medications (Hollar & Silverstein, 2019).

Pituitary Tumors

Almost all pituitary tumors are benign and are slow growing. The tumors may be primary or secondary and functional or nonfunctional (Norris, 2019). Functional tumors secrete pituitary hormones, whereas nonfunctional tumors do not. Pituitary tumors can cause clinical sequelae from the pressure that they exert on adjoining tissues, from the endocrine dysfunction that they cause, or from their dysfunctional effects on target organs. The principal types of pituitary tumors represent an overgrowth of eosinophilic cells, basophilic cells, or chromophobic cells (i.e., cells with no affinity for either eosinophilic or basophilic stains).

Clinical Manifestations

Eosinophilic tumors that develop early in life result in gigantism. The affected person may be more than 7 feet tall and large in all proportions, yet so weak and lethargic that they can hardly stand. If the disorder begins during adult life, the excessive skeletal growth occurs only in the feet, the hands, the superciliary ridge, the molar eminences, the nose, and the chin, giving rise to the clinical picture called *acromegaly.* However, enlargement involves all tissues and organs of the body, and many of these patients suffer from severe headaches and visual disturbances because the tumors exert pressure on the optic nerves (Norris, 2019). Assessment of central vision and visual fields may reveal loss of color discrimination, diplopia (double vision), or blindness in a portion of a field of vision. Decalcification of the skeleton, muscular weakness, and endocrine disturbances, similar to those occurring in patients with hyperthyroidism, also are associated with this type of tumor.

Basophilic tumors give rise to Cushing's syndrome with features largely attributable to hyperadrenalism, including masculinization and amenorrhea in females, truncal obesity, hypertension, osteoporosis, and polycythemia.

Chromophobic tumors represent 90% of pituitary tumors. These tumors usually produce no hormones but destroy the rest of the pituitary gland, causing hypopituitarism. People with this disease often have obesity, are somnolent, and exhibit fine, scanty hair; dry, soft skin; a pasty complexion;

and small bones. They also experience headaches, loss of libido, and visual defects progressing to blindness. Other signs and symptoms include polyuria, polyphagia, a lowering of the **basal metabolic rate** (chemical reactions occurring when the body is at rest), and a subnormal body temperature (Sadiq & Silverstein, 2019b).

Assessment and Diagnostic Findings

Diagnostic evaluation requires a careful history and physical examination, including assessment of visual acuity and visual fields. CT and MRI scans are used to diagnose the presence and extent of pituitary tumors. Serum levels of pituitary hormones may be obtained along with measurements of hormones of target organs (e.g., thyroid, adrenal) to assist in diagnosis.

Medical Management

Hypophysectomy, or surgical removal of the pituitary gland through a transsphenoidal approach, is the usual treatment. Stereotactic radiation therapy, which requires the use of a neurosurgery-type stereotactic frame, may be used to deliver external-beam radiation therapy precisely to the pituitary tumor with minimal effect on normal tissue (see Chapter 12). Other treatments include conventional radiation therapy, bromocriptine, and octreotide. These medications inhibit the production or release of GH and may bring about marked improvement of symptoms. Octreotide and lanreotide may also be used preoperatively to improve the patient's clinical condition and to shrink the tumor (American Association of Neurological Surgeons, 2019).

Surgical Management

Hypophysectomy is the treatment of choice in patients with Cushing's disease resulting from excessive production of ACTH by a pituitary tumor. Hypophysectomy may also be performed on occasion as a palliative measure to relieve bone pain secondary to metastasis of malignant lesions of the breast and prostate.

Several approaches are used to remove or destroy the pituitary gland, including surgical removal by transfrontal, subcranial, or oronasal–transsphenoidal approaches; irradiation; and cryosurgery. The transsphenoidal approach and the nursing management of a patient undergoing cranial surgery are discussed in Chapter 61. Features or symptoms of acromegaly are unaffected by surgical removal of the tumor.

The absence of the pituitary gland alters the function of many body systems. Menstruation ceases and infertility occurs after total or near-total ablation of the pituitary gland. Replacement therapy with corticosteroids and thyroid hormone is necessary.

Diabetes Insipidus

Diabetes insipidus (DI) is a rare disorder that occurs due to injury to the hypothalamus or pituitary gland with a deficiency of ADH (vasopressin) that results in excretion of large volumes of dilute urine and extreme thirst. DI is characterized as central, nephrogenic, or dipsogenic, as well as gestational (Hollar & Silverstein, 2019).

The primary etiology for central DI is head trauma but other causes include surgery, infection, inflammation, brain tumors, or cerebral vascular disease; it also may be idiopathic. Nephrogenic DI etiologic factors include kidney injury, medications such as lithium, hypokalemia, and hypercalcemia. Dipsogenic DI is caused by a defect in the hypothalamus and may be the result of damage to the pituitary gland from a head injury, surgery, infection, inflammatory process, or a tumor (National Institute of Diabetes and Digestive and Kidney Diseases, 2019). DI must be differentiated from diabetes, which may also cause polydipsia and excessive urination.

Clinical Manifestations

Without the action of ADH on the distal nephron of the kidney, an enormous daily output (greater than 250 mL per hour) of very dilute urine with a specific gravity of 1.001 to 1.005 occurs (Hollar & Silverstein, 2019). The urine contains no abnormal substances such as glucose or albumin. Because of the intense thirst, the patient tends to drink 2 to 20 L of fluid daily and craves cold water. In adults, the onset of DI may be insidious or abrupt.

The disease cannot be controlled by limiting fluid intake, because the high-volume loss of urine continues even without fluid replacement. Attempts to restrict fluids cause the patient to experience an insatiable craving for fluid and to develop hypernatremia and severe dehydration.

Assessment and Diagnostic Findings

The fluid deprivation test is carried out by withholding fluids for 8 to 12 hours or until 3% to 5% of the body weight is lost. The patient is weighed frequently during the test. Plasma and urine osmolality studies are performed at the beginning and end of the test. The inability to increase the specific gravity and osmolality of the urine is characteristic of DI. The patient continues to excrete large volumes of urine with low specific gravity and experiences weight loss, increasing serum osmolality, and elevated serum sodium levels. The patient's condition needs to be monitored frequently during the test, and the test is terminated if tachycardia, excessive weight loss, or hypotension develops.

Other diagnostic procedures include concurrent measurements of plasma levels of ADH and plasma and urine osmolality as well as a trial of

desmopressin therapy and intravenous (IV) infusion of hypertonic saline solution. If the diagnosis is confirmed and the cause (e.g., head injury) is not obvious, the patient is carefully assessed for tumors that may be causing the disorder.

Medical Management

The objectives of therapy are to replace ADH (which is usually a long-term therapeutic program), ensure adequate fluid replacement, and identify and correct the underlying intracranial pathology. Nephrogenic causes require different management approaches (Hollar & Silverstein, 2019).

Pharmacologic Therapy

Desmopressin, a synthetic vasopressin without the vascular effects of natural ADH, is the drug of choice for central DI. The drug may be given orally or intranasally (Norris, 2019). Vasopressin causes vasoconstriction; therefore, it must be used cautiously in patients with coronary artery disease. Chlorpropamide and thiazide diuretics are also used in mild forms of the disease because they potentiate the action of vasopressin but are used with caution due to the risk for hypoglycemia (Norris, 2019).

If the DI is renal in origin, the previously described treatments are ineffective. Thiazide diuretics, mild salt depletion, and prostaglandin inhibitors (e.g., indomethacin and aspirin) are used to treat the nephrogenic form of DI.

Nursing Management

Ongoing physical assessment and patient education are the pillars of skilled nursing management of the patient with a diagnosis of DI. Initially, the nurse reviews the patient history and physical assessment and monitors for clinical manifestations of dehydration. Severe dehydration can lead to decreased cardiac output and, therefore, decreased perfusion of the vital organs, specifically the brain and kidneys. Ongoing monitoring of vital signs as well as intake and output (I&O) is essential. The nurse is responsible to educate the patient, family, and other caregivers about follow-up care, prevention of complications, and emergency measures. Specific verbal and written instructions should include the dose, actions, side effects, and administration of all medications and the signs and symptoms of hyponatremia. The nurse should demonstrate and observe a return demonstration of medication administration to ensure that the patient received the prescribed dosage. The patient should be advised to wear a medical identification bracelet and carry required medication and information about DI at all times.

Syndrome of Inappropriate Antidiuretic Hormone Secretion

The **syndrome of inappropriate antidiuretic hormone (SIADH)** results from a failure of the negative feedback system that regulates the release and inhibition of ADH (Norris, 2019). Patients with SIADH cannot excrete a dilute urine, retain fluids, and develop a sodium deficiency known as dilutional hyponatremia. SIADH is often of nonendocrine origin; for instance, the syndrome may occur in patients with bronchogenic carcinoma in which malignant lung cells synthesize and release ADH. SIADH has also occurred in patients with severe pneumonia, pneumothorax, and other disorders of the lungs, as well as malignant tumors that affect other organs (Norris, 2019).

Disorders of the central nervous system, such as head injury, brain surgery or tumor, and infection, are thought to produce SIADH by direct stimulation of the pituitary gland (Norris, 2019). Some medications (e.g., vincristine, phenothiazines, tricyclic antidepressants, thiazide diuretics) and nicotine have been implicated in SIADH; they either directly stimulate the pituitary gland or increase the sensitivity of renal tubules to circulating ADH.

Medical Management

SIADH is generally self-limiting and treatment is focused on eliminating the underlying cause, if possible, and restricting fluid intake (Parham & Silverstein, 2019). Because retained water is excreted slowly through the kidneys, the extracellular fluid volume contracts and the serum sodium concentration gradually increases toward normal. Diuretic agents such as furosemide may be used along with fluid restriction. In severe hyponatremia sometimes a hypertonic NaCl (3%) may be prescribed and administered IV (Norris, 2019).

Nursing Management

Close monitoring of fluid I&O, daily weight, urine and blood chemistries, and neurologic status is indicated for the patient at risk for SIADH. Supportive measures and explanations of procedures and treatments assist the patient in managing this disorder.

THE THYROID GLAND

The thyroid gland—the largest endocrine gland—is a butterfly-shaped organ located in the lower neck, anterior to the trachea (Fig. 45-3). It consists of two lateral lobes connected by an isthmus. The gland is about 5 cm long and 3 cm wide and weighs about 30 g. The blood flow to the thyroid is very high (about 5 mL/min per gram of thyroid tissue), approximately five times the blood flow

to the liver. The thyroid gland produces three hormones: **thyroxine (T_4)**, **triiodothyronine (T_3)**, and **calcitonin**. Thyroxine and triiodothyronine are needed by all body cells for metabolism (Moore, 2018).

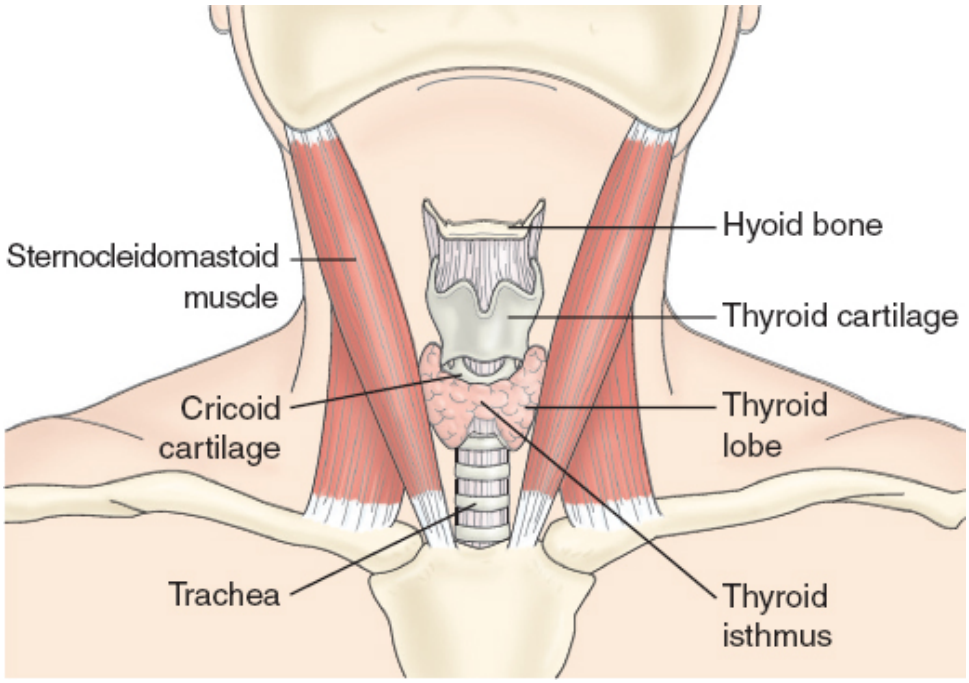

Figure 45-3 • The thyroid gland and surrounding structures.

Anatomic and Physiologic Overview

Various hormones and chemicals are responsible for normal thyroid function. Key among them are thyroid hormone, calcitonin, and iodine.

Thyroid Hormone

Thyroid hormone is comprised of T_4 and T_3, two separate hormones produced by the thyroid gland. Both are amino acids that contain iodine molecules bound to the amino acid structure; T_4 contains four iodine atoms in each molecule, and T_3 contains three. These hormones are synthesized and stored bound to proteins in the cells of the thyroid gland until needed for release into the bloodstream. Three thyroid-binding hormones—thyroxine-binding globulin (TBG), transthyretin (formerly known as thyroid-binding prealbumin), and albumin—bind and transport T_3 and T_4 (Norris, 2019).

Synthesis of Thyroid Hormone

Iodine is essential to the thyroid gland for synthesis of its hormones. The major use of iodine in the body is by the thyroid, and the major derangement in

iodine deficiency is alteration of thyroid function. Iodide is ingested in the diet and absorbed into the blood in the GI tract. The thyroid gland is extremely efficient at taking up iodide from the blood and concentrating it within the cells, where iodide ions are converted to iodine molecules, which react with tyrosine (an amino acid) to form the thyroid hormones (Norris, 2019).

Regulation of Thyroid Hormone

The secretion of T_3 and T_4 by the thyroid gland is controlled by TSH (also called *thyrotropin*) from the anterior pituitary gland. TSH controls the rate of thyroid hormone release through a negative feedback mechanism. In turn, the level of thyroid hormone in the blood determines the release of TSH. If the thyroid hormone concentration in the blood decreases, the release of TSH increases, which causes increased output of T_3 and T_4. The term **euthyroid** refers to thyroid hormone production that is normal.

TRH, secreted by the hypothalamus, exerts a modulating influence on the release of TSH from the pituitary. Environmental factors, such as a decrease in temperature, may lead to increased secretion of TRH, resulting in elevated secretion of thyroid hormones. Figure 45-4 shows the hypothalamic–pituitary–thyroid axis, which regulates thyroid hormone production.

Function of Thyroid Hormone

The main function of thyroid hormone is to control cellular metabolic activity. T_4, a relatively weak hormone, maintains body metabolism in a steady state. T_3 is about five times as potent as T_4 and has a more rapid metabolic action. These hormones accelerate metabolic processes by increasing the level of specific enzymes that contribute to oxygen consumption and altering the responsiveness of tissues to other hormones. The thyroid hormones influence cell replication, are important in brain development, and are necessary for normal growth. Thyroid hormones affect virtually every major organ system and tissue function, including the basal metabolic rate, tissue thermogenesis, serum cholesterol levels, and vascular resistance (Norris, 2019).

Calcitonin

Calcitonin, or thyrocalcitonin, is another important hormone secreted by the thyroid gland. The hormone is secreted in response to high plasma levels of calcium, and it reduces the plasma level of calcium by increasing its deposition in bone.

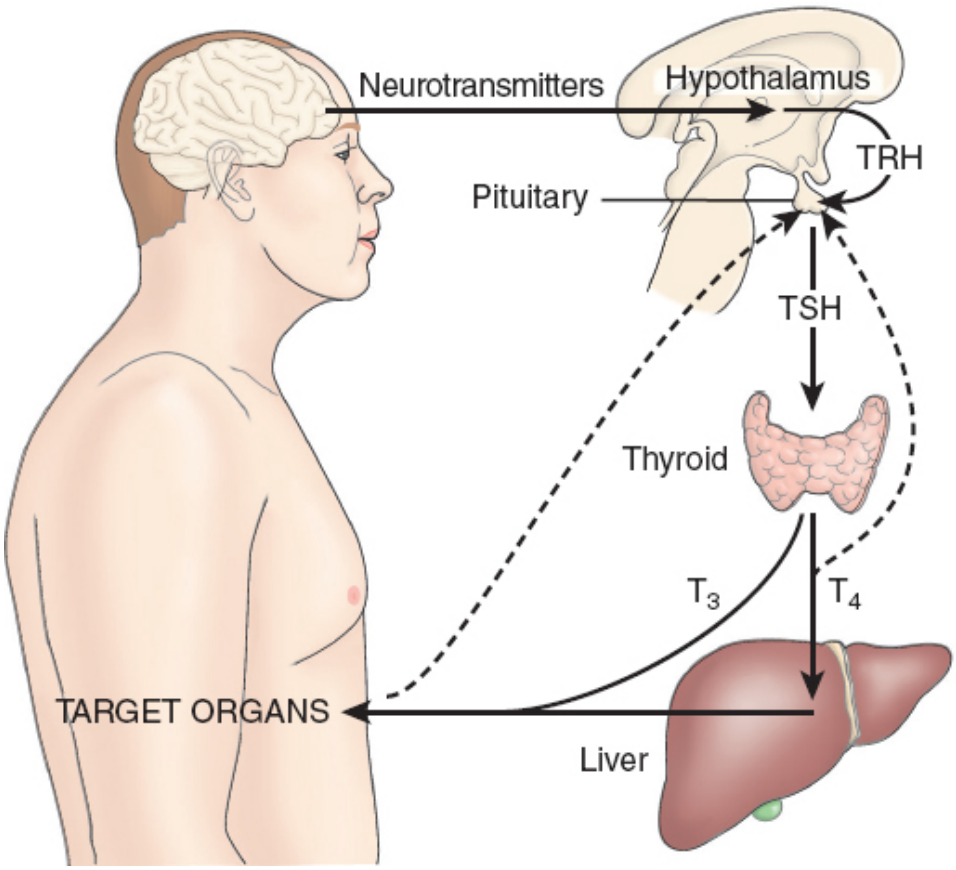

Figure 45-4 • The hypothalamic–pituitary–thyroid axis. Thyroid-releasing hormone (TRH) from the hypothalamus stimulates the pituitary gland to secrete thyroid-stimulating hormone (TSH). TSH stimulates the thyroid to produce thyroid hormone (triiodothyronine [T_3] and thyroxine [T_4]). High circulating levels of T_3 and T_4 inhibit further TSH secretion and thyroid hormone production through a negative feedback mechanism (*dashed lines*).

Pathophysiology

Congenital hypothyroidism, which occurs when there is inadequate secretion of thyroid hormone during fetal and neonatal development, results in intellectual disability and stunted physical growth because of general depression of metabolic activity (Norris, 2019). In adults, hypothyroidism manifests as lethargy, slow mentation, weight gain, constipation, cold intolerance, and generalized slowing of body functions (Singh & Clutter, 2019).

Hyperthyroidism (oversecretion of thyroid hormones) is manifested by a greatly increased metabolic rate. Many of the other characteristics of hyperthyroidism result from the increased response to circulating catecholamines (epinephrine and norepinephrine).

Oversecretion of thyroid hormones is usually associated with an enlarged thyroid gland known as a **goiter**. Goiter also commonly occurs with iodine deficiency. In this latter condition, lack of iodine results in low levels of circulating thyroid hormones, which causes increased release of TSH; the elevated TSH causes overproduction of thyroglobulin (a precursor of T_3 and T_4) and hypertrophy of the thyroid gland.

Assessment

Physical Examination

The thyroid gland is inspected and palpated routinely in all patients. Inspection begins with identification of landmarks. The lower neck region between the sternocleidomastoid muscles is inspected for swelling or asymmetry. The patient is instructed to extend the neck slightly and swallow. Thyroid tissue rises normally with swallowing. The thyroid is then palpated for size, shape, consistency, symmetry, and the presence of tenderness.

The health care provider may examine the thyroid from an anterior or a posterior position. In the posterior position, both hands encircle the patient's neck. The thumbs rest on the nape of the neck, while the index and middle fingers palpate for the thyroid isthmus and the anterior surfaces of the lateral lobes. When palpable, the isthmus is perceived as firm and of a rubber-band consistency.

The left lobe is examined by positioning the patient so that the neck flexes slightly forward and to the left. The thyroid cartilage is then displaced to the left with the fingers of the right hand. This maneuver displaces the left lobe deep into the sternocleidomastoid muscle, where it can be more easily palpated. The left lobe is then palpated by placing the left thumb deep into the posterior area of the sternocleidomastoid muscle, while the index and middle fingers exert opposite pressure in the anterior portion of the muscle. Having the patient swallow during the maneuver may assist the examiner to locate the thyroid as it ascends in the neck. The procedure is reversed to examine the right lobe. The isthmus is the only portion of the thyroid that is normally palpable. If a patient has a very thin neck, two thin, smooth, nontender lobes may also be palpable.

If palpation discloses an enlarged thyroid gland, both lobes are auscultated using the diaphragm of the stethoscope. Auscultation identifies the localized audible vibration of a bruit. This is indicative of increased blood flow through the thyroid gland associated with hyperthyroidism and necessitates referral to a primary provider. Other abnormal findings that require referral for further evaluation may include a soft texture (Graves disease), firmness (Hashimoto thyroiditis or malignancy), and tenderness (thyroiditis) (Jensen, 2019).

Diagnostic Evaluation

Assessment measures in addition to palpation and auscultation include thyroid function tests, such as laboratory measurement of thyroid hormones, thyroid scanning, biopsy, and ultrasonography. The most widely used tests are serum immunoassay for TSH and free T_4. Free T_4 levels correlate with metabolic status; they are elevated in hyperthyroidism and decreased in hypothyroidism (Fischbach & Fischbach, 2018). Ultrasound, CT, and MRI may be used to clarify or confirm the results of other diagnostic studies.

Thyroid Tests

Serum Thyroid-Stimulating Hormone

Measurement of the serum TSH concentration is the primary screening test of thyroid function. The ability to detect minute changes in serum TSH makes it possible to distinguish subclinical thyroid disease from euthyroid states in patients with low or high normal values. Measurement of TSH is also used for monitoring thyroid hormone replacement therapy and for differentiating between disorders of the thyroid gland itself and disorders of the pituitary or hypothalamus.

The American Thyroid Association recommends that pregnant women be screened for thyroid disease (Alexander, Pearce, Brent, et al., 2017); however, there is lack of consensus among professional organizations regarding routine screening of adults for thyroid disease. The US Preventive Services Task Force (USPSTF) does not recommend routine screening of adults (USPSTF, 2019).

Serum Free T_4

Serum free T_4 is a direct measurement of free (unbound) thyroxine, the only metabolically active fraction of T_4. The range of free T_4 in serum is normally 0.7 to 2.0 ng/dL (10 to 26 pmol/L) (Fischbach & Fischbach, 2018). When measured by the dialysis method, free T_4 is not affected by variations in protein binding and is the procedure of choice for monitoring the changes in T_4 secretion during treatment for hyperthyroidism.

Serum T_3 and T_4

Measurement of total T_3 or T_4 includes protein-bound and free hormone levels that occur in response to TSH secretion. T_4 is 70% bound to TBG; T_3 is bound less firmly. Only 0.03% of T_4 and 0.3% of T_3 are unbound. Serious systemic illnesses, medications (e.g., oral contraceptives, corticosteroids, carbamazepine, salicylates), and protein wasting as a result of nephrosis or the use of androgens may interfere with accurate test results. Normal range for T_4

is 5.4 to 11.5 µg/dL (57 to 148 nmol/L) (Fischbach & Fischbach, 2018). Although serum T_3 and T_4 levels generally increase or decrease together, the T_3 level appears to be a more accurate indicator of hyperthyroidism or severity of the disorder, as T_4 levels are often within normal range. The normal range for serum T_3 is 260 to 480 pg/dL (4.0 to 7.4 pmol/L) (Fischbach & Fischbach, 2018).

T_3 Resin Uptake Test

The T_3 resin uptake test is an indirect measure of unsaturated TBG. Its purpose is to determine the amount of thyroid hormone bound to TBG and the number of available binding sites. This provides an index of the amount of thyroid hormone already present in the circulation. Normally, TBG is not fully saturated with thyroid hormone, and additional binding sites are available to combine with radioiodine-labeled T_3 added to the blood specimen. The normal T_3 uptake value is 25% to 35% (relative uptake fraction, 0.25 to 0.35), which indicates that about one third of the available sites of TBG are occupied by thyroid hormone. If the number of free or unoccupied binding sites is low, as in hyperthyroidism, the T_3 uptake is greater than 35% (0.35). If the number of available sites is high, as occurs in hypothyroidism, the test result is less than 25% (0.25).

T_3 uptake is useful in evaluating thyroid hormone levels in patients who have received diagnostic or therapeutic doses of iodine. The test results may be altered by the use of estrogens, androgens, salicylates, phenytoin, anticoagulants, or corticosteroids (Fischbach & Fischbach, 2018).

Thyroid Antibodies

Autoimmune thyroid diseases include both hypo- and hyperthyroid conditions. Results of testing by immunoassay techniques for antithyroid antibodies are positive in chronic autoimmune thyroid disease (90%), Hashimoto thyroiditis (100%), Graves disease (80%), and other organ-specific autoimmune diseases, such as systemic lupus erythematosus (SLE) and rheumatoid arthritis. Antithyroid antibody titers are normally present in 5% to 10% of the population and increase with age.

Radioactive Iodine Uptake

The radioactive iodine uptake test measures the rate of iodine uptake by the thyroid gland. The patient is given a tracer dose of iodine 123 (^{123}I) or another radionuclide, and a count is made over the thyroid gland with a scintillation counter, which detects and counts the gamma rays released from the breakdown of ^{123}I in the thyroid. The radioactive iodine uptake test is a simple test with reliable results. The test measures the proportion of the given dose

that is present in the thyroid gland at a specific time after its administration. Since the test is affected by the patient's intake of iodide or thyroid hormone, a careful preliminary clinical history is essential in evaluating results. Normal values vary from one geographic region to another and with the intake of iodine. Patients with hyperthyroidism exhibit a high uptake of the ^{123}I (in some patients, as high as 90%), whereas patients with hypothyroidism exhibit a very low uptake.

Fine-Needle Aspiration Biopsy

The use of a small-gauge needle to sample the thyroid tissue for biopsy is a safe and accurate method of detecting malignancy and is often the initial test for evaluation of thyroid masses. Results are reported as benign, malignant, suspicious, or nondiagnostic/insufficient (Ross, Cooper, & Mulder, 2019). Within the malignancy category, masses are reported as a follicular neoplasm or a follicular lesion.

Thyroid Scan, Radioscan, or Scintiscan

In a thyroid scan, a scintillation detector or gamma camera moves back and forth across the area to be studied in a series of parallel tracks, and a visual image is made of the distribution of radioactivity in the area being scanned. The most commonly used isotopes of iodine are ^{123}I and ^{131}I (Fischbach & Fischbach, 2018).

Scans are helpful in determining the location, size, shape, and anatomic function of the thyroid gland, particularly when thyroid tissue is substernal or large (Fischbach & Fischbach, 2018). Identifying areas of increased function ("hot" areas) or decreased function ("cold" areas) can assist in diagnosis. Although most areas of decreased function do not represent malignancies, lack of function increases the likelihood of malignancy, particularly if only one nonfunctioning area is present. Scanning of the entire body, to obtain the total body profile, may be carried out in a search for a functioning thyroid metastasis (i.e., a lesion that produces thyroid hormones).

Serum Thyroglobulin

Thyroglobulin (Tg) can be measured reliably in the serum by radioimmunoassay. Clinically, it is used to detect persistence or recurrence of thyroid carcinoma.

Nursing Implications

Since thyroid tests involve the use of iodine, determining if the patient has any allergies to iodine or is taking medications that contain iodine is essential. The relationship between having an allergy to shellfish and having an allergy to

iodine is a long held belief; however, an allergy to shellfish is due to specific proteins in the shellfish and not iodine (American College of Allergy, Asthma and Immunology, 2019). Patients should be asked if they have had a reaction to iodine previously and to shellfish so that the radiologist can determine what precautions need to be taken, if any (American College of Allergy, Asthma and Immunology, 2019). Patients should be asked about obvious sources of iodine-containing medications such as contrast agents and those used to treat thyroid disorders such as radioactive iodine. They should also be asked whether they eat kelp or seaweed. Numerous medications may also affect test results because they affect the thyroid. Chart 45-2 gives a list of select medications that may interfere with accurate testing of thyroid gland function (Fischbach & Fischbach, 2018). This information should be documented in the patient's electronic health record (EHR) and communicated clearly to personnel conducting the test.

Chart 45-2 PHARMACOLOGY

Select Medications That May Alter Thyroid Test Results

amiodarone
aspirin
cimetidine
diazepam
estrogens
furosemide
glucocorticoids
heparin
lithium
phenytoin and other anticonvulsants
propranolol

Hypothyroidism

Hypothyroidism results from suboptimal levels of thyroid hormone. Thyroid deficiency can affect all body functions and can range from mild, subclinical forms to **myxedema** (severe deficiency discussed later), an advanced life-threatening form. The most common cause of hypothyroidism in adults is autoimmune thyroiditis (Hashimoto disease), in which the immune system attacks the thyroid gland. Symptoms of hyperthyroidism may later be followed

by those of hypothyroidism and myxedema. Hypothyroidism also commonly occurs in patients with previous hyperthyroidism that has been treated with radioiodine or antithyroid medications or **thyroidectomy** (surgical removal of all or part of the thyroid gland). Testing of thyroid function is recommended for all patients who receive radiation therapy to the neck. See Chart 45-3 for other causes of hypothyroidism.

More than 95% of patients with hypothyroidism have primary or thyroidal hypothyroidism, which refers to dysfunction of the thyroid gland itself. If the cause of the thyroid dysfunction is failure of the pituitary gland, the hypothalamus, or both, the hypothyroidism is known as central hypothyroidism. If the cause is entirely a pituitary disorder, it may be referred to as pituitary or secondary hypothyroidism. If the cause is a disorder of the hypothalamus resulting in inadequate secretion of TSH due to decreased stimulation of TRH, it is referred to as hypothalamic or tertiary hypothyroidism. If thyroid deficiency is present at birth, it is referred to as neonatal hypothyroidism. In such instances, the mother may also have thyroid deficiency. The term *myxedema* refers to the accumulation of mucopolysaccharides in subcutaneous and other interstitial tissues. Although myxedema occurs in long-standing hypothyroidism, the term is used appropriately only to describe the extreme symptoms of severe hypothyroidism (Chaker, Bianco, Janklaas, et al., 2017).

Chart 45-3

Causes of Hypothyroidism

Autoimmune disease (Hashimoto thyroiditis, post-Graves disease)
Atrophy of thyroid gland with aging
Infiltrative diseases of the thyroid (amyloidosis, scleroderma, lymphoma)
Iodine deficiency, iodine excess, and iodine compounds
Medications (e.g., Lithium)
Radioactive iodine (^{131}I)
Therapy for hyperthyroidism
Thyroidectomy
Radiation to head and neck in treatment for head and neck cancers, lymphoma

Clinical Manifestations

Presenting clinical manifestations in adults frequently reflect the decrease in metabolism resulting from the decrease in thyroid function. Clinical manifestations include complaints of fatigue and lethargy that may interfere with activities of daily living, weight gain without an increased intake of calories, cold intolerance, dry skin, and, in some patients, a deepening of the

voice. Other clinical manifestations are related to gender, age, and duration of the decrease in thyroid function (see Fig. 45-5). These include cardiovascular-related manifestations such as bradycardia and changes in electrical conduction of the heart which will be noted on the electrocardiogram (ECG). In women, changes in the menstrual cycle will be noted (Chaker et al., 2017).

Severe hypothyroidism results in a subnormal body temperature and pulse rate. The patient usually begins to gain weight even without an increase in food intake, although they may be cachectic. The skin becomes thickened because of an accumulation of mucopolysaccharides in the subcutaneous tissues. The hair thins and falls out, and the face becomes expressionless and masklike. The patient often complains of being cold even in a warm environment.

At first, the patient may be irritable and may complain of fatigue, but as the condition progresses, the emotional responses are subdued. The mental processes become dulled, and the patient appears apathetic. Speech is slow, the tongue enlarges, the hands and feet increase in size, and deafness may occur. The patient frequently reports constipation.

Advanced hypothyroidism may produce personality and cognitive changes characteristic of dementia. Inadequate ventilation and sleep apnea can occur with severe hypothyroidism. Pleural effusion, pericardial effusion, and respiratory muscle weakness may also occur (Chaker et al., 2017).

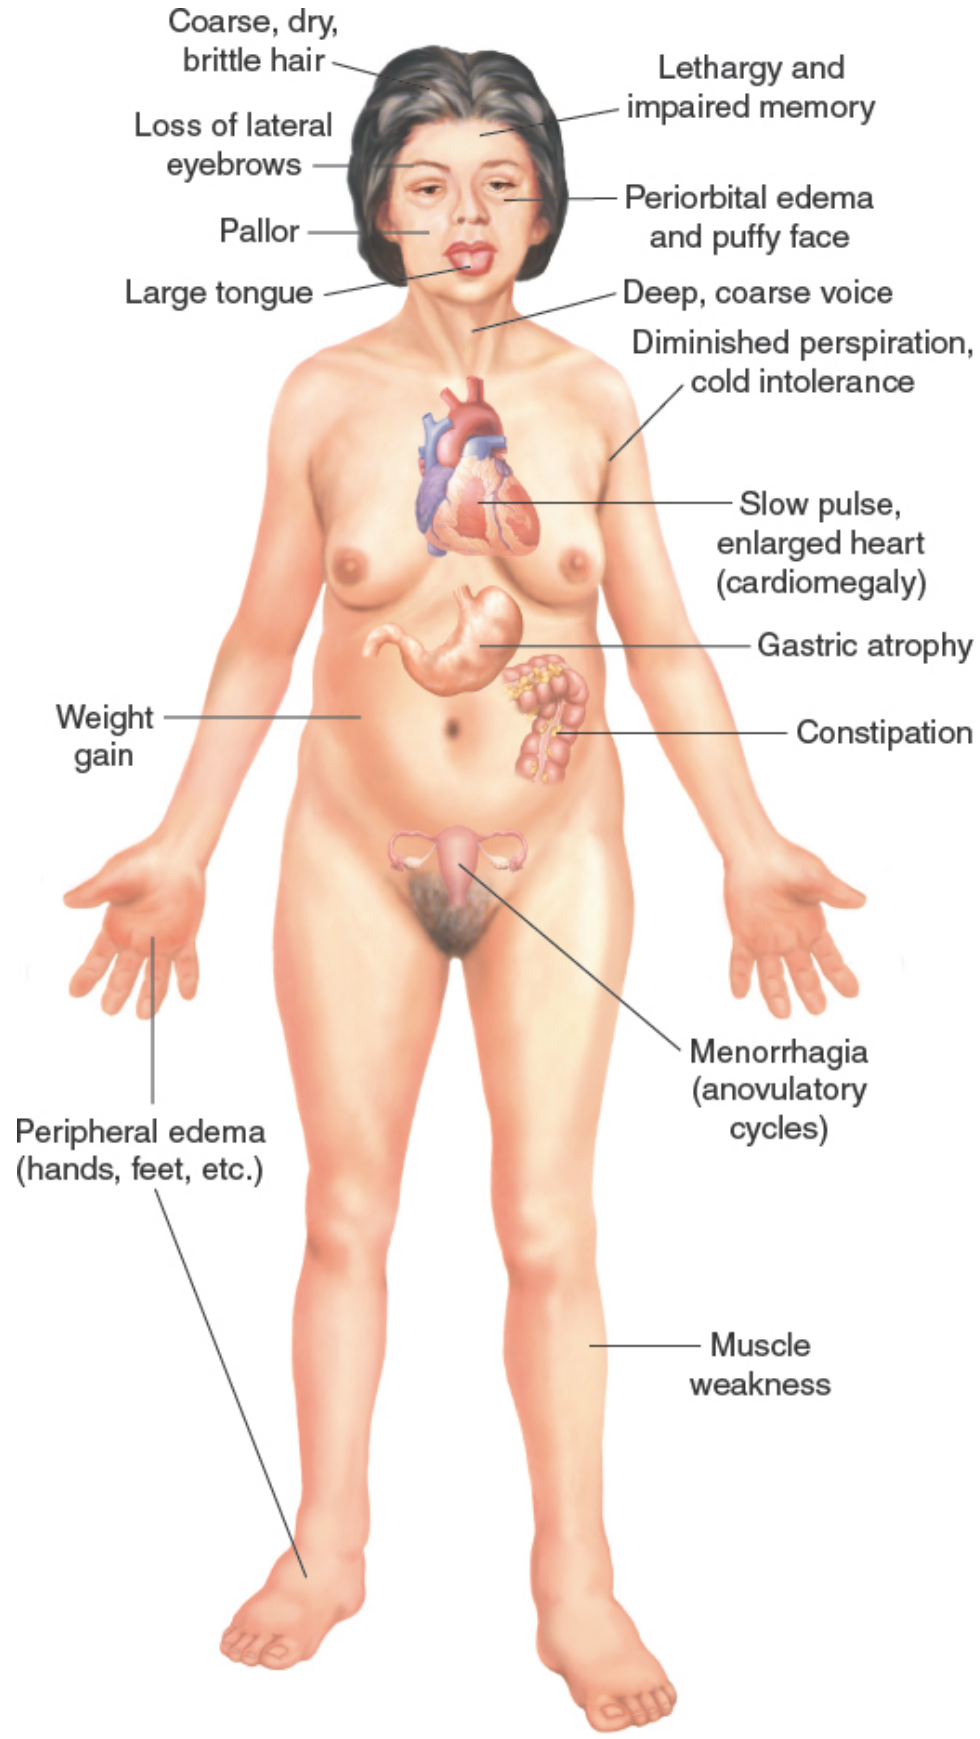

Figure 45-5 • Clinical manifestations of hypothyroidism. Reprinted with permission from Norris, T. L. (2019). *Porth's pathophysiology:*

Concepts of altered health states (10th ed., Fig. 41.5). Philadelphia, PA: Wolters Kluwer.

Severe hypothyroidism is associated with an elevated serum cholesterol level, atherosclerosis, coronary artery disease, and poor left ventricular function. The patient with advanced hypothyroidism is hypothermic and abnormally sensitive to sedative, opioid, and anesthetic agents, which must be given with extreme caution.

Patients with unrecognized hypothyroidism who are undergoing surgery are at increased risk for intraoperative hypotension, postoperative heart failure, and altered mental status.

Myxedema coma is a rare life-threatening condition and a decompensated state of severe hypothyroidism in which the patient is hypothermic and unconscious. This condition may develop with undiagnosed hypothyroidism and may be precipitated by infection or other systemic disease or by use of sedatives or opioid analgesic agents. Patients may also experience myxedema coma if they forget to take their thyroid replacement medication. The condition occurs most often among older women in the winter months and appears to be precipitated by cold. However, the disorder can affect any age group.

In myxedema coma, the patient may initially show signs of depression, diminished cognitive status, lethargy, and somnolence (Chaker et al., 2017).

Increasing lethargy may progress to stupor. The patient's respiratory drive is depressed, resulting in alveolar hypoventilation, progressive carbon dioxide retention, narcosis, and coma. In addition, patients with myxedema coma can also exhibit hyponatremia, hypoglycemia, hypoventilation, hypotension, bradycardia, and hypothermia. These symptoms, along with cardiovascular collapse and shock, require aggressive and intensive supportive and hemodynamic therapy if the patient is to survive. Although there has been a decline in mortality rates over the past two decades due to early intervention and improved therapies, the mortality rate remains at 40% despite treatment; proper diagnosis and prompt treatment is essential (Eledrisi, 2018).

Medical Management

The objectives in the management of hypothyroidism are to restore a normal metabolic state by replacing the missing hormone, as well as prevention of disease progression and complications.

Pharmacologic Therapy

Synthetic levothyroxine is the drug of choice for the treatment of hypothyroidism (Drake, 2018). The general range is 75 to 150 mcg per day and treatment is generally started at the lower dose and titrated slowly until desired levels of serum TSH concentration are achieved (Singh & Clutter,

2019). Older adult patients generally require a lower dose; normal TSH levels are often achieved with 50 mcg per day (Singh & Clutter, 2019). Some patients on thyroid hormone replacement may complain of continued clinical manifestations despite normal TSH levels (Chaker et al., 2017).

Prevention of Cardiac Dysfunction

Any patient who has had hypothyroidism for a long period usually has associated elevated serum cholesterol, atherosclerosis, and coronary artery disease. As long as metabolism is subnormal and the tissues (including the myocardium) require relatively little oxygen, a reduction in blood supply is tolerated without overt symptoms of coronary artery disease. When thyroid hormone is given, the oxygen demand increases, but oxygen delivery cannot be increased unless, or until, the atherosclerosis improves. This occurs very slowly, if at all. The occurrence of angina and acute coronary syndrome (see Chapter 23) is the signal that the oxygen needs of the myocardium exceed its blood supply. Angina or arrhythmias can occur when thyroid replacement is initiated because thyroid hormones enhance the cardiovascular effects of catecholamines.

Quality and Safety Nursing Alert

The nurse must monitor for signs and symptoms of cardiac dysfunction, which can occur in response to therapy in patients with severe, long-standing hypothyroidism or myxedema coma, especially during the early phase of treatment. Acute coronary syndrome must be aggressively treated to avoid morbid complications (e.g., myocardial infarction).

If angina or arrhythmias occur, thyroid hormone administration must be discontinued immediately. Later, when it can be resumed safely, it should be prescribed cautiously at a lower dosage and with close monitoring by the primary provider and the nurse.

Prevention of Medication Interactions

Oral thyroid hormones interact with many other medications. They increase the effect of warfarin and the cardiovascular effects of adrenergic agents (bronchodilators and vasopressors). In addition, the dosage of insulin and oral hypoglycemic medications used to treat diabetes may require adjustment. Caution is also needed in patients who are concomitantly taking estrogen, which may necessitate an increased dosage of the oral thyroid hormone. Absorption may be affected by any supplement or food that contains calcium, iron, magnesium or zinc (Vallerand & Sanoski, 2018).

Even in small IV doses, hypnotic and sedative agents may induce profound somnolence, lasting far longer than anticipated and leading to narcosis (stuporlike condition). Furthermore, they are likely to cause respiratory depression, which can easily be fatal because of decreased respiratory reserve and alveolar hypoventilation. The dose of these medications should be one half or one third of that typically prescribed for patients of similar age and weight with normal thyroid function.

Supportive Therapy

Severe hypothyroidism and myxedema coma require prompt, aggressive management to maintain vital functions. Arterial blood gases may be measured to determine carbon dioxide retention and to guide the use of assisted ventilation to combat hypoventilation. Oxygen saturation levels should be monitored using pulse oximetry. Fluids are given cautiously because of the danger of water intoxication. Passive rewarming with a blanket is recommended versus active rewarming such as application of external heat (e.g., heating pads). The latter should be avoided to prevent increased oxygen demands and hypotension.

Nursing Management

Nursing care of the patient with hypothyroidism and myxedema is summarized in the plan of nursing care in Chart 45-4. In patients with hypothyroidism, the effects of analgesic, sedative, and anesthetic agents are prolonged. The nurse should carefully monitor patients who are prescribed these agents for adverse effects. Older patients are at increased risk because of age-related changes in liver and renal function.

Chart 45-4  **PLAN OF NURSING CARE**

Care of the Patient with Hypothyroidism

NURSING DIAGNOSIS: Impaired breathing associated with depressed ventilation
GOAL: Improved respiratory status and maintenance of normal breathing pattern

Nursing Interventions	Rationale	Expected Outcomes
1. Assess respiratory rate, depth, pattern, pulse oximetry, and arterial blood gases. 2. Encourage deep breathing, coughing, and the use of incentive spirometry. 3. Verify with the provider orders to administer any hypnotic and sedative until euthyroid state achieved. If these medications are needed, monitor for adverse side effects. 4. Maintain patient airway through suction and ventilator support if needed (see Chapter 19 for care of patients requiring mechanical ventilation).	1. Identifies patient's baseline to monitor further changes and evaluate effectiveness of interventions. 2. Prevents atelectasis and promotes adequate ventilation. 3. Patients with hypothyroidism are susceptible to respiratory depression with the use of hypnotics and sedatives. 4. The use of artificial airway and ventilator support may be necessary.	• Shows improved respiratory status and normal respiratory rate, depth, and pattern • Takes deep breaths, coughs and uses incentive spirometry • Explains rationale for cautious use of medications • Maintains adequate oxygenation

NURSING DIAGNOSIS: Risk for impaired cardiac function associated with

altered metabolism

GOAL: Improved cardiac status and maintenance of adequate cardiac output

Nursing Interventions	Rationale	Expected Outcomes
1. Assess heart rate and rhythm and blood pressure 2. Monitor serum cholesterol value and complaints of anginal pain. 3. Monitor ECG for the presence of any arrhythmias, especially after thyroid hormone replacement therapy is initiated.	1. Identifies patient's baseline to monitor further changes and evaluate effectiveness of interventions 2. The presence of atherosclerosis and cardiac disease prior to onset of hypothyroidism/myxedema may contribute to decreased perfusion 3. Initiation of thyroid therapy enhances the cardiovascular effects of catecholamines.	• Shows improved cardiac status and maintenance of normal cardiac pattern • Reports free of anginal pain • Maintains normal sinus rhythm

NURSING DIAGNOSIS: Risk for impaired thermoregulation

GOAL: Maintenance of normal body temperature

Nursing Interventions	Rationale	Expected Outcomes
1. Provide extra layer of clothing or extra blanket. 2. Avoid and discourage the use of external heat source (e.g., heating pads, electric or	1. Minimizes heat loss 2. Reduces risk of peripheral vasodilation and vascular collapse 3. Detects decreased body temperature and onset of myxedema coma 4. Increases patient's level of comfort and decreases	• Experiences relief of discomfort and cold intolerance • Maintains baseline body temperature • Reports adequate feeling of

warming blankets). 3. Monitor patient's body temperature and report decreases from patient's baseline value. 4. Protect from exposure to cold and drafts.	further heat loss	warmth and lack of chilling • Uses extra layer of clothing or extra blanket • Explains rationale for avoiding external heat source
NURSING DIAGNOSIS: Acute confusion associated with altered cardiovascular and respiratory status and depression **GOAL:** Improved thought process		
Nursing Interventions	**Rationale**	**Expected Outcomes**
1. Orient patient to time, place, date, and events around them. 2. Provide stimulation through conversation and nonthreatening activities. 3. Explain to patient and family that change in cognitive and mental functioning is a result of disease process. 4. Monitor cognitive and mental processes and	1. Provides reality orientation to patient 2. Provides stimulation within patient's level of tolerance for stress 3. Reassures patient and family about the cause of the cognitive changes and that a positive outcome is possible with appropriate treatment 4. Permits evaluation of the effectiveness of treatment	• Shows improved cognitive functioning • Identifies time, place, date, and events correctly • Responds appropriately when stimulated • Responds spontaneously as treatment becomes effective • Interacts spontaneously with family and environment • Explains that change in mental and cognitive

response of these to medication and other therapy.		processes is a result of disease processes • Takes medications as prescribed to prevent decrease in cognitive processes
NURSING DIAGNOSIS: Activity intolerance associated with insufficient physiologic or psychological energy **Goal:** Increased participation in activities and increased independence		
Nursing Interventions	**Rationale**	**Expected Outcomes**
1. Promote independence in self-care activities. a. Space activities to promote rest and exercise as tolerated. b. Assist with self-care activities when patient is fatigued. c. Provide stimulation through conversation and nonstressful activities. d. Monitor patient's response to increasing activities.	1. Encouragement needed in patients with decreased energy Encourages activities while a. allowing time for adequate rest b. Permits patient to participate to the extent possible in self-care activities c. Promotes interest without stressing the patient d. Guards against over- and underexertion by the patient	• Participates in self-care activities • Reports increased level of energy • Displays interest and awareness in environment • Participates in activities and events in environment • Participates in family events and activities • Reports free of chest pain, increased fatigue, or breathlessness with increased level of activity

NURSING DIAGNOSIS: Constipation associated with diminished gastrointestinal peristalsis

GOAL: Return of normal bowel function

Nursing Interventions	Rationale	Expected Outcomes
1. Encourage increased fluid intake within limits of fluid restriction. 2. Provide foods high in fiber. 3. Instruct patient about foods with high water content. 4. Monitor bowel function. 5. Encourage increased mobility within patient's exercise tolerance. 6. Encourage patient to use laxatives and enemas sparingly.	1. Promotes passage of soft stools 2. Increases bulk of stools and more frequent bowel movements 3. Provides rationale for patient to increase fluid intake 4. Permits detection of constipation and return to normal bowel pattern 5. Promotes evacuation of the bowel 6. Minimizes patient's dependence on laxatives and enemas and encourages normal pattern of bowel evacuation	• Reports normal bowel function • Identifies and consumes foods high in fiber • Drinks recommended amount of fluid each day • Participates in gradually increasing exercises • Uses laxatives as prescribed and avoids excessive dependence on laxatives and enemas

NURSING DIAGNOSIS: Lack of knowledge about the therapeutic regimen for lifelong thyroid replacement therapy

GOAL: Knowledge and acceptance of the prescribed therapeutic regimen

Nursing Interventions	Rationale	Expected Outcomes
1. Explain rationale for thyroid hormone replacement.	1. Provides rationale for patient to use thyroid hormone replacement as prescribed 2. Provides encouragement to patient by identifying	• Describes therapeutic regimen correctly • Explains rationale for

2. Describe desired effects of medication to patient. 3. Assist patient to develop schedule and checklist to ensure self-administration of thyroid replacement. 4. Describe signs and symptoms of over- and underdose of medication. 5. Explain the necessity for long-term follow-up to patient and family.	improved physical status and well-being that will occur with thyroid hormone therapy and return to a euthyroid state 3. Increases chances that medication will be taken as prescribed 4. Serves as check for patient to determine if therapeutic goals are met 5. Increases likelihood that hypo- or hyperthyroidism will be detected and treated	thyroid hormone replacement • Identifies positive outcomes of thyroid hormone replacement • Administers medication to self as prescribed • Identifies adverse side effects that should be reported promptly to primary provider: recurrence of symptoms of hypothyroidism and occurrence of symptoms of hyperthyroidism • Restates need for periodic/long-term follow-up visits to primary provider

COLLABORATIVE PROBLEM: Myxedema and myxedema coma
GOAL: Evidence of progression to pre-coma baseline without incurring additional complications

Nursing Interventions	Rationale	Expected Outcomes
1. Monitor patient for increasing severity of signs and symptoms of hypothyroidism: a. Decreased level of consciousness b. Decreased vital signs (blood pressure, respiratory rate, temperature, pulse rate) c. Increasing difficulty in awakening or arousing patient 2. Assist in ventilator support if respiratory depression and failure occur. 3. Administer prescribed medications (e.g., thyroxine) with extreme caution. 4. Turn and reposition patient at least every 2 hours. 5. Avoid the use of hypnotic,	1. Extreme hypothyroidism may lead to myxedema, myxedema coma, and slowing of all body systems if untreated 2. Ventilator support is necessary to maintain adequate oxygenation and maintenance of airway 3. The slow metabolism and atherosclerosis of myxedema may result in angina with administration of thyroxine 4. Minimizes risks associated with immobility 5. Altered metabolism of these agents greatly increases the risks of their use in myxedema	• Exhibits reversal of myxedema and myxedema coma • Responds appropriately to questions and surroundings • Vital signs return to normal or near-normal ranges • Respiratory status improves with adequate spontaneous ventilatory effort • Reports free of angina or other indicators of cardiac insufficiency • Experiences minimal or no complications caused by immobility

sedative and analgesic agents.

Quality and Safety Nursing Alert

Medications are given to the patient with hypothyroidism with extreme caution because of the potential for altered metabolism and excretion, as well as depressed metabolic rate and respiratory status.

Promoting Home, Community-Based, and Transitional Care

Educating Patients About Self-Care

The patient and family require education and support to manage this complex disorder at home. Oral and written instructions should be provided regarding the following:

- The importance of life-long therapy and the need to take thyroid medication everyday
- Desired actions and side effects of medications
- Correct medication administration ("Take first thing in the morning with a full glass of water on an empty stomach.")
- Importance of continuing to take the medications as prescribed even after symptoms improve
- When to seek medical attention
- Importance of nutrition and diet to promote weight loss and normal bowel patterns
- Importance of periodic follow-up testing

The patient and family should be educated that the symptoms observed during the course of the disorder will disappear with effective treatment (see Chart 45-5).

Continuing and Transitional Care

If indicated, a referral is made for home, community-based or transitional care. The nurse monitors the patient's recovery and ability to cope with changes, and assesses the patient's physical and cognitive status and the patient's and family's understanding of previous education. The nurse documents and reports to the patient's primary provider subtle signs and symptoms that may indicate either inadequate or excessive thyroid hormone.

Chart 45-5  HOME CARE CHECKLIST

The Patient with Hypothyroidism (Myxedema)

At the completion of education, the patient and/or caregiver will be able to:

- State the impact of hypothyroidism and treatment on physiologic functioning, ADLs, IADLs, roles, relationships, and spirituality.
- State the need to avoid extreme cold temperature until condition is stable.
- State precipitating factors and interventions for complications (hyperthyroidism, myxedema coma).
- State the continuing potential effects of hypothyroidism on the body.
- State the potential for menstrual irregularities and potential for pregnancy in women.
- State the importance of avoiding infection.
- Relate how to reach primary provider with questions or complications.
- State time and date of follow-up medical appointments, therapy, and testing.
- Identify sources of support (e.g., friends, relatives, faith community).
- Identify the contact details for support services for patients and their caregivers/families.
- Identify the need for health promotion, disease prevention, and screening activities.

ADLs, activities of daily living; IADLs, instrumental activities of daily living.

Gerontologic Considerations

The prevalence of hypothyroidism increases with age, most often among women (Calsolaro, Niccolai, Pasqualetti, et al., 2019). The higher prevalence of hypothyroidism among older adults may be related to age-related alterations in immune function and complicated by multiple comorbidities.

Most patients with primary hypothyroidism present with long-standing mild to moderate hypothyroidism. Subclinical disease is common among older women and can be asymptomatic or mistaken for other medical conditions. Subtle symptoms of hypothyroidism, such as fatigue, muscle aches, and mental confusion, may be attributed to the normal aging process by patients, families, and health care providers; therefore, these symptoms require close attention (Calsolaro et al., 2019). In addition, signs and symptoms of

hypothyroidism in older adults are often atypical, and manifestations of hypothyroidism and hyperthyroidism may blur. Patients may have few or no symptoms until dysfunction is severe. Depression, apathy, and decreased mobility or activity may be the major initial symptoms and may be accompanied by significant weight loss. Constipation affects one fourth of older patients.

In those with mild to moderate hypothyroidism, thyroid hormone replacement is individually tailored and must be started with low dosages and increased gradually to prevent serious cardiovascular side effects (Calsolaro et al., 2019). Angina, for example, may occur with rapid thyroid replacement in the presence of coronary artery disease secondary to the hypothyroid state. Heart failure and tachyarrhythmias may worsen during the transition from the hypothyroid state to the normal metabolic state. Dementia may become more apparent during early thyroid hormone replacement in older patients with concomitant dementia.

Older patients with severe hypothyroidism and atherosclerosis may become confused and agitated if their metabolic rate is increased too quickly. Marked clinical improvement follows the administration of hormone replacement; such medication must be continued for life, even though signs of hypothyroidism disappear within 3 to 12 weeks.

Older patients require periodic follow-up monitoring of serum TSH levels, because poor adherence with therapy may occur or the patient may take the medications erratically. A careful history can identify the need for further education about the importance of the medication.

Hyperthyroidism

Hyperthyroidism, a common endocrine disorder, is a form of **thyrotoxicosis** resulting from an excessive synthesis and secretion of endogenous or exogenous thyroid hormones by the thyroid (Norris, 2019). The most common causes are Graves disease, toxic multinodular goiter, and toxic adenoma. Other causes include **thyroiditis** (inflammation of the thyroid gland) and excessive ingestion of thyroid hormone.

Graves disease is an autoimmune disorder that results from an excessive output of thyroid hormones caused by abnormal stimulation of the thyroid gland by circulating immunoglobulins. This disease affects women eight times more frequently than men, with onset usually between the second and fourth decades. The disorder may appear after an emotional shock, stress, or an infection, but the exact significance of these relationships is not understood (Norris, 2019).

Clinical Manifestations

Patients with hyperthyroidism exhibit a characteristic group of signs and symptoms (see Fig. 45-6). Clinical manifestations are related to the increase in metabolic rate and increased oxygen consumption. The patient may appear anxious, seem restless and irritable, and exhibit fine tremors of the hands. The patient will be tachycardic and complain of palpitations. Heat intolerance will be noted with increased perspiration. Additional clinical manifestations include an increase in appetite, diarrhea, weight loss, and thin skin. Patients with Graves disease may present with exophthalmos and may exhibit reduced blinking and lid retraction. Treatment may not reverse ocular manifestations (Medford, 2019). Women experience changes in menstruation including oligomenorrhea (Lee & Khardori, 2018).

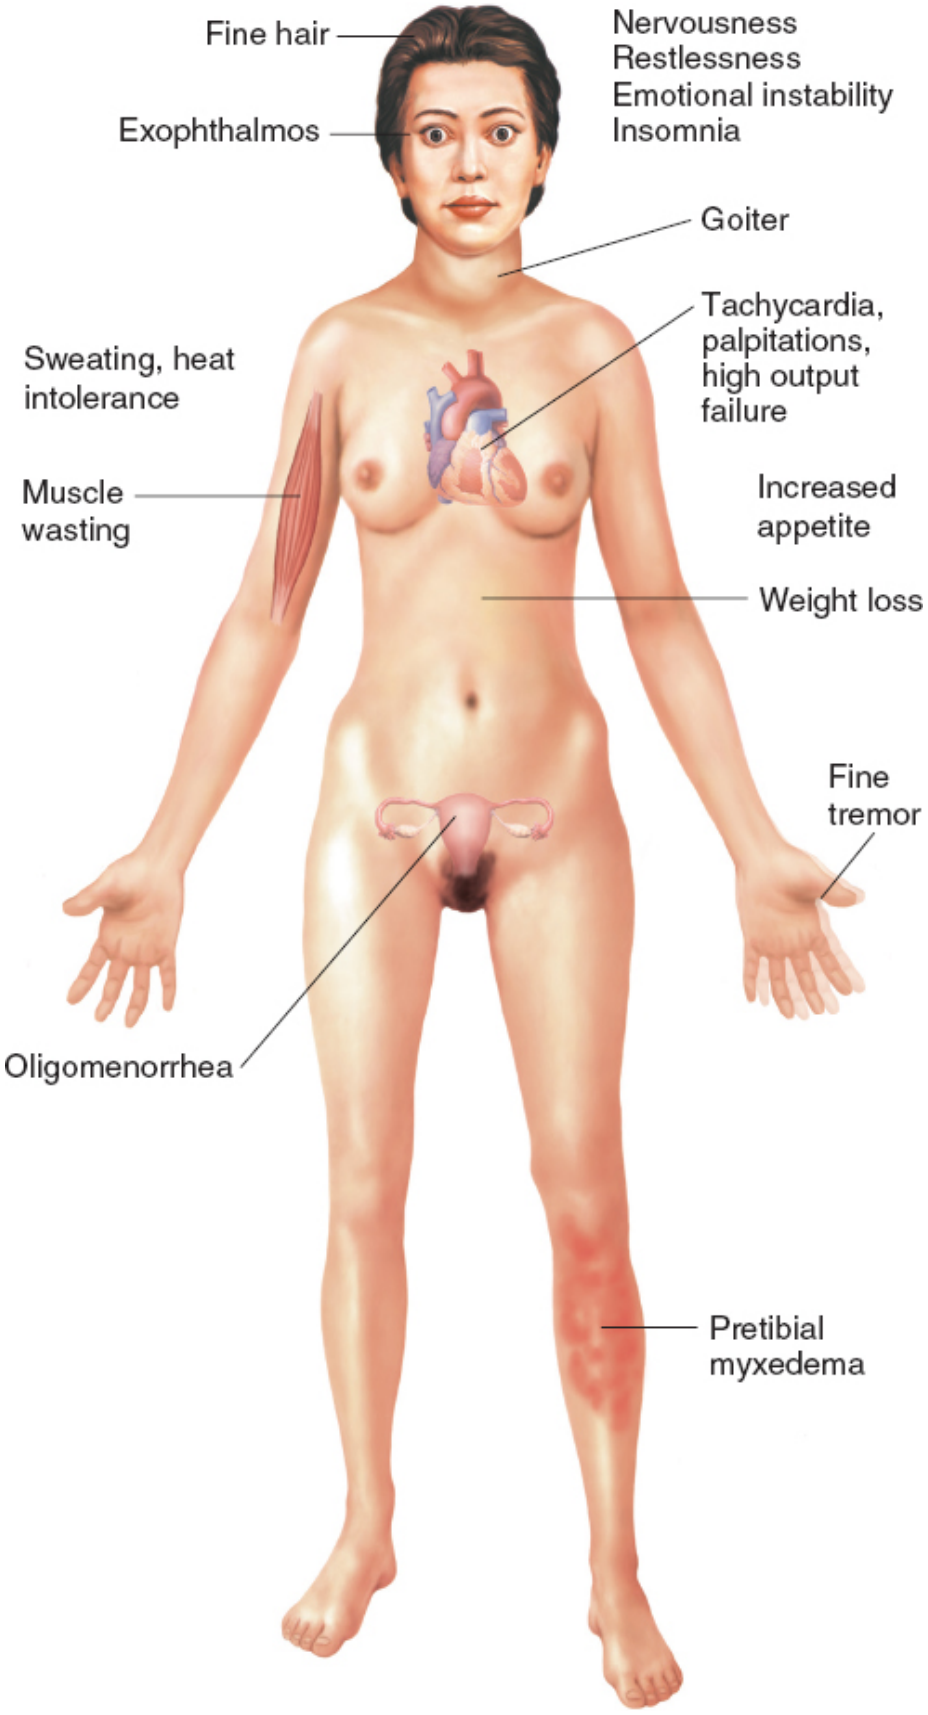

Figure 45-6 • Clinical manifestations of hyperthyroidism. Reprinted with permission from Norris, T. L. (2019). *Porth's pathophysiology:*

Concepts of altered health states (10th ed., Fig. 41.5). Philadelphia, PA: Wolters Kluwer.

Cardiac effects may include sinus tachycardia or arrhythmias, decreased cardiac output, increased pulse pressure, and palpitations; these changes may be related to increased sensitivity to catecholamines or to changes in neurotransmitter turnover. Myocardial hypertrophy and heart failure may occur if the hyperthyroidism is severe and untreated.

The course of the disease may be mild, characterized by remissions and exacerbations, and terminate with spontaneous recovery in a few months or years. Conversely, it may progress relentlessly, with the untreated person becoming emaciated, intensely nervous, delirious, and even disoriented; eventually, the heart fails.

Symptoms of hyperthyroidism may occur with the release of excessive amounts of thyroid hormone as a result of inflammation after irradiation of the thyroid or destruction of thyroid tissue by tumor. Such symptoms may also occur with excessive administration of thyroid hormone for the treatment of hypothyroidism. Long-standing use of thyroid hormone in the absence of close monitoring may be a cause of symptoms of hyperthyroidism. It is also likely to result in premature osteoporosis, particularly in women.

Assessment and Diagnostic Findings

The thyroid gland is enlarged to some extent. It is soft and may pulsate; a thrill often can be palpated, and a bruit is heard over the thyroid arteries (Norris, 2019). These are signs of greatly increased blood flow through the thyroid gland. In advanced cases, the diagnosis is made on the basis of the symptoms, a decrease in serum TSH, increased free T_4, and an increase in radioactive iodine uptake.

Medical Management

Appropriate treatment of hyperthyroidism depends on the underlying cause and often consists of a combination of therapies, including antithyroid agents, radioactive iodine, and surgery. Treatment of hyperthyroidism is directed toward reducing thyroid hyperactivity to relieve symptoms and preventing complications. The use of radioactive iodine is the most common form of treatment for Graves disease. Beta-adrenergic blocking agents (e.g., propranolol, atenolol, metoprolol) are used as adjunctive therapy for symptomatic relief, particularly in transient thyroiditis (Lee & Khardori, 2018). The three treatments (radioactive iodine therapy, antithyroid medications [e.g., thionamides], and surgery) share the same complications: relapse or recurrent hyperthyroidism and permanent hypothyroidism. The rate

of relapse increases in patients who have had very severe disease, a long history of dysfunction, ocular and cardiac symptoms, large goiter, or relapse after previous treatment. Patients with Graves disease may sustain remission for up to 12 to 18 months but often experience recurrence within 12 months of treatment (Lee & Khardori, 2018).

Pharmacologic Therapy

Two forms of pharmacotherapy are available for treating hyperthyroidism and controlling excessive thyroid activity: (1) the use of irradiation by administration of the radioisotope ^{131}I for destructive effects on the thyroid gland and (2) antithyroid medications that interfere with the synthesis of thyroid hormones and other agents that control manifestations of hyperthyroidism.

Radioactive Iodine Therapy

Radioactive iodine has been used to treat toxic adenomas, toxic multinodular goiter, and most varieties of thyrotoxicosis and is considered the treatment of choice because a single dose is effective in treating 80% to 90% of cases (Bauerle & Clutter, 2019). Radioactive iodine is contraindicated during pregnancy because it crosses the placenta. Women of childbearing age should be given a pregnancy test 48 hours before administration of radioactive iodine. They should also be instructed to not conceive for at least 6 months following treatment. In addition, breast-feeding for up to 6 weeks prior to radioactive iodine treatment is contraindicated (Lee & Khardori, 2018).

The goal of radioactive iodine therapy (^{131}I) is to eliminate the hyperthyroid state with the administration of sufficient radiation in a single dose (Lee & Khardori, 2018). Almost all of the iodine that enters and is retained in the body becomes concentrated in the thyroid gland. Therefore, the radioactive isotope of iodine is concentrated in the thyroid gland, where it destroys thyroid cells without jeopardizing other radiosensitive tissues. Over a period of several weeks, thyroid cells exposed to the radioactive iodine are destroyed, resulting in reduction of the hyperthyroid state and inevitably hypothyroidism.

The use of an ablative dose of radioactive iodine initially causes an acute release of thyroid hormone from the thyroid gland and may cause increased symptoms. The patient is observed for signs of **thyroid storm** (see Chart 45-6), a life-threatening condition manifested by cardiac arrhythmias, fever, and neurologic impairment (Norris, 2019) which may lead to heart failure, circulatory collapse and dangerous elevation of body temperature, all related to the increase in metabolism. Beta-blockers are used to control these symptoms.

Thyroid hormone replacement is started 4 to 18 weeks after the antithyroid medications have been stopped based on the results of thyroid function tests. TSH measurements can be misleading in the early months following treatment

with radioactive iodine. Therefore, serum free T_4 is the principal test measured at 3 to 6 weeks following administration of radioactive iodine and then every 1 to 2 months until normal thyroid function is established. If TSH and free T_4 are both persistently low, the total T_3 then must be measured to differentiate between persistent hyperthyroidism (T_3 elevated) or transient hypothyroidism (T_3 normal or low). Once a normal thyroid state has been established, TSH should be measured every 6 to 12 months for life (Fischbach & Fischbach, 2018).

A major advantage of treatment with radioactive iodine is that it avoids many of the side effects associated with antithyroid medications. However, some patients may elect to be treated with antithyroid medications rather than radioactive iodine for a variety of reasons, including fear of radiation.

Chart 45-6

Thyroid Storm (Thyrotoxic Crisis, Thyrotoxicosis)

Thyroid storm (thyrotoxic crisis) is a form of severe hyperthyroidism, usually of abrupt onset. Untreated, it is almost always fatal, but with proper treatment the mortality rate is reduced substantially. The patient with thyroid storm or crisis is critically ill and requires astute observation and aggressive and supportive nursing care during and after the acute stage of illness.

Clinical Manifestations

Thyroid storm is characterized by:

- Hyperpyrexia (high fever), >38.5°C (>101.3°F)
- Extreme tachycardia (>130 bpm)
- Exaggerated symptoms of hyperthyroidism with disturbances of a major system—for example, gastrointestinal (weight loss, diarrhea, abdominal pain) or cardiovascular (edema, chest pain, dyspnea, palpitations)
- Altered neurologic or mental state, which frequently appears as delirium psychosis, somnolence, or coma

Life-threatening thyroid storm is usually precipitated by stress, such as injury, infection, thyroid and nonthyroid surgery, tooth extraction, insulin reaction, diabetic ketoacidosis, pregnancy, digitalis intoxication, abrupt withdrawal of antithyroid medications, extreme emotional stress, or vigorous palpation of the thyroid. These factors can precipitate thyroid storm in the partially controlled or completely untreated patient with hyperthyroidism. Current methods of diagnosis and treatment for hyperthyroidism have greatly decreased the incidence of thyroid storm, making it uncommon today.

Management

Immediate objectives are reduction of body temperature and heart rate and prevention of vascular collapse. Measures to accomplish these objectives include:

- A hypothermia mattress or blanket, ice packs, a cool environment, hydrocortisone, and acetaminophen. Salicylates (e.g., aspirin) are not used because they displace thyroid hormone from binding proteins and worsen the hypermetabolism.
- Humidified oxygen is given to improve tissue oxygenation and meet the high metabolic demands. Arterial blood gas levels or pulse oximetry may be used to monitor respiratory status.
- IV fluids containing dextrose are given to replace liver glycogen stores that have been decreased in the patient who is hyperthyroid.
- Propylthiouracil or methimazole is given to impede formation of thyroid hormone and block conversion of T_4 to T_3, the more active form of thyroid hormone.
- Hydrocortisone is prescribed to treat shock or adrenal insufficiency.

- Iodine is given to decrease output of T_4 from the thyroid gland. For cardiac problems such as atrial fibrillation, arrhythmias, and heart failure, sympatholytic agents may be given. Propranolol, combined with digitalis, has been effective in reducing severe cardiac symptoms.

T_3, triiodothyronine; T_4, thyroxine.

Adapted from Morton, P. G., & Fontaine, D. K. (2018). *Critical care nursing: A holistic approach* (10th ed.). Philadelphia, PA: Wolters Kluwer; Comerford, K. C., & Durkin, M. T. (2020). *Nursing 2020 drug handbook*. Philadelphia, PA: Wolters Kluwer.

Patients who receive radioactive iodine should be informed that they can contaminate their household and other people through saliva, urine, or radiation emitting from their body. They should avoid sexual contact, sleeping in the same bed with other people, having close contact with children and pregnant women, and sharing utensils and cups. The patient should follow the instructions provided regarding the time restrictions for these cautions because they are dose related (Fischbach & Fischbach, 2018).

Antithyroid Medications

Antithyroid medications (thionamides) are summarized in Table 45-1. The objective of pharmacotherapy is to inhibit one or more stages in thyroid hormone synthesis or hormone release. Antithyroid agents block the utilization of iodine by interfering with the iodination of tyrosine and the coupling of iodotyrosines in the synthesis of thyroid hormones. This prevents the synthesis of thyroid hormone. The most commonly used antithyroid drugs in the United States are methimazole or propylthiouracil. The medications are used until the patient is euthyroid (i.e., neither hyperthyroid nor hypothyroid). These medications block extrathyroidal conversion of T_4 to T_3 (Bauerle & Clutter, 2019).

Prior to initiating therapy with these drugs, baseline blood tests are performed, including complete blood count (white blood cell [WBC] count with differential) and liver profile (transaminases and bilirubin) (Bauerle & Clutter, 2019). The therapeutic dose is determined on the basis of clinical criteria, including changes in pulse rate, pulse pressure, body weight, size of the goiter, and results of laboratory studies. The patient should be instructed to take the medication in the morning on an empty stomach 30 minutes before eating to avoid decrease in absorption associated with some foods such as walnuts, soybean flour, cottonseed meal, and dietary fiber. Because antithyroid medications do not interfere with release or activity of previously formed thyroid hormones, it may take several weeks until symptom relief occurs. At that time, the maintenance dose is established, and the medication is gradually tapered over several months.

Toxic complications of antithyroid medications are relatively uncommon; nevertheless, the importance of periodic follow-up is emphasized, because medication sensitization, fever, rash, urticaria, or even agranulocytosis and thrombocytopenia (decrease in granulocytes and platelets) may develop (Bauerle & Clutter, 2019). With any sign of infection, especially pharyngitis and fever or the occurrence of mouth ulcers, the patient is advised to stop the medication, notify the primary provider immediately, and undergo hematologic studies (Bauerle & Clutter, 2019). Propylthiouracil is recommended during the first trimester of pregnancy rather than methimazole due to the teratogenic effects of methimazole. Due to risk of hepatotoxicity, propylthiouracil should be discontinued after the first trimester and the patient should be switched to methimazole for the remainder of the pregnancy and when breast-feeding (Bauerle & Clutter, 2019).

TABLE 45-1 Pharmacologic Agents Used to Treat Hyperthyroidism

Agent	Action	Nursing Considerations
Propylthiouracil	Blocks synthesis of hormones (conversion of T_4 to T_3)	Monitor cardiac parameters. Observe for conversion to hypothyroidism. Must be given by mouth. Watch for rash, nausea, vomiting, agranulocytosis, SLE.
Methimazole	Inhibits synthesis of thyroid hormone	More toxic than propylthiouracil. Watch for rash and other symptoms as for propylthiouracil.
Sodium iodide	Suppresses release of thyroid hormone	Given 1 h after propylthiouracil or methimazole. Watch for edema, hemorrhage, gastrointestinal upset.
Potassium iodide	Suppresses release of thyroid hormone	Discontinue for rash. Watch for signs of toxic iodinism.
Saturated solution of potassium iodide (SSKI)	Suppresses release of thyroid hormone	Mix with juice or milk. Given by straw to prevent staining of teeth.
Beta-blocker (e.g., propranolol)	Beta-adrenergic blocking agent	Monitor cardiac status. Hold for bradycardia or decreased cardiac output. Use with caution in patients with heart failure.

SLE, systemic lupus erythematosus; T_3, triiodothyronine; T_4, thyroxine.

Adapted from Bauerle, K. T., & Clutter, W. E. (2019). Hyperthyroidism. In T. J. Braranski, J. B. McGill, & J. M. Silverstein (Eds.). *The Washington manual endocrinology subspecialty consult* (4th ed.). Philadelphia, PA: Wolters Kluwer; Comerford, K. C., & Durkin, M. T. (2020). *Nursing 2020 drug handbook*. Philadelphia, PA: Wolters Kluwer.

Discontinuation of antithyroid medications before therapy is complete usually results in relapse within 6 months. It is important that the possibility of relapse be discussed so that a treatment strategy will be in place if relapse occurs.

Adjunctive Therapy

Additional medications may be necessary. Potassium iodide (SSKI) may be used in combination with antithyroid agents or beta-adrenergic blockers to prepare the patient with hyperthyroidism for surgery. The drugs reduce the effects of hyperthyroidism quickly and help to prevent the onset of thyroid

storm. The usual dosage for SSKI is 5 drops every 6 hours. The usual dose of propylthiouracil is 200 mg every 6 hours and the usual dose of propranolol is 60 to 80 mg orally every 6 hours to prevent tachycardia. The patient will need to continue to take the propylthiouracil and any cardiac medication until the free T_4 and T_3 levels are near normal (Bauerle & Clutter, 2019).

Surgical Management

Surgery to remove thyroid tissue is reserved for special circumstances, for example, in pregnant women who are allergic to antithyroid medications, in patients with large goiters, or in patients who are unable to take antithyroid agents. Surgery for treatment of hyperthyroidism is performed soon after the thyroid function has returned to normal (4 to 6 weeks).

The surgical removal of about five sixths of the thyroid tissue (subtotal thyroidectomy) reliably results in a prolonged remission in most patients with exophthalmic goiter. Its use today is reserved for patients with obstructive symptoms, some pregnant women, and for patients with a need for rapid normalization of thyroid function. Before surgery, an antithyroid medication is given until signs of hyperthyroidism have disappeared. A beta-adrenergic blocking agent (e.g., propranolol) may be used to reduce the heart rate and other signs and symptoms of hyperthyroidism. Medications that may prolong clotting (e.g., aspirin) are stopped several weeks before surgery to reduce the risk of postoperative bleeding. Patients receiving iodine medication must be monitored for evidence of iodine toxicity, which requires immediate withdrawal of the medication. Symptoms of toxicity include mucosa membranes stained brown, burning pain in the mouth and esophagus, laryngeal edema, and shock (Fischbach & Fischbach, 2018).

Gerontologic Considerations

Although hyperthyroidism is much less common in older adults than hypothyroidism, patients 65 years and older need careful assessment to avoid missing subtle signs and symptoms. This age group may present with atypical vague and nonspecific signs and symptoms of thyroid disease such as anorexia and weight loss with absence of ocular signs, or isolated atrial fibrillation (Morton & Fontaine, 2018). New or worsening heart failure or angina is more likely to occur in older patients rather than in younger patients. Symptoms such as tachycardia, fatigue, mental confusion, weight loss, change in bowel habits, and depression can be attributed to age and other illnesses that are common in older adults (Eliopoulos, 2018). The older patient may complain of difficulty climbing stairs or rising from a chair because of muscle weakness. Evaluation for thyroid disease with a serum TSH measurement is indicated in older patients who have unexplained physical or mental deterioration

(Samuels, 2018). Free T_4 and T_3 should be included in the initial screening when hyperthyroidism is highly suspected. Once thyrotoxicosis is confirmed, additional tests such as radioactive iodine uptake and thyroid scan are prescribed to differentiate between causes such as Graves disease, toxic nodular goiter, acute thyroiditis, and other disorders. Toxic nodular goiter is the most common cause of thyrotoxicosis in older patients. Patients have the option of treatment using antithyroid medications, radioactive iodine, and surgery. Radioactive iodine is generally recommended for treatment of thyrotoxicosis caused by toxic nodular goiter in older patients unless an enlarged thyroid gland is pressing on the airway. Long-term use of certain antithyroid medications such as propylthiouracil is not recommended for treatment of hyperthyroidism in older adults due to potential side effects (Samuels, 2018).

The use of beta-adrenergic blocking agents (e.g., propranolol and atenolol) may be indicated to decrease the cardiovascular and neurologic signs and symptoms of thyrotoxicosis. These agents must be used with extreme caution in older patients to minimize adverse effects on cardiac function that may produce heart failure. The dosage of other medications used to treat other chronic illnesses in older patients may also need to be modified because of the altered rate of metabolism associated with hyperthyroidism.

NURSING PROCESS

The Patient with Hyperthyroidism

Assessment

The health history and examination focus on symptoms related to accelerated or exaggerated metabolism. These include the patient's and family's reports of irritability and increased emotional reaction and the impact that these changes have had on the patient's interactions with family, friends, and coworkers. The history includes other stressors and the patient's ability to cope with stress.

The nurse initially and periodically assesses the patient's nutritional status and the presence of symptoms related to the hypermetabolic state. This hypermetabolic state may affect the cardiovascular system, causing changes in vital signs including heart rate and rhythm, blood pressure, heart sounds, and peripheral pulses. Other specific changes may include alteration in vision and appearance of the external eye. Because emotional changes are associated with hyperthyroidism, the patient's emotional state and psychological status are evaluated, as well as such symptoms as irritability, anxiety, sleep disturbances, apathy, and lethargy, all of which may occur with hyperthyroidism (Bauerle & Clutter, 2019). The family may also provide information about recent changes in the patient's emotional status.

Diagnosis

NURSING DIAGNOSES

Based on the assessment data, major priority nursing diagnoses may include the following:

- Risk for impaired cardiac function associated with alteration in heart rate and rhythm.
- Impaired nutritional status associated with exaggerated metabolic rate, excessive appetite, and increased GI activity
- Difficulty coping associated with irritability, hyperexcitability, apprehension, and emotional instability
- Situational low self-esteem associated with changes in appearance, excessive appetite, and weight loss
- Risk for impaired thermoregulation

COLLABORATIVE PROBLEMS/POTENTIAL COMPLICATIONS

Potential complications may include the following:

- Thyrotoxicosis or thyroid storm
- Hypothyroidism

Planning and Goals

The major goals for the patient may include maintenance of adequate cardiac function, maintenance of adequate nutritional status, improved coping ability, improved self-esteem, maintenance of normal body temperature, and absence of complications.

Nursing Interventions

MAINTAINING ADEQUATE CARDIAC OUTPUT

Due to the effects of hyperthyroidism on the cardiac system, it is important to critically assess vital signs, especially heart rate and rhythm and body temperature. Nurses need to be alert to complaints of palpitations which may be reported as "my heart is racing." The nurse monitors the patient for signs of heart failure (dyspnea, jugular vein distention, crackles, and peripheral edema; see Chapter 25).

In the presence of thyroid storm the patient should be placed on a cardiac monitor in order to adequately monitor for arrhythmias. Monitoring of electrolytes and strict I&O assessment is also essential. The nurse is prepared to administer beta-blockers as prescribed. Acetaminophen is the drug of choice to reduce elevated body temperature because medications containing salicylates may result in higher levels of unbound thyroid hormone. A cooling blanket as well as a cool environment may also be needed.

IMPROVING NUTRITIONAL STATUS

Hyperthyroidism affects all body systems, including the GI system. Rapid movement of food through the GI tract may result in nutritional imbalance and weight loss. In addition, the patient will report an increased appetite and should be encouraged to eat small frequent nutritious meals. If necessary, the patient is referred to a nutritionist or dietician to develop a meal plan to address dietary concerns.

Foods and fluids are selected to replace fluid lost through diarrhea and diaphoresis and to control the diarrhea that results from increased peristalsis. To reduce diarrhea, highly seasoned foods, coffee, tea, cola, and alcohol are discouraged while high-calorie, high-protein foods are encouraged. A quiet atmosphere during mealtime may aid digestion. The patient should be encouraged to record weight and dietary intake.

ENHANCING COPING MEASURES

The patient with hyperthyroidism needs reassurance that the emotional reactions being experienced are a result of the disorder and that with effective treatment those symptoms will be controlled. Because of the negative effect that these symptoms can have on family and friends, they too need reassurance that the symptoms are expected to disappear with treatment. A calm, unhurried approach is beneficial for the patient. Stressful experiences should be minimized and a quiet, uncluttered

environment should be maintained. The patient should be instructed to balance periods of activity with rest.

If a thyroidectomy is planned, the patient needs to know that pharmacologic therapy is necessary to prepare the thyroid gland for surgical treatment. The nurse provides education and reminds the patient to take the medications as prescribed. Because of hyperexcitability and shortened attention span, the patient may require repetition of this education and written instructions.

IMPROVING SELF-ESTEEM

The patient with hyperthyroidism is likely to experience changes in appearance, appetite, and weight. These factors, along with the patient's inability to cope well with family and the illness, may result in loss of self-esteem. The nurse conveys an understanding of the patient's concern about these problems and promotes the use of effective coping strategies. The patient and family should be reassured that these changes are a result of the thyroid dysfunction and are, in fact, out of the patient's control. The nurse refers the patient to professional counseling as necessary.

If the patient experiences ocular changes secondary to hyperthyroidism, eye care and protection may be necessary. The nurse educates the patient about instillation of eye drops or ointment prescribed to soothe the eyes and protect the exposed corneas. Smoking should be highly discouraged, and smoking cessation strategies are recommended. The patient may be embarrassed by the need to eat large meals. The nurse explains the need for increased food consumption to caregivers and family members in order to address the possibility of their commenting on the patient's increased appetite.

MAINTAINING NORMAL BODY TEMPERATURE

The patient with hyperthyroidism frequently finds a normal room temperature too warm because of an exaggerated metabolic rate and increased heat production. If the patient is hospitalized, the environment should be maintained at a cool, comfortable temperature, and the bedding and clothing should be changed as needed. Cool baths and cool or cold fluids may also provide relief.

MONITORING AND MANAGING POTENTIAL COMPLICATIONS

The nurse closely monitors the patient with hyperthyroidism for signs and symptoms that may be indicative of thyroid storm. Cardiac and respiratory functions are assessed by measuring vital signs and cardiac output, electrocardiographic (ECG) monitoring, arterial blood gases, and pulse oximetry. Assessment continues after treatment is initiated because of the potential effects of treatment on cardiac function. Oxygen is given to prevent hypoxia, to improve tissue oxygenation, and to meet the high metabolic demands. IV fluids may be necessary to maintain blood glucose

levels and to replace lost fluids. Antithyroid medications (methimazole or propylthiouracil) may be prescribed to reduce thyroid hormone levels. In addition, beta-blockers and digitalis may be prescribed to treat cardiac symptoms. If shock develops, treatment strategies must be implemented (see Chapter 11).

Hypothyroidism is likely to occur with any of the treatments used for hyperthyroidism. Therefore, the nurse periodically monitors the patient. Most patients report a greatly improved sense of well-being after treatment of hyperthyroidism, and some fail to continue to take prescribed thyroid replacement therapy. Therefore, part of patient and family education is instruction about the importance of continuing therapy indefinitely after discharge and a discussion of the consequences of failing to take medication.

PROMOTING HOME, COMMUNITY-BASED, AND TRANSITIONAL CARE

Educating Patients About Self-Care. The nurse educates the patient with hyperthyroidism about how and when to take prescribed medication and provides education about the essential role of the medication in the broader therapeutic plan. Because of the hyperexcitability and decreased attention span associated with hyperthyroidism, the nurse provides a written plan for the patient to take home and use. The type and amount of information given depend on the patient's stress and anxiety levels. The patient and family members receive verbal and written education about the actions and possible side effects of the medications as well as adverse effects that should be reported if they occur (see Chart 45-7).

Chart 45-7  **HOME CARE CHECKLIST**

The Patient with Hyperthyroidism

At the completion of education, the patient and/or caregiver will be able to:

- State the impact of hyperthyroidism, treatment on physiologic functioning, ADLs, IADLs, roles, relationships, and spirituality.
- State that emotional lability is part of disease process.
- Identify the potential for menstrual irregularities and pregnancy, and increased risk of osteoporosis in women.
- State that long-term treatment and follow-up is necessary.
- Describe the potential benefits and risks of surgical intervention or radioactive iodine therapy.
- State the name, dose, side effects, frequency, and schedule for all medications.
- Explain the purpose, dose, route, schedule, side effects, and precautions of treatment of hyperthyroidism (antithyroid medications, radioactive iodine).
- State the need to contact primary provider before taking over-the-counter medications.
- State changes in lifestyle (e.g., diet, activity) necessary to maintain health.
- Identify the need for increased dietary intake until weight stabilizes.
- Identify foods to be avoided.
- Identify the need for planned rest periods and methods to improve sleep patterns.
- Identify areas of stress and management techniques.
- Identify rationale for smoking cessation and steps to stop use of any tobacco product.
- State precipitating factors and interventions for complications (hypothyroidism, thyroid storm).
- Relate how to reach primary provider with questions or complications.
- State time and date of follow-up medical appointments, therapy, and testing.
    - Identify sources of support (e.g., friends, relatives, faith community).
    - Identify the contact details for support services for patients and their caregivers/families.
- Identify the need for health promotion, disease prevention, and screening activities.

ADLs, activities of daily living; IADLs, instrumental activities of daily living.

If a total or subtotal thyroidectomy is anticipated, the patient needs to be educated about what to expect. Information is repeated as the time of surgery approaches. The nurse also advises the patient to avoid stressful situations that may precipitate thyroid storm.

Continuing and Transitional Care. Referral for home, community-based or transitional care, if indicated, allows the nurse to assess the home and family environment, as well as the patient's and family's understanding of the importance of adhering to the therapeutic regimen and the recommended follow-up monitoring. The nurse reinforces to the patient and family the importance of long-term follow-up because of the risk of hypothyroidism after thyroidectomy or treatment with antithyroid medications or radioactive iodine. The patient is assessed for changes indicating return to normal thyroid function and signs and symptoms of hyperthyroidism and hypothyroidism. Furthermore, the patient and family are reminded about the importance of health promotion activities and recommended health screening.

Evaluation

Expected patient outcomes may include:

1. Improved cardiac status
   a. Vital signs within normal limits
   b. Absence of dyspnea, crackles, and peripheral edema
   c. Reports absence of palpitations
2. Improved nutritional status
   a. Reports adequate dietary intake and decreased hunger
   b. Identifies high-calorie, high-protein foods; identifies foods to be avoided
   c. Avoids the use of alcohol and stimulants
   d. Stops smoking
   e. Reports decreased episodes of diarrhea
3. Demonstrates effective coping methods in dealing with family, friends, and coworkers
   a. Explains reasons for irritability and emotional instability
   b. Avoids stressful situations, events, and people
   c. Participates in relaxing, nonstressful activities
4. Achieves increased self-esteem
   a. Verbalizes feelings about self and illness
   b. Describes feelings of frustration and loss of control
   c. Describes reasons for increased appetite
5. Maintains normal body temperature
6. Absence of complications

a. Serum thyroid hormone and TSH levels within normal limits
b. Identifies signs and symptoms of thyroid storm and hypothyroidism
c. Vital signs and results of ECG, arterial blood gases, and pulse oximetry within normal limits
d. States importance of regular follow-up and lifelong maintenance of prescribed therapy

Thyroid Tumors

Tumors of the thyroid gland are classified on the basis of being benign or malignant, the presence or absence of associated thyrotoxicosis, and the diffuse or irregular quality of the glandular enlargement. If the enlargement is sufficient to cause a visible swelling in the neck, the tumor is referred to as a goiter.

All grades of goiter are encountered, from those that are barely visible to those producing disfigurement. Some are symmetric and diffuse; others are nodular. Some are accompanied by hyperthyroidism, in which case they are described as toxic; others are associated with a euthyroid state and are referred to as nontoxic goiters.

Endemic (Iodine-Deficient) Goiter

The most common type of goiter that occurs when iodine intake is deficient is the simple or colloid goiter. In addition to being caused by an iodine deficiency, simple goiter may be caused by an intake of large quantities of goitrogenic substances in patients with unusually susceptible glands. These substances include excessive amounts of iodine. Lithium prescribed for the treatment of bipolar disorder has also been found to also have antithyroid actions (Singh & Clutter, 2019).

Simple goiter is a compensatory hypertrophy of the thyroid gland, caused by stimulation by the pituitary gland. The pituitary gland produces thyrotropin or TSH, a hormone that controls the release of thyroid hormone from the thyroid gland. Its production increases if there is subnormal thyroid activity, as when insufficient iodine is available for production of the thyroid hormone. Such goiters usually cause no symptoms, except for the swelling in the neck, which may result in tracheal compression when excessive swelling is present.

Many goiters of this type recede after the iodine imbalance is corrected. Supplementary iodine, such as SSKI, is prescribed to suppress the pituitary's thyroid-stimulating activity. When surgery is indicated, the risk of postoperative complications is minimized by ensuring a preoperative euthyroid state through treatment with antithyroid medications and iodide to reduce the

size and vascularity of the goiter. The introduction of iodized salt has been the single most effective means of preventing goiter in at-risk populations.

Nodular Goiter

Some thyroid glands are nodular because of areas of hyperplasia (overgrowth). No symptoms may arise as a result of this condition, but not uncommonly these nodules slowly increase in size, with some descending into the thorax, where they cause local pressure symptoms. Some nodules become malignant, and some are associated with a hyperthyroid state. Therefore, the patient with many thyroid nodules may eventually require surgery.

Thyroid Cancer

Cancer of the thyroid is less prevalent than other forms of cancer; however, the incidence has tripled in the last 30 years (American Cancer Society [ACS], 2019) and accounts for 90% of endocrine malignancies. Although it has the fastest-growing cancer rate among both men and women, women are three times more likely to develop this cancer than men. In addition, thyroid cancer is more likely to develop in patients that are younger than 50 years (ACS, 2019; Yoo, Yu, & Choi, 2018).

Chart 45-8  **NURSING RESEARCH PROFILE**

Lifestyle Factors and the Risk of Thyroid Cancer

Yoo, Y. G., Yu, B. J., & Choi, E. (2018) A comparison study: The risk factors in the lifestyles of thyroid cancer patients and healthy adults of South Korea. *Cancer Nursing*, *41*(1), E48–E56.

Purpose

In South Korea and in the United States, rates of thyroid cancer have increased significantly. This study investigated which risk factors might be influencing the rates of thyroid cancer in South Korea.

Design

This retrospective comparison study compared a group of patients with thyroid cancer to a group of healthy adults. The Health Belief Model framework guided the study. The Lifestyle Measurement Scale was used to assess the 6 domains of dietary habits, alcohol consumption, smoking habits, rest and physical activity, stress management, and annual physical and health screenings. Participants self-completed the surveys.

Findings

There were 217 usable surveys completed. In the patient group (n = 102), mean age was 50 years; in the healthy adult group (n = 115), 52 years. In both the patient group and the healthy adult group, females made up the majority (85% and 76%, respectively) and most of the participants were married (94% and 93%, respectively). A history of previous smoking, lower physical activity levels, higher stress, and unhealthy eating habits (consumption of more instant food products and fewer vegetables) were all identified as risk factors for developing thyroid cancer.

Nursing Implications

All health care professionals can be instrumental in helping prevent thyroid cancer. Nurses should encourage higher physical activity levels, effective stress management, avoidance of direct and indirect exposure to smoking, and a healthy diet that includes consumption of fewer instant food products and more vegetables to help in prevention efforts.

External radiation of the head, neck, or chest in infancy and childhood increases the risk of thyroid carcinoma. The incidence of thyroid cancer appears to increase 5 to 40 years after irradiation. Consequently, people who underwent radiation treatment or were otherwise exposed to radiation as children should consult their primary provider, request an isotope thyroid scan as part of the evaluation, follow recommended treatment of abnormalities of the gland, and continue with annual checkups.

Additional risk factors that have been identified include smoking, low physical activity, unhealthy eating habits and high stress levels (Yoo et al.,

2018). See the Nursing Research Profile in Chart 45-8 for more information on lifestyle risk factors.

Assessment and Diagnostic Findings

Lesions that are single, hard, and fixed on palpation or associated with cervical lymphadenopathy suggest malignancy. Thyroid function tests may be helpful in evaluating thyroid nodules and masses; however, results are rarely conclusive. An ultrasound-guided fine needle biopsy of the thyroid gland is the standard diagnostic procedure for evaluating thyroid nodules. It is performed as an outpatient procedure to make a diagnosis of thyroid cancer, to differentiate cancerous thyroid nodules from noncancerous nodules, and to stage the cancer if detected (Amdur & Dagan, 2019). The procedure is safe and usually requires only a local anesthetic agent. Additional diagnostic studies include ultrasound, MRI, CT, thyroid scans, radioactive iodine uptake studies, and thyroid suppression tests.

Medical Management

The medical management depends on the classification of cell type found on biopsy. The three common groups include well-differentiated thyroid cancer (DTC), papillary thyroid carcinoma (PTC), and follicular thyroid carcinoma (FTC) (Amdur & Dagan, 2019).

The treatment of choice for localized thyroid carcinoma is surgical removal (Amdur & Dagan, 2019). Total or near-total thyroidectomy is performed if possible (ACS, 2019). Modified neck dissection or more extensive radical neck dissection is performed if there is lymph node involvement.

Efforts are made to spare parathyroid tissue to reduce the risk of postoperative hypocalcemia and tetany. After surgery, ablation procedures are carried out with radioactive iodine to eradicate residual microscopic disease (ACS, 2019). Radioactive iodine is also used for thyroid cancers with metastasis (ACS, 2019).

After surgery, thyroid hormone is given to lower the levels of TSH to a euthyroid state (Bauerle & Riek, 2019). If the remaining thyroid tissue is inadequate to produce sufficient thyroid hormone, thyroxine is required permanently.

Several routes are available for administering radiation to the thyroid or tissues of the neck, including oral administration of radioactive iodine (Bauerle & Riek, 2019) and external administration of radiation therapy. Administration of radioactive iodine for DTC is the most successful targeted therapy in oncology (Amdur & Dagan, 2019). Short-term side effects of radioactive iodine treatment may include neck soreness, nausea, and upset stomach; tender and swollen salivary glands; dry mouth; changes in taste; and, rarely, pain

(Bauerle & Riek, 2019). The patient who receives external sources of radiation therapy is at risk for mucositis, dryness of the mouth, dysphagia, redness of the skin, anorexia, and fatigue (see Chapter 12). Chemotherapy is infrequently used to treat thyroid cancer.

Patients whose thyroid cancer is detected early, who are younger than 50 years, and who are appropriately treated have a good prognosis (Amdur & Dagan, 2019). Patients who have had papillary cancer—the most common and least aggressive tumor—have the best prognosis of all thyroid cancers (ACS, 2019). Long-term survival is also common in follicular cancer, which is a more aggressive form of thyroid cancer (Bauerle & Riek, 2019). However, continued thyroid hormone therapy and periodic follow-up and diagnostic testing are important to ensure the patient's well-being.

Later follow-up includes clinical assessment for recurrence of nodules or masses in the neck and signs of hoarseness, dysphagia, or dyspnea. The recommendations for long-term follow-up of patients with differentiated thyroid cancer are based on the stage of cancer and results of the follow-up examination 1 year following the initial treatment. The first year evaluation includes clinical examination, TSH and free thyroxine, and measurement of serum thyroglobulin within 6 months following the initial treatment, and a routine neck ultrasound with the first 6 to 12 months following initial treatment. Tests used to confirm sites of metastasis if there is clinical evidence of recurrence include radioiodine imaging, CT, MRI, skeletal x-rays, and skeletal radionucleotide imaging.

Fluorodeoxyglucose (FDG) PET is useful to establish prognosis if there is evidence of distant metastases (ACS, 2019). Free T_4, TSH, and serum calcium and phosphorus levels are monitored to determine whether the thyroid hormone supplementation is adequate and to note whether calcium balance is maintained.

Patient education emphasizes the importance of taking prescribed medications and following recommendations for follow-up monitoring. The patient who is undergoing radiation therapy is also instructed in how to assess and manage side effects of treatment (see Chapter 12).

Nursing Management

Important preoperative goals are to prepare the patient for surgery and reduce anxiety. Often, the patient's home life has become tense because of their restlessness, irritability, and nervousness secondary to hyperthyroidism. Efforts are necessary to protect the patient from tension and stress to avoid precipitating thyroid storm. Suggestions are made to limit stressful situations. Quiet and relaxing activities are encouraged.

Providing Preoperative Care

The nurse educates the patient about the importance of eating a diet high in carbohydrates and proteins. A high daily caloric intake is necessary because of the increased metabolic activity and rapid depletion of glycogen reserves. Supplementary vitamins, particularly thiamine and ascorbic acid, may be prescribed. The patient is reminded to avoid tea, coffee, cola, and other stimulants.

The nurse also informs the patient about the purpose of preoperative tests, if they are to be performed, and explains what preoperative preparations to expect. This information should help to reduce the patient's anxiety about the surgery. In addition, special efforts are made to ensure a good night's rest before surgery.

Preoperative education includes demonstrating to the patient how to support the neck with the hands after surgery to prevent stress on the incision. This involves raising the elbows and placing the hands behind the neck to provide support and reduce strain and tension on the neck muscles and the surgical incision.

Providing Postoperative Care

In the postoperative period, the priorities are to observe for any difficulty in breathing due to edema of the glottis, hematoma formation, or injury to the recurrent laryngeal nerve which requires the insertion of an airway, and to monitor the pulse and blood pressure for any indication of internal bleeding. The nurse must be alert for complaints of a sensation of pressure or fullness at the incision site which may indicate subcutaneous hemorrhage and hematoma formation and should be reported. In addition, the nurse periodically assesses the surgical dressings and reinforces as necessary. When the patient is in a recumbent position, the nurse observes the sides and the back of the neck as well as the anterior dressing for bleeding. A tracheostomy set is kept at the bedside at all times, and the surgeon is summoned at the first indication of respiratory distress. If the respiratory distress is caused by hematoma, surgical evacuation is required.

The intensity of pain is assessed, and analgesic agents are given as prescribed for pain. The nurse should anticipate apprehension in the patient and should inform the patient that oxygen will assist breathing. When moving and turning the patient, the nurse carefully supports the patient's head and avoids tension on the sutures. The most comfortable position is the semi-Fowler position, with the head elevated and supported by pillows.

IV fluids are given during the immediate postoperative period. Water may be given by mouth as soon as nausea subsides and bowel sounds are present. Usually, there is a little difficulty in swallowing; initially, cold fluids and ice may be taken better than other fluids. Often, patients prefer a soft diet to a liquid diet in the immediate postoperative period.

The patient is advised to talk as little as possible to reduce edema to the vocal cords; however, when the patient does speak, any voice changes are noted, indicating possible injury to the recurrent laryngeal nerve, which lies just behind the thyroid next to the trachea. An overbed table is provided for access to frequently used items so that the patient avoids turning their head. The table can also be used to support a humidifier when vapor-mist inhalations are prescribed for the relief of excessive mucous accumulation.

Quality and Safety Nursing Alert

An essential assessment following a thyroidectomy is of voice changes. Difficulty in speaking (the act of moving air to vibrate vocal cords) may indicate increasing edema, damage to laryngeal nerve, or hemorrhage and should be reported immediately.

The patient is encouraged to be out of bed as soon as possible and to eat foods that are easily swallowed. A high-calorie diet may be prescribed to promote weight gain. The incision may be closed using absorbable sutures, nonabsorbable sutures, and adhesive strips. Absorbable sutures dissolve within the body. If nonabsorbable sutures are used, the timeline for removal may vary; however, these types of sutures are usually removed 5 to 7 days following surgery. Adhesives will peel off spontaneously. The patient is usually discharged from the hospital on the day of surgery or soon afterward if the postoperative course is uncomplicated.

Monitoring and Managing Potential Complications

Hemorrhage, hematoma formation, edema of the glottis, and injury to the laryngeal nerve are complications reviewed previously in this chapter. Occasionally in thyroid surgery, the parathyroid glands are injured or removed, producing a disturbance in calcium metabolism. As the blood calcium level falls, hyperirritability of the nerves occurs, with spasms of the hands and feet and muscle twitching (see Chapter 10). This group of symptoms is termed *tetany,* and the nurse must immediately report its appearance because laryngospasm, although rare, may occur and obstruct the airway. Tetany of this type is usually treated with IV calcium gluconate. This calcium abnormality is usually temporary after thyroidectomy unless all parathyroid tissues were removed.

Quality and Safety Nursing Alert

Following thyroid surgery, the patient should be monitored closely for signs of tetany, including hyperirritability of the nerves, with spasms of the hands and feet and muscle twitching. Laryngospasm, although rare, may occur and obstruct the airway.

Promoting Home, Community-Based, and Transitional Care

Predischarge education is essential because these patients have short hospital stays. The patient, family, and caregivers need to be knowledgeable about the signs and symptoms that should be reported. Discharge education includes strategies for managing postoperative pain at home and for increasing humidification. The nurse explains to the patient and family the need for rest, relaxation, and adequate nutrition and to avoid putting strain on the incision and sutures. The patient is permitted to resume their former activities and responsibilities completely once recovered from surgery.

Family responsibilities and factors relating to the home environment that produce emotional tension have often been implicated as precipitating causes of thyrotoxicosis. A home visit provides an opportunity to evaluate these factors and to suggest ways to improve the home and family environment. If indicated, a referral to home, community-based or transitional care is made. The nurse reviews the history; performs a physical assessment; assesses the surgical incision; develops a plan of care with the patient and family; and educates the patient, family, and caregivers about wound care, signs and symptoms to report, stress reduction, and the importance of keeping appointments with the primary provider.

THE PARATHYROID GLANDS

Anatomic and Physiologic Overview

The parathyroid glands (normally four) are situated in the neck and embedded in the posterior aspect of the thyroid gland (see Fig. 45-7). Parathormone (parathyroid hormone)—the protein hormone produced by the parathyroid glands—regulates calcium and phosphorus metabolism. Increased secretion of parathormone results in increased calcium absorption from the kidney, intestine, and bones, which raises the serum calcium level (Norris, 2019). Some actions of this hormone are increased by the presence of vitamin D. Parathormone also tends to lower the blood phosphorus level. The serum level of ionized calcium regulates the output of parathormone. Increased serum calcium results in decreased parathormone secretion, creating a negative feedback system.

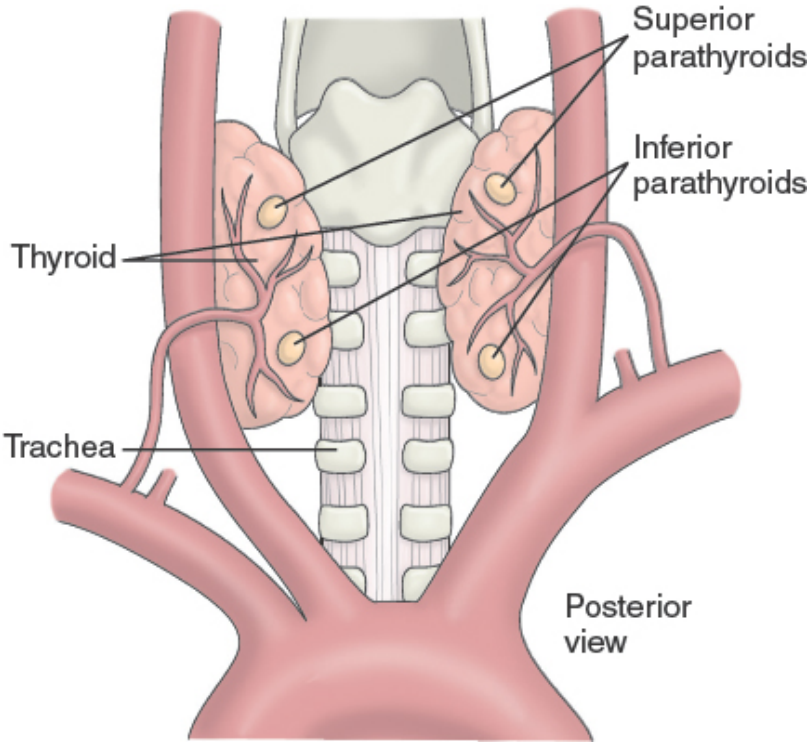

Figure 45-7 • The parathyroid glands are located behind the thyroid gland. The parathyroids may be embedded in the thyroid tissue.

Pathophysiology

Excess parathormone can result in markedly increased levels of serum calcium, which is a potentially life-threatening situation. When the product of serum calcium and serum phosphorus (calcium × phosphorus) rises, calcium phosphate may precipitate in various organs of the body (e.g., the kidneys) and cause tissue calcification.

Hyperparathyroidism

Hyperparathyroidism is caused by overproduction of parathormone by the parathyroid glands and is characterized by bone decalcification and the development of renal calculi (kidney stones) containing calcium.

Primary hyperparathyroidism occurs two to four times more often in women than in men and is most common in people between 60 and 70 years of age. Its incidence is approximately 25 cases per 100,000 people. The disorder is rare in children younger than 15 years, but its incidence increases 10-fold between the ages of 15 and 65 years. Half of the people diagnosed with hyperparathyroidism do not have symptoms (Yalla & Hickey, 2019). Secondary hyperparathyroidism, with manifestations similar to those of

primary hyperparathyroidism, occurs in patients who have chronic kidney failure and the so-called renal rickets as a result of phosphorus retention, increased stimulation of the parathyroid glands, and increased parathormone secretion.

Clinical Manifestations

The patient may have no symptoms or may experience signs and symptoms resulting from involvement of several body systems. Apathy, fatigue, muscle weakness, nausea, vomiting, constipation, hypertension, and cardiac arrhythmias may occur. All of these signs and symptoms are attributable to the increased concentration of calcium in the blood. Psychological effects may vary from irritability and neurosis to psychoses caused by the direct action of calcium on the brain and nervous system. An increase in calcium produces a decrease in the excitation potential of nerve and muscle tissue.

Nephrolithiasis (formation of stones in one or both kidneys), related to the increased urinary excretion of calcium and phosphorus, is one of the major complications of hyperparathyroidism. Although the incidence is on the decline in the United States, nephrolithiasis occurs in 15% to 20% of newly diagnosed patients (Yalla & Hickey, 2019). Kidney damage can result from the precipitation of calcium phosphate in the renal pelvis and parenchyma, which causes renal calculi, obstruction, pyelonephritis, and kidney injury.

Musculoskeletal symptoms accompanying hyperparathyroidism may be caused by demineralization of the bones or by bone tumors composed of benign giant cells resulting from overgrowth of osteoclasts. The patient may develop skeletal pain and tenderness, especially of the back and joints; pain on weight bearing; pathologic fractures; deformities; and shortening of body stature. Bone loss attributable to hyperparathyroidism increases the risk of fracture.

The incidence of peptic ulcer and pancreatitis is increased with hyperparathyroidism and may be responsible for many of the GI symptoms that occur.

Assessment and Diagnostic Findings

Primary hyperparathyroidism is diagnosed by persistent elevation of serum calcium levels and an elevated concentration of parathormone. Radioimmunoassays for parathormone are sensitive and differentiate primary hyperparathyroidism from other causes of hypercalcemia in more than 80% of patients with elevated serum calcium levels (Silverberg & Fuleihan, 2019). An elevated serum calcium level alone is a nonspecific finding, because serum levels may be altered by diet, medications, and kidney and bone changes. Bone changes may be detected on x-ray or bone scans in advanced disease. The

double-antibody parathyroid hormone test is used to distinguish between primary hyperparathyroidism and malignancy as a cause of hypercalcemia. Ultrasound, MRI, thallium scan, and fine-needle biopsy have been used to evaluate the function of the parathyroid glands and to localize parathyroid cysts, adenomas, or hyperplasia.

Medical Management

Surgical Management

The recommended treatment for primary hyperparathyroidism is parathyroidectomy, the surgical removal of abnormal parathyroid tissue (Silverberg & Fuleihan, 2019). In the past, the standard parathyroidectomy involved a bilateral neck exploration under general anesthesia. Today, minimally invasive parathyroidectomy techniques allow for unilateral neck exploration using local anesthesia; these are performed on an outpatient basis. In some cases, only the removal of a single diseased gland is necessary, reducing morbidity rates associated with surgery. For asymptomatic patients who have only mildly elevated serum calcium concentrations and normal kidney function, surgery may be delayed and the patient monitored closely for worsening of hypercalcemia, bone deterioration, renal impairment, or the development of kidney stones.

Surgery is recommended for patients who are asymptomatic and who meet one or more of the following criteria: younger than 50 years; unable or unlikely to participate in follow-up care; serum calcium level more than 1 mg/dL (0.25 mmol/L) above normal reference range; GFR less than 60 mL/min; urinary calcium level greater than 400 mg per day (10 mmol per day); bone density at hip, lumbar spine, or distal radius with T score less than –2.5 or previous fracture at any site; or nephrolithiasis or nephrocalcinosis (Yalla & Hickey, 2019).

Hydration Therapy

Patients with hyperparathyroidism are at risk for renal calculi. Therefore, a daily fluid intake of 2000 mL or more is encouraged to help prevent calculus formation. The patient is instructed to report other manifestations of renal calculi, such as abdominal pain and hematuria. Thiazide diuretics are avoided, because they decrease the renal excretion of calcium and further elevate serum calcium levels. Because of the risk of hypercalcemic crisis (see later discussion), the patient is instructed to avoid dehydration and to seek immediate health care if conditions that commonly produce dehydration (e.g., vomiting, diarrhea) occur.

Mobility

The nurse encourages the patient to be mobile. The patient with limited mobility is encouraged to walk. Bones subjected to the normal stress of walking give up less calcium. Bed rest increases calcium excretion and the risk of renal calculi. Oral phosphates lower the serum calcium level in some patients; long-term use is not recommended because of the risk of ectopic calcium phosphate deposition in soft tissues.

Diet and Medications

Nutritional needs are met, but the patient is advised to avoid a diet with restricted or excess calcium. If the patient has a coexisting peptic ulcer, prescribed antacids and protein feedings are necessary. Because anorexia is common, efforts are made to improve the appetite. Prune juice, stool softeners, and physical activity, along with increased fluid intake, help offset constipation, which is common postoperatively.

Nursing Management

The insidious onset and chronic nature of hyperparathyroidism along with its diverse and commonly vague symptoms may result in depression and frustration. The family may have considered the patient's illness to be psychosomatic. An awareness of the course of the disorder and an understanding approach by the nurse may help the patient and family deal with their reactions and feelings.

The nursing management of the patient undergoing parathyroidectomy is essentially the same as that of a patient undergoing thyroidectomy. However, the previously described precautions about airway patency, dehydration, immobility, and diet are particularly important in the patient who is awaiting or recovering from parathyroidectomy. Although not all parathyroid tissue is removed during surgery in an effort to control the calcium–phosphorus balance, the nurse closely monitors the patient to detect symptoms of tetany (which may be an early postoperative complication). Most patients quickly regain function of the remaining parathyroid tissue and experience only mild, transient postoperative hypocalcemia. In patients with significant bone disease or bone changes, a more prolonged period of hypocalcemia should be anticipated. The nurse educates the patient and family about the importance of follow-up laboratory testing to ensure return of serum calcium levels to normal (see Chart 45-9).

Chart 45-9  **HOME CARE CHECKLIST**

The Patient with Hyperparathyroidism

At the completion of education, the patient and/or caregiver will be able to:

- State the impact of hyperparathyroidism and treatment on physiologic functioning, ADLs, IADLs, roles, relationships, and spirituality.
- Describe potential benefits and risks of parathyroidectomy.
- State the name, dose, side effects, frequency, and schedule for all medications.
- Explain the purpose, dose, route, schedule, side effects, and precautions of pharmacologic treatment (loop diuretics, phosphates, and calcitonin) of hyperparathyroidism.
- State the need to contact primary provider before taking over-the-counter medication containing calcium.
- State changes in lifestyle (e.g., diet, activity) necessary to maintain health, including:
- Recommended intake of dietary calcium.
- Maintenance of regular bowel habits and management of constipation (e.g., prune juice, stool softeners, increased physical activity and fluids).
- Monitoring of fluid intake as indicated, generally 2000 mL daily.
- Managing pain (medication and nonpharmacologic interventions).
- Increasing mobility as indicated.
- Relate how to reach primary provider with questions or complications.
- State time and date of follow-up medical appointments, therapy, and testing.
- Identify sources of support (e.g., friends, relatives, faith community).
- Identify the contact details for support services for patients and their caregivers/families.
- Identify the need for health promotion, disease prevention, and screening activities.

ADLs, activities of daily living; IADLs, instrumental activities of daily living.

Complications: Hypercalcemic Crisis

Acute hypercalcemic crisis can occur with extreme elevation of serum calcium levels. Serum calcium levels greater than 13 mg/dL (3.25 mmol/L) result in neurologic, cardiovascular, and kidney symptoms that can be life-threatening (Fischbach & Fischbach, 2018). Rapid rehydration with large volumes of IV isotonic saline fluids to maintain urine output of 100 to 150 mL per hour is combined with administration of calcitonin (Shane & Berenson, 2019).

Calcitonin promotes renal excretion of excess calcium and reduces bone resorption. The saline infusion should be stopped and a loop diuretic may be needed if the patient develops edema. Dosage and rates of infusion depend on the patient profile. The patient should be monitored carefully for fluid overload. Loop diuretics are not recommended as initial therapy in the absence of heart failure and kidney insufficiency. Bisphosphonates are added to promote a sustained decrease in serum calcium levels by promoting calcium deposition in bone and reducing the GI absorption of calcium. Cytotoxic agents (e.g., mithramycin), calcitonin, and dialysis may be used in emergency situations to decrease serum calcium levels quickly.

Quality and Safety Nursing Alert

The patient in acute hypercalcemic crisis requires close monitoring for life-threatening complications (e.g., airway obstruction) and prompt treatment to reduce serum calcium levels.

A combination of calcitonin and corticosteroids is given in emergencies to reduce the serum calcium level by increasing calcium deposition in bone. Other agents that may be given to decrease serum calcium levels include bisphosphonates (e.g., etidronate, pamidronate) (Shane & Berenson, 2019).

Expert assessment and care are required to minimize complications and reverse the life-threatening hypercalcemia. Medications are given with care, and attention is given to fluid balance to promote return of normal fluid and electrolyte balance. Supportive measures are necessary for the patient and family. See Chapter 12, Table 12-13, for further discussion of hypercalcemic crisis.

Hypoparathyroidism

Hypoparathyroidism is caused by abnormal parathyroid development, destruction of the parathyroid glands (surgical removal or autoimmune response), and vitamin D deficiency. The most common cause is the near-total removal of the thyroid gland. The result is inadequate secretion of parathormone (Goltzman, 2019).

Deficiency of parathormone results in hyperphosphatemia (increased blood phosphate levels) and hypocalcemia (decreased blood calcium levels). In the absence of parathormone, there is decreased intestinal absorption of dietary calcium and decreased resorption of calcium from bone and through the renal tubules. Decreased renal excretion of phosphate causes hypophosphaturia, and low serum calcium levels result in hypocalciuria.

Clinical Manifestations

Hypocalcemia causes irritability of the neuromuscular system and contributes to the chief symptom of hypoparathyroidism—tetany. Tetany is general muscle hypertonia, with tremor and spasmodic or uncoordinated contractions occurring with or without efforts to make voluntary movements. Symptoms of latent tetany are numbness, tingling, and cramps in the extremities, and the patient complains of stiffness in the hands and feet. In overt tetany, the signs include bronchospasm, laryngeal spasm, carpopedal spasm (flexion of the elbows and wrists and extension of the carpophalangeal joints and dorsiflexion of the feet), dysphagia, photophobia, cardiac arrhythmias, and seizures. Other symptoms include anxiety, irritability, depression, and even delirium. ECG changes and hypotension also may occur.

Assessment and Diagnostic Findings

A positive Chvostek sign or a positive Trousseau sign suggests latent tetany. **Chvostek sign** is positive when a sharp tapping over the facial nerve just in front of the parotid gland and anterior to the ear causes spasm or twitching of the mouth, nose, and eye (see Fig. 10-8A). **Trousseau sign** is positive when carpopedal spasm is induced by occluding the blood flow to the arm for 3 minutes with a blood pressure cuff (see Fig. 10-8B). The diagnosis of hypoparathyroidism often is difficult because of the vague symptoms, such as aches and pains. Therefore, laboratory studies are especially helpful. Tetany develops at very low serum calcium levels. Serum phosphate levels are increased, and x-rays of bone show increased density. Calcification is detected on x-rays of the subcutaneous or paraspinal basal ganglia of the brain.

Medical Management

The goal of therapy is to increase the serum calcium level to 9 to 10 mg/dL (2.2 to 2.5 mmol/L) and to eliminate the symptoms of hypoparathyroidism and hypocalcemia. Management is determined by the underlying cause and patient profile. Treatment may include combinations of calcium, magnesium, and ergocalciferol or calcitriol, the latter being preferred. A thiazide diuretic (e.g., hydrochlorothiazide) may be given to help decrease urinary calcium excretion (Goltzman, 2019). Recombinant parathyroid hormone has been approved for the treatment of osteoporosis but not for hypoparathyroidism at this time (Goltzman, 2019).

When hypocalcemia and tetany occur after a thyroidectomy, the immediate treatment is administration of IV calcium gluconate. If this does not decrease neuromuscular irritability and seizure activity immediately, sedative agents such as pentobarbital may be given.

Because of neuromuscular irritability, the patient with hypocalcemia and tetany requires an environment that is free of noise, drafts, bright lights, or sudden movement. If the patient develops respiratory distress, a tracheostomy or mechanical ventilation may become necessary, along with medications that cause bronchodilation in order to provide respiratory support.

Therapy for chronic hypoparathyroidism is determined after serum calcium levels are obtained. A diet high in calcium and low in phosphorus is prescribed. Although milk, milk products, and egg yolk are high in calcium, they are restricted because they also contain high levels of phosphorus. Spinach also is avoided because it contains oxalate, which would form insoluble calcium substances. Oral tablets of calcium salts, such as calcium gluconate, may be used to supplement the diet. Aluminum hydroxide gel or aluminum carbonate also is given after meals to bind phosphate and promote its excretion through the GI tract.

Nursing Management

Nursing management of the patient with possible acute hypoparathyroidism includes the following:

- Care of postoperative patients who have undergone thyroidectomy, parathyroidectomy, or radical neck dissection is directed toward detecting early signs of hypocalcemia and anticipating signs of tetany, seizures, and respiratory difficulties.
- Calcium gluconate should be available for emergency IV administration. If the patient requiring administration of calcium gluconate has a cardiac disorder, is subject to arrhythmias, or is receiving digitalis, the calcium gluconate is given slowly and cautiously.
- Calcium and digitalis increase systolic contraction and also potentiate each other; this can produce potentially fatal arrhythmias. Consequently, the cardiac patient requires continuous cardiac monitoring and careful assessment.

An important aspect of nursing care is patient education about medications and diet therapy. The patient needs to know the reason for high calcium and low phosphate intake and the symptoms of hypocalcemia and hypercalcemia; they should know to contact the primary provider immediately if these symptoms occur (see Chart 45-10).

Chart 45-10  **HOME CARE CHECKLIST**

The Patient with Hypoparathyroidism

At the completion of education, the patient and/or caregiver will be able to:

- State the impact of hypoparathyroidism and treatment on physiologic functioning, ADLs, IADLs, roles, relationships, and spirituality.
- State purpose, dose, route, schedule, side effects, and precautions of prescribed medications (calcium, phosphate binders).
- State changes in lifestyle (e.g., diet, activity) necessary to maintain health, including:
- Ensuring a diet high in calcium and vitamin D, low in phosphorous.
- Alternating activity and rest periods.
- State precipitating factors and interventions for complications (seizure, cardiac arrhythmias, cardiac arrest).
- State necessary actions for seizure activity.
- Relate how to reach primary provider with questions or complications.
- State time and date of follow-up medical appointments, therapy, and testing.
- Identify sources of support (e.g., friends, relatives, faith community).
- Identify the contact details for support services for patients and their caregivers/families.
- Identify the need for health promotion, disease prevention, and screening activities.

ADLs, activities of daily living; IADLs, instrumental activities of daily living.

THE ADRENAL GLANDS

Anatomic and Physiologic Overview

Each person has two adrenal glands, one attached to the upper portion of each kidney. Each adrenal gland is, in reality, two endocrine glands with separate, independent functions. The adrenal medulla at the center of the gland secretes catecholamines, and the outer portion of the gland, the adrenal cortex, secretes steroid hormones (Norris, 2019). The secretion of hormones from the adrenal cortex is regulated by the hypothalamic–pituitary–adrenal axis. The hypothalamus secretes corticotropin-releasing hormone (CRH), which stimulates the pituitary gland to secrete ACTH, which in turn stimulates the adrenal cortex to secrete glucocorticoid hormone (cortisol). Increased levels of the adrenal hormone then inhibit the production or secretion of CRH and ACTH. This system is an example of a negative feedback mechanism.

Adrenal Medulla

The adrenal medulla functions as part of the autonomic nervous system. Stimulation of preganglionic sympathetic nerve fibers, which travel directly to the cells of the adrenal medulla, causes release of the catecholamine hormones epinephrine and norepinephrine. About 90% of the secretion of the human adrenal medulla is epinephrine (also called *adrenaline*). Catecholamines regulate metabolic pathways to promote catabolism of stored fuels to meet caloric needs from endogenous sources. The major effects of epinephrine release are to prepare to meet a challenge (fight-or-flight response). Secretion of epinephrine causes decreased blood flow to tissues that are not needed in emergency situations, such as the GI tract, and increased blood flow to tissues that are important for effective fight or flight, such as cardiac and skeletal muscle. Catecholamines also induce the release of free fatty acids, increase the basal metabolic rate, and elevate the blood glucose level.

Adrenal Cortex

A functioning adrenal cortex is necessary for life; adrenocortical secretions make it possible for the body to adapt to stress of all kinds. The three types of steroid hormones produced by the adrenal cortex are glucocorticoids, mainly cortisol; mineralocorticoids, mainly aldosterone; and sex hormones, mainly androgens (Norris, 2019). Without the adrenal cortex, severe stress would cause peripheral circulatory failure, circulatory shock, and prostration. Survival in the absence of a functioning adrenal cortex is possible only with nutritional, electrolyte, and fluid replacement and appropriate replacement with exogenous adrenocortical hormones.

Glucocorticoids

The **glucocorticoids** are so named because they have an important influence on glucose metabolism: Increased cortisol secretion results in elevated blood glucose levels. However, the glucocorticoids have major effects on the metabolism of almost all organs of the body. Glucocorticoids are secreted from the adrenal cortex in response to the release of ACTH from the anterior lobe of the pituitary gland. This system represents an example of negative feedback. The presence of glucocorticoids in the blood inhibits the release of CRH from the hypothalamus and also inhibits ACTH secretion from the pituitary. The resultant decrease in ACTH secretion causes diminished release of glucocorticoids from the adrenal cortex.

Corticosteroids are the classification of drugs that include glucocorticoids. These drugs are given to inhibit the inflammatory response to tissue injury and to suppress allergic manifestations. Their side effects include the development of diabetes, osteoporosis, and peptic ulcer; increased protein breakdown

resulting in muscle wasting and poor wound healing; and redistribution of body fat. When large doses of exogenous glucocorticoids are given, the release of ACTH and endogenous glucocorticoids are inhibited. This can cause the adrenal cortex to atrophy. If exogenous glucocorticoid administration is discontinued suddenly, adrenal insufficiency results because of the inability of the atrophied cortex to respond adequately.

Mineralocorticoids

Mineralocorticoids exert their major effects on electrolyte metabolism. They act principally on the renal tubular and GI epithelium to cause increased sodium ion absorption in exchange for excretion of potassium or hydrogen ions. ACTH only minimally influences aldosterone secretion. It is primarily secreted in response to the presence of angiotensin II in the bloodstream. Angiotensin II is a substance that elevates the blood pressure by constricting arterioles. Its concentration is increased when renin is released from the kidney in response to decreased perfusion pressure. The resultant increased aldosterone levels promote sodium reabsorption by the kidney and the GI tract, which tends to restore blood pressure to normal. The release of aldosterone is also increased by hyperkalemia. Aldosterone is the main hormone for the long-term regulation of sodium balance.

Adrenal Sex Hormones (Androgens)

Androgens, the third major type of steroid hormones produced by the adrenal cortex, exert effects similar to those of male sex hormones. The adrenal gland may also secrete small amounts of some estrogens, or female sex hormones. ACTH controls the secretion of adrenal androgens. When secreted in normal amounts, the adrenal androgens have little effect, but when secreted in excess, they produce masculinization in women, feminization in men, or premature sexual development in children. This is called the adrenogenital syndrome.

Pheochromocytoma

Pheochromocytoma is a rare tumor that is usually benign and originates from the chromaffin cells of the adrenal medulla. This tumor is the cause of high blood pressure in 0.1% of patients with hypertension and is usually fatal if undetected and untreated; however, it is usually cured by surgery. In 90% of patients the tumor arises in the medulla; in the remaining patients, it occurs in the extra-adrenal chromaffin tissue located in or near the aorta, ovaries, spleen, or other organs. Pheochromocytoma may occur at any age, but its peak incidence is between 40 and 50 years of age and affects men and women equally (U.S. National Library of Medicine, 2019). Ten percent of the tumors are bilateral, and 10% are malignant. Because of the high incidence of

pheochromocytoma in family members of affected people, the patient's family members should be alerted and screened for this tumor. Pheochromocytoma may occur in the familial form as part of multiple endocrine neoplasia type 2; therefore, it should be considered a possibility in patients who have medullary thyroid carcinoma and parathyroid hyperplasia or tumor.

Clinical Manifestations

The nature and severity of symptoms of functioning tumors of the adrenal medulla depend on the relative proportions of epinephrine and norepinephrine secretion. The typical triad of symptoms is headache, diaphoresis, and palpitations in the patient with hypertension. Hypertension and other cardiovascular disturbances are common. The hypertension may be intermittent or persistent. If the hypertension is sustained, it may be difficult to distinguish from other causes of hypertension. Other symptoms may include tremor, headache, flushing, and anxiety. Hyperglycemia may result from conversion of liver and muscle glycogen to glucose due to epinephrine secretion; insulin may be required to maintain normal blood glucose levels.

The clinical picture in the paroxysmal form of pheochromocytoma is usually characterized by acute, unpredictable attacks lasting seconds or several hours. Symptoms usually begin abruptly and subside slowly. During these attacks, the patient is extremely anxious, tremulous, and weak. The patient may experience headache, vertigo, blurring of vision, tinnitus, air hunger, and dyspnea. Other symptoms include polyuria, nausea, vomiting, diarrhea, abdominal pain, and a feeling of impending doom. Palpitations and tachycardia are common (Singh & Herrick, 2019). Blood pressures exceeding 250/150 mm Hg have been recorded. Such blood pressure elevations are life-threatening and can cause severe complications, such as cardiac arrhythmias, dissecting aneurysm, stroke, and acute kidney failure. Orthostatic hypotension (decrease in systolic blood pressure, lightheadedness, dizziness on standing) occurs in 70% of patients with untreated pheochromocytoma.

Assessment and Diagnostic Findings

Pheochromocytoma is suspected if signs of sympathetic nervous system overactivity occur in association with marked elevation of blood pressure. These signs can be associated with the "five Hs": ***h***ypertension, ***h***eadache, ***h***yperhidrosis (excessive sweating), ***h***ypermetabolism, and ***h***yperglycemia. The presence of these signs is highly predictive of pheochromocytoma. Paroxysmal symptoms of pheochromocytoma commonly develop in the fifth decade of life.

Measurements of urine and plasma levels of catecholamines and metanephrine (MN), a catecholamine metabolite, are the most direct and

conclusive tests for overactivity of the adrenal medulla. A test for detecting pheochromocytoma measures free MN in plasma by high-pressure liquid chromatography and electrochemical detection. A negative test result virtually excludes pheochromocytoma. Measurements of catecholamine metabolites (MN and vanillylmandelic acid [VMA]) or free catecholamines have been extensively used in the clinical setting. In most cases, pheochromocytoma can be diagnosed or confirmed based on a properly collected 24-hour urine sample. Levels can be as high as two times the normal limit. A 24-hour urine specimen is collected to detect free catecholamines, MN, and VMA; the use of combined tests increases the diagnostic accuracy of testing. A number of medications and foods, such as coffee and tea (including decaffeinated varieties), bananas, chocolate, vanilla, and aspirin, may alter the results of these tests; therefore, careful instructions to avoid restricted items must be given to the patient. Urine collected over a 2- or 3-hour period after an attack of hypertension can be assayed for catecholamine content (Singh & Herrick, 2019).

The total plasma catecholamine (epinephrine and norepinephrine) concentration is measured with the patient supine and at rest for 30 minutes. To prevent elevation of catecholamine levels resulting from the stress of venipuncture, a butterfly needle, scalp vein needle, or venous catheter may be inserted 30 minutes before the blood specimen is obtained.

Factors that may elevate catecholamine concentrations must be controlled to obtain valid results; these factors include consumption of coffee or tea (including decaffeinated varieties), the use of tobacco, emotional and physical stress, and the use of many prescription and over-the-counter medications (e.g., amphetamines, nose drops or sprays, decongestant agents, bronchodilators).

Normal plasma values of epinephrine are 100 pg/mL (590 pmol/L); normal values of norepinephrine are generally less than 100 to 550 pg/mL (590 to 3240 pmol/L). Values of epinephrine greater than 400 pg/mL (2180 pmol/L) or norepinephrine values greater than 2000 pg/mL (11,800 pmol/L) are considered diagnostic of pheochromocytoma. Values that fall between normal levels and those diagnostic of pheochromocytoma indicate the need for further testing.

A clonidine suppression test may be performed if the results of plasma and urine tests of catecholamines are inconclusive. Clonidine is a centrally acting antiadrenergic medication that suppresses the release of neurogenically mediated catecholamines. The suppression test is based on the principle that catecholamine levels are normally increased through the activity of the sympathetic nervous system. In pheochromocytoma, increased catecholamine levels result from the diffusion of excess catecholamines into the circulation, bypassing normal storage and release mechanisms. Therefore, in patients with pheochromocytoma, clonidine does not suppress the release of catecholamines (Singh & Herrick, 2019).

Imaging studies, such as CT, MRI, and ultrasonography, may also be carried out to localize the pheochromocytoma and to determine whether more than one tumor is present. The use of ^{131}I-metaiodobenzylguanidine (MIBG) scintigraphy may be required to determine the location of the pheochromocytoma and to detect metastatic sites outside the adrenal gland. MIBG is a specific isotope for catecholamine-producing tissue. It has been helpful in identifying tumors not detected by other tests or procedures. MIBG scintigraphy is a noninvasive, safe procedure that has increased the accuracy of diagnosis of adrenal tumors (Fischbach & Fischbach, 2018).

Other diagnostic studies may focus on evaluating the function of other endocrine glands because of the association of pheochromocytoma in some patients with other endocrine tumors.

Medical Management

During an episode or attack of hypertension, tachycardia, anxiety, and the other symptoms of pheochromocytoma, bed rest with the head of the bed elevated is prescribed to promote an orthostatic decrease in blood pressure.

Pharmacologic Therapy

The patient may be treated preoperatively on an inpatient or outpatient basis. Regardless of the setting, monitoring of blood pressure and cardiac function is essential. The goals are to control hypertension before and during surgery and volume expansion, and to prevent a catecholamine storm as a result of surgery (Singh & Herrick, 2019).

Preoperatively, the patient may begin treatment with a low dose of an alpha-adrenergic blocker, either phenoxybenzamine or doxazosin, 10 to 14 days or longer prior to surgery (Singh & Herrick, 2019). The patient should be informed about the potential for adverse effects of these medications, which include orthostasis, nasal stuffiness, increased fatigue, and retrograde ejaculation in men. The medication dosages are started at a low dose and increased every 2 to 3 days as needed to control blood pressure. Patients may be required to consume a high-sodium diet or take salt supplements.

After administration of the alpha-blockers, the blood pressure should be monitored closely. In an outpatient setting, the blood pressure should be taken twice daily in a sitting and standing position. The targets are less than 130/80 mm Hg (seated) with a standing systolic pressure greater than 90 mm Hg and target heart rate of 60 to 70 beats per minute sitting and 70 to 80 beats per minute standing (Singh & Herrick, 2019). Age and comorbid disease should be taken into consideration when establishing and evaluating targets. Propranolol and metoprolol may be administered with caution to achieve the target heart rate (Singh & Herrick, 2019).

Calcium channel blockers such as nifedipine are sometimes used as an alternative or supplement to preoperative alpha- and beta-blockers, when blood pressure control is inadequate or the patient is unable to tolerate the side effects. Nifedipine and nicardipine may be used safely without causing undue hypotension. For episodes of severe hypertension, nifedipine is a fast and effective treatment, because the capsules can be pierced and chewed. The patient needs to be well hydrated before, during, and after surgery to prevent hypotension. Additional medications that may be used preoperatively include catecholamine synthesis inhibitors, such as alpha-methyl-*p*-tyrosine (metyrosine). These are occasionally used if adrenergic blocking agents (i.e., alpha- and beta-blockers) are not effective. Long-term use of metyrosine may result in many adverse effects, including sedation, depression, diarrhea, anxiety, nightmares, dysuria, impotence, elevated aspartate aminotransferase, anemia, thrombocytopenia, crystalluria, galactorrhea (breast discharge), and extrapyramidal signs (e.g., drooling, speech impairment, tremors).

Surgical Management

The definitive treatment of pheochromocytoma is surgical removal of the tumor, usually with **adrenalectomy** (removal of one or both adrenal glands); surgical treatment is considered high risk in this patient population. Surgery may be performed using a laparoscopic approach or an open operation. The laparoscopic approach is the preferred method for patients with pheochromocytomas including large tumors because of the decreased blood loss, decreased hospitalization time, and decreased morbidity. Bilateral adrenalectomy may be necessary if tumors are present in both adrenal glands. Patient preparation includes control of blood pressure and blood volumes; usually, this is carried out over 10 to 14 days, as described previously. A calcium channel blocker (nicardipine) can be given intraoperatively exclusively or in combination with the alpha- and beta-blockers to control blood pressure.

A hypertensive crisis, however, can still arise as a result of manipulation of the tumor during surgical excision, causing a release of stored epinephrine and norepinephrine, with marked increases in blood pressure and changes in heart rate. Exploration of other possible tumor sites is frequently undertaken to ensure removal of all tumor tissue. As a result, the patient is subject to the stress and effects of a long surgical procedure, which may increase the risk of hypertension postoperatively.

Corticosteroid replacement is required if bilateral adrenalectomy has been necessary. Corticosteroids may also be required for the first few days or weeks after removal of a single adrenal gland. IV administration of corticosteroids (methylprednisolone) may begin on the evening before surgery and continue during the early postoperative period to prevent adrenal insufficiency. Oral

preparations of corticosteroids (prednisone) are prescribed after the acute stress of surgery diminishes.

Hypotension and hypoglycemia may occur in the postoperative period because of the sudden withdrawal of excessive amounts of catecholamines. Therefore, careful attention is directed toward monitoring and treating these changes. Hypertension may continue if not all pheochromocytoma tissue was removed, if pheochromocytoma recurs, or if the blood vessels were damaged by severe and prolonged hypertension. Several days after surgery, urine and plasma levels of catecholamines and their metabolites are measured to determine whether the surgery was successful.

Nursing Management

The patient who has undergone surgery to treat pheochromocytoma has experienced a stressful preoperative and postoperative course and may remain fearful of repeated attacks. Although it is usually expected that all pheochromocytoma tissue has been removed, there is a possibility that other sites were undetected and that attacks may recur. The patient is monitored until stable with special attention given to ECG changes, arterial pressures, fluid and electrolyte balance, and blood glucose levels. IV access will be required for administration of fluids and medications.

Promoting Home, Community-Based, and Transitional Care

Educating Patients About Self-Care

During the pre- and postoperative phases of care, the nurse educates the patient about the importance of follow-up monitoring to ensure that pheochromocytoma does not recur undetected. After adrenalectomy, the use of corticosteroids may be needed. Therefore, the nurse educates the patient about their purpose, the medication schedule, and the risks of skipping doses or stopping their administration abruptly.

The patient and family are educated about how to measure the patient's blood pressure and when to notify the primary provider about changes in blood pressure. In addition, the nurse provides verbal and written instructions about the procedure for collecting 24-hour urine specimens to monitor urine catecholamine levels.

Continuing and Transitional Care

A follow-up visit from a home, community-based or transitional care nurse may be indicated to assess the patient's postoperative recovery, surgical incision, knowledge regarding medication, and adherence to the medication

schedule. This may help reinforce previous education about management and monitoring. The nurse also obtains blood pressure measurements and assists the patient in preventing or dealing with problems that may result from long-term use of corticosteroids.

Because of the risk of recurrence of hypertension, periodic checkups are required, especially in young patients and in those whose families have a history of pheochromocytoma. The patient is scheduled for periodic follow-up appointments to observe for return of normal blood pressure and plasma and urine levels of catecholamines.

Adrenocortical Insufficiency (Addison's Disease)

Primary adrenal insufficiency, also called **Addison's disease**, is the result of dysfunction of the hypothalamus–pituitary gland–adrenal gland feedback loop which results in insufficient production of steroids by the adrenal glands (Norris, 2019). Addison's disease is considered rare. In 70% to 90% of cases, the cause is an autoimmune disorder but tuberculosis and histoplasmosis are also associated with destruction of adrenal tissue; therefore, both should be considered in the diagnostic workup. Other causes include surgical removal of both adrenal glands; medications such as rifampin, barbiturates, ketoconazole, and tyrosine kinase inhibitors; and metastatic cancers such as lung, breast, colon, and melanoma (Zhang & Carmichael, 2019). Secondary adrenal insufficiency may result from the sudden cessation of exogenous adrenocortical hormonal therapy, which suppresses the body's normal response to stress and interferes with normal feedback mechanisms. Treatment with daily administration of corticosteroids for 2 to 4 weeks may suppress function of the adrenal cortex; therefore, adrenal insufficiency should be considered in any patient who has been treated with corticosteroids (Zhang & Carmichael, 2019).

Clinical Manifestations

The loss of mineralocorticoids leads to increased excretion of sodium, chloride, and water with increased retention of potassium. This may lead to a deficiency in extracellular fluid causing decreased cardiac output. The loss of glucocorticoids results in hypoglycemia with complaints of muscle weakness, lethargy, and GI symptoms including anorexia, weight loss, nausea and vomiting. In addition, the increase in levels of ACTH results in hyperpigmentation of the skin and mucous membranes, especially of the knuckles, knees, and skin folds (Norris, 2019).

Patients with Addison's disease are at risk to develop an **Addisonian crisis**, a life-threatening complication in which severe hypotension, cyanosis, fever,

nausea, vomiting, and signs of shock develop. In addition, the patient may have pallor; complain of headache, abdominal pain, and diarrhea; and may show signs of confusion and restlessness. Even slight overexertion, exposure to cold, acute infection, or a decrease in salt intake may lead to circulatory collapse, shock, and death, if untreated. The stress of surgery or dehydration resulting from preparation for diagnostic tests or surgery may precipitate an Addisonian or hypotensive crisis because of the inhibited feedback loop.

Assessment and Diagnostic Findings

Although the clinical manifestations presented appear specific, the onset of Addison's disease usually occurs with nonspecific symptoms. The diagnosis is confirmed by laboratory test results. Combined measurements of early-morning serum cortisol and plasma ACTH are performed to differentiate primary adrenal insufficiency from secondary adrenal insufficiency and from normal adrenal function. Patients with primary insufficiency have a greatly increased plasma ACTH level and a serum cortisol concentration lower than the normal range or in the low-normal range (Zhang & Carmichael, 2019). Other laboratory findings include hypoglycemia (decreased levels of blood glucose), hyponatremia (decreased levels of sodium), hyperkalemia (increased serum potassium concentration), and leukocytosis (increased white blood cell count).

Medical Management

Immediate treatment is directed toward combating circulatory shock: restoring blood circulation, administering fluids and corticosteroids, monitoring vital signs, and placing the patient in a recumbent position with the legs elevated. Hydrocortisone is administered by IV, followed by 3 to 4 L of normal saline or 5% dextrose solution. Vasopressors may be required if hypotension persists.

Antibiotics may be given if infection has precipitated adrenal crisis in a patient with chronic adrenal insufficiency. In addition, the patient is assessed closely to identify other factors, stressors, or illnesses that led to the acute episode.

Oral intake may be initiated as soon as tolerated. IV fluids are gradually decreased after oral fluid intake is adequate to prevent hypovolemia. If the adrenal gland does not regain function, the patient needs lifelong replacement of corticosteroids and mineralocorticoids to prevent recurrence of adrenal insufficiency. Patients who are undergoing stressful procedures, surgery, significant illnesses, or are in the third trimester of pregnancy require additional supplementary therapy with corticosteroid medications to prevent Addisonian crisis. In addition, dietary intake may need to be supplemented

with additional salt to manage GI losses of fluids through vomiting and diarrhea (Zhang & Carmichael, 2019).

Nursing Management

Assessing the Patient

The health history and examination focus on the presence of symptoms of fluid imbalance and the patient's level of stress. The nurse should monitor the blood pressure and pulse rate as the patient moves from a lying, sitting, and standing position to assess for inadequate fluid volume. A decrease in systolic pressure (20 mm Hg or more) may indicate depletion of fluid volume, especially if accompanied by symptoms. The skin should be assessed for changes in color and turgor, which could indicate chronic adrenal insufficiency and hypovolemia. The patient is assessed for change in weight, muscle weakness, fatigue, and any illness or stress that may have precipitated the acute crisis.

Monitoring and Managing Addisonian Crisis

The patient at risk is monitored for signs and symptoms indicative of Addisonian crisis, which can include shock; hypotension; rapid, weak pulse; rapid respiratory rate; pallor; and extreme weakness (see Chapter 11). Physical and psychological stressors such as cold exposure, overexertion, infection, and emotional distress should be avoided.

The patient with Addisonian crisis requires immediate treatment with IV administration of fluid, glucose, and electrolytes, especially sodium; replacement of missing steroid hormones; and vasopressors. The nurse anticipates and meets the patient's needs to promote return to a precrisis state.

Restoring Fluid Balance

The nurse encourages the patient to consume foods and fluids that assist in restoring and maintaining fluid and electrolyte balance which in turn maintains adequate cardiac output. Along with the dietitian, the nurse helps the patient select foods high in sodium during GI disturbances and in very hot weather.

The nurse educates the patient and family to administer hormone replacement as prescribed and to modify the dosage during illness and other stressful situations. Written and verbal instructions are provided about the administration of exogenous glucocorticoids (i.e., corticosteroid medications such as hydrocortisone, cortisone, and prednisone) and mineralocorticoids (fludrocortisone) as prescribed. The patient should be instructed to take prescribed corticosteroids with antacids or meals. The patient should be informed that the steroid therapy usually corrects the mood swings and mental status changes which adrenal insufficiency frequently causes (Quintanar, 2019).

Improving Activity Tolerance

Until the patient's condition is stabilized, the nurse takes precautions to avoid unnecessary activity and stress that could precipitate another hypotensive episode. Efforts are made to detect signs of infection or the presence of other stressors. Explaining the rationale for minimizing stress during the acute crisis assists the patient to increase activity gradually.

Promoting Home, Community-Based, and Transitional Care

Educating Patients About Self-Care

Because of the need for lifelong replacement of adrenal cortex hormones to prevent Addisonian crises, the patient and family members receive explicit education about the rationale for replacement therapy and proper dosage. In addition, the patient, family, and caregivers are educated about the signs of excessive or insufficient hormone replacement. Stress can precipitate an Addisonian crisis, and in times of stress the usual dose may need to be adjusted. The patient should have an emergency kit available with syringe and either hydrocortisone or dexamethasone as prescribed by the primary provider (Zhang & Carmichael, 2019). Specific verbal and written instructions about how and when to use the injection are also provided to the patient and family or caregivers. Chart 45-11 summarizes education for patients with Addison's disease and their caregivers.

Continuing and Transitional Care

Although most patients can return to their job and family responsibilities soon after hospital discharge, others cannot do so because of concurrent illnesses or incomplete recovery from the episode of adrenal insufficiency. In these circumstances, a referral for home, community-based or transitional care enables the nurse to assess the patient's recovery, monitor hormone replacement, and evaluate stress in the home. The nurse assesses the patient's and family's knowledge about medication therapy and dietary modifications and provides education as needed. The home health nurse educates the patient and family on the importance of keeping follow-up visits with the primary provider and participating in health promotion activities and health screening.

Chart 45-11  **HOME CARE CHECKLIST**

The Patient with Adrenal Insufficiency (Addison's Disease)

At the completion of education, the patient and/or caregiver will be able to:

- State the impact of adrenal insufficiency and treatment on physiologic functioning, ADLs, IADLs, roles, relationships, and spirituality.
- State the purpose, dose, route, schedule, side effects, and precautions of prescribed medications (corticosteroid replacement).
- State that compliance with medical regimen is lifelong.
- Recognize the need for dosage adjustment during times of stress.
- State changes in lifestyle (e.g., diet, activity) necessary to maintain health, including:
- Wearing medical alert identification, and carrying medical information card.
- Avoiding strenuous activity in hot, humid weather.
- Identifying strategies for dealing with stress and avoiding adrenal crisis.
- Notifying primary providers about disease before treatment or procedure.
- Increasing fluid intake and salt with excessive perspiration.
- Ensuring high-carbohydrate, high-protein diet with adequate sodium intake.
- State warning signs of adrenal crisis and the need for emergency care.
- Explain components of an emergency kit and indications for their use; demonstrate how to use them.
- Relate how to reach primary provider with questions or complications.
- State time and date of follow-up medical appointments, therapy, and testing.
- Identify sources of support (e.g., friends, relatives, faith community).
- Identify the contact details for support services for patients and their caregivers/families.
- Identify the need for health promotion, disease prevention, and screening activities.

ADLs, activities of daily living; IADLs, instrumental activities of daily living.

Cushing's Syndrome

The most common cause of Cushing's syndrome (also known as Cushing's disease) is the use of corticosteroid medications, but the syndrome can also be due to excessive glucocorticoid production secondary to hyperplasia of the

adrenal cortex (Sadiq & Silverstein, 2019a). However, overproduction of endogenous glucocorticoids may be caused by several mechanisms, including a tumor of the pituitary gland that produces ACTH and stimulates the adrenal cortex to increase its hormone secretion despite production of adequate amounts. Primary hyperplasia of the adrenal glands in the absence of a pituitary tumor is less common. Another less common cause of Cushing's syndrome is the ectopic production of ACTH by malignancies; bronchogenic carcinoma is the most common type. Regardless of the cause, the normal feedback mechanisms that control the function of the adrenal cortex become ineffective, and the usual diurnal pattern of cortisol is lost. The signs and symptoms of Cushing's syndrome are primarily a result of oversecretion of glucocorticoids and androgens, although mineralocorticoid secretion may be affected as well (Norris, 2019).

Clinical Manifestations

When overproduction of the adrenocortical hormone occurs, arrest of growth, obesity, and musculoskeletal changes occur along with glucose intolerance. The classic picture of Cushing's syndrome in the adult is that of central-type obesity, with a fatty "buffalo hump" in the neck and supraclavicular areas, a heavy trunk, and relatively thin extremities. The skin is thin, fragile, and easily traumatized; ecchymoses (bruises) and striae develop. The patient complains of weakness and lassitude. Sleep is disturbed because of altered diurnal secretion of cortisol.

Excessive protein catabolism occurs, producing muscle wasting and osteoporosis. Kyphosis, backache, and compression fractures of the vertebrae may result. Retention of sodium and water occurs as a result of increased mineralocorticoid activity, producing hypertension and heart failure.

The patient develops a "moon-faced" appearance and may experience increased oiliness of the skin and acne. Hyperglycemia or overt diabetes may develop. The patient may also report weight gain, slow healing of minor cuts, and bruises.

Women between the ages of 20 and 40 years are five times more likely than men to develop Cushing's syndrome. In females of all ages, virilization may occur as a result of excess androgens. Virilization is characterized by the appearance of masculine traits and the recession of feminine traits. Hirsutism (excessive growth of hair on the face) occurs, the breasts atrophy, menses cease, the clitoris enlarges, and the voice deepens. Libido is lost in men and women. Distress and depression are common and are increased by the severity of the physical changes that occur with this syndrome. If Cushing's disease is a consequence of pituitary tumor, visual disturbances may occur because of pressure of the growing tumor on the optic chiasm. Chart 45-12 summarizes the clinical manifestations of Cushing's syndrome.

This woman with Cushing syndrome has several classic signs, including facial hair, buffalo hump, and moon face. Reprinted with permission from Rubin, R., Strayer, D. S., & Rubin, E. (2012). *Rubin's pathology* (6th ed.). Philadelphia, PA: Lippincott Williams & Wilkins.

Assessment and Diagnostic Findings

The three tests used to diagnose Cushing's syndrome are serum cortisol, urinary cortisol, and low-dose dexamethasone suppression tests. Two of these three tests need to be unequivocally abnormal to diagnose Cushing's syndrome. If the results of all three tests are normal, the patient likely does not have Cushing's syndrome (but may have a mild case, or the manifestations may be cyclic). For these patients, further testing is not recommended unless symptoms progress. If test results are either slightly abnormal or discordant, further testing is recommended.

Serum cortisol levels are usually higher in the early morning (6 to 8 am) and lower in the evening (4 to 6 pm). This variation is lost in patients with Cushing's syndrome (Fischbach & Fischbach, 2018).

A urinary cortisol test requires a 24-hour urine collection. The nurse instructs the patient how to collect and store the specimen. If the results of the urinary cortisol test are three times the upper limit of the normal range and one other test is abnormal, Cushing's syndrome can be assumed.

An overnight dexamethasone suppression test is used to diagnosis pituitary and adrenal causes of Cushing's syndrome. It can be performed on an outpatient basis. Dexamethasone (1 or 8 mg) is given orally late in the evening or at bedtime, and a plasma cortisol level is obtained at 8 am the next morning. Suppression of cortisol to less than 5 mg/dL indicates that the hypothalamic–pituitary–adrenal axis is functioning properly (Fischbach & Fischbach, 2018). Stress, obesity, depression, and medications such as anticonvulsant agents, estrogen (during pregnancy or as oral medications), and rifampin can falsely elevate cortisol levels.

Indicators of Cushing's syndrome include an increase in serum sodium and blood glucose levels and a decrease in serum potassium, a reduction in the number of blood eosinophils, and disappearance of lymphoid tissue. Measurements of plasma and urinary cortisol levels are obtained. Several blood samples may be collected to determine whether the normal diurnal variation in plasma levels is present; this variation is frequently absent in adrenal dysfunction. If several blood samples are required, they must be collected at the times specified, and the time of collection must be noted on the requisition slip.

Medical Management

If Cushing's syndrome is caused by pituitary tumors rather than tumors of the adrenal cortex, treatment is directed at the pituitary gland. Surgical removal of the tumor by transsphenoidal hypophysectomy (see Chapter 61) is the treatment of choice. Radiation of the pituitary gland has also been successful, although it may take several months for control of symptoms. Adrenalectomy is the treatment of choice in patients with unilateral primary adrenal hypertrophy. Medical management is recommended for bilateral adrenal dysplasia.

Postoperatively, symptoms of adrenal insufficiency may begin to appear 12 to 48 hours after surgery because of reduction of the high levels of circulating adrenal hormones. Temporary replacement therapy with hydrocortisone may be necessary for several months, until the adrenal glands begin to respond normally to the body's needs.

Adrenal enzyme inhibitors (e.g., metyrapone, aminoglutethimide, mitotane, and ketoconazole) may be used to reduce hyperadrenalism if the syndrome is caused by ectopic ACTH secretion by a tumor that cannot be eradicated. Close monitoring is necessary, because symptoms of inadequate adrenal function may result, and side effects of the medications may occur.

If Cushing's syndrome is a result of the administration of corticosteroids, an attempt is made to reduce or taper the medication to the minimum dosage needed to treat the underlying disease process (e.g., autoimmune or allergic disease, rejection of a transplanted organ). Frequently, alternate-day therapy decreases the symptoms of Cushing's syndrome and allows recovery of the adrenal glands' responsiveness to ACTH.

Diabetes and peptic ulcer are common in patients with Cushing's syndrome. Therefore, insulin therapy and medication to prevent or treat peptic ulcer are initiated if needed. Before, during, and after surgery, blood glucose monitoring and assessment of stools for blood are carried out to monitor for these complications. If the patient has other symptoms of Cushing's syndrome, these are considered in the preoperative preparation. For example, if the patient has experienced weight gain, special instruction is given about postoperative breathing exercises.

NURSING PROCESS

The Patient with Cushing's Syndrome

Assessment

The health history and examination focus on the effects on the body of high concentrations of adrenal cortex hormones and on the inability of the adrenal cortex to respond to changes in cortisol and aldosterone levels. The history includes information about the patient's level of activity and ability to carry out routine and self-care activities. The skin is observed and assessed for trauma, infection, breakdown, bruising, and edema. Changes in physical appearance are noted, and the patient's responses to these changes are elicited. The nurse assesses the patient's mental function, including mood, responses to questions, awareness of environment, and level of depression. The family is often a good source of information about gradual changes in the patient's physical appearance as well as emotional status.

Diagnosis

NURSING DIAGNOSES

Based on the assessment data, major priority nursing diagnoses include the following:

- Risk for impaired cardiac function associated with changes in cardiac function
- Risk for injury associated with weakness
- Risk for infection associated with altered immune system function
- Impaired skin integrity associated with edema, impaired healing, and thin and fragile skin
- Disturbed body image associated with altered physical appearance, impaired sexual functioning, and decreased activity level
- Difficulty coping associated with mood swings, irritability, and depression

COLLABORATIVE PROBLEMS/POTENTIAL COMPLICATIONS

Potential complications may include the following:

- Addisonian crisis
- Adverse effects of adrenocortical activity

Planning and Goals

The major goals for the patient include maintenance of adequate cardiac function, decreased risk of injury, decreased risk of infection, improved skin integrity, improved body image, improved mental function, and absence of complications.

Nursing Interventions

MAINTAINING ADEQUATE CARDIAC FUNCTION

The patient who is taking corticosteroid medications should be monitored for the presence of hypertension and hypokalemia. The nurse assesses fluid and electrolyte status by monitoring laboratory values and daily weights. The patient should be educated about foods low in sodium to decrease fluid retention and foods high in potassium; referral to a dietitian may be useful. The patient should also be instructed to report and pedal edema or changes in activity tolerance.

DECREASING RISK OF INJURY

Establishing a protective environment helps prevent falls, fractures, and other injuries to bones and soft tissues. The patient who is very weak may require assistance from the nurse in ambulating to avoid falling or bumping into sharp corners of furniture. Foods high in protein, calcium, and vitamin D are recommended to minimize muscle wasting and osteoporosis. Referral to a dietitian may assist the patient in selecting appropriate foods that are also low in sodium and calories.

DECREASING RISK OF INFECTION

The patient should avoid unnecessary exposure to others with infections. The nurse frequently assesses the patient for subtle signs of infection, because the anti-inflammatory effects of corticosteroids may mask the common signs of inflammation and infection.

PROMOTING SKIN INTEGRITY

Meticulous skin care is necessary to avoid traumatizing the patient's fragile skin. The use of adhesive tape is avoided, because it can irritate the skin and tear the fragile tissue when the tape is removed. The nurse frequently assesses the skin and bony prominences and encourages and assists the patient to change positions frequently to prevent skin breakdown.

IMPROVING BODY IMAGE

The patient may benefit from discussion of the effect the changes have had on their self-concept and relationships with others. Weight gain and edema may be modified by a low-carbohydrate, low-sodium diet, and a high-protein intake may reduce some of the other bothersome symptoms. The patient may also benefit from discussion of the changes being temporary if the treatment with corticosteroids is temporary.

IMPROVING COPING

Explanations to the patient and family members about the cause of emotional instability are important in helping them cope with the mood swings, irritability, and depression that may occur. Psychotic behavior may occur in a few patients and should be reported. The nurse encourages the patient and family members to verbalize their feelings and concerns.

MONITORING AND MANAGING POTENTIAL COMPLICATIONS

Addisonian Crisis. The patient with Cushing's syndrome whose symptoms are treated by withdrawal of corticosteroids, by adrenalectomy, or by removal of a pituitary tumor is at risk for adrenal hypofunction and Addisonian crisis. If high levels of circulating adrenal hormones have suppressed the function of the adrenal cortex, atrophy of the adrenal cortex is likely. If the circulating hormone level is decreased rapidly because of surgery or abrupt cessation of corticosteroid agents, manifestations of adrenal hypofunction and Addisonian crisis may develop. Therefore, the patient with Cushing's syndrome should be assessed for signs and symptoms of Addisonian crisis as discussed previously. If Addisonian crisis occurs, the patient is treated for circulatory collapse and shock (see Chapter 11).

Adverse Effects of Adrenocortical Activity. The nurse assesses fluid and electrolyte status by monitoring laboratory values and daily weights. Because of the increased risk of glucose intolerance and hyperglycemia, blood glucose monitoring is initiated. The nurse reports elevated blood glucose levels to the primary provider so that treatment can be prescribed if needed. If indicated, the patient may need to be educated in self-monitoring of blood glucose and insulin injections.

PROMOTING HOME, COMMUNITY-BASED, AND TRANSITIONAL CARE

Educating Patients About Self-Care. The patient, family, and caregivers should be educated that acute adrenal insufficiency and underlying symptoms will recur if medication is stopped abruptly without medical supervision. The nurse stresses the need for dietary modifications to ensure adequate calcium intake without increasing the risks for hypertension, hyperglycemia, and weight gain. The nurse educates the patient and family about how to monitor blood pressure, blood glucose levels, and weight. Patients should be advised to wear a medical alert bracelet and to notify other health care providers (e.g., dentist) about their condition (see Chart 45-13).

Continuing and Transitional Care. The need for follow-up depends on the origin and duration of the disease and its management. The patient who has been treated by adrenalectomy or removal of a pituitary tumor requires close monitoring to ensure that adrenal function has returned to normal and adequacy of circulating adrenal hormones. Home care referral may be indicated to ensure a safe environment that minimizes stress and risk of falls and other side effects. The home health nurse assesses the patient's physical and psychological status and reports changes to the primary provider. The nurse also assesses the patient's understanding of and ability to manage the medication regimen and reinforces previous education about the medications and the importance of taking them as prescribed. The nurse

emphasizes the importance of regular medical follow-up, the side effects and toxic effects of medications, and the need to wear medical identification with Addison's and Cushing's diseases. In addition, the patient and family are reminded about the importance of health promotion activities and recommended health screening, including bone mineral density testing.

Chart 45-13  **HOME CARE CHECKLIST**

The Patient with Cushing's Syndrome

At the completion of education, the patient and/or caregiver will be able to:

- State the impact of Cushing's syndrome and treatment on physiologic functioning, ADLs, IADLs, roles, relationships, and spirituality.
- State the relationship between adrenal hormones, emotional state, and stress.
- State the purpose, dose, route, schedule, side effects, and precautions for prescribed medications (adrenocortical inhibitors).
- State importance of compliance with medical regimen.
- State the need to contact primary provider before taking over-the-counter medications.
- State changes in lifestyle (e.g., diet, activity) necessary to maintain health, including:
- Wearing medical alert identification, and carrying medical information card.
- Identifying methods for managing labile emotions.
- Describing protective skin care measures and the use of protective devices and practices to decrease injury/fracture.
- Identifying foods high in potassium and low in sodium, calories, and carbohydrates.
- Describing measures to decrease risk of infection.
- Balancing rest and activity.
- Monitoring blood pressure, blood glucose levels, and weight.
- Identify signs and symptoms of excessive and insufficient adrenal hormone.
- Relate how to reach primary provider with questions or complications.
- State time and date of follow-up medical appointments, therapy, and testing.
- Identify sources of support (e.g., friends, relatives, faith community).
- Identify the contact details for support services for patients and their caregivers/families.
- Identify the need for health promotion, disease prevention, and screening activities.

ADLs, activities of daily living; IADLs, instrumental activities of daily living.

Evaluation

Expected patient outcomes may include:

1. Maintains adequate cardiac function
    a. Blood pressure is maintained within acceptable ranges
    b. Potassium levels are within normal ranges
    c. Absence of pedal edema
2. Decreases risk of injury
    a. Is free of fractures or soft tissue injuries
    b. Is free of ecchymotic areas
3. Decreases risk of infection
    a. Experiences no temperature elevation, redness, pain, or other signs of infection or inflammation
    b. Avoids contact with others who have infections
4. Attains/maintains skin integrity
    a. Has intact skin, without evidence of breakdown or infection
    b. Exhibits decreased edema in extremities and trunk
    c. Changes position frequently and inspects bony prominences daily
5. Achieves improved body image
    a. Verbalizes feelings about changes in appearance, sexual function, and activity level
    b. States that physical changes are a result of excessive glucocorticoids
6. Exhibits improved thought processes
7. Exhibits absence of complications
    a. Exhibits normal vital signs and weight and is free of symptoms of Addisonian crisis
    b. Identifies signs and symptoms of adrenocortical hypofunction that should be reported and measures to take in case of severe illness and stress
    c. Identifies strategies to minimize complications of Cushing's syndrome
    d. Adheres to recommendations for follow-up appointments and health screening

Primary Aldosteronism

The principal action of aldosterone is to conserve body sodium. Under the influence of this hormone, the kidneys excrete less sodium and more potassium and hydrogen. Primary aldosteronism is also known as Conn syndrome. Etiologic factors for primary aldosteronism include tumors of the adrenal gland, ovarian tumors that secrete aldosterone, and a family history. The true incidence of primary aldosteronism is unknown (Ma & Baranski,

2019) but studies have indicated that it is underestimated (Monticone, Burrello, Tizzani, et al., 2017). Excessive production of aldosterone causes a distinctive pattern of biochemical changes and a corresponding set of clinical manifestations that are diagnostic of this condition.

Clinical Manifestations

Hypertension is the most prominent and almost universal sign of primary aldosteronism. Patients with uncomplicated, complicated, and treatment-resistant hypertension and hypertension with hypokalemia should be considered at risk for this disorder. However, hypokalemia should no longer be considered a requisite for this diagnosis. It is now recognized that hypokalemia occurs in less than half of the patients (Ma & Baranski, 2019). If hypokalemia is present, it may be responsible for the variable muscle weakness or paralysis, cramping, and fatigue in patients with aldosteronism, as well as the kidneys' inability to acidify or concentrate the urine. Accordingly, the urine volume is excessive, leading to polyuria. Serum, by contrast, becomes abnormally concentrated, contributing to polydipsia (excessive thirst) and arterial hypertension. A secondary increase in blood volume and possible direct effects of aldosterone on nerve receptors, such as the carotid sinus, are other factors that result in hypertension.

Hypokalemic alkalosis may decrease the ionized serum calcium level and predispose the patient to tetany and paresthesias. Chvostek and Trousseau signs may be used to assess neuromuscular irritability before overt paresthesia and tetany occur. Glucose intolerance may occur, because hypokalemia interferes with insulin secretion from the pancreas.

Assessment and Diagnostic Findings

Withholding antihypertensive medication before laboratory testing is not required. If the patient is taking an antihypertensive agent, this information should be considered when interpreting the results of the PAC/PRA (plasma aldosterone concentration/plasma renin activity) study as well as the ARR (aldosterone-renin ratio) (Ma & Baranski, 2019).

Medical Management

The recommended treatment of unilateral primary aldosteronism is total surgical removal of the adrenal tumor through laparoscopic adrenalectomy rather than open surgery. Laparoscopic surgery is associated with shorter hospital stays and generally fewer complications following surgery (Ma & Baranski, 2019). During the preoperative period, blood pressure and potassium levels are closely monitored. During the immediate postoperative period, the

patient is susceptible to fluctuations in adrenocortical hormones and requires administration of corticosteroids, fluids, and other agents to maintain blood pressure and prevent acute complications. If the adrenalectomy is bilateral, replacement of corticosteroids will be lifelong. A normal serum glucose level is maintained with insulin, appropriate IV fluids, and dietary modifications. Hypokalemia typically resolves for all patients after surgery and hypertension is resolved in 35% to 60%. Postoperatively, spironolactone and potassium supplements should be discontinued and antihypertensives should be decreased. Potassium levels should be checked once a week for 4 weeks postoperatively (Ma & Baranski, 2019). Medical treatment rather than surgery is recommended for patients with bilateral adrenal involvement due to poor blood pressure control and other risks.

Pharmacologic Therapy

Pharmacologic management is required for patients with bilateral adrenal hyperplasia or unilateral aldosterone hypersecretion who do not undergo surgery. Spironolactone is recommended as the first-line drug to control hypertension. Eplerenone, a more expensive drug, is recommended as a second-line drug if the patient cannot tolerate side effects of spironolactone (Ma & Baranski, 2019). Serum potassium and creatinine should be monitored frequently during the first 4 to 6 weeks of taking spironolactone. Ongoing monitoring will be determined by the clinical course. The half-life of digoxin may be increased when taken with spironolactone, and its dosage may need to be adjusted.

Nursing Management

Nursing management in the postoperative period includes frequent assessment of vital signs to detect early signs and symptoms of adrenal insufficiency and crisis or hemorrhage. Explaining all treatments and procedures, providing comfort measures, and providing rest periods can reduce the patient's stress and anxiety level.

TABLE 45-2  Commonly Used Corticosteroid Preparations

Generic Names	Select Trade Names
beclomethasone	Beconase AQ, Qnasl
betamethasone	Beta-Val, Dermabet, Luxiq, Valnac
dexamethasone	Dexamethasone Intensol
hydrocortisone	Colocort, Cortef, Cortenema, Solu-Cortef
methylprednisolone	Depo-Medrol, Solu-Medrol
prednisone	Prednisone Intensol, Rayos
prednisolone	Prelone
triamcinolone	Kenalog, Triderm

Adapted from Comerford, K. C., & Durkin, M. T. (2020). *Nursing 2020 drug handbook*. Philadelphia, PA: Wolters Kluwer.

Corticosteroid Therapy

Corticosteroids are used extensively for adrenal insufficiency and are also widely used in suppressing inflammation and autoimmune reactions, controlling allergic reactions, and reducing the rejection process in transplantation. Commonly used corticosteroid preparations are listed in Table 45-2. Their anti-inflammatory and antiallergy actions make corticosteroids effective in treating rheumatic or connective tissue diseases, such as rheumatoid arthritis and SLE. They are also frequently used in the treatment of asthma, multiple sclerosis, and other autoimmune disorders.

High doses appear to allow patients to tolerate high degrees of stress. Such antistress action may be caused by the ability of corticosteroids to aid circulating vasopressor substances in keeping the blood pressure elevated; other effects, such as maintenance of the serum glucose level, also may keep blood pressure elevated.

Side Effects

Although the synthetic corticosteroids are safer for some patients because of relative freedom from mineralocorticoid activity, most natural and synthetic corticosteroids produce similar kinds of side effects. The dose required for anti-inflammatory and antiallergy effects also produces metabolic effects, pituitary and adrenal gland suppression, and changes in the function of the central nervous system. Therefore, although corticosteroids are highly effective therapeutically, they may also be very dangerous. Dosages of these medications are frequently altered to allow high concentrations when necessary and then tapered in an attempt to avoid undesirable effects. This

requires that patients be observed closely for side effects and that the dose be reduced when high doses are no longer required. Suppression of the adrenal cortex may persist up to 1 year after a course of corticosteroids.

Therapeutic Uses of Corticosteroids

The dosage of corticosteroids is determined by the nature and chronicity of the illness as well as the patient's other medical conditions. Rheumatoid arthritis, bronchial asthma, and multiple sclerosis are chronic disorders that corticosteroids do not cure; however, these medications may be useful when other measures do not provide adequate control of symptoms. In addition, corticosteroids may be used to treat acute exacerbations of these disorders.

In such situations, the adverse effects of corticosteroids are weighed against the patient's current condition. These medications may be used for a period but then are gradually reduced or tapered as the symptoms subside. The nurse plays an important role in providing encouragement and understanding during times when the patient is experiencing (or is apprehensive about experiencing) recurrence of symptoms while taking smaller doses.

Treatment of Acute Conditions

Acute flare-ups and crises are treated with large doses of corticosteroids. Examples include emergency treatment for bronchial obstruction in status asthmaticus and for septic shock from septicemia caused by gram-negative bacteria. Other measures, such as anti-infective agents or medications, are also used with corticosteroids to treat shock and other major symptoms. At times, corticosteroids are continued past the acute flare-up stage to prevent serious complications.

Ophthalmologic Treatment

Outer eye infections can be treated by topical application of corticosteroid eye drops, because the agents do not cause systemic toxicity. However, long-term application can cause an increase in intraocular pressure, which leads to glaucoma in some patients. In addition, prolonged use of corticosteroids can sometimes lead to cataract formation.

Dermatologic Disorders

Topical administration of corticosteroids in the form of creams, ointments, lotions, and aerosols is especially effective in many dermatologic disorders. It may be more effective in some conditions to use occlusive dressings around the affected part to achieve maximum absorption of the medication. Penetration and absorption are also increased if the medication is applied when the skin is hydrated or moist (e.g., immediately after bathing).

Absorption of topical agents varies with body location. For example, absorption is greater through the layers of skin on the scalp, face, and genital area than on the forearm; as a result, the use of topical agents on these sites increases the risk of side effects. The availability of over-the-counter topical corticosteroids increases the risk of side effects in patients who are unaware of their potential risks. Excessive use of these agents, especially on large surface areas of inflamed skin, can lead to decreased therapeutic effects and increased side effects.

Dosage

Attempts have been made to determine the best time to administer pharmacologic doses of steroids. If symptoms have been controlled on a 6- or 8-hour program, a once-daily or every-other-day schedule may be implemented. In keeping with the natural secretion of cortisol, the best time of day for the total corticosteroid dose is in the early morning, between 7 and 8 am. Large-dose therapy at 8 am, when the adrenal gland is most active, produces maximal suppression of the gland. A large 8 am dose is more physiologic because it allows the body to escape effects of the steroids from 4 pm to 6 am, when serum levels are normally low, hence minimizing cushingoid effects. If symptoms of the disorder being treated are suppressed, alternate-day therapy is helpful in reducing pituitary–adrenal suppression in patients requiring prolonged therapy. Some patients report discomfort associated with symptoms of their primary illness on the second day; therefore, the nurse must explain to patients that this regimen is necessary to minimize side effects and suppression of adrenal function.

Tapering

Corticosteroid dosages are tapered (reduced gradually) to allow normal adrenal function to return and to prevent steroid-induced adrenal insufficiency. Up to 1 year or longer after the use of corticosteroids, the patient is still at risk for adrenal insufficiency in times of stress. For example, if surgery for any reason is necessary, the patient is likely to require IV corticosteroids during and after surgery to reduce the risk of acute adrenal crisis.

Nursing Management

Nursing management of corticosteroid therapy includes many important interventions. Table 45-3 provides an overview of the effects of corticosteroid therapy and the nursing implications.

Promoting Home, Community-Based, and Transitional Care

Educating Patients About Self-Care

The nurse educates the patient, family, and caregivers that acute adrenal insufficiency and underlying symptoms will recur if corticosteroid therapy is stopped abruptly without medical supervision. The patient should be instructed to always have an adequate supply of the corticosteroid medication to avoid running out.

Continuing and Transitional Care

The patient who requires continued corticosteroid therapy is monitored to ensure understanding of the medications and the need for a dosage that treats the underlying disorder while minimizing the side effects. Home care referral may be indicated to ensure a safe environment that minimizes stress, risk of falls, and other side effects. The nurse assesses the patient's physical and psychological status and reports changes to the primary provider. The nurse also assesses the patient's understanding of and ability to manage the medication regimen and reinforces previous education about the medications and the importance of taking them as prescribed. The nurse emphasizes the importance of regular medical follow-up, the side effects of the medications, and the effects of abruptly discontinuing corticosteroids. In addition, the patient and family are reminded about the importance of health promotion activities and recommended health screening, including bone mineral density testing.

TABLE 45-3  Corticosteroid Therapy and Implications for Nursing Practice

Side Effects	Nursing Interventions
Cardiovascular Effects	
Hypertension	Monitor for elevated blood pressure.
Thrombophlebitis	Assess for signs and symptoms of deep venous thrombosis: redness, warmth, tenderness, and edema of an extremity.
Thromboembolism	Remind patient to avoid positions and situations that restrict blood flow (e.g., crossing legs, prolonged sitting in same position).
Accelerated atherosclerosis	Encourage foot and leg exercises when recumbent. Encourage low-sodium diet. Encourage limited intake of fat.
Immunologic Effects	
Increased risk of infection and masking of signs of infection	Assess for subtle signs of infection and inflammation. Encourage patient to avoid exposure to others with upper respiratory infection. Monitor patient for fungal infections. Encourage good hand hygiene.
Ophthalmologic Changes	
Glaucoma	Encourage yearly eye examinations.
Corneal lesions	Refer patient to ophthalmologist if changes in visual acuity are detected.
Musculoskeletal Effects	
Muscle wasting	Encourage high-protein intake.
Poor wound healing	Encourage high-protein intake and vitamin C supplementation.
Osteoporosis with vertebral compression fractures, pathologic fractures of long bones, aseptic necrosis of head of the femur	Encourage diet high in calcium and vitamin D or calcium and vitamin D supplementation if indicated. Take measures to avoid falls and other trauma. Use caution in moving and turning patient. Encourage postmenopausal women on corticosteroids to consider bone mineral density testing and treatment, if indicated. Instruct patient to rise slowly from bed or chair to avoid falling due to orthostatic hypotension.
Metabolic Effects	
Alterations in glucose metabolism	Monitor blood glucose levels at periodic intervals.

Steroid withdrawal syndrome	Instruct patient about medications, diet, and exercise prescribed to control blood glucose level. Report signs of adrenal insufficiency. Administer corticosteroids and mineralocorticoids as prescribed. Instruct patient about importance of taking corticosteroids as prescribed without abruptly stopping therapy. Encourage patient to obtain and wear a medical identification bracelet. Advise patient to notify all health care providers (e.g., dentist) about the need for corticosteroid therapy.
Changes in Appearance	
Moon face Weight gain Acne	Encourage low-calorie, low-sodium diet. Assure patient that most changes in appearance are temporary and will disappear if and when corticosteroid therapy is no longer necessary.
Fluid and Electrolyte Imbalances	Monitor I&O and electrolytes. Administer fluids and electrolytes as prescribed.

I&O, intake and output.

CRITICAL THINKING EXERCISES

1 ebp A 62-year-old man has been recently diagnosed with hypothyroidismn and requires education to manage his condition. What evidence-based practices will you include when educating this patient? Identify at least three essential pieces of information you would include.

2 pq You are caring for a patient who requires long-term administration of prednisone. Identify three priority nursing diagnoses for this patient related to the use of the prednisone. State the expected outcomes and at least three priority interventions with scientific rationales for each nursing diagnosis.

3 ipc A patient with a 6-month history of Addison's disease is hospitalized for Addisonian crisis and is transferred to a medical unit after a 2-day stay in the intensive care unit. During interprofessional collaborative rounds, the team discusses this patient. What information will the primary provider, the nurse, the physical therapist, and the discharge planner contribute to the discussion? What patient-centered goals will each discipline set for the patient?

4 pq Identify the priorities, approach, and techniques you would use to perform a comprehensive assessment on a 60-year-old patient newly diagnosed with Cushing's syndrome. How will your priorities, approach, and techniques differ if the patient has a visual impairment or is hard of hearing? If the patient is from a culture with very different values from your own?

46 Management of Patients with Diabetes

LEARNING OUTCOMES

On completion of this chapter, the learner will be able to:

1. Differentiate between the types of diabetes, associated etiologic factors, and pathophysiologic alterations.
2. Identify the diagnostic and clinical significance of blood glucose test results.
3. Describe the relationships among diet and dietary modifications, exercise, and medication (i.e., insulin or oral antidiabetic agents) for people with diabetes.
4. Use the nursing process as a framework for care of the patient who has hyperglycemia with diabetic ketoacidosis or hyperglycemic hyperosmolar syndrome.
5. Describe management strategies for a person with diabetes to use during "sick days."
6. Outline the major complications of diabetes and the self-care behaviors that are important in their prevention.

NURSING CONCEPTS

Acid–Base Balance
Family
Fluids and Electrolytes
Infection
Metabolism
Patient Education

GLOSSARY

diabetes: a group of metabolic diseases characterized by hyperglycemia resulting from defects in insulin secretion, insulin action, or both

diabetic ketoacidosis (DKA): a metabolic derangement, most commonly occurring in type 1 diabetes, that results from a deficiency of insulin; highly acidic ketone bodies are formed, resulting in acidosis

fasting plasma glucose (FPG): blood glucose determination obtained in the laboratory after fasting for at least 8 hours

gestational diabetes: any degree of glucose intolerance with its onset during pregnancy

glycated hemoglobin: a measure of glucose control that is a result of glucose molecule attaching to hemoglobin for the life of the red blood cell (120 days) (*synonyms*: glycosylated hemoglobin, $HgbA_{1C}$, or A1C)

glycemic index: the amount a given food increases the blood glucose level compared with an equivalent amount of glucose

hyperglycemia: elevated blood glucose level

hyperglycemic hyperosmolar syndrome (HHS): a metabolic disorder, most commonly of type 2 diabetes resulting from a relative insulin deficiency initiated by an illness that raises the demand for insulin

hypoglycemia: low blood glucose level

impaired fasting glucose (IFG) or impaired glucose tolerance (IGT): a metabolic stage intermediate between normal glucose homeostasis and diabetes; referred to as prediabetes

insulin: a hormone secreted by the beta cells of the islets of Langerhans of the pancreas that is necessary for the metabolism of carbohydrates, proteins, and fats; a deficiency of insulin results in diabetes

ketone: a highly acidic substance formed when the liver breaks down free fatty acids in the absence of insulin

latent autoimmune diabetes of adults (LADA): a subtype of diabetes

medical nutrition therapy (MNT): nutritional therapy prescribed for management of diabetes that usually is given by a registered dietitian

nephropathy: a long-term complication of diabetes in which the kidney cells are damaged; characterized by microalbuminuria in early stages and progressing to end-stage kidney disease

neuropathy: a long-term complication of diabetes resulting from damage to the nerve cell

prediabetes: impaired glucose metabolism in which blood glucose concentrations fall between normal levels and those considered diagnostic for diabetes; includes impaired fasting glucose and impaired glucose tolerance, not clinical entities in their own right but risk factors for future diabetes and cardiovascular disease

retinopathy: a condition that occurs when the small blood vessels that nourish the retina in the eye are damaged

self-monitoring of blood glucose (SMBG): a method of capillary blood glucose testing

type 1 diabetes: a metabolic disorder characterized by an absence of insulin production and secretion from autoimmune destruction of the beta cells of the islets of Langerhans in the pancreas (*formerly*: insulin-dependent diabetes, or juvenile diabetes)

type 2 diabetes: a metabolic disorder characterized by the relative deficiency of insulin production and a decreased insulin action and increased insulin resistance (*formerly:* non–insulin-dependent diabetes, or adult-onset diabetes)

Diabetes is a group of metabolic diseases characterized by **hyperglycemia** (an elevated level of glucose in the blood) resulting from defects in insulin secretion, insulin action, or both (Centers for Disease Control and Prevention [CDC], 2020). Care of the patient with diabetes, formerly known as diabetes mellitus but now more commonly referred to as diabetes, requires an understanding of the epidemiology, pathophysiology, diagnostic testing, medical and nursing care, and rehabilitation of patients with diabetes. The field of diabetes is dynamic with constant advances in technology, research, and medications that can improve the life and well-being of people with diabetes. Nurses care for patients with diabetes in all settings. This chapter focuses on the nursing management of patients with diabetes.

DIABETES

Epidemiology

It is estimated that more than 34.1 million adults in the United States have diabetes, although almost one third of these cases are undiagnosed (CDC, 2020). The number of people older than 20 years newly diagnosed with diabetes increases by 1.7 million per year. If this trend continues, one in every three adults in the United States could have diabetes by 2050. In 2018, the percentage of adults with diabetes increased with age, reaching 28.3% of those age 65 years or older (CDC, 2020).

The rate of prediabetes is also steadily increasing. It is estimated that 35.5% of U.S. adults aged 18 years or older (88 million people) had prediabetes in 2018, based on laboratory findings. Nearly half (48.3%) of adults aged 65 years or older had prediabetes (CDC, 2020). Over $237 billion a year is spent in medical costs and $90 billion a year is lost in productivity related to diabetes (CDC, 2020).

Ethnic and racial minority populations are disproportionately affected by diabetes. The age-adjusted prevalence of diabetes is increasing among all gender and racial groups, but compared with Caucasians, African Americans, and members of other racial and ethnic groups (Native Americans and persons of Hispanic origin) are more likely to develop diabetes, are at greater risk for many of the complications, and have higher death rates due to diabetes (CDC, 2020). Chart 46-1 summarizes risk factors for diabetes.

Diabetes can have far-reaching and devastating physical, social, and economic consequences, including the following (CDC, 2020; Virani, Alonso, Benjamin, et al., 2020):

- In the United States, diabetes is the leading cause of nontraumatic amputations and end-stage kidney disease (ESKD).
- Diabetes is the seventh leading cause of death in the United States and the leading cause of new blindness in adults aged 18 to 64 years.
- Emergency department visits and hospitalization rates for adults and children with diabetes are greater than for the general population.

The economic cost of diabetes continues to increase because of increasing health care costs and an aging population.

Classification

The major classifications of diabetes are type 1 diabetes, type 2 diabetes, gestational diabetes, latent autoimmune diabetes of adults (LADA), and diabetes associated with other conditions or syndromes (American Diabetes Association [ADA], 2020). The different types of diabetes vary in cause, clinical course, and treatment (see Table 46-1). The classification system is dynamic in two ways. First, research findings suggest many differences among individuals within each category. Second, except for people with type 1 diabetes, patients may move from one category to another. For example, a woman with gestational diabetes may, after delivery, move into type 2 diabetes. **Prediabetes** is classified as **impaired glucose tolerance (IGT) or impaired fasting glucose (IFG)** and refers to a condition in which blood glucose concentrations fall between normal levels and those considered diagnostic for diabetes (ADA, 2020; CDC, 2020).

Chart 46-1 RISK FACTORS

Diabetes

- Age >30 years for type 2 and <30 years for type 1
- High-density lipoprotein (HDL) cholesterol level ≤35 mg/dL (0.90 mmol/L) and/or triglyceride level ≥250 mg/dL (2.8 mmol/L)
- History of gestational diabetes or delivery of a baby over 9 lb
- Hypertension
- Family history of diabetes (e.g., parents or siblings with diabetes)
- Obesity (i.e., ≥20% over desired body weight or body mass index ≥30 kg/m^2)
- Previously identified impaired fasting glucose or impaired glucose tolerance
- Race/ethnicity (e.g., African Americans, Hispanic Americans, Native Americans, Asian Americans, Pacific Islanders)

Adapted from American Diabetes Association (ADA). (2020). Standards of medical care in diabetes—2020. *Diabetes Care*, *43*(Suppl 1), S1–S212.

TABLE 46-1 Common Types of Diabetes and Related Glucose Intolerances

Classification	Clinical Characteristics and Implications
Type 1 (5–10% of all patients with diabetes; formerly juvenile diabetes, or insulin-dependent diabetes)	Onset any age, but usually young (<30 yrs) Usually thin at diagnosis; recent weight loss Etiology includes genetic, immunologic, and environmental factors (e.g., virus) Often have islet cell antibodies Often have antibodies to insulin even before insulin treatment Little or no endogenous insulin Need exogenous insulin to preserve life Ketosis prone when insulin absent Acute complication of hyperglycemia: diabetic ketoacidosis
Type 2 (90–95% of all diabetes: patients with obesity—80% of type 2, patients without obesity—20% of type 2; formerly adult-onset diabetes, or non–insulin-dependent diabetes)	Onset any age, usually ≥30 yrs Usually obesity is present at diagnosis Causes include obesity, heredity, and environmental factors No islet cell antibodies Decrease in endogenous insulin, or increased with insulin resistance Most patients can control blood glucose through weight loss if they have obesity Oral antidiabetic agents may improve blood glucose levels if dietary modification and exercise are unsuccessful May need insulin on a short- or long-term basis to prevent hyperglycemia Ketosis uncommon, except in stress or infection Acute complication: hyperglycemic hyperosmolar syndrome
Diabetes associated with other conditions or syndromes (previously classified as secondary diabetes)	Accompanied by conditions known or suspected to cause the disease: pancreatic diseases, hormonal abnormalities, medications such as corticosteroids and estrogen-containing preparations Depending on the ability of the pancreas to produce insulin, the patient may require treatment with oral antidiabetic agents or insulin.
Gestational diabetes	Onset during pregnancy, usually in the second or third trimester Because of hormones secreted by the placenta, which inhibit the action of insulin Above-normal risk for perinatal complications, especially macrosomia (abnormally large babies) Treated with diet and, if needed, insulin to strictly maintain normal blood glucose levels Occurs in about 18% of pregnancies Glucose intolerance transitory but may recur: • In subsequent pregnancies • 35–60% will develop diabetes (usually type 2) within 10–20 yrs, especially if they have obesity Risk factors include obesity, age >30 yrs, family history of diabetes, previous large babies (>9 lb) Screening tests (glucose challenge test) should be performed on all pregnant women between 24 and 28 wks of gestation Should be screened for diabetes every 3 yrs
Prediabetes (previously classified as abnormality of glucose tolerance)	Previous history of hyperglycemia (e.g., during pregnancy or illness) Current normal glucose metabolism Impaired glucose tolerance or impaired fasting glucose screening after age 40 yrs if there is a family history of diabetes or if symptomatic Encourage ideal body weight, because loss of 10–15 lb may improve glycemic control

Adapted from American Diabetes Association (ADA). (2020). Standards of medical care in diabetes—2020. *Diabetes Care*, *43*(Suppl 1), S1–S212; Virani, S. S., Alonso, A., Benjamin, E. J., et al. (2020). Heart disease and stroke statistics—2020 update: A report from the American Heart Association. *Circulation*, *141*(9), e139–e596.

COVID-19 Considerations

The coronavirus disease 2019 (COVID-19) pandemic began in Wuhan, China, in late 2019. Since that time, several risks for both severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) infection and pathogenesis to COVID-19 have been posed (see Chapter 66). Epidemiologic data from China suggest that having any type of diabetes could be an important risk factor for becoming infected with SARS-CoV-2 as well as for being hospitalized to manage COVID-19 (Sommerstein, Kochen, Messerli, et al., 2020). Patients with diabetes who are hospitalized with COVID-19 have higher rates of intubation and mortality. Researchers who looked at 486 patients hospitalized with COVID-19 reported those who were older than 60 years of age, male, and had a history of diabetes were at greater risk of requiring intubation (Hur, Price, Gray, et al., 2020). Another study reported that increased mortality in patients with diabetes was associated with older age, having a positive C-reactive protein laboratory finding, and being on insulin (Chen, Yang, Chen, et al., 2020).

Pathophysiology

Insulin is a hormone secreted by beta cells, which are one of four types of cells in the islets of Langerhans in the pancreas (Norris, 2019). Insulin is an anabolic, or storage, hormone. When a person eats a meal, insulin secretion increases and moves glucose from the blood into muscle, liver, and fat cells. In those cells, insulin has the following actions:

- Transports and metabolizes glucose for energy
- Stimulates storage of glucose in the liver and muscle (in the form of glycogen)
- Signals the liver to stop the release of glucose
- Enhances storage of dietary fat in adipose tissue
- Accelerates transport of amino acids (derived from dietary protein) into cells
- Inhibits the breakdown of stored glucose, protein, and fat

During fasting periods (between meals and overnight), the pancreas continuously releases a small amount of insulin (basal insulin); another pancreatic hormone called *glucagon* (secreted by the alpha cells of the islets of Langerhans) is released when blood glucose levels decrease, which stimulates the liver to release stored glucose. The insulin and the glucagon together maintain a constant level of glucose in the blood by stimulating the release of glucose from the liver.

Initially, the liver produces glucose through glycogenolysis (the breakdown of glycogen). After 8 to 12 hours without food, the liver forms glucose from the breakdown of noncarbohydrate substances, including amino acids, through the process of gluconeogenesis.

Type 1 Diabetes

Type 1 diabetes is characterized by the destruction of the pancreatic beta cells (Norris, 2019). Combined genetic, immunologic, and possibly environmental (e.g., viral) factors are thought to contribute to beta-cell destruction. Although the events that lead to beta-cell destruction are not fully understood, it is generally accepted that a genetic susceptibility is a common underlying factor in the development of type 1 diabetes. People do not inherit type 1 diabetes itself but rather a genetic predisposition, or tendency, toward the development of type 1 diabetes. This genetic tendency has been found in people with certain human leukocyte antigen types. There is also evidence of an autoimmune response in type 1 diabetes. This is an abnormal response in which antibodies are directed against normal tissues of the body, responding to these tissues as if they were foreign. Autoantibodies against islet cells and against endogenous (internal) insulin have been detected in people at the time of diagnosis and even several years before the development of clinical signs of type 1 diabetes. In addition to genetic and immunologic components, environmental factors such as viruses or toxins that may initiate destruction of the beta cell continue to be investigated.

Regardless of the specific cause, the destruction of the beta cells results in decreased insulin production, increased glucose production by the liver, and fasting hyperglycemia. In addition, glucose derived from food cannot be stored in the liver but instead remains in the bloodstream and contributes to postprandial (after meals) hyperglycemia. If the concentration of glucose in the blood exceeds the renal threshold for glucose, usually 180 to 200 mg/dL (9.9 to 11.1 mmol/L), the kidneys may not reabsorb all of the filtered glucose; glycosuria then occurs (i.e., the glucose then appears in the urine). When excess glucose is excreted in the urine, it is accompanied by excessive loss of fluids and electrolytes. This is called *osmotic diuresis.*

Because insulin normally inhibits glycogenolysis and gluconeogenesis, these processes occur in an unrestrained fashion in people with insulin deficiency and contribute further to hyperglycemia. In addition, fat breakdown occurs, resulting in an increased production of **ketone** bodies, a highly acidic substance formed when the liver breaks down free fatty acids in the absence of insulin.

Diabetic ketoacidosis (DKA) is a metabolic derangement that occurs most commonly in persons with type 1 diabetes and results from a deficiency of insulin; highly acidic ketone bodies are formed, and metabolic acidosis occurs. The three major metabolic derangements are hyperglycemia, ketosis, and metabolic acidosis (Norris, 2019). DKA is commonly preceded by a day or more of polyuria, polydipsia, nausea, vomiting, and fatigue with eventual stupor and coma if not treated. The breath has a characteristic fruity odor due to the presence of ketoacids.

Type 2 Diabetes

Type 2 diabetes occurs more commonly among people who are older than 30 years and who have obesity, although its incidence is rapidly increasing in younger people because of the growing epidemic of obesity in children, adolescents, and young adults (CDC, 2020).

The two main problems related to insulin in type 2 diabetes are insulin resistance and impaired insulin secretion. Insulin resistance refers to a decreased tissue sensitivity to insulin. Normally, insulin binds to special receptors on cell surfaces and initiates a series of reactions involved in glucose metabolism. In type 2 diabetes, these intracellular reactions are diminished, making insulin less effective at stimulating glucose uptake by the tissues and at regulating glucose release by the liver (see Fig. 46-1). The exact mechanisms that lead to insulin resistance and impaired insulin secretion in type 2 diabetes are unknown, although genetic factors are thought to play a role.

To overcome insulin resistance and to prevent the buildup of glucose in the blood, increased amounts of insulin must be secreted to maintain the glucose level at a normal or slightly elevated level. If the beta cells cannot keep up with the increased demand for insulin, the glucose level rises and type 2 diabetes develops. Insulin resistance may also lead to metabolic syndrome, which is a constellation of symptoms, including hypertension, hypercholesterolemia, abdominal obesity, and other abnormities (Norris, 2019).

Despite the impaired insulin secretion that is characteristic of type 2 diabetes, there is enough insulin present to prevent the breakdown of fat and the accompanying production of ketone bodies. Therefore, DKA does not typically occur in type 2 diabetes. However, uncontrolled type 2 diabetes may lead to another acute problem—**hyperglycemic hyperosmolar syndrome (HHS)** (see discussion later in chapter).

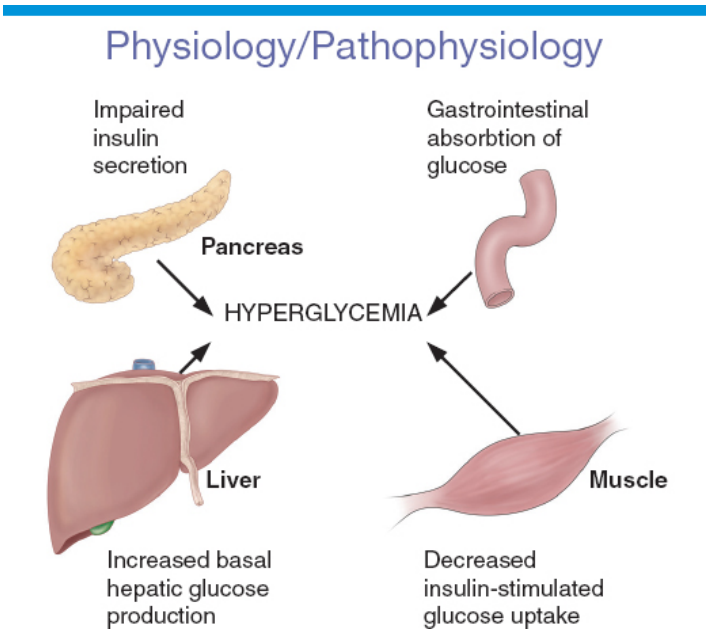

Figure 46-1 • Pathogenesis of type 2 diabetes.

Because type 2 diabetes is associated with a slow, progressive glucose intolerance, its onset may go undetected for many years. If the patient experiences symptoms, they are frequently mild and may include fatigue, irritability, polyuria, polydipsia, poorly healing skin wounds, vaginal infections, or blurred vision (if glucose levels are very high).

For most patients (approximately 75%), type 2 diabetes is detected incidentally (e.g., when routine laboratory tests or ophthalmoscopic examinations are performed). One consequence of undetected diabetes is that long-term diabetes complications (e.g., eye disease, peripheral neuropathy, peripheral vascular disease)

may have developed before the actual diagnosis of diabetes is made (ADA, 2020), signifying that the blood glucose has been elevated for a time before diagnosis.

Gestational Diabetes

Gestational diabetes is any degree of glucose intolerance with its onset during pregnancy (Norris, 2019). Hyperglycemia develops during pregnancy, particularly in the second and third trimesters, because of the secretion of placental hormones that cause insulin resistance.

Women who are considered to be at high risk for gestational diabetes and should be screened by blood glucose testing at their first prenatal visit are those with marked obesity, a personal history of gestational diabetes, glycosuria, or a strong family history of diabetes. High-risk ethnic groups include Hispanic Americans, Native Americans, Asian Americans, African Americans, and Pacific Islanders. If these high-risk women do not have gestational diabetes at initial screening, they should be retested between 24 and 28 weeks of gestation. All women of average risk should be tested at 24 to 28 weeks of gestation. Testing is not specifically recommended for women identified as being at low risk. Low-risk women are those who meet all of the following criteria: age younger than 25 years, normal weight before pregnancy, member of an ethnic group with low prevalence of gestational diabetes, no history of abnormal glucose tolerance, no known history of diabetes in first-degree relatives, and no history of poor obstetric outcomes (ADA, 2020). Women considered to be at high or average risk should have either an oral glucose tolerance test or a glucose challenge test followed by an oral glucose tolerance test in women who exceed the glucose threshold value of 140 mg/dL (7.8 mmol/L) (ADA, 2020).

Initial management includes dietary modification and blood glucose monitoring. Between 70% and 85% of women with gestational diabetes can control blood glucose levels with lifestyle modifications alone. Dietary recommendations include a daily minimum of 175 g of carbohydrates, 71-g protein, 28-g fiber, and low saturated fats (ADA, 2020). If hyperglycemia persists, insulin is prescribed. Target ranges for blood glucose levels during pregnancy are 140 to 180 mg/dL (7.8 to 10 mmol/L) (ADA, 2020).

After delivery, blood glucose levels in women with gestational diabetes usually return to normal. However, many women who have had gestational diabetes develop type 2 diabetes later in life. Women with a history of gestational diabetes should be screened for the development of diabetes or prediabetes every 3 years (ADA, 2020).

Latent Autoimmune Diabetes of Adults (LADA)

In adults, **LADA** is a subtype of diabetes in which the progression of autoimmune beta cell destruction in the pancreas is slower than in types 1 and 2 diabetes. Patients with LADA are at high risk of becoming insulin dependent. Most patients with LADA have at least two of the following: age of onset less than 50 years, body mass index (BMI) less than 25 kg/m^2, history of autoimmune disease, acute symptoms prior to diagnosis, or positive family history of autoimmune disease (Fischbach & Fischbach, 2018).

Prevention

The Diabetes Prevention Program Research Group (2002) reported that type 2 diabetes can be prevented with appropriate changes in lifestyle. Participants at high risk for type 2 diabetes (BMI greater than 24 kg/m^2, fasting and postprandial plasma glucose levels elevated but not to levels diagnostic of diabetes) received standard lifestyle recommendations plus metformin, an oral antidiabetic agent; standard lifestyle recommendations plus placebo; or an intensive program of lifestyle modifications. The 16-lesson curriculum of the intensive program of lifestyle modifications focused on weight reduction of greater than 7% of initial body weight and physical activity of moderate intensity. It also included behavior modification strategies designed to help patients achieve the goals of weight reduction and participation in exercise. Compared to the placebo group, the lifestyle intervention group had a 58% lower incidence of diabetes and the metformin group had a 31% lower incidence of diabetes. These findings were found in both genders and all racial and ethnic groups. This research demonstrates that type 2 diabetes can be prevented or delayed in persons at high risk for the disease (Diabetes Prevention Program Research Group, 2002). The Diabetes Prevention Program Outcomes Study followed participants for 15 years and demonstrated that those who enrolled in the program continued to develop type 2 diabetes at a lower rate compared to controls (Diabetes Prevention Program Research Group, 2015).

Researchers have also reported in a study of more than 7000 participants followed for 8 years that those who took glucosamine, a supplement that decreases osteoarthritis and joint pain, had a lower risk of developing type 2 diabetes compared to those not taking the supplement (Ma, Li, Zhou, et al., 2020).

Clinical Manifestations

Clinical manifestations depend on the patient's level of hyperglycemia. Classic clinical manifestations of diabetes include the "three Ps": *p*olyuria, *p*olydipsia, and *p*olyphagia. Polyuria (increased urination) and polydipsia (increased thirst) occur as a result of the excess loss of fluid associated with osmotic diuresis. Patients also experience polyphagia (increased appetite) that results from the catabolic state induced by insulin deficiency and the breakdown of proteins and fats (Norris, 2019). Other symptoms include fatigue and weakness, sudden vision changes, tingling or numbness in hands or feet, dry skin, skin lesions or wounds that are slow to heal, and recurrent infections. The onset of type 1 diabetes may also be associated with sudden weight loss or nausea, vomiting, or abdominal pains, if DKA has developed.

Chart 46-2

Criteria for the Diagnosis of Diabetes

- Symptoms of diabetes plus casual plasma glucose concentration equal to or greater than 200 mg/dL (11.1 mmol/L). Casual is defined as any time of day without regard to time since last meal. The classic symptoms of diabetes include polyuria, polydipsia, and unexplained weight loss.

Or

- Fasting plasma glucose greater than or equal to 126 mg/dL (7.0 mmol/L). Fasting is defined as no caloric intake for at least 8 hours.

Or

- Two-hour postload glucose equal to or greater than 200 mg/dL (11.1 mmol/L) during an oral glucose tolerance test. The test should use a glucose load containing the equivalent of 75-g anhydrous glucose dissolved in water.

Or

- Hemoglobin A1C ≥6.5% (48 mmol/mol).

In the absence of unequivocal hyperglycemia with acute metabolic decompensation, these criteria should be confirmed by repeat testing on a different day. The third measure is not recommended for routine clinical use.

A1C, glycosylated hemoglobin

Adapted from American Diabetes Association (ADA). (2020). Standards of medical care in diabetes—2020. *Diabetes Care*, *43*(Suppl 1), S1–S212.

Assessment and Diagnostic Findings

An abnormally high blood glucose level is the basic criterion for the diagnosis of diabetes. **Fasting plasma glucose (FPG)** (blood glucose determination obtained in the laboratory after fasting for at least 8 hours), random plasma glucose, and glucose level 2 hours after receiving glucose (2-hour postprandial load) may be used (Fischbach & Fischbach, 2018). See Chart 46-2 for the ADA's diagnostic criteria for diabetes (ADA, 2020).

In addition to the assessment and diagnostic evaluation performed to diagnose diabetes, ongoing specialized assessment of patients with known diabetes and evaluation for complications in patients with newly diagnosed diabetes are important components of care. Parameters that should be regularly assessed are discussed in Chart 46-3.

Gerontologic Considerations

Diabetes is particularly prevalent in older adults. In fact, type 2 diabetes is the seventh leading cause of death and affects approximately 20% of older adults (Eliopoulos, 2018). There is a high prevalence among African Americans and those who are 65 to 74 years of age (Eliopoulos, 2018).

Early detection is important but may be challenging because symptoms may be absent or nonspecific. A glucose tolerance test is more effective in diagnosis than urine testing for glucose in older patients due to the higher renal threshold for glucose (Eliopoulos, 2018).

Medical Management

The main goal of diabetes treatment is to normalize insulin activity and blood glucose levels to reduce the development of complications. The Diabetes Control and Complications Trial Research Group (DCCT), a 10-year prospective clinical trial conducted from 1983 to 1993, demonstrated the importance of achieving blood glucose control in the normal, nondiabetic range. This landmark trial demonstrated that intensive glucose control dramatically reduced the development and progression of complications such as **retinopathy** (damage to small blood vessels that nourish the retina), **nephropathy** (damage to kidney cells), and **neuropathy** (damage to nerve cells). Intensive treatment is defined as 3 or 4 insulin injections per day or an insulin pump (i.e., a continuous subcutaneous insulin infusion) plus frequent blood glucose monitoring and weekly contacts with diabetes educators (DCCT, 1993). The ADA recommends that all patients with diabetes strive for glucose control ($HgbA_{1C}$ less than 7%) to reduce their risk of complications (ADA, 2020a).

Chart 46-3  **ASSESSMENT**

Assessing the Patient with Diabetes

History

- Symptoms related to the diagnosis of diabetes:
  Symptoms of hyperglycemia
  Symptoms of hypoglycemia
  Frequency, timing, severity, and resolution
- Results of blood glucose monitoring
- Status, symptoms, and management of chronic complications of diabetes:
  Eye; kidney; nerve; genitourinary and sexual, bladder, and gastrointestinal
  Cardiac; peripheral vascular; foot complications associated with diabetes
- Adherence to/ability to follow prescribed dietary management plan
- Adherence to prescribed exercise regimen
- Adherence to/ability to follow prescribed pharmacologic treatment (insulin or oral antidiabetic agents)
- Use of tobacco, alcohol, and prescribed and over-the-counter medications/drugs
- Lifestyle, cultural, psychosocial, and economic factors that may affect diabetes treatment
- Effects of diabetes or its complications on functional status (e.g., mobility, vision)

Physical Examination

- Blood pressure (sitting and standing to detect orthostatic changes)
- Body mass index (height and weight)
- Funduscopic examination and visual acuity
- Foot examination (lesions, signs of infection, pulses)
- Skin examination (lesions and insulin injection sites)
- Neurologic examination
  Vibratory and sensory examination using monofilament
  Deep tendon reflexes
- Oral examination

Laboratory Examination

- $HgbA_{1C}$ (A1C)
- Fasting lipid profile
- Test for microalbuminuria
- Serum creatinine level
- Urinalysis
- Electrocardiogram

Need for Referrals

- Ophthalmologist
- Podiatrist
- Dietitian
- Diabetes educator
- Others if indicated

A1C, glycosylated hemoglobin

Adapted from American Diabetes Association (ADA). (2020). Standards of medical care in diabetes—2020. *Diabetes Care*, *43*(Suppl 1), S1–S212.

Intensive therapy must be initiated with caution and must be accompanied by thorough education of the patient and family and by responsible behavior of the patient. Careful screening of patients for capability and responsibility is a key step in initiating intensive therapy.

The therapeutic goal for diabetes management is to achieve euglycemia (normal blood glucose levels) without **hypoglycemia** while maintaining a high quality of life. Diabetes management has five components: nutritional therapy, exercise, monitoring, pharmacologic therapy, and education. Diabetes management involves constant assessment and modification of the treatment plan by health professionals and daily adjustments in therapy by the patient. Although the health care team directs the treatment, it is the individual patient who must manage the complex therapeutic regimen. For this reason, patient and family education is an essential component of diabetes treatment and is as important as all other components of the regimen.

Nutritional Therapy

Nutrition, meal planning, weight control, and increased activity are the foundation of diabetes management (ADA, 2020; Evert, Dennison, Gardner, et al., 2019; Franz, MacLeod, Evert, et al., 2017). The most important objectives in the dietary and nutritional management of diabetes are control of total caloric intake to attain or maintain a reasonable body weight, control of blood glucose levels, and normalization of lipids and blood pressure to prevent heart disease. Success in this area alone is often associated with reversal of hyperglycemia in type 2 diabetes. However, achieving these goals is not easy. Because **medical nutrition therapy (MNT)**—nutritional therapy prescribed for management of diabetes usually given by a registered dietitian—is complex, a registered dietitian who understands the therapy has the major responsibility for designing and educating about this aspect of the therapeutic plan. Nurses and all other members of the health care team must be knowledgeable about nutritional therapy and supportive of patients who need to implement nutritional and lifestyle changes. Nutritional management of diabetes includes the following goals:

1. To achieve and maintain:
   a. Blood glucose levels in the normal range or as close to normal as is safely possible
   b. A lipid and lipoprotein profile that reduces the risk for vascular disease
   c. Blood pressure levels in the normal range or as close to normal as is safely possible
2. To prevent, or at least slow, the rate of development of the chronic complications of diabetes by modifying nutrient intake and lifestyle
3. To address individual nutrition needs, taking into account personal and cultural preferences and willingness to change
4. To maintain the pleasure of eating by only limiting food choices when indicated by scientific evidence

 For patients who have obesity and diabetes (especially those with type 2 diabetes), weight loss is the key to treatment. (It is also a major factor in preventing diabetes.) In general, overweight is considered to be a BMI of 25 kg/m^2 to 29 kg/m^2; obesity is defined as 20% above ideal body weight or a BMI equal to or greater than 30 kg/m^2 (ADA, 2020; WHO, 2018). Calculation of BMI is discussed in Chapter 4, and obesity is discussed further in Chapter 42. Patients who have obesity, type 2 diabetes, and require insulin or oral agents to control blood glucose levels may be able to reduce or eliminate the need for medication through weight loss. A weight loss of 5% to 10% of total weight may significantly improve blood glucose levels. For patients who have obesity and diabetes but do not take insulin or an oral antidiabetic medication, consistent meal content or timing is important but not as critical. Rather, decreasing the overall caloric intake is of greater importance. Meals should not be skipped. Pacing food intake throughout the day decreases demands on the pancreas.

The actions of several oral antidiabetic medications include weight loss. For example, the glucagonlike peptide-1 (GLP-1) agonists are associated with delayed gastric emptying and weight loss. The dipeptidyl peptidase-4 (DPP4) and sodium-glucose cotransporter-2 (SGLT2) inhibitors improve glucose control assisting with weight loss (Keresztes & Peacock-Johnson, 2019). See discussion later in the chapter about oral antidiabetic medications.

Consistently following a meal plan is one of the most challenging aspects of diabetes management. It may be more realistic to restrict calories only moderately. For patients who have lost weight incorporating new dietary habits into their lifestyles, diet education, behavioral therapy, group support, and ongoing nutrition counseling are encouraged to maintain weight loss.

Meal Planning and Related Education

The meal plan must consider the patient's food preferences, lifestyle, usual eating times, and ethnic and cultural background. For patients who require insulin to help control blood glucose levels, maintaining as much consistency as possible in the amount of calories and carbohydrates ingested at each meal is essential. In addition, consistency in the approximate time intervals between meals, with the addition of snacks if necessary, helps prevent hypoglycemic reactions and maintain overall blood glucose control. For patients who can master the insulin-to-carbohydrate calculations, lifestyle can be more flexible and diabetes control more predictable. For those using intensive insulin therapy, there may be greater flexibility in the timing and content of meals by allowing adjustments in insulin dosage for changes in eating and exercise habits. Newer insulin analogues, insulin algorithms, and insulin pumps permit greater flexibility of schedules than was previously possible. This contrasts with the concept of maintaining a constant dose of insulin, requiring strict scheduling of meals to match the onset and duration of the insulin.

The first step in preparing a meal plan is a thorough review of the patient's diet history to identify eating habits and lifestyle and cultural eating patterns (ADA, 2020; Evert et al., 2019; Franz et al., 2017). This includes a thorough assessment of the patient's need for weight loss, gain, or maintenance. In most instances, people with type 2 diabetes require weight reduction.

In educating about meal planning, clinical dietitians use various tools, materials, and approaches. Initial education addresses the importance of consistent eating habits, the relationship of food and insulin, and the provision of an individualized meal plan. In-depth follow-up education then focuses on management skills, such as eating at restaurants; reading food labels; and adjusting the meal plan for exercise, illness, and special occasions. The nurse plays an important role in communicating pertinent information to the dietitian and reinforcing the patient's understanding. Communication between the team is important.

Certain aspects of meal planning, such as the food exchange system, may be difficult to learn. This may be related to limitations in the patient's intellectual level or to emotional issues, such as difficulty accepting the diagnosis of diabetes or feelings of deprivation and undue restriction in eating. In any case, it helps to emphasize that using the exchange system (or any food classification system) provides a new way of thinking about food rather than a new way of eating. It is also important to simplify information as much as possible and to provide opportunities for the patient to practice and repeat activities and information.

Caloric Requirements

Calorie-controlled diets are planned by first calculating a person's energy needs and caloric requirements based on age, gender, height, and weight. An activity element is then factored in to provide the actual number of calories required for weight maintenance. To promote a 1- to 2-lb weight loss per week, 500 to 1000 calories are subtracted from the daily total. The calories are distributed into carbohydrates, proteins, and fats, and a meal plan is then developed, taking into account the patient's lifestyle and food preferences.

Patients may be underweight at the onset of type 1 diabetes because of rapid weight loss from severe hyperglycemia. The goal initially may be to provide a higher-calorie diet to regain lost weight and blood glucose control.

Caloric Distribution

A meal plan for diabetes focuses on the percentages of calories that come from carbohydrates, proteins, and fats (Evert et al., 2019; Franz et al., 2017).

Carbohydrates. The caloric distribution currently recommended is higher in carbohydrates than in fat and protein. In general, carbohydrate foods have the greatest effect on blood glucose levels because they are more quickly digested than other foods and are converted into glucose rapidly. However, research into the appropriateness of a higher-carbohydrate diet in patients with decreased glucose tolerance is ongoing, and recommendations may change accordingly. Currently, the ADA and the Academy of Nutrition and Dietetics (formerly the American Dietetic Association) recommend that for all levels of caloric intake, 50% to 60% of calories should be derived from carbohydrates, 20% to 30% from fat, and the remaining 10% to 20% from protein (Evert et al., 2019). The majority of the selections for carbohydrates should come from whole grains. These recommendations are also consistent with those of the American Heart Association and American Cancer Society.

Carbohydrates consist of sugars (e.g., sucrose) and starches (e.g., rice, pasta, bread). Low glycemic index diets (described later) may reduce postprandial glucose levels. Therefore, the nutrition guidelines recommend that all carbohydrates should be eaten in moderation to avoid high postprandial blood glucose levels (Evert et al., 2019; Franz et al., 2017).

Foods high in carbohydrates, such as sucrose (concentrated sweets), are not totally eliminated from the diet but should be eaten in moderation (up to 10% of total calories), because they are typically high in fat and lack vitamins, minerals, and fiber.

Fats. The recommendations regarding fat content of the diabetic diet include both reducing the total percentage of calories from fat sources to less than 30% of total calories and limiting the amount of saturated fats to 10% of total calories. Additional recommendations include limiting the total intake of dietary cholesterol to less than 300 mg/day. This approach may help reduce risk factors such as increased serum cholesterol levels, which are associated with the development of coronary artery disease—the leading cause of death and disability among people with diabetes (ADA, 2020; Evert et al., 2019).

Protein. The meal plan may include the use of some nonanimal sources of protein (e.g., legumes, whole grains) to help reduce saturated fat and cholesterol intake. In addition, the amount of protein intake may be reduced in patients with early signs of kidney disease.

Fiber. Increased fiber in the diet may improve blood glucose levels, decrease the need for exogenous insulin, and lower total cholesterol and low-density lipoprotein levels in the blood (Evert et al., 2019).

There are two types of dietary fibers: soluble and insoluble. Soluble fiber—in foods such as legumes, oats, and some fruits—plays more of a role in lowering blood glucose and lipid levels than does insoluble

fiber, although the clinical significance of this effect is probably small (Evert et al., 2019). Soluble fiber slows stomach emptying and the movement of food through the upper digestive tract. The potential glucose-lowering effect of fiber may be caused by the slower rate of glucose absorption from foods that contain soluble fiber. Insoluble fiber is found in whole-grain breads and cereals and in some vegetables. This type of fiber along with soluble fiber increases satiety, which is helpful for weight loss. At least 28 g of fiber should be ingested daily (ADA, 2020).

One risk involved in suddenly increasing fiber intake is that it may require adjusting the dosage of insulin or oral agents to prevent hypoglycemia. Other problems may include abdominal fullness, nausea, diarrhea, increased flatulence, and constipation if fluid intake is inadequate. If fiber is added to or increased in the meal plan, it should be done gradually and in consultation with a dietitian. Exchange lists (ADA, 2020) serve as an excellent guide for increasing fiber intake. Fiber-rich food choices within the vegetable, fruit, and starch/bread exchanges are highlighted in the lists.

Food Classification Systems

To educate about diet principles and help in meal planning, several systems have been developed in which foods are organized into groups with common characteristics, such as number of calories, composition of foods (i.e., amount of protein, fat, carbohydrate in the food), or effect on blood glucose levels. Several of these are listed next.

TABLE 46-2 Select Sample Menus from Exchange Lists

Exchanges	Sample Lunch #1	Sample Lunch #2	Sample Lunch #3
2 starch	2 slices bread	Hamburger bun	1 cup cooked pasta
3 meat	2-oz sliced turkey and 1-oz low-fat cheese	3-oz lean beef patty	3-oz boiled shrimp
1 vegetable	Lettuce, tomato, onion	Green salad	½ cup plum tomatoes
1 fat	1-tsp mayonnaise	1-tbsp salad dressing	1-tsp olive oil
1 fruit	1 medium apple	1¼ cup watermelon	1¼ cup fresh strawberries
"Free" items (optional)	Unsweetened iced tea Mustard, pickle, hot pepper	Diet soda 1 tbsp catsup, pickle, onions	Ice water with lemon Garlic, basil

Exchange Lists. A commonly used tool for nutritional management is the exchange lists for meal planning (ADA, 2020). There are six main exchange lists: bread/starch, vegetable, milk, meat, fruit, and fat. Foods within one group (in the portion amounts specified) contain equal numbers of calories and are approximately equal in grams of protein, fat, and carbohydrate. Meal plans can be based on a recommended number of choices from each exchange list. Foods on one list may be interchanged with one another, allowing for variety while maintaining as much consistency as possible in the nutrient content of foods eaten. Table 46-2 presents three sample lunch menus that are interchangeable in terms of carbohydrate, protein, and fat content.

Exchange list information on combination foods such as pizza, chili, and casseroles, as well as convenience foods, desserts, snack foods, and fast foods, is available from the ADA (see the Resources section). Some food manufacturers and restaurants publish exchange lists that describe their products.

Nutrition Labels. Food manufacturers are required to have the nutrition content of foods listed on their packaging, and reading food labels is an important skill for patients to learn and use when food shopping. The label includes information about how many grams of carbohydrate are in a serving of food. This information can be used to determine how much medication is needed. For example, a patient who takes premeal insulin may use the algorithm of 1 unit of insulin for 15 g of carbohydrate. Patients can also be educated to have a "carbohydrate budget" per meal (e.g., 45 to 60 g).

Carbohydrate counting is a nutritional tool used for blood glucose management because carbohydrates are the main nutrients in food that influence blood glucose levels. This method provides flexibility in food choices, can be less complicated to understand than the diabetic food exchange list, and allows more accurate management with multiple daily injections (insulin before each meal). However, if carbohydrate counting is not used with other meal-planning techniques, weight gain can result. A variety of methods are used to count carbohydrates. When developing a diabetic meal plan using carbohydrate counting, all food sources should be considered.

Once digested, 100% of carbohydrates are converted to glucose. Approximately 50% of protein foods (meat, fish, and poultry) are also converted to glucose, and this has minimal effect on blood glucose levels.

While carbohydrate counting is commonly used for blood glucose management with type 1 and type 2 diabetes, it is not a perfect system. All carbohydrates affect the blood glucose level to different degrees, regardless of equivalent serving size (i.e., the glycemic index—see later discussion). When carbohydrate

counting is used, reading labels on food items is the key to success. Knowing what the "carbohydrate budget" for the meal is and knowing how many grams of carbohydrate are in a serving of a food, the patient can calculate the amount in one serving.

Healthy Food Choices. An alternative to counting grams of carbohydrate is measuring servings or choices. This method is used more often by people with type 2 diabetes. It is similar to the food exchange list and emphasizes portion control of total servings of carbohydrate at meals and snacks. One carbohydrate serving is equivalent to 15 g of carbohydrate. Examples of one serving are an apple 2 inches in diameter and one slice of bread. Vegetables and meat are counted as one third of a carbohydrate serving. This system works well for those who have difficulty with more complicated systems.

MyPlate Food Guide. The Food Guide (i.e., MyPlate) is another tool used to develop meal plans. It is commonly used for patients with type 2 diabetes who have a difficult time following a calorie-controlled diet. Foods are categorized into five major groups (grains, vegetables, fruits, dairy, and protein), plus fats and oils (see Chapter 4, Fig. 4-5). Foods (grains, fruits, and vegetables) that are lowest in calories and fat and highest in fiber should make up the basis of the diet. For those with diabetes, as well as for the general population, 50% to 60% of the daily caloric intake should be from these three groups. Foods higher in fat (particularly saturated fat) should account for a smaller percentage of the daily caloric intake. Fats, oils, and sweets should be used sparingly to obtain weight and blood glucose control and to reduce the risk for cardiovascular disease. Reliance on MyPlate may result in fluctuations in blood glucose levels, however, because high-carbohydrate foods may be grouped with low-carbohydrate foods. The guide is appropriately used only as a first-step educational tool for patients who are learning how to control food portions and how to identify which foods contain carbohydrate, protein, and fat.

Glycemic Index. One of the main goals of diet therapy in diabetes is to avoid sharp, rapid increases in blood glucose levels after food is eaten. The term **glycemic index** is used to describe how much a given food increases the blood glucose level compared with an equivalent amount of glucose. The effects of the use of the glycemic index on blood glucose levels and on long-term patient outcomes are unclear, but it may be beneficial (ADA, 2020; Evert et al., 2019). Although more research is necessary, the following guidelines may be helpful when making dietary recommendations:

- Combining starchy foods with protein- and fat-containing foods tends to slow their absorption and lower the glycemic index.
- In general, eating foods that are raw and whole results in a lower glycemic index than eating chopped, puréed, or cooked foods (except meat).
- Eating whole fruit instead of drinking juice decreases the glycemic index, because fiber in the fruit slows absorption.
- Adding foods with sugars to the diet may result in a lower glycemic index if these foods are eaten with foods that are more slowly absorbed.

Patients can create their own glycemic index by monitoring their blood glucose level after ingestion of a particular food. This can help improve blood glucose control through individualized manipulation of the diet. Many patients who use frequent monitoring of blood glucose levels can use this information to adjust their insulin doses in accordance with variations in food intake.

Other Dietary Concerns

Alcohol Consumption

Patients with diabetes do not need to give up alcoholic beverages entirely, but patients and primary providers must be aware of the potential adverse effects of alcohol specific to diabetes. Alcohol is absorbed before other nutrients and does not require insulin for absorption. Large amounts can be converted to fats, increasing the risk for DKA. In general, the same precautions regarding the use of alcohol by people without diabetes should be applied to patients with diabetes. Moderation is recommended. A major danger of alcohol consumption by the patient with diabetes is hypoglycemia, especially for patients who take insulin or insulin secretagogues (medications that increase the secretion of insulin by the pancreas). Alcohol may decrease the normal physiologic reactions in the body that produce glucose (gluconeogenesis). Therefore, if a patient with diabetes consumes alcohol on an empty stomach, there is an increased likelihood of hypoglycemia. In addition, excessive alcohol intake may impair the patient's ability to recognize and treat hypoglycemia or to follow a prescribed meal plan to prevent hypoglycemia. To reduce the risk of hypoglycemia, the patient should be cautioned to consume food along with the alcohol; however, carbohydrate consumed with alcohol may raise blood glucose.

Alcohol consumption may lead to excessive weight gain (from the high caloric content of alcohol), hyperlipidemia, and elevated glucose levels (especially with mixed drinks and liqueurs). Patient education regarding alcohol intake must emphasize moderation in the amount of alcohol consumed. Moderate intake is

considered to be one alcoholic beverage per day for women and two per day for men. Lower-calorie or less-sweet drinks (e.g., light beer, wine) and food intake along with alcohol consumption are advised (ADA, 2020; Evert et al., 2019). Patients with type 2 diabetes who wish to control their weight should incorporate the calories from alcohol into the overall meal plan.

Sweeteners

The use of artificial sweeteners is acceptable, especially if it assists in overall dietary adherence. Moderation in the amount of sweetener used is encouraged to avoid potential adverse effects. There are two main types of sweeteners: nutritive and nonnutritive. The nutritive sweeteners contain calories, and the nonnutritive sweeteners have few or no calories in the amounts normally used.

Nutritive sweeteners include fructose (fruit sugar), sorbitol, and xylitol, all of which provide calories in amounts similar to those in sucrose (table sugar). They cause less elevation in blood sugar levels than sucrose does and are often used in sugar-free foods. Sweeteners containing sorbitol may have a laxative effect.

Nonnutritive sweeteners have minimal or no calories. They are used in food products and are also available for table use. They produce minimal or no elevation in blood glucose levels, and the U.S. Food and Drug Administration (FDA) lists them as safe for people with diabetes.

Misleading Food Labels

Foods labeled "sugarless" or "sugar-free" may still provide calories equal to those of the equivalent sugar-containing products if they are made with nutritive sweeteners. Therefore, these foods should not be considered "free" foods to be eaten in unlimited quantity, because they can elevate blood glucose levels. Foods labeled "dietetic" are not necessarily reduced-calorie foods. Patients are advised that foods labeled dietetic may still contain significant amounts of sugar or fat.

Patients must read the labels of "health foods"—especially snacks—because they often contain carbohydrates (e.g., honey, brown sugar, corn syrup, flour) and saturated vegetable fats (e.g., coconut or palm oil), hydrogenated vegetable fats, or animal fats, which may be contraindicated in people with elevated blood lipid levels.

Exercise

Exercise is extremely important in diabetes management because of its effects on lowering blood glucose and reducing cardiovascular risk factors (ADA, 2020). Exercise lowers blood glucose levels by increasing the uptake of glucose by body muscles and by improving insulin utilization. It also improves circulation and muscle tone. Resistance (strength) training, such as weight lifting, can increase lean muscle mass, thereby increasing the resting metabolic rate. These effects are useful in diabetes in relation to losing weight, easing stress, and maintaining a feeling of well-being. Exercise also alters blood lipid concentrations, increasing levels of high-density lipoproteins and decreasing total cholesterol and triglyceride levels. This is especially important for people with diabetes because of their increased risk of cardiovascular disease.

Exercise Recommendations

Ideally, a person with diabetes should engage in regular exercise. General considerations for exercise in patients with diabetes are presented in Chart 46-4. Exercise recommendations must be altered as necessary for patients with diabetic complications, such as retinopathy, autonomic neuropathy, sensorimotor neuropathy, and cardiovascular disease (ADA, 2020). Increased blood pressure associated with exercise may aggravate diabetic retinopathy and increase the risk of a hemorrhage into the vitreous or retina.

Chart 46-4  **PATIENT EDUCATION**

General Considerations for Exercise in People with Diabetes

The nurse instructs the patient to:

- Exercise three times each week with no more than 2 consecutive days without exercise.
- Perform resistance training twice a week if you have type 2 diabetes.
- Exercise at the same time of day (preferably when blood glucose levels are at their peak) and for the same duration each session.
- Use proper footwear and, if appropriate, other protective equipment (i.e., helmets for cycling).
- Avoid trauma to the lower extremities, especially if you have numbness due to peripheral neuropathy.
- Inspect feet daily after exercise.
- Avoid exercise in extreme heat or cold.
- Avoid exercise during periods of poor metabolic control.
- Stretch for 10 to 15 minutes before exercising.

Adapted from American Diabetes Association (ADA). (2020). Standards of medical care in diabetes—2020. *Diabetes Care*, *43*(Suppl 1), S1–S212.

In general, a slow, gradual increase in the exercise period is encouraged. For many patients, walking is a safe and beneficial form of exercise that requires no special equipment (except for proper shoes) and can be performed anywhere. People with diabetes should discuss an exercise program with their primary provider and undergo a careful medical evaluation with appropriate diagnostic studies before beginning a program (ADA, 2020).

For patients who are older than 30 years and who have two or more risk factors for heart disease, an exercise stress test is recommended prior to starting an exercise program (ADA, 2020). Risk factors for heart disease include hypertension, obesity, high cholesterol levels, abnormal resting electrocardiogram (ECG), sedentary lifestyle, smoking, male gender, and a family history of heart disease. An abnormal stress test may indicate cardiac ischemia. Typically, an abnormal stress test is followed by a cardiac catheterization and, in some cases, with an intervention such as angioplasty, stent placement, or cardiac surgery.

Exercise Precautions

Patients who have blood glucose levels exceeding 250 mg/dL (14 mmol/L) and who have ketones in their urine should not begin exercising until the urine test results are negative for ketones and the blood glucose level is closer to normal. Exercising with elevated blood glucose levels increases the secretion of glucagon, growth hormone, and catecholamines. The liver then releases more glucose, and the result is an increase in the blood glucose level (ADA, 2020).

The physiologic decrease in circulating insulin that normally occurs with exercise cannot occur in patients treated with insulin. Initially, patients who require insulin should be taught to eat a 15-g carbohydrate snack (a fruit exchange) or a snack of complex carbohydrates with a protein before engaging in moderate exercise to prevent unexpected hypoglycemia. The exact amount of food needed varies from person to person and should be determined by blood glucose monitoring.

Another concern for patients who take insulin is hypoglycemia that occurs many hours after exercise. To avoid post-exercise hypoglycemia, especially after strenuous or prolonged exercise, the patient may need to eat a snack at the end of the exercise session and at bedtime and monitor the blood glucose level more frequently. Patients who are capable, knowledgeable, and responsible can learn to adjust their own insulin doses by working closely with a diabetes educator. Others need specific instructions on what to do when they exercise.

Patients taking insulin and participating in extended periods of exercise should test their blood glucose levels before, during, and after the exercise period, and they should snack on carbohydrates as needed to maintain blood glucose levels. Other participants or observers should be aware that the person exercising has diabetes, and they should know what assistance to give if severe hypoglycemia occurs.

In people with type 2 diabetes who are overweight or have obesity, exercise in addition to dietary management both improves glucose metabolism and enhances loss of body fat. Exercise coupled with weight loss improves insulin sensitivity and may decrease the need for insulin or oral antidiabetic agents (ADA, 2020). Eventually, the patient's glucose tolerance may return to normal. Patients with type 2 diabetes who are not taking insulin or an oral agent may not need extra food before exercise.

Gerontologic Considerations

Physical activity that is consistent and realistic is beneficial to older adults with diabetes. Physical fitness in the older adult population with diabetes may lead to improved glycemic control, decreased risk for chronic vascular disease, and an improved quality of life (Eliopoulos, 2018). Advantages of exercise in this population include a decrease in hyperglycemia, a general sense of well-being, and better use of ingested calories, resulting in weight reduction. Because there is an increased incidence of cardiovascular problems in older adults, a physical examination and exercise stress test may be warranted before an exercise program is initiated. A pattern of gradual, consistent exercise, including a combination of stretching, aerobic exercise, and resistance training, should be planned that does not exceed the patient's physical capacity. Physical impairment because of other chronic diseases must also be considered. In some cases, a physical therapy evaluation may be indicated, with the goal of determining exercises specific to the patient's needs and abilities. Tools such as the Go4Life senior fitness booklet may be helpful (see Resources section at the end of chapter).

Monitoring Glucose Levels and Ketones

Blood glucose monitoring is a cornerstone of diabetes management, and **self-monitoring of blood glucose (SMBG)** levels have dramatically altered diabetes care. SMBG is a method of capillary blood glucose testing in which the patient pricks their finger and applies a drop of blood to a test strip that is read by a meter. It is recommended that SMBG occurs when circumstances call for it (e.g., before meals, snacks, exercise) for many patients taking insulin (ADA, 2020).

Self-Monitoring of Blood Glucose

Using SMBG and learning how to respond to the results enable people with diabetes to individualize their treatment regimen to obtain optimal blood glucose control. This allows for detection and prevention of hypoglycemia and hyperglycemia and plays a crucial role in normalizing blood glucose levels, which in turn may reduce the risk of long-term diabetic complications.

Various methods for SMBG are available. Most involve obtaining a drop of blood from the fingertip, applying the blood to a special reagent strip, and allowing the blood to stay on the strip for the amount of time specified by the manufacturer (usually 5 to 30 seconds). The meter gives a digital readout of the blood glucose value. The meters available for SMBG offer various features and benefits such as monthly averages, tracking of events such as exercise and food consumption, and downloading capacity. Most meters are biosensors that can use blood obtained from alternative test sites, such as the forearm. There is a special lancing device that is useful for patients who have painful fingertips or experience pain with fingersticks.

Because laboratory methods measure plasma glucose, most blood glucose monitors approved for patient use in the home and some test strips calibrate blood glucose readings to plasma values. Plasma glucose values are 10% to 15% higher than whole blood glucose values, and it is crucial for patients with diabetes to know whether their monitor and strips provide whole blood or plasma results.

Methods for SMBG must match the skill level and physical capabilities of patients. Factors affecting SMBG performance include visual acuity, fine motor coordination, cognitive ability, comfort with technology and willingness to use it, and cost (Eliopoulos, 2018). Some meters can be used by patients with visual impairments; these meters have audio components to assist in performing the test and obtaining the result. In addition, meters are available to check both blood glucose and blood ketone levels by those who are particularly susceptible to DKA. Most insurance companies, and programs such as Medicare and Medicaid, cover some or all of the costs of meters and strips.

All methods of SMBG carry the risk that patients may obtain and report erroneous blood glucose values as a result of incorrect techniques. Some common sources of error include improper application of blood (e.g., drop too small), damage to the reagent strips caused by heat or humidity, the use of outdated strips, and improper meter cleaning and maintenance.

Nurses play an important role in providing initial education about SMBG techniques. Equally important is evaluating the techniques of patients who are experienced in self-monitoring. Every 6 to 12 months, patients should conduct a comparison of their meter result with a simultaneous laboratory-measured blood glucose level in their provider's office and have their technique observed. The accuracy of the meter and strips can also be assessed with control solutions specific to that meter whenever a new vial of strips is used and whenever the validity of the reading is in doubt.

Candidates for Self-Monitoring of Blood Glucose

SMBG is a useful tool for managing self-care for everyone with diabetes. It is a key component of treatment for any intensive insulin therapy regimen (i.e., 2 to 4 injections per day or the use of an insulin pump) and for diabetes management during pregnancy. It is also recommended for patients with the following conditions:

- Unstable diabetes (severe swings from very high to very low blood glucose levels within a 24-hour day)
- A tendency to develop severe ketosis or hypoglycemia
- Hypoglycemia without warning symptoms

For patients not taking insulin, SMBG is helpful for monitoring the effectiveness of exercise, diet, and oral antidiabetic agents. For patients with type 2 diabetes, SMBG is recommended during periods of suspected hyperglycemia (e.g., illness) or hypoglycemia (e.g., unusual increased activity levels) and when the medication or dosage of medication is modified (ADA, 2020).

Frequency of Self-Monitoring of Blood Glucose

For most patients who require insulin, SMBG is recommended two to four times daily (usually before meals and at bedtime). For patients who take insulin before each meal, SMBG is required at least three times daily before meals to determine each dose (ADA, 2020). Those not receiving insulin may be instructed to assess their blood glucose levels at least two or three times per week, including a 2-hour postprandial test. For all patients, testing is recommended whenever hypoglycemia or hyperglycemia is suspected; with changes in medications, activity, or diet; and with stress or illness.

Responding to Self-Monitoring of Blood Glucose Results

Patients are asked to keep a record or logbook of blood glucose levels so that they can detect patterns. Testing is done at the peak action time of the medication to evaluate the need for dosage adjustments. To evaluate basal insulin and determine bolus insulin doses, testing is performed before meals. To determine the need for bolus doses of regular or rapid-acting insulin (lispro, aspart, or glulisine), testing is done 2 hours after meals. Patients with type 2 diabetes are encouraged to test daily before and 2 hours after the largest meal of the day until individualized blood glucose levels are reached. Thereafter, testing should be done periodically before and after meals. Patients who take insulin at bedtime or who use an insulin infusion pump should also test at 3 am once a week to document that the blood glucose level is not decreasing during the night. If the patient is unwilling or cannot afford to test frequently, then once or twice a day may be sufficient if the time of testing is varied (e.g., before breakfast one day, before lunch the next day).

Patients are more likely to discontinue SMBG if they are not instructed how to use the results to alter the treatment regimen, if they receive no positive reinforcement, and if testing costs increase. At the very least, the patient should be given parameters for contacting the primary provider. Patients using intensive insulin therapy regimens may be instructed in the use of algorithms (rules or decision trees) for changing the insulin doses based on patterns of values greater or less than the target range and the amount of carbohydrate to be consumed. Baseline patterns should be established by SMBG for 1 to 2 weeks.

Using a Continuous Glucose Monitoring System

A continuous glucose monitoring (CGM) system is an advanced way that people living with diabetes can use to monitor blood glucose levels. A CGM can be used with or without an insulin pump (see Fig. 46-2A). A sensor attached to a transmitter is inserted subcutaneously in the abdomen or back of the arm and connected to a wireless monitoring device, where the glucose levels are displayed in real time (see Fig. 46-2B). Sensors are replaced every 7 to 14 days. The data from the CGM device are downloaded, and blood glucose readings are analyzed. The newest CGM is implantable and can be worn for 90 days (Kropff, Choudhary, Neupane, et al., 2017). Although the CGM cannot be used for making decisions about specific insulin doses, it can be used to determine whether treatment is adequate over a 24-hour period. This device is most useful in patients with type 1 diabetes (ADA, 2020).

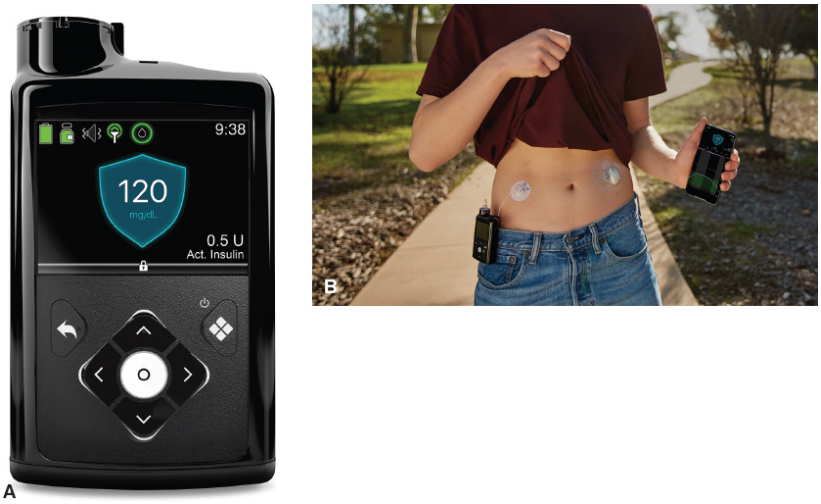

Figure 46-2 • **A.** The MiniMed™ 770G Hybrid Closed Loop System offers SmartGuard™, a feature using continuous glucose monitoring to automatically adjust insulin delivery. **B.** Patient using this insulin pump for self-management of blood glucose and insulin doses. Parts A and B: Manufactured by the diabetes division of Medtronic, Inc. Used with permission.

Testing for Glycated Hemoglobin

Glycated hemoglobin (also referred to as glycosylated hemoglobin, $HgbA_{1C}$, or A1C) is a measure of glucose control for the past 3 months (ADA, 2020). When blood glucose levels are elevated, glucose molecules attach to hemoglobin in red blood cells. The longer the amount of glucose in the blood remains above normal, the more glucose binds to hemoglobin and the higher the glycated hemoglobin level becomes. This complex (hemoglobin attached to the glucose) is permanent and lasts for the life of an individual red blood cell, approximately 120 days. If near-normal blood glucose levels are maintained, with only occasional increases, the overall value will not be greatly elevated. However, if the blood glucose values are consistently high, then the test result is also elevated. If the patient reports mostly normal SMBG results but the glycated hemoglobin is high, there may be errors in the methods used for glucose monitoring, errors in recording results, or frequent elevations in glucose levels at times during the day when the patient is not usually monitoring blood sugar levels. Normal values typically range from 4% to 6% and indicate consistently near-normal blood glucose concentrations. The target range for people with diabetes is less than 7% (53 mmol/mol) (ADA, 2020).

Testing for Ketones

Ketones (or ketone bodies) are by-products of fat breakdown, and they accumulate in the blood and urine. Ketones in the urine signal that there is a deficiency of insulin and control of type 1 diabetes is deteriorating. When there is almost no effective insulin available, the body starts to break down stored fat for energy.

The patient may use a urine dipstick (Ketostix or Chemstrip uK) to detect ketonuria. The reagent pad on the strip turns purple when ketones are present. (One of the ketone bodies is called *acetone,* and this term is frequently used interchangeably with the term *ketones.*) Other strips are available for measuring both urine glucose and ketones (Keto-Diastix or Chemstrip uGK). Large amounts of ketones may depress the color response of the glucose test area, meters that text the blood for ketones are available.

Urine ketone testing should be performed whenever patients with type 1 diabetes have glycosuria or persistently elevated blood glucose levels (more than 240 mg/dL or 13.2 mmol/L for two testing periods in a row) and during illness, in pregnancy with preexisting diabetes, and in gestational diabetes (ADA, 2020).

Pharmacologic Therapy

Insulin is secreted by the beta cells of the islets of Langerhans and lowers the blood glucose level after meals by facilitating the uptake and utilization of glucose by muscle, fat, and liver cells. In the absence of adequate insulin, pharmacologic therapy is essential.

Insulin Therapy

In type 1 diabetes, exogenous insulin must be given for life because the body loses the ability to produce insulin. In type 2 diabetes, insulin may be necessary on a long-term basis to control glucose levels if meal planning and oral agents are ineffective or when insulin deficiency occurs. In addition, some patients in

whom type 2 diabetes is usually controlled by meal planning alone or by meal planning and an oral antidiabetic agent may require insulin temporarily during illness, infection, pregnancy, surgery, or some other stressful event. In many cases, insulin injections are given two or more times daily to control the blood glucose level. Because the insulin dose required by the individual patient is determined by the level of glucose in the blood, accurate monitoring of blood glucose levels is essential; thus, SMBG is a cornerstone of insulin therapy.

TABLE 46-3 Select Categories of Insulin

Time Course	Agent	Onset	Peak	Duration	Indications
Rapid acting	lispro aspart glulisine	15–30 min 15 min 5–15 min	30–90 min 1–3 h 1 h	≤5 h 3–4 h 5 h	Used for rapid reduction of glucose level, to treat postprandial hyperglycemia, or to prevent nocturnal hypoglycemia
Short acting	regular	30–60 min	2–3 h	4–6 h	Usually given 15 min before a meal; may be taken alone or in combination with longer-acting insulin
Intermediate acting	NPH (neutral protamine Hagedorn)	1–1.5 h	4–12 h	Up to 24 h	Food should be taken around the time of onset and peak
Long acting	glargine detemir	3–6 h unknown	Continuous (no peak)	24 h 24 h	Used for basal dose
Rapid-acting inhalation powder	Afrezza	<15 min	~50 min	2–3 h	Administer at the beginning of a meal

Adapted from Comerford, K. C., & Durkin, M. T. (2020). *Nursing 2020 drug handbook.* Philadelphia, PA: Wolters Kluwer; Keresztes, P., & Peacock-Johnson, A. (2019). Type 2 diabetes: A pharmacological update. *American Journal of Nursing, 119*(2), 32–40.

Preparations

A number of insulin preparations are available. They vary according to three main characteristics: time course of action, species (source), and manufacturer (Comerford & Durkin, 2020). Human insulins are produced by recombinant deoxyribonucleic acid (DNA) technology and are the only type of insulin available in the United States.

Time Course of Action. Insulins may be grouped into several categories based on the onset, peak, and duration of action (see Table 46-3).

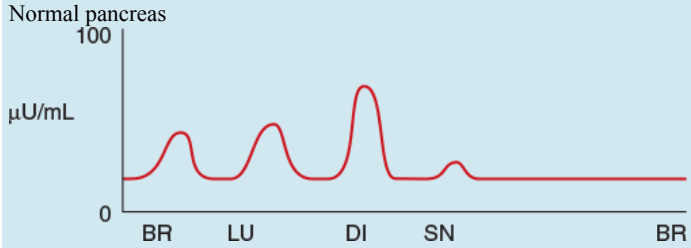
Rapid-acting insulins produce a more rapid effect that is of shorter duration than regular insulin. Because of their rapid onset, the patient should be instructed to eat no more than 5 to 15 minutes after injection. Because of the short duration of action of these insulin analogues, patients with type 1 diabetes and some patients with type 2 or gestational diabetes also require a long-acting insulin (basal insulin) to maintain glucose control. Basal insulin is necessary to maintain blood glucose levels irrespective of meals. A constant level of insulin is required at all times. Intermediate-acting insulins function as basal insulins but may have to be split into 2 injections to achieve 24-hour coverage.

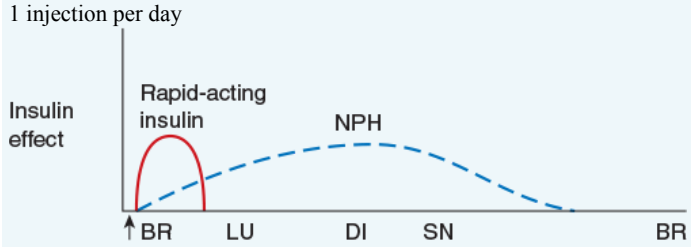
Short-acting insulins are called *regular insulin* (marked R on the bottle). Regular insulin is a clear solution and is usually given 15 minutes before a meal, either alone or in combination with a longer-acting insulin. Regular insulin can be administered IV (Comerford & Durkin, 2020).

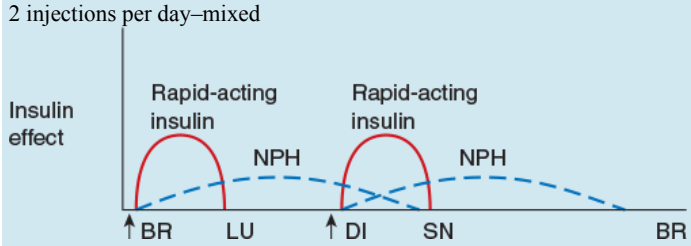
Intermediate-acting insulins are called *NPH insulin* (neutral protamine Hagedorn), which are similar in their time course of action, appear uniformly milky and cloudy. If an NPH insulin is taken alone, it is not crucial that it be taken before a meal but patients should eat some food around the time of the onset and peak of these insulins.

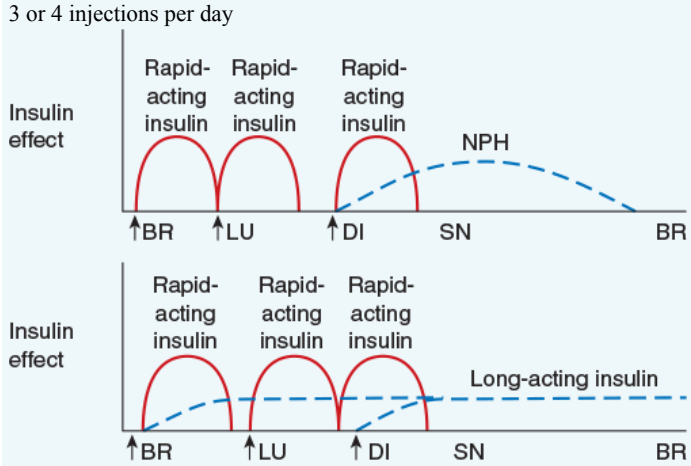
"Peakless" basal or long-acting insulins are used as a basal insulin—that is, the insulin is absorbed very slowly over 24 hours and can be given once a day (Comerford & Durkin, 2020). Because the insulin is in a suspension with a pH of 4, it cannot be mixed with other insulins because this would cause precipitation. It is administered once a day at any time of the day but must be given at the same time each day to prevent overlap of action. Many patients fall asleep, forgetting to take their bedtime insulin, or may be wary of taking insulin before going to sleep. Having these patients take their insulin in the morning ensures that the dose is taken.

Quality and Safety Nursing Alert

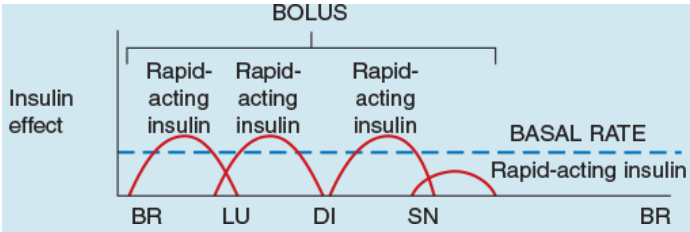








When administering insulin, it is very important to read the label carefully and to be sure that the correct type and dose of insulin is given.



The nurse should emphasize which meals—and snacks—are being "covered" by which insulin doses. In general, the rapid- and short-acting insulins are expected to cover the increase in glucose levels after meals, immediately after the injection; the intermediate-acting insulins are expected to cover subsequent meals; and the long-acting insulins provide a relatively constant level of insulin and act as a basal insulin.

Insulin Regimens

Insulin regimens vary from 1 to 4 injections per day. Usually, there is a combination of a short-acting insulin and a longer-acting insulin. The normally functioning pancreas continuously secretes small amounts of insulin during the day and night. In addition, whenever blood glucose increases after ingestion of food, there is a rapid burst of insulin secretion in proportion to the glucose-raising effect of the food. The goal of all but the simplest, 1-injection insulin regimens is to mimic this normal pattern of insulin secretion in response to food intake and activity patterns. Table 46-4 describes several insulin regimens and the advantages and disadvantages of each.

TABLE 46-4 Insulin Regimens

Schematic Representation	Description	Advantages	Disadvantages
Normal pancreas 	Insulin release increases when blood glucose levels rise and continues at a low steady rate between meals		
1 injection per day 	Before breakfast: • NPH or • NPH with rapid-acting insulin	Simple regimen	Difficult to control fasting blood glucose if effects of NPH do not last Afternoon hypoglycemia may result from attempts to control fasting glucose level by increasing NPH dose
2 injections per day–mixed 	Before breakfast and dinner: • NPH or • NPH with rapid-acting insulin or • Premixed (rapid-acting insulin) insulin	Simplest regimen that attempts to mimic normal pancreas	Need relatively fixed schedule of meals and exercise Cannot independently adjust NPH or regular if premixed insulin is used
3 or 4 injections per day 	Rapid-acting insulin before each meal with: • NPH at dinner or • NPH at bedtime or • Long-acting insulin one or two times a day	More closely mimics normal pancreas than 3-injection regimen Each premeal dose of regular insulin decided independently More flexibility with meals and exercise	Requires more injections than other regimens Requires multiple blood glucose tests on a daily basis Requires intensive education and follow-up
Insulin pump	Uses ONLY rapid-acting insulin infused at continuous, low rate called *basal*	Most closely mimics normal pancreas Decreases unpredictable peaks of	Requires intensive training and frequent follow-up Potential for mechanical

	*rate* (commonly 0.5–1.5 units/h) and premeal *bolus doses* activated by pump wearer	intermediate- and long-acting insulins Increases meal and exercise flexibility	problems Requires multiple blood glucose tests on a daily basis Potential increase in expenses (depending on insurance coverage)

Note: Rapid-acting insulin—lispro, aspart, or glulisine.
BR, breakfast; DI, dinner; ↑, insulin injections; LU, lunch; NPH, neutral protamine Hagedorn; regular; SN, snack.
Adapted from Comerford, K. C., & Durkin, M. T. (2020). *Nursing 2020 drug handbook*. Philadelphia, PA: Wolters Kluwer.

There are two general approaches to insulin therapy: conventional and intensive (described in detail later). The patient can learn to use SMBG results and carbohydrate counting to vary the insulin doses. This allows more flexibility in timing and content of meals and exercise periods. However, complex insulin regimens require a strong level of commitment, intensive education, and close follow-up by the health care team.

The patient should be very involved in the decision regarding which insulin regimen to use. The patient should compare the potential benefits of different regimens with the potential costs (e.g., time involved, number of injections, fingersticks for glucose testing, amount of record keeping). There are no set guidelines as to which insulin regimen should be used for which patient. Members of the health care team should not assume that older patients should automatically be given a simplified regimen, or that all people want to be involved in a complex treatment regimen. The nurse plays an important role in educating the patient about the various approaches to insulin therapy. The nurse should refer the patient to a diabetes and education care specialist, certified diabetes educator (CDE), or a diabetes education center, if available, for further training and education in the insulin treatment regimens.

Conventional Regimen. One approach is to simplify the insulin regimen as much as possible, with the aim of avoiding the acute complications of diabetes (hypoglycemia and symptomatic hyperglycemia). With this type of simplified regimen (e.g., one or more injections of a mixture of short- and intermediate-acting insulins per day), the patient should not vary meal patterns and activity levels. The simplified regimen would be appropriate for the terminally ill, the older adult who is frail and has limited self-care abilities, or patients who are completely unwilling or unable to engage in the self-management activities that are part of a more complex insulin regimen.

Intensive Regimen. The second approach is to use a more complex insulin regimen to achieve as much control over blood glucose levels as is safe and practical. A more complex insulin regimen allows the patient more flexibility to change the insulin doses from day to day in accordance with changes in eating and activity patterns, with stress and illness, and as needed for variations in the prevailing glucose level.

While intensive treatment (3 or 4 injections of insulin per day) reduces the risk of complications, not all people with diabetes are candidates for very tight control of blood glucose. The risk of severe hypoglycemia increases threefold in patients receiving intensive treatment (ADA, 2020). Patients who have received a kidney transplant because of nephropathy and chronic kidney disease should follow an intensive insulin regimen to preserve function of the new kidney.

Those who are not candidates include those with:

- Nervous system disorders rendering them unaware of hypoglycemic episodes (e.g., those with autonomic neuropathy)
- Recurring severe hypoglycemia
- Irreversible diabetic complications, such as blindness or ESKD
- Severe cerebrovascular or cardiovascular disease
- Ineffective self-care skills

Complications of Insulin Therapy

Local Allergic Reactions. A local allergic reaction (redness, swelling, tenderness, and induration or a 2- to 4-cm wheal) may appear at the injection site 1 to 2 hours after the administration of insulin. Reactions usually resolve in a few hours or days. If they do not resolve, another type of insulin can be prescribed (Comerford & Durkin, 2020).

Systemic Allergic Reactions. Systemic allergic reactions to insulin are rare. When they do occur, there is an immediate local skin reaction that gradually spreads into generalized urticaria (hives). These rare

reactions are occasionally associated with generalized edema or anaphylaxis. The treatment is desensitization, with small doses of insulin given in gradually increasing amounts using a desensitization kit.

Insulin Lipodystrophy. Lipodystrophy refers to a localized reaction, in the form of either lipoatrophy or lipohypertrophy, occurring at the site of insulin injections. Lipoatrophy is the loss of subcutaneous fat; it appears as slight dimpling or more serious pitting of subcutaneous fat. The use of human insulin has almost eliminated this disfiguring complication.

Lipohypertrophy, the development of fibrofatty masses at the injection site, is caused by the repeated use of an injection site. If insulin is injected into scarred areas, absorption may be delayed. This is one reason that rotation of injection sites is so important. Patients should avoid injecting insulin into these areas until the hypertrophy disappears.

Resistance to Injected Insulin. Patients may develop insulin resistance and require large insulin doses to control symptoms of diabetes (Comerford & Durkin, 2020). In most patients with diabetes who take insulin, immune antibodies develop and bind the insulin, thereby decreasing the insulin available for use. All insulins cause some antibody production in humans.

Very few patients who are resistant develop high levels of antibodies. Many of these patients have a history of insulin therapy interrupted for several months or longer. Treatment consists of administering a more concentrated insulin preparation, such as U-500, which is available by special order (Comerford & Durkin, 2020). U-500 insulin is never stored with other insulin preparations due to the risk of overdose if accidentally given to the wrong patient (Comerford & Durkin, 2020). Occasionally, corticosteroid therapy is needed to block the production of antibodies. This may be followed by a gradual reduction in the insulin requirement. Therefore, patients must monitor their blood for hypoglycemia.

Morning Hyperglycemia. An elevated blood glucose level on arising in the morning is caused by an insufficient level of insulin, which may be caused by several factors: the dawn phenomenon, the Somogyi effect, or insulin waning. The dawn phenomenon is characterized by a relatively normal blood glucose level until approximately 3 AM, when blood glucose levels begin to rise. The phenomenon is thought to result from nocturnal surges in growth hormone secretion, which creates a greater need for insulin in the early morning hours in patients with type 1 diabetes. It must be distinguished from insulin waning (the progressive increase in blood glucose from bedtime to morning) and from the Somogyi effect (nocturnal hypoglycemia followed by rebound hyperglycemia). Insulin waning is frequently seen if the evening NPH dose is given before dinner; it is prevented by moving the evening dose of NPH insulin to bedtime.

Chart 46-5

Characteristics and Treatment of Morning Hyperglycemia

Insulin Waning

Progressive rise in blood glucose from bedtime to morning.
Treated by increasing evening (predinner or bedtime) dose of intermediate- or long-acting insulin, or instituting a dose of insulin before the evening meal if one is not already part of the treatment regimen.

Dawn Phenomenon

Relatively normal blood glucose until early morning hours when levels begin to rise.
Treated by changing time of injection of evening intermediate-acting insulin from dinnertime to bedtime.

Somogyi Effect

Normal or elevated blood glucose at bedtime, early morning hypoglycemia, and a subsequent increased blood glucose caused by the production of counter-regulatory hormones.
Treated by decreasing evening (predinner or bedtime) dose of intermediate-acting insulin, or increasing bedtime snack.

Adapted from Norris, T. L. (2019). *Porth's pathophysiology: Concepts of altered health state* (10th ed.). Philadelphia, PA: Wolters Kluwer.

It may be difficult to tell from a patient's history what the cause is for morning hyperglycemia. To determine the cause, the patient must be awakened once or twice during the night to test blood glucose levels. Testing at bedtime, at 3 am, and on awakening provides information that can be used to make adjustments in insulin to avoid morning hyperglycemia.

Chart 46-5 summarizes the differences among insulin waning, the dawn phenomenon, and the Somogyi effect.

Methods of Insulin Delivery

Methods of insulin delivery include traditional subcutaneous injections, insulin pens, jet injectors, and insulin pumps. (See later Nursing Management discussion of traditional subcutaneous injections.)

Insulin Pens. Insulin pens use small (150- to 300-unit) prefilled insulin cartridges that are loaded into a penlike holder. A disposable needle is attached to the device for insulin injection. Insulin is delivered by dialing in a dose or pushing a button for every 1- or 2-unit increment given. People using these devices still need to insert the needle for each injection (see Fig. 46-3); however, they do not need to carry insulin bottles or draw up insulin before each injection. These devices are most useful for patients who need to inject only one type of insulin at a time (e.g., premeal rapid-acting insulin three times a day, bedtime NPH insulin) or who can use the premixed insulins. These pens are convenient for those who administer insulin before dinner if eating out or traveling. They are also useful for patients with impaired manual dexterity, vision, or cognitive function, which makes the use of traditional syringes difficult.

Jet Injectors. As an alternative to needle injections, jet injection devices deliver insulin through the skin under pressure in an extremely fine stream. These devices are more expensive and require thorough training and supervision when first used. In addition, patients should be cautioned that absorption rates, peak insulin activity, and insulin levels may be different when changing to a jet injector. (Insulin given by jet injector is usually absorbed faster.) The use of jet injectors has been associated with bruising in some patients.

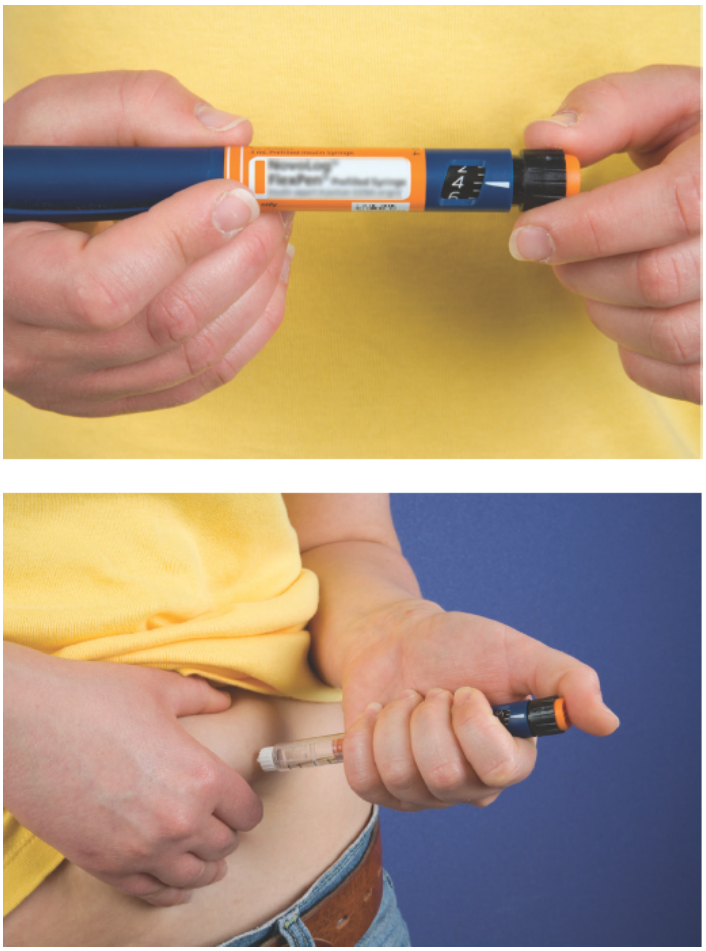


Figure 46-3 • Prefilled insulin syringe.

Insulin Pumps. Continuous subcutaneous insulin infusion involves the use of small, externally worn devices called insulin pumps (ADA, 2020). This technology mimics the functions of a healthy pancreas by providing automated systems that can adjust insulin delivery based on basal (background) insulin every 5 minutes. Insulin pumps contain a 3-mL syringe attached to a long (24- to 42-inch), thin, narrow-lumen tube with a needle or Teflon catheter attached to the end. The patient inserts the needle or catheter into subcutaneous tissue (usually on the abdomen) and secures it with tape or a transparent dressing. The needle or catheter is changed at least every 3 days. The pump is then worn either on the patient's clothing or in a pocket. Some women keep the pump tucked into the front or side of the bra. Additional accessories, such as belt, clip or pouch can be used to carry an insulin pump.

When an insulin pump is used, insulin is delivered by subcutaneous infusion at a basal rate that ranges from 0.25 to 2 units per hour depending on the device. When a meal is consumed, the patient calculates a dose of insulin to metabolize the meal by counting the total amount of carbohydrate for the meal using a predetermined insulin-to-carbohydrate ratio; for example, a ratio of 1 unit of insulin for every 15 g of carbohydrate would require 3 units for a meal with 45 g of carbohydrate. This allows flexibility of meal timing and content.

Possible disadvantages of insulin pumps are unexpected disruptions in the flow of insulin from the pump that may occur if the tubing or needle becomes occluded, if the supply of insulin runs out, or if the battery is depleted, increasing the risk of DKA. Effective education to produce knowledgeable patients minimizes this risk. There is the potential for infection at needle insertion sites. Hypoglycemia may occur with insulin pump therapy; however, this is usually related to the lowered blood glucose levels that many patients achieve rather than to a specific problem with the pump itself. The tight diabetes control associated with the use of an insulin pump may increase the incidence of hypoglycemia unawareness because of the very gradual decline in serum glucose level, from more than 70 mg/dL (3.9 mmol/L) to less than 60 mg/dL (3.3 mmol/L).

Some patients find that wearing the pump for 24 hours each day is inconvenient. However, the pump can easily be disconnected, per patient preference, for limited periods, such as for showering, exercise, swimming, or sexual activity.

Candidates for the insulin pump must be willing to assess their blood glucose level several times daily with either SMBG or CGM (ADA, 2020). In addition, they must be psychologically stable and comfortable about having diabetes, because the insulin pump is often a visible sign to others and a constant reminder to patients that they have diabetes. Most important, patients using insulin pumps must have extensive education in the use of the pump and in self-management of blood glucose and insulin doses. They must work closely with a team of health care professionals who are experienced in insulin pump therapy—specifically, a diabetologist/endocrinologist, a dietitian, and a diabetes and education specialist or CDE.

The most common risk of insulin pump therapy is DKA which can occur if there is an occlusion in the infusion set or tubing. Because only rapid-acting insulin is used in the pump, any interruption in the flow of insulin may rapidly cause the patient to be without insulin. The patient should be taught to administer insulin by manual injection if an insulin interruption is suspected (e.g., no response in blood glucose level after a meal bolus).

Many insurance companies cover the cost of pump therapy. If not, the extra expense of the pump and associated supplies may be a deterrent for some patients. Medicare covers insulin pump therapy for patients with type 1 diabetes.

Insulin pumps have been used in patients with type 2 diabetes whose beta-cell function has diminished and who require insulin. Patients with a hectic lifestyle often do well with an insulin pump. There is no risk of DKA when there is an interruption of the flow of insulin in people with type 2 diabetes wearing an insulin pump.

Transplantation of Pancreatic Cells. Transplantation of the whole pancreas or a segment of the pancreas is being performed on a limited population (mostly patients with diabetes who are receiving a kidney transplantation simultaneously) (Aref, Zayan, Pararajasingam, et al., 2019). Patients must weigh the risks of antirejection medications against the advantages of pancreas transplantation. Implantation of insulin-producing pancreatic islet cells is another approach. This latter approach involves a less extensive surgical procedure and a potentially lower incidence of immunogenic problems. However, thus far, independence from exogenous insulin has been limited to 2 years after transplantation of islet cells. Results of studies of patients younger than 50 years of age with islet cell transplants using less toxic antirejection drugs have shown some promise (Aref et al., 2019). These procedures are not widely available due to a shortage of organs for transplantation.

Oral Antidiabetic Agents

Oral antidiabetic agents may be effective for patients who have type 2 diabetes that cannot be treated effectively with MNT and exercise alone. In the United States, oral antidiabetic agents include second-generation sulfonylureas, biguanides, alpha-glucosidase inhibitors, non-sulfonylurea insulin secretogogues (meglitinides, phenylalanine derivatives), thiazolidinediones (glitazones), dipeptide peptidase-4 (DPP-4) inhibitors, glucagonlike peptide-1 receptor agonists (GLP-1), and sodium-glucose cotransporter 2 (SGL-2) inhibitors (see Table 46-5). The thiazolidinediones are a class of oral antidiabetic medications that reduce insulin resistance in target tissues, enhancing insulin action without directly stimulating insulin secretion. Second-generation sulfonylureas and meglitinides are insulin secretagogues (Keresztes & Peacock-Johnson, 2019). Patients must understand that oral agents are prescribed as an addition to (not a substitute for) other treatment modalities, such as MNT and exercise. The use of oral antidiabetic medications may need to be

halted temporarily and insulin prescribed if hyperglycemia develops that is attributable to infection, trauma, or surgery. See later section on glycemic control in the patient who is hospitalized.

Because mechanisms of action vary (see Fig. 46-4), effects may be enhanced with the use of a multidose, or more than one medication (ADA, 2020). A combination of oral agents with insulin, usually glargine at bedtime, has also been used as a treatment for some patients with type 2 diabetes. Insulin therapy may be used from the onset for newly diagnosed patients with type 2 diabetes who are symptomatic and have high blood glucose and A1C levels (ADA, 2020).

Other Pharmacologic Therapy

Additional medications are available for use in the pharmacologic management of diabetes. These injectables are adjunct therapies, not a substitute for insulin if insulin is required to control diabetes.

Pramlintide, a synthetic analogue of human amylin, a hormone that is secreted by the beta cells of the pancreas, is approved for treatment of both type 1 and type 2 diabetes (Comerford & Durkin, 2020). It is used to control hyperglycemia in adults who have not achieved acceptable levels of glucose control despite the use of insulin at mealtimes. It is used with insulin, not in place of insulin. It acts to slow the rate at which food leaves the stomach and reduces appetite (Comerford & Durkin, 2020). The goal of therapy is to minimize fluctuations in daily glucose levels and provide better glucose control. Pramlintide must be injected subcutaneously 2 in from an insulin injection site (Comerford & Durkin, 2020). Patients are instructed to monitor their blood glucose levels closely during the initial period of use of pramlintide.

Nursing Management

Nursing management of patients with diabetes can involve treatment of a wide variety of physiologic disorders, depending on the patient's health status and whether the patient is newly diagnosed or seeking care for an unrelated health problem. Glucose control in patients diagnosed with diabetes as well as those who have not been diagnosed is an important consideration in the hospital setting. Nursing management of patients with DKA and HHS and of those with diabetes as a secondary diagnosis is discussed in subsequent sections of this chapter.

Because all patients with diabetes must master the concepts and skills necessary for long-term management and avoidance of potential complications of diabetes, a solid educational foundation is necessary for competent self-care and is an ongoing focus of nursing care.

TABLE 46-5  Select Oral Antidiabetic Medications

Generic Name	Action/Indications	Side Effects	Nursing Implications
Alpha-Glucosidase Inhibitors			
acarbose miglitol	Delay absorption of complex carbohydrates in the intestine and slow entry of glucose into systemic circulation Does not increase insulin secretion Can be used alone or in combination with sulfonylureas, metformin, or insulin to improve glucose control	Hypoglycemia (risk increased if used with insulin or other antidiabetic agents) GI side effects (abdominal discomfort or distention, diarrhea, flatulence) Drug–drug interactions	Must be taken with first bite of food to be effective Monitor for GI side effects (diarrhea, abdominal distention). Monitor for blood glucose levels to assess effectiveness of therapy. Monitor liver function studies every 3 mo for 1 yr, then periodically. Contraindicated in patients with GI or kidney dysfunction, or cirrhosis. ***Alert:*** Hypoglycemia must be treated with glucose, not sucrose.
Biguanides			
metformin metformin with glyburide	Inhibit production of glucose by the liver Increase body tissue sensitivity to insulin Decrease hepatic synthesis of cholesterol	Lactic acidosis Hypoglycemia if metformin is used in combination with insulin or other antidiabetic agents Drug–drug interaction GI disturbances Contraindicated in patients with impaired kidney or liver function, respiratory insufficiency, severe infection, or alcohol abuse	Monitor for lactic acidosis and hypoglycemia. Monitor kidney function. Patients taking metformin are at increased risk for acute kidney injury and lactic acidosis with the use of iodinated contrast material for diagnostic studies; metformin should be stopped 48 h prior to and for 48 h after the use of contrast agent or until kidney function is evaluated and normal. Check for interactions with other medications.
Dipeptidyl Peptidase-4 (DPP-4) Inhibitors			
alogliptin linaglipitin saxagliptin sitagliptin vildagliptin	Increase and prolong the action of incretin, a hormone that increases insulin release and decreases glucagon levels, with the result of improved glucose control	Upper respiratory infection Stuffy or runny nose and sore throat Headache Stomach discomfort and diarrhea Hypoglycemia, if used with sulfonylurea	Usually given once a day. Used alone or with other oral antidiabetic agents. Instruct patient about signs and symptoms of hypoglycemia and other adverse effects to report. Monitor kidney function.
Glucagonlike peptide-1 agonist (GLP-1)			
dulaglutide liraglutide	Enhances glucose-dependent insulin secretion and exhibit other antihyperglycemic actions following their release into the circulation from the gastrointestinal tract.	Pancreatitis, weight loss, diarrhea, nausea, vomiting, reaction at injection site, cough	Given once a day by subcutaneous injection.
Non-Sulfonylurea Insulin Secretagogues			
nateglinide categorized as a D-phenylalanine derivative repaglinide categorized as a meglitinide	Stimulate pancreas to secrete insulin Can be used alone or in combination with metformin or thiazolidinediones to improve glucose control	Hypoglycemia/weight gain less likely than sulfonylureas Drug–drug interactions (with ketoconazole, fluconazole, erythromycin, rifampin, isoniazid)	Monitor blood glucose levels to assess effectiveness of therapy. Has rapid action and short half-life Should be taken only if able to eat a meal immediately. Educate patients about symptoms of hypoglycemia. Monitor patients with impaired liver function and renal impairment. Has no effect on plasma lipids. Is taken before each meal. Check for interactions with other medications.
Second-Generation Sulfonylureas			
glimepiride	Stimulate beta cells of the	Hypoglycemia	Monitor patient for hypoglycemia.

glipizide glyburide	pancreas to secrete insulin; may improve binding between insulin and insulin receptors or increase the number of insulin receptors Have more potent effects than first-generation sulfonylureas May be used in combination with metformin or insulin to improve glucose control	Mild GI symptoms Weight gain Drug–drug interactions (NSAIDs, warfarin, sulfonamides)	Monitor blood glucose and urine ketone levels to assess effectiveness of therapy. Patients at high risk for hypoglycemia: advanced age, renal insufficiency. When taken with beta-adrenergic blocking agents, may mask usual warning signs and symptoms of hypoglycemia. Instruct patients to avoid the use of alcohol. Contraindicated with sulfa allergy.
Sodium-glucose co-transporter 2 (SGL-2) Inhibitors			
anagliflozin dapagliflozin empagliflozin	Prevents the kidneys from reabsorbing glucose back into the blood, therefore lowering glucose by releasing glucose into the urine	Urinary tract infections Hypoglycemia May increase LDL and HDL cholesterol	Should be taken once daily before first meal in the morning. Monitor for genital or urinary tract infections.
Thiazolidinediones (or Glitazones)			
pioglitazone rosiglitazone	Sensitize body tissue to insulin; stimulate insulin receptor sites to lower blood glucose and improve action of insulin May be used alone or in combination with sulfonylurea, metformin, or insulin	Hypoglycemia (risk increased with the use of insulin or other antidiabetic agents) Anemia Weight gain, edema Decrease effectiveness of oral contraceptives Possible liver dysfunction Drug–drug interactions Hyperlipidemia (has variable effect on lipids; pioglitazone may be preferred choice in patients with lipid abnormalities) Impaired platelet function	Monitor blood glucose levels to assess effectiveness of therapy. Monitor liver function tests. Arrange dietary education to establish weight control program. Instruct patient taking oral contraceptives about increased risk of pregnancy.

GI, gastrointestinal; NSAIDs, nonsteroidal anti-inflammatory drugs.

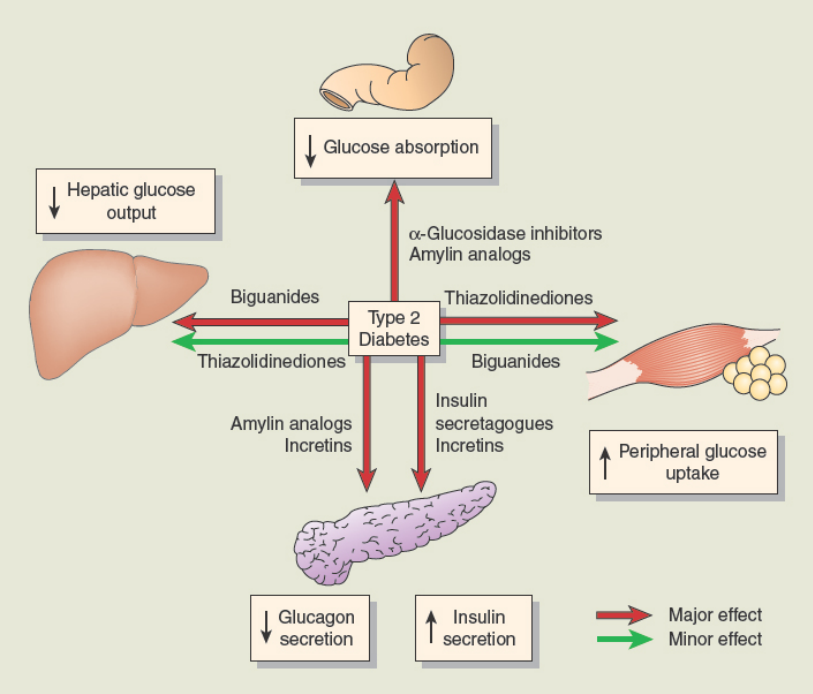

Figure 46-4 • Action sites of hypoglycemic agents and mechanisms of lowering blood glucose in type 2 diabetes. The incretins are the dipeptidyl peptidase-4 inhibitors and glucagonlike peptide-1 agonists.

Managing Glucose Control in the Hospital Setting

Hyperglycemia can prolong lengths of stay and increase infection rates and mortality; thus, nurses need to address glucose management in all hospital patients. Hyperglycemia occurs most often in patients with known diabetes (i.e., type 1, type 2, gestational) and in those newly diagnosed with diabetes or stress hyperglycemia. Nursing management of hyperglycemia in the hospital uses the following principles (ADA, 2020):

- Blood glucose targets are 140 to 180 mg/dL.
- Insulin (subcutaneous or IV) is preferred to oral antidiabetic agents to manage hyperglycemia.
- Hospital insulin protocols or order sets should minimize complexity, ensure adequate staff training, include standardized hypoglycemic treatment, and make guidelines available for glycemic goals and insulin dosing.
- Appropriate timing of blood glucose checks, meal consumption, and insulin dose are all crucial for glucose control and to avoid hypoglycemia.

Providing Patient Education

Diabetes is a chronic illness that requires a lifetime of special self-management behaviors (ADA, 2020). Because MNT, physical activity, medication, and physical and emotional stress affect diabetic control, patients must learn to balance a multitude of factors.

Developing a Diabetes Education Plan

Patients with new-onset type 1 diabetes are hospitalized for short periods or may be managed completely on an outpatient basis. Patients with new-onset type 2 diabetes are rarely hospitalized for initial care. Outpatient diabetes education and training programs have proliferated with the availability of third-party reimbursement. All encounters with patients with diabetes are opportunities for reinforcement of self-management skills, regardless of the setting.

Many health systems employ nurses and registered dietitians who specialize in diabetes education and management and who are certified by the National Certification Board for Diabetes Educators as CDEs. However, because of the large number of patients with diabetes all nurses play a vital role in identifying patients with diabetes, assessing self-care skills, providing basic education, reinforcing the education

provided by the specialist, and referring patients for follow-up care. Diabetes patient education programs that have been peer-reviewed by the ADA as meeting National Standards for Diabetes Self-Management Education can be reimbursed for education (Davidson, Ross, & Castor, 2018).

Unfolding Patient Stories: Skyler Hansen • Part 2

Recall from Chapter 5 **Skyler Hansen**, a high school student recently diagnosed with type 1 diabetes. Outline a diabetes education plan for Skyler and his parents. What are important patient education topics, resources, and methods for the nurse to consider? How would the nurse evaluate whether the patient and his family understand the education provided?

Care for Skyler and other patients in a realistic virtual environment: ***vSim** for Nursing* (**thepoint.lww.com/vSimMedicalSurgical**). Practice documenting these patients' care in DocuCare (**thepoint.lww.com/DocuCareEHR**).

Organizing Information

There are various strategies for organizing and prioritizing the vast amount of information that must be taught to patients with diabetes. In addition, many hospitals and outpatient diabetes centers have devised written guidelines, care plans, and documentation forms (often based on ADA guidelines) that may be used to document and evaluate education (Davidson et al., 2018).

A general approach is to organize information and skills into two main categories: basic or initial, and in-depth (advanced) or continuing education.

Educating Patients About Basic Skills. Basic skills must be learned by all patients with newly diagnosed type 1 or type 2 diabetes and all patients receiving insulin for the first time. Basic information that patients must know is included in Chart 46-6.

For patients with newly diagnosed type 2 diabetes, emphasis is initially placed on meal planning, exercise, and weight loss if applicable. Those who are starting to take oral antidiabetic agents need to know about detecting, preventing, and treating hypoglycemia. If diabetes has gone undetected for many years, the patient may already be experiencing some chronic complications from diabetes. Therefore, for some patients with newly diagnosed type 2 diabetes, basic diabetes education must include information on preventive skills, such as foot care (Davidson et al., 2018) and eye care (e.g., planning yearly or more frequent complete [dilated eye] examinations by an ophthalmologist, understanding that retinopathy is largely asymptomatic until advanced stages).

Patients also need to realize that once they master the basic skills and information, diabetes education is a life-long process. Acquiring in-depth and advanced diabetes knowledge occurs both formally through programs of continuing education and informally through experience and sharing of information with other people with diabetes.

Chart 46-6 **PATIENT EDUCATION**

Basic Skills for People with Diabetes

The nurse includes the following basic information in education:

1. Pathophysiology
   a. Basic definition of diabetes (having a high blood glucose level)
   b. Normal blood glucose ranges and target blood glucose levels
   c. Effect of insulin and exercise (decrease glucose)
   d. Effect of food and stress, including illness and infections (increase glucose)
   e. Basic treatment approaches
2. Treatment modalities
   a. Administration of insulin and oral antidiabetic medications
   b. Meal planning (food groups, timing of meals)
   c. Monitoring of blood glucose and urine ketones
3. Recognition, treatment, and prevention of acute complications
   a. Hypoglycemia
   b. Hyperglycemia
4. Pragmatic information
   a. Where to buy and store insulin, syringes, and glucose monitoring supplies
   b. When and how to contact the primary provider

Adapted from American Diabetes Association (ADA). (2020). Standards of medical care in diabetes—2020. *Diabetes Care*, *43*(Suppl 1), S1–S212.

Planning In-Depth and Continuing Education. This education involves more details related to basic skills (e.g., learning to vary food choices [carbohydrate counting], type of insulin, preparing for travel) as well as learning preventive measures for avoiding long-term complications from diabetes. Preventive measures include foot care, eye care, general hygiene (e.g., skin care, oral hygiene), and risk factor management (e.g., control of blood pressure, blood glucose, cholesterol, weight) (ADA, 2020; Davidson et al., 2018).

More advanced continuing education may include alternative methods for insulin delivery, such as the insulin pump, CGM, and algorithms or rules for evaluating and adjusting insulin doses. The degree of advanced diabetes education to be provided depends on the patient's interest and ability. However, learning preventive measures (especially foot and eye care) is mandatory for early detection and treatment to reduce the occurrence of amputations and blindness in patients with diabetes.

Assessing Readiness to Learn

Before initiating diabetes education, the nurse assesses the patient's (and family's) readiness to learn. When patients are first diagnosed with diabetes (or first told of their need for insulin), they often go through stages of the grieving process. These stages may include shock and denial, anger, depression, negotiation, and acceptance. The amount of time it takes for the patient and family members to work through the grieving process varies from patient to patient. They may experience helplessness, guilt, altered body image, loss of self-esteem, and concern about the future. The nurse must assess the patient's coping strategies and reassure the patient and family that feelings of depression and shock are normal.

Asking the patient and family about their major concerns or fears is an important way to learn about any misinformation that may be contributing to anxiety. Simple, direct information should be provided to dispel misconceptions. Once the patient masters basic skills, more information is provided.

Patients who are in the hospital rarely have the luxury of waiting until they feel ready to learn; short lengths of hospital stay necessitate initiation of basic skill education as early as possible. This gives the patient the opportunity to practice skills with supervision by the nurse before discharge. Follow-up in the home is often necessary for reinforcement of skills.

The nurse evaluates the patient's social situation for factors that may influence the diabetes treatment and education plan, such as:

- Low literacy level (may be evaluated while assessing for visual deficits by having the patient read from educational materials)
- Limited financial resources or lack of health insurance
- Presence or absence of family support
- Typical daily schedule (the patient is asked about the timing and number of usual daily meals, work and exercise schedule, plans for travel)

- Cognitive deficits or other disabling conditions, obtained from the patient's health history and physical assessment (the patient is assessed for aphasia or decreased ability to follow simple commands)

Cultural beliefs may also impact adherence to a regimen.

Educating Experienced Patients

Nurses need to annually assess the skills and self-care behaviors of patients who have had diabetes for many years (Davidson et al., 2018). Assessment of these patients must include direct observation of skills, not just the patient's self-report of self-care behaviors. In addition, these patients must be fully aware of preventive measures related to foot care, eye care, and risk factor management. Those experiencing long-term complications from diabetes for the first time may go through the grieving process again. Some patients may have a renewed interest in diabetes self-care in the hope of delaying further complications. Others may have guilt and depression. The patient is encouraged to discuss feelings and fears related to complications. Meanwhile, the nurse provides appropriate information regarding complications from diabetes.

Determining Education Methods

Maintaining flexibility with regard to education approaches is important. Providing education on skills and information in a logical sequence is not always the most helpful method for patients. For example, many patients fear self-injection. Before they learn how to prepare, purchase, store, and mix insulins, they should be taught to insert the needle and inject insulin (or practice with saline solution).

Various tools can be used to complement education. Many of the companies that manufacture products for diabetes self-care also provide booklets, videotapes, DVDs, or on-line materials to assist in patient education. Educational materials are also available from many sources (see the Resources section). It is important to use a variety of written handouts that match the patient's learning needs (including different languages, low-literacy information, and large print) and reading level and to ensure that these materials are technically accurate. Patients can continue learning about diabetes care by participating in community-based educational programs and other sources such as Web-based programs (Davidson et al., 2018).

Educating Patients to Self-Administer Insulin

Insulin injections are self-administered into the subcutaneous tissue with the use of special insulin syringes. Basic information includes explanations of the equipment, insulins, and syringes and how to mix insulin, if necessary.

Storing Insulin

Whether insulin is the short- or the long-acting preparation, vials not in use, including spare vials or pens, should be refrigerated. Extremes of temperature should be avoided; insulin should not be allowed to freeze and should not be kept in direct sunlight or in a hot car. The insulin vial in use should be kept at room temperature to reduce local irritation at the injection site, which may occur if cold insulin is injected. If a vial of insulin will be used up within 1 month, it may be kept at room temperature. The patient should be instructed to always have a spare vial of the type or types of insulin used (ADA, 2020). Cloudy insulins should be thoroughly mixed by gently inverting the vial or rolling it between the hands before drawing the solution into a syringe or a pen (Comerford & Durkin, 2020). The patient needs to be educated to pay attention to the expiration date on any type of insulin.

Bottles of intermediate-acting insulin should also be inspected for flocculation, which is a frosted, whitish coating inside the bottle. This occurs most commonly with insulins that are exposed to extremes of temperature. If a frosted, adherent coating is present, some of the insulin is bound, inactive, and should not be used.

Selecting Syringes

Syringes must be matched with the insulin concentration (e.g., U-100). Currently, three sizes of U-100 insulin syringes are available:

- 1-mL syringe, 100-unit capacity
- 0.5-mL syringe, 50-unit capacity
- 0.3-mL syringe, 30-unit capacity

The concentration of insulin used in the United States is U-100; that is, there are 100 units per milliliter (or cubic centimeter). Small syringes allow patients who require small amounts of insulin to measure and draw up the amount of insulin accurately. There is a U-500 (500 units/mL) concentration of insulin available by special order for patients who have severe insulin resistance and require massive doses of insulin.

Most insulin syringes have a disposable 27- to 29-gauge needle that is approximately 0.5 in long. The smaller syringes are marked in 1-unit increments and may be easier to use for patients with visual deficits

and those taking very small doses of insulin. The 1-mL syringes are marked in 1- and 2-unit increments. A small disposable insulin needle (31 gauge, 8 mm long) is available for very thin patients and children.

Mixing Insulins

When rapid- or short-acting insulins are to be given simultaneously with longer-acting insulins, they are usually mixed together in the same syringe; the longer-acting insulins must be mixed thoroughly before drawing into the syringe. It is important that patients prepare their insulin injections consistently from day to day.

There are varying opinions regarding which type of insulin (short- or longer-acting) should be drawn up into the syringe first when they are going to be mixed, but the ADA recommends that the regular insulin be drawn up first. The most important issues are that patients are consistent in technique, so as not to draw up the wrong dose in error or the wrong type of insulin, and that patients not inject one type of insulin into the bottle containing a different type of insulin. Injecting cloudy insulin into a vial of clear insulin contaminates the entire vial of clear insulin and alters its action.

For patients who have difficulty mixing insulins, several options are available. They may use a premixed insulin, they may have prefilled syringes prepared (see Fig. 46-3), or they may take 2 injections. Premixed insulins are available in many different ratios of NPH insulin to regular insulin (Comerford & Durkin, 2020). The ratio of 70/30 (70% NPH and 30% regular insulin in one bottle) is most common. Combinations with a ratio of 75% NPL (neutral protamine lispro) and 25% insulin lispro are also available. The appropriate initial dosage of premixed insulin must be calculated so that the ratio of NPH to regular insulin most closely approximates the separate doses needed.

For patients who can inject insulin but who have difficulty drawing up a single or mixed dose, syringes may be prefilled with the help of home health nurses or family and friends. A 3-week supply of insulin syringes may be prepared and kept in the refrigerator but warmed to room temperature before administration. The prefilled syringes should be stored with the needle in an upright position to avoid clogging of the needle; they should be mixed thoroughly by inverting syringe several times before the insulin is injected.

Withdrawing Insulin

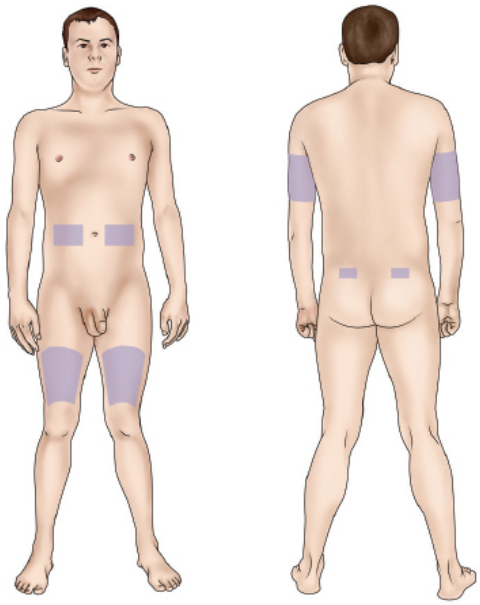
Most (if not all) of the printed materials available on insulin dose preparation instruct patients to inject air into the bottle of insulin equivalent to the number of units of insulin to be withdrawn. The rationale for this is to prevent the formation of a vacuum inside the bottle, which would make it difficult to withdraw the proper amount of insulin.

Selecting and Rotating the Injection Site

The four main areas for injection are the abdomen, upper arms (posterior surface), thighs (anterior surface), and hips (see Fig. 46-5). Insulin is absorbed faster in some areas of the body than others. The speed of absorption is greatest in the abdomen and decreases progressively in the arm, thigh, and hip, respectively.

Systematic rotation of injection sites within an anatomic area is recommended to prevent lipodystrophy (localized changes in fatty tissue). In addition, to promote consistency in insulin absorption, the patient should be encouraged to use all available injection sites within one area rather than randomly rotating sites from area to area. For example, some patients almost exclusively use the abdominal area, administering each injection 0.5 to 1 inch away from the previous injection. Another approach to rotation is always to use the same area at the same time of day. For example, patients may inject morning doses into the abdomen and evening doses into the arms or legs.

A few general principles apply to all rotation patterns. First, the patient should try not to use the exact same site more than once in 2 to 3 weeks. In addition, if the patient is planning to exercise, insulin should not be injected into the limb that will be exercised because this will cause the drug to be absorbed faster, which may result in hypoglycemia.



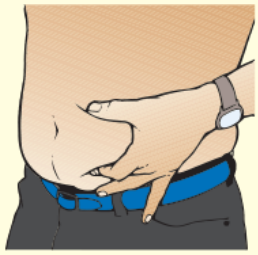


Figure 46-5 • Suggested areas for insulin injection.

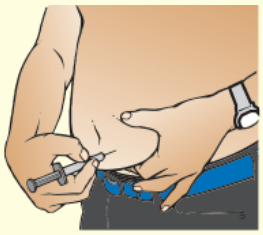
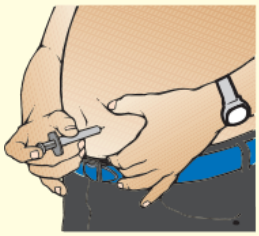
Chart 46-7 **PATIENT EDUCATION**

Self-Injection of Insulin



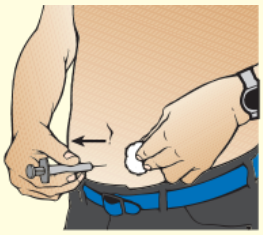
The nurse instructs the patient to:

1. With one hand, stabilize the skin by spreading it or pinching up a large area.



Pinching the skin

2. Pick up syringe with the other hand, and hold it as you would a pencil. Insert needle straight into the skin.[a]



Inserting the needle into the skin

3. To inject the insulin, push the plunger all the way in.

Injecting the insulin

4. Pull needle straight out of skin. Press cotton ball over injection site for several seconds.

Removing the needle and holding cotton ball over site

5. Use disposable syringe *only once* and discard into hard plastic container (with a tight-fitting top) such as an empty bleach or detergent container.[b] Follow state regulations for disposal of syringes and needles.

Disposing of syringe

[a]Some patients may be taught to insert the needle at a 45-degree angle.

[b]Although some studies suggest that reusing disposable syringes may be safe, it is recommended that this be done only in the absence of poor personal hygiene, an acute concurrent illness, open wounds on the hands, or decreased resistance to infection.

Preparing the Skin

The use of alcohol to cleanse the skin is not necessary, but patients who have learned this technique often continue to use it. They should be cautioned to allow the skin to dry after cleansing with alcohol. If the skin is not allowed to dry before the injection, the alcohol may be carried into the tissues, resulting in a localized reddened area and a burning sensation.

Inserting the Needle

There are varying approaches to inserting the needle for insulin injections. The correct technique is based on the need for the insulin to be injected into the subcutaneous tissue (see Chart 46-7). Injection that is too deep (e.g., intramuscular) or too shallow (intradermal) may affect the rate of absorption of the insulin. For a normal or overweight person, a 90-degree angle is the best insertion angle. Aspiration (inserting the needle and then pulling back on the plunger to assess for blood being drawn into the syringe and needle in vein) is not necessary. Many patients who have been using insulin for an extended period have eliminated this step from their insulin injection routine with no apparent adverse effects. Chart 46-8 details how to evaluate the effectiveness of self-injection of insulin education.

Disposing of Syringes and Needles

Insulin syringes and pens, needles, and lancets should be disposed of according to local regulations. If community disposal programs are unavailable, used sharps should be placed in a puncture-resistant container. The patient should contact local trash authorities for instructions about proper disposal of filled containers, which should not be mixed with containers to be recycled.

Promoting Home, Community-Based, and Transitional Care

Educating the Patient About Self-Care

If poor glucose control or preventable complications occur, the nurse needs to assess the reasons for the patient's ineffective management of the treatment regimen. It should not be assumed that problems with diabetes management are related to the patient's decision to ignore self-management. The patient may have forgotten or may have never learned certain information, or there may be cultural or religious beliefs that interfere with adherence. The problem may be correctable simply through providing complete information and ensuring that the patient understands the information. The focus of diabetes education should be patient empowerment. Patient education must address behavior change, self-efficacy, and health beliefs.

Chart 46-8

Criteria for Determining Effectiveness of Self-Injection of Insulin Education

Equipment

Insulin

1. Identifies information on label of insulin bottle:
   - Type (e.g., NPH, regular, 70/30)
   - Manufacturer
   - Concentration (e.g., U-100)
   - Expiration date
2. Checks appearance of insulin:
   - Clear or milky white
   - Checks for flocculation (clumping, frosted appearance)
   - Identifies where to purchase and store insulin:
   - Indicates approximately how long bottle will last (1000 units per bottle U-100 insulin)
   - Indicates how long opened bottles can be used

Syringes

1. Identifies concentration (U-100) marking on syringe
2. Identifies size of syringe (e.g., 100 units, 50 units, 30 units)
3. Describes appropriate disposal of used syringe

Preparation and Administration of Insulin Injection

1. Draws up correct amount and type of insulin
2. Properly mixes 2 insulins if necessary
3. Inserts needle and injects insulin
4. Describes site rotation:
   - Demonstrates injection with all anatomic areas to be used
   - Describes pattern for rotation, such as using abdomen only or using certain areas at the same time of day
   - Describes system for remembering site locations, such as horizontal pattern across the abdomen as if drawing a dotted line

Knowledge of Insulin Action

1. Lists prescription:
   - Type and dosage of insulin
   - Timing of insulin injections
2. Describes approximate time course of insulin action:
   - Identifies long- and short-acting insulins by name
   - States approximate time delay until the onset of insulin action
   - Identifies need to delay food until 5 to 15 minutes after injection of rapid-acting insulin (lispro, aspart, glulisine)
   - Knows that longer time delays are safe when blood glucose level is high and that time delays may need to be shortened when blood glucose level is low

Incorporation of Insulin Injections into Daily Schedule

1. Recites proper order of premeal diabetes activities:
   - May use mnemonic device such as the word “tie,” which helps the patient remember the order of activities (“t” = test [blood glucose], “i” = insulin injection, “e” = eat)
   - Describes daily schedule, such as test, insulin, eat before breakfast and dinner; test and eat, before lunch and bedtime
2. Describes information regarding hypoglycemia:
   - Symptoms: shakiness, sweating, nervousness, hunger, weakness
   - Causes: too much insulin, too much exercise, not enough food
   - Treatment: 15-g concentrated carbohydrate, such as 2 or 3 glucose tablets, 1 tube glucose gel, 0.5 cup juice
   - After initial treatment, follow with snack including starch and protein, such as cheese and crackers, milk and crackers, half sandwich.
3. Describes information regarding prevention of hypoglycemia:
   - Avoids delays in meal timing

- Eats a meal or snack approximately every 4 to 5 hours (while awake)
- Does not skip meals
- Increases food intake before exercise if blood glucose level is less than 100 mg/dL
- Checks blood glucose regularly
- Identifies safe modification of insulin doses consistent with management plan
- Carries a form of fast-acting sugar at all times
- Wears a medical identification bracelet
- Educates family, friends, and coworkers about signs and treatment of hypoglycemia
- Has family, roommates, and traveling companions learn to use injectable glucagon for severe hypoglycemic reactions

4. Maintains regular follow-up for evaluation of diabetes control:
- Keeps written record of blood glucose, insulin doses, hypoglycemic reactions, variations in diet
- Keeps all appointments with health professionals
- Sees primary provider regularly (usually two to four times per year)
- States how to contact primary provider in case of emergency
- States when to call primary provider to report variations in blood glucose levels

If knowledge deficit is not the issue, physical or emotional factors may be impairing the patient's ability to perform self-care skills. For example, decreased visual acuity may impair the patient's ability to administer insulin accurately, measure the blood glucose level, or inspect the skin and feet. In addition, decreased joint mobility (especially in older adults) or preexisting disability may impair the patient's ability to inspect the bottom of the feet. Denial of the diagnosis or depression may impair the patient's ability to carry out multiple daily self-care measures. The patient whose family, personal, or work problems may be of higher priority may benefit from assistance in establishing priorities. The nurse must also assess the patient for infection or emotional stress, which may lead to elevated blood glucose levels despite adherence to the treatment regimen.

The following approaches are helpful for promoting self-care management skills:

- Address any underlying factors (e.g., knowledge deficit, self-care deficit, illness) that may affect control of diabetes.
- Simplify the treatment regimen if it is too difficult for the patient to follow.
- Adjust the treatment regimen to meet patient requests (e.g., adjust diet or insulin schedule to allow increased flexibility in meal content or timing).
- Establish a specific plan or contract with each patient with simple, measurable goals.
- Provide positive reinforcement of self-care behaviors performed instead of focusing on behaviors that were neglected (e.g., positively reinforce blood glucose tests that were performed instead of focusing on the number of missed tests).
- Help the patient identify personal motivating factors rather than focusing on wanting to please primary providers.
- Encourage the patient to pursue life goals and interests, and discourage an undue focus on diabetes.

Continuing and Transitional Care

The degree to which patients interact with primary providers to obtain ongoing care depends on many factors. Age, socioeconomic level, existing complications, type of diabetes, and comorbid conditions may dictate the frequency of follow-up visits. Many patients with diabetes are seen by home health, community-based, or transitional care nurses for diabetes education, wound care, insulin preparation, or assistance with glucose monitoring. Even patients who achieve excellent glucose control and have no complications can expect to see their primary provider at least twice a year for ongoing evaluation and should receive routine nutrition updates. In addition, the nurse should remind the patient to participate in recommended health promotion activities (e.g., annual flu vaccines) and age-appropriate health screenings (e.g., pelvic examinations, mammograms).

Participation in support groups (in person or online) is encouraged for patients who have had diabetes for many years as well as for those who are newly diagnosed. Such participation may help the patient and family cope with changes in lifestyle that occur with the onset of diabetes and its complications. People who participate in support groups often share valuable information and experiences and learn from others. Support groups provide an opportunity for discussion of strategies to deal with diabetes and its management and to clarify and verify information with nurses or other health care professionals leading to healthier behaviors.

Acute Complications of Diabetes

There are three major acute complications of diabetes related to short-term imbalances in blood glucose levels: hypoglycemia, DKA, and HHS (Fayfman, Pasquel, & Umpeirrez, 2017).

Hypoglycemia (Insulin Reactions)

Hypoglycemia means low (hypo) sugar in the blood (glycemia) and occurs when the blood glucose falls to less than 70 mg/dL (3.9 mmol/L) (ADA, 2020). It can occur when there is too much insulin or oral hypoglycemic agents, too little food, or excessive physical activity. Hypoglycemia may occur at any time of the day or night. It often occurs before meals, especially if meals are delayed or snacks are omitted. For example, midmorning hypoglycemia may occur when the morning insulin is peaking, whereas hypoglycemia that occurs in the late afternoon coincides with the peak of the morning NPH insulin. Middle-of-the-night hypoglycemia may occur because of peaking evening or predinner NPH insulins, especially in patients who have not eaten a bedtime snack.

Gerontologic Considerations

In older patients with diabetes, hypoglycemia is a particular concern for many reasons:

- Older adults frequently live alone and may not recognize the symptoms of hypoglycemia.
- With decreasing kidney function, it takes longer for oral hypoglycemic agents to be excreted by the kidneys.
- Skipping meals may occur because of decreased appetite or financial limitations.
- Decreased visual acuity may lead to errors in insulin administration.

Clinical Manifestations

The clinical manifestations of hypoglycemia may be grouped into two categories: adrenergic symptoms and central nervous system (CNS) symptoms.

In mild hypoglycemia, as the blood glucose level falls, the sympathetic nervous system is stimulated, resulting in a surge of epinephrine and norepinephrine. This causes symptoms such as sweating, tremor, tachycardia, palpitation, nervousness, and hunger.

In moderate hypoglycemia, the drop in blood glucose level deprives the brain cells of needed fuel for functioning. Signs of impaired function of the CNS may include inability to concentrate, headache, lightheadedness, confusion, memory lapses, numbness of the lips and tongue, slurred speech, impaired coordination, emotional changes, irrational or combative behavior, double vision, and drowsiness. Any combination of these symptoms (in addition to adrenergic symptoms) may occur with moderate hypoglycemia.

In severe hypoglycemia, CNS function is so impaired that the patient needs the assistance of another person for treatment of hypoglycemia. Symptoms may include disoriented behavior, seizures, difficulty arousing from sleep, or loss of consciousness.

Concept Mastery Alert

It is important to check the patient's blood glucose level and correlate it with the patient's symptoms. If the blood glucose level is low but the patient is not exhibiting any symptoms, the nurse should double-check the glucose level to ensure that it is correct.

Assessment and Diagnostic Findings

Symptoms of hypoglycemia may occur suddenly and vary considerably from person to person. Decreased hormonal (adrenergic) response to hypoglycemia may contribute to lack of symptoms of hypoglycemia. This occurs in some patients who have had diabetes for many years. It may be related to autonomic neuropathy, which is a chronic diabetic complication (see later discussion). As the blood glucose level falls, the normal surge in adrenalin does not occur, and the usual adrenergic symptoms, such as sweating and shakiness, do not take place. The hypoglycemia may not be detected until moderate or severe CNS impairment occurs.

Affected patients must perform SMBG on a frequent regular basis, especially before driving or engaging in other potentially dangerous activities.

Management

Treating with Carbohydrates

Immediate treatment must be given when hypoglycemia occurs (ADA, 2020). The usual recommendation is for 15 to 20 g of a fast-acting concentrated source of carbohydrate. It is not necessary to add sugar to juice, even if it is labeled as unsweetened juice, because the fruit sugar in juice contains enough carbohydrate to raise the blood glucose level. Adding table sugar to juice may cause a sharp increase in the blood glucose level, and patients may experience hyperglycemia for hours after treatment.

Initiating Emergency Measures

In adults whose glucose level is less than 54 mg/dL (3.0 mmol/L) or who are unconscious and cannot swallow, an injection of glucagon 1 mg can be given either subcutaneously or intramuscularly (ADA, 2020). Glucagon is a hormone produced by the alpha cells of the pancreas that stimulates the liver to breakdown glycogen, the stored glucose. Injectable glucagon is packaged as a powder in 1-mg vials and must be mixed with a diluent immediately before being injected. After injection of glucagon, the patient may take as long as 20 minutes to regain consciousness. A concentrated source of carbohydrate followed by a snack should be given to the patient on awakening to prevent recurrence of hypoglycemia (because the duration of the action of 1 mg of glucagon is brief—its onset is 8 to 10 minutes, and its action lasts 12 to 27 minutes) and to replenish liver stores of glucose. Some patients experience nausea after the administration of glucagon. If this occurs, the patient should be turned to the side to prevent aspiration in case the patient vomits.

Glucagon is sold by prescription only and should be part of the emergency supplies available to patients with diabetes who require insulin. Family members, caregivers, and coworkers should be instructed in the use of glucagon, especially for patients who have little or no warning of hypoglycemic episodes (ADA, 2020). Patients should be instructed to notify their primary provider after severe hypoglycemia has occurred and been treated. Close monitoring for 24 hours following a hypoglycemic episode is indicated because the patient is at increased risk of another episode (ADA, 2020).

In hospitals and emergency departments, for patients who are unconscious or cannot swallow, 25 to 50 mL of dextrose 50% in water ($D_{50}W$) may be administered IV. The effect is usually seen within minutes. The patient may complain of a headache and of pain at the injection site. Ensuring patency of the IV line used for injection of 50% dextrose is essential because hypertonic solutions such as 50% dextrose are very irritating to veins.

Providing Patient Education

Hypoglycemia is prevented by a consistent pattern of eating, administering insulin, and exercising. Between-meal and bedtime snacks may be needed to counteract the maximum insulin effect. In general, the patient should cover the time of peak activity of insulin by eating a snack and by taking additional food when physical activity is increased. Routine blood glucose tests are performed so that changing insulin requirements may be anticipated and the dosage adjusted. Because unexpected hypoglycemia can occur, all patients treated with insulin should wear an identification bracelet or tag stating that they have diabetes.

Patients, family members, and coworkers must be instructed to recognize the symptoms of hypoglycemia. Family members in particular must be made aware that any subtle (but unusual) change in behavior may be an indication of hypoglycemia. They should be taught to encourage and even insist that the person with diabetes assess blood glucose levels if hypoglycemia is suspected. Some patients become very resistant to testing or eating and become angry with family members who are trying to treat the hypoglycemia. Family members must be taught to persevere and to understand that the hypoglycemia can cause irrational behavior, due to low supply of glucose to the brain.

Autonomic neuropathy or beta-blockers such as propranolol to treat hypertension or cardiac arrhythmias may mask the typical symptoms of hypoglycemia. It is very important that patients taking these medications perform blood glucose tests on a frequent and regular basis. Patients who have type 2 diabetes and who take oral sulfonylurea agents may also develop hypoglycemia, which can be prolonged and severe; this is a particular risk for older adult patients.

It is important that patients with diabetes, especially those receiving insulin, learn to carry some form of simple sugar with them at all times (ADA, 2020; Davidson et al., 2018). There are commercially prepared

glucose tablets and gels that the patient may find convenient to carry. If the patient has a hypoglycemic reaction and does not have any of the recommended emergency foods available, any available food (preferably a carbohydrate food) should be eaten.

Patients are advised to refrain from eating high-calorie, high-fat dessert foods (e.g., cookies, cakes, doughnuts, ice cream) to treat hypoglycemia because their high-fat content may slow the absorption of the glucose and resolution of the hypoglycemic symptoms. The patient may subsequently eat more of the foods when symptoms do not resolve rapidly, which may cause very high blood glucose levels for several hours and may contribute to weight gain.

Patients who feel unduly restricted by their meal plan may view hypoglycemic episodes as a time to reward themselves with desserts. Instructing these patients to incorporate occasional desserts into the meal plan may be more effective, because this may make it easier for them to limit their treatment of hypoglycemic episodes to simple (low-calorie) carbohydrates such as juice or glucose tablets. Patients should be instructed to report all severe hypoglycemic episodes in addition to any increase in the incidence, frequency, and severity to the primary provider.

Diabetic Ketoacidosis

DKA is caused by an absence or markedly inadequate amount of insulin. This deficit in available insulin results in disorders in the metabolism of carbohydrate, protein, and fat. The three main clinical features of DKA are as follows:

- Hyperglycemia
- Dehydration and electrolyte loss
- Acidosis

Pathophysiology

Without insulin, the amount of glucose entering the cells is reduced, and gluconeogenesis (the production and release of glucose by the liver) is increased, leading to hyperglycemia (see Fig. 46-6). In an attempt to rid the body of the excess glucose, the kidneys excrete the glucose along with water and electrolytes (e.g., sodium, potassium). This osmotic diuresis, which is characterized by polyuria, leads to dehydration and marked electrolyte loss (Norris, 2019). Patients with severe DKA may lose up to 6.5 L of water and up to 400 to 500 mEq each of sodium, potassium, and chloride over a 24-hour period.

Another effect of insulin deficiency or deficit is lipolysis, the breakdown of fat into free fatty acids and glycerol. The free fatty acids are converted into ketone bodies by the liver. Ketone bodies are acids; their accumulation in the circulation due to lack of insulin leads to metabolic acidosis.

Three main causes of DKA are decreased or missed dose of insulin, illness or infection, and undiagnosed and untreated diabetes (DKA may be the initial manifestation of type 1 diabetes). An insulin deficiency may result from an insufficient dosage of insulin prescribed or from insufficient insulin being given by the patient. Errors in insulin dosage may be made by patients who are ill and who assume that if they are eating less or if they are vomiting, they must decrease their insulin doses. (Because illness, especially infections, can cause increased blood glucose levels, the patient does not need to decrease the insulin dose to compensate for decreased food intake when ill and may even need to increase the insulin dose.)

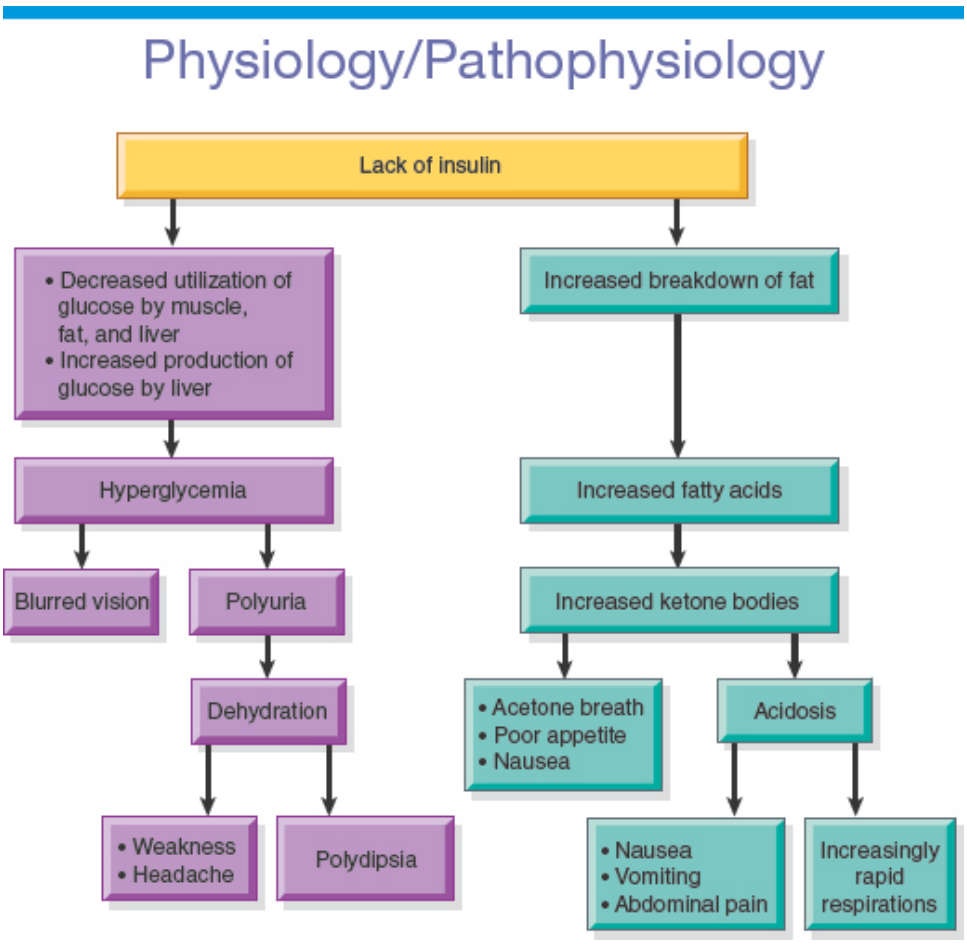


Figure 46-6 • Abnormal metabolism causes signs and symptoms of diabetic ketoacidosis. Redrawn from Pearce, M. A., Rosenberg, C. S., & Davidson, M. D. (2003). Patient education. In Davidson, M. B. (Ed.). *Diabetes mellitus: Diagnosis and treatment*. New York: Churchill Livingstone.

Other potential causes of decreased insulin include patient error in drawing up or injecting insulin (especially in patients with visual impairments), intentional skipping of insulin doses (especially in adolescents with diabetes who are having difficulty coping with diabetes or other aspects of their lives), or equipment problems (e.g., occlusion of insulin pump tubing). Illness and infections are associated with insulin resistance. In response to physical (and emotional) stressors, there is an increase in the level of "stress" hormones—glucagon, epinephrine, norepinephrine, cortisol, and growth hormone. These hormones promote glucose production by the liver and interfere with glucose utilization by muscle and fat tissue, counteracting the effect of insulin. If insulin levels are not increased during times of illness and infection, hyperglycemia may progress to DKA (ADA, 2020).

Prevention

For prevention of DKA related to illness, "sick day rules" for managing diabetes when ill (see Chart 46-9) should be reviewed with patients. The most important concept in this is to never eliminate insulin doses when nausea and vomiting occur. Instead, the patient should take the usual insulin dose (or previously prescribed special sick day doses) and then attempt to consume frequent small portions of carbohydrates (including foods usually avoided, such as juices, regular sodas, and gelatin). Drinking fluids every hour is important to prevent dehydration. Blood glucose and urine ketones must be assessed every 3 to 4 hours.

If the patient cannot take fluids without vomiting, or if elevated glucose or ketone levels persist, the provider must be contacted. Patients are taught to have foods available for use on sick days (Down, 2018). In addition, a supply of urine test strips (for ketone testing) and blood glucose test strips should be available. The patient must know how to contact their primary provider 24 hours a day. These materials should be assembled in a "sick day" kit.

Chart 46-9  **PATIENT EDUCATION**

Guidelines to Follow During Periods of Illness ("Sick Day Rules")

The nurse instructs the patient to:

- Take insulin or oral antidiabetic agents as usual.
- Test blood glucose and urine ketones every 3 to 4 hours.
- Report elevated glucose levels as specified or urine ketones to your primary provider.
- Take supplemental doses of regular insulin every 3 to 4 hours, if needed, if you take insulin.
- Substitute soft foods (e.g., 1/3 cup regular gelatin, 1 cup cream soup, ½ cup custard, 3 squares graham crackers) six to eight times a day if you cannot follow your usual meal plan.
- Take liquids (e.g., ½ cup regular cola or orange juice, ½ cup broth, 1 cup sports drink [Gatorade]) every ½ to 1 hour to prevent dehydration and to provide calories, if vomiting, diarrhea, or fever persists.
- Report nausea, vomiting, and diarrhea to your primary provider, because extreme fluid loss may be dangerous.
- Be aware that if you are unable to retain oral fluids, you may require hospitalization to avoid diabetic ketoacidosis and possibly coma.

After the acute phase of DKA has resolved, the nurse should assess for underlying causes. If there are psychological reasons for the patient missing

insulin doses, the patient and family may be referred for evaluation and counseling or therapy.

Clinical Manifestations

The hyperglycemia of DKA leads to polyuria, polydipsia, and marked fatigue. In addition, the patient may experience blurred vision, weakness, and headache. Patients with marked intravascular volume depletion may have orthostatic hypotension (drop in systolic blood pressure of 20 mm Hg or more on changing from a reclining to a standing position). Volume depletion may also lead to frank hypotension with a weak, rapid pulse.

The ketosis and acidosis of DKA lead to gastrointestinal symptoms, such as anorexia, nausea, vomiting, and abdominal pain. The patient may have acetone breath (a fruity odor), which occurs with elevated ketone levels. In addition, hyperventilation (with very deep, but not labored, respirations) may occur. These Kussmaul respirations represent the body's attempt to decrease the acidosis, counteracting the effect of the ketone buildup (Norris, 2019). In addition, mental status in DKA varies widely. The patient may be alert, lethargic, or comatose.

Assessment and Diagnostic Findings

Blood glucose levels may vary between 250 and 800 mg/dL (16.6 and 44.4 mmol/L). Some patients have lower glucose values, and others have values of 1000 mg/dL (55.5 mmol/L) or higher (usually depending on the degree of dehydration). The severity of DKA is not necessarily related to the blood glucose level. Evidence of ketoacidosis is reflected in low serum bicarbonate (0 to 15 mEq/L) and low pH (6.8 to 7.3) values. A low partial pressure of carbon dioxide ($PaCO_2$ 10 to 30 mm Hg) reflects respiratory compensation (Kussmaul respirations) for the metabolic acidosis. Accumulation of ketone bodies (which precipitates the acidosis) is reflected in blood and urine ketone measurements (Down, 2018).

Sodium and potassium concentrations may be low, normal, or high, depending on the amount of dehydration present. Despite the plasma concentration, there has been a marked total body depletion of these (and other) electrolytes, and they will need to be replaced. Increased levels of creatinine, blood urea nitrogen (BUN), and hematocrit may also be seen with dehydration. After rehydration, continued elevation in the serum creatinine and BUN levels suggests underlying renal insufficiency.

Management

In addition to treating hyperglycemia, management of DKA is aimed at correcting dehydration, electrolyte loss, and acidosis before correcting the hyperglycemia with insulin (Fayfman et al., 2017; Joyner Blair, Hamilton, & Spurlock, 2018).

Rehydration

In dehydrated patients, rehydration is important for maintaining tissue perfusion. In addition, fluid replacement enhances the excretion of excessive glucose by the kidneys. The patient may need as much as 6 to 10 L of IV fluid to replace fluid losses caused by polyuria, hyperventilation, diarrhea, and vomiting.

Initially, 0.9% sodium chloride (normal saline [NS]) solution is given at a rapid rate, usually 0.5 to 1 L per hour for the first 2 to 4 hours (Fayfman et al., 2017). Half-strength NS (0.45%) solution (also known as hypotonic saline solution) may be used for patients with hypertension or hypernatremia and those at risk for heart failure. After the first few hours, half-strength NS solution is the fluid of choice for continued rehydration, provided the blood pressure is stable and the sodium level is not low. Moderate to high rates of infusion (200 to 500 mL per hour) may be needed for several more hours. When the blood glucose level reaches 300 mg/dL (16.6 mmol/L) or less, the IV solution may be changed to dextrose 5% in water (D_5W) to prevent a precipitous decline in the blood glucose level (Fayfman et al., 2017).

Monitoring of fluid volume status involves frequent measurements of vital signs (including monitoring for orthostatic changes in blood pressure and heart rate), lung assessment, and monitoring of intake and output. Initial urine output lags behind IV fluid intake as dehydration is corrected. Plasma expanders may be necessary to correct severe hypotension that does not respond to IV fluid treatment. Monitoring for signs of fluid overload is especially important for patients who are older, have renal impairment, or are at risk for heart failure.

Restoring Electrolytes

The major electrolyte of concern during treatment of DKA is potassium. The initial plasma concentration of potassium may be low, normal, or high, but more often than not, tends to be high (hyperkalemia) from disruption of the cellular sodium-potassium pump (in the face of acidosis). Therefore, the serum potassium level must be monitored frequently. Some of the factors related to treating DKA that affect potassium concentration include rehydration, which leads to increased plasma volume and subsequent decreases in the concentration of serum potassium. Rehydration also leads to increased urinary excretion of potassium. Insulin administration enhances the movement of potassium from the extracellular fluid into the cells.

Cautious but timely potassium replacement is vital to avoid arrhythmias that may occur with hypokalemia. As much as 40 mEq/ h may be needed for several hours. Because extracellular potassium levels decrease during DKA treatment, potassium must be infused even if the plasma potassium level is normal.

Frequent (every 2 to 4 hours initially) ECGs and laboratory measurements of potassium are necessary during the first 8 hours of treatment. Potassium replacement is withheld only if hyperkalemia is present or if the patient is not urinating.

Quality and Safety Nursing Alert

Because a patient's serum potassium level may drop quickly as a result of rehydration and insulin treatment, potassium replacement must begin once potassium levels drop to normal in the patient with DKA.

Reversing Acidosis

Ketone bodies (acids) accumulate as a result of fat breakdown. The acidosis that occurs in DKA is reversed with insulin, which inhibits fat breakdown, thereby ending ketone production and acid buildup. Insulin is usually infused IV at a slow, continuous rate (e.g., 5 units per hour). Hourly blood glucose values must be measured. IV fluid solutions with higher concentrations of glucose, such as NS solution (e.g., D_5NS, D_5 0.45% NS), are given when blood glucose levels reach 250 to 300 mg/dL (13.9 to 16.6 mmol/L) to avoid too rapid a drop in the blood glucose level (i.e., hypoglycemia) during treatment.

Regular insulin, the only type of insulin approved for IV use, may be added to IV solutions. The nurse must convert hourly rates of insulin infusion (frequently prescribed as units per hour) to IV drip rates. For example, if 100 units of regular insulin are mixed into 500 mL of 0.9% NS, then 1 unit of insulin equals 5 mL; therefore, an initial insulin infusion rate of 5 units per hour would equal 25 mL per hour. The insulin is often infused separately from the rehydration solutions to allow frequent changes in the rate and content of the latter (Fayfman et al., 2017).

Insulin must be infused continuously until subcutaneous administration of insulin can be resumed. Any interruption in administration may result in the reaccumulation of ketone bodies and worsening acidosis. Even if blood glucose levels are decreasing and returning to normal, the insulin drip must not be stopped until subcutaneous insulin therapy has been started. Rather, the rate or concentration of the dextrose infusion may be increased to prevent hypoglycemia. Blood glucose levels are usually corrected before the acidosis

is corrected. Therefore, IV insulin may be continued for 12 to 24 hours, until the serum bicarbonate level increases (to at least 15 to 18 mEq/L) and until the patient can eat. In general, bicarbonate infusion to correct severe acidosis is avoided during treatment of DKA because it precipitates further, sudden (and potentially fatal) decreases in serum potassium levels. Continuous insulin infusion is usually sufficient for reversal of DKA (Down, 2018; Fayfman et al., 2017).

Quality and Safety Nursing Alert

When hanging the insulin drip, the nurse must flush the insulin solution through the entire IV infusion set and discard the first 50 mL of fluid. Insulin molecules adhere to the inner surface of plastic IV infusion sets; therefore, the initial fluid may contain a decreased concentration of insulin.

Hyperglycemic Hyperosmolar Syndrome

HHS is a metabolic disorder most often of type 2 diabetes resulting from a relative insulin deficiency initiated by an illness that raises the demand for insulin. This is a serious condition in which hyperosmolality and hyperglycemia predominate, with alterations of the sensorium (sense of awareness). At the same time, ketosis is usually minimal or absent. The basic biochemical defect is the lack of effective insulin (i.e., insulin resistance). Persistent hyperglycemia causes osmotic diuresis, which results in losses of water and electrolytes. To maintain osmotic equilibrium, water shifts from the intracellular fluid space to the extracellular fluid space. With glycosuria and dehydration, hypernatremia and increased osmolarity occur. Table 46-6 compares DKA and HHS.

HHS occurs most often in older adults (50 to 70 years of age) who have no known history of diabetes or who have type 2 diabetes (Fayfman et al., 2017). HHS often can be traced to an infection or a precipitating event such as an acute illness (e.g., stroke), medications that exacerbate hyperglycemia (e.g., thiazides), or treatments such as dialysis. The history includes days to weeks of polyuria with adequate fluid intake. What distinguishes HHS from DKA is that ketosis and acidosis generally do not occur in HHS, partly because of differences in insulin levels. In DKA, no insulin is present, and this promotes the breakdown of stored glucose, protein, and fat, which leads to the production of ketone bodies and ketoacidosis. In HHS, the insulin level is too low to prevent hyperglycemia (and subsequent osmotic diuresis), but it is high enough to prevent fat breakdown. Patients with HHS do not have the ketosis-

related gastrointestinal symptoms that lead them to seek medical attention. Instead, they may tolerate polyuria and polydipsia until neurologic changes or an underlying illness (or family members or others) prompts them to seek treatment.

TABLE 46-6 Comparison of Diabetic Ketoacidosis and Hyperglycemic Hyperosmolar Syndrome

Characteristics	DKA	HHS
Patients most commonly affected	Can occur in type 1 or type 2 diabetes; more common in type 1 diabetes	Can occur in type 1 or type 2 diabetes; more common in type 2 diabetes, especially older adults with type 2 diabetes
Precipitating event	Omission of insulin; physiologic stress (infection, surgery, stroke, MI, untreated type 1 diabetes)	Physiologic stress (infection, surgery, stroke, MI), medications (e.g., thiazides), treatments (e.g., dialysis)
Onset	Rapid (<24 h)	Slower (over several days)
Blood glucose levels	Usually >250 mg/dL (>13.9 mmol/L)	Usually >600 mg/dL (>33.3 mmol/L)
Arterial pH level	<7.3	Normal
Serum and urine ketones	Present	Absent
Serum osmolality	275–320 mOsm/L	>320 mOsm/L
Plasma bicarbonate level	<15 mEq/L	Normal
BUN and creatinine levels	Elevated	Elevated
Mortality rate	<1%	5–16%

BUN, blood urea nitrogen; DKA, diabetic ketoacidosis; HHS, hyperglycemic hyperosmolar syndrome; MI, myocardial infarction.

Adapted from Fayfman, M., Pasquel, F. J., & Umpeirrez, G. E. (2017). Management of hyperglycemic crises: Diabetic ketoacidosis and hyperglycemic hyperosmolar state. *Medical Clinics of North America*, *101*(3), 587–606.

Clinical Manifestations

The clinical picture of HHS is one of hypotension, profound dehydration (dry mucous membranes, poor skin turgor), tachycardia, and variable neurologic signs (e.g., alteration of consciousness, seizures, hemiparesis) (Down, 2018; Fayfman et al., 2017) (see Table 46-6).

Assessment and Diagnostic Findings

Diagnostic assessment includes a range of laboratory tests, including blood glucose, electrolytes, BUN, complete blood count, serum osmolality, and arterial blood gas analysis. The blood glucose level is greater than 600 mg/dL, the osmolality exceeds 320 mOsm/kg, and ketoacidosis is absent (Fayfman et al., 2017). Electrolyte and BUN levels are consistent with the clinical picture of severe dehydration (see Chapter 10). Mental status changes, focal neurologic deficits, and hallucinations are common secondary to the cerebral dehydration that results from extreme hyperosmolality. Orthostatic hypotension accompanies the dehydration (Fayfman et al., 2017).

Management

The overall approach to the treatment of HHS is similar to that of DKA: fluid replacement, correction of electrolyte imbalances, and insulin administration. Because patients with HHS are typically older, close monitoring of volume and electrolyte status is important for prevention of fluid overload, heart failure, and cardiac arrhythmias. Fluid treatment is started with 0.9% or 0.45% NS, depending on the patient's sodium level and the severity of volume depletion. Central venous or hemodynamic pressure monitoring guides fluid replacement. Potassium is added to IV fluids when urinary output is adequate and is guided by continuous ECG monitoring and frequent laboratory determinations of potassium (Fayfman et al., 2017).

Extremely elevated blood glucose concentrations decrease as the patient is rehydrated. Insulin plays a less important role in the treatment of HHS because it is not needed for reversal of acidosis, as in DKA. Nevertheless, insulin is usually given at a continuous low rate to treat hyperglycemia, and replacement IV fluids with dextrose are given (as in DKA) after the glucose level has decreased to the range of 250 to 300 mg/dL (13.8 to 16.6 mmol/L) (Fayfman et al., 2017).

Other therapeutic modalities are determined by the underlying illness and the results of continuing clinical and laboratory evaluation. It may take 3 to 5 days for neurologic symptoms to clear, and treatment of HHS usually continues well after metabolic abnormalities have resolved. After recovery from HHS, many patients can control their diabetes with MNT alone or with MNT and oral antidiabetic medications. Insulin may not be needed once the acute hyperglycemic complication is resolved. Frequent SBGM is important in prevention of recurrence of HHS (Fayfman et al., 2017).

NURSING PROCESS

The Patient with Diabetic Ketoacidosis or Hyperglycemic Hyperosmolar Syndrome

Assessment

For the patient with DKA, the nurse monitors the ECG for arrhythmias indicating abnormal potassium levels. Vital signs (especially blood pressure and pulse), arterial blood gases, breath sounds, and mental status are assessed every hour and recorded on a flow sheet. Neurologic status checks are included as part of the hourly assessment because cerebral edema can be a severe and sometimes fatal outcome. Blood glucose levels are checked every hour (Fayfman et al., 2017).

For the patient with HHS, the nurse assesses vital signs, fluid status, and laboratory values. Fluid status and urine output are closely monitored because of the high risk of kidney failure secondary to severe dehydration. Because HHS tends to occur in older patients, the physiologic changes that occur with aging should be considered. Careful assessment of cardiovascular, pulmonary, and kidney function throughout the acute and recovery phases of HHS is important (Fayfman et al., 2017).

Diagnosis

NURSING DIAGNOSES

Based on the assessment data, major nursing diagnoses may include the following:

- Risk for hypovolemia associated with polyuria and dehydration
- Fluid imbalance associated with fluid loss or shifts
- Lack of knowledge about diabetes self-care skills or information
- Anxiety associated with loss of control, fear of inability to manage diabetes, misinformation associated with diabetes, fear of diabetes complications

COLLABORATIVE PROBLEMS/POTENTIAL COMPLICATIONS

Potential complications may include the following:

- Fluid overload, pulmonary edema, and heart failure
- Hypokalemia
- Hyperglycemia and ketoacidosis
- Hypoglycemia
- Cerebral edema

Planning and Goals

The major goals for the patient may include maintenance of fluid and electrolyte balance, increased knowledge about diabetes basic skills and self-care, decreased anxiety, and absence of complications.

Nursing Interventions

MAINTAINING FLUID AND ELECTROLYTE BALANCE

Intake and output are measured. IV fluids and electrolytes are given as prescribed, and oral fluid intake is encouraged when it is permitted. Laboratory values of serum electrolytes (especially sodium and potassium) are monitored. Vital signs are monitored hourly for signs of dehydration (tachycardia, orthostatic hypotension) along with assessment of breath sounds, level of consciousness, presence of edema, and cardiac status (ECG rhythm strips).

INCREASING KNOWLEDGE ABOUT DIABETES MANAGEMENT

The development of DKA or HHS suggests the need for the nurse to carefully assess the patient's understanding of and adherence to the diabetes management plan. Furthermore, factors that may have led to the development of DKA or HHS are explored with the patient and family. If the patient's blood glucose monitoring, dietary intake, use of antidiabetic medications (insulin or oral agents), and exercise patterns differ from those identified in the diabetes management plan, their relationship to the development of DKA or HHS is discussed, along with early manifestations of DKA or HHS. If other factors, such as trauma, illness, surgery, or stress, are implicated, appropriate strategies to respond to these and similar situations in the future are described so that the patient can respond in the future without developing life-threatening complications. The nurse may need to provide education about basic skills again to patients who may not be able to recall the instructions. If the patient has omitted insulin or oral antidiabetic agents that have been prescribed, the nurse explores the reasons for doing so and addresses those issues to prevent future recurrence and readmissions for treatment of these complications.

If the patient has not previously been diagnosed with diabetes, the opportunity is used to educate the patient about the need for maintaining blood glucose at a normal level and learning about diabetes management and basic skills.

DECREASING ANXIETY

Educating the patient about cognitive strategies may be useful for relieving tension, overcoming anxiety, decreasing fear, and achieving relaxation (see Chapter 3). Examples include:

- *Imagery:* The patient concentrates on a pleasant experience or restful scene.
- *Distraction:* The patient thinks of an enjoyable story or recites a favorite poem or song.
- *Optimistic self-recitation:* The patient recites optimistic thoughts ("I know all will go well").

- *Music:* The patient listens to soothing music (an easy-to-administer, inexpensive, noninvasive intervention).

MONITORING AND MANAGING POTENTIAL COMPLICATIONS

Fluid Overload. Fluid overload can occur because of the administration of a large volume of fluid at a rapid rate, which is often required to treat patients with DKA or HHS. This risk is increased in older patients and in those with preexisting cardiac or kidney disease. To avoid fluid overload and resulting heart failure and pulmonary edema, the nurse monitors the patient closely during treatment by measuring vital signs and intake and output at frequent intervals. Central venous pressure monitoring and hemodynamic monitoring may be initiated to provide additional measures of fluid status. Physical examination focuses on assessment of cardiac rate and rhythm, breath sounds, venous distention, skin turgor, and urine output. The nurse monitors fluid intake and keeps careful records of IV and other fluid intake, along with urine output measurements.

Hypokalemia. Hypokalemia is a potential complication during the treatment of DKA. Low serum potassium levels may result from rehydration, increased urinary excretion of potassium, movement of potassium from the extracellular fluid into the cells with insulin administration, and restoration of the cellular sodium–potassium pump. Prevention of hypokalemia includes cautious replacement of potassium; however, before its administration, it is important to ensure that a patient's kidneys are functioning. Because of the adverse effects of hypokalemia on cardiac function, monitoring of the cardiac rate, cardiac rhythm, ECG, and serum potassium levels is essential.

Cerebral Edema. Although the exact cause of cerebral edema is unknown, rapid correction of hyperglycemia, resulting in fluid shifts, is thought to be the cause. Cerebral edema, which occurs more often in children than in adults, can be prevented by a gradual reduction in the blood glucose level. An hourly flow sheet is used to enable close monitoring of the blood glucose level, serum electrolyte levels, fluid intake, urine output, mental status, and neurologic signs. Precautions are taken to minimize activities that could increase intracranial pressure.

EDUCATING PATIENTS ABOUT SELF-CARE

The patient is educated about basic skills, including treatment modalities (diet, insulin administration, monitoring of blood glucose, and, for type 1 diabetes, monitoring of urine ketones); the patient is also educated about recognition, treatment, and prevention of DKA and HHS (Down, 2018; Fayfman et al., 2017). Education addresses those factors leading to DKA or HHS. Follow-up education is arranged with a home health nurse and

dietitian or an outpatient diabetes education center. This is particularly important for patients who have experienced DKA or HHS because of the need to address factors that led to its occurrence (e.g., dehydration). For patients who have had HHS, avoiding dehydration and paying attention to increased urination or thirst are even more important than insulin administration. The importance of self-monitoring and of monitoring and follow-up by primary providers is reinforced, and the patient is reminded about the importance of keeping follow-up appointments.

Evaluation

Expected patient outcomes may include:

1. Achieves fluid and electrolyte balance
   a. Demonstrates intake and output balance
   b. Exhibits electrolyte values within normal limits
   c. Exhibits vital signs that remain stable, with resolution of orthostatic hypotension and tachycardia
2. Demonstrates knowledge about DKA and HHS
   a. Identifies factors leading to DKA and HHS
   b. Describes signs and symptoms of DKA and HHS
   c. Describes short- and long-term consequences of DKA and HHS
   d. Identifies strategies to prevent the development of DKA and HHS
   e. States when contact with primary provider is needed to treat early signs of DKA and HHS
3. Decreased anxiety
   a. Identifies strategies to decrease anxiety and fear
4. Absence of complications
   a. Exhibits normal cardiac rate and rhythm and normal breath sounds
   b. Exhibits no jugular venous distention
   c. Exhibits blood glucose and urine ketone levels within target range
   d. Exhibits no manifestations of hypoglycemia or hyperglycemia
   e. Shows improved mental status without signs of cerebral edema

Long-Term Complications of Diabetes

The number of deaths attributable to ketoacidosis and infection in patients with diabetes has steadily declined, but diabetes related complications have increased. Long-term complications are becoming more common as more people live longer with diabetes; these complications can affect almost every organ system of the body and are a major cause of disability. The general

categories of long-term diabetic complications are macrovascular disease, microvascular disease, and neuropathy.

The causes and pathogenesis of each type of complication are still being investigated. However, it appears that increased levels of blood glucose play a role in neuropathic disease, microvascular complications, and risk factors contributing to macrovascular complications. Hypertension may also be a major contributing factor, especially in macrovascular and microvascular diseases (ADA, 2020).

Long-term complications are seen in both type 1 and type 2 diabetes but usually do not occur within the first 5 to 10 years after diagnosis. However, evidence of these complications may be present at the time of diagnosis of type 2 diabetes, because patients may have had undiagnosed diabetes for many years. Kidney (microvascular) disease is more prevalent in patients with type 1 diabetes, and cardiovascular (macrovascular) complications are more prevalent in older patients with type 2 diabetes.

Macrovascular Complications

Diabetic macrovascular complications result from changes in the medium to large blood vessels. Blood vessel walls thicken, sclerose, and become occluded by plaque that adheres to the vessel walls. Eventually, blood flow is blocked. These atherosclerotic changes tend to occur more often and at an earlier age in patients with diabetes. Coronary artery disease, cerebrovascular disease, and peripheral vascular disease are the three main types of macrovascular complications that occur frequently in patients with diabetes.

Myocardial infarction (MI) is twice as common in men with diabetes and three times as common in women with diabetes, compared with people without diabetes. There is also an increased risk of complications resulting from MI and an increased likelihood of a second MI. Coronary artery disease accounts for an increased incidence of death among patients with diabetes. The typical ischemic symptoms may be absent in patients with diabetes. Therefore, the patient may not experience the early warning signs of decreased coronary blood flow and may have “silent” MIs, which may be discovered only as changes on the ECG. In some cases, ECG changes may not be apparent. This lack of ischemic symptoms may be secondary to autonomic neuropathy (see later discussion). See Chapter 23 for a detailed discussion of coronary vascular disorders.

Cerebral blood vessels are similarly affected by accelerated atherosclerosis. Occlusive changes or the formation of an embolus elsewhere in the vasculature that lodges in a cerebral blood vessel can lead to transient ischemic attacks and strokes. People with diabetes have twice the risk of developing cerebrovascular disease and an increased risk of death from stroke (Virani et

al., 2020). In addition, recovery from a stroke may be impaired in patients who have elevated blood glucose levels at the time of and immediately after a stroke. Because symptoms of a stroke may be similar to symptoms of acute diabetic complications (HHS or hypoglycemia), it is very important to assess the blood glucose level (and treat abnormal levels) rapidly in patients with these symptoms so that testing and treatment of a stroke can be initiated promptly if indicated.

Atherosclerotic changes in the large blood vessels of the lower extremities are responsible for the increased incidence (two to three times higher than in people without diabetes) of occlusive peripheral arterial disease in patients with diabetes (ADA, 2020). Signs and symptoms of peripheral vascular disease include diminished peripheral pulses and intermittent claudication (pain in the buttock, thigh, or calf during walking). The severe form of arterial occlusive disease in the lower extremities is largely responsible for the increased incidence of gangrene and subsequent amputation in patients with diabetes. Neuropathy and impairments in wound healing also play a role in diabetic foot disease (see later discussion).

Role of Diabetes in Macrovascular Diseases

Researchers continue to investigate the relationship between diabetes and macrovascular diseases. The main feature unique to diabetes is elevated blood glucose; however, a direct link has not been found between hyperglycemia and atherosclerosis. Although it may be tempting to attribute the increased prevalence of macrovascular diseases to the increased prevalence of certain risk factors (e.g., obesity, increased triglyceride levels, hypertension) in patients with diabetes, there is a higher-than-expected rate of macrovascular diseases among patients with diabetes compared with patients without diabetes who have the same risk factors (ADA, 2020). Therefore, diabetes itself is seen as an independent risk factor for accelerated atherosclerosis. Other potential factors that may play a role in diabetes-related atherosclerosis include platelet and clotting factor abnormalities, decreased flexibility of red blood cells, decreased oxygen release, changes in the arterial wall related to hyperglycemia, and possibly hyperinsulinemia.

Management

The focus of management is an aggressive modification and reduction of risk factors. This involves prevention and treatment of the commonly accepted risk factors for atherosclerosis. MNT and exercise are important in managing obesity, hypertension, and hyperlipidemia. In addition, the use of medications to control hypertension and hyperlipidemia is indicated. Smoking cessation is essential. Control of blood glucose levels may reduce triglyceride

concentrations and can significantly reduce the incidence of complications (ADA, 2020; Evert et al., 2019).

Microvascular Complications

Diabetic microvascular disease (or microangiopathy) is characterized by capillary basement membrane thickening. The basement membrane surrounds the endothelial cells of the capillary. Researchers believe that increased blood glucose levels react through a series of biochemical responses to thicken the basement membrane to several times its normal thickness. Two areas affected by these changes are the retina and the kidneys (Norris, 2019).

Diabetic Retinopathy

Diabetic retinopathy is the leading cause of blindness among people between 20 and 74 years of age in the United States; it occurs in both type 1 and type 2 diabetes (ADA, 2020).

People with diabetes are subject to many visual complications (see Table 46-7). The pathology referred to as diabetic retinopathy is caused by changes in the small blood vessels in the retina, which is the area of the eye that receives images and sends information about the images to the brain (see Fig. 46-7). The retina is richly supplied with blood vessels of all kinds: small arteries and veins, arterioles, venules, and capillaries. Retinopathy has three main stages: nonproliferative (background), preproliferative, and proliferative.

Almost all patients with type 1 diabetes and the majority of patients with type 2 diabetes have some degree of retinopathy after 20 years (ADA, 2020). Changes in the microvasculature include microaneurysms, intraretinal hemorrhage, hard exudates, and focal capillary closure. Although most patients do not develop visual impairment, it can be devastating if it occurs. A complication of nonproliferative retinopathy—macular edema—occurs in approximately 10% of people with type 1 or type 2 diabetes and may lead to visual distortion and loss of central vision (ADA, 2020).

TABLE 46-7 Ocular Complications of Diabetes

Eye Disorder	Characteristics
Retinopathy	Damage to the small blood vessels that nourish the retina.
Background	Early-stage, asymptomatic retinopathy. Blood vessels within the retina develop microaneurysms that leak fluid, causing swelling and forming exudates (deposits). In some cases, macular edema causes distorted vision.
Preproliferative	Represents increased destruction of retinal blood vessels.
Proliferative	Abnormal growth of new blood vessels on the retina. New vessels rupture, bleeding into the vitreous and blocking light. Ruptured blood vessels in the vitreous form scar tissue, which can pull on and detach the retina.
Cataracts	Opacity of the lens of the eye; cataracts occur at an earlier age in patients with diabetes.
Lens Changes	The lens of the eye can swell when blood glucose levels are elevated. For some patients, visual changes related to lens swelling may be the first symptoms of diabetes. It may take up to 2 mo of improved blood glucose control before hyperglycemic swelling subsides and vision stabilizes. Therefore, patients are advised not to change eyeglass prescriptions during the 2 mo after discovery of hyperglycemia.
Extraocular Muscle Palsy	This may occur as a result of diabetic neuropathy. The involvement of various cranial nerves responsible for ocular movements may lead to double vision. This usually resolves spontaneously.
Glaucoma	Results from occlusion of the outflow channels by new blood vessels. Glaucoma may occur with slightly higher frequency among patients with diabetes.

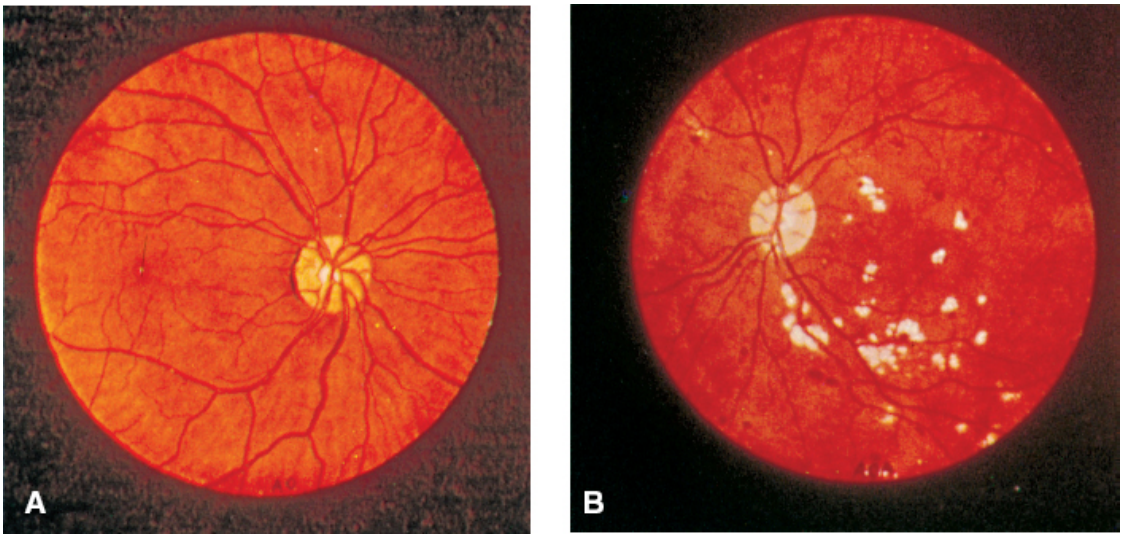

Figure 46-7 • Diabetic retinopathy. **A.** In the fundus photograph of a normal eye, the light circular area over which a number of blood vessels converge is the optic disc, where the optic nerve meets the back of the eye. **B.** The fundus photograph of a patient with diabetic retinopathy shows characteristic waxy-looking retinal lesions, microaneurysms of the vessels, and hemorrhages. Courtesy of American Optometric Association.

An advanced form of background retinopathy—preproliferative retinopathy—is considered to be a precursor to the more serious proliferative retinopathy. In preproliferative retinopathy, there are more widespread vascular changes and loss of nerve fibers. Epidemiologic evidence suggests that 10% to 50% of patients with preproliferative retinopathy will develop proliferative retinopathy within a short time (possibly as little as 1 year). As with background retinopathy, if visual changes occur during the preproliferative stage, they are usually caused by macular edema.

Proliferative retinopathy represents the greatest threat to vision and is characterized by the proliferation of new blood vessels growing from the retina into the vitreous. These new vessels are prone to bleeding. The visual loss associated with proliferative retinopathy is caused by this vitreous hemorrhage, retinal detachment, or both. The vitreous is normally clear, allowing light to be transmitted to the retina. When there is a hemorrhage, the vitreous becomes clouded and cannot transmit light, resulting in loss of vision. Another consequence of vitreous hemorrhage is that resorption of the blood in the vitreous leads to the formation of fibrous scar tissue. This scar tissue may place traction on the retina, resulting in retinal detachment and subsequent visual loss.

Clinical Manifestations

Retinopathy is a painless process. In non- and preproliferative retinopathy, blurry vision secondary to macular edema occurs in some patients, although many patients are asymptomatic. Even patients with a significant degree of proliferative retinopathy and some hemorrhaging may not experience major visual changes. However, symptoms indicative of hemorrhaging include floaters or cobwebs in the visual field, sudden visual changes including spotty or hazy vision, or complete loss of vision.

Assessment and Diagnostic Findings

Diagnosis is by direct visualization of the retina through dilated pupils with an ophthalmoscope or with a technique known as fluorescein angiography. Fluorescein angiography can document the type and activity of the retinopathy. Dye is injected into an arm vein and is carried to various parts of the body through the blood, but especially through the vessels of the retina of the eye. This technique allows an ophthalmologist, using special instruments, to see the retinal vessels in bright detail and gives useful information that cannot be obtained with just an ophthalmoscope.

Side effects of this diagnostic procedure may include nausea during the dye injection; yellowish, fluorescent discoloration of the skin and urine lasting 12 to 24 hours; and occasionally allergic reactions, usually manifested by hives or itching. However, the diagnostic procedure is generally safe.

Medical Management

The first focus of management of retinopathy is on primary and secondary prevention. The DCCT study (1993) demonstrated that in patients without preexisting retinopathy, maintenance of blood glucose to a normal or near-normal level in type 1 diabetes through intensive insulin therapy and patient education decreased the risk of retinopathy by 76%, compared with conventional therapy. The progression of retinopathy was decreased by 54% in patients with very mild to moderate nonproliferative retinopathy at the time of initiation of treatment. Additional research demonstrated similar results in patients with type 2 diabetes (Action to Control Cardiovascular Risk in Diabetes Follow-On [ACCORDIAN] Eye Study Group, 2016). Thus, control of blood glucose levels in patients with both types of diabetes reduces the risk of retinopathy as well (ADA, 2020).

Other strategies that may slow the progression of diabetic retinopathy include control of hypertension, control of blood glucose, and cessation of smoking.

For advanced cases of diabetic retinopathy, the main treatment is argon laser photocoagulation. The laser treatment destroys leaking blood vessels and areas of neovascularization. For patients who are at increased risk for

hemorrhage, panretinal photocoagulation may significantly reduce the rate of progression to blindness. Panretinal photocoagulation involves the systematic application of multiple (more than 1000) laser burns throughout the retina (except in the macular region). This stops the widespread growth of new vessels and hemorrhaging of damaged vessels. The role of "mild" panretinal photocoagulation (with only one third to one half as many laser burns) in the early stages of proliferative retinopathy or in patients with preproliferative changes is being investigated. For patients with macular edema, focal photocoagulation is used to apply smaller laser burns to specific areas of microaneurysms in the macular region. This may reduce the rate of visual loss from macular edema (ADA, 2020).

Photocoagulation treatments are usually performed on an outpatient basis, and most patients can return to their usual activities by the next day. Limitations may be placed on activities involving weight bearing or bearing down. In most cases, the treatment does not cause intense pain, although patients may report varying degrees of discomfort such as a headache. Usually, an anesthetic eye drop is all that is needed during the treatment. A few patients may experience slight visual loss, loss of peripheral vision, or impairments in adaptation to the dark. However, the risk of slight visual changes from the laser treatment itself is much less than the potential for loss of vision from progression of retinopathy.

A major hemorrhage into the vitreous may occur, with the vitreous fluid becoming mixed with blood, preventing light from passing through the eye; this can cause blindness. A vitrectomy is a surgical procedure in which vitreous humor filled with blood or fibrous tissue is removed with a special drill-like instrument and replaced with saline or another liquid. A vitrectomy is performed for patients who already have visual loss and in whom the vitreous hemorrhage has not cleared on its own after 6 months. The purpose is to restore useful vision; recovery to near-normal vision is not usually expected.

Nursing Management

Nursing management of patients with diabetic retinopathy or other eye disorders involves implementing the individual plan of care and providing patient education. Education focuses on prevention through regular ophthalmologic examinations, blood glucose control, and self-management of eye care regimens. The effectiveness of early diagnosis and prompt treatment is emphasized in educating the patient and family.

If vision loss occurs, nursing care must also address the patient's adjustment to impaired vision and the use of adaptive devices for diabetes self-care as well as activities of daily living. See Chapter 58 for discussion of nursing care for patients with low vision and blindness.

Promoting Home, Community-Based, and Transitional Care

Educating Patients About Self-Care

Because the course of the retinopathy may be long and stressful, patient education is essential. In educating and counseling patients, it is important to stress the following:

- Retinopathy may appear after many years of diabetes, and its appearance does not necessarily mean that the diabetes is on a downhill course.
- The odds for maintaining vision are in the patient's favor, especially with adequate control of glucose levels and blood pressure.
- Frequent eye examinations allow for the detection and prompt treatment of retinopathy.

A patient's response to vision loss depends on personality, self-concept, and coping mechanisms. Acceptance of blindness occurs in stages; some patients may learn to accept blindness in a rather short period, and others may never do so. An important issue in educating patients is that several complications of diabetes may occur simultaneously. For example, a patient who is blind due to diabetic retinopathy may also have peripheral neuropathy and may experience impairment of manual dexterity and tactile sensation, or kidney failure. This can be devastating to the patient and family. Psychological counseling may be warranted. To prevent further losses, glycemic control remains a priority.

Continuing and Transitional Care

The importance of careful diabetes management is emphasized as one means of slowing the progression of visual changes. The patient is reminded of the need to see an ophthalmologist regularly. If eye changes are progressive and unrelenting, the patient should be prepared for inevitable blindness. Therefore, consideration is given to making referrals for educating the patient in Braille and for training the patient with guide (i.e., service) dogs. Referral to state agencies should be made to ensure that the patient receives services for the blind. Family members are also taught how to assist the patient to remain as independent as possible despite decreasing visual acuity.

Referral for home care may be indicated for some patients, particularly those who live alone, those who are not coping well, and those who have other health problems or complications of diabetes that may interfere with their ability to perform self-care. During home visits, the nurse can assess the patient's home environment and their ability to manage diabetes despite visual impairments. See Chapter 58 for a detailed discussion of medical management and nursing care for patients with visual disturbances.

Nephropathy

Nephropathy, or kidney disease secondary to diabetic microvascular changes in the kidney, is a common complication of diabetes (ADA, 2020). In the United States each year, people with diabetes account for almost 50% of new cases of ESKD, and about 25% of those require dialysis or transplantation. About 20% to 30% of people with type 1 or types 2 diabetes develop nephropathy, but fewer of those with type 2 diabetes progress to ESKD. Native American, Latino, African American, Asian American, and Pacific Island people with type 2 diabetes are at greater risk for ESKD than non-Latino Whites (ADA, 2020).

Patients with type 1 diabetes frequently show initial signs of kidney disease after 10 to 15 years, while patients with type 2 diabetes tend to develop kidney disease within 10 years after the diagnosis of diabetes. Many patients with type 2 diabetes have had diabetes for many years before the diabetes is diagnosed and treated. Therefore, they may have evidence of nephropathy at the time of diagnosis (ADA, 2020). If blood glucose levels are elevated consistently for a significant period of time, the kidney's filtration mechanism is stressed, allowing blood proteins to leak into the urine. As a result, the pressure in the blood vessels of the kidney increases. It is thought that this elevated pressure serves as the stimulus for the development of nephropathy. Various medications and diets are being tested to prevent these complications.

The DCCT (1993) results showed that intensive treatment for type 1 diabetes with a goal of achieving a glycolated hemoglobin level as close to the nondiabetic range as possible reduced the occurrence of early signs of nephropathy. Similarly, the United Kingdom Prospective Diabetes Study Group (UKPDS, 1998) demonstrated a reduced incidence of overt nephropathy in patients with type 2 diabetes who controlled their blood glucose levels.

Clinical Manifestations

Most of the signs and symptoms of kidney dysfunction in patients with diabetes are similar to those seen in patients without diabetes (see Chapter 48). In addition, as kidney failure progresses, the catabolism (breakdown) of both exogenous and endogenous insulin decreases, and frequent hypoglycemic episodes may result. Insulin needs change as a result of changes in the catabolism of insulin, changes in diet related to the treatment of nephropathy, and changes in insulin clearance that occur with decreased kidney function.

Assessment and Diagnostic Findings

Albumin is one of the most important blood proteins that leak into the urine. Although small amounts may leak undetected for years, its leakage into the

urine is among the earliest signs that can be detected. Clinical nephropathy eventually develops in more than 85% of people with microalbuminuria but in fewer than 5% of people without microalbuminuria. The urine should be checked annually for the presence of microalbumin. If the microalbuminuria exceeds 30 mg/24 hours on two consecutive random urine tests, a 24-hour urine sample should be obtained and tested. If results are positive, treatment is indicated (see later discussion).

In addition, tests for serum creatinine and BUN levels should be conducted annually. Diagnostic testing for cardiac or other systemic disorders may also be required with progression of other complications, and caution is indicated if contrast agents are used with these tests. Contrast agents and dyes used for some diagnostic tests may not be easily cleared by the damaged kidney, and the potential benefits of these diagnostic tests must be weighed against their potential risks.

Hypertension often develops in patients (with and without diabetes) who are in the early stages of kidney disease. However, hypertension is the most common complication in all people with diabetes (ADA, 2020). Therefore, this symptom may or may not be due to kidney disease; other diagnostic criteria must also be present.

Management

In addition to achieving and maintaining near-normal blood glucose levels, management for all patients with diabetes should include careful attention to the following:

- Control of hypertension (the use of angiotensin-converting enzyme [ACE] inhibitors, such as captopril), because control of hypertension may also decrease or delay the onset of early proteinuria
- Prevention or vigorous treatment of urinary tract infections
- Avoidance of nephrotoxic medications and contrast dye
- Adjustment of medications as kidney function changes
- Low-sodium diet
- Low-protein diet

If the patient has already developed microalbuminuria with levels that exceed 30 mg/24 hours on two consecutive tests, an ACE inhibitor should be prescribed. ACE inhibitors lower blood pressure and reduce microalbuminuria, thereby protecting the kidney. Alternatively, angiotensin receptor–blocking agents may be prescribed. This preventive strategy should be part of the standard of care for all people with diabetes (ADA, 2020). Carefully designed low-protein diets also appear to reverse early leakage of small amounts of protein from the kidney.

In chronic or ESKD, two types of treatment are available: dialysis (hemodialysis or peritoneal dialysis) and transplantation from a relative or a deceased donor. Hemodialysis for patients with diabetes is similar to that for patients without the disease (see Chapter 48). Because hemodialysis creates additional stress on patients with cardiovascular disease, it may not be appropriate for some patients.

Continuous ambulatory peritoneal dialysis is being used by patients with diabetes, mainly because of the independence it allows. In addition, insulin can be mixed into the dialysate, which may result in better blood glucose control and end the need for insulin injections. Some patients may require higher doses of insulin because the dialysate contains glucose. Major risks of peritoneal dialysis are infection and peritonitis. The mortality rate for patients with diabetes undergoing dialysis is higher than that for patients without diabetes undergoing dialysis and is closely related to the severity of cardiovascular problems.

Kidney disease is frequently accompanied by advancing retinopathy that may require laser treatments and surgery. Severe hypertension also worsens eye disease because of the additional stress it places on the blood vessels. Patients being treated with hemodialysis who require eye surgery may be changed to peritoneal dialysis and have their hypertension aggressively controlled for several weeks before surgery to prevent bleeding and damage to the retina. The rationale for this change is that hemodialysis requires anticoagulant agents that can increase the risk of bleeding after the surgery, and peritoneal dialysis minimizes pressure changes in the eyes.

In medical centers performing large numbers of transplantations, the chances are 75% to 80% that the transplanted kidney will continue to function in patients with diabetes for at least 5 years. Like the original kidneys, transplanted kidneys can eventually be damaged if blood glucose levels are consistently high after the transplantation. Therefore, monitoring blood glucose levels frequently and adjusting insulin levels in patients with diabetes are essential for long-term success of kidney transplantation. Optimal treatment is a simultaneous kidney and pancreatic transplantation (Aref et al., 2019).

Diabetic Neuropathies

Diabetic neuropathy refers to a group of diseases that affect all types of nerves, including peripheral (sensorimotor), autonomic, and spinal nerves. The disorders appear to be clinically diverse and depend on the location of the affected nerve cells. The prevalence increases with the age of the patient and the duration of the disease (National Institute of Diabetes and Digestive and Kidney Diseases [NIDDK], 2018).

The etiology of neuropathy may involve elevated blood glucose levels over a period of years. Control of blood glucose levels to normal or near-normal levels decreases the incidence of neuropathy. The pathogenesis of neuropathy may be attributed to either a vascular or metabolic mechanism or both. Capillary basement membrane thickening and capillary closure may be present. In addition, there may be demyelinization of the nerves, which is thought to be related to hyperglycemia. Nerve conduction is disrupted when there are aberrations of the myelin sheaths.

The two most common types of diabetic neuropathy are sensorimotor polyneuropathy and autonomic neuropathy. Sensorimotor polyneuropathy is also called *peripheral neuropathy.* Cranial mononeuropathies—those affecting the oculomotor nerve—also occur in diabetes, especially in older adults.

Peripheral Neuropathy

Peripheral neuropathy most commonly affects the distal portions of the nerves, especially the nerves of the lower extremities; it affects both sides of the body symmetrically and may spread in a proximal direction.

Clinical Manifestations

Although approximately half of patients with diabetic neuropathy do not have symptoms, initial symptoms may include paresthesias (prickling, tingling, or heightened sensation) and burning sensations (especially at night). As the neuropathy progresses, the feet become numb. In addition, a decrease in proprioception (awareness of posture and movement of the body and of position and weight of objects in relation to the body) and a decreased sensation of light touch may lead to an unsteady gait. Decreased sensations of pain and temperature place patients with neuropathy at increased risk for injury due to falls and undetected foot infections (Hickey & Strayer, 2020). Deformities of the foot may also occur; neuropathy-related joint changes are sometimes referred to as Charcot joints. These joint deformities result from the abnormal weight distribution on joints resulting from lack of proprioception.

On physical examination, a decrease in deep tendon reflexes and vibratory sensation is found. For patients with fewer or no symptoms of neuropathy, these physical findings may be the only indication of neuropathic changes. For patients with signs or symptoms of neuropathy, it is important to rule out other possible causes, including alcohol-induced and vitamin-deficiency neuropathies.

Management

Intensive insulin therapy and control of blood glucose levels delay the onset and slow the progression of neuropathy. Pain, particularly of the lower extremities, is a disturbing symptom in some people with neuropathy secondary to diabetes. In some cases, neuropathic pain spontaneously resolves within 6 months; for others, pain persists for many years. Various approaches to pain management can be tried. These include analgesic agents (preferably nonopioid); tricyclic antidepressants and other antidepressant medications (duloxetine); anticonvulsant medications (pregabalin or gabapentin); mexiletine, an antiarrhythmic agent; and transcutaneous electrical nerve stimulation (Hickey & Strayer, 2020).

Autonomic Neuropathies

Neuropathy of the autonomic nervous system results in a broad range of dysfunctions affecting almost every organ system of the body (NIDDK, 2018).

Clinical Manifestations

Three manifestations of autonomic neuropathy are related to the cardiac, gastrointestinal, and renal systems. Cardiovascular symptoms range from a fixed, slightly tachycardic heart rate and orthostatic hypotension to silent, or painless, myocardial ischemia and infarction. Research suggests that cardiovascular health may also be impacted by diabetes distress and depressive symptoms (McCarthy, Whittemore, Gholson, et al., 2019). See the Nursing Research Profile in Chart 46-10.

Delayed gastric emptying may occur with the typical gastrointestinal symptoms of early satiety, bloating, nausea, and vomiting. “Diabetic” constipation or diarrhea (especially nocturnal diarrhea) may occur as a result. In addition, there may be unexplained wide swings in blood glucose levels related to inconsistent absorption of the glucose from ingested foods secondary to the inconsistent gastric emptying.

Urinary retention, a decreased sensation of bladder fullness, and other urinary symptoms of neurogenic bladder result from autonomic neuropathy. The patient with a neurogenic bladder is predisposed to development of urinary tract infections because of the inability to empty the bladder completely. This is especially true of patients with poorly controlled diabetes because hyperglycemia impairs resistance to infection.

Hypoglycemic Unawareness

Autonomic neuropathy affecting the adrenal medulla is responsible for diminished or absent adrenergic symptoms of hypoglycemia. Patients may report that they no longer feel the typical shakiness, sweating, nervousness, and palpitations associated with hypoglycemia. Frequent blood glucose

monitoring is recommended for these patients. The inability to detect and treat these warning signs of hypoglycemia puts patients at risk for development of dangerously low blood glucose levels. Therefore, goals for blood glucose levels may need to be adjusted to reduce the risk for hypoglycemia. Patients and families need to be taught to recognize subtle and atypical symptoms of hypoglycemia, such as numbness around the mouth and impaired ability to concentrate.

Sudomotor Neuropathy

The neuropathic condition called *sudomotor neuropathy* refers to a decrease or absence of anhidrosis (sweating) of the extremities, with a compensatory increase in upper body anhidrosis. Dryness of the feet increases the risk for the development of foot ulcerations.

Sexual Dysfunction

Sexual dysfunction, especially erectile dysfunction in men, is a complication of diabetes. The effects of autonomic neuropathy on female sexual functioning are not well documented. Reduced vaginal lubrication has been mentioned as a possible neuropathic effect. Other possible changes in sexual function in women with diabetes include decreased libido and lack of orgasm. Vaginal infection, which increases in the incidence in women with diabetes, may be associated with decreased lubrication and vaginal pruritus (itching) and tenderness. Urinary tract infections and vaginitis may also affect sexual function.

Chart 46-10  **NURSING RESEARCH PROFILE**

Health Factors in Adults with Type 1 Diabetes

McCarthy, M. M., Whittemore, R., Gholson, G., et al. (2019). Diabetes distress, depressive symptoms, and cardiovascular health in adults with type 1 diabetes. *Nursing Research*, *68*(6), 445–452.

Purpose

The prevalence of type 1 diabetes in adults is increasing. The purpose of this study was to describe the relationships among the psychological factors of depressive symptoms and diabetes distress and six cardiovascular risk factors.

Design

This was a cross-sectional survey of a sample of 83 adults with type 1 diabetes. Data were collected about sociodemographic information, depressive symptoms, diabetes distress, and cardiovascular health factors (body mass index [BMI], blood pressure, cholesterol, smoking, hemoglobin A1C, and physical activity).

Findings

The mean age of participants was 45 years, with a mean duration of 20 years with type 1 diabetes. The majority had low scores on the Diabetes Distress Scale while 18% had moderate, and another 18% had high scores. Twenty-two percent of participants had an increased level of depressive symptoms. Significant correlations were found between diabetes distress and fear of hypoglycemia ($r = .65$, $p < .0001$), depressive symptoms ($r = .55$, $p < .0001$), hemoglobin A1C ($r = .41$, $p < .001$), and total cholesterol ($r = .26$, $p < .05$). There were significant correlations between depressive symptom scores and fear of hypoglycemia ($r = .35$, $p < .01$), as well as hemoglobin A1C ($r = .25$, $p < .05$). There were small to medium nonsignificant correlations between depressive symptoms scores and weekly step counts and BMI.

Nursing Implications

Nurses working with patients with type 1 diabetes need to be aware that elevated diabetes distress and depressive symptoms may further affect these patients' already high risk of cardiovascular disease. Interventions are needed that affect both physical and psychological factors that have the potential to adversely affect cardiovascular health.

Erectile dysfunction occurs with greater frequency in men with diabetes than in other men of the same age. Some men with autonomic neuropathy have normal erectile function and can experience orgasm but do not ejaculate normally. Retrograde ejaculation occurs; seminal fluid is propelled backward through the posterior urethra and into the urinary bladder. Examination of the

urine confirms the diagnosis because of the large number of active sperm present. Fertility counseling may be necessary for couples attempting conception.

Diabetic neuropathy is not the only cause of erectile dysfunction in men with diabetes. Medications such as antihypertensive agents, psychological factors, and other medical conditions (e.g., vascular insufficiency) that may affect other men also play a role in erectile dysfunction in men with diabetes (see Chapter 53).

Management

Management strategies for autonomic neuropathy focus on alleviating symptoms and on modification and management of risk factors. Detection of painless cardiac ischemia is important so that education about avoiding strenuous exercise can be provided. Orthostatic hypotension may respond to a diet high in sodium, discontinuation of medications that impede autonomic nervous system responses, the use of sympathomimetic and other agents (e.g., caffeine) that stimulate an autonomic response, mineralocorticoid therapy, and the use of lower-body elastic garments that maximize venous return and prevent pooling of blood in the extremities.

Treatment of delayed gastric emptying includes a low-fat diet, frequent small meals, frequent blood glucose monitoring, and the use of agents that increase gastric motility (e.g., metoclopramide, bethanechol). Treatment of diabetic diarrhea may include bulk-forming laxatives or antidiarrheal agents. Constipation is treated with a high-fiber diet and adequate hydration; medications, laxatives, and enemas may be necessary if constipation is severe. Management of sexual dysfunction in women and men is discussed in Chapters 51 and 53, respectively. Intermittent straight catheterization may be necessary to prevent urinary tract infections in patients with neurogenic bladders.

Treatment of sudomotor dysfunction focuses on education about skin care and heat intolerance.

Foot and Leg Problems

Lower limb amputations in adults with diabetes increased by 50% between 2009 and 2015 compared to prior years (Virani et al., 2020). Amputations are preventable, provided patients are taught appropriate foot care measures and practice them on a daily basis (ADA, 2020). Complications of diabetes that contribute to the increased risk of foot problems and infections include the following:

- *Neuropathy:* Sensory neuropathy leads to loss of pain and pressure sensation, and autonomic neuropathy leads to increased dryness and fissuring of the skin (secondary to decreased sweating). Motor neuropathy results in muscular atrophy, which may lead to changes in the shape of the foot.
- *Peripheral vascular disease:* Poor circulation of the lower extremities contributes to poor wound healing and the development of gangrene.
- *Immunocompromise:* Hyperglycemia impairs the ability of specialized leukocytes to destroy bacteria. Therefore, in poorly controlled diabetes, there is a lowered resistance to certain infections.

Figure 46-8 • Neuropathic ulceration occurs on pressure points in areas with diminished sensation in diabetic polyneuropathy. Because pain is absent, the ulceration may go unnoticed.

The typical sequence of events in the development of a diabetic foot ulceration begins with a soft tissue injury of the foot, formation of a fissure between the toes or in an area of dry skin, or formation of a callus (see Fig. 46-8). Patients with an insensitive foot do not feel injuries, which may be thermal (e.g., from using heating pads, walking barefoot on hot concrete, testing bathwater with the foot), chemical (e.g., burning the foot while using caustic agents on calluses, corns, or bunions), or traumatic (e.g., injuring skin while cutting nails, walking with an undetected foreign object in the shoe, or wearing ill-fitting shoes and socks).

If the patient is not in the habit of thoroughly inspecting both feet on a daily basis, the injury or fissure may go unnoticed until a serious infection has developed. Drainage, swelling, redness of the leg (from cellulitis), or gangrene may be the first sign of foot problems that the patient notices. Treatment of foot ulcerations involves keeping the patient off their feet, antibiotics, and débridement. In addition, controlling glucose levels, which tend to increase when infections occur, is important for promoting wound healing. When peripheral vascular disease is present, foot ulcerations may not heal because of the decreased ability of oxygen, nutrients, and antibiotics to reach the injured tissue. Amputation (see Chapter 37) may be necessary to prevent the spread of infection, particularly if it involves the bone (osteomyelitis) (see Chapter 36).

Foot assessment and foot care instructions are most important when caring for patients who are at high risk for foot infections (Johnson, Osbourne, Rispoli, et al., 2018). Some of the high-risk characteristics include:

- Duration of diabetes more than 5 years
- Age greater than 40 years
- Current smoker and history of smoking
- Decreased peripheral pulses
- Decreased sensation
- Anatomic deformities or pressure areas (e.g., bunions, calluses, hammer toes)
- History of previous foot ulcerations or amputation

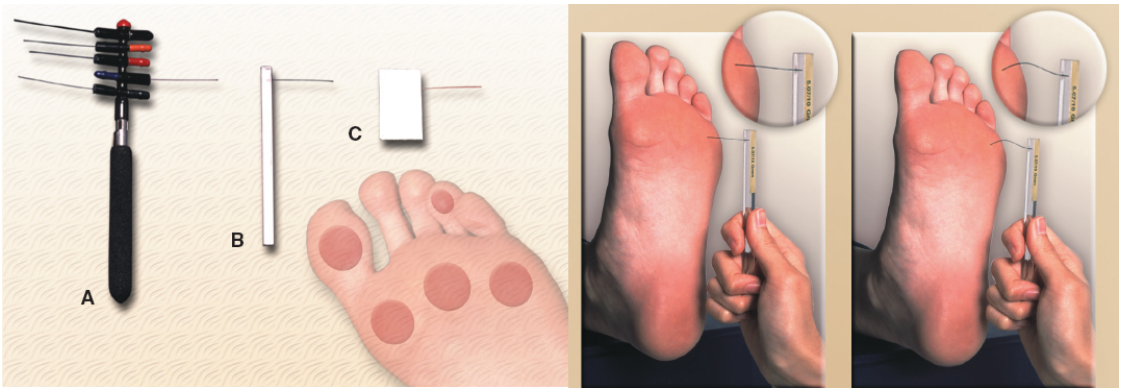

Figure 46-9 • The monofilament test is used to assess the sensory threshold in patients with diabetes. The test instrument—a monofilament—is gently applied to about five pressure points on the foot (as shown in image on *left*). **A.** Example of a monofilament used for advanced quantitative assessment. **B.** Semmes-Weinstein monofilament used by clinicians. **C.** Disposable monofilament used by patients. The examiner applies the monofilament to the test area to determine whether the patient feels the device. Adapted with permission from Cameron, B. L. (2002). Making diabetes management routine. *American Journal of Nursing*, *102*(2), 26–32.

Medical Management

The feet of a patient with diabetes should be examined during every health care visit or at least once per year (more often if there is an increase in risk) by a podiatrist, physician, or nurse (ADA, 2020; Johnson et al., 2018). All patients should be assessed for neuropathy and undergo evaluation of neurologic status by an experienced examiner using a monofilament device (ADA, 2020; Johnson et al., 2018) (see Fig. 46-9). Pressure areas, such as calluses, or thick toenails should be treated by a podiatrist in addition to routine trimming of nails. Blood glucose control is essential for avoiding decreased resistance to infections and for preventing diabetic neuropathy.

Nursing Management

The nurse facilitates or conducts a foot assessment at each visit to a health care provider (Johnson et al., 2018). Educating patients about proper foot care is an essential nursing intervention that can prevent costly and painful complications that result in disability (see Chart 46-11).

SPECIAL ISSUES IN DIABETES CARE

Patients with Diabetes Who Are Undergoing Surgery

During periods of physiologic stress, such as surgery, blood glucose levels tend to increase, because levels of stress hormones (epinephrine, norepinephrine, glucagon, cortisol, and growth hormone) increase. If hyperglycemia is not controlled during surgery, the resulting osmotic diuresis may lead to excessive loss of fluids and electrolytes. Patients with type 1 diabetes also risk developing DKA during periods of stress.

Hypoglycemia is also a concern in patients with diabetes who are undergoing surgery. This is a special concern during the preoperative period if surgery is delayed beyond the morning in a patient who received a morning injection of intermediate-acting insulin.

There are various approaches to managing glucose control during the perioperative period. Frequent blood glucose monitoring is essential throughout the pre- and postoperative periods, regardless of the method used for glucose control. Examples of these approaches are described in Chart 46-12. The use of IV insulin and dextrose has become widespread with the increased availability of intraoperative glucose monitoring.

During the postoperative period, patients with diabetes must also be closely monitored for cardiovascular complications because of the increased prevalence of atherosclerosis, wound infections, and skin breakdown (especially in patients with decreased sensation in the extremities due to

neuropathy). Maintaining adequate nutrition and blood glucose control promote wound healing.

Management of Patients with Diabetes Who Are Hospitalized

At any one time, as many as 25% of hospitalized general medical-surgical patients have diabetes (ADA, 2020). Often, diabetes is not the primary medical diagnosis, yet problems with control of diabetes frequently result from changes in the patient's normal routine or from surgery or illness. Patients who are hospitalized and have a diagnosis of diabetes should have this clearly indicated on their electronic health record (EHR), and glucose monitoring needs to be prescribed (ADA, 2020). During the course of treatment, blood glucose control may worsen. Control of blood glucose levels is important because hyperglycemia in patients who are hospitalized can increase the length of hospital stay, the risk of infection, and mortality (ADA, 2020).

In addition, this is an opportunity for patients with diabetes to update their knowledge about diabetes self-care and prevention of complications. Nurses caring for patients with diabetes should focus attention on the diabetes as well as the primary health issue.

Chart 46-11  **PATIENT EDUCATION**

Foot Care Tips

The nurse instructs the patient to:
Take care of your diabetes.

- Work with your health care team to keep your blood glucose level within a normal range.

Inspect your feet every day.

- Look at your bare feet every day for cuts, blisters, red spots, and swelling.
- Use a mirror to check the bottoms of your feet, or ask a family member for help if you have trouble seeing.
- Check for changes in temperature.

Wash your feet every day.

- Wash your feet in warm, not hot, water.
- Dry your feet well. Be sure to dry between the toes.
- Do not soak your feet.
- Do not check water temperature with your feet; use a thermometer or elbow.

Keep the skin soft and smooth.

- Rub a thin coat of skin lotion over the tops and bottoms of your feet, but not between your toes.

Smooth corns and calluses gently.

- Use a pumice stone to smooth corns and calluses.
- Do not shave calluses.
- See a podiatrist as needed.

Trim your toenails each week or when needed.

- Trim your toenails straight across, and file the edges with an emery board or nail file.

Wear shoes and socks at all times.

- Never walk barefoot.
- Wear comfortable shoes that fit well and protect your feet.
- Feel inside your shoes before putting them on each time to make sure that the lining is smooth and there are no objects inside.
- Be aware that a podiatrist can provide inserts (orthotics) to remove pressure from pressure points on the foot.
- Break in new shoes slowly (i.e., wear for 1 to 2 hours initially, with gradual increases in the length of time worn) to avoid blister formation.
- If you have bony deformities, custom-made shoes with extra width or depth may be needed.

Protect your feet from hot and cold.

- Wear shoes at the beach or on hot pavement.
- Wear socks at night if your feet get cold.

Keep the blood flowing to your feet.

- Put your feet up when sitting.
- Wiggle your toes and move your ankles up and down for 5 minutes, two or three times a day.
- Do not cross your legs for long periods of time.
- Do not smoke.

Check with your primary provider.

- Have your primary provider check your bare feet and find out whether you are likely to have serious foot problems. Remember that you may not feel the pain of an injury.
- Call your primary provider right away if a cut, sore, blister, or bruise on your foot does not begin to heal after 1 day.
- Follow your primary provider's advice about foot care.
- Do not self-medicate or use home remedies or over-the-counter agents to treat foot problems.

Chart 46-12

Approaches to Management of Glucose Control During the Perioperative Period for Those with a Diagnosis of Diabetes

- Monitor blood glucose levels frequently (every 1 to 2 hours).
- For patients taking insulin:

1. The morning of surgery, all subcutaneous insulin doses are withheld, unless the blood glucose level is elevated (e.g., >200 mg/dL [11.1 mmol/L]), in which case a small dose of subcutaneous regular insulin may be prescribed. The blood glucose level is controlled during surgery with the IV infusion of regular insulin, which is balanced by an infusion of dextrose. The insulin and dextrose infusion rates are adjusted according to frequent (hourly) capillary glucose determinations. After surgery, the insulin infusion may be continued until the patient can eat. If IV insulin is discontinued, subcutaneous regular insulin may be given at set intervals (every 4 to 6 hours), or intermediate-acting insulin may be given every 12 hours with supplemental regular insulin as necessary until the patient is eating and the usual pattern of insulin dosing is resumed.

- Carefully monitor the insulin infusion rate and blood glucose levels in a patient with diabetes who is receiving IV insulin. IV insulin has a much shorter duration of action than subcutaneous insulin. If the infusion is interrupted or discontinued, hyperglycemia will develop rapidly (within 1 hour in type 1 diabetes and within a few hours in type 2 diabetes).
- Ensure that subcutaneous insulin is given 30 minutes before the IV insulin infusion is discontinued.

2. One half to two thirds of the patient's usual morning dose of insulin (either intermediate-acting insulin alone or both short- and intermediate-acting insulins) is given subcutaneously in the morning before surgery. The remainder is then given after surgery.

3. The patient's usual daily dose of subcutaneous insulin is divided into 4 equal doses of regular insulin. These are then given at 6-hour intervals. The last 2 approaches do not provide the control achieved by IV administration of insulin and dextrose.

- Patients with type 2 diabetes who do not usually take insulin may require insulin during the perioperative period to control blood glucose elevations. Patients who are taking metformin may be instructed to discontinue the oral agent 24 to 48 hours before surgery, if possible. Some of these patients may resume their usual regimen of diet and oral agent during the recovery period. Other patients (whose diabetes is probably not well controlled with diet and an oral antidiabetic agent before surgery) need to continue with insulin injections after discharge.
- For patients with type 2 diabetes who are undergoing minor surgery but who do not normally take insulin, glucose levels may remain stable provided no dextrose is infused during the surgery. After surgery, these patients may require small doses

of regular insulin until the usual diet and oral agent are resumed.

Self-Care Issues

For patients who are actively involved in diabetes self-management (especially insulin dose adjustment), relinquishing control over meal timing, insulin timing, and insulin dosage can be particularly difficult and anxiety provoking. The patient may fear hypoglycemia and express much concern over possible delays in receiving attention from the nurse if hypoglycemic symptoms occur or may disagree with a planned dose of insulin.

The nurse acknowledges the patient's concerns and involves the patient in the plan of care as much as possible. If the patient disagrees with certain aspects of the care related to diabetes, the nurse must communicate this to other members of the health care team. Nurses and other health care providers must pay particular attention to patients who are successful in managing self-care; they should assess these patients' self-care management skills and encourage them to continue if their performance is correct and effective.

Hospitalization of a patient with diabetes should be considered an opportunity to evaluate the patient's self-care skills and to reinforce or deliver education that might be needed. The nurse observes the patient preparing and injecting the insulin, monitoring blood glucose, and performing foot care. Simply questioning the patient about these skills without actually observing performance of the skills is not sufficient. The patient's knowledge about diet can be assessed with the help of a dietitian through direct questioning and review of the patient's menu choices. The patient's understanding about signs and symptoms, treatment, and prevention of hypoglycemia and hyperglycemia is assessed, along with knowledge of risk factors for macrovascular disease, including hypertension, increased lipids, and smoking. In addition, the patient is asked the date of their last eye examination (including dilation of the pupils). Education about these issues is critical.

Hyperglycemia During Hospitalization

Hyperglycemia may occur in patients who are hospitalized as a result of the original illness that led to the need for hospitalization. A number of other factors may contribute to hyperglycemia; examples include:

- Changes in the usual treatment regimen (e.g., increased food, decreased insulin, decreased activity)

- Medications (e.g., corticosteroids such as prednisone, which are used in the treatment of a variety of inflammatory disorders)
- IV dextrose, which may be part of the maintenance fluids or may be used for the administration of antibiotics and other medications, without adequate insulin therapy
- Overly vigorous treatment of hypoglycemia
- Inappropriate withholding of insulin or inappropriate use of "sliding scales"
- Mismatched timing of meals and insulin (e.g., postmeal hyperglycemia may occur if short-acting insulin is given immediately before or even after a meal)

Nursing actions to correct some of these factors are important for avoiding hyperglycemia. Assessment of the patient's usual home routine is important. The nurse should try to approximate as much as possible the home schedule of insulin, meals, and activities. Monitoring blood glucose levels has been identified by the ADA as an additional "vital sign" essential in assessment of patients (ADA, 2020). The results of blood glucose monitoring provide information needed to obtain orders for extra doses of insulin (at times when insulin is usually taken), which is an important nursing function. Insulin doses must not be withheld when blood glucose levels are normal. It is very important to test blood glucose before a meal and administer insulin at that time, not on a rigid set time schedule as other medications are given. Insulin should be given when the meal is served to prevent hypoglycemia and elicit a physiologic response.

Short-acting insulin is usually needed to avoid postprandial hyperglycemia (even in patients with normal premeal glucose levels), and NPH insulin does not peak until many hours after the dose is given. IV antibiotics should be mixed in NS (if possible) to avoid excess infusion of dextrose (especially in patients who are eating). It is important to avoid overly vigorous treatment of hypoglycemia, which may lead to hyperglycemia.

Hypoglycemia During Hospitalization

Hypoglycemia in patients who are hospitalized is usually the result of too much insulin or delays in eating. Specific examples include:

- Overuse of sliding-scale regular insulin, particularly as a supplement to regularly scheduled, twice-daily short- and intermediate-acting insulins
- Lack of change in insulin dosage when dietary intake is changed (e.g., in the patient taking nothing by mouth [NPO])
- Overly vigorous treatment of hyperglycemia (e.g., giving too-frequent successive doses of regular insulin before the time of peak

insulin activity is reached), resulting in a cumulative effect
- Delayed meal after administration of lispro, aspart, or glulisine insulin (patient should eat within 5 to 15 minutes after insulin administration)

Treatment of hypoglycemia should be based on the established hospital protocol (ADA, 2020). If the initial treatment does not increase the glucose level adequately, the same treatment may be repeated after 15 minutes. The nurse must assess the pattern of glucose values and avoid giving doses of insulin that repeatedly lead to hypoglycemia. Successive doses of subcutaneous regular insulin should be given no more frequently than every 3 to 4 hours. For patients receiving intermediate insulin before breakfast and dinner, the nurse must use caution in administering supplemental doses of regular insulin at lunch and bedtime. Hypoglycemia may occur when two insulins peak at similar times (e.g., morning NPH peaks with lunchtime regular insulin and may lead to late-afternoon hypoglycemia; dinnertime NPH peaks with bedtime regular insulin and may lead to nocturnal hypoglycemia). To avoid hypoglycemic reactions caused by delayed food intake, the nurse should arrange for snacks to be given to the patient if meals are going to be delayed because of procedures, physical therapy, or other activities.

Common Alterations in Diet

Dietary modifications commonly prescribed during hospitalization require special consideration for patients who have diabetes (ADA, 2020).

Nothing by Mouth

For patients who must be NPO in preparation for diagnostic or surgical procedures, the nurse must ensure that the usual insulin dosage has been changed. These changes may include eliminating the rapid-acting insulin and giving a decreased amount (e.g., half the usual dose) of intermediate-acting insulin. Another approach is to use frequent (every 3 to 4 hours) dosing of rapid-acting insulin only. IV dextrose may be given to provide calories and to avoid hypoglycemia.

Even without food, glucose levels may increase as a result of hepatic glucose production, especially in patients with type 1 diabetes and lean patients with type 2 diabetes. Furthermore, in type 1 diabetes, elimination of the insulin dose may lead to the development of DKA. Administration of basal insulin to patients with type 1 diabetes who are NPO is an important nursing action.

For patients with type 2 diabetes who are taking insulin, DKA does not usually develop when insulin doses are eliminated because the patient's pancreas produces some insulin. Therefore, skipping the insulin dose

altogether (when the patient is receiving IV dextrose) may be safe; however, close monitoring of blood glucose levels is essential.

For patients who are NPO for extended periods (24 hours), glucose testing and insulin administration should be performed at regular intervals, usually four times per day. Insulin regimens for the patient who is NPO for an extended period may include NPH insulin every 12 hours, rapid-acting insulin only every 4 to 6 hours, or an IV insulin drip. These patients should receive dextrose infusions to provide some calories and limit ketosis.

To prevent the problems that result from the need to withhold food, diagnostic tests and procedures and surgery should be scheduled early in the morning when possible.

Clear Liquid Diet

When the diet is advanced to include clear liquids, patients with diabetes receive more simple carbohydrate foods, such as juice and gelatin desserts, than are usually included in the diabetic diet. Because patients who are hospitalized should maintain their nutritional status as much as possible to promote healing, the use of reduced-calorie substitutes such as diet soda or diet gelatin desserts would not be appropriate when the only source of calories is clear liquids. Simple carbohydrates, if eaten alone, cause a rapid rise in blood glucose levels; therefore, it is important to try to match peak times of insulin effect with peaks in the blood glucose concentration. If the patient receives insulin at regular intervals while NPO, the scheduled times for glucose tests and insulin injections should match mealtimes.

Enteral Tube Feedings

Tube feeding formulas contain more simple carbohydrates and less protein and fat than the typical meal plan for diabetes (see Chapter 39). This results in increased levels of glucose in patients with diabetes who are receiving tube feedings. Insulin doses must be given at regular intervals (e.g., NPH every 12 hours or regular insulin every 4 to 6 hours) when continuous tube feedings are given. If insulin is administered at routine (prebreakfast and predinner) times, hypoglycemia during the day may result (because the patient receives more insulin without more calories); hyperglycemia may occur during the night if feedings continue but insulin action decreases.

A common cause of hypoglycemia in patients receiving both continuous tube feedings and insulin is inadvertent or purposeful discontinuation of the feeding. The nurse must discuss with the medical team any plans for temporarily discontinuing the tube feeding (e.g., when the patient is away from the unit). Planning ahead may allow for alterations to be made in the insulin dose or for administration of IV dextrose. In addition, if problems with the tube feeding develop unexpectedly (e.g., the patient pulls out the tube, the tube

clogs, the feeding is discontinued when residual gastric contents are found), the nurse must notify the primary provider, assess blood glucose levels more frequently, and administer IV dextrose if indicated.

Parenteral Nutrition

Patients receiving parenteral nutrition may receive both IV insulin (added to the parenteral nutrition IV bag) and subcutaneous intermediate- or short-acting insulins. If the patient is receiving continuous parenteral nutrition, the blood glucose level should be monitored and insulin given at regular intervals. If the parenteral nutrition is infused over a limited number of hours, subcutaneous insulin should be given so that peak times of insulin action coincide with times of parenteral nutrition infusion (see Chapter 41 for discussion of parenteral nutrition).

Hygiene

Nurses caring for hospitalized patients with diabetes must focus attention on oral hygiene and skin care. Because these patients are at increased risk for periodontal disease, the nurse assists with at least daily dental care. The patient may also require assistance in keeping the skin clean and dry, especially in areas of contact between two skin surfaces (e.g., groin, axilla, under the breasts), where chafing and fungal infections tend to occur.

Careful assessments of the oral cavity and the skin are important. The skin is assessed for dryness, cracks, breakdown, and redness, especially at pressure points and on the lower extremities. The patient is asked about symptoms of neuropathy, such as tingling and pain or numbness of the feet. Deep tendon reflexes are assessed.

As with any patient confined to bed, nursing care must emphasize the prevention of skin breakdown at pressure points. The heels are particularly susceptible to breakdown because of loss of sensation of pain and pressure associated with sensory neuropathy.

Feet should be cleaned, dried, lubricated with lotion (but not between the toes), and inspected frequently. If the patient is in the supine position, pressure on the heels can be alleviated by elevating the lower legs on a pillow, with the heels positioned over the edge of the pillow. When the patient is seated in a chair, the feet should be positioned so that pressure is not placed on the heels. If the patient has an ulceration on one foot, the nurse provides preventive care to the unaffected foot as well as special care of the affected foot.

As always, every opportunity should be taken to educate the patient about diabetes self-management, including daily oral, skin, and foot care. Female patients should also be instructed about measures for the avoidance of vaginal infections, which occur more frequently when blood glucose levels are

elevated. Patients often take their cues from nurses and realize the importance of daily personal hygiene if this is emphasized during their hospitalization.

Stress

Physiologic stress, such as infections and surgery, contributes to hyperglycemia and may precipitate DKA or HHS. Emotional stress related to hospitalization for any reason can also have a negative impact on diabetic control. An increase in stress hormones leads to an increase in glucose levels, especially if intake of food and insulin remains unchanged. In addition, during periods of emotional stress, people with diabetes may alter their usual pattern of meals, exercise, and medication. This can contribute to hyperglycemia or even hypoglycemia (e.g., in the patient taking insulin or oral antidiabetic agents who stops eating in response to stress).

People with diabetes must be made aware of the potential deterioration in diabetic control that can accompany emotional stress. They must be encouraged to follow the diabetes treatment plan as much as possible during times of stress. In addition, learning strategies for minimizing stress and coping with stress when it does occur are important aspects of diabetes education.

Gerontologic Considerations

Because people with diabetes are living longer, both type 1 and type 2 diabetes are being seen more frequently in older patients hospitalized for various reasons. Regardless of the type or duration of diabetes, the goals of diabetes treatment may need to be altered when caring for older adults who are hospitalized. The focus is on quality-of-life issues, such as maintaining independent functioning and promoting general well-being.

Some of the barriers to learning and self-care during hospital stays and in preparing patients for discharge include decreased vision, hearing loss, memory deficits, decreased mobility and fine motor coordination, increased tremors, depression and isolation, decreased financial resources, and limitations related to disability and other medical disorders. Assessing these barriers is important in planning diabetes treatment and educational activities. Presenting brief, simplified instructions with ample opportunity for practice of skills is important. The use of special devices such as a magnifier for the insulin syringe, an insulin pen, or a mirror for foot inspection is helpful. Frequent evaluation of self-care skills (insulin administration, blood glucose monitoring, foot care, diet planning) is essential, especially in patients with deteriorating vision and memory. Providing written instructions with handouts to take home also assists with management in the home setting.

If appropriate, family members may be called on to assist with diabetes basic skills, and referral to community resources may be made. It is preferable to educate the patient or family members to test blood glucose at home; the choice of meter should be tailored to the patient's visual and cognitive status and dexterity.

Quality and Safety Nursing Alert

Careful monitoring for complications of diabetes in older adults is vital. Hypoglycemia is especially dangerous, because it may go undetected and result in falls. Dehydration is a concern in patients who have chronically elevated blood glucose levels. Assessment for long-term complications, especially eye and foot problems, is important. Avoiding blindness and amputation through early detection and treatment of retinopathy and foot ulcerations may mean the difference between placement in a long-term care facility and continued independent living for the older adult with diabetes.

Nursing Management

Monitoring and Managing Potential Complications

Assessment for hypo- and hyperglycemia involves frequent blood glucose monitoring (usually prescribed before meals and at bedtime) and monitoring for signs and symptoms of hypoglycemia or prolonged hyperglycemia (including DKA or HHS), as described previously. Inadequate control of blood glucose levels may hinder recovery from the primary health problem. Blood glucose levels are monitored, and insulin is given as prescribed. The nurse must ensure that prescribed insulin dosage is modified as needed to compensate for changes in the patient's schedule or eating pattern. Treatment is given for hypoglycemia (with oral glucose) or hyperglycemia (with supplemental regular insulin no more often than every 3 to 4 hours). Blood glucose records are assessed for patterns of hypo- and hyperglycemia at the same time of day, and findings are reported to the primary provider for modification in insulin orders. In the patient with prolonged elevations in blood glucose, laboratory values and the patient's physical condition are monitored for signs and symptoms of DKA or HHS.

Promoting Home, Community-Based, and Transitional Care

Educating Patients About Self-Care

Even if patients have had diabetes for many years, their knowledge and adherence to the plan of care must be assessed. A new plan of care may need to be devised using updated evidence. The nurse also reminds the patient and family about the importance of health promotion activities and recommended health screening.

Continuing and Transitional Care

A patient who is hospitalized may require referral for home, community-based or transitional care. The nurse can use this opportunity to assess the patient's knowledge about diabetes management and the patient's and family's ability to carry out that management. The nurse reinforces the education provided in the hospital, clinic, office, or diabetes education center and assesses the home care environment to determine its adequacy for self-care and safety.

CRITICAL THINKING EXERCISES

1 ipc An 18-year-old woman is newly diagnosed with type 1 diabetes in the clinic where you work. How will you educate this patient about this new diagnosis? Which referrals are appropriate to help this patient manage her type 1 diabetes? What steps will the interdisciplinary team take to address the patient's health care needs?

2 ebp A 45-year-old patient has had type 2 diabetes for 6 years. During his annual examination at the clinic where you work, a small ulceration is identified on the bottom of his foot. What is the evidence for management of a foot ulceration in this patient? What criteria would you use to assess the strength of the evidence? What is the evidence for the timing of future foot assessments?

3 pq A 65-year-old patient is admitted to the emergency department with possible HHS. Identify the pathophysiology and signs and symptoms of HHS. What are your priorities for the assessment, medical management, and nursing care for this patient with HHS? What are your priorities for discharge planning to prevent another episode?

UNIT 11 Kidney and Urinary Tract Function

Case Study

AVOIDING FALLS FOR THE PATIENT AT RISK

You are a nurse working in an intermediate medical unit caring for a 78-year-old man who was admitted from the emergency department (ED) with a change in level of consciousness and falling at home. His diagnostic and laboratory findings show that he has a lower urinary tract infection (UTI). Your initial assessment

reveals the patient is still not oriented to person, place, or time. In addition, he is trying to get up to the bathroom due to urinary urgency caused by the UTI. Because of his change in level of consciousness and urgency, you determine that safety is a priority. You implement falls precautions.

QSEN Competency Focus: Safety

The complexities inherent in today's health care system challenge nurses to demonstrate integration of specific interdisciplinary core competencies. These competencies are aimed at ensuring the delivery of safe, quality patient care (Institute of Medicine, 2003). The Quality and Safety Education for Nurses project (Cronenwett, Sherwood, Barnsteiner, et al., 2007; QSEN, 2020) provides a framework for the knowledge, skills, and attitudes (KSAs) required for nurses to demonstrate competency in these key areas, which include ***patient-centered care***, ***interdisciplinary teamwork and collaboration***, ***evidence-based practice***, ***quality improvement***, ***safety***, and ***informatics.***

Safety Definition: Minimizes risk of harm to patients and providers through both system effectiveness and individual performance.

SELECT PRE-LICENSURE KSAs	APPLICATION AND REFLECTION
Knowledge	
Examine human factors and other basic safety design principles as well as commonly used unsafe practices (such as, work-arounds and dangerous abbreviations)	Describe how you will prioritize care for this patient. How does safety impact priority decisions for this patient? Based on the assessment findings, why was the patient placed on falls precautions?
Skills	
Demonstrate effective use of technology and standardized practices that support safety and quality	Identify the technology and standardized practices you will use to implement falls precautions for this patient. How will you determine when the falls precautions can be discontinued?
Attitudes	
Value vigilance and monitoring (even of own performance of care activities) by patients, families, and other members of the health care team	Reflect on what you learned from this case study. The nurse's role in patient safety is essential. How can the nurse educate the patient and family to value safety in the home environment to prevent falls? Which additional health care team members could be consulted to assist the patient and family in a home assessment for safety?

47 Assessment of Kidney and Urinary Function

LEARNING OUTCOMES

On completion of this chapter, the learner will be able to:

1. Describe the structure and function of the renal and urinary systems.
2. Explain the role of the kidneys in regulating fluid and electrolyte balance, acid–base balance, and blood pressure.
3. Identify the diagnostic studies used to determine upper and lower urinary tract function and related nursing implications.
4. Discriminate between normal and abnormal assessment findings of upper and lower urinary tract function.
5. Initiate education and preparation for patients undergoing assessment of the urinary system.

NURSING CONCEPTS

Acid–Base Balance
Acid–Base Balance Assessment
Comfort
Elimination
Fluids and Electrolytes
Infection
Patient Education

GLOSSARY

aldosterone: hormone synthesized and released by the adrenal cortex; causes the kidneys to reabsorb sodium

antidiuretic hormone (ADH): hormone secreted by the posterior pituitary gland; causes the kidneys to reabsorb more water (*synonym:* vasopressin)

anuria: decreased urine output of less than 50 mL in 24 hours

bacteriuria: bacteria in the urine

creatinine: endogenous waste product of muscle energy metabolism

diuresis: increased urine volume

dysuria: painful or difficult urination

erythropoietin: glycoprotein produced by kidney; stimulates bone marrow to produce red blood cells

glomerular filtration rate (GFR): amount of plasma filtered through the glomeruli per unit of time

glomerulus: tuft of capillaries forming part of the nephron through which filtration occurs

glycosuria: excretion of glucose in the urine

hematuria: red blood cells in the urine

micturition: urination or voiding

nephrons: structural and functional units of the kidney responsible for urine formation

nocturia: awakening at night to urinate

oliguria: urine output less than 400 mL in 24 hours or less than 0.5 mL/kg/h over 6 hours

proteinuria: protein in the urine

pyuria: white blood cells in the urine

renal clearance: ability of the kidneys to clear solutes from the plasma

specific gravity: expression of the degree of concentration of the urine

urea nitrogen: end product of protein metabolism (*synonym:* blood urea nitrogen [BUN])

urinary frequency: voiding more frequently than every 3 hours

Function of the renal and urinary systems is essential to life. The primary purpose of the renal and urinary systems is to maintain the body's state of homeostasis by carefully regulating fluid and electrolytes, removing wastes, and providing other functions (see Chart 47-1). Dysfunction of the kidneys and lower urinary tract is common and may occur at any age and with varying degrees of severity. Assessment of upper and lower urinary tract function is

part of every health examination and requires the nurse to understand the anatomy and physiology of the urinary system as well as the effects of changes in the system on other physiologic functions.

Anatomic and Physiologic Overview

A focused assessment of kidney and urinary tract function requires an understanding of the anatomy and physiology of these systems.

Anatomy of the Kidney and Urinary Systems

The kidney and urinary systems include the kidneys, ureters, bladder, and urethra. Urine is formed by the kidney and flows through the other structures to be eliminated from the body.

Kidneys

The kidneys are a pair of bean-shaped, brownish-red structures located retroperitoneally (behind and outside the peritoneal cavity) on the posterior wall of the abdomen—from the 12th thoracic vertebra to the 3rd lumbar vertebra in the adult (see Fig. 47-1A). The rounded outer convex surface of each kidney is called the hilum. Each hilum is penetrated with blood vessels, nerves, and the ureter. The average adult kidney weighs approximately 113 to 170 g (about 4.5 oz) and is 10 to 12 cm long, 6 cm wide, and 2.5 cm thick (Norris, 2019; Russell, 2017). The right kidney is slightly lower than the left due to the location of the liver.

Externally, the kidneys are well protected by the ribs and by the muscles of the abdomen and back. Internally, fat deposits surround each kidney, providing protection against jarring. The kidneys and surrounding fat are suspended from the abdominal wall by renal fascia made of connective tissue which holds the kidney in place (Norris, 2019). The fibrous connective tissue, blood vessels, and lymphatics surrounding each kidney are known as the renal capsule. An adrenal gland lies on top of each kidney. The kidneys and adrenals are independent in function, blood supply, and innervation.

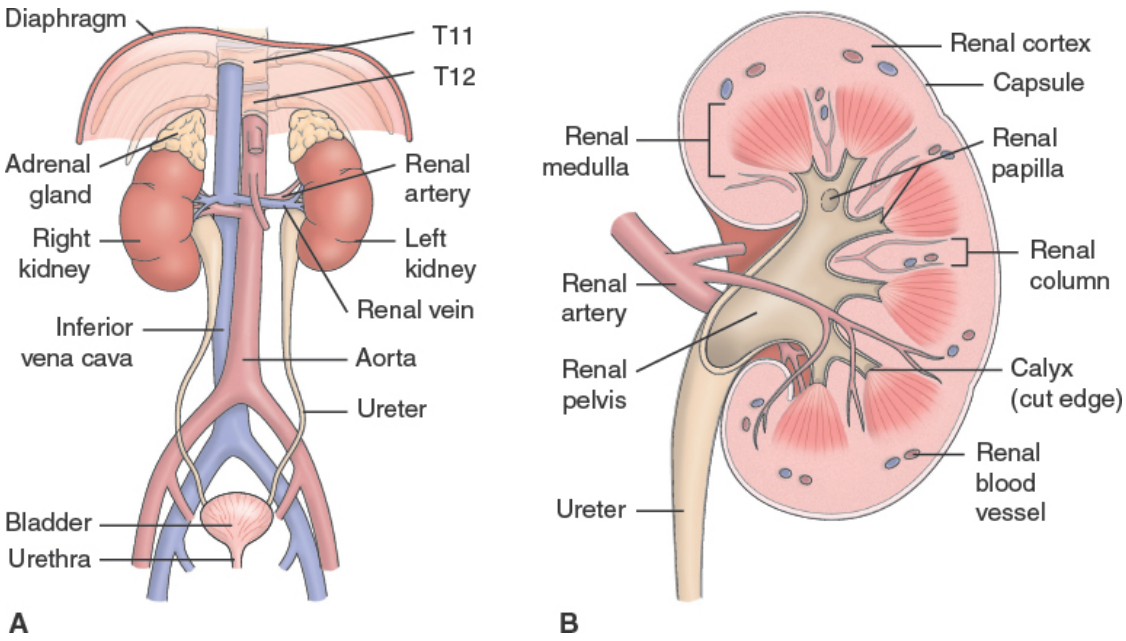

Figure 47-1 • **A.** Kidneys, ureters, and bladder. **B.** Internal structure of the kidney. Redrawn with permission from Porth, C. M., & Matfin, G. (2009). *Pathophysiology: Concepts of altered health states* (8th ed.). Philadelphia, PA: Lippincott Williams & Wilkins.

The renal parenchyma is divided into two parts: the cortex and the medulla (see Fig. 47-1B). The medulla, which is approximately 5 cm wide, is the inner portion of the kidney. It contains the loops of Henle, the vasa recta, and the collecting ducts of the juxtamedullary nephrons. The collecting ducts from both the juxtamedullary and the cortical nephrons connect to the renal pyramids, which are triangular and are situated with the base facing the concave surface of the kidney and the point (papilla) facing the hilum, or pelvis. Each kidney contains approximately 8 to 18 pyramids. The pyramids drain into minor calyces, which drain into major calyces that open directly into the renal pelvis. The tip of each pyramid is called a papilla and projects into the minor calyx. The renal pelvis is the beginning of the collecting system and is composed of structures that are designed to collect and transport urine. Once the urine leaves the renal pelvis, the composition or amount of urine does not change.

The cortex, which is approximately 1 cm wide, is located farthest from the center of the kidney and around the outermost edges (Norris, 2019). It contains the **nephrons** (the structural and functional units of the kidney responsible for urine formation), which are discussed later.

Blood Supply to the Kidneys

The hilum is the concave portion of the kidney through which the renal artery enters and the ureters and renal vein exit. The kidneys receive 20% to 25% of the total cardiac output, which means that all of the body's blood circulates through the kidneys approximately 12 times per hour (Norris, 2019). The renal artery (arising from the abdominal aorta) divides into smaller and smaller vessels, eventually forming the afferent arterioles. Each afferent arteriole branches to form a **glomerulus**, which is the tuft of capillaries forming part of the nephron through which filtration occurs. Blood leaves the glomerulus through the efferent arteriole and flows back to the inferior vena cava through a network of capillaries and veins.

Nephrons

Each kidney has one million nephrons that are located within the renal parenchyma and are responsible for the formation of filtrate that will become urine (Norris, 2019). The large number of nephrons allows for adequate renal function even if the opposite kidney is damaged or becomes nonfunctional. If the total number of functioning nephrons is less than 20% of normal, kidney replacement therapy needs to be considered.

There are two types of nephrons. The cortical nephrons (80% to 85%) are located in the outermost part of the cortex, and the juxtamedullary nephrons (15% to 20%) are located deeper in the cortex (Norris, 2019). The juxtamedullary nephrons are distinguished by long loops of Henle and are surrounded by long capillary loops called vasa recta that dip into the medulla of the kidney. The length of the tubular component of the nephron is directly related to its ability to concentrate urine.

Nephrons are made up of two basic components: a filtering element composed of an enclosed capillary network (the glomerulus) and the attached tubule (see Fig. 47-2). The glomerulus is a unique network of capillaries suspended between the afferent and efferent blood vessels, which are enclosed in an epithelial structure called the Bowman capsule. The glomerular membrane is composed of three filtering layers: the capillary endothelium, the basement membrane, and the epithelium. This membrane normally allows filtration of fluid and small molecules yet limits passage of larger molecules, such as blood cells and albumin. Pressure changes and the permeability of the glomerular membrane of the Bowman capsule facilitate the passage of fluids and various substances from the blood vessels, filling the space within the Bowman capsule with this filtered solution.

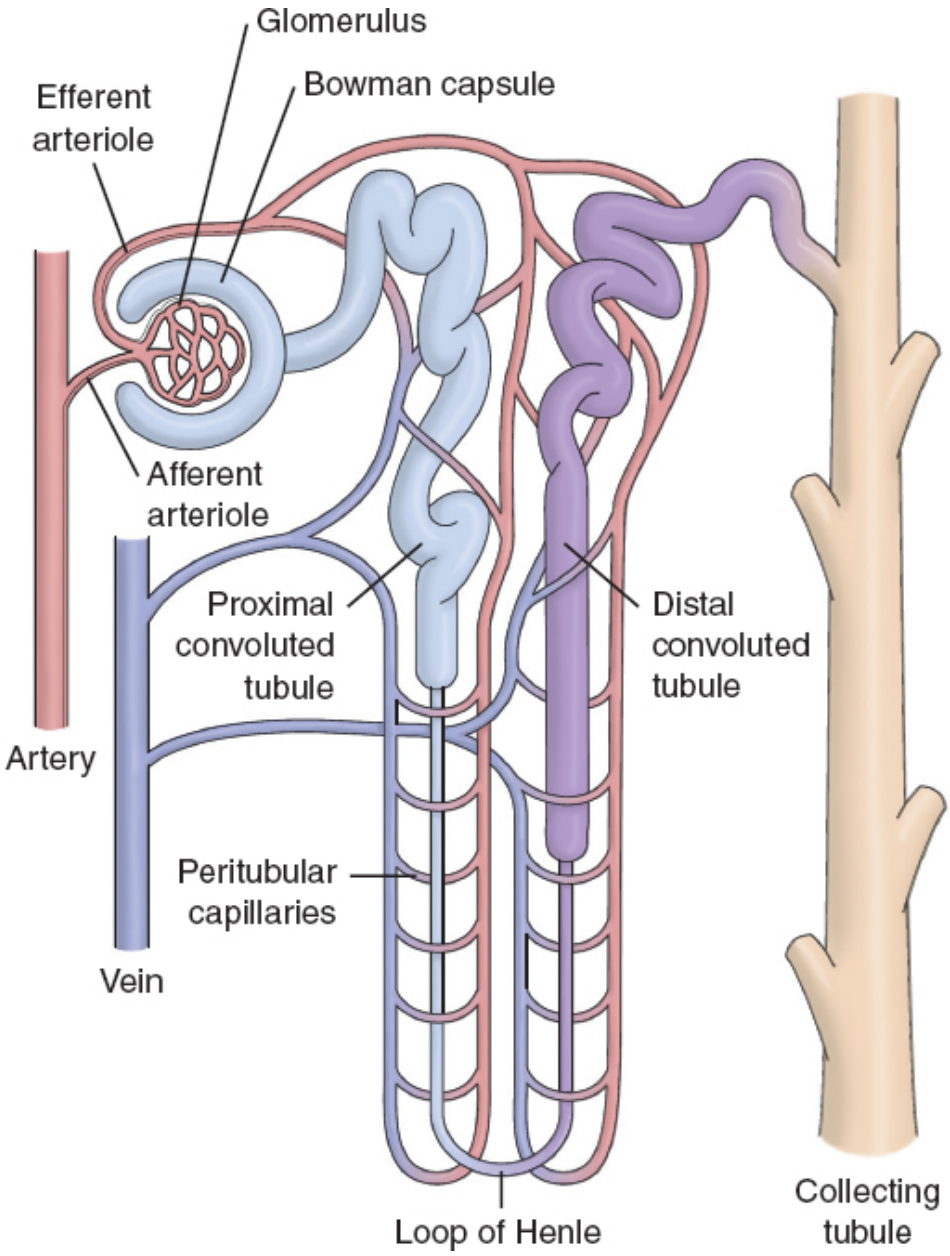

Figure 47-2 • Representation of a nephron. Each kidney has about one million nephrons of two types: cortical and juxtamedullary. Cortical nephrons are located in the cortex of the kidney; juxtamedullary nephrons are adjacent to the medulla.

The tubular component of the nephron begins in the Bowman capsule. The filtrate created in the Bowman capsule travels first into the proximal tubule, which is made up of epithelial cells resting on the basement membrane, then the loop of Henle, the distal tubule, and either the cortical or medullary collecting ducts. The structural arrangement of the tubule allows the distal tubule to lie in close proximity to where the afferent and efferent arterioles, respectively, enter and leave the glomerulus. The distal tubular cells located in this area, known as the macula densa, function with the adjacent afferent

arteriole and create what is known as the juxtaglomerular apparatus. This is the site of renin production. Renin is a hormone directly involved in the control of arterial blood pressure; it is essential for proper functioning of the glomerulus (see later discussion).

The tubular component consists of the Bowman capsule, the proximal tubule, the descending and ascending limbs of the loop of Henle, and the cortical and medullary collecting ducts. This portion of the nephron is responsible for making adjustments in the filtrate based on the body's needs. Changes are continually made as the filtrate travels through the tubules until it enters the collecting system and is expelled from the body (see Fig. 47-2).

Ureters, Bladder, and Urethra

The urine formed in the nephrons flows through the renal calyces and then into the ureters, which are long fibromuscular tubes that connect each kidney to the bladder (Verlander & Clapp, 2019). These narrow tubes, each 24 to 30 cm long, originate at the lower portion of the renal pelvis and terminate in the trigone (tissue between the opening of the ureters and urethra) of the bladder wall.

The lining of the ureters is made up of transitional cell epithelium called urothelium. The urothelium prevents reabsorption of urine. The movement of urine from each renal pelvis through the ureter into the bladder is facilitated by peristaltic contraction of the smooth muscles in the ureter wall. Each ureter has three narrow areas that are prone to obstruction by renal calculi (kidney stones) or stricture. These three areas include the ureteropelvic junction, the ureteral segment near the sacroiliac junction, and the ureterovesical junction. Obstruction of the ureteropelvic junction is the most serious because of its close proximity to the kidney and the risk of associated kidney dysfunction.

The urinary bladder is a distensible muscular sac located just behind the pubic bone (Weber & Kelley, 2018). The usual capacity of the adult bladder is 400 to 500 mL, but it can distend to hold a larger volume. The bladder is characterized by its central, hollow area, called the vesicle, which has two inlets (the ureters) and one outlet (the urethra). The area surrounding the bladder neck is called the ureterovesical junction. The angling of the ureterovesical junction is the primary means of providing antegrade, or downward, movement of urine, also referred to as efflux of urine. This angling prevents vesicoureteral reflux (retrograde, or backward, movement of urine) from the bladder, up the ureter, toward the kidney.

The wall of the bladder contains four layers. The outermost layer is the adventitia, which is made up of connective tissue. Immediately beneath the adventitia is a smooth muscle layer known as the detrusor. Beneath the detrusor is a submucosal layer of loose connective tissue that serves as an interface between the detrusor and the innermost layer, a mucosal lining. The inner layer contains specialized transitional cell epithelium, a membrane that is

impermeable to water and prevents reabsorption of urine stored in the bladder. The bladder neck contains bundles of involuntary smooth muscle that form a portion of the urethral sphincter known as the internal sphincter. An important portion of the sphincter mechanism that helps maintain continence is the external urinary sphincter at the anterior urethra, which is the segment most distal from the bladder (Norris, 2019). During **micturition** (voiding or urination), increased intravesical pressure keeps the ureterovesical junction closed and urine within the ureters. As soon as micturition is completed, intravesical pressure returns to its normal low baseline value, allowing efflux of urine to resume. Therefore, the only time that the bladder is completely empty is in the last seconds of micturition, before efflux of urine resumes.

The urethra arises from the base of the bladder: In the male, it passes through the penis; in the female, it opens just anterior to the vagina. In the male, the prostate gland, which lies just below the bladder neck, surrounds the urethra posteriorly and laterally.

Physiology of the Kidney and Urinary Systems

Understanding the physiology of the kidney and urinary systems includes comprehending urine formation, antidiuretic hormone, osmolarity and osmolality; the regulation of water excretion, electrolyte excretion, and acid–base balance; autoregulation of blood pressure, renal clearance, regulation of red blood cell (RBC) production, vitamin D synthesis, secretion of prostaglandins and other substances, excretion of waste products, urine storage as well as bladder emptying.

Urine Formation

The healthy human body is composed of approximately 60% water. Water balance is regulated by the kidneys and results in the formation of urine. Urine is formed in the nephrons through a complex three-step process: glomerular filtration, tubular reabsorption, and tubular secretion (see Fig. 47-3). Each nephron functions independently from other nephrons because each has its own blood supply (Norris, 2019). The various substances normally filtered by the glomerulus, reabsorbed by the tubules, and excreted in the urine include sodium, chloride, bicarbonate, potassium, glucose, urea, creatinine, and uric acid. Within the tubule, some of these substances are selectively reabsorbed into the blood. Others are secreted from the blood into the filtrate as it travels down the tubule.

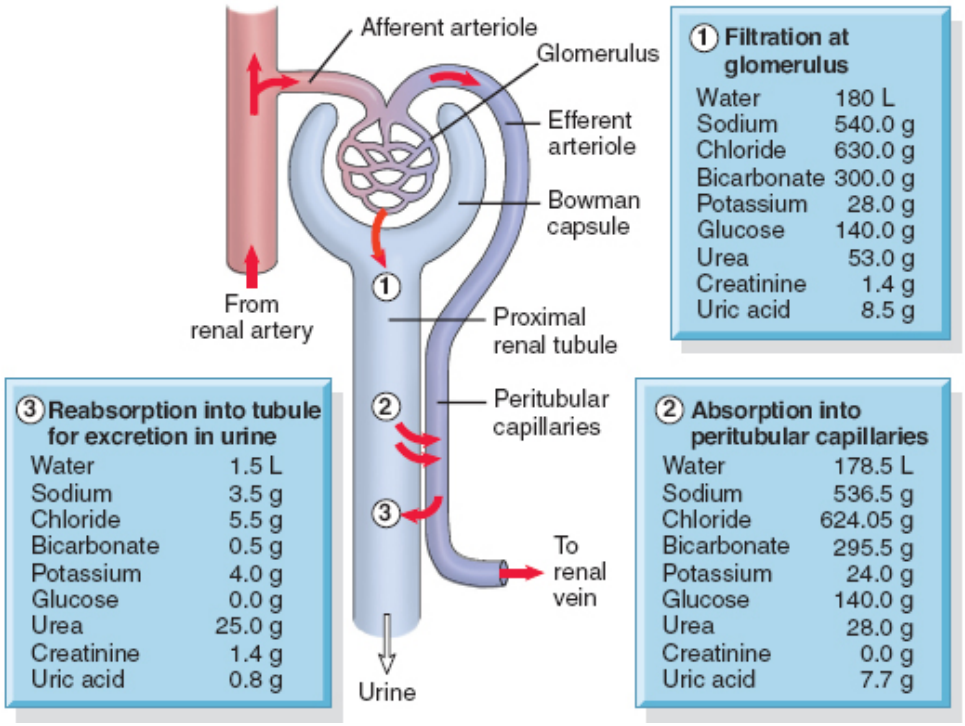

Figure 47-3 • Urine is formed in the nephrons in a three-step process: filtration, reabsorption, and secretion. Water, electrolytes, and other substances, such as glucose and creatinine, are filtered by the glomerulus; varying amounts of these substances are reabsorbed in the renal tubule or excreted in the urine. Approximate normal volumes of these substances during the steps of urine formation are shown at the top. Wide variations may occur in these values depending on diet.

Amino acids and glucose are usually filtered at the level of the glomerulus and reabsorbed so that neither is excreted in the urine. Normally, glucose does not appear in the urine. However, **glycosuria** (excretion of glucose in the urine) occurs if the amount of glucose in the blood and glomerular filtrate exceeds the amount that the tubules are able to reabsorb. Renal glycosuria can occur on its own as a benign condition. It also occurs in poorly controlled diabetes—the most common condition that causes the blood glucose level to exceed the kidney's reabsorption capacity.

Protein molecules also are not usually found in the urine; however, low-molecular-weight proteins (globulins and albumin) may periodically be excreted in small amounts. Protein in the urine is referred to as **proteinuria** (Fischbach & Fischbach, 2018).

Glomerular Filtration

The normal blood flow through the kidneys is between 1000 and 1300 mL/min (Norris, 2019). As blood flows into the glomerulus from an afferent arteriole, filtration occurs. The filtered fluid, also known as filtrate or ultrafiltrate, then enters the renal tubules. Under normal conditions, about 20% of the blood passing through the glomeruli is filtered into the nephron, amounting to about 180 L/day of filtrate (Norris, 2019). The filtrate normally consists of water, electrolytes, and other small molecules, because water and small molecules are allowed to pass, whereas larger molecules stay in the bloodstream. As blood enters the glomerulus from the afferent arteriole, filtration depends on adequate blood flow that maintains a consistent pressure through the glomerulus called hydrostatic pressure. Many factors can alter this blood flow and pressure, including hypotension, decreased oncotic pressure in the blood, and increased pressure in the renal tubules from an obstruction (Norris, 2019).

Tubular Reabsorption and Tubular Secretion

The second and third steps of urine formation occur in the renal tubules. In tubular reabsorption, a substance moves from the filtrate back into the peritubular capillaries or vasa recta. In tubular secretion, a substance moves from the peritubular capillaries or vasa recta into tubular filtrate. Of the 180 L (45 gallons) of filtrate that the kidneys produce each day, 99% is reabsorbed into the bloodstream, resulting in the formation of 1 to 2 L of urine each day. Although most reabsorption occurs in the proximal tubule, reabsorption occurs along the entire tubule. Reabsorption and secretion in the tubule frequently involve passive and active transport and may require the use of energy. Tubular secretion occurs when substances move from the peritubular capillary blood plasma (blood) into the tubular lumen (filtrate). Tubular secretion helps with the elimination of potassium, hydrogen ions, ammonia, uric acid, some drugs, and other waste products (Fischbach & Fischbach, 2018). Filtrate becomes concentrated in the distal tubule and collecting ducts under hormonal influence and becomes urine, which then enters the renal pelvis. In the absence of tubular reabsorption, volume depletion would rapidly occur.

Antidiuretic Hormone

Antidiuretic hormone (ADH), also known as vasopressin, is a hormone that is secreted by the posterior portion of the pituitary gland in response to changes in osmolality of the blood. With decreased water intake, blood osmolality tends to increase, stimulating ADH release. ADH then acts on the kidney, increasing reabsorption of water and thereby returning the osmolality of the blood to normal. With excess water intake, the secretion of ADH by the pituitary is suppressed; therefore, less water is reabsorbed by the kidney tubule, leading to **diuresis** (increased urine volume).

A dilute urine with a fixed **specific gravity** (about 1.010) or fixed osmolality (about 300 mOsm/L) indicates an inability to concentrate and dilute

the urine, which is a common early sign of kidney disease (Fischbach & Fischbach, 2018).

Osmolarity and Osmolality

Osmolarity refers to the ratio of solute to water. The regulation of salt and water is paramount for control of the extracellular volume and both serum and urine osmolarity. Controlling either the amount of water or the amount of solute can change osmolarity. Osmolarity and ionic composition are maintained by the body within very narrow limits. As little as a 1% to 2% change in the serum osmolarity can cause a conscious desire to drink and conservation of water by the kidneys (Emmett & Palmer, 2018).

The degree of dilution or concentration of the urine is also measured in terms of osmolality (the number of osmoles [the standard unit of osmotic pressure] dissolved per kilogram of solution). The filtrate in the glomerular capillary normally has the same osmolality as the blood—280 to 300 mOsm/kg. Serum and urine osmolality and osmolarity are discussed in more detail in Chapter 10.

Regulation of Water Excretion

Regulation of the amount of water excreted is an important function of the kidney. With high fluid intake, a large volume of dilute urine is excreted. Conversely, with a low fluid intake, a small volume of concentrated urine is excreted. A person normally ingests about 1300 mL of oral liquids and 1000 mL of water in food per day. Of the fluid ingested, approximately 800 mL is lost through the skin and lungs and 200 mL through feces (called insensible loss). It is important to consider all fluid gained and lost when evaluating total fluid status. Daily weight measurements are a reliable means of determining overall fluid status. One pound (1 lb) equals approximately 500 mL, so a weight change of as little as 1 lb could suggest an overall fluid gain or loss of 500 mL (Norris, 2019).

Regulation of Electrolyte Excretion

When the kidneys are functioning normally, the volume of electrolytes excreted per day is equal to the amount ingested. For example, the average American daily diet contains 6 to 15 g each of sodium chloride (salt) and 8 g potassium chloride, and approximately the same amounts are excreted in the urine.

The regulation of sodium volume excreted depends on **aldosterone,** a hormone synthesized and released by the adrenal cortex. With increased aldosterone in the blood, less sodium is excreted in the urine, because aldosterone fosters renal reabsorption of sodium. Release of aldosterone from the adrenal cortex is largely under the control of angiotensin II. Angiotensin II

levels are in turn controlled by renin, an enzyme that is released from specialized cells in the kidneys (see Fig. 47-4). This complex system is activated when pressure in the renal arterioles falls below normal levels, as occurs with shock, dehydration, or decreased sodium chloride delivery to the tubules. Activation of this system increases the retention of water and expansion of the intravascular fluid volume, thereby maintaining enough pressure within the glomerulus to ensure adequate filtration.

The regulation of serum sodium and potassium is discussed in detail in Chapter 10.

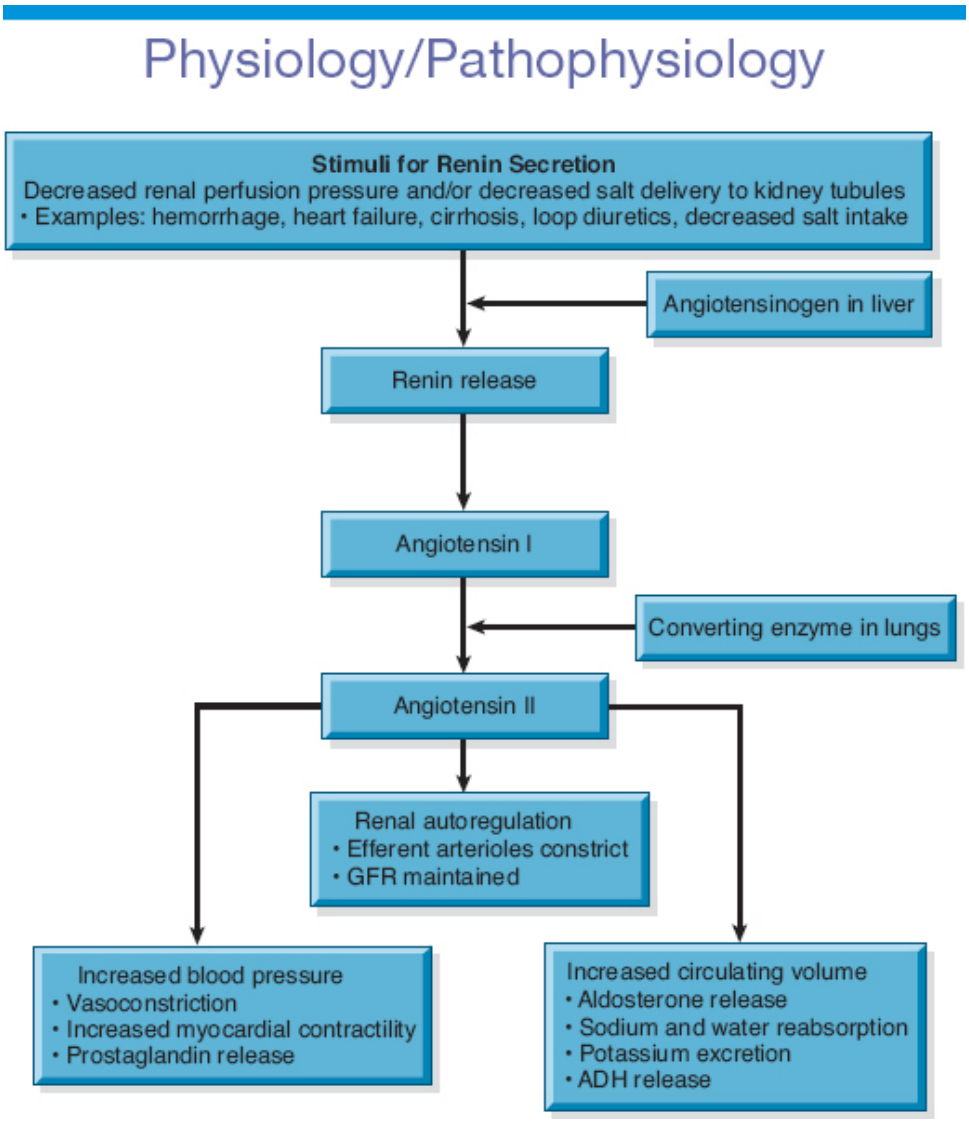

Figure 47-4 • The renin–angiotensin system. ADH, antidiuretic hormone; GFR, glomerular filtration rate.

Regulation of Acid–Base Balance

The normal serum pH is about 7.35 to 7.45 and must be maintained within this narrow range for optimal physiologic function (Norris, 2019). The kidney

performs major functions to assist in this balance. One function is to reabsorb and return to the body's circulation any bicarbonate from the urinary filtrate; other functions are to excrete or reabsorb acid, synthesize ammonia, and excrete ammonium chloride (Fischbach & Fischbach, 2018). Because bicarbonate is a small ion, it is freely filtered at the glomerulus. The renal tubules actively reabsorb most of the bicarbonate in the urinary filtrate. To replace any lost bicarbonate, the renal tubular cells generate new bicarbonate through a variety of chemical reactions. This newly generated bicarbonate is then reabsorbed by the tubules and returned to the body.

The body's acid production is the result of catabolism, or breakdown, of proteins, which produces acid compounds, particularly phosphoric and sulfuric acids. The normal daily diet also includes a certain amount of acid materials. Unlike carbon dioxide (CO_2), phosphoric and sulfuric acids cannot be eliminated by the lungs. Because accumulation of these acids in the blood lowers pH (making the blood more acidic) and inhibits cell function, they must be excreted in the urine. However, if the hydrogen ions are low, they will be reabsorbed. A person with normal kidney function excretes about 70 mEq of acid each day. The kidney is able to excrete some of this acid directly into the urine until the urine pH reaches 4.5, which is 1000 times more acidic than blood (Norris, 2019).

However, more acid usually needs to be eliminated from the body than can be secreted directly as free acid in the urine. These excess acids are bound to chemical buffers so that they can be excreted in the urine. Two important chemical buffers are phosphate ions and ammonia (NH_3). When buffered with acid, ammonia becomes ammonium (NH_4). Phosphate is present in the glomerular filtrate, and ammonia is produced by the cells of the renal tubules and secreted into the tubular fluid. Through the buffering process, the kidney is able to excrete large quantities of acid in a bound form without further lowering the pH of the urine.

Autoregulation of Blood Pressure

Regulation of blood pressure is an important function of the kidney. Specialized vessels of the kidney, called the vasa recta, constantly monitor blood pressure as blood begins its passage into the kidney. When the vasa recta detect a decrease in blood pressure, specialized juxtaglomerular cells near the afferent arteriole, distal tubule, and efferent arteriole secrete the hormone renin. Renin converts angiotensinogen to angiotensin I, which is then converted to angiotensin II—the most powerful vasoconstrictor known; angiotensin II causes the blood pressure to increase (Norris, 2019). The adrenal cortex secretes aldosterone in response to stimulation by the pituitary gland, which occurs in response to poor perfusion or increasing serum osmolality. The result is an increase in blood pressure. When the vasa recta

recognize the increase in blood pressure, renin secretion stops. Failure of this feedback mechanism is one of the primary causes of hypertension (see Fig. 47-4).

Renal Clearance

Renal clearance refers to the ability of the kidneys to clear solutes from the plasma. A 24-hour collection of urine is the primary test of renal clearance used to evaluate how well the kidney performs this important excretory function. Renal clearance depends on several factors: how quickly the substance is filtered across the glomerulus, how much of the substance is reabsorbed along the tubules, and how much of the substance is secreted into the tubules. It is possible to measure the renal clearance of any substance, but the one measure that is particularly useful is the creatinine clearance.

Creatinine is an endogenous waste product of skeletal muscle that is filtered at the glomerulus, passed through the tubules with minimal change, and excreted in the urine. Hence, creatinine clearance is a good measure of the **glomerular filtration rate (GFR),** the amount of plasma filtered through the glomeruli per unit of time. To calculate creatinine clearance, a 24-hour urine specimen is collected. Midway through the collection, the serum creatinine level is measured. The following formula is then used to calculate the creatinine clearance:

$$\frac{(\text{Volume of urine [mL/min]} \times \text{Urine creatinine [mL/dL]})}{\text{Serum creatinine (mg/dL)}}$$

The adult glomerular filtration rate (GFR) can vary from a normal of approximately 125 mL/min (1.67 to 2 mL/s) to a high of 200 mL/min (Norris, 2019). Creatinine clearance is the best approximation of renal function. As renal function declines, both creatinine clearance and renal clearance (the ability to excrete solutes) decrease.

Regulation of Red Blood Cell Production

When the kidneys detect a decrease in the oxygen tension in renal blood flow, because of anemia, arterial hypoxia, or inadequate blood flow, they release erythropoietin. **Erythropoietin** is a glycoprotein from the kidney that stimulates the bone marrow to produce RBCs, which carry oxygen throughout the body (Norris, 2019).

Vitamin D Synthesis

The kidneys are also responsible for the final conversion of inactive vitamin D to its active form, 1,25-dihydroxycholecalciferol. Vitamin D is necessary for maintaining normal calcium balance in the body.

Secretion of Prostaglandins and Other Substances

The kidneys also produce prostaglandin E and prostacyclin, thromboxanes, and leukotrienes, which have vasoactive effects. These substances help the afferent and efferent arterioles maintain renal blood flow by causing selective vasodilation or vasoconstriction (Norris, 2019).

Excretion of Waste Products

The kidneys eliminate the body's metabolic waste products. The major waste product of protein metabolism is urea, of which about 25 to 30 g are produced and excreted daily (Norris, 2019). All of this urea must be excreted in the urine; otherwise, it accumulates in body tissues. Other waste products of metabolism that must be excreted are creatinine, phosphates, and sulfates. Uric acid, formed as a waste product of purine metabolism, is also eliminated in the urine. The kidneys serve as the primary mechanism for excreting drug metabolites.

Urine Storage

The bladder is the reservoir for urine. Both filling and emptying of the bladder are mediated by coordinated sympathetic and parasympathetic nervous system control mechanisms involving the detrusor muscle and the bladder outlet. Conscious awareness of bladder filling occurs as a result of sympathetic neuronal pathways that travel via the spinal cord to the level of T10 through T12, where peripheral, hypogastric nerve innervation allows for continued bladder filling. As bladder filling continues, stretch receptors in the bladder wall are activated, coupled with the desire to void. This information from the detrusor muscle is relayed back to the cerebral cortex via the parasympathetic pelvic nerves at the levels of S1 through S4 (Norris, 2019). Overall bladder pressure remains low due to the bladder's compliance (ability to expand or collapse) as urine volume changes.

Bladder compliance is due in part to the smooth muscle lining of the bladder and collagen deposits within the wall of the bladder, as well as to neuronal mechanisms that inhibit the detrusor muscle from contracting (specifically, adrenergic receptors that mediate relaxation). To maintain adequate kidney filtration rates, bladder pressure during filling must remain lower than 40 cm water (H_2O). This low pressure allows the urine to freely leave the renal pelvis and enter the ureters. The sensation of bladder fullness is transmitted to the central nervous system when the bladder has reached about 150 to 200 mL in adults, and an initial desire to void occurs (Weber & Kelley, 2018). A marked sense of fullness and discomfort with a strong desire to void usually occurs when the bladder reaches its functional capacity of 400 to 500 mL of urine. Neurologic changes to the bladder at the level of the supraspinal nerves, the spinal nerves, or the bladder wall itself can cause abnormally high

volumes (up to 2000 mL) of urine to be stored due to a decreased or absent urge to void.

Under normal circumstances with average fluid intake of approximately 1 to 2 L/day, the bladder should be able to store urine for periods of 2 to 4 hours at a time during the day (Norris, 2019). At night, the release of vasopressin in response to decreased fluid intake causes a decrease in the production of urine and makes it more concentrated. This phenomenon usually allows the bladder to continue filling for periods of 6 to 8 hours in adolescents and adults, making them able to sleep for longer periods before needing to void. In older adults, decreasing bladder compliance and decreased vasopressin levels often cause **nocturia** (awakening during the night to urinate).

Bladder Emptying

Micturition normally occurs approximately eight times in a 24-hour period. It is activated via the micturition reflex arc within the sympathetic and parasympathetic nervous systems, which causes a coordinated sequence of events. Initiation of voiding occurs when the efferent pelvic nerve, which originates in the S1 to S4 area, stimulates the bladder to contract, resulting in complete relaxation of the striated urethral sphincter. This is followed by a decrease in urethral pressure, contraction of the detrusor muscle, opening of the vesical neck and proximal urethra, and flow of urine. This coordinated effort by the parasympathetic system is mediated by muscarinic and, to a lesser extent, cholinergic receptors within the detrusor muscle. The pressure generated in the bladder during micturition is about 20 to 40 cm H_2O in females. It is somewhat higher and more variable in males 45 years and older due to the normal hyperplasia of the cells of the middle lobes of the prostate gland, which surround the proximal urethra. Any obstruction of the bladder outlet, such as in advanced benign prostatic hyperplasia (BPH), results in a high voiding pressure. High voiding pressures make it more difficult to start urine flow and maintain it.

If the spinal pathways from the brain to the urinary system are destroyed (e.g., after a spinal cord injury), reflex contraction of the bladder is maintained, but voluntary control over the process is lost. In both situations, the detrusor muscle can contract and expel urine, but the contractions are generally insufficient to empty the bladder completely, so residual urine (urine left in the bladder after voiding) remains. Normally, residual urine amounts to no more than 50 mL in the middle-age adult and less than 50 to 100 mL in the older adult (Weber & Kelley, 2018).

Gerontologic Considerations

Upper and lower urinary tract function changes with age. The GFR decreases, starting between 35 and 40 years of age, and a yearly decline of about 1 mL/min continues thereafter. Older adults are more susceptible to acute kidney injury and chronic kidney disease due to the structural and functional changes in the kidney. Examples include sclerosis of the glomerulus and renal vasculature, decreased blood flow, decreased GFR, altered tubular function, and acid–base imbalance. Although renal function usually remains adequate, renal reserve is decreased and may reduce the kidneys' ability to respond effectively to drastic or sudden physiologic changes. This steady decrease in glomerular filtration, combined with the use of multiple medications in which metabolites are cleared by the kidneys, puts the older person at higher risk for adverse drug effects and drug–drug interactions (Eliopoulos, 2018).

Older adults are more prone to develop hypernatremia and fluid volume deficit, because increasing age is also associated with diminished osmotic stimulation of thirst. Thirst is defined as one's awareness of the desire to drink. The sense of thirst is so protective that hypernatremia almost never occurs in adults younger than 60 years.

Structural or functional abnormalities that occur with aging may also prevent complete emptying of the bladder. This may be due to decreased bladder wall contractility; secondary to myogenic or neurogenic factors; or related to bladder outlet obstruction, such as in BPH or after prostatectomy. Vaginal and urethral tissues atrophy (become thinner) in aging women due to decreased estrogen levels. This causes decreased blood supply to the urogenital tissues, resulting in urethral and vaginal irritation and urinary incontinence.

Urinary incontinence is present in 15% to 30% of community-dwelling older adults, 50% of older adults who are institutionalized, and 30% of older adults who are hospitalized (Eliopoulos, 2018). Many older adults and their families are unaware that urinary incontinence stems from many causes. The nurse needs to inform the patient and family that with appropriate evaluation, urinary incontinence can often be managed at home, and in many cases it can be eliminated. Many treatments are available for urinary incontinence in older adults, including noninvasive, behavioral interventions that the patient or caregiver can carry out. Treatment modalities for urinary incontinence are described in further detail in Chapter 49.

Preparation of the older adult patient for diagnostic tests must be managed carefully to prevent dehydration, which might precipitate kidney disease in a patient with marginal renal function. Limitations in mobility may affect an older patient's ability to void adequately or to consume an adequate volume of fluids. The patient may limit fluid intake to minimize the frequency of voiding or the risk of incontinence.

Concept Mastery Alert

Providing education about the dangers of an inadequate fluid intake is an important role of the nurse caring for the older patient. The nurse emphasizes the need to drink throughout the day even if the patient does not feel thirsty, because the thirst stimulation is decreased.

Older adults often have incomplete emptying of the bladder and urinary stasis, which may result in urinary tract infection (UTI) or increasing bladder pressure, leading to overflow incontinence, hydronephrosis, pyelonephritis, or chronic kidney disease (Eliopoulos, 2018). Urologic symptoms can mimic disorders such as appendicitis, peptic ulcer disease, and cholecystitis, which can make diagnosis difficult in older adults due to decreased neurologic innervation (Eliopoulos, 2018).

TABLE 47-1  Risk Factors for Select Kidney or Urologic Disorders

Risk Factor	Possible Kidney or Urologic Disorder
Advanced age	Incomplete emptying of bladder, leading to urinary tract infection and urosepsis
Benign prostatic hyperplasia	Obstruction to urine flow, leading to frequency, oliguria, anuria
Diabetes	Chronic kidney disease, neurogenic bladder
Gout, hyperparathyroidism, Crohn's disease, ileostomy	Kidney stone formation
Hypertension	Renal insufficiency, chronic kidney disease
Instrumentation of urinary tract, cystoscopy, catheterization	Urinary tract infection, incontinence
Immobilization	Kidney stone formation
Multiple sclerosis	Incontinence, neurogenic bladder, and other complications
Occupational, recreational, or environmental exposure to chemicals (plastics, pitch, tar, rubber)	Acute kidney injury
Obstetric injury, tumors	Incontinence
Parkinson's disease	Incontinence and other complications
Pregnancy	Proteinuria, urinary frequency
Radiation therapy to pelvis	Cystitis, fibrosis of ureter, or fistula in urinary tract
Recent pelvic surgery	Inadvertent trauma to ureters or bladder
Sickle cell disease, multiple myeloma	Chronic kidney disease
Spinal cord injury	Neurogenic bladder, urinary tract infection, incontinence
Strep throat, impetigo, nephrotic syndrome	Chronic kidney disease
Systemic lupus erythematosus	Nephritis, chronic kidney disease

Adapted from Norris, T. L. (2019). *Porth's pathophysiology: Concepts of altered health states* (10th ed.). Philadelphia, PA: Wolters Kluwer.

Assessment of the Kidney and Urinary Systems

An assessment of the kidney and urinary systems involves conducting a health history and physical assessment.

Health History

Obtaining a urologic health history requires excellent communication skills, because many patients are embarrassed or uncomfortable discussing genitourinary function or symptoms (Ball, Dains, Flynn, et al., 2019; Weber & Kelley, 2018). It is important to use language the patient can understand and to avoid medical jargon. It is also important to review risk factors, particularly for those patients who are at high risk. For example, the nurse needs to be aware that multiparous women delivering their children vaginally have a high risk for stress urinary incontinence, which, if severe enough, can also lead to urge incontinence. People with neurologic disorders such as diabetic neuropathy, multiple sclerosis, or Parkinson's disease often have incomplete emptying of the bladder and urinary stasis, which may result in UTI or increasing bladder pressure, leading to overflow incontinence, hydronephrosis, pyelonephritis, or chronic kidney disease (Eliopoulos, 2018). Risk factors for specific disorders and kidney and lower urinary tract dysfunction are summarized in Table 47-1 and discussed in Chapters 48 and 49.

TABLE 47-2 Identifying Characteristics of Genitourinary Pain

Type	Location	Characteristics	Associated Signs and Symptoms	Possible Etiology
Kidney	Costovertebral angle; may extend to umbilicus	Dull constant ache; if sudden distention of capsule, pain is severe, sharp, stabbing, and colicky in nature	Nausea and vomiting, diaphoresis, pallor, signs of shock	Acute obstruction, kidney stone, blood clot, acute pyelonephritis, trauma
Bladder	Suprapubic area	Dull, continuous pain that may be intense with voiding; may be severe if bladder full	Urgency, pain at end of voiding, painful straining	Overdistended bladder, infection, interstitial cystitis; tumor
Ureteral	Costovertebral angle, flank, lower abdominal area, testis, or labium	Severe, sharp, stabbing pain, colicky in nature	Nausea and vomiting, paralytic ileus	Ureteral stone, edema or stricture, blood clot
Prostatic	Perineum and rectum	Vague discomfort, feeling of fullness in perineum, vague back pain	Suprapubic tenderness, obstruction to urine flow; frequency, urgency, dysuria, nocturia	Prostatic cancer, acute or chronic prostatitis
Urethral	*Male:* Along penis to meatus *Female:* Urethra to meatus	Pain variable, most severe during and immediately after voiding	Frequency, urgency, dysuria, nocturia, urethral discharge	Irritation of bladder neck, infection of urethra, trauma, foreign body in lower urinary tract

Adapted from Norris, T. L. (2019). *Porth's pathophysiology: Concepts of altered health states* (10th ed.). Philadelphia, PA: Wolters Kluwer; Weber, J. R., & Kelley, J. H. (2018). *Health assessment in nursing* (6th ed.). Philadelphia, PA: Wolters Kluwer.

When obtaining the health history, the nurse should inquire about the following:

- The patient's chief concern or reason for seeking health care, the onset of the problem, and its effect on the patient's quality of life
- The location, character, and duration of **dysuria** (painful or difficult urination), if present, and its relationship to voiding; factors that precipitate dysuria, and those that relieve it
- History of UTIs, including past treatment or hospitalization for UTI
- Fever or chills

- Previous renal or urinary diagnostic tests, surgeries or procedures; or the use of indwelling urinary catheters
- Hesitancy, straining to urinate, or frequency of urination
- Urinary incontinence (stress incontinence, urge incontinence, overflow incontinence, or functional incontinence)
- **Hematuria** (RBCs in the urine) or change in color or volume of urine
- Nocturia and its date of onset
- Renal calculi (kidney stones), passage of stones or gravel in urine
- In female patients, the number and type (vaginal or cesarean) of deliveries; the use of forceps; vaginal infection, discharge, or irritation; contraceptive practices
- History of **anuria** (decreased urine production of less than 50 mL in 24 hours) or other kidney problem
- Presence or history of genital lesions or sexually transmitted infections
- The use of tobacco, alcohol, or recreational drugs
- Any prescription and over-the-counter medications (including those prescribed for renal or urinary problems)

Common Symptoms

Dysfunction of the kidney can produce a complex array of symptoms throughout the body. Pain, changes in voiding, and gastrointestinal symptoms are particularly suggestive of urinary tract disease.

Pain

Genitourinary pain is usually caused by distention of some portion of the urinary tract as a result of obstructed urine flow or inflammation and swelling of tissues. Severity of pain is related to the sudden onset, rather than the extent of distention.

Table 47-2 lists the various types of genitourinary pain, characteristics of the pain, associated signs and symptoms, and possible causes. However, kidney disease does not always involve pain. It tends to be diagnosed because of other symptoms that cause a patient to seek health care, such as pedal edema, shortness of breath, and changes in urine elimination (Weber & Kelley, 2018).

Changes in Voiding

Micturition is normally a painless function that occurs approximately eight times in a 24-hour period. The average person voids 1 to 2 L of urine in 24 hours, although this amount varies depending on fluid intake, sweating, environmental temperature, vomiting, or diarrhea. Common problems

associated with voiding include **urinary frequency** (voiding more frequently than every 3 hours), urgency, dysuria, hesitancy, incontinence, enuresis, polyuria, **oliguria** (urine output less than 400 mL in 24 hours or less than 0.5 mL/kg/h over 6 hours), and hematuria. These problems and others are described in Table 47-3. Increased urinary urgency and frequency, coupled with decreasing urine volumes strongly suggest urine retention. Depending on the acuity of the onset of these symptoms, immediate bladder emptying via catheterization and evaluation may be necessary to prevent kidney dysfunction.

Gastrointestinal Symptoms

Gastrointestinal signs and symptoms are often associated with urologic conditions because of shared autonomic and sensory innervation and renointestinal reflexes (see Table 47-3). The proximity of the right kidney to the colon, duodenum, head of the pancreas, common bile duct, liver, and gallbladder may cause gastrointestinal disturbances. The proximity of the left kidney to the colon (splenic flexure), stomach, pancreas, and spleen may also result in intestinal symptoms. The most common signs and symptoms are nausea, vomiting, diarrhea, abdominal discomfort, and abdominal distention.

TABLE 47-3 Problems Associated with Changes in Voiding

Problem	Definition	Possible Etiology
Anuria	Urine output <50 mL/day	Acute kidney injury or chronic kidney disease (see Chapter 48), complete obstruction
Bacteriuria	Bacterial count >100,000 colonies/mL in the urine	Infection
Dysuria	Painful or difficult voiding	Lower urinary tract infection, inflammation of bladder or urethra, acute prostatitis, stones, foreign bodies, tumors in bladder
Enuresis	Involuntary voiding during sleep	Delay in functional maturation of central nervous system (bladder control usually achieved by 5 yrs of age), obstructive disease of lower urinary tract, genetic factors, failure to concentrate urine, urinary tract infection, psychological stress
Frequency	Frequent voiding—more than every 3 h	Infection, obstruction of lower urinary tract leading to residual urine and overflow, anxiety, diuretic agents, benign prostatic hyperplasia, urethral stricture, diabetic neuropathy
Hematuria	Red blood cells in the urine	Cancer of genitourinary tract, acute glomerulonephritis, renal stones, renal tuberculosis, blood dyscrasia, trauma, extreme exercise, rheumatic fever, hemophilia, leukemia, sickle cell trait or disease
Hesitancy	Delay, difficulty in initiating voiding	Benign prostatic hyperplasia, compression of urethra, outlet obstruction, neurogenic bladder
Incontinence	Involuntary loss of urine	External urinary sphincter injury, obstetric injury, lesions of bladder neck, detrusor dysfunction, infection, neurogenic bladder, medications, neurologic abnormalities
Nocturia	Awakening during the night to urinate	Decreased renal concentrating ability, heart failure, diabetes, incomplete bladder emptying, excessive fluid intake at bedtime, nephrotic syndrome, cirrhosis with ascites
Oliguria	Urine output <400 mL in 24 h or <0.5 mL/kg/h over 6 h	Acute kidney injury or chronic kidney disease, inadequate fluid intake
Polyuria	Increased volume of urine voided	Diabetes, diabetes insipidus, the use of diuretics, excess fluid intake, lithium toxicity, some forms of kidney disease (hypercalcemic and hypokalemic nephropathy)
Proteinuria	Protein in the	Acute kidney injury or chronic kidney disease, nephrotic

	urine	syndrome, vigorous exercise, heatstroke, severe heart failure, diabetic nephropathy, multiple myeloma
Urgency	Strong desire to void	Infection, chronic prostatitis, urethritis, obstruction of lower urinary tract leading to residual urine and overflow, anxiety, diuretic agents, benign prostatic hyperplasia, urethral stricture, diabetic neuropathy

Unexplained Anemia

Gradual kidney dysfunction can be insidious in its presentation, although fatigue is a common symptom. Fatigue, shortness of breath, and exercise intolerance all result from the condition known as anemia of inflammation formerly known as anemia of chronic disease. See Chapter 29 for more information on anemia of inflammation.

Past Health, Family, and Social History

Data collection about previous health problems or diseases provides the health care team with useful information for evaluating the patient's current urinary status. People with diabetes who have hypertension are at risk for renal dysfunction. Older men are at risk for prostatic enlargement, which causes urethral obstruction and can result in UTIs and kidney disease. People with a family history of urinary tract problems are at increased risk for renal disorders. Genetics may also influence renal conditions (see Chart 47-2).

It is also important to assess the patient's psychosocial status, level of anxiety, perceived threats to body image, available support systems, and sociocultural patterns.

Physical Assessment

Several body systems can affect upper and lower urinary tract dysfunction, and conversely that dysfunction can affect several end organs; therefore, a head-to-toe assessment is indicated. Areas of emphasis include the abdomen, suprapubic region, genitalia, lower back, and lower extremities.

The kidneys are not usually palpable. However, palpation of the kidneys may detect an enlargement that could prove to be very important (Weber & Kelley, 2018). The correct technique for palpation is illustrated in Figure 47-5. It may be possible to palpate the smooth, rounded lower pole of the kidney between the hands. The right kidney is easier to detect, because it is somewhat lower than the left one. In patients with obesity, palpation of the kidneys is more difficult.

Chart 47-2 GENETICS IN NURSING PRACTICE

Kidney and Urinary Disorders

Various conditions that affect the renal system and urinary tract function are influenced by genetic factors. Some examples of these genetic disorders are:
Autosomal Dominant:

- Familial Wilms tumor
- Polycystic kidney disease
- Renal cystic disease in tuberous sclerosis complex

X-Linked Recessive:

- Alport syndrome (primarily X-linked but autosomal dominant and recessive forms exist)

Congenital Kidney Disorders:

- Congenital absence of the vas deferens (caused by *CFTR* gene mutation for cystic fibrosis)
- Horseshoe kidney
- Multicystic dysplastic kidneys

Other Genetic Disorders that Impact the Renal System:

- $Alpha_1$-antitrypsin deficiency
- Anderson–Fabry disease
- Diabetes
- Coronary artery disease
- Pulmonary hypertension
- von Hippel–Lindau syndrome

Nursing Assessments

Refer to Chapter 4, Chart 4-2: Genetics in Nursing Practice: Genetic Aspects of Health Assessment

Family History Specific to Kidney and Urinary Disorders

- Inquire about other family members with a history of renal and/or urinary tract malformations, kidney disease, or end-stage kidney disease and age of onset.
- Determine if other family members have diabetic kidney disease (clustering of this within the family could indicate genetic susceptibility).
- Identify family history of male infertility and cystic fibrosis (congenital absence of vas deferens).
- Be alert to family members with history of early-onset renal (Wilms tumor) or other cancers.

Physical Assessment Specific to Genetic Kidney and Urinary Disorders

- Be alert to signs and symptoms of kidney disease at an early age.

- Ascertain for presence and frequency of kidney stones or urinary tract infections.
- Assess for the presence and frequency of:
  - Abdominal pain or presence of an abdominal mass
  - Hematuria
  - Hypertension
  - Peripheral or orbital edema
  - Proteinuria
- Assess for clinical findings suggesting that kidney disease is a component of a genetic syndrome (e.g., seizures, intellectual disability, skin involvement).
- Assess for bleeding tendencies, abnormal clotting, or history of anemia.

Genetics Resources

Alport Syndrome Foundation, www.alportsyndrome.org
American Kidney Fund, www.kidneyfund.org
See Chapter 6, Chart 6-7 for components of genetic counseling resources.

Renal dysfunction may produce tenderness over the costovertebral angle, which is the angle formed by the lower border of the 12th, or bottom, rib and the spine (see Fig. 47-6). The abdomen (just slightly to the right and left of the midline in both upper quadrants) is auscultated to assess for bruits (low-pitched murmurs that indicate renal artery stenosis or an aortic aneurysm). The abdomen is also assessed for the presence of ascites (accumulation of fluid in the peritoneal cavity), which may occur with kidney as well as liver dysfunction (see Chapter 43 for further discussion of ascites and liver disorders).

Figure 47-5 • The left kidney is palpated by reaching over to the patient's left side and placing the right hand beneath the patient's lower left rib. Push the hand on top forward as the patient inhales deeply. Reprinted with permission from Weber, J. R., & Kelley, J. H. (2018). *Health assessment in nursing* (6th ed., Fig. 23-27). Philadelphia, PA: Wolters Kluwer.

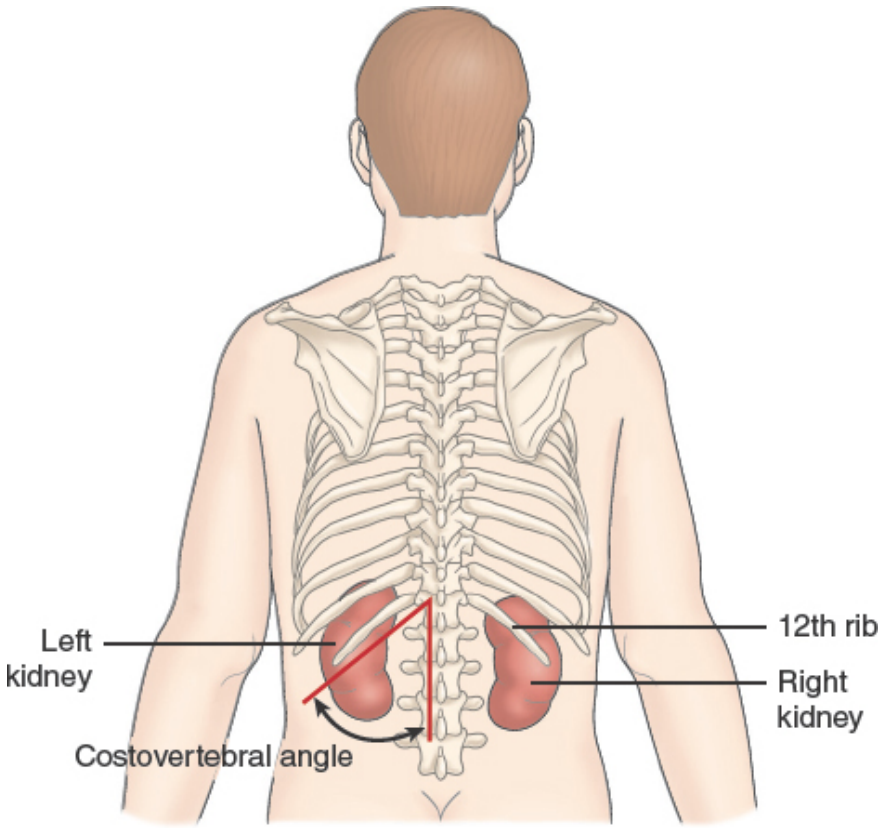

Figure 47-6 • Location of the costovertebral angle.

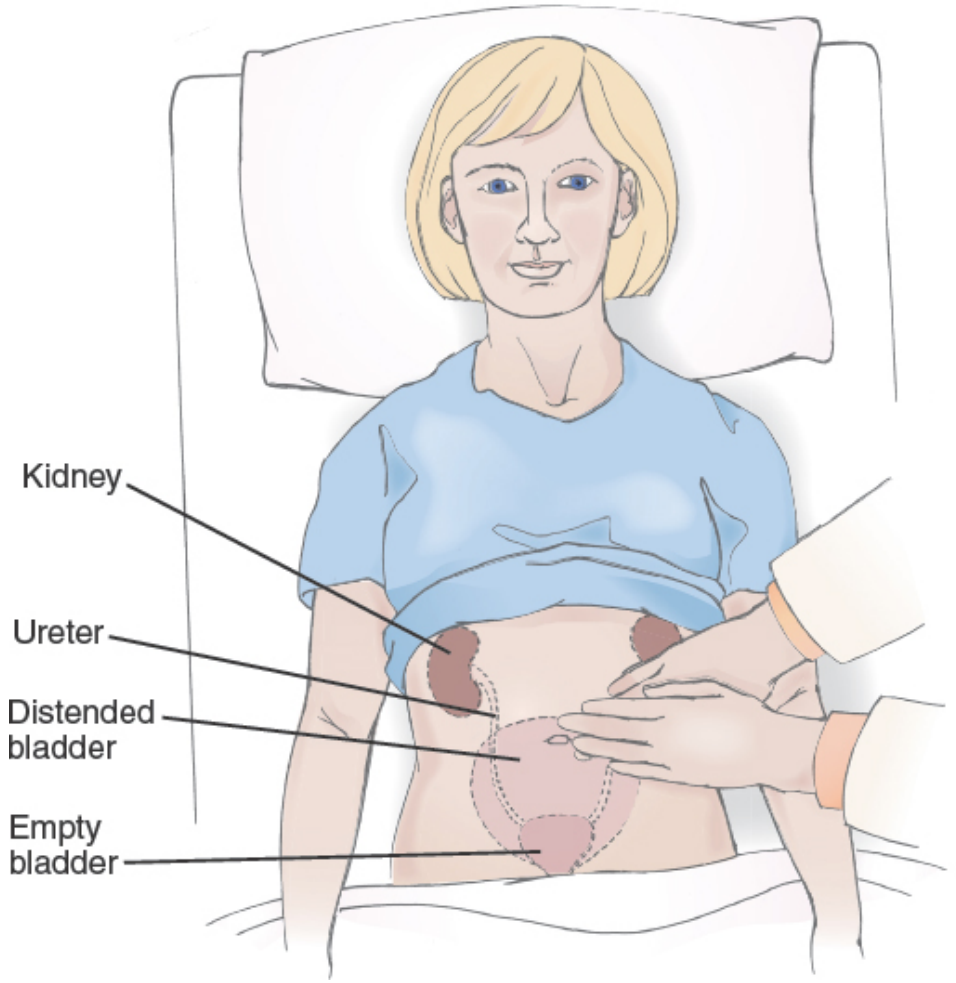

Figure 47-7 • Palpating distended bladder (larger *dotted line* is area of distention). Reprinted with permission from Weber, J. R., & Kelley, J. H. (2018). *Health assessment in nursing* (6th ed., Fig. 23-28). Philadelphia, PA: Wolters Kluwer.

To check for residual urine, the bladder can be percussed after the patient voids. Percussion of the bladder begins at the midline just above the umbilicus and proceeds downward. The sound changes from tympanic to dull when percussing over the bladder. The bladder, which can be palpated only if it is moderately distended, feels like a smooth, firm, round mass rising out of the abdomen, usually at midline (see Fig. 47-7). Dullness to percussion of the bladder after voiding indicates incomplete bladder emptying (Weber & Kelley, 2018).

Chart 47-3 NURSING RESEARCH PROFILE

Positive Outcomes with the Use of a Portable Bladder Ultrasound

Chen, S., Chen, P., Chen, G., et al. (2018). Portable bladder ultrasound reduces incidence of urinary tract infection and shortens hospital length of stay in patients with acute ischemic stroke. *Journal of Cardiovascular Nursing*, *31*(6), 551–558.

Purpose

Certain patient populations, such as those who have had a stroke, have high rates of urinary tract infections (UTIs). The purpose of this study was to investigate whether there was a change in patient outcomes, such as UTI rates, following implementation of the use of portable bladder ultrasound to measure postvoid urine residuals on a unit that provided care for patients following an acute ischemic stroke.

Design

The medical records of all patients admitted to one unit for a 3-year period prior to the implementation of the use of portable bladder ultrasound were retrospectively reviewed and outcomes compared to all patients admitted for a 3-year period after the implementation of the use of portable bladder ultrasound.

Findings

Those patients admitted during the period after the implementation of the portable bladder ultrasound had a lower incidence of UTI (4% vs. 6.9%) and a shorter hospital length of stay (11.9 days vs. 13.6 days). Multivariate analysis revealed that patients at higher risk of UTI were patients 75 years of age or older, women, and those with a more severe stroke.

Nursing Implications

Nurses can make a difference in patient outcomes by using portable bladder ultrasound to measure postvoid urine residuals in patients at risk for UTI when this technology is available. This study reported that UTI rates and hospital length of stay were lower following implementation of this technology. This study needs to be replicated in other patient populations at high risk for UTI.

Portable bladder ultrasound is another method of detecting urinary retention. These devices provide a three-dimensional image of the bladder and should be used after voiding to detect urine retention. Researchers have reported that the use of a portable bladder ultrasound reduces the rate of UTIs and shortens the length of stay for patients who have had an ischemic stroke (Chen, Chen, Chen, et al., 2018). See the Nursing Research Profile in Chart 47-3 and the later discussion in the bladder ultrasonography section.

In older men, BPH or prostatitis can cause difficulty with urination. Because the signs and symptoms of prostate cancer can mimic those of BPH,

the prostate gland is palpated by digital rectal examination (DRE) as part of the yearly physical examination in men 40 years and older (see Chapter 53). In addition, a blood specimen is obtained to test the prostate-specific antigen (PSA) level annually; the results of the DRE and PSA are then correlated. Blood is drawn for PSA before the DRE, because manipulation of the prostate can cause the PSA level to increase temporarily. The inguinal area is examined for enlarged nodes, an inguinal or femoral hernia, and varicocele (varicose veins of the spermatic cord).

In women, the vulva, urethral meatus, and vagina are examined (Weber & Kelley, 2018). The urethra is palpated for diverticula, and the vagina is assessed for adequate estrogen effect and any of five types of herniation: urethrocele, cystocele, pelvic prolapse, enterocele, and rectocele. Urethrocele is the bulging of the anterior vaginal wall into the urethra. Cystocele is the herniation of the bladder wall into the vaginal vault. Pelvic prolapse is bulging of the cervix into the vaginal vault. Enterocele is herniation of the bowel into the posterior vaginal wall. Rectocele is herniation of the rectum into the vaginal wall. These prolapses are graded depending on the degree of herniation. See Chapter 51 for more information.

The woman is asked to cough and perform a Valsalva maneuver to assess the urethra's system of muscular and ligament support. If urine leakage occurs, the index and middle fingers of the examiner's gloved hand are used to support either side of the urethra as the woman is asked to repeat the Valsalva maneuver; this is called the *Marshall–Bonney maneuver.* If this produces urinary leakage, referral is suggested.

The patient is assessed for edema and changes in body weight. Edema may be observed, particularly in the face and dependent parts of the body, such as the ankles and sacral areas, and suggests fluid retention. An increase in body weight commonly accompanies edema. A 1 kg weight gain equals approximately 1000 mL of fluid (1 lb is approximately 500 mL) (Weber & Kelley, 2018).

The deep tendon reflexes of the knee are examined for quality and symmetry. This is an important part of testing for neurologic causes of bladder dysfunction, because the sacral area, which innervates the lower extremities, is the same peripheral nerve area responsible for urinary continence. The gait pattern of the person with bladder dysfunction is also noted, as well as the patient's ability to walk toe to heel. These tests evaluate possible supraspinal causes for urinary incontinence.

Unfolding Patient Stories: Lloyd Bennett • Part 2

Recall from Chapter 28 **Lloyd Bennett**, who presented to the emergency department with a hip fracture. What effect can significant blood loss from surgery to repair the fracture have on renal function? What clinical findings would indicate to the nurse that kidney function is impaired? What clinical assessment findings would alert the nurse of potential trauma to the urinary tract resulting from the hip fracture? What diagnostic tests may be used to identify a urinary tract complication that the nurse would consider for preparatory patient education?

Care for Lloyd and other patients in a realistic virtual environment: *vSim* (**thepoint.lww.com/.vSimMedicalSurgical**). Practice documenting these patients' care in DocuCare (**thepoint.lww.com/DocuCareEHR**).

Diagnostic Evaluation

A wide range of diagnostic studies may be performed in patients with urinary conditions. A comprehensive health history is used to determine the appropriate laboratory and diagnostic tests. The following sections review some of the specific tests that might be used.

The nurse educates the patient about the purpose, what to expect, and any possible side effects related to these examinations prior to testing. The nurse should also note trends in results, because they provide information about disease progression as well as the patient's response to therapy.

Most patients undergoing urologic testing or imaging studies are apprehensive, even those who have had these tests in the past. Patients frequently feel discomfort and embarrassment about such a private and personal function as voiding. Voiding in the presence of others can frequently cause guarding, a natural reflex that inhibits voiding due to situational anxiety. Because the outcomes of these studies determine the plan of care, the nurse must help the patient relax by providing as much privacy and explanation about the procedure as possible (see Chart 47-4). In addition, Chart 47-5 provides a plan of nursing care for the patient undergoing diagnostic testing.

Chart 47-4 PATIENT EDUCATION

Before and After Urodynamic Testing

The nurse instructs the patient on what to expect before, during, and after the procedure:
Preprocedure

- An in-depth interview will be conducted. Questions related to your urologic symptoms and voiding habits will be asked.

During the Procedure

- You will be asked to describe sensations felt.
- You might be asked to change positions (e.g., from supine to sitting or standing).
- You may be asked to cough or perform the Valsalva maneuver (bear down).
- You will probably need to have one or two urethral catheters inserted so that bladder pressure and bladder filling can be measured. Another catheter may be placed in the rectum or vagina to measure abdominal pressure.
- You may also have electrodes (surface, wire, or needle) placed in the perianal area for electromyography. This may be uncomfortable initially during insertion and later during position changes.
- Your bladder will be filled through the urethral catheter one or more times.

After the Procedure

- You may experience urinary frequency, urgency, or dysuria from the urethral catheters. Avoid caffeinated, carbonated, and alcoholic beverages because they can further irritate the bladder. These symptoms usually decrease or subside by the day after the procedure.
- You might notice slight hematuria (blood-tinged urine) right after the procedure (especially in men with benign prostatic hyperplasia). Drinking fluids will help to clear the hematuria.
- If the urinary meatus is irritated, a warm sitz bath may be helpful.
- Be alert to signs of a urinary tract infection. Contact your primary provider if you experience fever, chills, lower back pain, or continued dysuria and hematuria.
- If you receive an antibiotic medication before the procedure, you should continue taking the complete course of medication after the procedure. This is a measure to prevent infection.

Urinalysis and Urine Culture

The urinalysis provides important clinical information about kidney function and helps diagnose other diseases, such as diabetes. The urine culture

determines whether bacteria are present in the urine, as well as their strains and concentration. Urine culture and sensitivity also identify the antimicrobial therapy that is best suited for the particular strains identified, taking into consideration the antibiotic agents that have the best rate of resolution in that particular geographic region. Appropriate evaluation of any abnormality can assist in detecting serious underlying diseases.

Chart 47-5 PLAN OF NURSING CARE

Care of the Patient Undergoing Diagnostic Testing of the Renal–Urologic System

NURSING DIAGNOSIS: Lack of knowledge about procedures and diagnostic tests
GOAL: Patient demonstrates increased understanding of the procedure and tests and expected behaviors

Nursing Interventions	Rationale	Expected Outcomes
1. Assess patient's level of understanding of planned diagnostic tests 2. Provide a description of tests in language the patient can understand 3. Assess patient's understanding of test results after their completion 4. Reinforce information provided to patient about test results and implications for follow-up care	1. Provides basis for education and gives indication of patient's perception of tests 2. Understanding what is expected enhances patient adherence and cooperation 3. Apprehension may interfere with patient's ability to understand information and results provided by health care team 4. Provides opportunity for patient to clarify information and anticipate follow-up care	• States rationale for planned diagnostic tests and what tasks and behaviors are expected during the procedure • Adheres to prescribed urine collection, fluid modifications, or other procedures required for diagnostic evaluation • Restates in own words results of diagnostic tests • Asks for clarification of terms and procedures • Explains rationale for follow-up care • Participates in follow-up care

NURSING DIAGNOSIS: Acute pain associated with infection, edema, obstruction, or bleeding along urinary tract or associated with invasive diagnostic tests
GOAL: Patient reports decrease in pain and absence of discomfort

Nursing Interventions	Rationale	Expected Outcomes
1. Assess level of pain: dysuria, burning on	1. Provides baseline for	• Reports decreasing levels

urination, abdominal or flank pain, bladder spasm 2. Encourage fluid intake (unless contraindicated) 3. Encourage warm sitz baths 4. Report increased pain to primary provider 5. Administer analgesic and antispasmodic agents for pain and spasm as prescribed 6. Assess voiding patterns and hygiene practices and provide instructions about recommended voiding patterns and hygienic practices	evaluation of pain-relief strategies and progression of dysfunction 2. Promotes dilute urine and flushing of the lower urinary tract 3. Relieves local discomfort and promotes relaxation 4. May indicate progression or recurrence of dysfunction, or untoward signs (e.g., bleeding, calculi) 5. Prescribed to relieve pain or spasm 6. Delayed emptying of the bladder and poor hygiene may contribute to pain secondary to renal or urinary tract dysfunction	of pain • Reports absence of local symptoms • States ability to start and stop urinary stream without discomfort • Increases fluid intake, if indicated • Uses sitz bath as indicated • Identifies signs and symptoms to be reported to the primary provider • Takes medications as prescribed • Does not delay in emptying bladder • Uses appropriate hygienic measures, avoids bubble baths, uses appropriate hygiene after bowel movements

NURSING DIAGNOSIS: Fear associated with potential alteration in renal function and embarrassment secondary to discussion of urinary function and invasion of genitalia

GOAL: Patient appears relaxed and reports decreased fear and anxiety

Nursing Interventions	Rationale	Expected Outcomes
1. Assess patient's level of fear and apprehension	1. A high level of fear or apprehension	• Appears relaxed with a low level

2. Explain all procedures and tests to patient 3. Provide privacy and respect patient's modesty by closing doors and keeping patient covered. Keep urinal and bedpan covered and out of sight 4. Use correct terminology in a factual manner when questioning patient about urinary tract dysfunction 5. Assess patient's fears about perceived changes associated with tests and other procedures 6. Instruct patient in relaxation techniques	can interfere with learning and cooperation 2. Knowledge about what is expected helps reduce fear and apprehension 3. Communicates that you are aware of and accept patient's need for privacy and modesty 4. Conveys that you are comfortable discussing patient's urinary dysfunction and symptoms with patient 5. May uncover fears and misconceptions of the patient that can be alleviated by correct understanding 6. Promotes relaxation and assists patient in coping with uncertainty about outcomes	of fear or apprehension • States rationale for tests and procedures in a calm, relaxed manner • Maintains usual privacy and modesty • Discusses own urinary tract dysfunction using correct terminology without overt indications of embarrassment or discomfort • Relates fears and concerns • Demonstrates correct understanding of procedures and possible outcomes • Appears relaxed with low level of fear and apprehension

TABLE 47-4 Changes in Urine Color and Possible Causes

Urine Color	Possible Cause
Colorless to pale yellow	Dilute urine due to diuretic agents, alcohol consumption, diabetes insipidus, glycosuria, excess fluid intake, chronic kidney disease
Yellow to milky white	Pyuria, infection, vaginal cream
Bright yellow	Multiple vitamin preparations
Pink to red	Hemoglobin breakdown, red blood cells, gross blood, menses, bladder or prostate surgery, beets, blackberries, medications (phenytoin, rifampin, thioridazine, cascara sagrada, senna products)
Blue, blue green	Dyes, methylene blue, *Pseudomonas* species organisms, medications (amitriptyline HCl, triamterene)
Orange to amber	Concentrated urine due to dehydration, fever, bile, excess bilirubin or carotene, medications (phenazopyridine hydrochloride, nitrofurantoin)
Brown to black	Old red blood cells, urobilinogen, bilirubin, melanin, porphyrin, extremely concentrated urine due to dehydration, medications (cascara sagrada, metronidazole, iron preparations, quinine sulfate, senna products, methyldopa, nitrofurantoin)

Adapted from Comerford, K. C., & Durkin, M. T. (Eds.). (2020). *Nursing 2020 drug handbook*. Philadelphia, PA: Wolters Kluwer.

Components

Urine examination includes the following:

- Urine color (see Table 47-4)
- Urine clarity and odor
- Urine pH and specific gravity
- Tests to detect protein, glucose, and ketone bodies in the urine (proteinuria, renal glycosuria, and ketonuria, respectively)
- Microscopic examination of the urine sediment after centrifugation to detect hematuria, **pyuria** (white blood cells), casts (cylindruria), crystals (crystalluria), and **bacteriuria** (bacteria) (see Table 47-3)

Significance of Findings

Several abnormalities, such as hematuria and proteinuria, produce no symptoms but may be detected during a routine urinalysis using a dipstick. Normally, about one million RBCs pass into the urine daily, which is equivalent to one to three RBCs per high-power field. Hematuria (more than three RBCs per high-power field) can develop from an abnormality anywhere

along the genitourinary tract and is more common in women than in men. Common causes include acute infection (cystitis, urethritis, or prostatitis), renal calculi, and neoplasm. Other causes include systemic disorders, such as bleeding disorders; malignant lesions; and medications, such as warfarin and heparin. Although hematuria may initially be detected using a dipstick test, further evaluation is necessary and more accurate with a 24-hour collection (Fischbach & Fischbach, 2018).

Proteinuria may be a benign finding, or it may signify serious disease. Occasional loss of up to 150 mg/day of protein in the urine, primarily albumin and Tamm–Horsfall protein (also known as uromodulin), is considered normal and usually does not require further evaluation. A dipstick examination, which can detect from 30 to 1000 mg/dL of protein, should be used as a screening test only, because urine concentration, pH, hematuria, and radiocontrast materials all affect the results. Because dipstick analysis does not detect protein concentrations of less than 30 mg/dL, the test cannot be used for early detection of diabetic nephropathy. Microalbuminuria (excretion of 20 to 200 mg/dL of protein in the urine) is an early sign of diabetic nephropathy. Common benign causes of transient proteinuria are fever, strenuous exercise, and prolonged standing.

Causes of persistent proteinuria include glomerular diseases, malignancies, collagen diseases, diabetes, preeclampsia, hypothyroidism, heart failure, exposure to heavy metals, and the use of medications, such as nonsteroidal anti-inflammatory drugs and angiotensin-converting enzyme inhibitors (Comerford & Durkin, 2020).

Specific Gravity

Specific gravity is an expression of the degree of concentration of the urine that measures the density of a solution compared to the density of distilled water, which is 1.000. Specific gravity is altered by the presence of blood, protein, and casts in the urine. The normal range of urine specific gravity is 1.005 to 1.025 (Fischbach & Fischbach, 2018; Norris, 2019).

Methods for determination of specific gravity include the following:

- Multiple-test dipstick (most common method), with a specific reagent area for specific gravity
- Urinometer (least accurate method), in which urine is placed in a small cylinder and the urinometer is floated in the urine; a specific gravity reading is obtained at the meniscus level of the urine
- Refractometer, an instrument used in a laboratory setting, which measures differences in the speed of light passing through air and the urine sample; this is the most accurate test

Urine specific gravity depends largely on hydration status. When fluid intake decreases, specific gravity normally increases. With high fluid intake, specific gravity decreases. In patients with kidney disease, urine specific gravity does not vary with fluid intake, and the patient's urine is said to have a fixed specific gravity. Disorders or conditions that cause decreased urine specific gravity include diabetes insipidus, glomerulonephritis, and severe renal damage. Those that can cause increased specific gravity include diabetes, nephritis, and fluid deficit.

Osmolality

Osmolality is the most accurate measurement of the kidney's ability to dilute and concentrate urine. It measures the number of solute particles in a kilogram of water. Serum and urine osmolality are measured simultaneously to assess the body's fluid status. In healthy adults, serum osmolality is 275 to 290 mOsm/kg, and normal urine osmolality is 200 to 800 mOsm/kg. For a 24-hour urine sample, the normal value is 300 to 900 mOsm/kg (Fischbach & Fischbach, 2018).

TABLE 47-5 Renal Function Tests

Test	Purpose	Normal Values
Renal Concentration		
Specific gravity	A measure of the degree of concentration of the urine.	1.005–1.025
Urine osmolality	Concentrating ability is lost early in kidney disease; hence, these test findings may disclose early defects in renal function.	300–900 mOsm/kg/24 h, 50–1200 mOsm/kg random sample
24-h Urine		
Creatinine clearance	Detects and evaluates progression of kidney disease. Test measures volume of blood cleared of endogenous creatinine in 1 min, which provides an approximation of the glomerular filtration rate. Sensitive indicator of kidney disease used to follow progression of kidney disease.	Measured in mL/min/1.73 m^2
		Age (Years) / Male / Female
		<30: 88–146 / 81–134
		30–40: 82–140 / 75–128
		40–50: 75–133 / 69–122
		50–60: 68–126 / 64–116
		60–70: 61–120 / 58–110
		70–80: 55–113 / 52–105
Serum		
Creatinine level	Measures effectiveness of renal function. Creatinine is the end product of muscle energy metabolism. In normal function, the level of creatinine, which is regulated and excreted by the kidneys, remains fairly constant in the body.	Males: 0.6–1.2 mg/dL (71–106 mmol/L) Females: 0.4–1.0 mg/dL (36–90 mmol/L)
BUN	Serves as index of renal function. Urea is the nitrogenous end product of protein metabolism. Test values are affected by protein intake, tissue breakdown, and fluid volume changes.	8–20 mg/dL; patients >60 yrs: 8–23 mg/dL
BUN to creatinine ratio	Evaluates hydration status. An elevated ratio is seen in hypovolemia; a normal ratio with an elevated BUN and creatinine is seen with intrinsic kidney disease.	About 10:1

BUN, blood urea nitrogen.

Renal Function Tests

Renal function tests are used to evaluate the severity of kidney disease and to assess the status of the patient's kidney function. These tests also provide information about the effectiveness of the kidney in carrying out its excretory function. Renal function test results may be within normal limits until the GFR is reduced to less than 50% of normal. Renal function can be assessed most

accurately if several tests are performed and their results are analyzed together. Common tests of renal function include renal concentration tests, creatinine clearance, and serum creatinine and blood **urea nitrogen** (end product of protein metabolism) levels (see Table 47-5).

Other tests for evaluating renal function that may be helpful include serum electrolyte levels as well as urinary biomarkers to detect acute kidney injury (Fischbach & Fischbach, 2018) (see Chapter 10).

Diagnostic Imaging

There are a wide range of diagnostic studies used for the assessment of kidney and urinary function.

Kidney, Ureter, and Bladder Studies

An x-ray study of the abdomen or kidneys, ureters, and bladder (KUB) may be performed to delineate the size, shape, and position of the kidneys and to reveal urinary system abnormalities (Fischbach & Fischbach, 2018).

General Ultrasonography

Ultrasonography is a noninvasive procedure that uses sound waves passed into the body through a transducer to detect abnormalities of internal tissues and organs. Abnormalities such as fluid accumulation, masses, congenital malformations, changes in organ size, and obstructions can be identified. During the test, the lower abdomen and genitalia may need to be exposed. Ultrasonography requires a full bladder; therefore, fluid intake is encouraged before the procedure.

Bladder Ultrasonography

Bladder ultrasonography is a noninvasive method of measuring urine volume in the bladder. It may be indicated for urinary frequency, inability to void after removal of an indwelling urinary catheter, measurement of postvoiding residual urine volume, inability to void postoperatively, or assessment of the need for catheterization during the initial stages of an intermittent catheterization training program. Portable, battery-operated devices are available for bedside use. The scan head is placed on the patient's abdomen and directed toward the bladder (see Fig. 47-8). These devices automatically calculate and display an estimated urine volume (Taylor, Lynn, & Bartlett, 2019).

Computed Tomography and Magnetic Resonance Imaging

Computed tomography (CT) and magnetic resonance imaging (MRI) are noninvasive techniques that provide excellent cross-sectional views of the

anatomy of the kidney and urinary tract. They are used to evaluate genitourinary masses, nephrolithiasis, chronic renal infections, renal or urinary tract trauma, metastatic disease, and soft tissue abnormalities. Occasionally, an oral or intravenous (IV) radiopaque contrast agent is used in CT scanning to enhance visualization.

Nursing Interventions

Preparation includes educating the patient about relaxation techniques and explaining that they will be able to communicate with the staff by means of a microphone located inside the scanner. Many MRI suites provide headphones so that patients can listen to the music of their choice during the procedure. Nursing care guidelines for patient preparation and precautions for any imaging procedure that requires a contrast agent (contrast medium) are explained in Chart 47-6.

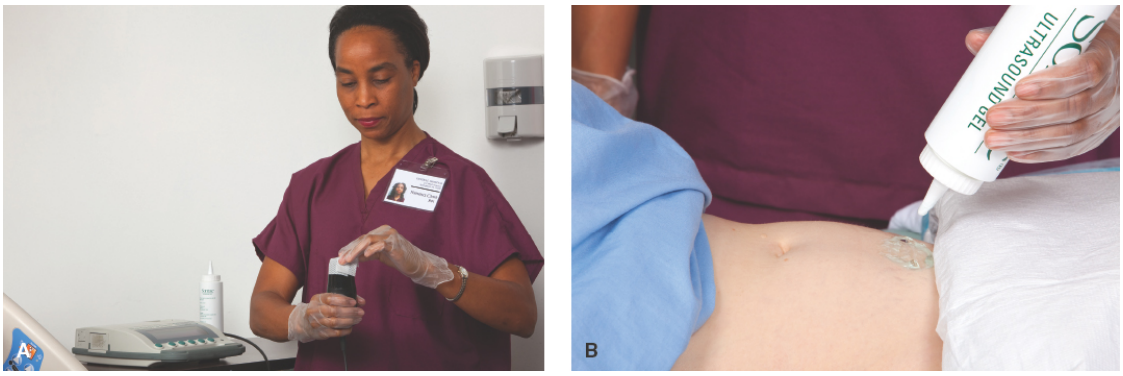

Figure 47-8 • Portable bladder ultrasound. **A.** The nurse puts on gloves and cleans the rounded end of the scan head with an alcohol pad. **B.** The nurse places ultrasound gel 2.5 cm (1 inch) superior to the symphysis pubis. (Photos by B. Proud.) Reprinted with permission from Taylor, C., Lynn, P., & Bartlett, J. L. (2019). *Fundamentals of nursing: The art and science of person-centered care* (9th ed.). Philadelphia, PA: Wolters Kluwer.

Before the patient enters the room where the MRI is to be performed, all metal objects and credit cards (the magnetic field can erase them) are removed. This includes medication patches (e.g., nicotine and nitroglycerin) that have a metal backing, which can cause burns if they are not removed. No metal objects (e.g., oxygen tanks, ventilators, stethoscopes) may be brought into the MRI room. The magnetic field is so strong that any metal-containing items will be pulled toward the magnet, causing severe injury and possible death. Patients with any type of cardiac implantable electronic device need to be screened to see if it is safe for the patient to undergo MRI (Indik, Gimbel, Abe, et al., 2017). A patient history is obtained to determine the presence of any internal objects containing metal such as aneurysm clips, orthopedic hardware,

artificial heart valves, or intrauterine devices. These objects could malfunction, be dislodged, or heat up as they absorb energy. Cochlear implants are inactivated by MRI; therefore, other imaging procedures are considered. A sedative agent may be prescribed, because claustrophobia is a problem for some patients.

Prior to MRI of the urinary system, the patient needs to be informed to avoid alcohol, caffeine-containing beverages, and smoking for at least 2 hours and food for at least 1 hour prior to the scan. Patients should continue taking their usual medication, except for iron supplements, which can interfere with the imaging (Fischbach & Fischbach, 2018).

Nuclear Scans

Nuclear scans require injection of a radioisotope (a technetium 99m–labeled compound or iodine 123 [^{123}I] hippurate) into the circulatory system; the isotope is then monitored as it moves through the blood vessels of the kidneys. A scintillation camera is placed behind the kidney with the patient in a supine, prone, or seated position. Hypersensitivity to the radioisotope is rare. The technetium scan provides information about kidney perfusion. The ^{123}I-hippurate renal scan provides information about kidney function, such as GFR.

Chart 47-6

Patient Care During Urologic Testing with Contrast Agents

For some patients, contrast agents are nephrotoxic and allergenic. Emergency equipment and medications should be available in case of an anaphylactic reaction to the contrast agent. Emergency supplies include epinephrine, corticosteroids, vasopressors, oxygen, and airway and suction equipment.

The following guidelines can help the nurse respond quickly in the event of a problem.

Nursing Actions for Patient Preparation

- Obtain the patient's allergy history with emphasis on allergy to iodine, shellfish, and other seafood, because many contrast agents contain iodine.
- Notify primary provider and radiologist if the patient is allergic or suspected to be allergic to iodine.
- Obtain health history. Contrast agents should be used with great caution in older patients and in patients who have multiple myeloma, renal impairment, or volume depletion.
- Obtain medication history. Nephrotoxic medications such as vancomycin, amphotericin B, metformin, and nonsteroidal anti-inflammatory drugs should be discontinued before contrast media administration.
- The use of both nonionic low osmolar contrast media (LOCM, e.g., iohexol) and ionic high osmolar contrast media (HOCM, e.g., diatrizoate), is indicated in patients with renal impairment and other risk factors to prevent contrast-induced nephropathy.
- Check kidney function in patients who are at risk. Patients should receive IV hydration prior to the procedure.
- Inform the patient that they may experience a temporary feeling of warmth, flushing of the face, and an unusual flavor (similar to that of seafood) in the mouth when the contrast agent is infused.

Nursing Actions During and Post Procedure

- Monitor patient closely for allergic reaction, and monitor urine output.
- Maintain hydration status.

Adapted from Andreucci, M., Solomon, R., & Tasanarong, A. (2014). Side effects of radiographic contrast media: Pathogenesis, risk factors, and prevention. Retrieved on 3/17/2020 at: www.hindawi.com/journals/bmri/2014/741018

Nuclear scans are used to evaluate acute and chronic kidney injury, renal masses, and blood flow before and after kidney transplantation. The radioisotope is injected at a specified time to achieve the proper concentration

in the kidneys. After the procedure is completed, the patient is encouraged to drink fluids to promote excretion of the radioisotope by the kidneys.

Intravenous Urography

IV urography includes various tests such as excretory urography, intravenous pyelography (IVP), and infusion drip pyelography. A radiopaque contrast agent is given IV. An IVP shows the kidneys, ureter, and bladder via x-ray imaging as the dye moves through the upper and then the lower urinary system. A nephrotomogram may be carried out as part of the study to visualize different layers of the kidney and the diffuse structures within each layer and to differentiate solid masses or lesions from cysts in the kidneys or urinary tract.

IV urography may be used as the initial assessment of many suspected urologic conditions, especially lesions in the kidneys and ureters. It also provides an approximate estimate of renal function. After the contrast agent (sodium diatrizoate or meglumine diatrizoate) is given IV, multiple x-rays are obtained to visualize drainage structures in the upper and lower urinary systems.

Infusion drip pyelography requires IV infusion of a large volume of a dilute contrast agent to opacify the renal parenchyma and fill the urinary tract. This examination method is useful when prolonged opacification of the drainage structures is desired so that tomograms (body-section radiography) can be made. Images are obtained at specified intervals after the start of the infusion. These images show the filled and distended collecting system. The patient preparation is the same as for excretory urography, except fluids are not restricted.

Retrograde Pyelography

In retrograde pyelography, catheters are advanced through the ureters into the renal pelvis by means of cystoscopy. A contrast agent is then injected. Retrograde pyelography is usually performed if IV urography provides inadequate visualization of the collecting systems. It may also be used before extracorporeal shock wave lithotripsy and in patients with urologic cancer who need follow-up and have an allergy to IV contrast agents. Possible complications include infection, hematuria, and perforation of the ureter. Retrograde pyelography is used infrequently because of improved techniques in excretory urography.

Cystography

Cystography aids in evaluating vesicoureteral reflux (backflow of urine from the bladder into one or both ureters) and in assessing for bladder injury. A catheter is inserted into the bladder, and a contrast agent is instilled to outline

the bladder wall. The contrast agent may leak through a small bladder perforation stemming from bladder injury, but such leakage is usually harmless. Cystography can also be performed with simultaneous pressure recordings inside the bladder.

Voiding Cystourethrography

Voiding cystourethrography uses fluoroscopy to visualize the lower urinary tract and assess urine storage in the bladder. It is commonly used as a diagnostic tool to identify vesicoureteral reflux. A urethral catheter is inserted, and a contrast agent is instilled into the bladder. When the bladder is full and the patient feels the urge to void, the catheter is removed, and the patient voids.

Renal Angiography

A renal angiogram, or renal arteriogram, provides an image of the renal arteries. The femoral (or axillary) artery is pierced with a needle, and a catheter is threaded up through the femoral and iliac arteries into the aorta or renal artery. A contrast agent is injected to opacify the renal arterial supply. Angiography is used to evaluate renal blood flow in suspected renal trauma, to differentiate renal cysts from tumors, and to evaluate hypertension. It is used preoperatively for renal transplantation.

Nursing Interventions

Before the procedure, a laxative may be prescribed to evacuate the colon so that unobstructed x-rays can be obtained. Injection sites (groin for femoral approach or axilla for axillary approach) may be shaved. The peripheral pulse sites (radial, femoral, and dorsalis pedis) are marked for easy access during postprocedural assessment. See Chart 47-6 for considerations for the patient receiving a contrast agent.

After the procedure, vital signs are monitored until stable. If the axillary artery was the injection site, blood pressure measurements are taken on the opposite arm. The injection site is examined for swelling and hematoma. Peripheral pulses are palpated, and the color and temperature of the involved extremity are noted and compared with those of the uninvolved extremity. Cold compresses may be applied to the injection site to decrease edema and pain. Possible complications include hematoma formation, arterial thrombosis or dissection, false aneurysm formation, and altered renal function.

MAG3 Renogram

This scan is used to further evaluate kidney function in some centers by permitting visualization of renal clearance (Fischbach & Fischbach, 2018). The patient is given an injection containing a small amount of radioactive material, which will show how the kidneys are functioning. The patient needs

to lie still for about 35 minutes while special cameras take images (Fischbach & Fischbach, 2018).

Urologic Endoscopic Procedures

Endourology, or urologic endoscopic procedures, can be performed in one of two ways: using a cystoscope inserted into the urethra, or percutaneously, through a small incision.

The cystoscopic examination is used to directly visualize the urethra and bladder. The cystoscope, which is inserted through the urethra into the bladder, has an optical lens system that provides a magnified, illuminated view of the bladder (see Fig. 47-9). The use of high-intensity light and interchangeable lenses allows excellent visualization and permits still and motion pictures to be taken. The cystoscope is manipulated to allow complete visualization of the urethra and bladder as well as the ureteral orifices and prostatic urethra. Small ureteral catheters can be passed through the cystoscope for assessment of the ureters and the pelvis of each kidney.

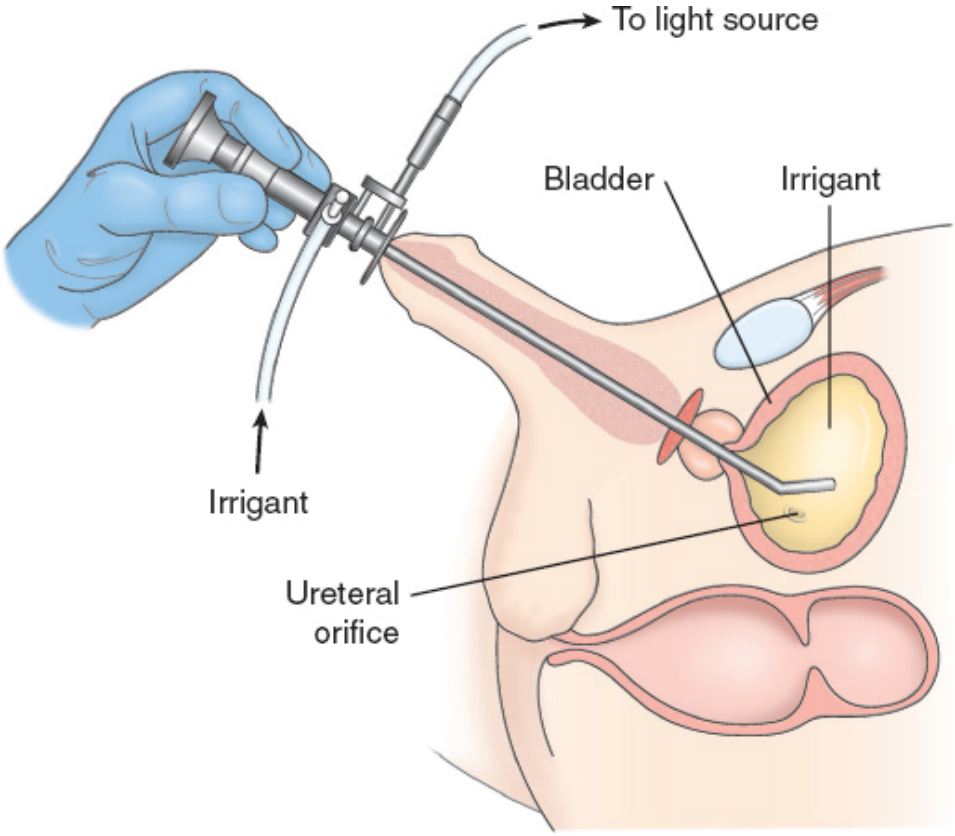

Figure 47-9 • Cystoscopic examination. A rigid or semirigid cystoscope is introduced into the bladder. The upper cord is an electric line for the light at the distal end of the cystoscope. The lower tubing leads from a reservoir of sterile irrigant that is used to inflate the bladder.

The cystoscope also allows the urologist to obtain a urine specimen from each kidney to evaluate its function. Cup forceps can be inserted through the cystoscope for biopsy. Calculi may be removed from the urethra, bladder, and ureter using cystoscopy. If a lower tract cystoscopy is performed, the patient is usually conscious, and the procedure is usually no more uncomfortable than a catheterization. To minimize posttest urethral discomfort, viscous lidocaine is given several minutes before the study. If the cystoscopy includes examination of the upper tracts, a sedative agent may be given before the procedure. General anesthesia is usually given to ensure that there are no involuntary muscle spasms when the scope is being passed through the ureters or kidneys.

Nursing Interventions

The nurse describes the procedure to the patient and family to prepare them and to allay their fears. If an upper cystoscopy is to be performed, the patient is usually restricted to nothing by mouth (NPO) for several hours beforehand.

Postprocedural management is directed at relieving any discomfort resulting from the examination. Some burning on voiding, blood-tinged urine, and urinary frequency from trauma to the mucous membranes can be expected. Moist heat to the lower abdomen and warm sitz baths are helpful in relieving pain and relaxing the muscles.

After a cystoscopic examination, the patient with obstructive pathology may experience urine retention if the instruments used during the examination caused edema. The nurse carefully monitors the patient with prostatic hyperplasia for urine retention. Warm sitz baths and antispasmodic medication, such as flavoxate, may be prescribed to relieve temporary urine retention caused by poor relaxation of the urinary sphincter; however, intermittent catheterization may be necessary for a few hours after the examination. The nurse monitors the patient for signs and symptoms of UTI. Because edema of the urethra secondary to local trauma may obstruct urine flow, the patient is also monitored for signs and symptoms of obstruction.

Biopsy

Renal and Ureteral Brush Biopsy

Brush biopsy techniques provide specific information when abnormal x-ray findings of the ureter or renal pelvis raise questions about whether a defect is a tumor, a stone, a blood clot, or an artifact. First, a cystoscopic examination is conducted. Then, a ureteral catheter is introduced, followed by a biopsy brush that is passed through the catheter. The suspected lesion is brushed back and forth to obtain cells and surface tissue fragments for histologic analysis.

Kidney Biopsy

Biopsy of the kidney is used to help diagnose and evaluate the extent of kidney disease. Indications for biopsy include unexplained acute kidney injury, persistent proteinuria or hematuria, transplant rejection, and glomerulopathies. A small section of renal cortex is obtained either percutaneously (needle biopsy) or by open biopsy through a small flank incision. Before the biopsy is carried out, coagulation studies are conducted to identify any risk of postbiopsy bleeding. Contraindications to kidney biopsy include bleeding tendencies, uncontrolled hypertension, sepsis, a solitary kidney, large polycystic kidneys, kidney neoplasm, UTI, and morbid obesity.

The patient may be prescribed a fasting regimen 6 to 8 hours before the test. An IV line is established. A urine specimen is obtained and saved for comparison with the postbiopsy specimen.

If a needle biopsy is to be performed, the patient is instructed to breathe in and hold that breath (to prevent the kidney from moving) while the needle is being inserted. The sedated patient is placed in a prone position with a sandbag under the abdomen. The skin at the biopsy site is infiltrated with a local anesthetic agent. The biopsy needle is introduced just inside the renal capsule of the outer quadrant of the kidney. The location of the needle may be confirmed by fluoroscopy or by ultrasound, in which case a special probe is used.

With open biopsy, a small incision is made over the kidney, allowing direct visualization. Preparation for an open biopsy is similar to that for any major abdominal surgery.

Nursing Interventions

After a biopsy procedure, nursing care includes monitoring vital signs to detect signs and symptoms of bleeding or infection (Fischbach & Fischbach, 2018). The nurse should assess for other signs and symptoms of internal bleeding such as pallor, dizziness, and flank or back pain. IV fluids may be given to help clear the kidneys and prevent clot formation. Urine may contain blood (usually clearing in 24 to 48 hours) from oozing at the site. Bed rest should be maintained and pressure dressings applied for prescribed periods of time to control bleeding. Puncture sites should be examined for signs and symptoms of infection. Analgesic agents should be given as prescribed and needed for pain.

CRITICAL THINKING EXERCISES

1 pq A 53-year-old female is scheduled for urodynamic testing. Describe your priorities for educating this patient about aspects of care during and after this procedure.

2 ebp You make a home visit to a 72-year-old male who had a cystoscopic examination the day before your visit. He complains of difficulty urinating since his return home. Identify assessments and possible interventions that you would use to evaluate and manage the patient's symptoms. Identify the evidence for the assessments and nursing interventions you chose and the strength of that evidence.

48 Management of Patients with Kidney Disorders

LEARNING OUTCOMES

On completion of this chapter, the learner will be able to:

1. Describe the key factors associated with the development of kidney disorders.
2. Explain the pathophysiology, clinical manifestations, medical management, and nursing management for patients with kidney disorders.
3. Differentiate between causes and understand the nursing management of patients with chronic kidney disease and acute kidney injury.
4. Compare and contrast the renal replacement therapies, including hemodialysis, peritoneal dialysis, continuous renal replacement therapies, and kidney transplantation.
5. Identify the nursing management of the hospitalized patient who is undergoing dialysis.
6. Develop a postoperative plan of nursing care for the patient undergoing kidney surgery and transplantation.

NURSING CONCEPTS

Comfort

Sexuality

GLOSSARY

acute kidney injury (AKI): rapid loss of renal function due to damage to the kidneys; formerly called acute renal failure

acute nephritic syndrome: type of kidney disease with glomerular inflammation

acute tubular necrosis (ATN): type of acute kidney injury in which there is damage to the kidney tubules

anuria: total urine output less than 50 mL in 24 hours

arteriovenous fistula: type of vascular access for dialysis which is created by surgically connecting an artery to a vein

arteriovenous graft: type of surgically created vascular access for dialysis by which a piece of biologic, semibiologic, or synthetic graft material connects the patient's artery to a vein

azotemia: abnormal concentration of nitrogenous waste products in the blood

chronic kidney disease (CKD): kidney damage or a decrease in the glomerular filtration rate lasting for 3 or more months

continuous ambulatory peritoneal dialysis (CAPD): method of peritoneal dialysis whereby a patient manually performs a prescribed number of exchanges or cycles throughout the day

continuous cyclic peritoneal dialysis (CCPD): method of peritoneal dialysis in which a peritoneal dialysis machine (cycler) automatically performs exchanges, usually while the patient sleeps

continuous renal replacement therapy (CRRT): method used to replace normal kidney function in patients who are hemodynamically unstable by circulating the patient's blood through a hemofilter and returning it to the patient

dialysate: the electrolyte solution that circulates through the dialyzer in hemodialysis and through the peritoneal membrane in peritoneal dialysis

dialyzer: artificial kidney; contains a semipermeable membrane through which particles of a certain size can pass

diffusion: movement of solutes (waste products) from an area of higher concentration to an area of lower concentration

effluent: term used to describe the drained fluid from a peritoneal dialysis exchange

end-stage kidney disease (ESKD): final stage of chronic kidney disease that results in retention of uremic waste products and the need for renal replacement therapies; formerly called end-stage renal disease (ESRD)

exchange: denotes a complete cycle including fill, dwell, and drain phases of peritoneal dialysis

glomerular filtration rate (GFR): amount of plasma filtered through the glomeruli per unit of time

glomerulonephritis: inflammation of the glomerular capillaries

hemodialysis (HD): procedure during which a patient's blood is circulated through a dialyzer to remove waste products and excess fluid

interstitial nephritis: inflammation within the renal tissue

nephrosclerosis: hardening of the renal arteries

nephrotic syndrome: type of kidney disease with increased glomerular permeability and massive proteinuria

nephrotoxic: any substance, medication, or action that is toxic to kidney tissue

oliguria: urine output less than 400 mL in 24 hours or less than 0.5 mL/kg/h over 6 hours

osmosis: movement of water through a semipermeable membrane from an area of lower solute concentration to an area of higher solute concentration

peritoneal dialysis (PD): procedure that uses the lining of the patient's peritoneal cavity, the peritoneal membrane, as the semipermeable membrane for exchange of fluid and solutes

peritonitis: inflammation of the peritoneal membrane

polyuria: excessive urine production

ultrafiltration: process whereby water is removed from the blood by means of a pressure gradient between the patient's blood and the dialysate

uremia: an excess of urea and other nitrogenous wastes in the blood

urinary casts: proteins secreted by damaged kidney tubules

The kidneys and urinary system help regulate the body's internal environment and are essential for the maintenance of life. Nurses working in all clinical settings will encounter patients with various kidney injuries and diseases and need to be knowledgeable about these disorders. This chapter provides an overview of electrolyte imbalances and systemic manifestations that are common in patients with kidney disorders. The main causes are discussed, together with management strategies to prevent damage and preserve renal function. Chronic kidney disease (CKD) and acute kidney injury (AKI) are discussed, as is the care of patients with other renal conditions requiring dialysis, continuous renal replacement therapy (CRRT), transplantation, and kidney surgery.

FLUID AND ELECTROLYTE IMBALANCES IN KIDNEY DISORDERS

Patients with kidney disorders commonly experience fluid and electrolyte imbalances and require careful assessment and close monitoring for signs of potential problems. The patient whose fluid intake exceeds the ability of the kidneys to excrete fluid is said to have fluid overload. If fluid intake is inadequate, the patient is said to be volume depleted and may show signs and symptoms of fluid volume deficit. The intake and output (I&O) record, a key monitoring tool, is used to document important fluid parameters, including the amount of fluid taken in (orally or parenterally), the volume of urine excreted, and other fluid losses (diarrhea, vomiting, diaphoresis). Patient weight is considered a more accurate indication of volume status than I&O, due to the challenges and multiple variables involved in accurately monitoring I&O. Documenting trends in weight is a key assessment strategy essential for determining the daily fluid allowance and indicating signs of fluid volume excess or deficit.

Quality and Safety Nursing Alert

The most accurate indicator of fluid loss or gain in patients who are acutely ill is weight. An accurate daily weight must be obtained and recorded. A 1-kg weight gain is equal to 1 L (1000 mL) of retained fluid.

Clinical Manifestations

The signs and symptoms of common fluid and electrolyte disturbances that can occur in patients with kidney disorders and general management strategies are listed in Table 48-1. The nurse continually assesses, monitors, and informs appropriate members of the health care team if the patient exhibits any of these signs. Management strategies for fluid and electrolyte disturbances in kidney disease are discussed in greater depth later in this chapter (see Chapter 10 for more discussion of fluid and electrolyte disturbances).

Gerontologic Considerations

With aging, the kidney is less able to respond to acute fluid and electrolyte changes. Older adult patients may develop atypical and nonspecific signs and symptoms of altered renal function and fluid and electrolyte imbalances. A fluid balance deficit in older adults can lead to falls, medication toxicity, constipation, urinary tract and respiratory tract infections, delirium, seizures, electrolyte imbalances, hyperthermia, and delayed wound healing. Recognition of acute changes in fluid and electrolytes is further hampered by their association with preexisting disorders and the misconception that they are normal changes of aging (Hain, 2017).

KIDNEY DISORDERS

Chronic Kidney Disease

Chronic kidney disease (CKD) is an umbrella term that describes kidney damage or a decrease in the glomerular filtration rate (GFR) lasting for 3 or more months. CKD is associated with decreased quality of life, increased health care expenditures, and premature death. Untreated CKD can result in **end-stage kidney disease (ESKD**, formerly known as end-stage renal disease [ESRD]), which is the final stage of CKD. ESKD results in retention of uremic waste products and the need for renal replacement therapy (RRT), such as dialysis or kidney transplantation (Chicca, 2020). Risk factors include cardiovascular disease, diabetes, hypertension, and obesity.

TABLE 48-1 Common Fluid and Electrolyte Disturbances in Kidney Disorders

Disturbance	Manifestations	General Management Strategies
Fluid volume deficit	Acute weight loss ≥5%, decreased skin turgor, dry mucous membranes, oliguria or anuria, increased hematocrit, BUN level increased out of proportion to creatinine level, hypothermia	Fluid challenge, fluid replacement orally or parenterally
Fluid volume excess	Acute weight gain ≥5%, edema, crackles, shortness of breath, decreased BUN, decreased hematocrit, distended neck veins	Fluid and sodium restriction, diuretic agents, dialysis
Hyponatremia (sodium deficit)	Nausea, malaise, lethargy, headache, abdominal cramps, apprehension, seizures	Diet, normal saline or hypertonic saline solutions
Hypernatremia (sodium excess)	Dry, sticky mucous membranes, thirst, rough dry tongue, fever, restlessness, weakness, disorientation	Fluids, diuretic agents, dietary restriction
Hypokalemia (potassium deficit)	Anorexia, abdominal distention, paralytic ileus, muscle weakness, ECG changes, arrhythmias	Diet, oral or parenteral potassium replacement therapy
Hyperkalemia (potassium excess)	Diarrhea, colic, nausea, irritability, muscle weakness, ECG changes	Dietary restriction, diuretics, IV glucose, insulin and sodium bicarbonate, cation-exchange resin, calcium gluconate, dialysis
Hypocalcemia (calcium deficit)	Abdominal and muscle cramps, stridor, carpopedal spasm, hyperactive reflexes, tetany, positive Chvostek or Trousseau sign, tingling of fingers and around mouth, ECG changes	Diet, oral or parenteral calcium salt replacement
Hypercalcemia (calcium excess)	Deep bone pain, flank pain, muscle weakness, depressed deep tendon reflexes, constipation, nausea and vomiting, confusion, impaired memory, polyuria, polydipsia, ECG changes	Fluid replacement, etidronate, pamidronate, mithramycin, calcitonin, corticosteroids, phosphate salts
Metabolic acidosis (bicarbonate deficit)	Headache, confusion, drowsiness, increased respiratory rate and depth, nausea and vomiting, warm flushed skin	Bicarbonate replacement, dialysis
Metabolic alkalosis (bicarbonate excess)	Depressed respirations, muscle hypertonicity, dizziness, tingling of fingers and toes	Fluid replacement if volume depleted; ensure adequate chloride
Hypoalbuminemia	Chronic weight loss, emotional	Diet, dietary supplements,

(protein deficit)	depression, pallor, fatigue, soft flabby muscles	hyperalimentation, albumin
Hypomagnesemia (magnesium deficit)	Dysphagia, muscle cramps, hyperactive reflexes, tetany, positive Chvostek or Trousseau sign, tingling of fingers, arrhythmias, vertigo	Diet, oral or parenteral magnesium replacement therapy
Hypermagnesemia (magnesium excess)	Facial flushing, nausea and vomiting, sensation of warmth, drowsiness, depressed deep tendon reflexes, muscle weakness, respiratory depression, cardiac arrest	Calcium gluconate, mechanical ventilation, dialysis
Hypophosphatemia (phosphorus deficit)	Deep bone pain, flank pain, muscle weakness and pain, paresthesia, apprehension, confusion, seizures	Diet, oral or parenteral phosphorus supplementation therapy

BUN, blood urea nitrogen; ECG, electrocardiographic; IV, intravenous.
Adapted from Fischbach, F., & Fischbach, M. (2018). *A manual of laboratory and diagnostic tests* (10th ed.). Philadelphia, PA: Wolters Kluwer.

Recent research reported that 15% of the adult U.S. population, 37 million people or 1 in 7 individuals, have CKD and 9 of 10 affected individuals are unaware of their disease (Centers for Disease Control and Prevention [CDC], 2019). On December 31, 2017, there were more than 746,000 Americans diagnosed with ESKD (United States Renal Data System [USRDS], 2019). The majority of people with CKD will die of a cardiovascular event (heart attack or stroke) prior to reaching ESKD (Subbiah, Chhabra, & Mahajan, 2016).

Diabetes and hypertension cause approximately 70% of cases of CKD (Chicca, 2020). About one in three adults with diabetes may have CKD (CDC, 2019). Diabetes is the leading cause of kidney disease in patients starting RRT. About one in five adults with hypertension may have CKD (CDC, 2019). Other causes include glomerulonephritis, pyelonephritis; polycystic, hereditary, or congenital disorders; and renal cancers.

Pathophysiology

In the early stages of CKD, there can be significant damage to the kidneys without signs or symptoms. The pathophysiology of CKD is not yet clearly understood, but the damage to the kidneys is thought to be caused by prolonged acute inflammation that is not organ specific and thus has subtle systemic manifestations.

Stages of Chronic Kidney Disease

CKD has been classified into five stages by the National Kidney Foundation (NKF) (see Chart 48-1). Stage 5 results when the kidneys cannot remove the body's metabolic wastes or perform their regulatory functions; thus, RRT is

required to sustain life. Screening and early intervention are important, because not all patients progress to stage 5 CKD. Patients with CKD are at increased risk for cardiovascular disease, which is the leading cause of morbidity and mortality (Carey & Whelton, 2018). Treatment of hypertension, anemia, and hyperglycemia and detection of proteinuria all help to slow disease progression and improve patient outcomes (Brooks, 2017).

Chart 48-1

Stages of Chronic Kidney Disease

Stages are based on the GFR. The normal GFR is 125 mL/min/1.73 m^2.

Stage 1

GFR ≥90 mL/min/1.73 m^2
Kidney damage with normal or increased GFR

Stage 2

GFR = 60–89 mL/min/1.73 m^2
Mild decrease in GFR

Stage 3

GFR = 30–59 mL/min/1.73 m^2
Moderate decrease in GFR

Stage 4

GFR = 15–29 mL/min/1.73 m^2
Severe decrease in GFR

Stage 5

GFR <15 mL/min/1.73 m^2
End-stage kidney disease or chronic kidney disease

Adapted from Norris, T. L. (2019). *Porth's pathophysiology: Concepts of altered health states* (10th ed.). Philadelphia, PA: Wolters Kluwer.

GFR, glomerular filtration rate.

Clinical Manifestations

Elevated serum creatinine levels indicate underlying kidney disease; as the creatinine level increases, symptoms of CKD begin. Those with CKD are one of the most symptomatic groups among patients with chronic diseases (Kalfoss, Schick-Makaroff, & Molzahn, 2019). Anemia, due to decreased erythropoietin production by the kidney, metabolic acidosis, and abnormalities in calcium and phosphorus balance herald the development of CKD (Brooks, 2017). Fluid

retention, evidenced by both edema and congestive heart failure, develops. As the disease progresses, abnormalities in electrolytes occur, heart failure worsens, and hypertension becomes more difficult to control, often due to fluid volume excess (Ku, Lee, Wei, et al., 2019).

Assessment and Diagnostic Findings

The **glomerular filtration rate (GFR)** is the amount of plasma filtered through the glomeruli per unit of time. Creatinine clearance is a measure of the amount of creatinine the kidneys are able to clear in a 24-hour period. Normal values differ in men and women. Calculation of GFR, an important assessment parameter in CKD, is discussed in Chapter 47.

Medical Management

The management of patients with CKD includes treatment of the underlying causes. Regular clinical and laboratory assessment is important to keep the blood pressure below 125 to 130/80 mm Hg (Ku et al., 2019). Controlling cardiovascular risk factors, treating hyperglycemia, managing anemia, encouraging smoking cessation, weight loss, and exercise programs as well as reducing salt and alcohol intake and minimizing nephrotoxins all slow progression toward ESKD. Medical management also includes early referral for initiation of RRT as indicated by the patient's renal status. Patient engagement and education are essential as many of these factors are under the patient's control.

Gerontologic Considerations

Changes in kidney function with normal aging increase the susceptibility of older patients to kidney dysfunction and kidney disease (Hain, 2017). With aging, the number of nephrons decline. In addition, the incidence of systemic diseases, such as atherosclerosis, hypertension, heart failure, diabetes, and cancer, increases with advancing age, predisposing older adults to kidney disease associated with these disorders. Therefore, acute problems need to be prevented if possible or recognized and treated quickly to avoid kidney damage. Nurses in all settings need to be alert to signs and symptoms of kidney dysfunction in older patients.

Older patients frequently take multiple prescription and over-the-counter medications. Because alterations in renal blood flow, glomerular filtration, and renal clearance increase the risk of medication-associated changes in renal function, precautions are indicated with all medications. When older patients undergo extensive diagnostic tests or when new medications (e.g., diuretic agents) are added, precautions must be taken to prevent dehydration, which can

compromise marginal renal function and exacerbate preexisting kidney dysfunction (Hain, 2017).

Nephrosclerosis

Nephrosclerosis (hardening of the renal arteries) is most often due to prolonged hypertension, diabetes, the aging process, and other factors. Individuals with nephrosclerosis generally experience slowly elevating blood urea nitrogen (BUN) and creatinine, and mild proteinuria (spilling of protein in the urine). Nephrosclerosis is a major cause of CKD and ESKD secondary to many disorders. Groups at increased risk include African Americans, those with uncontrolled hypertension, and individuals with underlying CKD, especially those with diabetic nephropathy. African American patients have an approximate eightfold elevation in the risk of hypertension-induced ESKD (Mann & Hilgers, 2019).

Pathophysiology

There are two forms of nephrosclerosis: acute hypertensive and benign. Acute hypertensive nephrosclerosis is often associated with significant and prolonged hypertension. Damage is caused by decreased blood flow to the kidney resulting in patchy necrosis of the renal parenchyma. Over time, fibrosis occurs and glomeruli are destroyed. Untreated, the disease process can progress rapidly. Benign nephrosclerosis can be found in older adults, associated with atherosclerosis, hypertension, and diabetes (Parikh, Haddad, & Hebert, 2019).

Assessment and Diagnostic Findings

Symptoms are rare early in the disease, even though the urine usually contains protein and occasional casts. CKD and associated signs and symptoms occur late in the disease.

Medical Management

Treatment of nephrosclerosis is antihypertensive therapy. An angiotensin-converting enzyme (ACE) inhibitor, alone or in combination with other antihypertensive medications, significantly reduces its incidence. See Chapter 27 for additional information on hypertension.

Primary Glomerular Diseases

Diseases that destroy the glomerulus of the kidney are the third most common cause of stage 5 CKD (USRDS, 2019). The glomeruli (a Greek word meaning "filter") are the multiple small blood vessels within the nephron that remove urea from the blood. There are two major categories of glomerular diseases: glomerulonephritis and glomerulosclerosis. Primary glomerular diseases are within the kidney itself, while secondary glomerular kidney disease is a result of systemic disease, such as diabetes or lupus nephritis. Primary glomerulonephritis means that the kidney is inflamed, often due to an autoimmune disorder (Norris, 2019).

Antigen–antibody complexes form in the blood and become trapped in the glomerular capillaries (the filtering portion of the kidney), inducing an inflammatory response. Immunoglobulin G (IgG)—the major immunoglobulin (antibody) found in the blood—can be detected in the glomerular capillary walls. The major clinical manifestations of glomerular injury include proteinuria, hematuria, decreased GFR, decreased excretion of sodium, edema, and hypertension (Mahaffey, 2017) (see Chart 48-2).

Chart 48-2

Terms Typically Used When Describing Glomerular Disease

Primary: Disease is mainly in glomeruli
Secondary: Glomerular diseases that are the consequence of systemic disease
Idiopathic: Cause is unknown
Acute: Occurs over days or weeks
Chronic: Occurs over months or years
Rapidly progressing: Constant, rapid loss of renal function with better chance of recovery with early diagnosis
Diffuse: Involves all glomeruli
Focal: Involves some glomeruli
Segmental: Involves portions of individual glomeruli
Membranous: Evidence of thickened glomerular capillary walls
Proliferative: Number of glomerular cells involved is increasing

Acute Nephritic Syndrome

Glomerulonephritis is an inflammation of the glomerular capillaries that can occur in acute and chronic forms. **Acute nephritic syndrome** is a type of acute glomerulonephritis. In acute nephritic syndrome, hematuria due to glomerular bleeding is seen as well as pus and cellular and granular casts in the urine. Variable proteinuria is noted. A decreased glomerular filtration rate is seen in severe cases of nephritic glomerular injury (Mahaffey, 2017; Norris, 2019).

Pathophysiology

Primary glomerular diseases include postinfectious glomerulonephritis, rapidly progressive glomerulonephritis, membrane proliferative glomerulonephritis, and membranous glomerulonephritis. Postinfectious causes are group A beta-hemolytic streptococcal infection of the throat that precedes the onset of glomerulonephritis by 2 to 3 weeks (see Fig. 48-1). Postinfectious glomerulonephritis may also follow impetigo (infection of the skin) and acute viral infections (upper respiratory tract infections, mumps, varicella zoster virus, Epstein–Barr virus, hepatitis B, and human immune deficiency virus [HIV] infection). In some patients, antigens outside the body (e.g., medications, foreign serum) initiate the process, resulting in antigen–antibody complexes being deposited in the glomeruli. In other patients, the kidney tissue itself serves as the inciting antigen (autoimmune phenomenon). With early diagnosis and treatment, the kidney damage is generally reversible (Mahaffey, 2017).

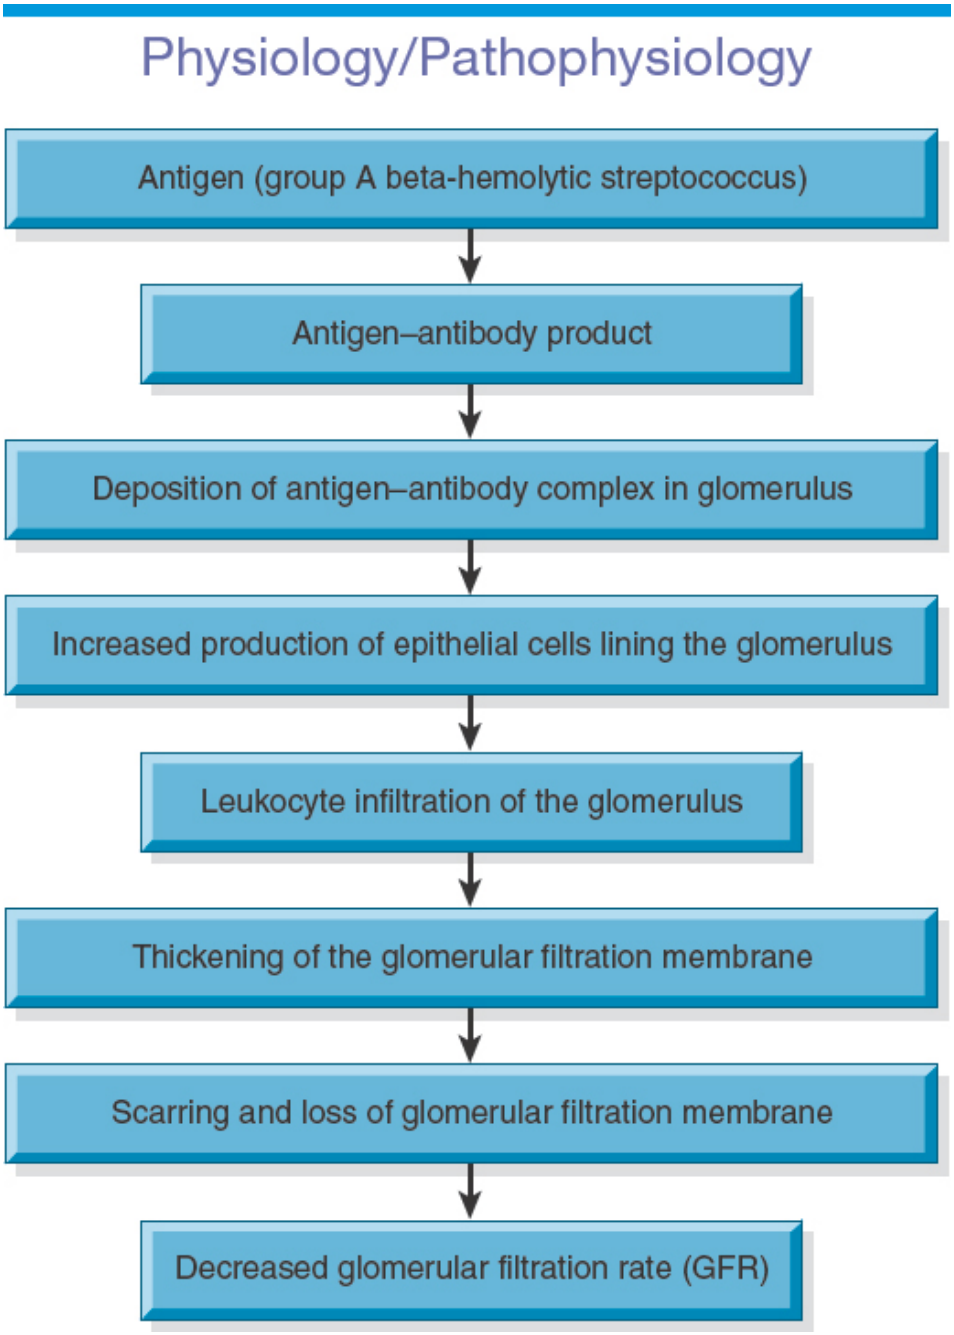

Figure 48-1 • Sequence of events in acute nephritic syndrome.

Clinical Manifestations

The primary presenting features of an acute glomerular inflammation are hematuria, edema, **azotemia** (an abnormal concentration of nitrogenous wastes in the blood), and **proteinuria** (excess protein in the urine) (Mahaffey, 2017; Norris, 2019). The hematuria may be microscopic (identifiable only through microscopic examination) or macroscopic (visible to the eye). The urine may appear cola-colored because of red blood cells (RBCs) and protein plugs or casts; RBC casts indicate glomerular injury. Glomerulonephritis may be mild

and the hematuria discovered incidentally through a routine urinalysis, or the disease may be severe, with AKI and oliguria.

Some degree of edema and hypertension is present in most patients. Marked proteinuria due to the increased permeability of the glomerular membrane may also occur, with associated pitting edema, hypoalbuminemia, hyperlipidemia, and fatty casts in the urine. BUN and serum creatinine levels may increase as urine output decreases. In addition, anemia may be present.

In the more severe form of the disease, patients also complain of headache, malaise, and flank pain. Older patients may experience circulatory overload with dyspnea, engorged neck veins, cardiomegaly, and pulmonary edema. Atypical symptoms include confusion, somnolence, and seizures, which are often confused with the symptoms of a primary neurologic disorder.

Assessment and Diagnostic Findings

In acute nephritic syndrome, the kidneys become large, edematous, and congested. All renal tissues, including the glomeruli, tubules, and blood vessels, are affected to varying degrees. Patients with an immunoglobulin A (IgA) nephropathy have an elevated serum IgA and low to normal complement levels. Electron microscopy and immunofluorescent analysis help identify the nature of the lesion; however, a kidney biopsy may be needed for definitive diagnosis. See Chapter 47 for discussion of kidney biopsy.

If the patient improves, the amount of urine will increase and the urinary protein and sediment will diminish. Some patients develop severe **uremia** (an excess of urea and other nitrogenous wastes in the blood) within weeks and require dialysis for survival. Others, after a period of apparent recovery, insidiously develop chronic glomerulonephritis.

Complications

Complications of acute glomerulonephritis include hypertensive encephalopathy, heart failure, and pulmonary edema. Hypertensive encephalopathy is a medical emergency, and therapy is directed toward reducing the blood pressure without impairing renal function. This can occur in acute nephritic syndrome or preeclampsia with chronic hypertension of greater than 130/80 mm Hg.

Rapidly progressive glomerulonephritis is characterized by a rapid decline in renal function. Without treatment, ESKD develops in a matter of weeks or months. Signs and symptoms are similar to those of acute glomerulonephritis (hematuria and proteinuria), but the course of the disease is more severe and rapid. Crescent-shaped cells accumulate in Bowman space, disrupting the filtering surface. Therapeutic plasma exchange and treatment with high-dose corticosteroids, cytotoxic agents or monoclonal antibodies have been used to reduce the inflammatory response.

Dialysis is initiated in acute glomerulonephritis if signs and symptoms of uremia are severe. However, the prognosis for patients with acute nephritic syndrome is excellent and it rarely causes CKD (Mahaffey, 2017).

Medical Management

Management consists primarily of treating symptoms, attempting to preserve kidney function, and treating complications promptly. Treatment may include prescribing corticosteroids, managing hypertension, and controlling proteinuria. Pharmacologic therapy depends on the cause of acute glomerulonephritis. If residual streptococcal infection is suspected, penicillin is the agent of choice. However, other antibiotic agents may be prescribed. Dietary protein may be restricted when renal insufficiency and nitrogen retention (elevated BUN) develop. Sodium is restricted when the patient has hypertension, edema, and heart failure.

Nursing Management

Although most patients with acute uncomplicated glomerulonephritis are cared for as outpatients, nursing care is important in every setting.

Providing Care in the Hospital

In a hospital setting, carbohydrates are given liberally to provide energy and reduce the catabolism of protein. I&O is carefully measured and recorded. Fluids are prescribed based on the patient's fluid losses and daily body weight. Insensible fluid loss through the lungs (300 mL) and skin (500 mL) is considered when estimating fluid loss (see Chapter 10, Table 10-2) (Norris, 2019). If treatment is effective, diuresis will begin, resulting in decreased edema and blood pressure. Proteinuria and microscopic hematuria may persist for many months. Other nursing interventions focus on patient education about the disease process, explanations of laboratory and other diagnostic tests, and preparation for safe and effective self-care at home.

Promoting Home, Community-Based, and Transitional Care

Educating Patients About Self-Care

Patient education is directed toward managing symptoms and monitoring for complications. Fluid and diet restrictions must be reviewed with the patient to avoid worsening of edema and hypertension. The patient is instructed verbally and in writing to notify the primary provider if symptoms of kidney disease occur (e.g., fatigue, nausea, vomiting, loss of appetite, diminishing urine output) or at the first sign of any infection.

Continuing and Transitional Care

The importance of follow-up evaluations of blood pressure, laboratory blood studies for BUN and creatinine levels, and urinalysis for protein, to determine if the disease has progressed, is stressed to the patient. A referral for transitional, home, or community-based care may be indicated. A home visit from a nurse provides an opportunity for careful assessment of the patient's progress and detection of early signs and symptoms of renal insufficiency. If corticosteroids, immunosuppressant agents, or antibiotic medications are prescribed, the nurse uses the opportunity to review the dosages, desired actions, and adverse effects of medications and the precautions to be taken.

Chronic Glomerulonephritis

Chronic glomerulonephritis may be due to repeated episodes of acute nephritic syndrome, hypertensive nephrosclerosis, hyperlipidemia, chronic tubulointerstitial injury, or hemodynamically mediated glomerular sclerosis. Secondary glomerular diseases that can have systemic effects include systemic lupus erythematosus, Goodpasture syndrome (caused by antibodies to the glomerular basement membrane), and diabetic glomerulosclerosis (Mahaffey, 2017).

Pathophysiology

The kidneys are reduced to as little as one fifth their normal size (consisting largely of fibrous tissue). The cortex layer shrinks to 1 to 2 mm in thickness or less. Bands of scar tissue distort the remaining cortex, making the surface of the kidney rough and irregular. Numerous glomeruli and their tubules become scarred, and the branches of the renal artery are thickened. The resulting severe glomerular damage can progress to stage 5 CKD and require RRT. Patients who initially have impaired kidney function or notable proteinuria tend to have increased progression of kidney disease (Parikh et al., 2019).

Clinical Manifestations

The symptoms of chronic glomerulonephritis vary. Some patients with severe disease have no symptoms at all for many years. The condition may be discovered when hypertension or elevated BUN and serum creatinine levels or proteinuria are detected. Most patients report general symptoms, such as loss of weight and strength, increasing irritability, and nocturia (an increased need to urinate at night). Headaches, dizziness, and digestive disturbances are also common. Early diagnosis and treatment are key to preventing CKD and ESKD and the development of late complications.

As chronic glomerulonephritis progresses, signs and symptoms of CKD may develop. With undiagnosed or untreated disease, the patient appears poorly

nourished, with a yellow-gray pigmentation of the skin and periorbital and peripheral (dependent) edema. Blood pressure may be normal or severely elevated. Retinal findings include hemorrhage, exudate, narrowed tortuous arterioles, and papilledema. Anemia causes pale mucous membranes. Cardiomegaly, a gallop rhythm, distended neck veins, and other signs and symptoms of heart failure may be present. Crackles can be heard in the bases of the lungs.

Peripheral neuropathy with diminished deep tendon reflexes and neurosensory changes occur late in the disease. The patient becomes confused and demonstrates a limited attention span. Additional late findings include evidence of pericarditis with a pericardial friction rub and pulsus paradoxus (difference in blood pressure during inspiration and expiration of greater than 10 mm Hg). Pleural effusions may be seen on chest x-ray.

Assessment and Diagnostic Findings

A number of laboratory abnormalities occur. Urinalysis reveals a fixed specific gravity of about 1.010, variable proteinuria, and **urinary casts** (proteins secreted by damaged kidney tubules). As kidney disease progresses and the GFR falls below 50 mL/min, the following changes occur:

- Anemia secondary to decreased erythropoiesis (production of RBCs)
- Decreased serum calcium level (calcium binds to phosphorus to compensate for elevated serum phosphorus levels)
- Hyperkalemia due to decreased urinary potassium excretion, acidosis, catabolism, and potassium intake from food and medications
- Hypoalbuminemia with edema secondary to protein loss through the damaged glomerular membrane
- Increased serum phosphorus level due to decreased renal excretion of phosphorus
- Impaired nerve conduction due to electrolyte abnormalities and uremia resulting in peripheral neuropathy
- Mental status changes
- Metabolic acidosis from decreased acid secretion by the kidney and inability to regenerate bicarbonate

Chest x-rays may show cardiac enlargement and pulmonary edema due to volume overload. The electrocardiogram (ECG) may be normal or may indicate left ventricular hypertrophy associated with hypertension and signs of electrolyte disturbances, such as tall, tented (or peaked) T waves associated with hyperkalemia. Renal ultrasound shows decreased renal mass in both kidneys (Norris, 2019).

Medical Management

Management of symptoms guides the treatment. If the patient has hypertension, efforts are made to reduce the blood pressure with sodium and water restriction, antihypertensive agents, or both. Weight is monitored daily, and diuretic medications are prescribed to treat fluid overload. Proteins of high-biologic value (eggs, meats, fish) are provided to promote good nutritional status. Adequate calories are provided to spare protein for tissue growth and repair. Urinary tract infections (UTIs) must be treated promptly to prevent further kidney damage. Nonsteroidal anti-inflammatory drugs (NSAIDs) are avoided as well as other nephrotoxic medications and diagnostic studies which necessitate the administration of intravenous (IV) contrast dye (Nahar, 2017).

Dialysis is initiated early in the course of the disease to keep the patient in optimal physical condition, prevent fluid and electrolyte imbalances, and minimize the risk of complications of kidney disease. The course of dialysis is smoother if treatment begins before the patient develops complications.

Nursing Management

Whether the patient is hospitalized or cared for in the home, the nurse observes the patient for common fluid and electrolyte disturbances in kidney disease (see Table 48-1). Changes in fluid and electrolyte status and in cardiac and neurologic status are promptly reported to the primary provider. Throughout the course of the disease and treatment, the nurse gives emotional support by providing opportunities for the patient and family to verbalize their concerns, have their questions answered, and explore their options (Mahaffey, 2017).

Promoting Home, Community-Based, and Transitional Care

Educating Patients About Self-Care

The nurse has a major role in educating the patient and family about the prescribed treatment plan and the risks associated with nonadherence. Instructions to the patient include explanations and scheduling for follow-up evaluations: blood pressure, urinalysis for protein and casts, and laboratory studies of BUN and serum creatinine levels. If long-term dialysis is needed, the nurse educates the patient and family about the procedure, how to care for the access site, dietary and fluid restrictions, and other necessary lifestyle modifications. These topics are discussed later in this chapter.

Periodic hospitalization, visits to the outpatient clinic or office, and home care referrals provide the nurse in each setting with the opportunity for careful assessment of the patient's progress and continued education about changes to report to the primary provider (worsening signs and symptoms of kidney disease, such as nausea, vomiting, loss of appetite, and diminished urine output). Specific education may include explanations of recommended diet and fluid modifications; medications (purpose, desired effects, adverse effects,

dosage, and administration schedule); and encouragement to achieve and maintain a healthy weight (Chicca, 2020). The nurse consults with the renal dietitian for detailed dietary education.

Continuing and Transitional Care

Periodic laboratory evaluations of creatinine clearance and BUN and serum creatinine levels are carried out to assess residual renal function and the need for dialysis or transplantation. If dialysis is initiated, the patient and family require considerable assistance and support in dealing with therapy and its long-term implications. The patient and family are reminded of the importance of participation in health promotion activities, including health screening. The patient is instructed to inform all health care providers about the diagnosis of glomerulonephritis so that all medical management, including pharmacologic therapy, is based on altered renal function.

Nephrotic Syndrome

Nephrotic syndrome is a type of kidney disease characterized by increased glomerular permeability and is manifested by massive proteinuria (Mahaffey, 2017). Clinical findings include proteinuria (a marked increase in protein [particularly albumin] in the urine), hypoalbuminemia (a decrease in albumin in the blood), diffuse edema, high serum cholesterol, and hyperlipidemia (elevated low-density lipoproteins). A hypercoagulable state is often present and the patient has an increased risk of deep venous thrombosis, renal vein thrombosis, and pulmonary embolism (Kelepouris & Rovin, 2019).

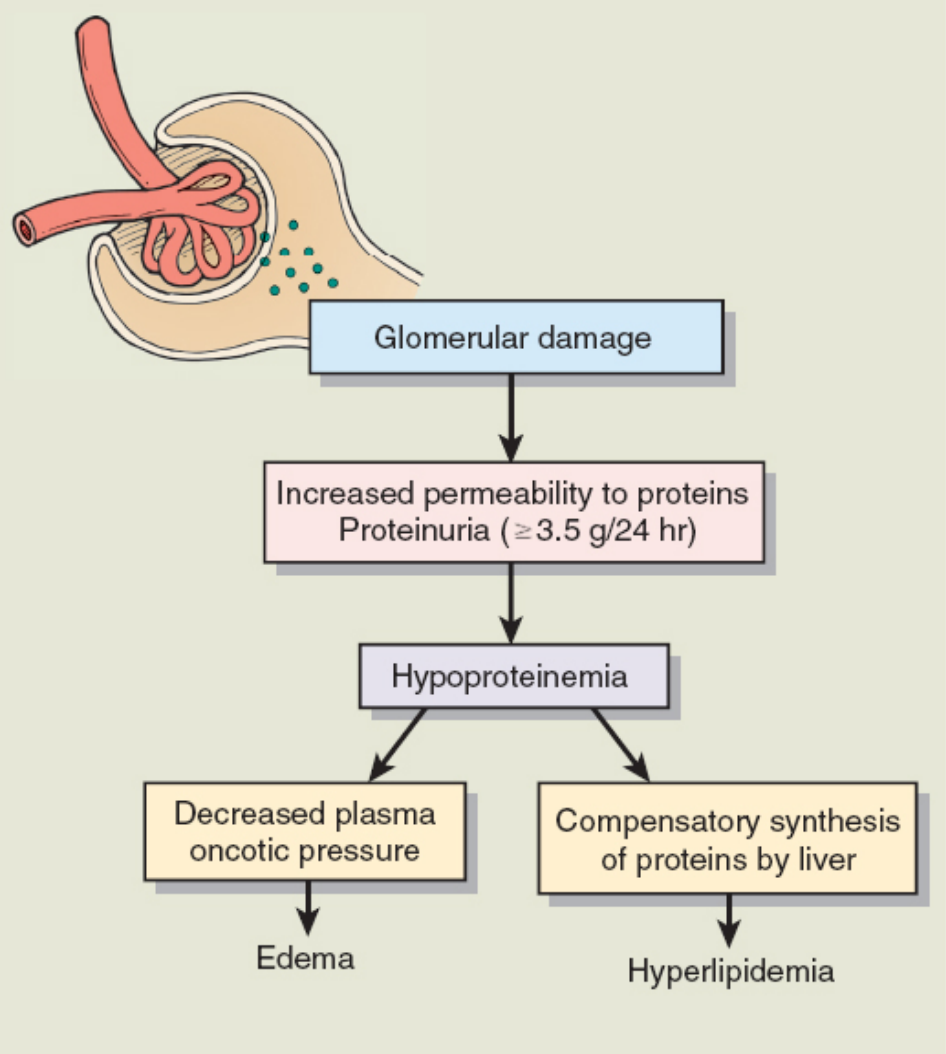

Figure 48-2 • Pathophysiology of the nephrotic syndrome. Reprinted with permission from Norris, T. L. (2019). *Porth's pathophysiology: Concepts of altered health state* (10th ed., Fig. 33-14). Philadelphia, PA: Wolters Kluwer.

The syndrome is apparent in any condition that seriously damages the glomerular capillary membrane and results in increased glomerular permeability to plasma proteins. Although the liver is capable of increasing the production of albumin, it cannot keep up with the daily loss of albumin through the kidneys. Thus, hypoalbuminemia results (see Fig. 48-2).

Pathophysiology

Nephrotic syndrome occurs with many intrinsic kidney diseases and systemic diseases that cause glomerular damage. It is not a specific glomerular disease but a constellation of clinical findings that result from the glomerular damage.

Clinical Manifestations

The major manifestation of nephrotic syndrome is edema. It is usually soft and pitting and commonly occurs around the eyes (periorbital), in dependent areas (sacrum, ankles, and hands), and in the abdomen (ascites). Patients may also exhibit irritability, headache, and malaise.

Assessment and Diagnostic Findings

Proteinuria (predominately albumin) exceeding 3.5 g/day is the hallmark of the diagnosis of nephrotic syndrome. Protein excretion can be measured on a 24-hour urine collection; the normal value is less than 150 mg/day (Kelepouris & Rovin, 2019). Urine protein electrophoresis and immunofixation may be performed to categorize the type of proteinuria. The urine may also contain increased white blood cells (WBCs) as well as granular and epithelial casts. A needle biopsy of the kidney may be performed for histologic examination of renal tissue to confirm the diagnosis.

Complications

Complications of nephrotic syndrome include infection (due to a deficient immune response), thromboembolism (especially of the renal vein and deep veins of the legs), pulmonary embolism, AKI (due to hypovolemia), and accelerated atherosclerosis (due to hyperlipidemia).

Medical Management

Treatment is focused on addressing the underlying disease state causing proteinuria, slowing progression of CKD, and relieving symptoms. Typical treatment includes diuretic agents for edema, ACE inhibitors to reduce proteinuria, lipid-lowering agents for hyperlipidemia, and dietary sodium restriction (approximately 2 g of sodium/day) (Kelepouris & Rovin, 2019).

Nursing Management

In the early stages of nephrotic syndrome, nursing management is similar to that of the patient with acute glomerulonephritis, but as the condition worsens, management is similar to that of the patient with ESKD (see the following section).

Patients with nephrotic syndrome need adequate education about the importance of following all medication and dietary regimens so that their condition can remain stable for as long as possible. Patients must be educated about the importance of promptly communicating any health-related change to their primary providers so that appropriate medication and dietary changes can be made before further changes occur within the glomeruli.

Polycystic Kidney Disease

Polycystic kidney disease (PKD) is a genetic disorder characterized by the growth of numerous fluid-filled cysts in the kidneys, which destroy the nephrons. PKD cysts can profoundly enlarge the kidneys while replacing much of the normal structure, resulting in reduced kidney function and leading to kidney failure (Mahaffey, 2017).

Pathophysiology

Patients with PKD can also have cysts in the liver and pancreas, aneurysms in blood vessels in the brain, and cardiovascular abnormalities. The number of cysts and the resulting complications distinguish PKD from the usually harmless cysts that can form in the kidneys in later years of life.

PKD is the most common inherited genetic cause of kidney failure (Bolignano, Palmer, Ruospo, et al., 2015). Two major inherited forms of PKD exist: autosomal dominant PKD and autosomal recessive PKD.

- Autosomal dominant PKD is the most common inherited form (90%). There are two subtypes. PKD1 has a mutation on chromosome 16 and is the most prevalent form with 78% of patients having this mutation. The second subtype is PKD2 with a mutation on chromosome 4. PKD2 progresses more slowly than PKD1. The average age for patients to progress to ESKD is 54.3 years among patients with PKD1 versus 74.0 years among patients with PKD2 (Torres & Bennett, 2019).
- Autosomal recessive PKD is a rare inherited form (10%) of PKD. Symptoms of autosomal recessive PKD begin in the earliest months of life or in utero. Since the gene is recessive, both parents are carriers but neither parent is affected (Mahaffey, 2017).

Clinical Manifestations

Signs and symptoms of PKD result from loss of renal function and the increasing size of the kidneys as the cysts grow. Kidney damage can result in hematuria, hypertension, and development of renal calculi with associated UTIs and proteinuria. As the cysts grow in size and number, the patient reports increasing abdominal fullness and flank pain (back and lower sides).

Assessment and Diagnostic Findings

PKD is a genetic disease; therefore, a careful evaluation of family history is necessary. Palpation of the abdomen will often reveal enlarged cystic kidneys. Ultrasound imaging of the kidneys is the preferred technique for diagnosis.

Genetic testing is performed if imaging results are uncertain (Torres & Bennett, 2019).

Medical Management

PKD has no cure, but tolvaptan slows the decrease in kidney function in patients with PKD. The most common side effects are **polyuria** (excessive urine production) and rare, but potentially serious liver injury, which is most often reversible when the drug is stopped (Comerford & Durkin, 2020). Other treatments are largely supportive and include blood pressure control, pain management, and antibiotic agents to resolve infections. Once the kidneys fail, RRT is indicated (see later discussion in chapter). Genetic studies and counseling may be indicated, particularly when screening family members for potential kidney donation (Torres & Bennett, 2019).

RENAL CANCER

Renal cancer is relatively rare in the United States and accounts for about 4.2% of all cancers. However, an increased incidence of renal cancer at all stages has been noted in the past two decades (National Cancer Institute, 2019). This increase may be due to improved detection as a result of incidental findings during other diagnostic tests. The incidence of renal cell carcinoma is higher in men and in individuals with an increased body mass index. Tobacco use continues to be a significant risk factor (see Chart 48-3). In addition, African Americans have higher rates of renal cancer than Caucasians (Conde & Workman, 2017).

Ninety percent of renal cancers derive from the renal parenchyma and are known as renal cell carcinomas or renal adenocarcinomas. Between 70% and 80% of all renal cell carcinomas are clear cell carcinoma (also known as conventional or nonpapillary) and arise from the proximal renal tubule. The next most prevalent form (10%) is papillary renal cell carcinomas (American Cancer Society [ACS], 2020). These tumors may metastasize to the lungs, abdominal and mediastinal lymph nodes, brain, bone, and liver; metastatic disease is seen in 30% of patients at diagnosis (ACS, 2020).

Chart 48-3  **RISK FACTORS**

Renal Cancer

African American Race
Certain medications such as diuretics and other medications for hypertension
Genetic factors
Hypertension
Male gender
Obesity
Occupational exposure to industrial chemicals, such as heavy metals (cadmium), some herbicides, and organic solvents (e.g., trichloroethylene)
Smoking

Adapted from American Cancer Society (ACS). (2020). Kidney cancer. Retrieved on 1/11/2020 at: www.cancer.org/cancer/kidney-cancer/causes-risks-prevention/what-causes.html

Staging is based on tumor size, lymph node involvement, and distant metastasis. The 5-year survival rate based on the stage of renal cancer at diagnosis is 92% with only local involvement, 65% with regional spread, and 12% with distant metastases (Conde & Workman, 2017). Although enhanced imaging techniques account for improved detection of early-stage kidney cancer, it is unknown why the rate of late-stage, metastatic renal cancers is high. Over 50% of renal cancers are found incidentally on radiologic studies in individuals who have no symptoms (Conde & Workman, 2017).

Clinical Manifestations

Many renal tumors produce no symptoms and are discovered on a routine physical examination as a palpable abdominal or flank mass. Signs and symptoms, which occur in only 10% of patients, include hematuria, pain, and a mass in the flank. The usual sign that first calls attention to the tumor is painless hematuria, which may be either intermittent and microscopic, or continuous and overt (gross hematuria) (Conde & Workman, 2017). There may be a dull pain in the back from the pressure produced by compression of the ureter, extension of the tumor into the perirenal area, or hemorrhage into the kidney tissue. Colicky pains occur if a clot or mass of tumor cells passes down the ureter. Symptoms from metastasis may be the first manifestations of a renal tumor and may include unexplained weight loss, fatigue, and anemia.

Assessment and Diagnostic Findings

The diagnosis of a renal tumor may require IV urography, cystoscopic examination, renal angiograms, ultrasonography, or a CT or MRI scan (see Chapter 47). These tests may be exhausting for patients already debilitated by the systemic effects of a tumor as well as for older patients and those who are anxious about the diagnosis and outcome. The nurse assists the patient to prepare physically and psychologically for these procedures and monitors carefully for signs and symptoms of dehydration and impaired coping.

Medical Management

The goal of medical management is to detect the tumor early and to eradicate tumors before metastasis occurs. Treatment most often includes a combination of surgery and pharmacologic management. Radiation therapy may be used for palliation in patients who are not candidates for surgery or other treatments or in those with metastatic disease (ACS, 2020).

Surgical Management

Nephrectomy

Open, laparoscopic, or robotic surgical procedures are utilized for radical and partial nephrectomies (ACS, 2020). A radical nephrectomy is the primary treatment if the tumor can be removed and if the tumor has spread to the inferior vena cava (Conde & Workman, 2017). This includes removal of the kidney (and tumor), adrenal gland, surrounding perinephric fat and Gerota fascia, and lymph nodes. Laparoscopic nephrectomy can be performed for removal of the kidney with a small tumor. This procedure incurs less morbidity and a shorter recovery time. Radiation therapy, hormonal therapy, or immunotherapy may be used along with surgery. Nephron-sparing surgery, or partial nephrectomy, is increasingly being used to treat patients with bilateral tumors, cancer of a functional single kidney, and for small local tumors with a normal contralateral kidney. This is the preferred surgery for local disease as well as for those individuals with risk factors for CKD. The success rate of partial nephrectomies is excellent with operative morbidity and mortality both low (Richie, Atkins, & Chen, 2019).

Renal Artery Embolization

In patients with metastatic renal carcinoma, the renal artery may be occluded to impede the blood supply to the tumor and thus kill the tumor cells. After angiographic studies are completed, a catheter is advanced into the renal artery, and embolizing materials (e.g., Gelfoam, autologous blood clot, steel coils) are injected into the artery and carried with the arterial blood flow to occlude the tumor vessels mechanically. This decreases the local blood supply, making nephrectomy easier. After renal artery embolization and tumor infarction, a characteristic symptom complex called postinfarction syndrome occurs, lasting

2 to 3 days. The patient has pain localized to the flank and abdomen, elevated temperature, and gastrointestinal (GI) symptoms. Pain is treated with parenteral analgesic agents, and acetaminophen is given to control fever. Antiemetic medications, restriction of oral intake, and IV fluids are used to treat the GI symptoms.

Minimally Invasive Technologies

Radiofrequency ablation, cryoablation, or microwave ablation are minimally invasive technologies performed by urologists or interventional radiologists. They are used instead of surgery in select patients for many types of tumors, including renal cell carcinomas. In renal cell carcinomas these nephron-sparing procedures can be used for either small, localized renal tumors, if patients are poor surgical candidates and/or to preserve renal function. In these procedures, temperature extremes are used to kill tumor cells (Hines & Goldberg, 2018).

Pharmacologic Therapy

Depending on the stage of the tumor, partial or radical nephrectomy may be followed by treatment with immunotherapy. Standard chemotherapy has not improved survival rates and is only used for those patients in whom immunotherapy has not been successful (ACS, 2020). For stage IV clear cell renal cell carcinomas, treatment with biologic response modifiers such as interleukin 2 (IL-2) and interferon has largely been replaced by targeted therapies, antiangiogenic therapy, and checkpoint inhibitors (George & Jonasch, 2019).

Experimental approaches to stimulate the host immune recognition of tumor through autologous tumor cell immunotherapy are being actively pursued in patients with stage IV renal cell carcinomas (George & Jonasch, 2019).

Nursing Management

The patient with a renal tumor usually undergoes extensive diagnostic and therapeutic procedures. Treatments may include surgery, radiation therapy, and immunotherapy. After surgery, the patient usually has catheters and drains in place to maintain a patent urinary tract, to remove drainage, and to permit accurate measurement of urine output. Because of the location of the surgical incision, the patient's position during surgery, and the nature of the surgical procedure, pain and muscle soreness are common. Pharmacologic management may include immunotherapy agents. Therefore, patients are monitored for infection.

The patient requires frequent analgesia during the postoperative period and assistance with turning, coughing, the use of incentive spirometry, and deep breathing to prevent atelectasis and other pulmonary complications (see Chapter 19). The patient and family require assistance and support to cope with the

diagnosis and uncertain prognosis. See discussion later in this chapter of postoperative care of the patient undergoing kidney surgery and Chapter 12 for discussion of care of the patient with cancer.

Promoting Home, Community-Based, and Transitional Care

Educating Patients About Self-Care

The nurse educates the patient and family about how to inspect and care for the incision and to perform other general postoperative care including activity, lifting and driving restrictions, and pain management. Instructions are provided about when to notify the primary provider about problems (e.g., fever, respiratory difficulty, wound drainage, blood in the urine, pain or swelling of the legs).

The nurse encourages the patient to eat a healthy diet and to drink adequate liquids to avoid constipation and to maintain an adequate urine volume. Stool softeners, mild stimulants (e.g., senna), and polyethylene glycol may also be prescribed to avoid constipation. Education and emotional support are provided related to the diagnosis, treatment, and continuing care because many patients are concerned about the loss of the other kidney, the possible need for dialysis, or the recurrence of cancer.

Continuing and Transitional Care

Follow-up care is essential to detect any signs of metastases and to reassure the patient and family about the patient's status and well-being. The patient who has had surgery for renal carcinoma should have a yearly physical examination and chest x-ray, because late metastases are not uncommon (George & Jonasch, 2019). All subsequent symptoms should be evaluated with possible metastases in mind.

If follow-up immunotherapy is necessary, the patient and family are informed about the treatment plan or immunotherapy protocol, what to expect with each visit, and when to notify the primary provider. Evaluation of remaining renal function (creatinine clearance, BUN, and serum creatinine levels) may also be carried out periodically. A home health nurse may monitor the patient's physical status and psychological well-being and coordinate other indicated services and resources.

KIDNEY DISEASE

Kidney disease results when the kidneys cannot remove the body's metabolic wastes or perform their regulatory functions. The substances normally eliminated in the urine accumulate in the body fluids as a result of impaired

renal excretion, affecting endocrine and metabolic functions as well as resulting in fluid, electrolyte, and acid–base disturbances. Kidney disease is a systemic disease and a final common pathway of many different kidney and urinary tract diseases. The impact of kidney failure in the United States continues to increase due to the aging of the U.S. population and the increasing incidence of obesity and diabetes (USRDS, 2019).

Acute Kidney Injury

Acute kidney injury (AKI) is a rapid loss of renal function due to damage to the kidneys. Depending on the duration and severity of AKI, a wide range of potentially life-threatening metabolic complications can occur, including metabolic acidosis as well as fluid and electrolyte imbalances. Treatment is aimed at replacing renal function temporarily to minimize potentially lethal complications and reduce potential causes of increased kidney injury with the goal of minimizing long-term loss of renal function.

AKI is a problem seen in patients who are hospitalized and those in outpatient settings. A widely accepted criterion for AKI is a 50% or greater increase in serum creatinine above baseline (normal creatinine is less than 1 mg/dL) (The Acute Dialysis Quality Initiative, 2004). Urine volume may be normal, or changes may occur including nonoliguria (greater than 800 mL/day), **oliguria** (less than 400 mL/day or 0.5 mL/kg/h over 6 hours), or **anuria** (less than 50 mL/day) (Odom, 2017).

COVID-19 Considerations

The coronavirus disease 2019 (COVID-19) pandemic began in Wuhan, China, in late 2019. Since that time, several risks for both severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) infection and pathogenesis to COVID-19 have been identified (see Chapter 66, Chart 66-8). Findings from a retrospective, single-center study of 1392 patients hospitalized with COVID-19 in Wuhan, China, reported that 7% developed AKI during hospitalization (Cheng, Luo, Wang, et al., 2020). Factors associated with high risk of developing AKI included more severe disease, a high serum creatinine at baseline, lymphopenia, and elevated D-dimer level (Cheng et al., 2020). Patients who developed AKI were more likely to be admitted to an intensive care unit and had a higher mortality rate compared to patients who did not develop AKI. Of those patients who survived to be discharged from the hospital, 68% recovered from AKI (Cheng et al., 2020).

Pathophysiology

Although the pathogenesis of AKI and oliguria is not always known, many times there is a specific underlying cause. Some of the factors may be reversible if identified and treated promptly, before kidney function is impaired. This is true of the following conditions that reduce blood flow to the kidney and impair kidney function: hypovolemia; hypotension; reduced cardiac output and heart failure; obstruction of the kidney or lower urinary tract by tumor, blood clot, or kidney stone; and bilateral obstruction of the renal arteries or veins. If these conditions are treated and corrected before the kidneys are permanently damaged, the increased BUN and creatinine levels, oliguria, and other signs may be reversed.

Although renal stones are not a common cause of AKI, some recurrent types may increase the risk of AKI. Some hereditary stone diseases (see Chapter 49), primary struvite stones, and infection-related urolithiasis associated with anatomic and functional urinary tract anomalies and spinal cord injury may cause repeated bouts of obstruction as well as crystal-specific damage to tubular epithelial cells and interstitial renal cells (Odom, 2017).

Classifications of Acute Kidney Injury

The term acute kidney injury has replaced the term acute renal failure because it better describes this syndrome, in both those who require RRT and also in those patients who experience minor changes in renal function. Classification criteria for AKI include assessment of three grades of severity and two outcome-level classifications. This 5-point system is known as the RIFLE classification system. RIFLE stands for *risk, injury, failure, loss, and ESKD* (Bellomo et al., 2004). Risk, injury, and failure are considered grades of AKI severity, whereas loss and ESKD are considered outcomes of loss that require some form of RRT, at least temporarily (Bellomo et al., 2004). Table 48-2 lists the classification criteria for the RIFLE system for AKI (Bellomo et al., 2004). This classification system is used by health care professionals to identify kidney injury and improve patient outcomes. A diagnosis of AKI results in significantly longer hospital stays, has an increased mortality rate, and is a major risk factor for the development of CKD (Medel-Herrero, Mitchell, & Moyce, 2019).

Categories of Acute Kidney Injury

The major categories of AKI are prerenal (hypoperfusion of kidney), intrarenal (actual damage to kidney tissue), and postrenal (obstruction to urine flow). Prerenal AKI, which occurs in 60% to 70% of cases, is the result of impaired blood flow that leads to hypoperfusion of the kidney commonly caused by volume depletion (burns, hemorrhage, GI losses), hypotension (sepsis, shock), and obstruction of renal vessels, ultimately leading to a decrease in the GFR (Odom, 2017). Intrarenal or intrinsic AKI is the result of actual parenchymal damage to the glomeruli or kidney tubules. **Acute tubular necrosis (ATN)**, or

AKI in which there is damage to the kidney tubules, is the most common type of intrinsic AKI. Characteristics of ATN are intratubular obstruction, tubular back leak (abnormal reabsorption of filtrate and decreased urine flow through the tubule), vasoconstriction, and changes in glomerular permeability. These processes result in a decrease of GFR, progressive azotemia, and fluid and electrolyte imbalances. CKD, diabetes, heart failure, hypertension, and cirrhosis can contribute to ATN. Postrenal AKI usually results from obstruction distal to the kidney by conditions such as renal calculi, strictures, blood clots, benign prostatic hyperplasia, malignancies, and pregnancy. Pressure rises in the kidney tubules, and eventually the GFR decreases. Common causes of each type of AKI are further summarized in Chart 48-4.

TABLE 48-2 The RIFLE Classification for Acute Kidney Injury

Class	GFR Criteria	Urinary Output Criteria
R (Risk)	Increased serum creatinine 1.5 × baseline OR GFR decreased ≥25%	0.5 mL/kg/h for 6 hrs
I (Injury)	Increased serum creatinine 2 × baseline OR GFR decreased ≥50%	0.5 mL/kg/h for 12 hrs
F (Failure)	Increased serum creatinine 3 × baseline OR GFR decreased ≥75% OR Serum creatinine ≥354 mmol/L with an acute rise of at least 44 mmol/L	<0.3 mL/kg/h for 24 hrs OR Anuria for 12 hrs
L (Loss)	Persistent acute kidney injury = complete loss of kidney function >4 wks	
E (ESKD)	ESKD >3 mo	

ESKD, end-stage kidney disease; GFR, glomerular filtration rate.

Acute renal failure-definition, outcome measures, animal models, fluid therapy and information technology needs: the Second International Consensus Conference of the Acute Dialysis Quality Initiative (ADQI) Group. *Critical Care*, *8*, B204.

Phases of Acute Kidney Injury

There are four phases of AKI: initiation, oliguria, diuresis, and recovery.

- The initiation period begins with the initial insult and ends when oliguria develops.
- The oliguria period is accompanied by an increase in the serum concentration of substances usually excreted by the kidneys (urea, creatinine, uric acid, organic acids, phosphorus, and the intracellular

cations [potassium and magnesium]). The minimum amount of urine needed to rid the body of normal metabolic waste products is approximately 400 mL in 24 hours or 0.5 mL/kg/h over 6 hours. In this phase, uremic symptoms first appear and life-threatening conditions such as hyperkalemia develop.

- The diuresis period is marked by a gradual increase in urine output, which signals that glomerular filtration has started to recover. Laboratory values stabilize and eventually decrease. Although the volume of urinary output may reach normal or elevated levels, renal function may still be markedly abnormal, since the filtration of urea and creatinine has not yet commenced. Because uremic symptoms may still be present, the need for expert medical and nursing management continues. The patient must be observed closely for dehydration during this phase; if dehydration occurs, the uremic symptoms are likely to increase and an elevated serum BUN and creatinine will be noted.
- The recovery period signals the improvement of renal function and may take 3 to 12 months. Laboratory values return to the patient's normal level. Although a permanent 1% to 3% reduction in the GFR may occur, it is not clinically significant. However, in those patients with preexisting CKD, an episode of AKI may necessitate beginning CRRT.

Chart 48-4

Causes of Acute Kidney Injury

Prerenal Failure

- Volume depletion resulting from:
  - Gastrointestinal losses (vomiting, diarrhea, nasogastric suction)
  - Hemorrhage
  - Renal losses (diuretic agents, osmotic diuresis)
- Impaired cardiac efficiency resulting from:
  - Arrhythmias
  - Cardiogenic shock
  - Heart failure
  - Myocardial infarction
- Vasodilation resulting from:
  - Anaphylaxis
  - Antihypertensive medications or other medications that cause vasodilation
  - Sepsis

Intrarenal Failure

- Prolonged renal ischemia resulting from:
  - Hemoglobinuria (transfusion reaction, hemolytic anemia)
  - Pigment nephropathy (associated with the breakdown of blood cells containing pigments that in turn occlude kidney structures)
  - Rhabdomyolysis/myoglobinuria (trauma, crush injuries, burns)
- Nephrotoxic agents such as:
  - Aminoglycoside antibiotics (gentamicin, tobramycin)
  - Angiotensin-converting enzyme inhibitors
  - Heavy metals (lead, mercury)
  - Nonsteroidal anti-inflammatory drugs
  - Radiopaque contrast agents
  - Solvents and chemicals (ethylene glycol, carbon tetrachloride, arsenic)
- Infectious processes such as:
  - Acute glomerulonephritis
  - Acute pyelonephritis

Postrenal Failure

- Urinary tract obstruction, including:
  - Benign prostatic hyperplasia
  - Blood clots
  - Calculi (stones)
  - Strictures
  - Tumors

Adapted from Norris, T. L. (2019). *Porth's pathophysiology: Concepts of altered health states* (10th ed.). Philadelphia, PA: Wolters Kluwer.

Some patients have decreased renal function with increasing nitrogen retention but actually excrete normal amounts of urine (1 to 2 L/day). This is the nonoliguric form of kidney injury and occurs predominantly after exposure of the patient to **nephrotoxic** agents (any substance or medication that damages kidney tissue), burns and traumatic injury.

Clinical Manifestations

Almost every system of the body is affected with failure of the normal renal regulatory mechanisms. The patient may appear critically ill and lethargic. Central nervous system signs and symptoms include drowsiness, headache, muscle twitching, and seizures. Table 48-3 summarizes common clinical characteristics in all three categories of AKI.

TABLE 48-3 Comparing Clinical Characteristics of Acute Kidney Injury

Characteristics	Categories		
	Prerenal	Intrarenal	Postrenal
Etiology	Hypoperfusion due to shock, hypovolemia	Parenchymal damage	Obstruction
Blood urea nitrogen value	↑ (out of normal 20:1 proportion to creatinine)	↑	↑
Creatinine	↑	↑	↑
Urine output	↓	Varies, often ↓	Varies, may be ↓, or sudden anuria
Urine sodium	↓ to <20 mEq/L	↑ to >40 mEq/L	Varies, often ↓ to ≤20 mEq/L
Urinary sediment	Normal, few hyaline casts	Abnormal casts and debris	Usually normal
Urine osmolality	↑ to 500 mOsm	~350 mOsm, similar to serum	Varies, ↑ or equal to serum
Urine specific gravity	↑	Low normal	Varies

↑, increased; ↓, decreased.

Assessment and Diagnostic Findings

Assessment of the patient with AKI includes evaluation for changes in the urine, diagnostic tests that evaluate the kidney contour, and a variety of

laboratory values. See Chapter 47 for information about the normal characteristics of urine, diagnostic findings, and laboratory values in the renal system.

In AKI, urine output varies from scanty to a normal volume, hematuria may be present, and the urine has a low specific gravity (compared with a normal value of 1.010 to 1.025). One of the earliest manifestations of tubular damage is the inability to concentrate the urine (Odom, 2017). Patients with prerenal azotemia have a decreased amount of sodium in the urine (less than 20 mEq/L) and normal urinary sediment. Patients with intrarenal azotemia usually have increased urinary sodium levels greater than 40 mEq/L with **urinary casts** and other cellular debris.

Ultrasonography is a critical component of the evaluation of patients with kidney disease. A renal sonogram or a noncontrast CT scan may show evidence of anatomic changes.

The BUN level increases steadily at a rate that depends on the degree of catabolism (breakdown of protein), renal perfusion, and protein intake. Serum creatinine levels are useful in monitoring kidney function and disease progression and increase with glomerular damage.

With a decline in the GFR, oliguria, and anuria, patients are at high risk for hyperkalemia. Protein catabolism results in the release of cellular potassium into the body fluids, causing severe hyperkalemia (high serum potassium levels). Hyperkalemia may lead to cardiac arrhythmias, such as ventricular tachycardia and cardiac arrest. Sources of potassium include normal tissue catabolism, dietary intake, blood in the GI tract, or blood transfusion and other sources (e.g., IV infusions, potassium penicillin, and extracellular shift in response to metabolic acidosis).

Progressive metabolic acidosis occurs in kidney disease because patients cannot eliminate the daily metabolic load of acid-type substances produced by the normal metabolic processes. In addition, normal renal buffering mechanisms fail. This is reflected by decreased serum carbon dioxide (CO_2) and pH levels.

Blood phosphorus concentrations may increase; calcium levels may be low due to decreased absorption of calcium from the intestine and as a compensatory mechanism for the elevated blood phosphate levels. Anemia is another common laboratory finding in AKI, as a result of reduced erythropoietin production, uremic GI lesions, reduced RBC lifespan, and blood loss from the GI tract.

Prevention

AKI has a high mortality rate that ranges from 10% to 80%. Factors that influence mortality include severity of kidney injury, level and availability of medical care, requirements for RRT, increased age, increased number of comorbid conditions, and preexisting kidney and vascular diseases and

respiratory failure (Odom, 2017). Therefore, prevention of AKI is essential (see Chart 48-5).

A careful history is obtained to identify exposure to nephrotoxic agents or environmental toxins. The kidneys are susceptible to the adverse effects of medications because the metabolic by-products of most medications are excreted by the kidneys. Patients taking nephrotoxic medications (e.g., aminoglycosides, such as gentamicin and tobramycin, polymyxin B, amphotericin B, vancomycin, amikacin, cyclosporine, tacrolimus) should have drug levels monitored closely, since high serum levels will cause changes in renal function. Kidney function needs to be monitored prior to initiation of these medications and during therapy (Schira, 2017).

Chart 48-5

Preventing Acute Kidney Injury

- Continually assess renal function (urine output, laboratory values) when appropriate.
- Monitor central venous and arterial pressures and hourly urine output of patients who are critically ill to detect the onset of kidney dysfunction as early as possible.
- Pay special attention to wounds, burns, and other precursors of sepsis.
- Prevent and treat infections promptly. Infections can produce progressive kidney damage.
- Prevent and treat hypotensive shock promptly with blood and fluid replacement.
- Provide adequate hydration to patients at risk for dehydration, including:
  - Before, during, and after surgery
  - Patients undergoing intensive diagnostic studies requiring fluid restriction and contrast agents (e.g., barium enema, IV pyelograms), especially older patients who may have marginal renal reserve or CKD
  - Patients with neoplastic disorders or disorders of metabolism (e.g., gout) and those receiving chemotherapy with potential tumor lysis syndrome
  - Patients with skeletal muscle injuries (e.g., crush injuries, compartment syndrome)
  - Patients with heat-induced illnesses (e.g., heat stroke, heat exhaustion)
- To prevent infections from ascending in the urinary tract, give meticulous care to patients with indwelling catheters. Remove catheters as soon as possible.
- To prevent toxic drug effects, closely monitor dosage, duration of use, and blood levels of all medications metabolized or excreted by the kidneys.

Chronic use of analgesic agents, particularly NSAIDs, may cause **interstitial nephritis** (inflammation within the renal tissue) and papillary necrosis. Patients with heart failure or cirrhosis with ascites are at particular risk for NSAID-induced kidney disease. Increased age, preexisting kidney disease, diabetes, and the simultaneous administration of several nephrotoxic agents increase the risk of kidney damage (Schira, 2017; Schonder, 2017).

Contrast-induced acute kidney injury is a major cause of hospital-acquired AKI. However, this is potentially preventable in many, but not all, cases. Patients at high risk for the development of contrast-induced AKI are those with CKD and/or elevated creatinine due to dehydration. Those who need to undergo a coronary interventional procedure, which requires larger amounts of contrast media to be given, are at the greatest risk. Limiting the patient's exposure to

contrast agents and nephrotoxic medications will reduce the risk of contrasted-induced AKI. Prehydration with IV normal saline is considered the most effective method to prevent contrast-induced AKI. N-acetylcysteine administration is no longer recommended as a preventative measure (Nahar, 2017).

Gerontologic Considerations

About half of all patients who develop AKI during hospitalization are older than 60 years and 40% have diabetes (Pavkov, Harding, & Burrows, 2018). The etiology of AKI in older adults includes prerenal causes such as dehydration, intrarenal causes such as nephrotoxic agents (e.g., medications, contrast agents), and complications of major surgery (Hain, 2017). Suppression of thirst, enforced bed rest, lack of access to drinking water, and confusion all contribute to the older patient's failure to consume adequate fluids and may lead to dehydration, further compromising already decreased renal function.

AKI in older adults is also often seen in the community setting. Nurses in the ambulatory setting need to be aware of the risk to patients taking medications that could result in damage to the kidney either through reduced circulation or nephrotoxicity. Outpatient procedures that require fasting or a bowel preparation may cause dehydration and, therefore, patients undergoing such procedures need careful monitoring.

Medical Management

The kidneys have a remarkable ability to recover from insult. The objectives of treatment for AKI are to restore normal chemical balance and prevent complications until repair of renal tissue and restoration of renal function can occur. Management includes eliminating the underlying cause; maintaining fluid balance; avoiding fluid excesses; and, when indicated, providing RRT. Prerenal azotemia is treated by optimizing renal perfusion, whereas postrenal failure is treated by relieving the obstruction. Intrarenal or intrinsic azotemia is treated with supportive therapy, with removal of causative agents, aggressive management of pre- and postrenal failure, and avoidance of associated risk factors. Shock and infection, if present, are treated promptly (see Chapter 11). The patient who has had a crush injury, compartment syndrome, or heat-induced illness with subsequent myoglobinuria (myoglobin in the urine) is treated for rhabdomyolysis (Odom, 2017) (see Chapter 67).

Maintenance of fluid balance is based on daily body weight, serial measurements of central venous pressure, serum and urine concentrations, fluid intake and output, blood pressure, and the clinical status of the patient. The parenteral and oral intake and the output of urine, gastric drainage, stools, wound drainage, and perspiration are calculated and are used as the basis for

fluid replacement. The insensible fluid produced through the normal metabolic processes and lost through the skin and lungs is also considered in fluid management.

Fluid excesses can be detected by the clinical findings of dyspnea, tachycardia, and distended neck veins. The patient's lungs are auscultated for moist crackles. Because pulmonary edema may be caused by excessive administration of parenteral fluids, extreme caution must be used to prevent fluid overload. The development of generalized edema is assessed by examining the presacral and pretibial areas several times daily. Furosemide or bumetanide, both loop diuretics, may be prescribed to initiate diuresis, although there is no consensus regarding the use of loop diuretics in AKI (Odom, 2017).

Adequate renal blood flow in patients with prerenal causes of AKI may be restored by IV fluids or transfusions of blood products. If AKI is caused by hypovolemia secondary to hypoproteinemia, an infusion of albumin may be prescribed. Dialysis may be initiated to prevent complications of AKI, such as hyperkalemia, metabolic acidosis, pericarditis, and pulmonary edema. Dialysis corrects many biochemical abnormalities; allows for liberalization of fluid, protein, and sodium intake; diminishes bleeding tendencies; and promotes wound healing. **Hemodialysis (HD)** (a procedure that circulates the patient's blood through an artificial kidney [dialyzer] to remove waste products and excess fluid), **peritoneal dialysis (PD)**; a procedure that uses the patient's peritoneal membrane (the lining of the peritoneal cavity) as the semipermeable membrane to exchange fluid and solutes, or a variety of **continuous renal replacement therapy (CRRT)** (methods used to replace normal kidney function by circulating the patient's blood through a hemofilter) may be performed (Odom, 2017). These and other treatment modalities for patients with renal dysfunction are discussed later in this chapter.

Pharmacologic Therapy

Hyperkalemia is the most life-threatening of the fluid and electrolyte changes that occur in patients with kidney disorders. Therefore, the patient is monitored for hyperkalemia through serial serum electrolyte levels (potassium value greater than 5.0 mEq/L [5 mmol/L]), ECG changes (tall, tented, or peaked T waves), and changes in clinical status (see Chapter 10). Other symptoms of hyperkalemia include irritability, abdominal cramping, diarrhea, paresthesia, and generalized muscle weakness. Muscle weakness may present as slurred speech, difficulty breathing, paresthesia, and paralysis. As the potassium level increases, both cardiac and other muscular function declines, making this a medical emergency.

The elevated potassium levels may be reduced by administering cation-exchange resins such as sodium polystyrene sulfonate orally or by retention enema that works by exchanging sodium ions for potassium ions in the intestinal tract. The slow onset of action of more than 6 hours limits its use to

those patients without emergent hyperkalemia causing ECG changes. Sorbitol may be given in combination with sodium polystyrene sulfonate to induce a diarrhea-type effect (by inducing water loss in the GI tract). If a sodium polystyrene sulfonate retention enema is given (the colon is the major site of potassium exchange), a rectal catheter with a balloon may be used to facilitate retention if necessary (Schonder, 2017). Afterward, a cleansing enema may be prescribed to remove remaining medication as a precaution against fecal impaction.

If the patient is experiencing ECG changes, IV dextrose 50%, insulin, and calcium replacement may be given to shift potassium back into the cells. Since the medications are administered IV, they take effect quickly. The shift of potassium into the intracellular space is temporary, so arrangements for dialysis need to be made on an emergent basis. The capillary glucose level is monitored for hypoglycemia with insulin administration (Ross, Nissenson, & Daugirdas, 2015).

Many medications are eliminated through the kidneys; therefore, dosages must be reduced when a patient has AKI. Examples of commonly used agents that require adjustment are antibiotic medications (especially aminoglycosides), digoxin, phenytoin, ACE inhibitors, and magnesium-containing agents.

In patients with severe acidosis, the arterial blood gases and serum bicarbonate levels must be monitored because the patient may require sodium bicarbonate therapy or dialysis. If respiratory problems develop, appropriate ventilatory measures must be instituted. The elevated serum phosphorus level may be controlled with phosphate-binding agents (e.g., calcium or lanthanum carbonate) that help prevent a continuing rise in serum phosphorus levels by binding with the phosphate from food in the intestinal tract and eliminating it in the stool, thus preventing absorption (Schonder, 2017).

Nutritional Therapy

AKI causes severe nutritional imbalances (because nausea and vomiting contribute to inadequate dietary intake), impaired glucose use and protein synthesis, and increased tissue catabolism. The patient is weighed daily and loses 0.2 to 0.5 kg (0.5 to 1 lb) daily if the nitrogen balance is negative (i.e., caloric intake falls below caloric requirements). If the patient gains or does not lose weight or develops hypertension, fluid retention should be suspected.

Nutritional support is based on the underlying cause of AKI, the catabolic response, the type and frequency of RRT, comorbidities, and nutritional status. Replacement of dietary proteins is individualized to provide the maximum benefit and minimize uremic symptoms. Caloric requirements are met with high-carbohydrate meals, because carbohydrates have a protein-sparing effect (i.e., in a high-carbohydrate diet, protein is not used for meeting energy requirements but is “spared” for growth and tissue healing). Foods and fluids

containing sodium, potassium, or phosphorus (e.g., bananas, citrus fruits and juices, dairy foods) are restricted.

The oliguric phase of AKI may last 10 to 14 days and is followed by the diuretic phase, at which time urine output begins to increase, signaling the patient is in the recovery phase (Odom, 2017). Results of blood chemistry tests are used to determine the amounts of sodium, potassium, and water needed for replacement, along with assessment for over- or under hydration (daily weights). Following the diuretic phase, the patient is placed on a high-protein, high-calorie diet and is encouraged to resume activities gradually.

Nursing Management

The nurse has an important role in caring for the patient with AKI. The nurse monitors for complications, participates in emergency treatment of fluid and electrolyte imbalances, assesses the patient's progress and response to treatment, and provides physical and emotional support. In addition, the nurse keeps family members informed about the patient's condition, helps them understand the treatments, and provides psychological support. Although the development of AKI may be the most serious problem, the nurse continues to provide nursing care indicated for the primary disorder (e.g., burns, shock, trauma, obstruction of the urinary tract).

Monitoring Fluid and Electrolyte Balance

Because of the serious fluid and electrolyte imbalances that can occur with AKI, the nurse monitors the patient's serum electrolyte levels and physical indicators of these complications during all phases of the disorder. IV solutions must be carefully selected based on the patient's fluid and electrolyte status. The patient's cardiac function and musculoskeletal status are monitored closely for signs of hyperkalemia.

Quality and Safety Nursing Alert

Hyperkalemia is the most immediate life-threatening imbalance seen in AKI. Parenteral fluids, all oral intake, and all medications are screened carefully to ensure that sources of potassium are not inadvertently given or consumed.

The nurse monitors fluid status by paying careful attention to fluid intake (IV medications should be given in the smallest volume possible), urine output, apparent edema, distention of the jugular veins, alterations in heart sounds and breath sounds, and increasing difficulty in breathing. Accurate daily weights, as well as I&O records, are essential. Indicators of deteriorating fluid and electrolyte status are reported immediately to the primary provider, and

preparation is made for emergency treatment. Severe fluid and electrolyte disturbances may be treated with HD, PD, or CRRT.

Reducing Metabolic Rate

The nurse takes steps to reduce the patient's metabolic rate. Fever and infection, both of which increase the metabolic rate and catabolism, are prevented and treated promptly; blood, urine and wound cultures are ordered as indicated.

Promoting Pulmonary Function

Attention is given to pulmonary function, and the patient is assisted to turn, cough, and take deep breaths frequently to prevent atelectasis and respiratory tract infection. Drowsiness and lethargy may prevent the patient from moving and turning without encouragement and assistance.

Preventing Infection

Asepsis is essential with invasive lines and catheters to minimize the risk of infection and increased metabolism. An indwelling urinary catheter is avoided whenever possible due to the high risk of UTI associated with its use, but may be required to provide ongoing data required to accurately monitor fluid I&O.

Providing Skin Care

The skin may be dry or susceptible to breakdown as a result of edema; therefore, meticulous skin care is important. In addition, excoriation and itching of the skin may result from the deposit of irritating toxins in the patient's tissues. Bathing the patient with cool water, frequent turning, and keeping the skin clean and well moisturized and the fingernails trimmed to avoid scratching are often comforting and prevent skin breakdown.

Providing Psychosocial Support

The patient with AKI may require treatment with HD, PD, or CRRT. The length of time that these treatments are necessary varies with the cause and extent of damage to the kidneys. The patient and family need assistance, explanation, and support during this period. The purpose of the treatment is explained to the patient and family by the primary provider. However, high levels of anxiety and fear may necessitate repeated explanation and clarification by the nurse. The family members may initially be afraid to touch and talk to the patient during these procedures but should be encouraged and assisted to do so.

In an intensive care setting, many of the nurse's functions are devoted to the technical aspects of patient care; however, it is essential that the psychological needs and other concerns of the patient and family be addressed. Continued assessment of the patient for complications of AKI and precipitating causes is essential (Odom, 2017).

End-Stage Kidney Disease or Chronic Kidney Disease

When a patient has sustained enough kidney damage to require RRT on a permanent basis, the patient has moved into the fifth or final stage of CKD, also referred to as ESKD. In 2017, 86.9% of patients newly diagnosed with ESKD began RRT with HD, 10.1% started with PD, and 2.9% received a preemptive kidney transplant. A preemptive transplant is when a patient undergoes kidney transplantation from a living donor before dialysis is initiated. Of great concern is that 33% of patients diagnosed with ESKD had received little or no pre-ESKD nephrology care and 19.2% received no nephrology care prior to requiring RRT. As of December 31, 2017, 62.7% of all patients previously diagnosed with ESKD were receiving HD therapy, 7.1% were being treated with PD, and 29.9% had a functioning kidney transplant. Among patients being treated with HD, 98.0% used in-center HD (USRDS, 2019).

In July 2019, the President, the U.S. Department of Health and Human Services (HHS) Secretary, and the Administrator of the Centers for Medicare and Medicaid Services (CMS) issued an Executive Order, with the goal of improving the lives of Americans with ESKD by expanding treatment options and reducing health care costs. As part of this Executive Order, a mandatory payment model promotes moving patients from in-center to home dialysis (both PD and home HD) and increasing the number of patients receiving kidney transplants. There is much work and policy development that will need to be done to reach this goal by the projected date of 2025 (Kear, Bednarski, Smith, et al., 2019).

Pathophysiology

As renal function declines, the end products of protein metabolism (normally excreted in urine) accumulate in the blood. Uremia develops and adversely affects every system in the body. The greater the buildup of waste products, the more pronounced the symptoms.

The rate of decline in renal function and progression of ESKD is related to the underlying disorder, the urinary excretion of protein, and the presence of hypertension. The disease tends to progress more rapidly in patients who excrete significant amounts of protein or have elevated blood pressure than in those without these conditions (Mahaffey, 2017).

Clinical Manifestations

Because virtually every body system is affected in ESKD, patients exhibit a number of signs and symptoms. The severity of these signs and symptoms depends in part on the degree of renal impairment, other underlying conditions,

and the patient's age. Cardiovascular disease is the predominant cause of death in patients with ESKD (Subbiah et al., 2016). Peripheral neuropathy, a disorder of the peripheral nervous system, is present in some patients, especially those with diabetes. Patients complain of severe pain and discomfort. Restless leg syndrome and burning feet can occur in the early stage of uremic peripheral neuropathy. The precise mechanisms for many of these systemic signs and symptoms have not been identified. However, it is generally thought that the accumulation of uremic waste products is the probable cause. Chart 48-6 summarizes the systemic signs and symptoms.

Assessment and Diagnostic Findings

Glomerular Filtration Rate

As the GFR decreases (due to nonfunctioning glomeruli), the creatinine clearance decreases, whereas the serum creatinine and BUN levels increase. Serum creatinine is a more sensitive indicator of renal function than BUN. The BUN is affected not only by kidney disease but also by protein intake in the diet, catabolism (tissue and RBC breakdown), parenteral nutrition, and medications such as corticosteroids.

Sodium and Water Retention

The kidney cannot concentrate or dilute the urine normally in ESKD. Appropriate responses by the kidney to changes in the daily intake of water and electrolytes, therefore, do not occur. Some patients retain sodium and water, increasing the risk for edema, heart failure, and hypertension. Hypertension may also result from activation of the renin–angiotensin–aldosterone axis and the concomitant increased aldosterone secretion. Other patients have a tendency to lose sodium and run the risk of developing hypotension and hypovolemia. Vomiting and diarrhea may cause water depletion, which may worsen the uremic state.

Acidosis

Metabolic acidosis occurs in ESKD because the kidneys are unable to excrete increased loads of acid. Decreased acid secretion results from the inability of the kidney tubules to excrete ammonia (NH_3^-) and to reabsorb sodium bicarbonate (HCO_3^-). There is also decreased excretion of phosphorus and other organic acids.

Anemia

Anemia develops as a result of inadequate erythropoietin production, the shortened lifespan of RBCs, nutritional deficiencies, and the patient's tendency to bleed, particularly from the GI tract. Erythropoietin, a substance normally

produced by the kidneys, stimulates bone marrow to produce RBCs. In ESKD, erythropoietin production decreases and profound anemia results, producing fatigue, angina, and shortness of breath (Evans, 2017).

Calcium and Phosphorus Imbalance

Another abnormality seen in ESKD is a disorder in calcium and phosphorus metabolism. Serum calcium and phosphate levels have a reciprocal relationship in the body: As one increases, the other decreases. With a decrease in filtration through the glomerulus of the kidney, there is an increase in the serum phosphorus level and a reciprocal or corresponding decrease in the serum calcium level. The decreased serum calcium level causes increased secretion of parathormone from the parathyroid glands. However, in kidney disease, the body cannot respond normally to the increased secretion of parathormone. As a result, calcium leaves the bone, often producing bone changes and bone disease as well as calcification of major blood vessels in the body. In addition, the active metabolite of vitamin D (1,25-dihydroxycholecalciferol) normally manufactured by the kidney decreases as kidney disease progresses (Brooks, 2017). Uremic bone disease, often called renal osteodystrophy, develops from the complex changes in calcium, phosphate, and parathormone balance. There is also evidence of calcification of blood vessels.

Chart 48-6  **ASSESSMENT**

Assessing for End-Stage Kidney Disease

Be alert to the following signs and symptoms:

Neurologic

- Asterixis
- Behavior changes
- Burning of soles of feet
- Confusion
- Disorientation
- Inability to concentrate
- Restlessness of legs
- Seizures
- Tremors
- Weakness and fatigue

Integumentary

- Coarse, thinning hair
- Dry, flaky skin
- Ecchymosis
- Gray-bronze skin color
- Pruritus
- Purpura
- Thin, brittle nails

Cardiovascular

- Engorged neck veins
- Hyperkalemia
- Hyperlipidemia
- Hypertension
- Pericardial effusion
- Pericardial friction rub
- Pericardial tamponade
- Pericarditis
- Periorbital edema
- Pitting edema (feet, hands, sacrum)

Pulmonary

- Crackles
- Depressed cough reflex
- Kussmaul-type respirations
- Pleuritic pain
- Shortness of breath

- Tachypnea
- Thick, tenacious sputum
- Uremic pneumonitis

Gastrointestinal

- Ammonia odor to breath ("uremic fetor")
- Anorexia, nausea, and vomiting
- Bleeding from gastrointestinal tract
- Constipation or diarrhea
- Hiccups
- Metallic taste
- Mouth ulcerations and bleeding

Hematologic

- Anemia
- Thrombocytopenia

Reproductive

- Amenorrhea
- Decreased libido
- Infertility
- Testicular atrophy

Musculoskeletal

- Bone fractures
- Bone pain
- Foot drop
- Loss of muscle strength
- Muscle cramps
- Renal osteodystrophy

Adapted from Weber, J. R., & Kelley, J. H. (2018). *Health assessment in nursing* (6th ed.). Philadelphia, PA: Wolters Kluwer.

Complications

There are a number of potential complications of ESKD that necessitate a collaborative approach to care. These include the following:

- Anemia due to decreased erythropoietin production, decreased RBC lifespan, bleeding in the GI tract from irritating toxins and ulcer formation, and blood loss in the dialysis circuit and dialyzer after HD has been completed

- Bone disease and metastatic and vascular calcifications due to retention of phosphorus, low serum calcium levels, and abnormal vitamin D metabolism
- Hyperkalemia due to decreased excretion, metabolic acidosis, catabolism, and excessive potassium intake from diet, medications, or IV solutions
- Hypertension due to sodium and water retention and malfunction of the renin–angiotensin–aldosterone system
- Pericarditis, pericardial effusion, and pericardial tamponade due to retention of uremic waste products and inadequate dialysis

Medical Management

The goal of management is to maintain kidney function and homeostasis for as long as possible. All factors that contribute to ESKD and all factors that are reversible (e.g., obstruction) are identified and treated. Management is accomplished primarily with medications and diet therapy, although dialysis may also be needed to decrease the level of uremic waste products in the blood and to control electrolyte balance. The close collaboration of a renal dietitian is essential in dietary therapy.

Pharmacologic Therapy

Complications can be prevented or delayed with the appropriate medication. Phosphate-binding agents, calcium and vitamin D supplements, antihypertensive and cardiac medications, as well as recombinant human erythropoietin are frequently prescribed (Parikh et al., 2019).

Calcium and Phosphorus Binders

Hyperphosphatemia and hypocalcemia are treated with medications that bind dietary phosphorus in the GI tract. Binders such as calcium carbonate or calcium acetate are prescribed, but there is a risk of hypercalcemia. If calcium is high or the calcium–phosphorus product exceeds 55 mg/dL, a polymeric phosphate binder such as sevelamer carbonate may be prescribed (Schonder, 2017). This medication binds dietary phosphorus in the intestinal tract; one to four tablets are given with the first bite of food to be effective.

Antihypertensive and Cardiovascular Agents

Hypertension is managed by intravascular volume control and a variety of antihypertensive agents (Schonder, 2017). Heart failure and pulmonary edema may also require treatment with fluid restriction, low-sodium diets, diuretic agents, inotropic agents, and dialysis. The metabolic acidosis of ESKD usually produces no symptoms and requires no treatment. However, sodium bicarbonate

supplements or dialysis may be needed to correct the acidosis if it causes symptoms.

Erythropoietin

Anemia associated with ESKD is treated with erythrocyte-stimulating agents (recombinant human erythropoietin). Patients with anemia present with nonspecific symptoms, such as malaise, general fatigability, and decreased activity tolerance. Erythrocyte stimulation therapy is initiated to achieve a target hemoglobin of 10 to 11 g/dL, which generally alleviates many of the symptoms of anemia without causing an increased risk of death and cardiovascular complications (Evans, 2017; Schonder, 2017).

Recombinant human erythropoietin may be administered IV or subcutaneously once or three times a week in ESKD. It will take 2 to 6 weeks for the hemoglobin to increase. Therefore, the medication is not indicated for patients who need immediate correction of severe anemia. Adverse effects seen with erythropoietin therapy include hypertension (especially during early stages of treatment), increased clotting of vascular access sites, seizures, cardiovascular events, and depletion of body iron stores (Evans, 2017; Schonder, 2017).

Management involves adjustment of heparin to prevent clotting of the lines during HD treatments and monitoring of hemoglobin and hematocrit, serum iron and transferrin levels. Prior to beginning therapy, iron studies are indicated and if iron deficiency is noted, a course of IV iron is prescribed since adequate stores of iron are needed for an adequate response. In addition, vitamin deficiencies are ruled out including folate or vitamin B_{12}. Common iron supplements include iron sucrose and ferric gluconate (Evans, 2017).

In addition, the patient's blood pressure and serum potassium level are monitored to detect hypertension and increasing serum potassium levels, which may occur with therapy and the increasing RBC mass. Recombinant erythropoietin therapy should be used cautiously in patients with uncontrolled hypertension (Schonder, 2017). The occurrence of hypertension requires initiation or adjustment of the patient's antihypertensive therapy.

Patients who have received erythropoietin therapy have reported decreased levels of fatigue, increased feelings of well-being, better tolerance of dialysis, higher-energy levels, and improved exercise tolerance (Evans, 2017). In addition, this therapy has decreased the need for transfusion and its associated risks, including bloodborne infectious disease, antibody formation, and iron overload (Evans, 2017).

Nutritional Therapy

A referral to a renal dietitian is essential. Dietary intervention is necessary with deterioration of renal function and includes careful regulation of protein intake, fluid intake to balance fluid losses, and restriction of potassium and sodium. At

the same time, adequate caloric intake and vitamin supplementation must be ensured. Patients on dialysis need a higher intake of protein than healthy adults and current protein recommendations for stable patients on HD is 1.2 g/kg/day and PD is 1.2 to 1.3 g/kg/day (National Kidney Foundation Kidney Disease Outcomes Quality Initiative [NKF KDOQI], 2000). The allowed protein must be of high-biologic value (eggs, meats, fish). High–biologic-value proteins are those that are complete proteins and supply the essential amino acids necessary for growth and cell repair.

Usually, the fluid allowance per day for patients who receive in-center HD who are anuric is about 1000 mL daily. For those who produce urine, recommendations are individualized based on the patient's 24-hour urinary volume. This is done in order to limit interdialytic weight gains to less than 4% of estimated dry weight (Gonyea, 2017). Adequate calories are supplied by carbohydrates, protein, and fat to prevent wasting. In addition, the patient on dialysis loses water-soluble vitamins during the dialysis treatment, so an oral vitamin B and C supplement is prescribed to be taken after dialysis.

Hyperkalemia is usually prevented by ensuring adequate dialysis treatments with potassium removal and careful restriction of diet, medications, and fluids for their potassium content.

Dialysis

The patient with increasing symptoms of kidney disease is referred to a dialysis and transplantation center early in the course of progressive kidney disease. Dialysis is usually initiated when the patient cannot maintain a reasonable quality of life with conservative treatment.

Nursing Management

The patient with ESKD requires astute nursing care to avoid the complications of reduced renal function and the stresses and anxieties of dealing with a life-threatening illness.

Nursing care is directed toward assessing fluid status and identifying potential sources of imbalance, working with a renal dietitian to implement a dietary program to ensure proper nutritional intake within the limits of the treatment regimen, and engaging the patient by encouraging increased self-care and greater independence. It is extremely important to provide explanations and information to the patient and family concerning ESKD, treatment options, and potential complications. A great deal of emotional support is needed by the patient and family because of the numerous changes experienced. A social worker is also a vital part of the interprofessional care at the dialysis center. Specific interventions, along with rationale and evaluation criteria, are presented in more detail in the plan of nursing care for the patient with ESKD (see Chart 48-7).

Chart 48-7  PLAN OF NURSING CARE

The Patient with End-Stage Kidney Disease

NURSING DIAGNOSIS: Hypervolaemia associated with decreased urine output, dietary excesses, and retention of sodium and water
GOAL: Maintenance of ideal body weight without excess fluid

Nursing Interventions	Rationale	Expected Outcomes
1. Assess fluid status: a. Daily weight b. Intake and output balance c. Skin turgor and presence of edema d. Distention of neck veins e. Blood pressure, pulse rate, and rhythm f. Respiratory rate and effort 2. Limit fluid intake to prescribed volume. 3. Identify potential sources of fluid: a. Medications and fluids used to take or administer medications: oral and IV b. Foods 4. Explain to patient and family the rationale for fluid restriction. 5. Assist patient to cope with the discomforts resulting from fluid restriction. 6. Provide or encourage frequent oral hygiene.	1. Assessment provides baseline and ongoing database for monitoring changes and evaluating interventions. 2. Fluid restriction will be determined on basis of weight, urine output, and response to therapy. 3. Unrecognized sources of excess fluids may be identified. 4. Understanding promotes patient and family cooperation with fluid restriction. 5. Increasing patient comfort promotes adherence to dietary restrictions. 6. Oral hygiene minimizes dryness of oral mucous membranes.	• Demonstrates no rapid weight changes • Maintains dietary and fluid restrictions • Exhibits normal skin turgor without edema • Exhibits normal vital signs • Exhibits no neck vein distention • Reports no difficulty breathing or shortness of breath • Performs oral hygiene frequently • Reports decreased thirst • Reports decreased dryness of oral mucous membranes

NURSING DIAGNOSIS: Impaired nutritional intake associated with anorexia, nausea, vomiting, dietary restrictions, and altered oral mucous membranes
GOAL: Maintenance of adequate nutritional intake

Nursing Interventions	Rationale	Expected Outcomes
1. Consult with renal dietitian for recommendations regarding appropriate diet: potassium, phosphorus, sodium restrictions, and protein requirements 2. Assess nutritional status: a. Weight changes b. Laboratory values (serum electrolyte, blood urea nitrogen [BUN], creatinine, protein, transferrin, and iron levels) (see Appendix A on thePoint) 3. Assess patient's nutritional dietary patterns: a. Diet history b. Food preferences c. Calorie counts 4. Assess for factors contributing to altered nutritional intake: a. Anorexia, nausea, or vomiting b. Diet unpalatable to patient c. Depression d. Lack of understanding of dietary restrictions e. Stomatitis 5. Provide patient's food preferences within dietary restrictions.	1. Involve multidisciplinary team in patient management. 2. Baseline data allow for monitoring of changes and evaluating effectiveness of interventions. 3. Past and present dietary patterns are considered in planning meals. 4. Information about other factors that may be altered or eliminated to promote adequate dietary intake is provided. 5. Increased dietary intake is encouraged. 6. Complete proteins are provided for positive nitrogen balance needed for growth and healing. 7. Reduces source of restricted foods and proteins and provides calories for energy, sparing protein for tissue growth and healing. 8. Ingestion of medications just before meals may produce anorexia	• Consumes protein of high-biologic value • Chooses foods within dietary restrictions that are appealing • Consumes high-calorie foods within dietary restrictions • Explains in own words rationale for dietary restrictions and relationship to urea and creatinine levels • Takes medications on schedule that does not produce anorexia or feeling of fullness • Consults written lists of acceptable foods • Reports increased appetite at meals

6. Promote intake of high–biologic-value protein foods: eggs, fish, meats.
7. Encourage high-calorie, low-phosphorus, low-sodium, and low-potassium snacks between meals.
8. Alter schedule of medications so that they are not given immediately before meals (except for phosphate binders which are given with the first bite of food).
9. Explain rationale for dietary restrictions and relationship to kidney disease and increased urea and serum creatinine levels.
10. Provide written lists of foods allowed and suggestions for improving their taste without the use of sodium or potassium.
11. Provide pleasant surroundings at mealtimes.
12. Weigh patient daily.
13. Assess for evidence of inadequate protein intake:
    a. Edema formation
    b. Delayed wound healing
    c. Decreased serum albumin levels

and feeling of fullness.
9. Promotes patient understanding of relationships between diet and urea and creatinine levels to kidney disease.
10. Lists provide a positive approach to dietary restrictions and a reference for patient and family to use when at home.
11. Unpleasant factors that contribute to patient's anorexia are eliminated.
12. Allows monitoring of fluid and nutritional status.
13. Inadequate protein intake can lead to decreased albumin and other proteins, edema formation, and delay in wound healing.

- Exhibits no rapid increases or decreases in weight
- Demonstrates normal skin turgor without edema; wound healing and acceptable plasma albumin levels

NURSING DIAGNOSIS: Lack of knowledge regarding condition and treatment

GOAL: Increased knowledge about condition and related treatment

Nursing Interventions	Rationale	Expected Outcomes
1. Assess understanding of cause of kidney disease, consequences of kidney disease, and its treatment: a. Cause of patient's kidney disease b. Meaning of kidney disease c. Understanding of renal function d. Relationship of fluid and dietary restrictions to kidney disease e. Rationale for treatment (HD, PD, transplantation) 2. Provide explanation of renal function and consequences of kidney disease at patient's level of understanding and guided by patient's readiness to learn. 3. Assist patient to identify ways to incorporate changes related to illness and its treatment into lifestyle. 4. Provide oral and written information as appropriate about: a. Renal function and failure b. Fluid and dietary restrictions c. Medications d. Reportable problems, signs,	1. Provides baseline for further explanations and education. 2. Patient can learn about kidney disease and treatment as they become ready to understand and accept the diagnosis and consequences. 3. Patient can see that their life does not have to revolve around the disease. 4. Provides patient with information that can be used for further clarification at home.	• Verbalizes relationship of cause of kidney disease to consequences • Explains fluid and dietary restrictions as they relate to failure of kidney's regulatory functions • States in own words relationship of kidney disease and need for treatment • Asks questions about treatment options, indicating readiness to learn • Verbalizes plans to continue as normal a life as possible • Uses written information and instructions to clarify questions and seek

and symptoms e. Follow-up schedule f. Community resources g. Treatment options		additional information

NURSING DIAGNOSIS: Activity intolerance associated with fatigue, anemia, retention of waste products, and dialysis procedure
GOAL: Participation in activity within tolerance

Nursing Interventions	Rationale	Expected Outcomes
1. Assess factors contributing to activity intolerance: a. Fatigue b. Anemia c. Fluid and electrolyte imbalances d. Retention of waste products e. Depression 2. Promote independence in self-care activities as tolerated; assist if fatigued. 3. Encourage alternating activity with rest. 4. Encourage patient to rest after dialysis treatments.	1. Indicates factors contributing to severity of fatigue. 2. Promotes improved self-esteem. 3. Promotes activity and exercise within limits and adequate rest. 4. Adequate rest is encouraged after dialysis treatments, which are exhausting to many patients.	• Participates in increasing levels of activity and exercise • Reports increased sense of well-being • Alternates rest and activity • Participates in selected self-care activities

NURSING DIAGNOSIS: Risk for situational low self-esteem associated with dependency, role changes, change in body image, and change in sexual function
GOAL: Improved self-esteem

Nursing Interventions	Rationale	Expected Outcomes
1. Assess patient's and family's responses and reactions to illness and treatment. 2. Assess relationship of patient and significant family members.	1. Provides data about problems encountered by patient and family in coping with changes in life. 2. Identifies strengths and supports of patient and family.	• Identifies previously used coping styles that have been effective and those no longer possible due to disease and treatment

3. Assess usual coping patterns of patient and family members. 4. Encourage open discussion of concerns about changes produced by disease and treatment: a. Role changes b. Changes in lifestyle c. Changes in occupation d. Sexual changes e. Dependence on health care team 5. Explore alternative ways of sexual expression other than penile-vaginal intercourse. 6. Discuss role of giving and receiving love, warmth, and affection. 7. Consult with medical social worker (MSW), psychiatry for unresolved problems	3. Coping patterns that may have been effective in past may be harmful in view of restrictions imposed by disease and treatment. 4. Encourages patient to identify concerns and steps necessary to deal with them. 5. Alternative forms of sexual expression may be acceptable. 6. Sexuality means different things to different people, depending on stage of maturity. 7. Collaborate with interprofessional team for unresolved patient care issues.	(alcohol or drug use; extreme physical exertion) • Patient and family identify and verbalize feelings and reactions to disease and necessary changes in their lives • Seeks professional counseling, if necessary, to cope with changes resulting from kidney disease • Reports satisfaction with method of sexual expression

COLLABORATIVE PROBLEMS: Hyperkalemia; pericarditis, pericardial effusion, and pericardial tamponade; hypertension; anemia; bone disease and metastatic calcifications

GOAL: Absence of complications

Nursing Interventions	Rationale	Expected Outcomes
Hyperkalemia		
1. Monitor serum potassium levels.	1. Hyperkalemia causes potentially	• Has normal potassium level

Notify primary provider if level is at or approaching >5.5 mEq/L, and prepare to treat hyperkalemia. 2. Assess patient for muscle weakness, diarrhea, electrocardiographic (ECG) changes (tall-tented T waves and widened QRS).	life-threatening changes in the body. 2. Cardiovascular signs and symptoms are characteristic of hyperkalemia.	Experiences no • muscle weakness or diarrhea • Exhibits normal ECG pattern • Vital signs are within normal limits
Pericarditis, Pericardial Effusion, and Pericardial Tamponade		
1. Assess patient for fever, chest pain, and a pericardial friction rub (signs of pericarditis); if present, notify primary provider. 2. If patient has pericarditis, assess for the following every 4 hours: a. Paradoxical pulse, >10 mm Hg b. Extreme hypotension c. Weak or absent peripheral pulses d. Altered level of consciousness e. Jugular venous distention 3. Prepare patient for echocardiogram to aid in diagnosis of pericardial effusion and cardiac tamponade.	1. Patients with chronic kidney disease may develop pericarditis due to uremia; fever, chest pain, and a pericardial friction rub are classic signs. 2. Pericardial effusion is a common sequela of pericarditis. Signs of an effusion include a paradoxical pulse (>10 mm Hg drop in blood pressure during inspiration) and signs of shock due to compression of the heart by a large effusion. Cardiac tamponade, which may be fatal, exists when the patient is severely compromised hemodynamically. 3. Echocardiogram is useful in visualizing pericardial effusions and cardiac tamponade.	• Has strong and equal peripheral pulses • Absence of a paradoxical pulse • Absence of pericardial effusion or tamponade on cardiac ultrasound • Has normal heart sounds

4. If cardiac tamponade develops, prepare patient for emergency pericardiocentesis.	4. Cardiac tamponade is a life-threatening condition, with a high mortality rate. Immediate drainage of fluid from the pericardial space via a pericardial window procedure is essential.	
Hypertension		
1. Monitor and record blood pressure as indicated. 2. Administer antihypertensive medications as prescribed. 3. Encourage adherence to dietary and fluid restriction therapy. 4. Instruct patient to report signs of fluid overload, vision changes, headaches, edema, or seizures.	1. Provides objective data for monitoring. Elevated levels may indicate nonadherence to the treatment regimen. 2. Antihypertensive medications play a key role in treatment of hypertension associated with chronic kidney disease. 3. Adherence to diet and fluid restrictions and dialysis schedule prevents excess fluid and sodium accumulation. 4. These are indications of inadequate control of hypertension and the need to alter therapy.	• Blood pressure and weight within normal limits • Reports no headaches, visual problems, or seizures • Edema is absent • Demonstrates adherence to dietary and fluid restrictions
Anemia		
1. Monitor red blood cell (RBC) count and hemoglobin	1. Provides assessment of degree of anemia.	• Patient has a normal skin color without pallor

and hematocrit levels as indicated. 2. Administer medications as prescribed, including iron and folic acid supplements, an erythrocyte-stimulating agent, and multivitamins. 3. Avoid drawing unnecessary blood specimens. 4. Educate patient to prevent bleeding: Avoid vigorous nose blowing and contact sports, and use a soft toothbrush. 5. Administer blood component therapy as indicated.	2. RBCs need iron, folic acid, and vitamins to be produced. An erythrocyte-stimulating agent stimulates the bone marrow to produce RBCs. 3. Anemia is worsened by drawing numerous specimens. 4. Bleeding from anywhere in the body worsens anemia. 5. Blood component therapy may be needed if the patient has symptoms.	• Exhibits hemoglobin levels within acceptable limits • Experiences no bleeding from any site
Bone Disease and Metastatic Calcifications		
1. Administer the following medications as prescribed: phosphate binders, calcium supplements, vitamin D supplements, calcimimetics. 2. Monitor serum laboratory values as indicated (calcium, phosphorus, ionized parathyroid [iPTH] hormone), and report abnormal findings to primary provider.	1. Chronic kidney disease causes numerous physiologic changes affecting calcium, phosphorus, and vitamin D metabolism. 2. Hyperphosphatemia, hypocalcemia, and hyperparathyroidism are common in chronic kidney disease. 3. Bone demineralization increases with immobility,	• Takes phosphate binders with the first bite of food. • Exhibits serum calcium, phosphorus, and iPTH levels within acceptable ranges • Exhibits no symptoms of hypocalcemia • Has no bone demineralization on bone scan • Discusses importance of

3. Assist patient with an exercise program. 4. Consult with renal dietitian	hyperphosphatemia, hyperparathyroidism. 4. Involve interprofessional team in patient management.	maintaining activity level and exercise program

Promoting Home, Community-Based, and Transitional Care

Educating Patients About Self-Care

The nurse plays an important role in educating the patient with ESKD. Because of the extensive education needed, the home health nurse, dialysis nurse, and nurses in the hospital and outpatient settings, as well as a renal dietitian, all provide ongoing education and reinforcement while monitoring the patient's progress and adherence to the treatment regimen. The patient is instructed to check the vascular access for patency and to use appropriate precautions, such as avoiding venipuncture and blood pressure measurements on the arm with the access device. In addition, the patient and family need to know what problems to report to the primary provider. These include the following:

- Worsening signs and symptoms of kidney disease (nausea, vomiting, change in usual urine output, metallic taste in the mouth, ammonia odor on breath)
- Signs and symptoms of hyperkalemia (muscle weakness, diarrhea, abdominal cramps)
- Signs and symptoms of access problems (clotted fistula or graft, infection)

Signs and symptoms of decreasing renal function, in addition to increasing BUN and serum creatinine levels, may indicate a need to alter the dialysis prescription. The dialysis nurses also provide ongoing education and support at each treatment visit.

Continuing and Transitional Care

The importance of follow-up examinations and treatment is stressed with the patient and family because of changing physical status, renal function, and dialysis requirements. Referral for home care provides the home health nurse with the opportunity to assess the patient's environment, emotional status, and the coping strategies used by the patient and family to deal with the changes in family roles often associated with chronic illness.

The home health nurse also assesses the patient for further deterioration of renal function and signs and symptoms of complications resulting from the primary kidney disorder, the resulting kidney disease, and effects of treatment

strategies (e.g., dialysis, medications, dietary restrictions). Patients need education and reinforcement of the dietary restrictions required, including fluid, sodium, potassium, and phosphorus restriction. Reminders about the need for health promotion activities and health screening are an important part of nursing care for the patient with kidney disease.

Gerontologic Considerations

Diabetes, hypertension, chronic glomerulonephritis, interstitial nephritis, and urinary tract obstruction are among the causes for ESKD in older adults. The fastest growing group of patients with CKD is older adults who also have more comorbidities (Brooks, 2017). The signs and symptoms of kidney disease in older adults are often nonspecific. The occurrence of symptoms of other disorders (heart failure, dementia) can mask the symptoms of kidney disease and delay or prevent diagnosis and treatment (Hain, 2017).

HD and PD are used effectively in treating older patients with ESKD. Initiation of dialysis among older adults has increased in the past decade as baby boomers have come of age. Implementation of palliative care has also increased among patients who choose not to start dialysis or who decide to stop dialysis. Although there is no specific age limitation for kidney transplantation, concomitant disorders (e.g., coronary artery disease, peripheral vascular disease) have made it a less common treatment for older adults. However, in the United States, when adults age 60 and older who have significant comorbidities are ruled out (i.e., not considered to be suitable) as transplant candidates, those who do receive a kidney transplant survive longer than patients on dialysis and those who remain on the transplant waiting list (Bunnapradist, Abdalla, & Reddy, 2017).

Some older patients elect not to undergo dialysis or transplantation. Conservative management and palliative care, also known as supportive care, including nutritional therapy, fluid control, and medications such as phosphate binders, may be considered in patients who are not suitable for or elect not to have dialysis or transplantation (Molzahn & Schick-Makaroff, 2017). Palliative care for the patient with ESKD focuses on relieving suffering, promoting health-related quality of life, and facilitating dignity at the end-of-life (see Chapter 13).

RENAL REPLACEMENT THERAPY (RRT)

The use of RRT becomes necessary when the kidneys can no longer remove wastes, maintain electrolytes, and regulate fluid balance. This can occur rapidly or over a long period of time, and the need for replacement therapy can be acute

(short term) or chronic (long term). RRT includes the various types of dialysis and kidney transplantation.

Dialysis

Types of dialysis include HD, CRRT, and PD. Acute or urgent dialysis is indicated when there is a high and increasing level of serum potassium, fluid overload, or impending pulmonary edema, increasing acidosis, pericarditis, and advanced uremia. It may also be used to remove medications or toxins (poisoning or medication overdose) from the blood or for edema or hypertension that does not respond to other treatment, and hyperkalemia.

Chronic or maintenance dialysis is indicated in advanced CKD and ESKD in the following instances: the presence of uremic signs and symptoms affecting all body systems (nausea and vomiting, severe anorexia, increasing lethargy, mental confusion), hyperkalemia, fluid overload not responsive to diuretics and fluid restriction, and a general lack of well-being. An urgent indication for dialysis in patients with kidney disease is pericardial friction rub, which is indicative of uremic pericarditis.

The decision to initiate dialysis should be reached only after thoughtful discussion among the patient, family, primary provider, and other health care team members. The nurse can assist the patient and family by answering their questions, clarifying the information provided, and supporting their decision.

Successful kidney transplantation eliminates the need for dialysis. Not only is the quality of life much improved in patients with ESKD who undergo transplantation, but physiologic function is improved as well. Patients who undergo kidney transplantation from living donors before dialysis is initiated (preemptive transplant) generally have longer survival of the transplanted kidney than patients who receive transplantation after dialysis treatment is initiated (Bunnapradist, Abdalla, & Reddy, 2017).

Hemodialysis (HD)

HD is used for patients who are acutely ill and require short-term dialysis for days to weeks until kidney function resumes, as in patients with AKI, and for patients with advanced CKD and ESKD who require long-term or permanent RRT. HD prevents death but does not cure kidney disease and does not compensate for the loss of endocrine or metabolic activities of the kidneys. Approximately 62.7% of patients requiring long-term RRT are on chronic HD (USRDS, 2019). Most patients receive intermittent HD that involves treatments three times a week with an average treatment duration of 3 to 4 hours in an outpatient setting. HD can also be performed at home by the patient and a caregiver. See later discussion on home HD.

The objectives of HD are to extract toxic nitrogenous substances from the blood and to remove excess fluid. A **dialyzer** (also referred to as an artificial kidney) is a synthetic semipermeable membrane through which blood is filtered to remove uremic toxins and a desired amount of fluid. In HD, the blood, laden with toxins and nitrogenous wastes, is diverted from the patient to a machine via the use of a blood pump to the dialyzer, where toxins are filtered from the blood and the cleansed blood is returned to the patient.

Diffusion, osmosis, and **ultrafiltration** are the principles on which HD is based (see Chapter 10). The toxins and wastes in the blood are removed by **diffusion**—that is, they move from an area of higher concentration in the blood to an area of lower concentration in the dialysate. The **dialysate** is a solution that circulates through the dialyzer, made up of all the electrolytes in their ideal extracellular concentrations. The electrolyte level in the patient's blood can be brought under control by properly adjusting the electrolytes in the dialysate solution. The semipermeable membrane impedes the diffusion of large molecules, such as RBCs and proteins.

Excess fluid is removed from the blood by **osmosis**, in which water moves from an area of low concentration potential (the blood) to an area of high concentration potential (the dialysate bath). In **ultrafiltration**, fluid moves under high pressure to an area of lower pressure. This process is much more efficient than osmosis for fluid removal and is accomplished by applying negative pressure (a suctioning-type force) to the dialysis membrane. Because patients with ESKD requiring dialysis usually cannot excrete enough water, this force is necessary to remove fluid to achieve fluid balance.

The body's buffer system is maintained using a dialysate bath made up of bicarbonate (most common) or acetate, which is metabolized to form bicarbonate. The anticoagulant heparin is given to keep blood from clotting in the extracorporeal dialysis circuit. Cleansed blood is returned to the body with the goal of removing fluid, balancing electrolytes, and managing acidosis (Hellebrand, Allen, & Hoffman, 2017).

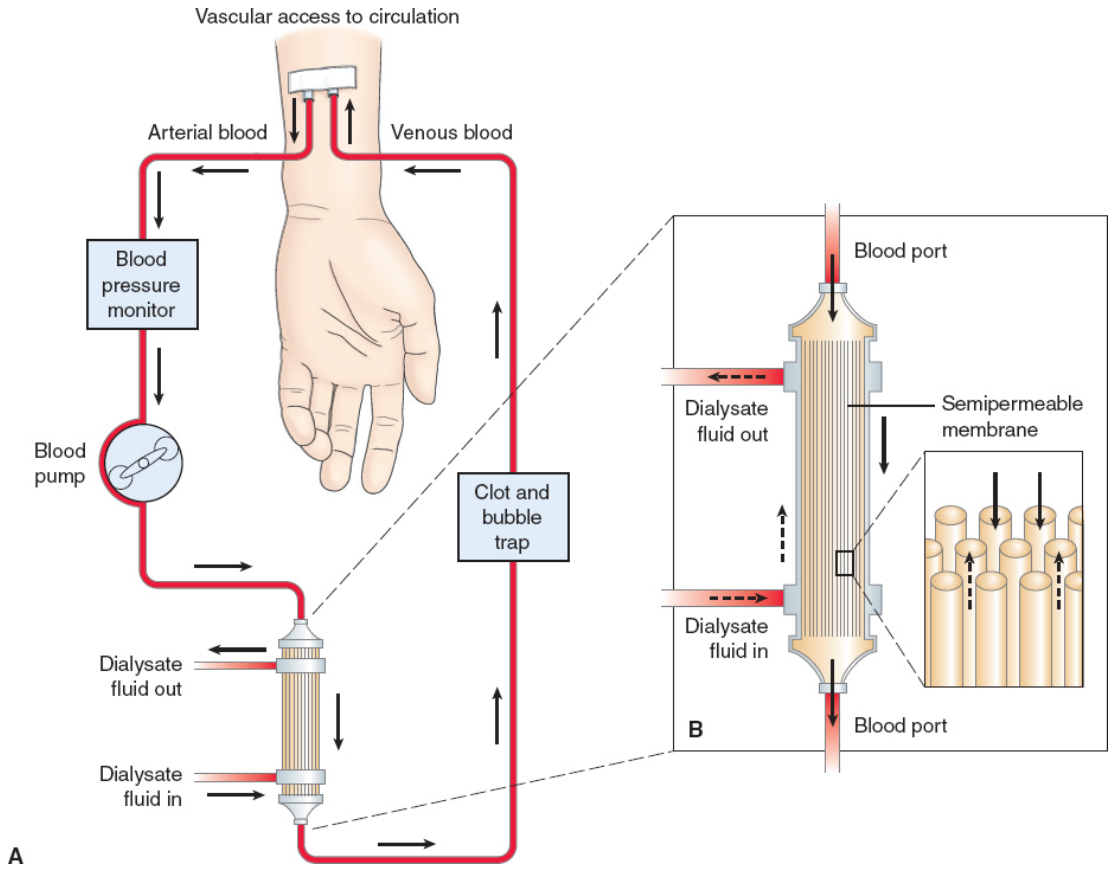

Figure 48-3 • HD system. Blood from the arteriovenous fistula or graft is pumped (**A**) into a dialyzer, where it flows through the synthetic capillary tubes (**B**), which act as the semipermeable membrane (*inset*). The dialysate, which has a particular chemical composition, flows into the dialyzer around the capillary tubes that the blood flows through. The waste products in the blood diffuse across the semipermeable membrane into the dialysate solution and flows out to the drain.

Dialyzers

Dialyzers are hollow-fiber devices containing thousands of tiny capillary tubes that carry the blood through the artificial kidney. The tubes are porous and act as a semipermeable membrane, allowing toxins, fluid, and electrolytes to pass across the membrane. The constant flow of the solution maintains the concentration gradient to facilitate the exchange of wastes from the blood across the semipermeable membrane into the dialysate solution, where they are removed and discarded (see Fig. 48-3).

Dialyzers have undergone many technologic changes in performance and biocompatibility. High-flux dialysis uses highly permeable membranes to increase the clearance of low- and mid–molecular-weight molecules. These special membranes are used with higher than traditional rates of flow for the blood entering and exiting the dialyzer (500 to 550 mL/min). High-flux dialysis

increases the efficiency of treatments while shortening their duration and reducing the need for heparin.

Vascular Access

Access to the patient's vascular system must be established to allow blood to be removed, cleansed, and returned to the patient's vascular system at the rapid rates of 300 and 500 mL/min. Several types of access can be surgically created or placed during procedures performed in interventional radiology suites or at the bedside.

Vascular Access Devices

Immediate access to the patient's circulation for acute HD is achieved by inserting a double-lumen, noncuffed, large-bore catheter into the right or left internal jugular or femoral vein of either leg by the physician, nurse practitioner, or physician assistant (see Fig. 48-4). The subclavian vein is rarely used as there is an increased risk for central stenosis (Pryor & Brouwer-Maier, 2017). This method of vascular access involves some risk (e.g., hematoma, bleeding, pneumothorax, infection, thrombosis of the vein, inadequate flow). The catheter is removed when no longer needed (e.g., because the patient's condition has improved or another type of permanent access has been established). Double-lumen, cuffed catheters may also be inserted, usually by either a surgeon or interventional radiologist, into the internal jugular vein of the patient. Because these catheters have cuffs under the skin, the insertion site heals, sealing the wound and reducing the risk for ascending infection. This feature makes these catheters safe for longer-term use. However, infection rates remain high, and sepsis continues to be a common cause for hospital admission (Pryor & Brouwer-Maier, 2017).

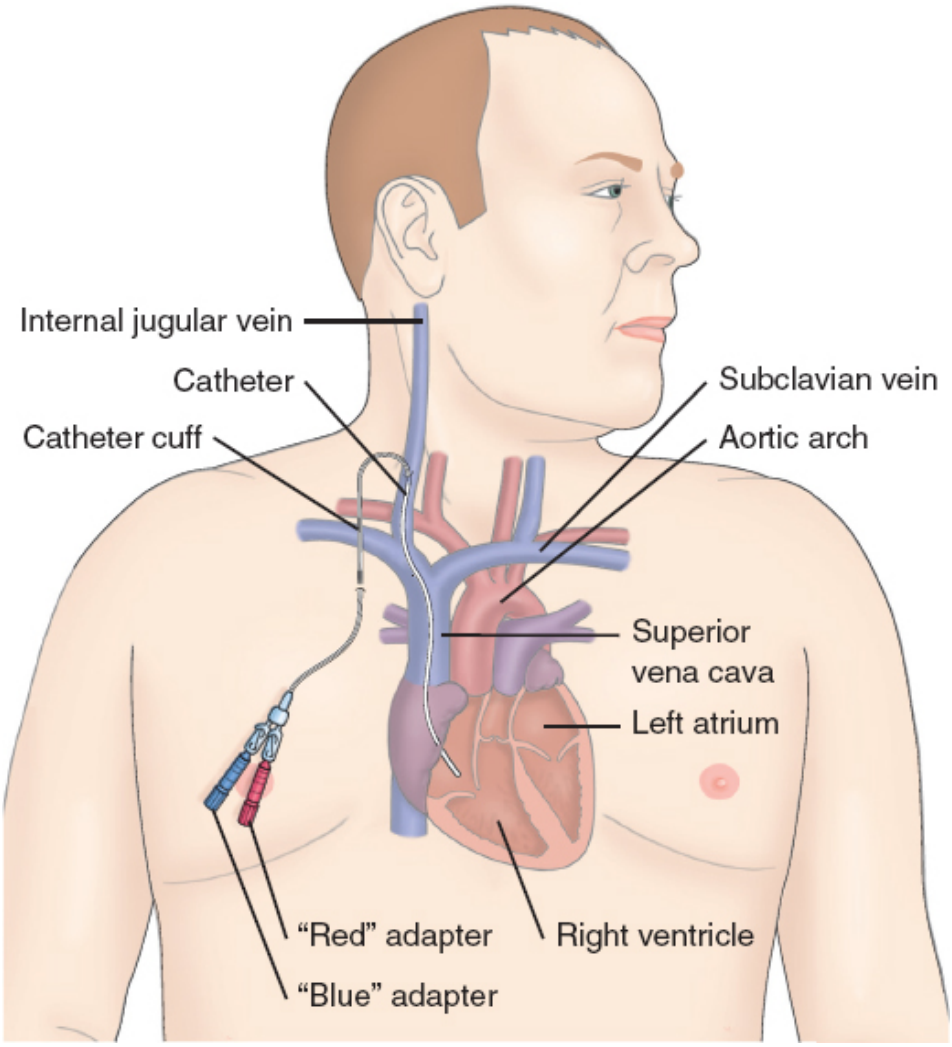

Figure 48-4 • Double-lumen, cuffed HD catheter used in acute HD. The red catheter lumen is attached to a blood line through which blood is pumped from the patient to the dialyzer. After the blood passes through the dialyzer (artificial kidney), it returns to the patient through the other lumen of the catheter.

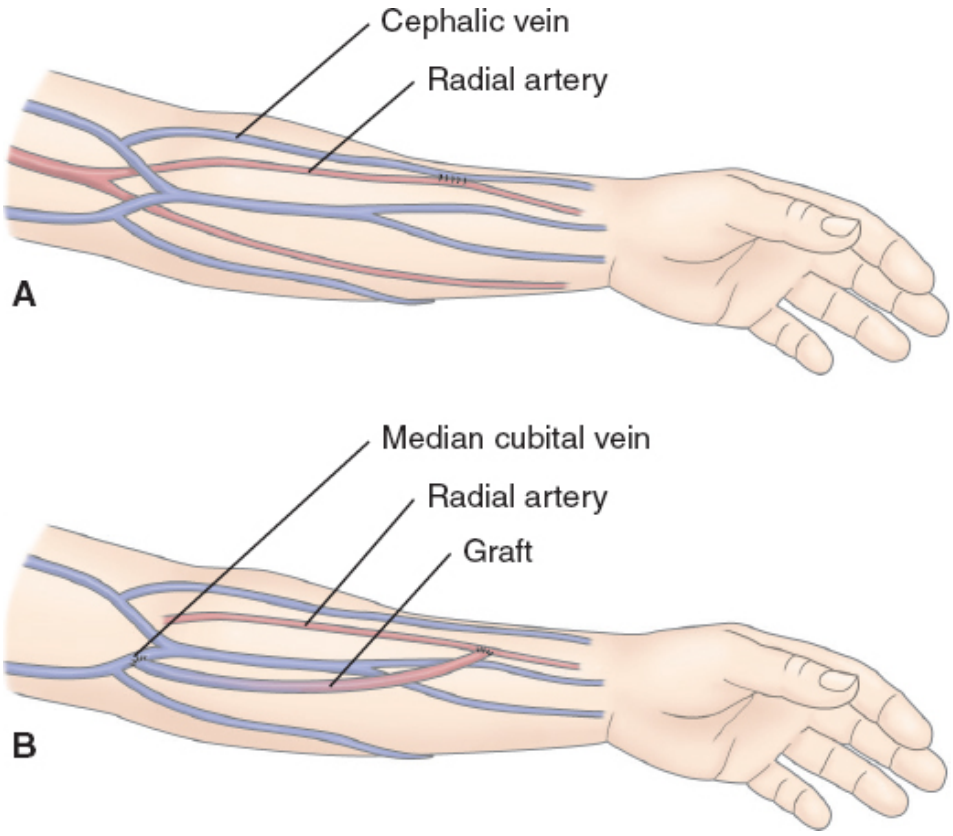

Figure 48-5 • **A.** Arteriovenous fistulas are created by anastomosing a patient's vein to an artery. This illustrates a side-to-side anastomosis. **B.** Arteriovenous grafts are established by connecting the artery and vein using synthetic tubing.

Arteriovenous Fistula

The preferred method of permanent vascular access for dialysis is an **arteriovenous fistula** (AVF) that is created surgically (usually in the forearm) by anastomosing (joining) an artery to a vein, either side to side or end to side (see Fig. 48-5A). Needles are inserted into the vessel to obtain blood flow which is adequate to pass through the dialyzer. The arterial segment of the fistula is used for outflow to the dialyzer and the venous segment for reinfusion of the dialyzed blood. This access will need time (at least 3 months) to "mature" before it can be used. As the AVF matures, the venous segment dilates due to the increased blood flow coming directly from the artery. Once sufficiently dilated, it will then accommodate two large-bore (14-, 15-, or 16-gauge) needles that are inserted for each dialysis treatment. The patient is encouraged to perform hand exercises (e.g., squeezing a rubber ball) to increase the size of these vessels to accommodate the large-bore needles. Once established, this access has the longest useful life and thus is considered the best option for vascular access for the patient requiring ongoing HD (Inglese, 2017).

Arteriovenous Graft

An **arteriovenous graft** can be created by subcutaneously interposing a biologic, semibiologic, or synthetic graft material between an artery and vein (see Fig. 48-5B). Usually, a graft is created when the patient's vessels are not suitable for creation of an AVF. Patients with compromised vascular systems (e.g., from diabetes) often require a graft because their native vessels may not be suitable for creation of an AVF. Grafts are usually placed in the arm but may be placed in the thigh or chest wall. Stenosis, infection, and thrombosis are the most common complications of this access. It is not at all uncommon to see a dialysis patient with numerous "old" or "nonfunctioning" accesses present on their arms. The patient is asked to identify the current access in use, and it is assessed carefully and regularly for the presence of a bruit and thrill.

See the Special Considerations: Nursing Management of the Patient on Dialysis Who Is Hospitalized section later in this chapter for nursing interventions and care of the patient with an arteriovenous graft or fistula.

Quality and Safety Nursing Alert

Failure of the permanent dialysis access (fistula or graft) accounts for many hospital admissions of patients undergoing chronic HD. Thus, protection of the access is of high priority. Although limb alert bracelets (Sturdivant & Johnson, 2019) are ideal to identify the access extremity, posted signs are also a good safety alert. The sign should state, "No lab draws, IVs, or blood pressures on access arm."

Complications

Although HD can prolong life, it does not alter the natural course of the underlying CKD, nor does it completely replace kidney function. The CKD complications previously discussed will continue to worsen and require treatment. With the initiation of dialysis, disturbances of lipid metabolism are accelerated and contribute to cardiovascular complications. Heart failure, coronary artery disease, angina, stroke, and peripheral vascular disease may occur and can incapacitate the patient. Cardiovascular disease remains the leading cause of death in patients receiving dialysis as well as for patients with CKD.

Many complications result from both the underlying ESKD and the HD treatments. The anemia of ESKD is compounded by blood loss during HD. Gastric ulcers may result from the physiologic stress of chronic illness, medication, and preexisting medical conditions (e.g., diabetes). Patients with uremia often report a metallic taste and nausea. Vomiting may occur during the HD treatment when rapid fluid shifts and hypotension occur. These contribute to the malnutrition seen in patients on dialysis. Disordered calcium metabolism and renal osteodystrophy can result in bone pain and fractures, interfering with

mobility. As time on dialysis continues, calcification of major blood vessels has been reported and linked to hypertension and other vascular complications. Phosphorus deposits in the skin can occur and cause itching.

Many people undergoing HD experience major sleep problems that further complicate their overall health status. Early-morning or late-afternoon dialysis may be a risk factor for developing sleep disturbances.

Other complications of dialysis may include the following:

- Episodes of shortness of breath often occur as fluid accumulates between dialysis treatments.
- Hypotension may occur during the treatment as fluid is removed. Nausea and vomiting, diaphoresis, tachycardia, and dizziness are common signs of hypotension.
- Painful muscle cramping may occur, usually late in dialysis as fluid and electrolytes rapidly leave the extracellular space.
- Exsanguination may occur if blood lines separate or dialysis needles become dislodged.
- Arrhythmias may result from electrolyte and pH changes or from removal of antiarrhythmic medications during dialysis.
- Air embolism is very rare since the advent of venous air detectors, but can occur if air enters the vascular system.
- Chest pain may occur in patients with anemia or arteriosclerotic heart disease.
- Dialysis disequilibrium results from cerebral fluid shifts. Signs and symptoms include headache, nausea and vomiting, restlessness, decreased level of consciousness, and seizures. It is rare and more likely to occur in AKI or when BUN levels are very high (exceeding 150 mg/dL) and the patient is dialyzed with high blood and dialysate flows. Therefore, short treatments with low blood and dialysate flow rates are prescribed (Hellebrand et al., 2017).

COVID-19 Considerations

Patients undergoing outpatient HD are at high risk of contracting the SARS-CoV-2 virus due to comorbidities (e.g., hypertension), their relatively suppressed immune status, and more frequent hospitalizations (Wu, Li, Zhu, et al., 2020). Travel to an outpatient dialysis center three times a week also increases their risk of contracting the virus (Ajaimy & Melamed, 2020). Findings from a retrospective, single-center study of 49 patients on HD compared to 52 patients without kidney disease all hospitalized with COVID-19 pneumonia in Wuhan, China, reported that the main symptoms of fever and cough were less prevalent in patients who were undergoing HD (Wu et al., 2020). Patients on HD were also more likely to be admitted to intensive care,

need ventilator support, and had a higher mortality rate compared to controls (Wu et al., 2020). These early findings suggest that patients receiving HD are not only at greater risk for COVID-19, they are also at risk for not being recognized as infected with SARS-CoV-2 at an early stage, when they may be amenable to treatment. These findings also suggest that patients on HD who are hospitalized with COVID-19 are more acutely ill and at greater risk for death compared to patients not on HD (Wu et al., 2020).

Nursing Management

The nurse in the dialysis unit has an important role in monitoring, supporting, assessing, and educating the patient. During HD, the patient, the dialyzer, and the dialysate bath require constant monitoring because numerous complications are possible, including clotting of the dialysis tubing or dialyzer, air embolism, inadequate or excessive fluid removal, hypotension, cramping, vomiting, blood leaks, contamination, and access complications. Nursing care of the patient and maintenance of the vascular access device are especially important and are discussed in the Special Considerations: Nursing Management of the Patient on Dialysis Who Is Hospitalized section.

Promoting Pharmacologic Therapy

Many medications are removed from the blood during HD. Therefore, dosage or timing of medication administration may require adjustment. Medications that are water soluble are readily removed during HD treatment, and those that are fat soluble or adhere to other substances (like albumin) are not dialyzed out very well. This is the reason some drug overdoses are treated with emergency HD and others are not.

Patients undergoing HD who require medications (e.g., cardiac glycosides, antibiotic agents, antiarrhythmic medications, antihypertensive agents) are monitored closely to ensure that blood and tissue levels of these medications are maintained without toxic accumulation. Antihypertensive therapy, often part of the regimen of patients on dialysis, is one example when communication, education, and evaluation can make a difference in patient outcomes. The patient must know when—and when not—to take the medication. For example, if an antihypertensive agent is taken on a dialysis day, hypotension may occur during dialysis, causing dangerously low blood pressure. Many medications that are taken once daily should be administered after the dialysis treatment.

Promoting Nutritional and Fluid Therapy

Diet is important for patients on HD. Goals of nutritional therapy are to minimize uremic symptoms and fluid and electrolyte imbalances; to maintain good nutritional status through adequate protein, calorie, vitamin, and mineral intake; and to enable the patient to eat a palatable and enjoyable diet. Restriction

of fluid is also part of the dietary prescription because fluid accumulation may occur, leading to fluid volume excess, heart failure, and pulmonary edema.

With the initiation of HD, the patient usually requires some restriction of dietary sodium, potassium, phosphorus, and fluid intake. Close collaboration with a renal dietitian is essential in helping the patient make good food choices. Protein intake is restricted to about 1.2 g/kg ideal body weight per day; therefore, protein must be of high-biologic quality. Sodium is usually restricted to 2 g/day; the fluid prescription is individualized based on residual urine output (generally 1000 to 1500 mL/day). The goal for patients on HD is to keep their interdialytic (between dialysis treatments) weight gain less than 4% of their estimated dry weight (Gonyea, 2017). Potassium restriction depends on the amount of residual renal function and the frequency of dialysis.

Chart 48-8  **NURSING RESEARCH PROFILE**

Resilience in Patients Receiving Dialysis

Kim, E., Lee, Y., & Chang, S. (2019). How do patients on hemodialysis perceive and overcome hemodialysis?: Concept development of the resilience of patients on hemodialysis. *Nephrology Nursing Journal*, *46*(5), 521–530.

Purpose

This qualitative study was designed to identify and conceptualize the concept of resilience in patients receiving HD.

Design

This study was conducted in three phases. In the first phase, called the theoretical phase, a literature review was undertaken and a definition of the resilience of patients on HD was constructed. In the fieldwork phase, interviews were held with 10 patients. Qualitative data from the 10 interviews were analyzed for patterns to identify attributes of resilience for patients on HD. The last phase compared the theoretical definition with the data collected in the fieldwork phase.

Findings

The purposive patient sample included 10 participants from one HD center at a university hospital in Korea who were chosen by nurses with expertise in HD who assessed the patients to have characteristics of resilience. The length of time participants had been on HD ranged between 1 and 10 years, and 60% were female. Through in-depth interviews, the concept of the resilience of patients on HD was found to have three dimensions: a willingness to actively solve problems, building daily routine strategies continuing roles as a family member and asserting the will to grow through overcoming HD; an acceptance of the HD situation, maintaining the homeostasis of the body and deliberating on death; and a positive self-perception and positively reinterpreting human relationships.

Nursing Implications

The nurse should assess and reinforce positive coping strategies that patients are using to cope with the issues encountered with the HD routine and change in lifestyle. By identifying the concept of resilience, nurses can encourage patients to use their positive coping skills to manage the financial, psychosocial, and medical challenges they may experience. The findings of this study could be used as a foundation for intervention strategies that incorporate the inventory of patients' strengths.

Dietary restriction is an unwelcome change in lifestyle for many patients with ESKD. Patients can feel stigmatized in social situations because there may be few food choices available for their diet. If the restrictions are ignored, life-threatening complications, such as hyperkalemia and pulmonary edema, may result. Thus, the patient may feel punished for responding to basic human drives

to eat and drink. The nurse and renal dietitian who care for a patient with symptoms or complications resulting from dietary indiscretion must avoid harsh, judgmental, or punitive tones when communicating with them. Regular education with reinforcement is needed to achieve these difficult changes in lifestyle.

Meeting Psychosocial Needs

Patients requiring long-term HD, as they engage in psychosocial adaptation, tend to feel mired in a cyclical routine (Lin, Han, & Pan, 2015). They often have financial problems, difficulty holding a job, waning sexual desire and impotence, clinical depression, and fear of dying. Younger patients worry about marriage, having children, and the burden that they bring to their families. The regimented lifestyle that frequent dialysis treatments and restrictions in food and fluid intake impose can be demoralizing to the patient and family. Researchers have studied how patients on HD perceive and cope with the treatment by developing resilience (Kim, Lee, & Chang, 2019). (See the Nursing Research Profile in Chart 48-8.)

Dialysis alters the lifestyle of the patient and family. The amount of time required for dialysis and primary provider visits and being chronically ill can create conflict, frustration, guilt, and depression. It may be difficult for the patient, spouse, and family to express anger and negative feelings.

The nurse needs to give the patient and family the opportunity to express feelings of anger and concern about the limitations that the disease and treatment impose, possible financial problems, and job insecurity. If anger is not expressed, it may be directed inward and lead to depression, despair, and attempts at suicide; however, if anger is projected outward to other people, it may damage family relationships.

Chart 48-9 ETHICAL DILEMMA

How Can Patient Rights Be Discerned during a Pandemic?

Case Scenario

B.J. is a 74-year-old widow with chronic kidney disease (CKD) managed with HD three times weekly in an outpatient dialysis center. She is admitted to the medical unit where you work as a staff nurse with fluid retention and dyspnea. It is reported that B.J. had been a "no show" at the dialysis center for at least the past week. As part of her therapeutic plan, she is supposed to be dialyzed while in the hospital. As you enter her room to prepare her for transport to the hospital's dialysis center, you find B.J. humming to herself, clapping her hands, and smiling. When you explain to her that she is going to be transported to the dialysis center, she says "Honey, I am not going anywhere. I want to see Jesus. It is my time and I am ready to see the Lord." You have heard from the medical social worker that this is not B.J.'s first admission to the hospital for poor adherence to her outpatient dialysis treatment. During past hospitalizations, her three adult daughters would visit her together and effectively cajole her into receiving dialysis treatments. Reportedly, the daughters have a loving and supportive relationship with each other and their mother. However, there is an outbreak of coronavirus disease 2019 (COVID-19) within your community and the hospital has responded with a no-visitor policy throughout the facility, so B.J.'s daughters may not visit her.

Discussion

The principle of autonomy is considered sacrosanct. Patients have the right to refuse treatments, even if those treatments are life-saving. However, in this particular instance, B.J. could be delirious as a manifestation of her poorly managed CKD. If she is delirious, it may be determined that she lacks the capacity to make her own decisions. Her daughters might be her surrogates and legally responsible to make health care decisions for her. However, her daughters' prohibition to visit her while she is hospitalized hampers their ability to discuss her options with her and gain her assent for treatment.

Analysis

- Describe the ethical principles that are in conflict in this case (see Chapter 1, Chart 1-7). Can the principle of beneficence and wishing to "do good" for B.J. trump her autonomous right to refuse treatment? Can she be forced to undergo dialysis?
- What if it is determined that B.J. lacks the capacity to make informed decisions? On the contrary, what if it is determined that B.J. is not delirious and has the capacity to refuse to be dialyzed? Describe methods that you might employ to engage B.J.'s daughters so that they might be able to communicate with her and with each other as a family unit.

- What resources might be mobilized to be of assistance to B.J., her daughters, and the health care team so that a treatment plan that preserves B.J.'s dignity during this pandemic might be devised?

Resources

See Chapter 1, Chart 1-10 for Steps of an Ethical Analysis and Ethics Resources.

Although these feelings are normal in this situation, they are often profound. Counseling and psychotherapy may be useful. All patients receiving dialysis should be screened for depression using a standard screening tool such as the Patient Health Questionnaire 9 (PHQ-9) or the Beck Depression Inventory (BDI) (Shirazian, Grant, Aina, et al., 2017). Depression may require treatment. Referring the patient and family to a mental health provider with expertise in the care of patients receiving dialysis may also be helpful. Clinical nurse specialists, psychologists, and social workers may be helpful in assisting the patient and family to cope with the changes brought about by kidney disease and its treatment by encouraging the development of resilience (Kim et al., 2019; Lieser, 2017).

The sense of loss that the patient experiences cannot be underestimated because every aspect of a "normal life" is disrupted. Some patients use denial to deal with the array of medical problems (e.g., infections, hypertension, anemia, neuropathy). Staff who are tempted to label the patient as nonadherent must consider the impact of kidney disease and its treatment on the patient and family and the coping strategies that they may use.

Palliative care principles that focus on symptom control are becoming increasingly important as greater attention is focused on quality-of-life issues. Patients and their families are encouraged to discuss end-of-life options and to develop advanced directives or living wills (Molzahn & Schick-Makaroff, 2017) (see Chart 48-9).

Promoting Home, Community-Based, and Transitional Care

Educating Patients About Self-Care

Preparing a patient for HD is essential. Assessment helps identify the learning needs of the patient and family members. In many cases, the patient is discharged home before learning needs and readiness to learn can be thoroughly evaluated; therefore, hospital-based nurses, dialysis staff, and home

health nurses must work together to provide appropriate education that meets the patient's and family's changing needs and readiness to learn (see Chart 48-10).

The diagnosis of ESKD and the need for dialysis is a big adjustment for the patient and family. In addition, many patients with ESKD have clinical depression, and chronic uremia contributes to a shortened attention span, a decreased level of concentration, and altered perception. Therefore, education must occur in brief, 10- to 15-minute sessions, with time added for clarification, repetition, reinforcement, and questions from the patient and family. The nurse needs to convey a nonjudgmental attitude to enable the patient and family to discuss options and their feelings about those options. Team conferences are helpful for sharing information and providing every team member the opportunity to discuss the needs of the patient and family.

Chart 48-10  **HOME CARE CHECKLIST**

The Patient Undergoing HD

At the completion of education, the patient and/or caregiver will be able to:

- Discuss kidney disease and its effects on the body.
- State the goal and purpose of HD and its impact on physiologic functioning, ADLs, IADLs, roles, relationships, and spirituality.
- Discuss common problems that may occur during HD and their prevention and management.
- State the name, dose, side effects, frequency, and schedule for all medications on dialysis and nondialysis days.
- Describe commonly measured laboratory values, results, and implications.
- State changes in lifestyle (e.g., diet, activity) necessary to maintain health.
  - Acknowledge dietary and fluid restrictions, rationale, and consequences of nonadherence.
  - State dietary restrictions and changes required to provide adequate protein, calorie, vitamin, and mineral intake.
- List guidelines for prevention and detection of fluid overload, meaning of “dry” weight, and how to weigh self.
- Demonstrate vascular access care, how to check patency, signs and symptoms of infection, and prevention of complications.
- Develop strategies to manage or reduce anxiety and maintain independence.
- Discuss strategies for detection, management, and relief of pruritus, neuropathy, and other potential complications of kidney disease.
- Relate how to reach primary provider with questions or complications.
- State time and date of follow-up medical appointments, therapy, and testing.
- Coordinate financial arrangements for HD and strategies to identify and obtain resources.
- Identify sources of support (e.g., friends, relatives, faith community).
- Identify the contact details for support services for patients and their caregivers/families.
- Identify the need for health promotion, disease prevention, and screening activities.

ADLs, activities of daily living; IADLs, instrumental activities of daily living.

Home Hemodialysis

Most patients who undergo HD do so in an outpatient setting, but home HD is an option for some. Prior to the COVID-19 pandemic, approximately 2% of

patients receiving RRT were on home HD (USRDS, 2019). Home HD requires a highly motivated patient who is willing to take responsibility for the procedure and is able to adjust each treatment to meet the body's changing needs. It also requires the commitment and cooperation of a caregiver to assist the patient. However, many patients are not comfortable imposing on others and do not wish to subject family members to the feeling that their home is being turned into a clinic. The health care team never forces a patient to use home HD, because this treatment requires changes in the home and family. Home HD must be the patient's and family's decision (Harwood & Dominski, 2017). However, more patients needing RRT are being encouraged to reassess the home dialysis option as this modality allows the patient to self-isolate and to avoid having to enter an HD center thrice weekly, thus lowering the risk of contracting the SARS-CoV-2 virus (Ajaimy & Melamed, 2020).

The patient undergoing home HD and the caregiver assisting that patient must be trained to prepare, operate, and disassemble the dialysis machine; maintain and clean the equipment; administer medications (e.g., heparin) into the machine lines; and handle emergency problems (HD dialyzer rupture, electrical or mechanical problems, hypotension, shock, and seizures) (Harwood & Dominski, 2017). Because home HD places primary responsibility for the treatment on the patient and the family member, they must understand and be capable of performing all aspects of the HD procedure.

Before home HD is initiated, the home environment, household and community resources, and ability and willingness of the patient and family to carry out this treatment are assessed. The home is surveyed to see if electrical outlets, plumbing facilities, and storage space are adequate. Modifications may be needed to enable the patient and caregiver to perform dialysis safely and to deal with emergencies.

Once home HD is initiated, the home health nurse must visit periodically to evaluate adherence with the recommended techniques, to assess the patient for complications, to reinforce previous education, and to provide feedback and reassurance.

Continuing and Transitional Care

The health care team's goal in treating patients with CKD is to maximize their vocational potential, functional status, and quality of life (Browne & Johnstone, 2017). To facilitate renal rehabilitation, appropriate follow-up and monitoring by members of the health care team (physicians, dialysis nurses, renal dietitian, social worker, psychologist, home health nurses, and others as appropriate) are essential to early identification and resolution of problems. Many patients with CKD can resume relatively normal lives, doing the things that are important to them: traveling, exercising, working, or actively participating in family activities. If appropriate interventions are available

early in the course of dialysis, the potential for better health improves, and the patient can remain active in family and community life. Outcome goals for renal rehabilitation include employment for those able to work, improved physical functioning of all patients, improved understanding about adaptation and options for living well, increased control over the effects of kidney disease and dialysis, and resumption of activities enjoyed before dialysis.

Continuous Renal Replacement Therapy

CRRT may be indicated for patients with acute or chronic kidney disease who are too clinically unstable for traditional HD, for patients with fluid overload secondary to oliguric (low urine output) kidney disease, and for patients whose kidneys cannot handle their acutely high metabolic or nutritional needs. Some forms of CRRT may not require dialysis machines or dialysis personnel to carry out the procedures and can be initiated quickly in the critical-care unit. Several types of CRRT are available and widely used in critical-care units (see Fig. 48-6). The methods are similar, as they require access to the circulation and blood to pass through an artificial filter. A hemofilter (an extremely porous blood filter containing a semipermeable membrane) is used in all types.

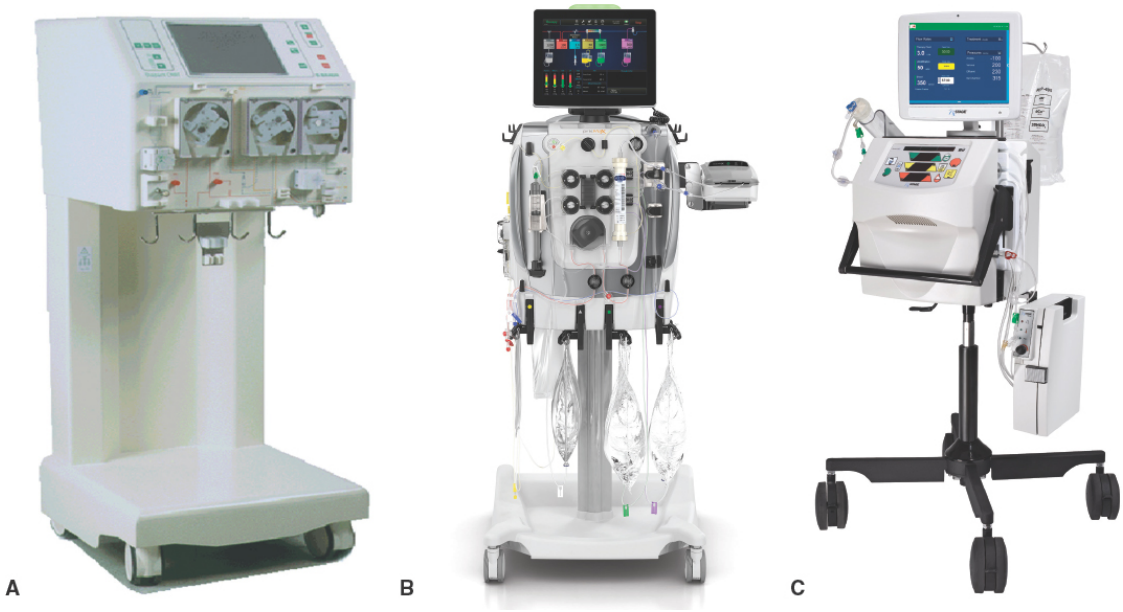

Figure 48-6 • Devices for administering continuous renal replacement therapy (CRRT) offer an integrated fluid warmer for the heating of infusion and dialysate fluids, a weighing or volumetric measuring system to reduce the possibility of error in assessing fluid balance, and a battery backup that allows treatments to continue when the patient is moved. **A.** Diapact CRRT System, B-Braun Medical, Inc., Bethlehem, PA. **B.** PrisMax, Baxter International, Inc., Chicago, Il. **C.** System One with NxView, NxStage Medical Inc. Continuous Venovenous Hemofiltration

Continuous venovenous hemofiltration (CVVH) is often used to manage AKI. Blood from a double-lumen venous catheter is pumped (using a small blood pump) through a hemofilter and then returned to the patient through a different lumen of the same catheter (Odom, 2017). CVVH provides **ultrafiltration** (continuous slow fluid removal); therefore, hemodynamic effects are mild and better tolerated by patients with unstable conditions. CVVH requires a dual-lumen venous catheter, a specialized machine, and critical-care nurses trained in management of the therapy who can set up, initiate, maintain, and terminate the system. Many hospitals have developed a collaborative approach to managing the CVVH therapy between the critical-care and nephrology nursing staff (Odom, 2017).

Continuous Venovenous Hemodialysis

Continuous venovenous hemodialysis (CVVHD) is similar to CVVH. Blood is pumped from a double-lumen venous catheter through a hemofilter and returned to the patient through a different lumen of the same catheter. In addition to the benefits of ultrafiltration, CVVHD uses a concentration gradient to facilitate the removal of uremic toxins and fluid by adding a dialysate solution into the jacket of the dialyzer, surrounding the blood in the fibers. Hemodynamic effects are usually mild and critical-care nurses can set up, initiate, maintain, and terminate the system with the support of the nephrology nursing staff (Odom, 2017).

Peritoneal Dialysis (PD)

The goals of PD are to remove toxic substances and metabolic wastes and to reestablish normal fluid and electrolyte balance. PD may be the treatment of choice for patients with kidney disease who are unable or unwilling to undergo HD or kidney transplantation. Patients who are susceptible to the rapid fluid, electrolyte, and metabolic changes that occur during HD experience fewer of these problems with the slower rate of PD. Therefore, patients with diabetes or cardiovascular disease, many older patients, and those who may be at risk for adverse effects of systemic heparin are likely candidates for PD. In addition, severe hypertension, heart failure, and pulmonary edema not responsive to usual treatment regimens have been successfully treated with PD. Fewer than 8% of patients with ESKD receive PD as their treatment modality (USRDS, 2019). Chart 48-11 discusses suitability for PD.

In PD, the peritoneal membrane that covers the abdominal organs and lines the abdominal wall serves as the semipermeable membrane. Sterile dialysate fluid, containing dextrose and electrolytes, is introduced into the peritoneal cavity through an abdominal catheter at established intervals. Once the sterile solution is in the peritoneal cavity, uremic toxins such as urea and creatinine begin to be cleared from the blood. Diffusion of these solutes occurs as waste products move from an area of higher concentration (the bloodstream) to an area of lesser concentration (the dialysate fluid) through a semipermeable membrane (the peritoneum). This movement of solute from the blood into the dialysate fluid is called clearance. Because substances cross the peritoneal membrane at different rates, adjustments in solution dwell time and volume are made to facilitate the process of clearance. Ultrafiltration occurs in PD through an osmotic gradient created by using a dialysate fluid with a higher glucose concentration than the blood.

Chart 48-11

Considerations for Peritoneal Dialysis

Although peritoneal dialysis (PD) is not suitable for all patients with end-stage kidney disease (ESKD), it is a viable therapy for those who can perform self-care and fluid exchanges and fit therapy into their own routines. Often, patients report having more energy and feeling healthier once they begin PD. Nurses can be instrumental in helping patients with ESKD find the dialysis therapy that best suits their lifestyle. Those considering PD need to understand the advantages and disadvantages along with the indications and contraindications for this form of therapy.

Advantages

- Freedom from a hemodialysis (HD) machine
- More control over daily activities
- Opportunities to eat a more liberal diet than allowed with HD; usually increased fluid allowance; improved serum hematocrit values; improved blood pressure control; avoidance of venipuncture; and improved sense of well-being.

Disadvantages

- Need for dialysis 7 days a week
- Dietary alterations related to protein and potassium losses. Patients may be encouraged to increase the intake of protein and potassium in the diet due to these losses with PD fluid exchanges

Indications

- Patient's willingness, motivation, and ability to perform dialysis at home
- Strong family or community support system (essential for success), particularly if the patient is an older adult
- Special problems with long-term HD, such as dysfunctional or failing vascular access devices, excessive thirst, severe hypertension, post-dialysis headaches, and severe anemia requiring frequent transfusion
- Interim therapy while awaiting kidney transplantation
- ESKD secondary to diabetes because hypertension, uremia, and hyperglycemia are easier to manage with PD than with HD

Contraindications

- Adhesions from previous surgery (adhesions reduce clearance of solutes) or systemic inflammatory disease
- Chronic backache and preexisting disc disease, which could be aggravated by the continuous pressure of dialysis fluid in the abdomen
- Severe arthritis or poor hand strength necessitating assistance in performing the exchange. However, patients who are blind or partially blind and those with other physical limitations can learn to perform PD

Procedure

As with other forms of treatment, the decision to begin PD is made by the patient and family in consultation with the nephrologist. With PD, the patient generally has ESKD and will need to receive ongoing treatments.

Preparing the Patient

The nurse's preparation of the patient and family for PD depends upon the assessment of the patient's physical and psychological status, mental status, previous experience with dialysis, and understanding of and familiarity with the procedure.

The nurse and surgeon or interventional radiologist or nephrologist explain the procedure to the patient. The nurse assists the provider in obtaining signed consent for insertion of the catheter. Baseline vital signs, weight, and serum electrolyte levels are recorded. Evaluation of the abdomen for placement of the catheter exit site is done to facilitate self-care. Typically, the catheter is placed on the nondominant side to allow the patient easier access to the catheter connection site when exchanges are done. The patient is instructed to empty the bladder and bowel to reduce the risk of puncture of internal organs during the insertion procedure. A prophylactic antibiotic agent will be given to prevent infection. The peritoneal catheter can be inserted in interventional radiology, in the operating room, or, rarely, at the bedside. Depending on the situation, this will need to be explained to the patient and family.

Preparing the Equipment

In addition to assembling the equipment to administer PD, the nurse consults with the physician to determine the concentration of dialysate to be used and the medications to be added. Heparin may be added to prevent fibrin formation and resultant occlusion of the peritoneal catheter. Potassium chloride may be prescribed to prevent hypokalemia. Antibiotic agents may be added to treat **peritonitis** (inflammation of the peritoneal membrane) caused by infection. Insulin is rarely added to PD fluid due to widespread use of subcutaneous insulin pumps and sliding scales (Kelman & Watson, 2017). Aseptic technique is imperative whenever medications are added to the PD solution. In a hospital setting, to prevent contamination, a pharmacist generally adds all medications to the dialysate bags in the pharmacy under a laminar flow hood. In the home setting, the nurse instructs the patient or family on how to aseptically add medications to PD fluid.

The dialysate is warmed to body temperature to prevent patient discomfort and abdominal pain and to dilate the vessels of the peritoneum to increase urea clearance. Solutions that are too cold cause pain, cramping, and vasoconstriction and reduce clearance. Dry heating (heating cabinet, incubator, or heating pad) is recommended. Methods that are never recommended include

soaking the bags of solution in warm water (introduces bacteria to the exterior of the bags of solution and increases the chance of peritonitis) and using a microwave oven to heat the fluid (increases the danger of burning the peritoneum) (Kelman & Watson, 2017).

Immediately before initiating dialysis, using aseptic technique, the nurse assembles the dialysate with attached tubing and drainage bag. All PD dialysate fluid, tubing, and drainage bags are manufactured as closed systems and no spiking of solution is needed. The tubing is primed with the prepared dialysate to prevent air from entering the catheter and peritoneal cavity, which would cause abdominal discomfort and interfere with instillation and drainage of the fluid.

Inserting the Catheter

In most cases, the peritoneal catheter is inserted in the operating room or radiology suite to maintain surgical asepsis and minimize the risk of contamination. Catheters for long-term use are usually soft and flexible and made of silicone with a radiopaque strip to permit visualization on x-ray. These catheters have three sections: an intraperitoneal section, with numerous openings and an open tip to allow dialysate to flow freely; a subcutaneous section that passes from the peritoneal membrane and tunnels through muscle and subcutaneous fat to the skin; and an external section for connection to the manufacturer specific transfer set which then connects to the dialysate tubing with attached dialysate. Most adult catheters have 2 cuffs made of Dacron polyester. The cuffs stabilize the catheter, limit movement, prevent leaks, and provide a barrier against microorganisms. One cuff is placed just distal to the peritoneum, and the other cuff is placed subcutaneously. The subcutaneous tunnel (5 to 10 cm long) further protects against bacterial infection (see Fig. 48-7).

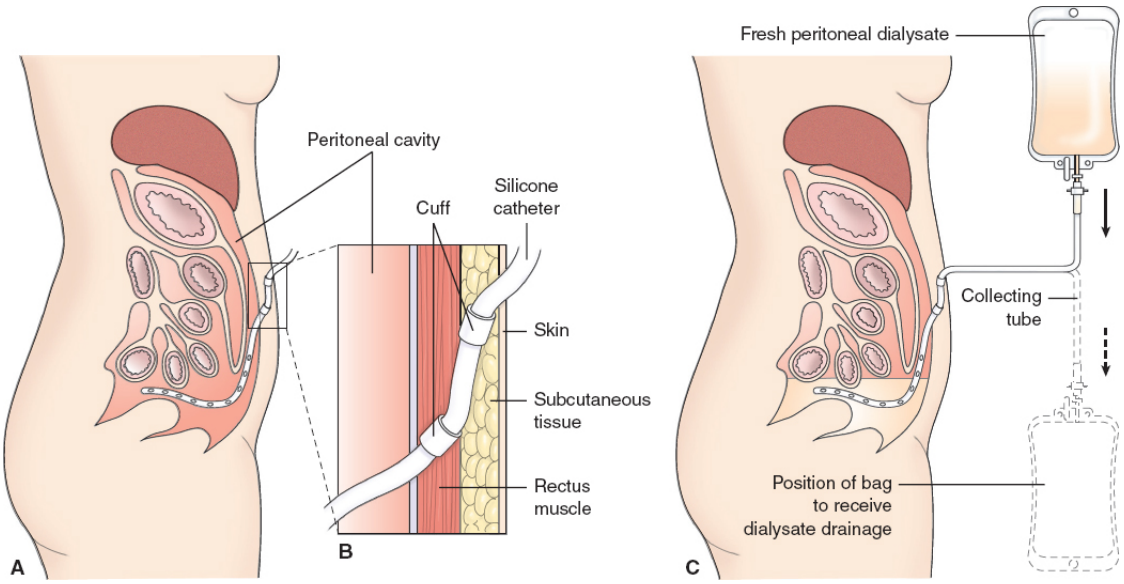

Figure 48-7 • Peritoneal dialysis. **A.** The peritoneal catheter is implanted through the abdominal wall. **B.** Dacron cuffs and a subcutaneous tunnel provide protection against bacterial infection. **C.** Continuous Ambulatory Peritoneal Dialysis (CAPD): Dialysate flows by gravity through the peritoneal catheter into the peritoneal cavity. After a prescribed period of time, the fluid is drained by gravity and discarded. New solution is then infused into the peritoneal cavity until the next drainage period. Dialysis thus continues on a 24-hour-a-day basis, during which the patient is free to move around and engage in their usual activities.

Performing the Exchange

All types of PD involve a series of exchanges or cycles. An **exchange** is the entire cycle including drainage of the **effluent** (fluid), instillation of the dialysate, and dwell. This cycle is repeated throughout the course of the dialysis.

At the end of the dwell time, the drainage portion of the exchange begins. The dialysate is infused by gravity into the peritoneal cavity. A period of about 10 minutes is usually required to infuse 2 to 3 L of fluid. A sterile cap is applied to the transfer set and the patient can perform ADLs. The prescribed dwell, or equilibration time, allows diffusion and osmosis to occur. At the end of the prescribed dwell, the patient performs hand hygiene, dons a mask, removes the sterile cap, unclamps the transfer set, and the solution drains from the peritoneal cavity by gravity through a closed system. Drainage is usually completed in 20 to 30 minutes. The drainage fluid is normally colorless or straw-colored and should not be cloudy. Bloody or pink-colored drainage may be seen in the first few exchanges after insertion of a new catheter, but should not occur after that time (Kelman & Watson, 2017).

The number of cycles or exchanges and their frequency are prescribed based on monthly laboratory values and the presence of uremic symptoms. The exchanges can be performed manually during the waking hours by the patient (continuous ambulatory peritoneal dialysis [CAPD]) or via the use of a PD machine (cycler) that automatically performs exchanges, usually while the patient is sleeping at night (continuous cycling peritoneal dialysis [CCPD]).

The removal of excess water during PD occurs because dialysate has a high dextrose concentration, making it hypertonic. An osmotic gradient is created between the blood and the dialysate solution. Dextrose solutions of 1.5%, 2.5%, and 4.25% are available in several volumes, from 1000 to 3000 mL. The higher the dextrose concentration, the greater the osmotic gradient and the more water will be removed. Selection of the appropriate solution is based on the patient's fluid status (Kelman & Watson, 2017).

Complications

Most complications of PD are often minor; however, several, if unattended, can have serious consequences.

Acute Complications

Peritonitis

Peritonitis is the most common and serious complication of PD. The first sign of peritonitis is cloudy dialysate effluent (Kelman & Watson, 2017). Diffuse abdominal pain and rebound tenderness often occur later. Hypotension and other signs of shock may also occur with advancing infection. The patient with peritonitis may be treated as an inpatient or outpatient (most common), depending on the severity of the infection and the patient's clinical status. Effluent is examined for WBC count. Gram stain and culture are used to identify the organism and guide treatment. If the effluent WBC count is greater than 100 µL (after a dwell time of at least 2 hours) with over 50% polymorphonuclear cells, then broad-spectrum antibiotic agents (aminoglycosides or cephalosporins) are usually added to subsequent exchanges until Gram stain or culture results are available for specific antibiotic sensitivity. Intraperitoneal administration of antibiotic agents is as effective as IV administration and, therefore, most often used. Antibiotic therapy continues for 14 to 21 days (Kelman & Watson, 2017). Careful selection and calculation of the antibiotic dosages are needed to prevent nephrotoxicity and further compromise of residual renal function.

During an episode of peritonitis, the patient loses large amounts of protein through the peritoneal membrane due to inflammation and increased permeability. Acute malnutrition and delayed healing and recovery from the

peritonitis may result. Therefore, attention must be given to educating the patient to detect and promptly seek treatment for peritonitis.

Leakage

In general, use of the PD catheter is delayed for at least 2 weeks post insertion to allow healing to occur and to prevent leakage through the tunnel and exit site. It also allows the exit site time to heal. However, leakage of dialysate through the catheter site may occur even after a healing period. Usually, the leak stops spontaneously when dialysis is withheld for several days, giving the tissue the opportunity to heal around the catheter cuffs and to seal the insertion tunnel. During this time, it is important to reduce factors that might delay healing, such as undue abdominal muscle activity (bending, lifting over 5 lb) and straining during bowel movements. In many cases, leakage can be avoided by using small volumes (500 mL) of dialysate, gradually increasing the volume up to 2000 to 3000 mL (Payton & Kennedy, 2017).

Bleeding

Bloody effluent may be observed occasionally, especially in young, menstruating women. (The hypertonic fluid pulls blood from the uterus, through the opening in the fallopian tubes, and into the peritoneal cavity.) Bleeding is also common during the first few exchanges after a new catheter insertion because some blood enters the abdominal cavity following insertion. The bleeding most often clears up after several exchanges. In many cases, no cause can be found for the bleeding, although catheter displacement from the pelvis has occasionally been associated with bleeding. Some patients have had bloody effluent after an enema or from minor trauma. Most often, bleeding stops in 1 to 2 days and requires no specific intervention. More frequent exchanges and the addition of heparin to the dialysate during this time may be necessary to prevent blood clots from obstructing the catheter (Kelman & Watson, 2017).

Long-Term Complications

Hypertriglyceridemia, likely due to the use of glucose containing dialysate, is common in patients on long-term PD, suggesting that the therapy may contribute to atherogenesis. Cardiovascular disease is the leading cause of morbidity and mortality in patients with both CKD and ESKD, and many patients have suboptimal blood pressure control which contributes to cardiovascular disease. Beta-blockers and ACE inhibitors are often used to control hypertension, decrease proteinuria, and protect the heart, and the use of aspirin and statins should be considered (Schonder, 2017).

Other complications that may occur with long-term PD include abdominal hernias (incisional, inguinal, diaphragmatic, and umbilical), likely resulting from continuously increased intra-abdominal pressure. The persistently

elevated intra-abdominal pressure also aggravates symptoms of hiatal hernia and hemorrhoids. Low back pain and anorexia from fluid in the abdomen and a constant sweet taste related to glucose absorption may also be experienced by the patient.

Mechanical problems occasionally occur and may interfere with instillation or drainage of the dialysate. Formation of clots and fibrin in the peritoneal catheter and constipation are factors that may contribute to these problems.

Approaches

PD can be performed using several different approaches: acute intermittent peritoneal dialysis, CAPD, and CCPD.

Acute Intermittent Peritoneal Dialysis

Indications for acute intermittent PD, a variation of PD, include uremic signs and symptoms (nausea, vomiting, fatigue, altered mental status), fluid overload, acidosis, and hyperkalemia. Although PD is not as efficient as HD in removing solute and fluid, it permits a more gradual change in the patient's fluid volume status and in waste product removal. Therefore, it may be the treatment of choice for the patient who is hemodynamically unstable. It can be carried out manually (the nurse warms and hangs each container of dialysate) or by a cycler machine. Exchange times range from 30 minutes to 2 hours. One example of a routine is hourly exchanges consisting of a 10-minute infusion, a 30-minute dwell time, and a 20-minute drain time. Acute intermittent PD is not indicated for long-term patient management, but for specific situations such as patients who are referred late in the course of CKD (CKD stage 5) and require immediate dialysis (Kelman & Watson, 2017).

Maintaining the PD cycle is a nursing responsibility. Aseptic technique is maintained when changing solution bags and emptying effluent bags. Vital signs, weight, I&O, laboratory values, and patient status are frequently monitored. The nurse uses a flow sheet on paper or within the electronic health record to document each exchange and records vital signs, dialysate concentration, medications added, exchange volume, dwell time, dialysate fluid balance for each exchange (fluid lost or gained), and cumulative fluid balance. The nurse also carefully assesses skin turgor and mucous membranes to evaluate fluid status and monitor the patient for edema. Daily weight is the most accurate indicator of fluid volume status. Patients receiving CAPD are generally weighed with a dwell, while those on CCPD may not carry a daytime dwell and may be weighed without a dwell. The presence of absence of a dwell during the daily weight should be documented.

Quality and Safety Nursing Alert

If the peritoneal fluid does not drain properly, the nurse can facilitate drainage by turning the patient from side to side, having the patient sit or stand, or raising the head of the bed. The peritoneal catheter should never be manipulated.

Other measures to promote drainage include checking the patency of the catheter by inspecting for kinks, closed clamps, or an air lock. The nurse monitors for complications, including peritonitis, bleeding, respiratory difficulty, and leakage of peritoneal fluid around the catheter. In addition, the nurse must ensure that the PD catheter remains secure and that the dressing remains dry and is changed on a routine basis. The patient and family are educated about the procedure and are kept informed about progress (fluid loss, weight loss, laboratory values). Emotional support and encouragement are given to the patient and family during this stressful and uncertain time.

Continuous Ambulatory Peritoneal Dialysis (CAPD)

Continuous ambulatory peritoneal dialysis (CAPD) works on the same principles as other forms of PD: diffusion and osmosis. Less extreme fluctuations in the patient's laboratory values occur with CAPD than with intermittent PD or HD because the dialysis is constantly in progress. The serum electrolyte levels often remain in the normal range.

Procedure

The patient performs exchanges four or five times a day, 24 hours a day, 7 days a week, at intervals scheduled throughout the day. Different manufacturers supply slightly different equipment. A closed Y-shaped system is most commonly used, in which a bag containing dialysate solution comes connected to one branch of the "Y" and a sterile empty bag is connected to the second branch. This leaves the third part of the "Y" open and available for connection to the transfer set on the PD catheter. To perform an exchange, the patient (or person doing the exchange) washes their hands, dons a mask, and then removes the cap from the transfer set while maintaining sterility. The open end of the "Y" set is connected to the end of the transfer set and the dialysate is drained into the attached empty sterile bag (effluent) (over about 20 to 30 minutes). Then the attached dialysate is infused, the patient clamps off the transfer set and the tubing set, disconnects the tubing set, and applies a new sterile cap to the transfer set, making it a closed system.

For some patients, depending on the characteristic of the peritoneal membrane, the longer the dwell time, the better the clearance of uremic toxins. If dwell time is excessive (e.g., overnight dwells), the patient will absorb some of the effluent back into the body simply because the osmotic gradient is lost.

Once equilibrium is reached, the movement of fluid and toxins stops (Kelman & Watson, 2017).

Complications

To reduce the risk of peritonitis, the patient (and all caregivers) must use meticulous aseptic care to avoid contaminating the catheter, fluid, or tubing and to avoid accidentally disconnecting the catheter from the tubing. Whenever a connection or disconnection is made, hand hygiene must be performed and a mask worn by anyone within 6 ft of the area to avoid contamination with airborne bacteria. Excess manipulation should be avoided, and meticulous care of the catheter exit site is provided using a standardized protocol. At home, a patient is taught to use clean technique for exit site care (Payton & Kennedy, 2017). In the hospital, due to the increased risk of infection, sterile technique is employed by the nurse and patient.

Continuous Cyclic Peritoneal Dialysis

Continuous cyclic peritoneal dialysis (CCPD) uses a machine called a cycler to provide the fluid exchanges. It is programmed to deliver an established amount of PD solution that will dwell in the peritoneal cavity for a programmed period of time before it drains from the peritoneal cavity via gravity. The cycler is also set to deliver a specific number of fluid changes in a designated period of time. Because it is programmed, it also keeps track of the total amounts removed and will sound an alarm if limits are not met. It requires that a person set up and break down the system for use, which typically takes about 30 minutes.

CCPD may combine overnight intermittent PD with a prolonged dwell time during the day. However, some patients are drained completely after completing the nighttime exchanges and do not carry a dwell during the day. This avoids reabsorption of fluid during the long daytime dwell. Every evening, the patient connects the peritoneal catheter to tubing on the cycler machine, usually just before the patient goes to sleep for the night. Because the machine is very quiet, the patient can sleep, and the extra-long tubing allows the patient to move and turn normally. In the morning, the patient disconnects from the cycler. This process is done every day to achieve the effects of dialysis required.

CCPD has a lower infection rate than other forms of PD because there are fewer opportunities for contamination with bag changes and tubing disconnections. It also allows the patient to be free from exchanges throughout the day, making it possible to engage in work and activities of daily living more freely (Kelman & Watson, 2017).

Nursing Management

Meeting Psychosocial Needs

In addition to the complications of PD described previously, patients who elect to do PD may experience altered body image because of the presence of the abdominal catheter, bag, tubing, and cycler. Waist size increases from 1 to 2 inches (or more) with fluid in the abdomen. This affects clothing selection and may make the patient feel distended or fat. The nurse may arrange for the patient to talk with other patients who have adapted well to PD. Although some patients have no psychological problems with the catheter—they think of it as their lifeline and as a life-sustaining device—other patients feel they are doing exchanges all day long and have no free time, particularly in the beginning. They may experience depression because they feel overwhelmed with the responsibility of self-care.

Patients undergoing PD may also experience altered sexuality patterns and sexual dysfunction. The patient and partner may be reluctant to engage in sexual activities, partly because of the catheter being psychologically "in the way" of sexual performance. In patients on CCPD, the presence of the dialysis cycler in the bedroom and the continual connection during the sleeping hours can also cause interference with intimacy. Although these problems may resolve with time, some problems may warrant special counseling. Questions by the nurse about concerns related to sexuality and sexual function often provide the patient with a welcome opportunity to discuss these issues and a first step toward assisting in their resolution.

Promoting Home, Community-Based, and Transitional Care

Educating Patients About Self-Care

Patients are educated as inpatients or outpatients to perform PD once their condition is medically stable. Education generally takes 5 days to 2 weeks. Patients are taught according to their own learning ability and knowledge level and only as much at one time as they can handle without feeling uncomfortable or becoming saturated. Education topics for the patient and family who will be performing PD at home are described in Chart 48-12. The use of an adult learning theory–based curriculum may decrease peritonitis and exit site infection rates (Kelman & Watson, 2017).

Chart 48-12 HOME CARE CHECKLIST

Peritoneal Dialysis, Continuous Ambulatory Peritoneal Dialysis, or Continuous Cycling Peritoneal Dialysis

At the completion of education, the patient and/or caregiver will be able to:

- Discuss kidney disease and its effects on the body.
- State the goal and purpose of dialysis and its impact on physiologic functioning, ADLs, IADLs, roles, relationships, and spirituality.
- Describe the basic principles of peritoneal dialysis (PD) and exchange options such as continuous ambulatory peritoneal dialysis (CAPD), or continuous cycling peritoneal dialysis (CCPD).
- State what types of changes are needed (if any) to support home PD therapy and maintain a clean home environment and prevent infection.
- State how to contact the primary provider, the team of home care professionals overseeing care, and supply vendor.
  - Discuss ordering, storage, and inventory of dialysis supplies.
  - List emergency phone numbers.
- State the name, dose, side effects, frequency, and schedule for all medications.
  - Demonstrate procedure for adding medications to the dialysis solution.
- Demonstrate catheter and exit site care.
- Demonstrate measurement of vital signs and weight measurement.
- Discuss monitoring and management of fluid balance.
- Discuss basic principles of aseptic technique.
- Demonstrate the CAPD or CCPD exchange procedure using aseptic technique (patients receiving CCPD should also demonstrate exchange procedure in case of failure or unavailability of cycling machine) and discuss cycling machine warning signals and how to address these signals.
- Demonstrate maintenance of home dialysis records.
- Demonstrate procedure for obtaining sterile PD fluid samples.
- Discuss routine laboratory tests needed and implications of results.
- Discuss high protein diet and diet to avoid constipation, any other dietary restrictions as indicated.
- Discuss complications of PD; prevention, recognition, and management of complications.
- Describe actions in case of emergency.
- Relate how to reach primary provider with questions or complications.
- State time and date of follow-up medical appointments, therapy, and testing.
- Collaborate with renal/dialysis social worker to coordinate financial arrangements for PD and strategies to identify and obtain resources.
- Identify sources of support (e.g., friends, relatives, faith community).

- Identify the contact details for support services for patients and their caregivers/families.
- Identify the need for health promotion, disease prevention, and screening activities.

ADLs, activities of daily living; IADLs, instrumental activities of daily living.

Because of protein loss with PD, the patient is instructed to eat a high-protein (1.2 to 1.3g/kg/day), low phosphorus, nutritious diet (NKF KDOQI, 2000). The patient is also encouraged to increase their daily fiber intake to help prevent constipation, which can impede the flow of dialysate into or out of the peritoneal cavity. Patients may gain 3 to 5 lb within a month of initiating PD, so they may be asked to limit their carbohydrate intake to avoid weight gain. Potassium and fluid restrictions are not usually necessary. Patients commonly lose at least 1 to 2 L of fluid over and above the volume of dialysate infused into the abdomen during a 24-hour period, permitting a moderate fluid intake.

Continuing and Transitional Care

Follow-up care through phone calls, visits to the dialysis clinic, outpatient department, and continuing home care assists patients in the transition to home and promotes their active participation in their own health care. Patients often check with the nurse to see if they are making the correct choices about dialysate or control of blood pressure, or simply to discuss a problem.

Patients may be seen by the PD team as outpatients once a month or more often if needed. The exchange procedure is evaluated at that time to reassess that strict aseptic technique is followed. Blood chemistry and effluent values are followed closely to make certain the therapy is adequate for the patient.

If a referral is made for home care, the home health nurse assesses the home environment and suggests modifications to accommodate the equipment and facilities needed to carry out PD. In addition, the nurse assesses the patient's and family's understanding of PD and evaluates their technique in performing PD. Assessments include checking for changes related to kidney disease; any complications such as peritonitis; medication management; and treatment-related problems such as heart failure, inadequate drainage, and weight gain or loss. The nurse continues to reinforce and clarify education about PD and ESKD and assesses the patient's and family's progress in coping with the procedure. This is also an opportunity to remind patients about the need to participate in appropriate health promotion activities and health screening (e.g., gynecologic examinations, colonoscopy).

Special Considerations: Nursing Management of the Patient on Dialysis Who Is Hospitalized

Whether undergoing HD or PD, the patient may be hospitalized for treatment of complications related to the dialysis treatment, the underlying kidney disorder, or health problems not related to renal dysfunction or its treatment.

Protecting Vascular Access

When the patient undergoing HD is hospitalized for any reason, care must be taken to protect the vascular access. The nurse assesses the vascular access for patency and takes precautions to ensure that the extremity with the vascular access is not used for measuring blood pressure or for obtaining blood specimens. Constricting dressings, restraints, or jewelry over the vascular access must be avoided as well (Inglese, 2017).

The bruit, or "thrill," over the venous access site must be evaluated at least every 8 to 12 hours. Absence of a palpable thrill or audible bruit may indicate blockage or clotting in the vascular access. Clotting can occur if the patient has an infection anywhere in the body (serum viscosity increases) or if the blood pressure has dropped. When blood flow is reduced through the access for any reason (hypotension, application of blood pressure cuff or tourniquet), the access can clot. When a patient has an HD catheter, the nurse must observe for signs and symptoms of infection such as redness, swelling, drainage from the exit site, fever, and chills. The nurse must assess the integrity of the dressing and change it as needed. Patients with kidney disease are more prone to infection; therefore, appropriate infection control measures must be used for all procedures. The patient's vascular access should not be used for any purpose other than dialysis, unless it is an emergency situation and no other access is available. In this situation, a dialysis nurse or physician should cannulate the vascular access. If accessing an HD catheter in an emergency, the catheter dwell volume should be withdrawn prior to medication or fluid administration.

Taking Precautions during Intravenous Therapy

When the patient needs IV therapy, the rate of administration must be as slow as possible to avoid volume overload in the patient with renal disease or ESKD. Accurate I&O records are essential.

Quality and Safety Nursing Alert

Because patients on dialysis cannot excrete water, rapid administration of IV fluid can result in pulmonary edema.

Monitoring Symptoms of Uremia

As metabolic end products accumulate, symptoms of uremia worsen. Patients whose metabolic rate accelerates (those receiving corticosteroid medications or parenteral nutrition, those with infections or bleeding disorders, those undergoing surgery) accumulate waste products more quickly and may require daily dialysis. These same patients are more likely than other patients receiving dialysis to experience complications.

Detecting Cardiac and Respiratory Complications

Cardiac and respiratory assessment must be conducted frequently. As fluid builds up, fluid overload, heart failure, and pulmonary edema develop. Crackles in the bases of the lungs, moist cough and frothy, blood-tinged sputum may indicate pulmonary edema.

Pericarditis may result from the accumulation of uremic toxins. If not detected and treated promptly, this serious complication may progress to pericardial effusion and cardiac tamponade. Pericarditis is detected by the patient's report of substernal chest pain, low-grade fever, and pericardial friction rub. A pulsus paradoxus (a decrease in blood pressure of more than 10 mm Hg during inspiration) is often present. When pericarditis progresses to effusion, the friction rub disappears, heart sounds become distant and muffled, ECG waves show very low voltage, and the pulsus paradoxus worsens (see Chapter 24 for further discussion of pericarditis).

The effusion may progress to life-threatening cardiac tamponade, noted by narrowing of the pulse pressure in addition to muffled or inaudible heart sounds, crushing chest pain, dyspnea, and hypotension. An emergent pericardial window procedure is performed and a chest tube is inserted to drain the pericardial effusion. The effusion fluid is sent for laboratory and cytology analysis.

Quality and Safety Nursing Alert

Although pericarditis, pericardial effusion, and cardiac tamponade can be detected by chest x-ray, they should also be detected through astute nursing assessment. Because of their clinical significance, assessment of the patient for these complications is a priority.

Controlling Electrolyte Levels and Diet

Electrolyte alterations are common, and potassium changes can be life-threatening. All IV solutions and medications to be given are evaluated for their electrolyte content. Serum laboratory values are assessed daily. If blood transfusions are required, they may be given during HD, if possible, so that excess potassium and fluid can be removed and hypervolemia is avoided. Dietary intake must also be monitored. The patient's frustrations related to

dietary restrictions typically increase if the food is unappetizing. The nurse needs to recognize that this may lead to dietary indiscretion with resultant hyperkalemia.

Hypoalbuminemia is an indicator of malnutrition in patients undergoing long-term or maintenance dialysis. Although some patients can be treated with adequate nutrition alone, some patients remain hypoalbuminemic for reasons that are poorly understood.

Managing Discomfort and Pain

Complications such as pruritus and pain secondary to neuropathy must be managed. Antihistamine agents, such as diphenhydramine, are commonly used, and analgesic medications may be prescribed. However, because elimination of the metabolites of medications occurs through dialysis rather than through renal excretion, medication dosages often need to be adjusted. Keeping the skin clean and well moisturized using bath oils, superfatted soap, and creams or lotions helps promote comfort and reduce itching. Instructing the patient to keep the nails trimmed to avoid scratching and excoriation also promotes comfort.

Monitoring Blood Pressure

Hypertension in kidney disease is common. It is usually the result of fluid overload and, in part, oversecretion of renin. Many patients undergoing dialysis receive some form of antihypertensive therapy. Patients require detailed education and reinforcement of information regarding their antihypertensive regimen, because it is not uncommon for patients to need more than one antihypertensive agent. Rapid fluid fluctuations in patients receiving dialysis also create challenges to maintaining blood pressure control. Antihypertensive agents are often withheld before dialysis and administered after dialysis to avoid hypotension due to the combined effect of fluid removal with the dialysis treatment and the medication (Campoy, 2017). Typically, these patients require multiple antihypertensive agents to achieve normal blood pressure, thus adding to the total number of medications needed on an ongoing basis (Campoy, 2017).

Preventing Infection

Patients with ESKD commonly have decreased phagocytic ability with low WBC counts, low RBC counts (anemia), impaired platelet function, and are often prescribed anticoagulants to prevent heart attacks and strokes. Together, these pose a high risk of infection and potential for bleeding after even minor trauma. Preventing and controlling infection are essential because the incidence of infection is high. Infection of the vascular access site and pneumonia are common (Inglese, 2017).

Caring for the Catheter Site

Patients receiving CAPD usually know how to care for the catheter exit site. However, the hospital stay is an opportunity to assess catheter care technique and correct misperceptions or deviations from recommended technique. Recommended daily or 3 or 4 times weekly routine catheter site care is typically performed during showering or bathing (Payton & Kennedy, 2017). The exit site should not be submerged in bathwater. The most common cleaning method is soap and water; liquid soap is recommended. During care, the nurse and patient need to make sure that the catheter remains secure to avoid tension and trauma. The patient may wear a gauze dressing over the exit site.

Administering Medications

All medications and the dosage prescribed for any patient on dialysis must be closely monitored to avoid those that are toxic to the kidneys and may threaten residual renal function. Medications are also scrutinized for potassium and magnesium content; those medications that contain them are avoided. Care must be taken to evaluate all problems and symptoms that the patient reports without automatically attributing them to kidney disease or to dialysis therapy.

Providing Psychological Support

Over time, patients undergoing chronic dialysis may begin to reevaluate their status, the treatment modality, their satisfaction with life, and the impact of these factors on their families and support systems. Nurses must provide opportunities for these patients to express their feelings and reactions and to explore options. The decision to begin dialysis does not require that dialysis be continued indefinitely, and it is not uncommon for patients to consider discontinuing treatment. These feelings and reactions must be taken seriously, and the patient should have the opportunity to discuss them with the dialysis team as well as with a psychologist, psychiatrist, psychiatric nurse, trusted friend, or spiritual advisor. After a psychiatric evaluation has ruled out depression, the patient's informed decision about discontinuing treatment should be respected. If the patient is thought to be depressed, treatment for depression should be initiated and the patient stabilized prior to participating in decisions on advanced directives (Molzahn & Schick-Makaroff, 2017).

KIDNEY SURGERY

A patient may undergo surgery or procedures in the interventional radiology department to remove obstructions that affect the kidney (tumors or calculi), to insert a tube for draining the kidney (nephrostomy, ureterostomy), or to

remove the kidney involved in unilateral kidney disease, renal carcinoma, or kidney transplantation.

Management of Patients Undergoing Kidney Surgery

Preoperative Considerations

Surgery is performed only after a thorough evaluation of renal function. Patient preparation to ensure that optimal renal function is maintained is essential. Fluids are encouraged to promote increased excretion of waste products before surgery unless contraindicated because of preexisting renal or cardiac dysfunction. If kidney infection is present preoperatively, broad-spectrum antimicrobial agents may be prescribed to prevent bacteremia. Antibiotic agents must be given with extreme care because many are toxic to the kidneys. Coagulation studies (prothrombin time, partial thromboplastin time, platelet count) may be indicated if the patient has a history of bruising and bleeding. The preoperative preparation is similar to that described in Chapter 14.

Because many patients facing kidney surgery are apprehensive, the nurse encourages the patient to recognize and verbalize concerns. Confidence is reinforced by establishing a relationship of trust and by providing expert care. Patients faced with the prospect of losing a kidney may think that they will have to depend on dialysis for the rest of their lives. The nurse reassures the patient and family that normal renal function can be maintained by a single healthy kidney.

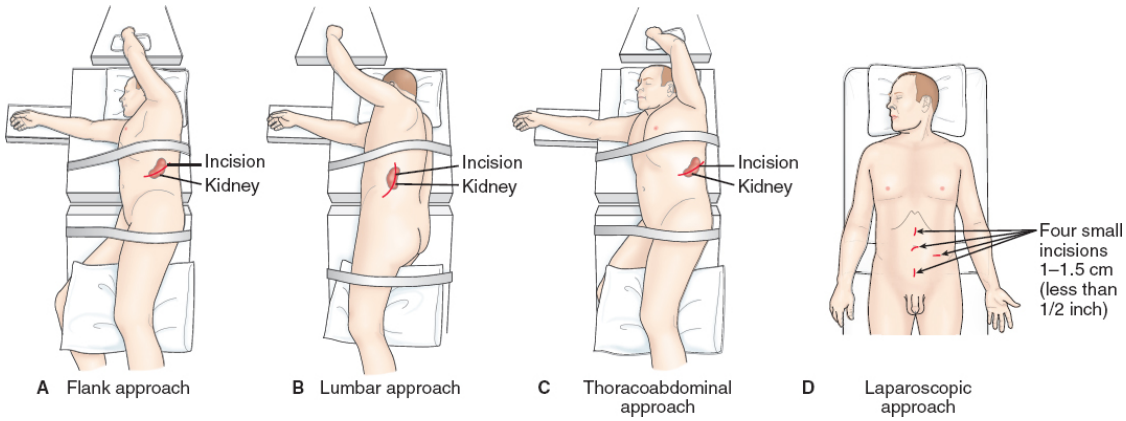

Figure 48-8 • Patient positioning and incisional approaches for nephrectomy—flank (**A**), lumbar (**B**), thoracoabdominal (**C**)—for kidney surgery are associated with significant postoperative discomfort. **(D)** Laparoscopic nephrectomy is associated with less discomfort and faster recovery times.

Perioperative Concerns

Kidney surgery requires various patient positions to expose the surgical site adequately. Three surgical approaches are common: flank, lumbar, and thoracoabdominal (see Fig. 48-8A–C). Laparoscopic urologic surgery is often performed as a less invasive option than open surgery (see Fig. 48-8D). During surgery, plans are carried out for managing altered urinary drainage. These may include inserting a nephrostomy or other drainage tube.

Postoperative Management

Because the kidney is a highly vascular organ, hemorrhage and shock are the chief potential complications of kidney surgery. Fluid and blood component replacement is frequently necessary in the immediate postoperative period to treat intraoperative blood loss.

Abdominal distention and paralytic ileus may occur after renal and ureteral surgery and are thought to be due to a reflex paralysis of intestinal peristalsis and manipulation of the colon or duodenum during surgery. Abdominal distention is relieved by decompression through a nasogastric tube. See Chapter 41 for treatment of paralytic ileus. Oral fluids are permitted when the passage of flatus is noted.

If infection occurs, antibiotics are prescribed after a culture reveals the causative organism. The toxic effects that antibiotic agents have on the kidneys (nephrotoxicity) must be kept in mind when assessing the patient. Low-dose heparin therapy may be initiated postoperatively to prevent thromboembolism in patients who have had any type of urologic surgery.

Nursing Management

In addition to those interventions listed in this section, Chart 48-13 provides a plan of nursing care for the patient undergoing kidney surgery.

Providing Immediate Postoperative Care

Immediate postoperative care of the patient who has undergone kidney surgery includes assessment of all body systems. Respiratory and circulatory status, pain level, fluid and electrolyte status, and patency and adequacy of urinary drainage systems are assessed.

Respiratory Status

As with any surgery, the use of anesthesia increases the risk of respiratory complications. Noting the location of the surgical incision assists the nurse in anticipating respiratory problems and pain. Respiratory status is assessed by monitoring the rate, depth, and pattern of respirations. The location of the

incision frequently causes pain on inspiration and coughing; therefore, the patient tends to splint the chest wall and take shallow respirations. Auscultation is performed to assess normal and adventitious breath sounds.

Circulatory Status and Blood Loss

The patient's vital signs and arterial or central venous pressure are monitored. Skin color and temperature and urine output provide information about circulatory status. The surgical incision and drainage tubes are observed frequently to help detect unexpected blood loss and hemorrhage.

Pain

Postoperative pain is a major problem for the patient because of the location of the surgical incision and patient's position on the operating table to permit access to the kidney. The location and severity of pain are assessed before and after analgesic medications are given. Abdominal distention, which increases discomfort, is also noted.

Urinary Drainage

Urine output and drainage from tubes inserted during surgery are monitored for amount, color, and type or characteristics. Decreased or absent drainage is promptly reported to the primary provider because it may indicate obstruction that could cause pain, infection, and disruption of the suture lines.

Chart 48-13 LAN OF NURSING CARE

Care of the Patient Undergoing Kidney Surgery

NURSING DIAGNOSIS: Impaired airway clearance associated with pain of high abdominal or flank incision, abdominal discomfort, and immobility; impaired breathing pattern associated with high abdominal incision
GOAL: Improved airway clearance

Nursing Interventions	Rationale	Expected Outcomes
1. Assess respiratory status: a. Rate b. Breath sounds 2. Administer analgesic agent as prescribed. 3. Splint incision with hands or pillow to assist patient in coughing. 4. Assist patient to change positions frequently. 5. Encourage the use of incentive spirometer as indicated or prescribed. 6. Assist with and encourage early ambulation.	1. Baseline data allow for monitoring of changes and evaluating effectiveness of interventions. 2. Adequate pain relief enables patient to take deep breaths and cough. 3. Splints incision and promotes adequate cough and prevention of atelectasis. 4. Promotes drainage and inflation of all lobes of the lungs. 5. Encourages adequate deep breaths. 6. Mobilizes pulmonary secretions.	• Exhibits respiratory rate of 12 to 18 breaths/min and normal breath sounds without adventitious sounds • Takes deep breaths and coughs adequately when encouraged and assisted • Exhibits full thoracic excursion without shallow respirations • Uses incentive spirometer with encouragement • Splints incision while taking deep breaths and coughing • Reports progressively less pain and discomfort with coughing and deep breaths

NURSING DIAGNOSIS: Acute pain and discomfort associated with surgical incision, positioning, and stretching of muscles during kidney surgery
GOAL: Relief of pain and discomfort

Nursing Interventions	Rationale	Expected Outcomes
1. Assess level of pain based on measureable scale rating. 2. Administer analgesic agents as prescribed. 3. Splint incision with hands or pillow during movement or deep breathing and coughing exercises. 4. Assist and encourage early ambulation. 5. Offer and educate patient how to use appropriate nonpharmacologic interventions. 6. Evaluate the effectiveness of pain relief using a scale rating.	1. Provides baseline for later evaluation of pain relief strategies. 2. Promotes pain relief. 3. Minimizes sensation of pulling or tension on incision and provides sense of support to the patient. 4. Promotes resumption of muscle activity exercise. 5. Many nonpharmacologic interventions, such as music, relaxation exercises, and imagery assist patients to decrease their pain. 6. A scale provides an objective measure of the efficacy of pain relief strategies.	• Reports decreased pain on pain scale to a level that is acceptable to the patient. • Takes analgesia as prescribed • Exercises aching muscles within recommendations • Uses music, relaxation exercises, and imagery to relieve pain • Exhibits no behavioral manifestations of pain and discomfort (e.g., restlessness, perspiration, verbal expressions of pain) • Participates in deep-breathing and coughing exercises • Gradually increases physical activity and exercise

NURSING DIAGNOSIS: Fear and anxiety associated with diagnosis, outcome of surgery, and alteration in urinary function

GOAL: Reduction of fear and anxiety

Nursing Interventions	Rationale	Expected Outcomes

1. Assess patient's anxiety and fear before surgery if possible. 2. Assess patient's knowledge about procedure and expected surgical outcome preoperatively. 3. Evaluate the meaning of alterations resulting from surgical procedure for the patient and family or partner. 4. Encourage patient to verbalize reactions, feelings, and fears. 5. Encourage patient to share feelings with spouse or partner. 6. Offer and arrange for visit from member of support group (e.g., ostomy group, transplant group, if indicated).	1. Provides a baseline for postoperative assessment. 2. Provides a basis for further education. 3. Enables understanding of patient's reactions and responses to expected and unexpected results of surgery. 4. Affirms patient's understanding of and ultimate resolution of feelings and fears. 5. Enables patient and partner to receive mutual support and reduces sense of isolation from each other. 6. Provides support from another person who has encountered the same or a similar surgical procedure and an example of how others have coped with the alteration.	• Verbalizes reactions and feelings to staff • Shares reactions and feelings with family or partner • Grieves appropriately for self and for changes in role and function • Identifies information needed to promote own adaptation and coping • Participates in activities and events in immediate environment • Accepts visit from support group if indicated • Identifies support person or support group

NURSING DIAGNOSIS: Impaired urination associated with urinary drainage; risk for urinary infection associated with altered urinary drainage
GOAL: Maintenance of urinary elimination; infection-free urinary tract

Nursing Interventions	Rationale	Expected Outcomes

1. Assess urinary drainage system immediately. 2. Assess adequacy of urinary output and patency of drainage system. 3. Assess pertinent laboratory values (see Chapter 47, Table 47-5). 4. Use asepsis and hand hygiene when providing care and manipulating drainage system. 5. Maintain closed urinary drainage system. 6. If irrigation of the drainage system is necessary, use sterile gloves and sterile irrigating solution and a closed drainage and irrigation system. 7. If irrigation is necessary and prescribed, perform it gently with sterile saline and the prescribed amount of irrigating fluid. 8. Assist patient in turning and moving in bed and when ambulating to prevent displacement or	1. Provides basis for further assessment and action. 2. Provides baseline. 3. Provides basis for further assessment and action. 4. Prevents or reduces risk of contamination of urinary drainage system. 5. Reduces risk of bacterial contamination and infection. 6. Permits irrigation when necessary while maintaining closed drainage system, minimizing risk of infection. 7. Maintains patency of the catheter or drainage system and prevents sudden increases in pressure in the urinary tract that may cause trauma, pressure on sutures or urinary tract structures, and pain. 8. Prevents trauma from accidental displacement of urinary stent or ureteral catheter necessitating repeated	• Exhibits adequate urinary output and patent drainage system • Exhibits urinary output consistent with fluid intake • Demonstrates normal laboratory values: blood urea nitrogen, serum creatinine levels, urine specific gravity, and osmolality • Exhibits sterile urine on urine culture • Exhibits clear, dilute urine without debris or encrustation in the drainage system • States rationale for avoiding manipulation of catheter, drainage, or irrigation system • Exhibits normal placement of urinary stent or ureteral catheters until removed by physician • Maintains closed urinary drainage system • Exhibits normal body temperature without signs or symptoms of

inadvertent removal of urinary stent or ureteral catheters if in place. 9. Observe urine color, volume, odor, and components. 10. Minimize trauma and manipulation of catheter, drainage system, and urethra. 11. Clean catheter gently with soap during bathing, avoiding any to-and-fro movement of catheter. 12. Anchor drainage tube with hospital-approved device (e.g., Stat-Lock). 13. Maintain adequate fluid intake. 14. Assist with and encourage early ambulation while ensuring placement of urinary drainage system. 15. If patient is to be discharged with urinary drainage system (catheter) in place or a urinary diversion, instruct patient and family member in care.	instrumentation of the urinary tract (e.g., cystoscopy) to replace them. 9. Provides information about adequacy of urine output, condition and patency of drainage system, and debris in urine. 10. Reduces risk of contamination of drainage system and eliminates site of bacterial invasion. 11. Removes debris and encrustations without causing trauma to or contamination of urethra. 12. Prevents movement or slipping of drainage tube, minimizing trauma to and contamination of urethra or catheter. 13. Promotes adequate urine output and prevents urinary stasis. 14. Minimizes cardiovascular and pulmonary complications while preventing loss, dislodging, or	urinary tract infection • Cleans catheter twice daily with soap and water or antibacterial meatal cleansing cloths • Consumes adequate fluid intake (6 to 8 glasses of water or more per day, unless contraindicated) • Urinary drainage system remains in place until physician orders discontinuation. • Maintains urinary drainage system without infection or obstruction • Maintains urinary diversion as instructed • Maintains self-care so that environment is odor free

	disruption of drainage system. 15. Knowledge and understanding of the drainage system or urinary diversion are essential to prevent infection and other complications.	
NURSING DIAGNOSIS: Risk for fluid imbalance associated with surgical fluid loss, altered urinary output, parenteral fluid administration **GOAL:** Normal fluid balance will be maintained		
Nursing Interventions	**Rationale**	**Expected Outcomes**
1. Weigh patient daily. 2. Document accurate intake and output. 3. Place all parenteral therapy on an infusion pump. 4. Monitor amount and characteristics of urine. 5. Monitor vital signs: temperature, pulse, respirations, and blood pressure. 6. Auscultate heart and lungs sounds every shift.	1. Daily weight is the most sensitive indicator of fluid loss or gain. 2. Assists in detection of fluid retention due to poor cardiac or renal output. 3. Ensures that the patient does not receive excess or insufficient IV fluids. 4. Assists in early detection of possible complications of surgery or tube insertion. 5. When fluid volume or cardiac output is altered, vital signs are affected.	• Patient's weight will be within 2 to 3 lb of patient's baseline. • Intake that exceeds output will be detected early. • The exact amount of solution is infused with no adverse effects resulting from over- or underinfusion. • Urine is clear and absent of blood, pus, or any foreign substances. • Temperature, pulse, respiration, and blood pressure are within defined limits.

	6. When fluid volume is increased because of poor cardiac or renal output, fluid accumulates in the lungs. In addition, heart sounds change as heart failure develops; frequent auscultation ensures early detection.	• Normal heart and lung sounds are present.

Monitoring and Managing Potential Complications

Bleeding is a major complication of kidney surgery. If undetected and untreated, it can result in hypovolemia and hemorrhagic shock. The nurse's role is to observe for these complications, to report their signs and symptoms, and to administer prescribed parenteral fluids and blood and blood components. Monitoring of vital signs, skin condition, the urinary drainage system, the surgical incision, and the level of consciousness is necessary to detect evidence of bleeding, decreased circulating blood, and fluid volume and cardiac output. Frequent monitoring of vital signs (initially monitored at least at hourly intervals) and urinary output is necessary for early detection of these complications.

If bleeding goes undetected or is not detected promptly, the patient may lose significant amounts of blood and may experience hypoxemia. In addition to hypovolemic shock due to hemorrhage, this type of blood loss may precipitate a myocardial infarction or transient ischemic attack. Bleeding may be suspected when the patient experiences fatigue and shortness of breath and when urine output is less than 400 mL within 24 hours. As bleeding persists, late signs of hypovolemia occur, such as cool skin, flat neck veins, and change in level of consciousness or responsiveness. Transfusions of blood components are indicated, along with surgical repair of the bleeding vessel.

Pneumonia may be prevented through the use of an incentive spirometer, adequate pain control, and early ambulation. Early signs of pneumonia include fever, increased heart and respiratory rates, and adventitious breath sounds.

Preventing infection involves using asepsis when changing dressings and handling and preparing catheters, other drainage tubes, central venous catheters, and IV catheters for administration of fluids. Insertion sites are monitored closely for signs and symptoms of inflammation: redness, drainage, heat, and pain. Special care must be taken to prevent UTI, which is associated

with the use of indwelling urinary catheters. Catheters and other invasive tubes are removed as soon as they are no longer needed.

Antibiotics are commonly given postoperatively to prevent infection. If antibiotic agents are prescribed, serum creatinine and BUN values must be monitored closely because many antibiotic agents are toxic to the kidney or can accumulate to toxic levels if renal function is compromised.

Preventing fluid imbalance is critical when caring for a patient undergoing kidney surgery, because both fluid loss and fluid excess are possible adverse effects of the surgery. Fluid loss may occur during surgery as a result of excessive urinary drainage when the obstruction is removed, or it may occur if diuretic agents are used. Such loss may also occur with GI losses, with diarrhea resulting from antibiotic use, or with nasogastric drainage. When postoperative IV therapy is inadequate to match the output or fluids lost, a fluid deficit results. Fluid excess, or overload, may result from cardiac effects of anesthesia, administration of excessive amounts of fluids, or the patient's inability to excrete fluid because of changes in renal function. Decreased urine output may be an indication of fluid excess.

Astute assessment skills are needed to detect early signs of fluid excess (such as weight gain, pedal edema, urine output below 400 mL/day, and slightly elevated pulmonary artery wedge pressure if available) before they become severe (appearance of adventitious breath sounds, shortness of breath).

Fluid excess may be treated with fluid restriction and administration of furosemide or other diuretic agents. If renal insufficiency is present, these medications may prove ineffective; therefore, dialysis may be necessary to prevent heart failure and pulmonary edema.

Deep vein thrombosis (DVT) may occur postoperatively because of surgical manipulation of the iliac vessels during surgery or prolonged immobility. Anti-embolism stockings are applied, and the patient is monitored closely for signs and symptoms of thrombosis and encouraged to exercise the legs. Heparin or other anticoagulants may be given postoperatively to reduce the risk of thrombosis.

Promoting Home, Community-Based, and Transitional Care

Educating Patients About Self-Care

If the patient has a drainage system in place, measures are taken to ensure that both the patient and family understand the importance of maintaining the system correctly at home and preventing infection. Verbal and written instructions and guidelines are provided to the patient and family at the time of hospital discharge. The patient may be asked to demonstrate or "teach back" management of the drainage system to validate understanding (see Chapter 3 for further discussion of the teach-back technique). Strategies to prevent

postoperative complications (urinary tract obstruction and infection, DVT, atelectasis, and pneumonia) are stressed to the patient and family. With both the patient and family, the nurse reviews the signs, symptoms, problems, and questions that should be referred to the physician or other primary provider.

Continuing and Transitional Care

The need for postoperative assessment and care after kidney surgery continues regardless of the setting: the home, subacute care unit, outpatient clinic or office, or rehabilitation facility. Referral for home care is indicated for the patient who is going home with a urinary drainage system in place. During the home visit, the home health nurse reviews the instructions and guidelines given to the patient at hospital discharge. The nurse assesses the patient's ability to carry out the instructions in the home and answers questions that the patient or family has about management of the drainage system and the surgical incision.

In addition, the home health nurse obtains vital signs and assesses the patient for signs and symptoms of urinary tract obstruction and infection. The nurse also ensures that pain is adequately controlled and that the patient is adhering to recommendations. The home health nurse encourages adequate fluid intake and increased levels of activity. Together, the nurse, patient, and family review the signs, symptoms, problems, and questions that should be referred to the primary provider. If the patient has a drainage tube in place, the nurse assesses the site and the patency of the system and monitors the patient for complications, such as DVT, bleeding, or pneumonia.

Because it is easy for the patient, family, and health care team to focus on the patient's immediate disorder to the exclusion of other health issues, the nurse reminds the patient and family about the importance of participating in health promotion activities, including appropriate health screenings.

Kidney Transplantation

Kidney transplantation is the treatment of choice for select and appropriately screened patients with ESKD. It is not considered a cure for ESKD since, in general, the transplant will not continue to function for the entire lifespan of most recipients (Danovitch, 2017). Patients choose kidney transplantation for various reasons, such as the desire to avoid dialysis or to improve their sense of well-being and the wish to lead a more normal life. Kidney transplantation is an elective procedure, not an emergency lifesaving procedure. Therefore, patients should be in the best possible physical condition prior to transplantation.

In the United States and globally, there are many more patients on the waiting list for kidney transplantation than there are organ donors. More than

103,356 Americans are on the waiting list to receive a kidney (Organ Procurement and Transplantation Network [OPTN], 2019). In the United States, the cost of a kidney transplant annually per person is estimated at $34,084 versus about $88,750 annually per person for in center HD (Saran, Robinson, Abbott, et al., 2018). Kidney transplantation involves transplanting a kidney from a living or deceased donor to a recipient who no longer has renal function. A living donor may or may not be related to the recipient. A deceased donor transplant comes from someone who has died and donated their organs. The term "cadaveric donor" is no longer used and the appropriate terminology is "deceased donor." Transplantation from well-matched living donors (those with compatible ABO and human leukocyte antigens) is more successful than from deceased donors, especially long term (Woodard & Arnold, 2017).

The NKF provides written information describing the organ donation program and a card specifying the organs to be donated in the event of death. The organ donation card is signed by the donor and two witnesses and should be carried by the donor at all times. In many states in the United States, drivers can indicate their desire to be organ donors on their driver's license application or renewal. However, the donor should discuss this decision with family members because the organ procurement agency will approach the family to explore this option.

Contemporary developments in kidney transplantation are paired exchanges and chains. In paired donor exchanges and chains, recipients swap compatibly matched kidneys with willing donors, who are unrelated or unknown to the recipient. Although medically eligible to donate a kidney, a willing donor may be incompatible with the intended recipient due to blood type or antigens. The donor then agrees to donate the kidney to a compatible and unknown recipient, with the intention that the donor's originally intended organ recipient will be part of the donation chain and be the recipient of a donated kidney through organized donor and recipient matches. Several national registry programs have organized systems to find a matching pair on the national level (Woodard & Arnold, 2017). See Resources at the end of the chapter.

Prior to either receiving or donating an organ, an extensive medical evaluation is performed; first on the potential recipient and then, if the recipient is deemed suitable for a transplant, the living donor is evaluated. Not everyone is suitable for kidney transplantation. Contraindications include recent malignancy, active or chronic infection (e.g., HIV, hepatitis B and C), severe irreversible extrarenal disease (e.g., inoperable cardiac disease, chronic lung disease, severe peripheral vascular disease), Class II obesity (body mass index greater than 35 kg/m^2), current substance use disorder (SUD), inability to give informed consent, active psychiatric disease, and history of nonadherence to treatment regimens (Bunnapradist et al., 2017; Woodard & Arnold, 2017).

Donors may be rejected for the same reasons or any condition that is determined to have an impact on the remaining kidney. Examples include hypertension and diabetes because both are known causes of kidney disease. It is imperative when donors are evaluated that serious consideration be given to the overall long-term health of the donor. Every precaution must be taken to ensure that the remaining kidney in the donor will remain healthy. When these conditions are met, the donor should remain healthy after donation and have a normal lifespan. Because one kidney can easily handle the body's needs, no long-term adjustments will need to be made. Routine health maintenance visits are stressed for blood pressure monitoring and preventative care.

The recipient's native kidneys are not usually removed, except for enlarged polycystic kidneys with cysts that may rupture or become infected (Bunnapradist et al., 2017). In some centers, for the patient with polycystic kidneys, the surgeon may perform a bilateral nephrectomy simultaneously with the renal transplant, while in others, the native nephrectomy precedes or is scheduled after the transplant procedure.

The transplanted kidney is placed in the patient's iliac fossa anterior to the iliac crest because it allows for easier access to the blood supply needed to perfuse the kidney. The ureter of the newly transplanted kidney is transplanted into the bladder or anastomosed to the ureter of the recipient (see Fig. 48-9). Once the blood supply has been reestablished to the transplanted kidney in the operating room, urine should begin to flow. For deceased donor kidneys, the production of urine at this stage is an important indicator of the overall success of the procedure and ultimate long-term outcome (Longton, 2017).

Preoperative Management

Preoperative management goals include bringing the patient's metabolic state to a level as close to normal as possible through diet, possibly dialysis and medical management, ensuring that the patient is free of infection, and educating the patient for surgery and the postoperative course.

Medical Management

A complete physical examination is performed on the living donor and the recipient to detect and treat any conditions that could cause complications after the living donor nephrectomy and recipient transplantation procedure. Tissue typing, blood typing, and antibody screening are performed to determine compatibility of the tissues and cells of the donor and recipient. Other diagnostic tests must be completed for both potential donor and recipient to identify conditions requiring treatment before the transplant procedure.

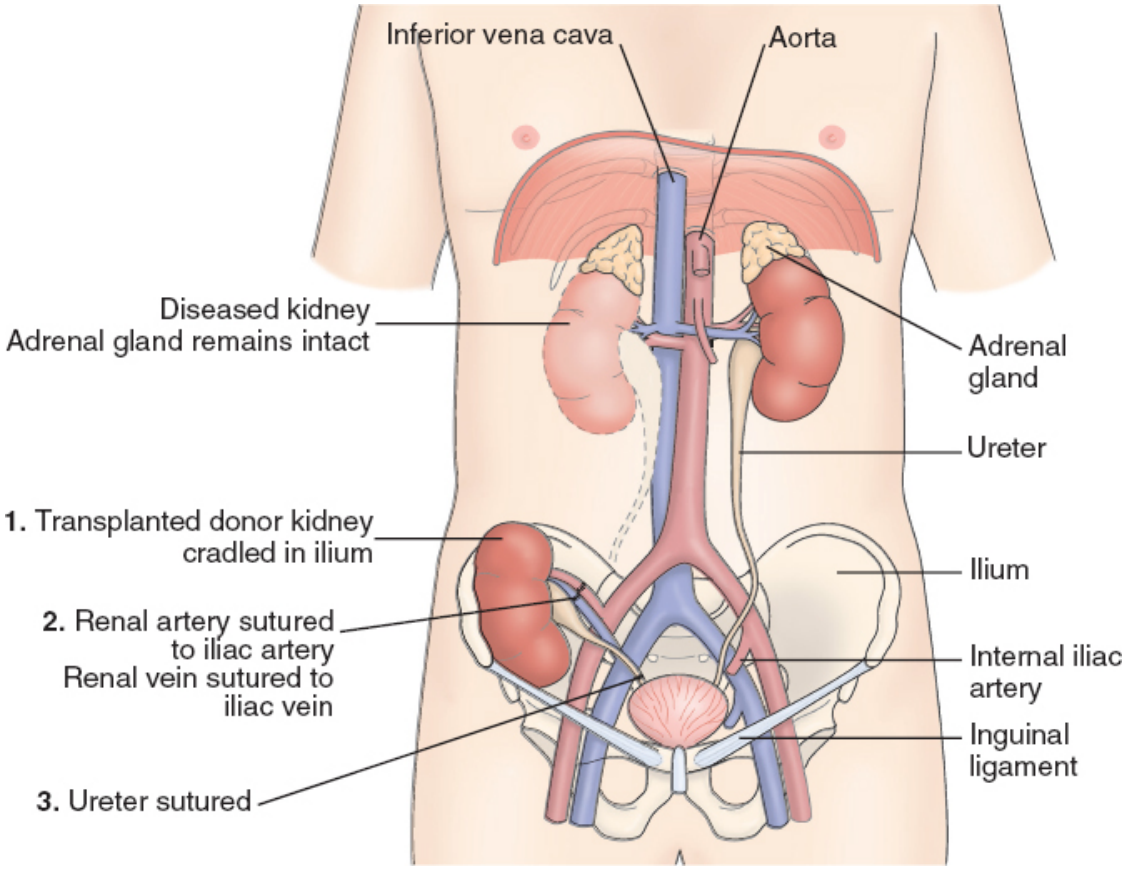

Figure 48-9 • Kidney transplantation. **1.** The transplanted kidney is placed in the iliac fossa. **2.** The renal vein of the donated kidney is sutured to the iliac vein, and the renal artery is sutured to the iliac artery. **3.** The ureter of the donated kidney is sutured to the bladder or to the patient's ureter.

Both patients must be free of infection at the time of kidney transplantation. After surgery, medications to prevent transplant rejection will be prescribed for the transplant recipient. These medications suppress the immune response, leaving the patient at risk for infection. Therefore, both the donor and recipient are evaluated and treated for any infections, including gingival (gum) disease and dental caries.

A psychosocial evaluation is conducted to assess the organ recipient's ability to adjust to the transplant, coping styles, social history, social support available, and financial resources. Psychiatric conditions are often aggravated by the corticosteroids and other medications needed for immunosuppression after transplantation, so a history of psychiatric illness is important to obtain (Shenoy & Danovitch, 2017). A psychosocial evaluation is also conducted to assess the motive of the donor for giving the organ. The donor should not be coerced to donate this organ; it should be an altruistic act (Rastogi, Hersh-Rifkin, Gritsch, et al., 2017).

Nursing Management

The nursing aspects of preoperative care for the patient undergoing kidney transplant and donation are similar to those for patients undergoing other types of kidney or elective abdominal surgery. Preoperative education can be conducted in a variety of settings, including the outpatient preadmission area, the hospital, or the transplantation clinic during the preliminary work up phase. Patient education for the kidney transplant donor and recipient addresses postoperative pulmonary hygiene, pain management options, dietary restrictions, IV lines, tubes (indwelling catheter), and early ambulation. Most patients have been on dialysis for months or years before transplantation, eagerly awaiting a kidney transplant, and are anxious about the surgery, possible rejection, and the need to return to dialysis. Helping the patient to deal with these concerns is part of the nurse's role in preoperative management, as is educating the patient about what to expect after surgery. HD may be performed before the kidney transplantation procedure. When the patient is receiving peritoneal dialysis, the patient will continue to dialyze until the surgery. The dwell will be drained prior to going to the operating room.

The patient who receives a kidney from a living related donor is often concerned about the donor and how the donor will tolerate the surgical procedure. If the patient is receiving a deceased donor transplant, the recipient may express sadness and grief over the loss of the donor's life. The nurse must maintain open communication with the recipient of the organ and allow the patient to express these concerns.

The nurse working in an intensive care setting may provide care to the organ donor who is declared brain dead prior to organ removal. In the absence of brain death, deceased donation may also occur after the heart has stopped beating (donation after cardiac death or non–heart-beating donor). The overall goal is to preserve the function of the organs through maintaining hemodynamic stability, decreasing the risk for infection, and monitoring laboratory values while providing dignified care to the donor and family members (Woodard & Arnold, 2017). Continuing care for the donor can be complex and last for more than several hours. Care is often provided in collaboration with the organ procurement and transplant coordinators.

Postoperative Management

The goal of postoperative care is to maintain homeostasis until the transplanted kidney is functioning well. The patient whose kidney functions immediately has a more favorable prognosis than the patient whose kidney does not (Longton, 2017).

Often, the living organ donor will be on the same unit as the transplant recipient. The donor will require the same level of care provided to the

recipient, including follow-up at prescribed intervals after the procedure and long-term. The organ donor often experiences more pain than the recipient, requiring more analgesia for pain control. Fluid, electrolyte, and hemodynamic status are also closely monitored in the living organ donor.

Medical Management

After a kidney transplantation, rejection and failure can occur within 24 hours (hyperacute), within 3 to 14 days (acute), or after many years (chronic). A hyperacute rejection is caused by an immediate antibody-mediated reaction that leads to generalized glomerular capillary thrombosis and necrosis. An acute rejection typically occurs within a few days to weeks of the transplant surgery, and the patient experiences an increase in serum creatinine values. If the rejection continues, the patient may have fever, tenderness at the transplant site, malaise, and oliguria, but these are generally considered late signs (Longton, 2017). An acute rejection requires early recognition and treatment with immunosuppressant therapy, whereas a hyperacute reaction would require immediate removal of the transplanted organ (Longton, 2017). The long-term survival of a transplanted kidney depends on how well it matches the recipient and how well the body's immune response is controlled. The body's immune system views the transplanted kidney as "foreign." Therefore, it continually works to reject it. To overcome or minimize the body's defense mechanisms, immunosuppressive agents are given. Optimally, medications modify the immune system enough to prevent rejection, although not enough to allow infections or malignancies to develop (see Table 48-4).

TABLE 48-4  Immunosuppressant Agents Used Following Organ Transplant

Agent	Action	Nursing Implications
tacrolimus	Calcineurin inhibitor: inhibits helper T lymphocytes	Monitor for nephrotoxicity, hyperkalemia, neurotoxicity (tremors). Assess for hypertension. Monitor tacrolimus levels
cyclosporine	Calcineurin inhibitor: selective and reversible inhibition of first phase of T-cell activation with T lymphocytes	Monitor for nephrotoxicity, hirsutism, gingival hyperplasia. Give medication with food to reduce gastrointestinal upset. Administer medication at the same time each day and ensure consistent food intake. Monitor cyclosporine levels.
sirolimus	mTOR inhibitor: inhibits the response of helper T and B lymphocytes	Instruct patient to swallow tablets whole and to avoid chewing or crushing tablets. Instruct patient to avoid grapefruit juice and grapefruit. Instruct the patient to limit exposure to sunlight. Administer 4 hours after oral cyclosporine.
mycophenolate mofetil mycophenolic acid	Antiproliferative: inhibition of T- and B-lymphocyte responses, thus inhibiting antibody formation and generation of cytotoxic T cells	Causes GI upset, diarrhea. Administer with food. Do not crush or open capsules and avoid contact with powder in capsules; wash hands thoroughly with soap and water if contact occurs. Obtain baseline complete blood count with differential prior to initiating therapy. Instruct the patient to avoid over-the-counter antacids.
belatacept	Costimulation blocker: inhibits T-lymphocyte proliferation and cytokine production	Contraindicated in patients with EBV seronegativity or unknown EBV serostatus, liver transplantation, breast-feeding. Monitor for symptoms of infection, anemia, GI symptoms, and, rarely, progressive multifocal leukoencephalopathy. Administer IV.
everolimus	mTOR inhibitor-proliferation signal inhibitors	Monitor for hypersensitivity reaction.

	Watch for changes in pulmonary status and cough. Avoid administration of live vaccines. Administer at the same time each day with food; do not crush or allow patient to chew tablet.

EBV, Epstein–Barr virus; GI, gastrointestinal; IV, intravenous; mTOR, mammalian target of rapamycin.

Adapted from Alquadan, K., Womer, K., & Casey, M. (2019). Immunosuppressive medications in kidney transplantation. In J. Feehally, J. Floege, M. Tonelli, et al. (Eds.), *Comprehensive clinical nephrology* (6th ed.). Philadelphia, PA: Elsevier.

Combinations of corticosteroids and medications specifically developed to affect the action of lymphocytes are used to minimize the body's reaction to the transplanted organ. Treatment with combinations of new agents has dramatically improved patient and graft survival rates, and now 90% to 95% of transplanted kidneys still function after 1 year (OPTN, 2019). Doses of immunosuppressive agents are often adjusted depending on the patient's immunologic response to the transplant. However, the patient will be required to take some form of immunosuppressive therapy for the entire time that they have the transplanted kidney. Grapefruit juice and grapefruit interact with many immunosuppressant medications and should be avoided (Comerford & Durkin, 2020).

The risks associated with taking these medications include nephrotoxicity, hypertension, hyperlipidemia, hirsutism, tremors, blood dyscrasias, cataracts, gingival hyperplasia, and several types of cancer (Sievers, Lum, & Danovitch, 2017).

COVID-19 Considerations

Because of the need for immunosuppression, patients who have undergone kidney transplantation are at higher risk of contracting SARS-CoV-2 (Ajaimy & Melamed, 2020). One study reported outcomes of 41 patients who had a transplanted kidney, 22 of whom had confirmed COVID-19 and 19 of whom had suspected COVID-19 (Husain, Dube, Morris, et al., 2020). Among the 41 patients, 13 needed to be hospitalized while the rest were managed on an outpatient basis being closely monitored with telehealth. The majority (80%) of patients reported fever but those requiring hospitalization were more likely to report dyspnea compared to those not requiring hospitalization. Patients requiring hospitalization also had higher serum creatinine levels upon admission, suggesting compromise of the function of their transplanted kidneys. More than half of the patients (63%), whether hospitalized or not, had a reduction in the immunosuppressive regimen but there was no reported

mortality (Husain et al., 2020). These findings suggest that it may be safe to lower the immunosuppressive regimen of patients who have undergone kidney transplantation to augment the ability of their immune system to fight COVID-19.

Nursing Management

Assessing the Patient for Transplant Rejection

After kidney transplantation, the nurse assesses the patient for signs and symptoms of transplant rejection: oliguria, edema, fever, increasing blood pressure, weight gain, and swelling or tenderness over the transplanted kidney or graft. Patients receiving cyclosporine may not exhibit the usual signs and symptoms of acute rejection. In these patients, the only sign may be an asymptomatic rise in the serum creatinine level (Longton, 2017).

Preventing Infection

The results of blood chemistry tests and leukocyte and platelet counts are monitored closely because immunosuppression depresses the formation of leukocytes and platelets. The patient is closely monitored for infection because of susceptibility to impaired healing and infections related to immunosuppressive therapy and complications of kidney disease. Clinical manifestations of infection include shaking chills, fever, tachycardia (rapid heartbeat), tachypnea (rapid respirations), as well as either leukocytosis (increase in WBCs) or leukopenia (decrease in WBCs).

Infection may be introduced through many sources. Urine cultures are performed frequently because of the high incidence of bacteriuria during early and late stages of transplantation. Any type of wound drainage should be viewed as a potential source of infection because drainage is an excellent culture medium for bacteria. Catheter and drain tips may be cultured when removed by cutting off the tip of the catheter or drain (using aseptic technique) and placing the tip in a sterile container to be sent to the laboratory for culture (see Chart 48-14).

The nurse ensures that the patient is protected from exposure to infection by hospital staff and in the environment (e.g., fresh flowers are not permitted in the transplant unit), visitors, and other patients with active infections. Attention to hand hygiene by all who come in contact with the patient is imperative.

Monitoring Urinary Function

A kidney from a living donor who is related to the patient usually begins to function immediately after surgery and may produce large quantities of dilute urine. A kidney from a deceased donor may undergo ATN and therefore may

not function for 2 or 3 weeks, during which time anuria, oliguria, or polyuria may be present. During this stage, the patient may experience significant changes in fluid and electrolyte status. Therefore, careful monitoring is indicated. The output from the urinary catheter is measured every hour. IV fluids are given on the basis of urine volume and serum electrolyte levels, as prescribed by the primary provider. HD may be necessary postoperatively to maintain homeostasis until the transplanted kidney is functioning well. It also may be required if fluid overload and hyperkalemia occur. The vascular access for HD is assessed to ensure patency and to evaluate for evidence of infection.

Chart 48-14

Kidney Transplant Rejection and Infection

Renal graft rejection and failure may occur within 24 hours (hyperacute), within 3 to 14 days (acute), or after many years (chronic). It is not uncommon for a treatable rejection episode to occur during the first year after transplantation.

Detecting Rejection

Ultrasonography may be used to detect hydronephrosis (enlargement of the kidney) due to obstruction of urine flow; percutaneous renal biopsy (most reliable) and nuclear medicine studies are used to evaluate transplant rejection. If the body rejects the transplanted kidney, the patient needs to commence dialysis. The rejected kidney may or may not be removed, depending on when the rejection occurs (acute vs. chronic) and the risk for infection if the kidney is left in place.

Potential Infection

Infection continues to be a major cause of morbidity and mortality in kidney transplant recipients, both due to the surgical procedure, the high doses of induction immunosuppression given in the postoperative period, and the continuing need for maintenance immunosuppression. The majority of infections happen in the first month after transplantation and are generally due to the complications of the surgery or invasive medical devices (IV, central line, and urinary catheters and ureteral stents) and mostly involve the genitourinary tract (since this is the focus of the surgery). The most common infections include genitourinary infections, pneumonia, wound and abdominal fluid collection infections, device-related infections, and, later in the transplant course, viral diseases. After 6 months, patients who have stable kidney function, have not required treatment for rejection or a need for reoperation are considered as having a successful outcome with stable maintenance immunosuppression and, thus, decreased infectious risks. When recipients have poor renal function, have had rejection treatments which have necessitated increased immunosuppression, and have ongoing issues with genitourinary dysfunction, opportunistic infections are more likely to present, such as cytomegalovirus (CMV) and other human herpesviruses (HHV) and polyoma virus. Despite the continuing menace of infection in renal transplant recipients, the 1-year patient survival rates are close to 100% and graft survival exceeds 90%.

Adapted from Schaenman, J., & Kubak, B. (2017). Infections in kidney transplantation. In G. Danovitch (Ed.), *Handbook of kidney transplantation* (6th ed.). Philadelphia, PA: Wolters Kluwer.

Addressing Psychological Concerns

The rejection of a transplanted kidney is of great and ongoing concern to the patient, the family, and the health care team. The fear of kidney rejection and the complications of immunosuppressive therapy (Cushing's syndrome,

diabetes, capillary fragility, osteoporosis, glaucoma, cataracts, acne, nephrotoxicity) place tremendous psychological stress on the patient. If the organ donor was a family member there may be added emotional responses that need to be addressed. Anxiety and uncertainty about the future and difficult post transplantation adjustment are often sources of stress for the patient and family.

An important nursing function is the assessment of the patient's stress and coping. Psychosocial issues are common in individuals and families with chronic diseases, and ESKD is a chronic disease (Shenoy & Danovitch, 2017). The nurse uses each visit with the patient to determine if the patient and family are coping effectively and the patient is adhering to the prescribed medication regimen. If indicated or requested, the nurse refers the patient for counseling (Longton, 2017).

Monitoring and Managing Potential Complications

The patient undergoing kidney transplantation is at risk for the postoperative complications that are associated with any surgical procedure. In addition, the patient's physical condition may be compromised because of the effects of long-standing kidney disease and its treatment. Therefore, careful assessment of the complications related to kidney disease and often, diabetes and hypertension, and those associated with a major surgery are important aspects of nursing care. Breathing exercises, early ambulation, and care of the surgical incision are priorities of postoperative care.

GI ulceration and corticosteroid-induced bleeding may occur. Therefore, preventative medications such as H_2-blockers (e.g., famotidine) or proton pump inhibitors (PPIs) (e.g., omeprazole) are prescribed. Fungal colonization of the GI tract (especially the mouth) and urinary bladder may occur secondary to immunosuppressive and antibiotic therapy; thus, prophylactic oral antifungal mouth rinses are prescribed. Closely assessing the patient and notifying the primary provider about the occurrence of these complications are important nursing interventions. In addition, the patient is monitored for any signs and symptoms of adrenal insufficiency if the immunosuppressive regimen has included the use of long-term corticosteroids.

Promoting Home, Community-Based, and Transitional Care

Educating Patients About Self-Care

The nurse works closely with the patient and family to be sure that they understand the need for continuing immunosuppressive therapy as prescribed. In addition, the patient and family are educated on how to assess for and report signs and symptoms of transplant rejection, infection, or significant adverse

effects of the immunosuppressive regimen. The patient and family are educated about the need to report decreased urine output; weight gain; malaise; fever; respiratory distress; tenderness over the transplanted kidney; anxiety; depression; changes in eating, drinking, or other habits; and changes in blood pressure. The patient is instructed to inform all health care providers (e.g., dentist) about the kidney transplant and the use of immunosuppressive agents.

Continuing and Transitional Care

The patient needs to know that follow-up care after transplantation is a lifelong necessity. Individual written instructions with verbal explanations are provided concerning diet, medication, fluids, daily weight, daily measurement of urinary output, management of oral intake, prevention of infection and rejection, resumption of activity, and avoidance of contact sports in which the transplanted kidney may be injured. Because of the risk of other potential complications, the patient is followed closely by a health care team that includes the nephrologist, transplant surgeon, transplant coordinator or nurse, social worker, transplant pharmacist, and dietitian. Medications are often obtained at one pharmacy or through the pharmacy at the hospital where the transplant surgery was performed for the purpose of accurate medication reconciliation. Follow-up with providers from the transplant team will initially occur once or twice a week upon discharge from the hospital and taper over time. Laboratory studies will also be obtained and followed on an ongoing basis to monitor the function of the kidney.

Cardiovascular disease is the major cause of morbidity and mortality after transplantation, due in part to the increasing age of patients with transplants. An additional problem is possible malignancy; patients receiving long-term immunosuppressive therapy are at higher risk for cancers than the general population (Huang & Kasiske, 2017). The nurse reminds the patient of the importance of health promotion and health screening and provides information on local transplantation support groups at the transplant hospital or through the procurement organization.

The American Association of Kidney Patients (AAKP) and the NKF (listed in the Resources section of this chapter) are nonprofit organizations that serve the needs of those with kidney disease. These groups can provide many helpful suggestions for patients and family members learning to cope with the journey of dialysis and transplantation.

RENAL TRAUMA

The kidneys are protected by the rib cage and musculature of the back posteriorly and by a cushion of abdominal wall and viscera anteriorly. They are highly mobile and are fixed only at the renal pedicle (stem of renal blood

vessels and the ureter). With traumatic injury, the kidneys can be thrust against the lower ribs, resulting in contusion and rupture. Rib fractures or fractures of the transverse process of the upper lumbar vertebrae may be associated with renal contusion or laceration.

Motor vehicle crashes, falls from heights, and assaults cause the majority of blunt renal trauma (Santucci & Chen, 2016). Failure to wear seat belts contributes to the incidence of renal trauma in motor vehicle crashes. Injuries may be blunt (deceleration forces in motor vehicle crashes, falls, athletic injuries, assaults) or penetrating (gunshot wounds, stabbings). Gunshot wounds are responsible for 86% of penetrating trauma, while stab wounds account for about 14% (Santucci & Chen, 2016).

Blunt renal trauma is classified into one of four groups, as follows:

- Contusion: Bruises or hemorrhages under the renal capsule; capsule and collecting system intact
- Minor laceration: Superficial disruption of the cortex; renal medulla and collecting system are not involved
- Major laceration: Parenchymal disruption extending into cortex and medulla, possibly involving the collecting system
- Vascular injury: Tears of renal artery or vein

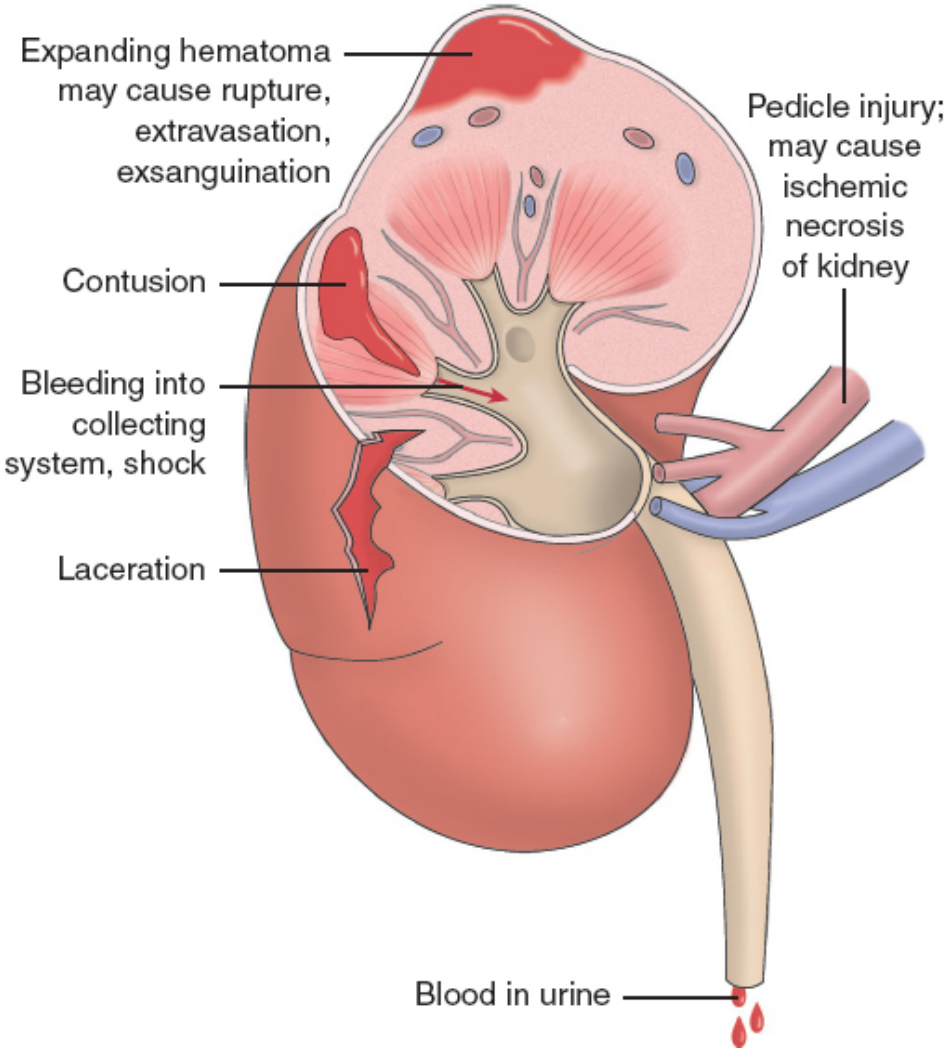

Figure 48-10 • Types and pathophysiologic effects of kidney injuries: contusions, lacerations, rupture, and pedicle injury.

The most common renal injuries are contusions, lacerations, ruptures, and renal pedicle injuries or small internal lacerations of the kidney (see Fig. 48-10). The kidneys receive half of the blood flow from the abdominal aorta; therefore, even a fairly small renal laceration can produce massive bleeding. The majority of patients are in shock when admitted to the hospitals. In some cases, there is an isolated renal artery thrombosis.

The best indicators of urinary system injury are gross and microscopic hematuria (on urinalysis or dipstick), especially in association with a history of injury or trauma (Santucci & Chen, 2016). Other clinical manifestations include pain, renal colic (due to blood clots or fragments obstructing the collecting system), mass or swelling in the flank, ecchymoses, and lacerations or wounds of the lateral abdomen and flank. There is no relationship between

the degree of hematuria and the degree of injury. Signs and symptoms of hypovolemia and shock (see Chapter 11) are likely with significant hemorrhage.

Medical Management

The goals of management in patients with renal trauma are to control hemorrhage, pain, and infection as well as to preserve and restore renal function. All urine is saved and sent to the laboratory for analysis to detect RBCs and to evaluate the course of bleeding. Serial hematocrit and hemoglobin levels are monitored closely; decreasing values indicate hemorrhage.

The patient is monitored for oliguria and signs of hemorrhagic shock, because a pedicle injury or shattered kidney can lead to rapid exsanguination (lethal blood loss). An expanding hematoma may cause rupture of the kidney capsule. To detect hematoma, the area around the lower ribs, upper lumbar vertebrae, flank, and abdomen is palpated for tenderness. A palpable flank or abdominal mass with local tenderness, swelling, and ecchymosis suggests renal hemorrhage. The area of the original mass can be outlined with a surgical marking pen so that the examiner can evaluate the area for change.

Renal trauma is often associated with other injuries to the abdominal organs (liver, colon, small intestines); therefore, the patient is assessed for skin abrasions, lacerations, and entry and exit wounds of the upper abdomen and lower thorax, because these may be associated with kidney injury. A contrast-enhanced computed tomography (CT) scan is the standard for genitourinary imaging in renal trauma when the patient is stable and not suspected of acute hemorrhage (Santucci & Chen, 2016).

With a contusion of the kidney, healing may take place with conservative measures. If the patient has microscopic hematuria and a normal CT scan, outpatient management is possible. If gross hematuria or a minor laceration is present, the patient is hospitalized and kept on bed rest until the hematuria clears. Antimicrobial medications may be prescribed to prevent infection from perirenal hematoma or urinoma (a cyst containing urine). Patients with retroperitoneal hematomas may develop low-grade fever as absorption of the clot takes place.

Surgical Management

Depending on the patient's condition and the nature of the injury, major lacerations may be treated through surgical intervention or interventional radiology treatment (angioembolization) or conservatively (bed rest, no surgery). The majority of blunt and penetrating injuries to the kidneys no longer require open surgical intervention (Santucci & Chen, 2016). However, any sudden change in the patient's condition suggests hemorrhage and requires

rapid surgical intervention. Vascular injuries require immediate exploratory surgery because of the high incidence of involvement of other organ systems and the serious complications that may result if these injuries are untreated. The patient is often in shock and requires aggressive fluid resuscitation. Nephrectomy, or surgery to remove the damaged kidney, may be required.

Early postoperative complications (within 6 months) include rebleeding, perinephric abscess formation, sepsis, urine extravasation, and fistula formation. Other complications include stone formation, infection, cysts, vascular aneurysms, and loss of renal function. Hypertension can be a complication of any surgery but usually is a late complication of kidney injury.

Nursing Management

The patient with renal trauma must be assessed frequently during the first few days after injury to detect flank and abdominal pain, muscle spasm, and swelling over the flank. During this time, the patient who has undergone surgery is educated about care of the incision and the importance of an adequate fluid intake. In addition, instructions are provided about changes that should be reported to the physician, such as fever, hematuria, flank pain, or any signs and symptoms of decreasing kidney function. Guidelines for gradually increasing activity, lifting, and driving are also explained in accordance with the physician's prescription.

Follow-up nursing care includes monitoring the blood pressure to detect hypertension and advising the patient to restrict activities for about 1 month after trauma to minimize the incidence of delayed or secondary bleeding. The patient should be advised to schedule periodic follow-up assessments of renal function (creatinine clearance, BUN, and serum creatinine analyses). If a nephrectomy was necessary, the patient is advised to wear medical identification.

CRITICAL THINKING EXERCISES

1 pq You are a staff nurse in an outpatient dialysis facility. A 28-year-old woman with ESKD is seen in the clinic for the first time and states that she wants to begin PD. The patient lives alone and is employed full-time. What are your priorities for educating this patient about the options for dialysis and what is involved with each method? How should the priorities change if the patient decides on home HD?

2 ipc A 62-year-old man who normally has HD 3 times a week has been admitted to the medical unit where you work. What nursing and interprofessional assessments are indicated during your initial interactions with him? What other interprofessional services might you try to engage?

3 ebp You are caring for a 45-year-old patient who is postoperative following a kidney transplant. What is the evidence base for treatment options for immunosuppression? Identify the criteria used to evaluate the strength of the evidence.

49 Management of Patients with Urinary Disorders

LEARNING OUTCOMES

On completion of this chapter, the learner will be able to:

1. Explain the factors contributing to upper and lower urinary tract infections.
2. Use the nursing process as a framework for care of the patient with a lower urinary tract infection.
3. Differentiate between the various adult dysfunctional voiding patterns and develop an education plan for a patient who has urinary incontinence.
4. Identify potential causes of an obstruction of the urinary tract along with the medical, surgical, and nursing management of the patient with this condition.
5. Describe the pathophysiology, clinical manifestations, medical management, and nursing management for patients with genitourinary trauma and urinary tract cancers.
6. Use the nursing process as a framework for care of the patient with renal calculi and for care of the patient undergoing urinary diversion surgery.

Inflammation
Patient Education

GLOSSARY

bacteriuria: bacteria in the urine

catheter-associated urinary tract infection (CAUTI): a urinary tract infection (UTI) associated with indwelling urinary catheters

cystectomy: surgical removal of the urinary bladder

cystitis: inflammation of the urinary bladder

functional incontinence: involuntary loss of urine due to physical or cognitive impairment

iatrogenic incontinence: involuntary loss of urine due to extrinsic medical factors

ileal conduit: transplantation of the ureters to an isolated section of the terminal ileum, with one end of the ureters brought to the abdominal wall (*synonym:* ileal loop)

interstitial cystitis: inflammation of the bladder wall that eventually causes disintegration of the lining and loss of bladder elasticity

micturition: voiding or urination

mixed incontinence: involuntary urinary leakage associated with urgency and also with exertion, effort, sneezing, or coughing

neurogenic bladder: bladder dysfunction that results from a disorder or dysfunction of the nervous system and leads to urinary incontinence

nocturia: awakening at night to urinate

overflow incontinence: involuntary urine loss associated with overdistention of the bladder

prostatitis: inflammation of the prostate gland

pyelonephritis: inflammation of the renal pelvis

pyuria: white blood cells in the urine

residual urine: urine that remains in the bladder after voiding

stress incontinence: involuntary loss of urine through an intact urethra as a result of exertion, sneezing, coughing, or changing position

suprapubic catheter: a urinary catheter that is inserted through a suprapubic incision into the bladder

ureterovesical or vesicoureteral reflux: backward flow of urine from the bladder into one or both ureters

urethritis: inflammation of the urethra

urethrovesical reflux: an obstruction to free-flowing urine leading to the reflux of urine from the urethra into the bladder

urge incontinence: involuntary loss of urine associated with a strong urge to void that cannot be suppressed

urinary frequency: voiding more often than every 3 hours

urinary incontinence: unplanned, involuntary, or uncontrolled loss of urine from the bladder

urosepsis: spread of infection from the urinary tract to the bloodstream that results in a systemic infection

The urinary system is responsible for providing the route for drainage of urine formed by the kidneys. Care of the patient with disorders of the urinary tract requires an understanding of the anatomy, physiology, diagnostic testing, medical, and nursing care, as well as rehabilitation of patients with the multiple processes that affect the urinary system. Nurses care for patients with urologic disorders in all settings. This chapter focuses on the nursing management of patients with common urinary dysfunctions, including infections, dysfunctional voiding patterns, urolithiasis, genitourinary trauma, cancer of the urinary tract, and urinary diversions.

INFECTIONS OF THE URINARY TRACT

Urinary tract infections (UTIs) are caused by pathogenic microorganisms in the urinary tract (the normal urinary tract is sterile above the urethra). UTIs are generally classified by location as infections of the lower urinary tract, involving the bladder and structures below the bladder, or upper urinary tract, involving the kidneys and ureters.

A UTI is the second most common infection in the body. UTIs account for nearly 25% of all infections and are commonly diagnosed in women visiting emergency departments in the United States. Approximately 8.1 million women are diagnosed with UTIs in the United States annually (Freeman, Martin, & Uithoven, 2017). In addition, UTIs are the cause of more than 100,000 hospital admissions annually (Freeman et al., 2017).

Fifty percent of all hospital-acquired infections are UTIs, and in the majority of cases these are **catheter-associated urinary tract infections (CAUTI)** (Freeman et al., 2017). A CAUTI is a UTI associated with indwelling urinary catheters. The definition used for ongoing monitoring is a UTI that occurs while the patient had an indwelling urinary catheter in place for more than 2 calendar days on the day that the infection was detected.

Lower Urinary Tract Infections

The sterility of the bladder is maintained by several mechanisms, especially important since the urethra is considered a clean, not a sterile space. The physical barrier of the urethra assists in keeping bacteria away from the bladder, while urine flow helps to carry any bacteria away from the bladder. In addition, ureterovesical junction competence, various antibacterial enzymes and antibodies, and antiadherent effects mediated by the mucosal cells of the

bladder all play a major part in protecting the sterility of the bladder. Abnormalities or dysfunctions of any of these mechanisms are contributing risk factors for lower UTIs (see Chart 49-1).

Lower UTIs include bacterial **cystitis** (inflammation of the urinary bladder), bacterial **prostatitis** (inflammation of the prostate gland), and bacterial **urethritis** (inflammation of the urethra).

Pathophysiology

For infection to occur, bacteria must gain access to the bladder, attach to and colonize the epithelium of the urinary tract to avoid being washed out with voiding, evade host defense mechanisms, and initiate inflammation. Many UTIs result from fecal organisms ascending from the perineum to the urethra and the bladder and then adhering to the mucosal surfaces.

Chart 49-1  **RISK FACTORS**

Urinary Tract Infection

- Contributing conditions such as:
  - Female gender
  - Diabetes
  - Pregnancy
  - Neurologic disorders
  - Gout
  - Altered states caused by incomplete emptying of the bladder and urinary stasis
- Decreased natural host defenses or immunosuppression
- Inability or failure to empty the bladder completely
- Inflammation or abrasion of the urethral mucosa
- Instrumentation of the urinary tract (e.g., catheterization, cystoscopic procedures)
- Obstructed urinary flow caused by:
  - Congenital abnormalities
  - Urethral strictures
  - Contracture of the bladder neck
  - Bladder tumors
  - Calculi (stones) in the ureters or kidneys
  - Compression of the ureters

Adapted from Eliopoulos, C. (2018). *Gerontological nursing* (9th ed.). Philadelphia, PA: Wolters Kluwer; Norris, T. L. (2019). *Porth's pathophysiology: Concepts of altered health state* (10th ed.). Philadelphia, PA: Wolters Kluwer.

Bacterial Invasion of the Urinary Tract

By increasing the normal slow shedding of bladder epithelial cells (resulting in bacteria removal), the bladder can clear large numbers of bacteria. Glycosaminoglycan (GAG), a hydrophilic protein, normally exerts a nonadherent protective effect against various bacteria. The GAG molecule attracts water molecules, forming a water barrier that serves as a defensive layer between the bladder and the urine. GAG may be impaired by certain agents (cyclamate, saccharin, aspartame, and tryptophan metabolites). The normal bacterial flora of the vagina and urethral area also interfere with adherence of *Escherichia coli.* Urinary immunoglobulin A (IgA) in the urethra may also provide a barrier to bacteria.

Reflux

An obstruction to free-flowing urine is a condition known as **urethrovesical reflux**, which is the reflux (backward flow) of urine from the urethra into the bladder (see Fig. 49-1). With coughing, sneezing, or straining, the bladder pressure increases, which may force urine from the bladder into the urethra. When the pressure returns to normal, the urine flows back into the bladder, bringing into the bladder bacteria from the anterior portions of the urethra. Urethrovesical reflux is also caused by dysfunction of the bladder neck or urethra. The urethrovesical angle and urethral closure pressure may be altered with menopause, increasing the incidence of infection in postmenopausal women.

Ureterovesical or vesicoureteral reflux refers to the backward flow of urine from the bladder into one or both ureters (see Fig. 49-1). Normally, the ureterovesical junction prevents urine from traveling back into the ureter. The ureters tunnel into the bladder wall so that the bladder musculature compresses a small portion of the ureter during normal voiding. When the ureterovesical valve is impaired by congenital causes or ureteral abnormalities, the bacteria may reach the kidneys and eventually destroy them.

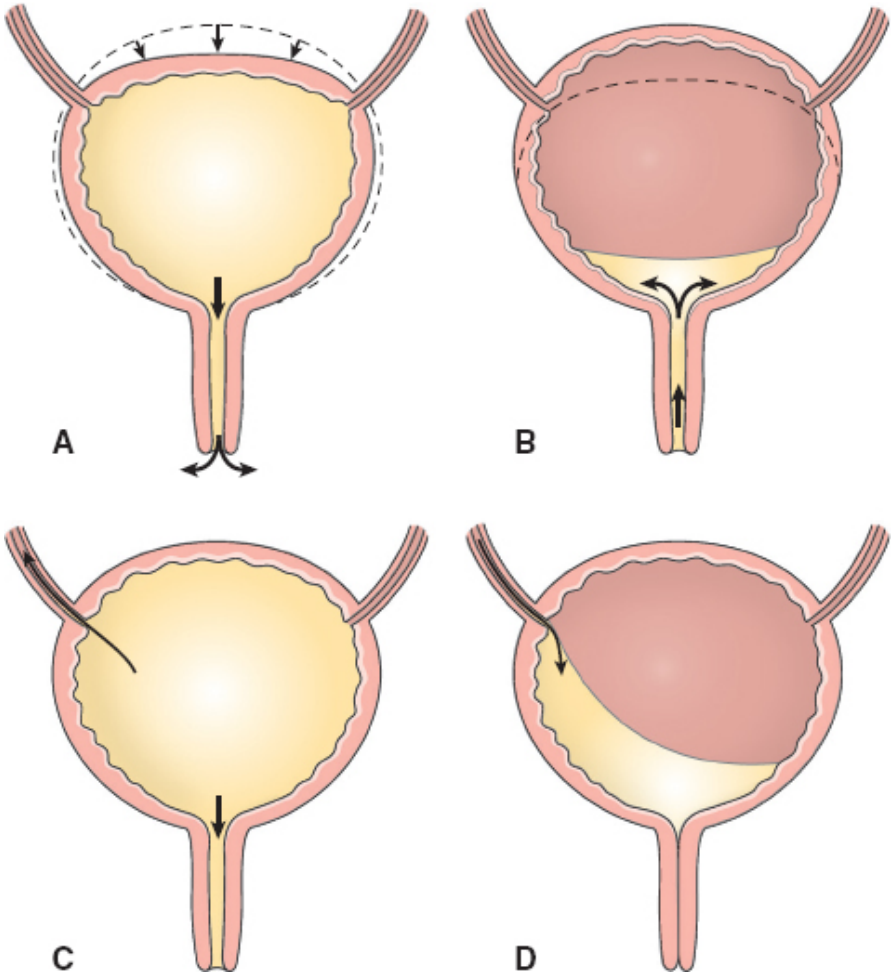

Figure 49-1 • Mechanisms of urethrovesical and ureterovesical reflux may cause urinary tract infection. *Urethrovesical reflux:* With coughing and straining, bladder pressure rises, which may force urine from the bladder into the urethra. **A.** When bladder pressure returns to normal, the urine flows back to the bladder (**B**), which introduces bacteria from the urethra to the bladder. *Ureterovesical reflux:* With failure of the ureterovesical valve, urine moves up the ureters during voiding (**C**) and flows into the bladder when voiding stops (**D**). This prevents complete emptying of the bladder. It also leads to urinary stasis and contamination of the ureters with bacteria-laden urine.

Uropathogenic Bacteria

Bacteriuria is the term used to describe the presence of bacteria in the urine. Because urine samples (especially in women) can be easily contaminated by the bacteria normally present in the urethral area, a clean-catch midstream urine specimen is the measure used to establish bacteriuria. In men, contamination of the collected urine sample occurs less frequently.

Routes of Infection

Bacteria enter the urinary tract in three ways: by the transurethral route (ascending infection), through the bloodstream (hematogenous spread), or by means of a fistula from the intestine (direct extension).

The most common route of infection is transurethral, in which bacteria (often from fecal contamination) colonize the periurethral area and subsequently enter the bladder by means of the urethra (Freeman et al., 2017; Norris, 2019). In women, the short urethra offers little resistance to the movement of uropathogenic bacteria. Penile-vaginal intercourse forces the bacteria from the urethra into the bladder. This accounts for the increased incidence of UTIs in women who engage in penile-vaginal intercourse. Bacteria may also enter the urinary tract by means of the blood from a distant site of infection or through direct extension by way of a fistula from the intestinal tract.

Clinical Manifestations

Signs and symptoms of UTI depend on whether the infection involves the lower (bladder) or upper (kidney) urinary tract and whether the infection is acute or chronic. Signs and symptoms of an uncomplicated lower UTI include burning on urination, **urinary frequency** (voiding more than every 3 hours), urgency, **nocturia** (awakening at night to urinate), incontinence, and suprapubic or pelvic pain. Hematuria and back pain may also be present (Martin, Wingo, & Holland, 2019). In older adults, these symptoms are less common (see Gerontologic Considerations section).

In patients with complicated UTIs, manifestations can range from asymptomatic bacteriuria to gram-negative sepsis with shock. Complicated UTIs often are caused by a broader spectrum of organisms, have a lower response rate to treatment, and tend to recur. Many patients with CAUTIs are asymptomatic; however, any patient with a catheter who suddenly develops signs and symptoms of septic shock should be evaluated for **urosepsis** (the spread of infection from the urinary tract to the bloodstream that results in a systemic infection).

Gerontologic Considerations

The incidence of bacteriuria in older adults differs from that in younger adults. Bacteriuria increases with age and disability, and women are affected more frequently than men. UTI is the most common infection of older adults and increases in prevalence with age. UTIs occur more frequently in women than in men at younger ages but the gap between the sexes narrows in later life, which is due to reduced penile-vaginal intercourse in women and a higher incidence of bladder outlet obstruction secondary to benign prostatic hyperplasia in men (Eliopoulos, 2018).

In older adults, structural abnormalities secondary to decreased bladder tone, **neurogenic bladder** (dysfunctional bladder) secondary to stroke, or autonomic neuropathy of diabetes may prevent complete emptying of the bladder and increase the risk of UTI (Eliopoulos, 2018). When indwelling catheters are used, the risk of CAUTI increases dramatically. Older women often have incomplete emptying of the bladder and urinary stasis. In the absence of estrogen, postmenopausal women are susceptible to colonization and increased adherence of bacteria to the vagina and urethra. Oral or topical estrogen has been used to restore the glycogen content of vaginal epithelial cells and an acidic pH for some postmenopausal women with recurrent cystitis.

The antibacterial activity of prostatic secretions that protect men from bacterial colonization of the urethra and bladder decreases with aging. The use of catheterization or cystoscopy in evaluation or treatment for prostatic hyperplasia or carcinoma, strictures of the urethra, and neuropathic bladder may contribute to the higher incidence of UTIs in men. The incidence of bacteriuria also increases in men with confusion, dementia, or bowel or bladder incontinence. The most common cause of recurrent UTIs in older males is chronic bacterial prostatitis. Resection of the prostate gland may help reduce its incidence (see Chapter 53).

Chart 49-2

Factors That Contribute to Urinary Tract Infection in Older Adults

- Cognitive impairment
- Frequent use of antimicrobial agents
- High incidence of multiple chronic medical conditions
- Immune compromised
- Immobility and incomplete emptying of bladder
- Low fluid intake and excessive fluid loss
- Obstructed flow of urine (e.g., urethral strictures, neoplasms, clogged indwelling catheter)
- Poor hygiene practices

Adapted from Eliopoulos, C. (2018). *Gerontological nursing* (9th ed.). Philadelphia, PA: Wolters Kluwer.

Chart 49-2 lists other factors that may contribute to UTI in older patients. Diligent hand hygiene, careful perineal care, and frequent toileting may decrease the incidence of UTIs.

The organisms responsible for UTIs in older adults residing in institutions may differ from those found in patients residing in the community; this is thought to result in part from the frequent use of antibiotic agents by patients

in long-term care facilities. *Escherichia coli* is the most common organism seen in older patients in the community or hospital. However, patients with indwelling catheters are more likely to be infected with organisms such as *Proteus, Klebsiella, Pseudomonas,* or *Staphylococcus*. Patients who have been previously treated with antibiotics may be infected with *Enterococcus* species. Frequent reinfections are common in older adults.

Early symptoms of UTI in postmenopausal women and older adults include malaise, nocturia, urinary incontinence, or a complaint of foul-smelling urine. Additional early symptoms include burning, urgency, and fever (Eliopoulos, 2018; Freeman et al., 2017). Some patients develop incontinence and delirium with the onset of a UTI.

Antibiotics are prescribed when bacteriuria is present (Eliopoulos, 2018). Treatment regimens are generally the same as those for younger adults, although age-related changes in the intestinal absorption of medications and decreased kidney function and hepatic flow may necessitate alterations in the antimicrobial regimen. Kidney function must be monitored, and medication dosages should be altered accordingly. The nurse carefully monitors fluid intake and output. Increasing fluid intake is advisable, provided that the patient's cardiac status does not contraindicate this action (Eliopoulos, 2018).

Assessment and Diagnostic Findings

Results of various tests, such as bacterial colony counts, cellular studies, and urine cultures, help confirm the diagnosis of UTI. In an uncomplicated UTI, the strain of bacteria determines the antibiotic of choice (Norris, 2019).

Urine Cultures

Urine cultures are useful for documenting a UTI and identifying the specific organism present. UTI is diagnosed by bacteria in the urine culture. A colony count greater than 100,000 CFU/mL of urine on a clean-catch midstream or catheterized specimen indicates infection (Fischbach & Fischbach, 2018). However, symptoms of UTI and subsequent sepsis have occurred with lower bacterial colony counts. The presence of any bacteria in specimens obtained by suprapubic needle aspiration of the urinary bladder, straight catheterization (insertion of a tube into the urinary bladder), or during surgery or cystoscopy is considered clinically significant (Fischbach & Fischbach, 2018).

The following groups of patients should have urine cultures obtained when bacteriuria is present (Fischbach & Fischbach, 2018; Norris, 2019):

- All children
- All men (because of the likelihood of structural or functional abnormalities)

- Patients who have been recently hospitalized or who live in long-term care facilities
- Patients who have undergone recent instrumentation (including catheterization) of the urinary tract
- Patients with diabetes
- Patients with prolonged or persistent symptoms
- Patients with three or more UTIs in the previous year
- Women who are postmenopausal
- Women who are pregnant
- Women who are sexually active
- Women who have new sexual partners
- Women with a history of compromised immune function or renal problems

Cellular Studies

Microscopic hematuria is present in about half of patients with an acute UTI (see Chapter 47). **Pyuria** (white blood cells [WBCs] in the urine) occurs in all patients with UTI; however, it is not specific for bacterial infection. Pyuria can also be seen with renal calculi, interstitial nephritis, and renal tuberculosis.

Other Studies

A multiple-test dipstick often includes testing for WBCs, known as the leukocyte esterase test, and nitrite testing (Norris, 2019). Tests for sexually transmitted infections may be performed because acute urethritis caused by sexually transmitted organisms (i.e., *Chlamydia trachomatis, Neisseria gonorrhoeae,* herpes simplex) or acute vaginitis infections (caused by *Trichomonas* or *Candida* species) may be responsible for symptoms similar to those of UTIs.

X-ray images, computed tomography (CT) scan, ultrasonography, and kidney scans are useful diagnostic tools. A CT scan may detect pyelonephritis or abscesses. Ultrasonography and kidney scans are extremely sensitive for detecting obstruction, abscesses, tumors, and cysts (Norris, 2019).

Medical Management

Management of UTIs typically involves pharmacologic therapy and patient education. Various prescribed medication regimens are used to treat UTI. The American Urological Association (AUA) guidelines for treatment of UTIs, particularly for recurrent uncomplicated UTIs in women, guide medical management (AUA, 2019a, 2019b).

Acute Pharmacologic Therapy

The ideal medication for treatment of UTI in women is an antibacterial agent that eradicates bacteria from the urinary tract with minimal effects on fecal and vaginal flora, thereby minimizing the incidence of vaginal yeast infections. The antibacterial agent should be affordable and should have few adverse effects and low resistance. Because the organism in initial, uncomplicated UTIs in women is most likely *E. coli* or other fecal flora, the agent should be effective against these organisms. Various treatment regimens have been successful in treating uncomplicated lower UTIs in women: single-dose administration, short-course (3-day) regimens, or 7-day regimens (Freeman et al., 2017). The trend is toward a shortened course of antibiotic therapy for uncomplicated UTIs, because most cases are cured after 3 days of treatment. Medications commonly used to treat UTIs are listed in Table 49-1. Regardless of the regimen prescribed, the patient is instructed to take all doses prescribed, even if relief of symptoms occurs promptly. Longer medication courses are indicated for men, pregnant women, and women with pyelonephritis and other types of complicated UTIs. Men with UTIs should be evaluated for possible prostatitis (Eliopoulos, 2018). Hospitalization and intravenous (IV) antibiotics are occasionally necessary (Freeman et al., 2017).

TABLE 49-1 Select Medications Used to Treat Urinary Tract Infections and Pyelonephritis

Drug Classes	Generic Name	Major Indications
Anti-infective, urinary tract Bactericidal	Nitrofurantoin	UTI
	Cephalexin	Genitourinary infection
Cephalosporin	Cefadroxil	UTI
Fluoroquinolone	Ciprofloxacin Ofloxacin Norfloxacin Gatifloxacin	UTI Pyelonephritis
Fluoroquinolone	levofloxacin	Uncomplicated UTI
Penicillin	ampicillin amoxicillin	UTI—not commonly used alone due to *Escherichia coli* resistance Pyelonephritis UTI—not commonly used alone due to *E. coli* resistance
Trimethoprim–sulfamethoxazole combination	Co-trimoxazole	UTI Pyelonephritis
Urinary analgesic agent	Phenazopyridine	For relief of burning, pain, and other symptoms associated with UTI

UTI, urinary tract infection.

Adapted from Comerford, K. C., & Durkin, M. A. (2020). *Nursing 2020 drug handbook* (40th ed.). Philadelphia, PA: Wolters Kluwer.

Long-Term Pharmacologic Therapy

Although pharmacologic treatment of UTIs for 3 days is usually adequate in women, infection recurs in about 20% of women treated for uncomplicated UTIs. Infections that recur within 2 weeks of therapy do so because organisms of the original offending strain remain. Relapses suggest that the source of bacteriuria may be the upper urinary tract or that initial treatment was inadequate or given for too short a time. Recurrent infections in men are usually caused by persistence of the same organism; further evaluation and treatment are indicated (Eliopoulos, 2018).

If infection recurs after completing antimicrobial therapy, another short course (3 to 4 days) of full-dose antimicrobial therapy followed by a regular bedtime dose of an antimicrobial agent may be prescribed.

A meta-analysis of nine studies reported the daily intake of cranberry, especially in the form of capsules, significantly reduced the rate of recurrent UTI compared to placebo with minor adverse effects such as rash and gastrointestinal symptoms (Tambunan & Rahardjo, 2019). The same meta-

analysis reported that antibiotics were more effective for the treatment of recurrent UTI compared to cranberry capsules but had more severe adverse effects including gastrointestinal symptoms and Stevens–Johnson syndrome (Tambunan & Rahardjo, 2019).

NURSING PROCESS

The Patient with a Lower Urinary Tract Infection

Nursing care of the patient with a lower UTI focuses on treating the underlying infection and preventing a recurrence.

Assessment

A history of pertinent signs and symptoms is obtained from the patient with a suspected UTI. The presence of pain, frequency, urgency, hesitancy, and changes in urine are assessed, documented, and reported. The patient's usual pattern of voiding is assessed to detect factors that may predispose them to UTI. Infrequent emptying of the bladder, the association of symptoms of UTI with penile-vaginal intercourse, contraceptive practices, and personal hygiene are assessed. The patient's knowledge about prescribed antimicrobial medications and preventive health care measures is also assessed. In addition, the urine is assessed for volume, color, concentration, cloudiness, and odor—all of which are altered by bacteria in the urinary tract. Patients need to be asked specifically about the use of complementary and alternative medicine (CAM) therapies. Women with **interstitial cystitis** (inflammation of the bladder wall) use both complementary and conventional therapies. CAM therapies reported include behavioral therapy, physical therapy, stress reduction, and dietary manipulation (Oh-oka, 2017). Clinical efficacy was reported in a year-long clinical trial of intensive dietary manipulation (Oh-oka, 2017).

Diagnosis

Nursing Diagnoses

Based on the assessment data, nursing diagnoses may include the following:

- Acute pain associated with infection within the urinary tract
- Lack of knowledge about factors predisposing the patient to infection and recurrence, detection and prevention of recurrence, and pharmacologic therapy

Collaborative Problems/Potential Complications

Potential complications may include the following:

- Sepsis (urosepsis)
- The long term result of either extensive infective or inflammatory processes have the potential to result in either acute kidney injury or chronic kidney disease.

Planning and Goals

Major goals for the patient may include relief of pain and discomfort, increased knowledge of preventive measures and treatment modalities, and absence of complications.

Nursing Interventions

Relieving Pain

The pain associated with a UTI is quickly relieved once effective antimicrobial therapy is initiated. Antispasmodic agents may also be useful in relieving bladder irritability and pain. Analgesic agents and the application of heat to the perineum help relieve pain and spasm. The patient is encouraged to drink liberal amounts of fluids (water and cranberry juice are the best choices) to promote renal blood flow and to flush the bacteria from the urinary tract. Urinary tract irritants (e.g., coffee, tea, citrus, spices, colas, alcohol) should be avoided. Frequent voiding (every 2 to 3 hours) is encouraged to empty the bladder completely, because doing so can lower urine bacterial counts, reduce urinary stasis, and prevent reinfection (Wu, Grealish, Moyle, et al., 2020).

Monitoring and Managing Potential Complications

Early recognition of UTI and prompt treatment are essential to prevent recurrent infection and the possibility of complications, such as kidney disease, sepsis (urosepsis), strictures, and obstructions. The goal of treatment is to prevent infection from progressing and causing permanent kidney damage and injury. Thus, the patient must be educated to recognize early signs and symptoms, to test for bacteriuria, and to initiate treatment as prescribed. Appropriate antimicrobial therapy, liberal fluid intake, frequent voiding, and hygienic measures are commonly prescribed for managing UTIs. The patient is instructed to notify the primary provider if fatigue, nausea, vomiting, fever, or pruritus occurs. Periodic monitoring of renal function and evaluation for strictures, obstructions, or stones may be indicated for patients with recurrent UTIs.

Chart 49-3 PATIENT EDUCATION

Preventing Recurrent Urinary Tract Infections

The nurse instructs the patient on the following basic information:

Hygiene

- Shower rather than bathe in the tub because bacteria in the bathwater may enter the urethra.
- Clean the perineum and urethral meatus from front to back after each bowel movement. This will help reduce concentrations of pathogens at the urethral opening and, in women, the vaginal opening.

Fluid Intake

- Drink liberal amounts of fluids daily to flush out bacteria. It may be helpful to include at least one glass of cranberry juice per day.
- Avoid coffee, tea, colas, alcohol, and other fluids that are urinary tract irritants.

Voiding Habits

Void every 2 to 3 hours during the day, and completely empty the bladder. This prevents overdistention of the bladder and compromised blood supply to the bladder wall. Both predispose the patient to urinary tract infection. Precautions expressly for women include voiding immediately after penile-vaginal intercourse.

Interventions

- Take medication *exactly* as prescribed. Special timing of administration may be required.
- Keep in mind that if bacteria continue to appear in the urine, long-term antimicrobial therapy may be required to prevent colonization of the periurethral area and recurrence of infection.
- For recurrent infection, consider daily consumption of cranberry juice or capsules.
- If prescribed, test urine for presence of bacteria following manufacturer's and health care provider's instructions.
- Notify the primary provider if fever occurs or if signs and symptoms persist.
- Consult the primary provider regularly for follow-up.

Adapted from Tambunan, M. P., & Rahardjo, H. E. (2019). Cranberries for women with recurrent urinary tract infection: A meta-analysis. *Medical Journal of Indonesia*, *28*(3), 268–275.

Patients with UTIs are at increased risk for gram-negative sepsis. For each day a urinary catheter is in place, the risk of developing CAUTI increases by 3% to 7% per day of catheterization (Gould, Umscheid, Agarwal, et al., 2019). The Centers for Medicare and Medicaid Services has classified a CAUTI as a "never event" which means no reimbursement to pay for the cost of treatment will be covered by CMS or other insurers if the CAUTI is incurred within an acute care or rehabilitation hospital (Gould et al., 2019). Urosepsis mortality rates following catheterization are reported to be 25% to 60% (Newman, 2017).

Careful assessment of vital signs and level of consciousness may alert the nurse to kidney involvement or impending sepsis. Positive blood cultures and elevated WBC counts must be reported immediately. At the same time, appropriate antibiotic therapy and increased fluid intake are prescribed (IV antibiotic therapy and fluids may be required). Aggressive early treatment is the key to reducing the mortality rate associated with CAUTI especially in older patients, those with anemia, and those with elevated blood glucose levels (McCoy, Paredes, Allen, et al., 2017; Taylor, 2018).

PROMOTING HOME, COMMUNITY-BASED, AND TRANSITIONAL CARE

Educating Patients About Self-Care. In helping patients learn about and prevent or manage a recurrent UTI, the nurse implements education that meets the patient's needs. Health-related behaviors that help prevent recurrent UTIs include practicing careful personal hygiene, increasing fluid intake to promote voiding and dilution of urine, urinating regularly and more frequently, and adhering to the therapeutic regimen (Martin et al., 2019). For a detailed discussion of patient education, see Chart 49-3.

Evaluation

Expected patient outcomes may include:

1. Experiences relief of pain
   a. Reports absence of pain, urgency, frequency, nocturia, or hesitancy on voiding
   b. Takes analgesic, antispasmodic, and antibiotic agents as prescribed
2. Explains UTIs and their treatment
   a. Demonstrates knowledge of preventive measures and prescribed treatments
   b. Drinks 8 to 10 glasses of fluids daily
   c. Voids every 2 to 3 hours
   d. Produces urine that is clear and odorless
3. Experiences no complications
   a. Reports no symptoms of infection (fever, frequency)

b. Has normal kidney function, negative urine and blood cultures
c. Exhibits normal vital signs and temperature; no signs or symptoms of sepsis (urosepsis)
d. Maintains adequate urine output more than 400 mL/day

Upper Urinary Tract Infections

Upper UTIs are much less common than those in the lower urinary tract. Acute pyelonephritis and chronic pyelonephritis are thought to be the most likely type, with interstitial nephritis (inflammation of the kidney) and kidney abscesses also a potential cause. Upper UTIs are a common cause of urosepsis (Freeman et al., 2017).

Pyelonephritis is a bacterial infection of the renal pelvis, tubules, and interstitial tissue of one or both kidneys. Causes involve either the upward spread of bacteria from the bladder or spread from systemic sources reaching the kidney via the bloodstream. Bacteria from a bladder infection can ascend into the kidney, resulting in pyelonephritis. An incompetent ureterovesical valve or obstruction occurring in the urinary tract increases the susceptibility of the kidneys to infection (see Fig. 49-1), because static urine provides a good medium for bacterial growth. Bladder or prostate tumors, strictures, benign prostatic hyperplasia, and urinary stones are some potential causes of obstruction that can lead to infections. Systemic infections (such as tuberculosis) can spread to the kidneys and result in abscesses. Pyelonephritis may be acute or chronic.

Acute Pyelonephritis

Acute pyelonephritis is the cause of more than 25,000 hospital admissions annually and usually leads to enlargement of the kidneys with interstitial infiltrations of inflammatory cells (Freeman et al., 2017; Norris, 2019). Abscesses may be noted on or within the renal capsule and at the corticomedullary junction. Eventually, atrophy and destruction of tubules and the glomeruli may result.

Clinical Manifestations

The patient with acute pyelonephritis has chills, fever, leukocytosis, bacteriuria, and pyuria. Low back pain, flank pain, nausea and vomiting, headache, malaise, and painful urination are common findings. Physical examination reveals pain and tenderness in the area of the costovertebral angle

(see Chapter 47, Fig. 47-6). In addition, symptoms of lower urinary tract involvement, such as urgency and frequency, are common.

Assessment and Diagnostic Findings

An ultrasound study or a CT scan may be performed to locate an obstruction in the urinary tract. Relief of obstruction is essential to prevent complications and eventual kidney damage. An IV pyelogram may be indicated if functional and structural renal abnormalities are suspected (Fischbach & Fischbach, 2018). Radionuclide imaging with gallium citrate and indium-111 (^{111}In)–labeled WBCs may be useful to identify sites of infection that may not be visualized on CT scan or ultrasound. Urine culture and sensitivity tests are performed to determine the causative organism so that appropriate antimicrobial agents can be prescribed (Fischbach & Fischbach, 2018).

Medical Management

Patients with acute uncomplicated pyelonephritis are most often treated on an outpatient basis if they are not exhibiting acute symptoms of sepsis, dehydration, nausea, or vomiting. Patients treated on an outpatient basis must be willing and able to take their medications as prescribed. For outpatients, a 2-week course of antibiotic agents is recommended because renal parenchymal disease is more difficult to eradicate than mucosal bladder infections. Commonly prescribed agents include many of the same medications prescribed for the treatment of UTIs (see Table 49-1).

Following acute pyelonephritis treatment, the patient may develop a chronic or recurring symptomless infection persisting for months or years. After the initial antibiotic regimen, the patient may need antibiotic therapy for up to 6 weeks if a relapse occurs. A follow-up urine culture is obtained 2 weeks after completion of antibiotic therapy to document clearing of the infection.

Hydration with oral or parenteral fluids is essential in all patients with UTIs when there is adequate kidney function. Hydration helps facilitate “flushing” of the urinary tract and reduces pain and discomfort.

Chronic Pyelonephritis

Repeated bouts of acute pyelonephritis may lead to chronic pyelonephritis. When pyelonephritis becomes chronic, the kidneys become scarred, contracted, and nonfunctioning. Chronic pyelonephritis is a cause of chronic kidney disease that can result in the need for renal replacement therapy (RRT) such as transplantation or dialysis (see Chapter 48 for discussion of RRT).

Clinical Manifestations

The patient with chronic pyelonephritis usually has no symptoms of infection unless an acute exacerbation occurs. Noticeable signs and symptoms may include fatigue, headache, poor appetite, polyuria, excessive thirst, and weight loss. Persistent and recurring infection may produce progressive scarring of the kidney, resulting in chronic kidney disease (see Chapter 48).

Assessment and Diagnostic Findings

The extent of the disease is assessed by an IV urogram and measurements of creatinine clearance, blood urea nitrogen, and creatinine levels (Fischbach & Fischbach, 2018).

Complications

Complications of chronic pyelonephritis include end-stage kidney disease (from progressive loss of nephrons secondary to chronic inflammation and scarring), hypertension, and formation of renal calculi (from chronic infection with urea-splitting organisms).

Medical Management

Bacteria, if detected in the urine, are eradicated if possible. Long-term use of prophylactic antimicrobial therapy may help limit recurrence of infections and kidney scarring. Impaired kidney function alters the excretion of antimicrobial agents and necessitates careful monitoring of kidney function, especially if the medications are potentially toxic to the kidneys.

Nursing Management

The patient may require hospitalization or may be treated as an outpatient. When the patient requires hospitalization, fluid intake and output are carefully measured and recorded. Unless contraindicated, 3 to 4 L of fluids per day is encouraged to dilute the urine, decrease burning on urination, and prevent dehydration. The nurse assesses the patient's temperature every 4 hours and administers antipyretic and antibiotic agents as prescribed.

TABLE 49-2 Conditions Causing Adult Voiding Disorders

Disorder	Voiding Dysfunction	Treatment
Neurogenic Disorders		
Cerebellar ataxia	Incontinence or dyssynergia	Timed voiding; anticholinergic agents
Stroke	Retention or incontinence	Anticholinergic agents; bladder retraining
Dementia	Incontinence	Prompted voiding; anticholinergic agents
Diabetes	Incontinence and/or incomplete bladder emptying	Timed voiding; EMG/biofeedback; pelvic floor nerve stimulation; anticholinergic/antispasmodic agents; well-controlled blood glucose levels
Multiple sclerosis	Incontinence or incomplete bladder emptying	Timed voiding; EMG/biofeedback to learn pelvic muscle exercises and urge inhibition; pelvic floor nerve stimulation; antispasmodic agents
Parkinson's disease	Incontinence	Anticholinergic/antispasmodic agents
Spinal Cord Dysfunction		
Acute injury	Urinary retention	Indwelling catheter
Degenerative disease	Incontinence and/or incomplete bladder emptying	EMG/biofeedback; pelvic floor nerve stimulation; anticholinergic agents
Nonneurogenic Disorder		
"Bashful bladder"	Inability to initiate voiding in public bathrooms	Relaxation therapy; EMG/biofeedback
Overactive bladder	Urgency, frequency, and/or urge incontinence	EMG/biofeedback; pelvic floor nerve stimulation; bladder drill (see Chart 49-6); anticholinergic agents
Post general surgery	Acute urine retention	Catheterization
Postprostatectomy	Incontinence	*Mild:* Biofeedback; bladder drill (see Chart 49-6); pelvic floor nerve stimulation *Moderate/severe:* Surgery—artificial sphincter
Stress incontinence	Incontinence with cough, laugh, sneeze, position change	*Mild:* Biofeedback; bladder drill (see Chart 49-6); periurethral bulking with collagen *Moderate/severe:* Surgery

EMG, electromyogram.

Adapted from Hickey, J. V., & Strayer, A. L. (2020). *The clinical practice of neurological and neurosurgical nursing* (8th ed.). Philadelphia, PA: Wolters Kluwer.

Patient education focuses on prevention of further infection by consuming adequate fluids, emptying the bladder regularly, and performing recommended perineal hygiene. The importance of taking antimicrobial medications exactly as prescribed is stressed, as is the need for keeping follow-up appointments.

ADULT VOIDING DYSFUNCTION

The **micturition** (voiding or urination) process involves several highly coordinated neurologic responses that mediate bladder function. A functional urinary system allows for appropriate bladder filling and complete bladder emptying (see Chapter 47). If voiding dysfunction goes undetected and untreated, the upper urinary system may be compromised. Both neurogenic and nonneurogenic disorders can cause adult voiding dysfunction (see Table 49-2). Chronic incomplete bladder emptying from poor detrusor pressure results in recurrent bladder infection. Incomplete bladder emptying due to bladder outlet obstruction (such as benign prostatic hyperplasia), causing high-pressure detrusor contractions, can result in hydronephrosis from the high detrusor pressure that radiates up the ureters to the renal pelvis.

Urinary Incontinence

More than 25 million adults in the United States are estimated to have **urinary incontinence** (unplanned, involuntary, or uncontrolled loss of urine from the bladder); however, it is difficult to determine exact numbers as there are many types of urinary incontinence. The prevalence is thought to be 9% to 12% of all adults in the United States, but women are affected twice as often as men (Norris, 2019). Urinary incontinence is more common in older adults, with rates of between 50% and 90% reported in older adults residing in institutions (Eliopoulos, 2018).

Chart 49-4 RISK FACTORS

Urinary Incontinence

- Age-related changes in the urinary tract
- Caregiver or toilet unavailable
- Cognitive disturbances—dementia, Parkinson's disease
- Class III obesity (also called extreme or severe obesity)
- Diabetes
- Genitourinary surgery
- High-impact exercise
- Immobility
- Incompetent urethra due to trauma or sphincter relaxation
- Medications—diuretic, sedative, hypnotic, and opioid agents
- Menopause
- Pelvic muscle weakness
- Pregnancy—vaginal delivery, episiotomy
- Stroke

Adapted from Wooldridge, L. S. (2017). Urinary incontinence. In D. K. Newman, J. F. Wyman, & V. W. Welch (Eds.). *Core curriculum for urologic nursing*. Pitman, NJ: Anthony J. Jannetti, Inc.

Despite widespread media coverage, urinary incontinence remains underdiagnosed, underreported, and undertreated. Patients may be too embarrassed to seek help, causing them to ignore or conceal symptoms. Many patients use absorbent pads or other devices without having their condition properly diagnosed and appropriately treated. Health care providers must be alert to subtle cues of urinary incontinence and stay informed about current management strategies.

The costs of care for patients with urinary incontinence include the expenses of absorbent products, medications, and surgical or nonsurgical treatment modalities, as well as psychosocial costs (i.e., embarrassment, loss of self-esteem, and social isolation) (Norris, 2019).

Although urinary incontinence is commonly regarded as a condition that occurs in older multiparous women, it can occur in young nulliparous women, especially during vigorous high-impact activity. Age, gender, and number of vaginal deliveries are established risk factors that explain, in part, the increased incidence in women (see Chart 49-4). Men can have urinary incontinence, especially those with certain comorbid conditions. Researchers have reported that 40% of men with Parkinson's disease reported urinary incontinence (McDonald, Winge, & Burn, 2017). Urinary incontinence may be a symptom of other disorders, such as UTI or fecal impaction.

Types of Urinary Incontinence

There are many types of urinary incontinence, including the following:

Stress incontinence is the involuntary loss of urine through an intact urethra as a result of exertion, sneezing, coughing, or changing position (Wooldridge, 2017). It predominantly affects women who have had vaginal deliveries and is thought to be the result of decreasing ligament and pelvic floor support of the urethra and decreasing or absent estrogen levels within the urethral walls and bladder base. In men, stress incontinence is often experienced after a radical prostatectomy for prostate cancer because of the loss of urethral compression that the prostate had supplied before the surgery, and possibly bladder wall irritability.

Urge incontinence is the involuntary loss of urine associated with a strong urge to void that cannot be suppressed (Wooldridge, 2017). The patient is aware of the need to void but is unable to reach a toilet in time. An uninhibited detrusor contraction is the precipitating factor. This can occur in a patient with neurologic dysfunction that impairs inhibition of bladder contraction or in a patient without overt neurologic dysfunction.

Functional incontinence is the involuntary loss of urine due to physical or cognitive impairment. This occurs when the lower urinary tract function is intact but other factors, such as severe cognitive impairment (e.g., Alzheimer's dementia), make it difficult for the patient to identify the need to void or physical impairments make it difficult or impossible for the patient to reach the toilet in time for voiding (Miller, 2019; Wooldridge, 2017).

Iatrogenic incontinence is the involuntary loss of urine due to extrinsic medical factors, predominantly medications. One such example is the use of alpha-adrenergic agents to decrease blood pressure. In some people with an intact urinary system, these agents adversely affect the alpha receptors responsible for bladder neck closing pressure; the bladder neck relaxes to the point of incontinence with a minimal increase in intra-abdominal pressure, thus mimicking stress incontinence. As soon as the medication is discontinued, the apparent incontinence resolves.

Mixed incontinence, which encompasses several types of urinary incontinence, is involuntary leakage associated with urgency and also with exertion, effort, sneezing, or coughing (Miller, 2019; Wooldridge, 2017).

Overflow incontinence occurs when there is continual leakage of urine from an overdistended bladder (Norris, 2019). This can occur because of detrusor muscle underactivity or an outlet obstruction caused by benign prostatic hyperplasia, pelvic organ prolapse, or tumors, among other things.

Only with appropriate recognition of the problem, assessment, and referral for diagnostic evaluation and treatment can the outcome of incontinence be determined. All people with incontinence should be considered for evaluation and treatment.

Gerontologic Considerations

Although urinary incontinence is not a normal consequence of aging, age-related changes in the urinary tract do predispose the older person to incontinence. However, if nurses and other health care providers accept incontinence as an inevitable part of illness or aging or consider it irreversible and untreatable, it cannot be treated successfully. Collaborative, interdisciplinary efforts are essential in assessing and effectively treating urinary incontinence. Urinary incontinence can decrease an older person's ability to maintain an independent lifestyle, which increases dependence on caregivers and may lead to institutionalization. Between 35% and 41% of older women have urinary incontinence (Wooldridge, 2017).

Many older adults experience transient episodes of incontinence that tend to be abrupt in onset. When this occurs, the nurse should question the patient, as well as the family if possible, about the onset of symptoms and any signs or symptoms of a change in other organ systems. Acute UTI, infection elsewhere in the body, constipation, decreased fluid intake, and a change in a chronic disease pattern, such as elevated blood glucose levels in patients with diabetes or decreased estrogen levels in menopausal women, can provoke the onset of urinary incontinence. If the cause is identified and modified or eliminated early at the onset of incontinence, the incontinence itself may be eliminated. Although the bladder of the older person is more vulnerable to altered detrusor activity, age alone is not a risk factor for urinary incontinence (Miller, 2019; Wooldridge, 2017).

Decreased bladder muscle tone is a normal age-related change found in older adults. This leads to decreased bladder capacity, increased **residual urine** (urine remaining in the bladder after voiding), and an increase in urgency.

Many medications affect urinary continence in addition to causing other unwanted or unexpected effects (Miller, 2019; Wooldridge, 2017). All medications need to be assessed for potential interactions.

Assessment and Diagnostic Findings

Once incontinence is recognized, a thorough history is necessary. This includes a detailed description of the problem and a history of medication use. The patient's voiding history, a diary of fluid intake and output, and bedside tests (e.g., residual urine, stress maneuvers) may be used to help determine the type of urinary incontinence involved. Urodynamic tests may be performed (see Chapter 47). Urinalysis and urine culture are performed to identify infection.

Urinary incontinence may be transient or reversible if the underlying cause is successfully treated and the voiding pattern reverts to normal. Chart 49-5 provides causes of transient incontinence.

Medical Management

Management depends on the type of urinary incontinence and its causes. Management of urinary incontinence may be behavioral, pharmacologic, or surgical.

Behavioral Therapy

Behavioral therapies, also known as nonpharmacologic, or conservative treatments, are the first choice to decrease or eliminate urinary incontinence (see Chart 49-6). These are recommended as first-line treatment for nonneurologic causes of incontinence in adults (AUA, 2019b). In using these techniques, health care professionals help patients avoid potential adverse effects of pharmacologic or surgical interventions. Pelvic floor muscle exercises (sometimes referred to as Kegel exercises) represent the cornerstone of behavioral intervention for addressing symptoms of stress, urge, and mixed incontinence (Miller, 2019; Wooldridge, 2017). Other behavioral treatments include the use of a voiding diary, biofeedback, verbal instruction (prompted voiding), and physical therapy (AUA, 2019b; Wooldridge, 2017).

Chart 49-5

Causes of Transient Incontinence

- Atrophic vaginitis, urethritis, prostatitis
- Delirium or confusion
- Excessive urine production (increased intake, diabetes, diabetic ketoacidosis)
- Limited or restricted activity
- Pharmacologic agents (anticholinergic agents, sedatives, alcohol, analgesic agents, diuretics, muscle relaxants, adrenergic agents)
- Psychological factors (depression, regression)
- Stool impaction or constipation
- Urinary tract infections (UTI)

Pharmacologic Therapy

Pharmacologic therapy works best when used as an adjunct to behavioral interventions. The particular antibiotic used will be dependent on the type of incontinence diagnosed (AUA, 2019a). Anticholinergic agents inhibit bladder contraction and are considered first-line medications for urge incontinence (AUA, 2019a; Wooldridge, 2017). Mirabegron, a beta-3 adrenergic agonist, may be used for urge incontinence and overactive bladder but should be used with caution in patients with hypertension as it can cause increased blood

pressure (Wooldridge, 2017). A tricyclic antidepressant medication (e.g., amitriptyline) can also decrease bladder contractions as well as increase bladder neck resistance (Wooldridge, 2017). Pseudoephedrine sulfate, which acts on alpha-adrenergic receptors, causing urinary retention, may be used to treat stress incontinence; it needs to be used with caution in men with prostatic hyperplasia and in patients with hypertension.

Surgical Management

Surgical correction may be indicated in patients who have not achieved continence using behavioral and pharmacologic therapy. Surgical options vary according to the underlying anatomy and the physiologic problem. Most procedures involve lifting and stabilizing the bladder or urethra to restore the normal urethrovesical angle or to lengthen the urethra.

Women with stress incontinence may undergo an anterior vaginal repair, retropubic suspension, or needle suspension to reposition the urethra. Procedures to compress the urethra and increase resistance to urine flow include sling procedures and placement of periurethral bulking agents such as artificial collagen.

Periurethral bulking is a minimally invasive procedure in which small amounts of artificial collagen are placed within the walls of the urethra to enhance the closing pressure of the urethra (Norris, 2019). This procedure takes only 10 to 20 minutes and may be performed under local anesthesia or moderate sedation. A cystoscope is inserted into the urethra. An instrument is inserted through the cystoscope to deliver a small amount of collagen into the urethral wall at locations selected by the urologist. The patient is usually discharged home after voiding. There are no restrictions following the procedure, although multiple sessions may be necessary for a cure (Norris, 2019). Collagen placement anywhere in the body is considered semipermanent because its durability averages between 12 and 24 months, until the body absorbs the material. Periurethral bulking with collagen is a relatively safe alternative to surgery. It is also an option for people who are seeking help with stress incontinence who prefer to avoid surgery and who do not have access to behavioral therapies.

Chart 49-6 HEALTH PROMOTION

Interventions for Urinary Incontinence

Behavioral strategies are largely carried out, coordinated, and monitored by the nurse. These interventions may or may not be augmented by the use of medications.

Fluid Management

An adequate daily fluid intake of approximately 1500 to 1600 mL, taken as small increments between breakfast and the evening meal, helps to reduce urinary urgency related to concentrated urine production, decreases the risk of urinary tract infection, and maintains bowel functioning. (Constipation, resulting from inadequate daily fluid intake, can increase urinary urgency and urine retention.) The best fluid is water, although some suggest it may be helpful to include at least one glass of cranberry juice per day. Fluids containing caffeine, carbonation, alcohol, or artificial sweetener should be avoided because they irritate the bladder wall, thus resulting in urinary urgency. Some patients who have heart failure or end-stage kidney disease need to discuss their daily fluid limit with their primary provider.

Standardized Voiding Frequency

After establishing a patient's natural voiding and urinary incontinence tendencies, voiding on a schedule can be very effective in those with and without cognitive impairment, although patients with cognitive impairment may require assistance with this technique from nursing personnel or family members. The object is to purposely empty the bladder before the bladder reaches the critical volume that would cause an urge or stress incontinence episode. This approach involves the following:

- **Timed voiding** involves establishing a set voiding frequency (such as every 2 hours if incontinent episodes tend to occur 2 or more hours after voiding). The individual chooses to "void by the clock" at the given interval while awake rather than wait until a voiding urge occurs.
- **Prompted voiding** is timed voiding that is carried out by staff or family members when the individual has cognitive difficulties that make it difficult to remember to void at set intervals. The caregiver checks the patient to assess if they have remained dry and, if so, assists the patient to use the bathroom while providing positive reinforcement for remaining dry.
- **Habit retraining** is timed voiding at an interval that is more frequent than the individual would usually choose. This technique helps to restore the sensation of the need to void in individuals who are experiencing diminished sensation of bladder filling due to various medical conditions such as a stroke.
- **Bladder retraining**, also known as "bladder drill," incorporates a timed voiding schedule and urinary urge inhibition exercises to inhibit

voiding, or leaking urine, in an attempt to remain dry for a set time. When the first timing interval is easily reached on a consistent basis without urinary urgency or incontinence, a new voiding interval, usually 10 to 15 minutes beyond the last, is established. Again, the individual practices urge inhibition exercises to delay voiding or avoid incontinence until the next preset interval arrives. When an acceptable voiding interval is reached, the patient continues that timed voiding sequence throughout the day.

Pelvic Muscle Exercise

Also known as Kegel exercises, pelvic muscle exercise (PME) aims to strengthen the voluntary muscles that assist in bladder and bowel continence in both men and women. Written or verbal instruction alone is usually inadequate to educate an individual about how to identify and strengthen the pelvic floor for sufficient bladder and bowel control. Biofeedback-assisted PME uses either electromyography or manometry to help the individual identify the pelvic muscles as they attempt to learn which muscle group is involved when performing PME. The biofeedback method also allows assessment of the strength of this muscle area.

PME involves gently tightening the same muscles used to stop flatus or the stream of urine for 5- to 10-second increments, followed by 10-second resting phases. To be effective, these exercises need to be performed two or three times a day for at least 6 weeks. Depending on the strength of the pelvic musculature when initially evaluated, anywhere from 10 to 30 repetitions of PME are prescribed at each session. Older patients may need to exercise for an even longer time to strengthen the pelvic floor muscles. Pelvic muscle exercises are helpful for women with stress, urge, or mixed incontinence and for men who have undergone prostate surgery.

Vaginal Cone Retention Exercises

Vaginal cone retention exercises are an adjunct to the Kegel exercises. Vaginal cones of varying weight are inserted intravaginally twice a day. The patient tries to retain the cone for 15 minutes by contracting the pelvic muscles.

Transvaginal or Transrectal Electrical Stimulation

Commonly used to treat urinary incontinence, electrical stimulation is known to elicit a passive contraction of the pelvic floor musculature, thus re-educating these muscles to provide enhanced levels of continence. This modality is often used with biofeedback-assisted pelvic muscle exercise training and voiding schedules. At high frequencies, it is effective for stress incontinence. At low frequencies, electrical stimulation can also relieve symptoms of urinary urgency,

frequency, and urge incontinence. Intermediate ranges are used for mixed incontinence.

Neuromodulation

Neuromodulation via transvaginal or transrectal nerve stimulation of the pelvic floor inhibits detrusor overactivity and hypersensory bladder signals and strengthens weak sphincter muscles.

Adapted from Hickey, J. V., & Strayer, A. L. (2020). *The clinical practice of neurological and neurosurgical nursing* (8th ed.). Philadelphia, PA: Wolters Kluwer.

An artificial urinary sphincter can be used to close the urethra and promote continence. Two types of artificial sphincters are a periurethral cuff and a cuff inflation pump.

Men with overflow and stress incontinence may undergo a transurethral resection to relieve symptoms of prostatic enlargement. An artificial sphincter can be used after prostatic surgery for sphincter incompetence (see Fig. 49-2). After surgery, periurethral bulking agents can be injected into the periurethral area to increase compression of the urethra.

Nursing Management

The nurse may encounter the patient with incontinence either in the hospital or as an outpatient. Nursing management of the patient with urinary incontinence in any setting is based on the premise that incontinence is not inevitable with illness or aging and that it is often reversible and treatable. Patients who are incontinent and hospitalized need routine skin assessment to distinguish between incontinence-associated dermatitis (IAD) and pressure injury (Francis, 2019; Qiang, Xian, Bin, et al., 2020). When either IAD or pressure injury are identified, appropriate management techniques must be implemented to avoid complications (Francis, 2019; Qiang et al., 2020). See the Nursing Research Profile in Chart 49-7.

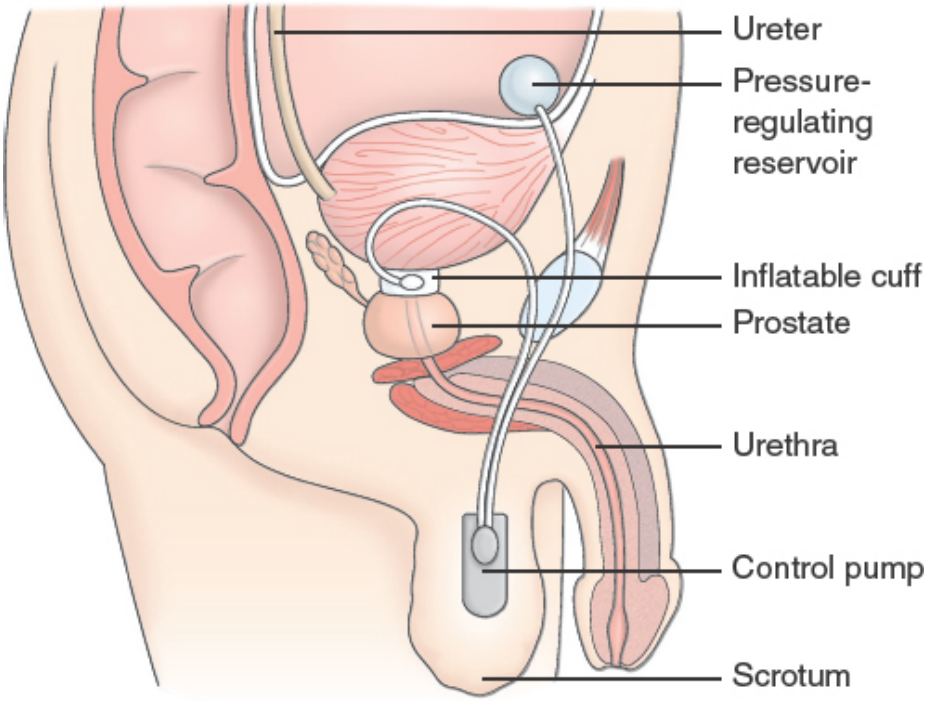

Figure 49-2 • Male artificial urinary sphincter. An inflatable cuff is inserted surgically around the urethra or neck of the bladder. To empty the bladder, the cuff is deflated by squeezing the control pump located in the scrotum.

The nursing interventions in the outpatient setting are determined in part by the type of treatment that is undertaken. For behavioral therapy to be effective, the nurse must provide support and encouragement, because it is easy for the patient to become discouraged if therapy does not quickly improve the level of continence. Patient education is important and should be provided verbally and in writing (see Chart 49-8). The patient should be educated to develop and use a log or diary to record timing of pelvic floor muscle exercises, frequency of voiding, any changes in bladder function, and any episodes of incontinence (Miller, 2019).

Chart 49-7 NURSING RESEARCH PROFILE

Understanding Incontinence-Associated Dermatitis

Qiang, L., Xian, L. W., Bin, P. Y., et al. (2020). Investigating ICU nurses' understanding of incontinence-associated dermatitis: An analysis of influencing factors. *World Council of Enterostomal Therapists Journal*, *40*(1), 32–38.

Purpose

Patients with urinary and bowel incontinence are at high risk for incontinence-associated dermatitis (IAD) in the hospital setting. The purpose of this study was to investigate the knowledge, attitude, and preventive behavior of ICU nurses related to IAD.

Design

This was a prospective study that used a questionnaire designed by the researchers. A convenience sample of 508 nurses who had been working in an ICU in China with at least 1 year of experience were asked to fill out an online version of the questionnaire which resulted in 500 useable surveys.

Findings

The mean score on the knowledge of IAD was 7 out of a possible 11, indicating the need to educate nurses on their knowledge of IAD. The mean score on the attitude toward prevention of IAD was 23 out of a possible 28. The lowest scores on this portion of the questionnaire were in the section about conducting quality control and monitoring of IAD that indicated the need to have a quality improvement program that recorded and followed rates of IAD. The mean score on prevention behaviors was 43 out of a possible 59, indicating the need for more education about daily behaviors such as assessment. Experience was the main influence on knowledge, attitude, and preventive behaviors, as nurses with the most years of experience scored highest.

Nursing Implications

This study provided information about the knowledge, attitude, and preventive behaviors associated with IAD. Nurses have a positive attitude but lack the knowledge and protocols needed to help prevent IAD. This study provides evidence for the need for educational programs and the implementation of standardized quality control and monitoring protocols.

Chart 49-8 PATIENT EDUCATION

Strategies for Promoting Urinary Continence

The nurse instructs the patient to:

- Avoid bladder irritants, such as caffeine, alcohol, and artificial sweeteners such as aspartame (NutraSweet).
- Avoid taking diuretic agents after 4 PM.
- Increase awareness of the amount and timing of all fluid intake.
- Perform all pelvic floor muscle exercises as prescribed, every day.
- Stop smoking (smokers usually cough frequently, which increases incontinence).
- Take steps to avoid constipation: Drink adequate fluids, eat a well-balanced diet high in fiber, exercise regularly, and take stool softeners if recommended.
- Void regularly, five to eight times a day (about every 2 to 3 hours):
  - First thing in the morning
  - Before each meal
  - Before retiring to bed
  - Once during the night if necessary

If pharmacologic treatment is used, the patient and family are educated about its purpose. Patients with mixed incontinence must be informed that anticholinergic and antispasmodic agents can help decrease urinary urgency and frequency and urge incontinence but do not decrease the urinary incontinence related to stress incontinence. If surgical correction is undertaken, the procedure and its desired outcomes are described to the patient and family. Follow-up contact with the patient enables the nurse to answer the patient's questions and to provide reinforcement and encouragement.

Urinary Retention

Urinary retention is the inability to empty the bladder completely during attempts to void. Chronic urine retention often leads to overflow incontinence (described previously). In a healthy adult younger than 60 years, complete bladder emptying should occur with each voiding, with no residual. In adults older than 60 years, 50 to 100 mL of residual urine may remain after each voiding because of the decreased contractility of the detrusor muscle.

Urinary retention can occur postoperatively in any patient, particularly if the surgery affected the perineal or anal regions and resulted in reflex spasm of the sphincters. General anesthesia reduces bladder muscle innervation and suppresses the urge to void, impeding bladder emptying.

Pathophysiology

Urinary retention may result from diabetes, prostatic enlargement, urethral pathology (infection, tumor, calculus), trauma (pelvic injuries), pregnancy, or neurologic disorders (e.g., stroke, spinal cord injury, multiple sclerosis, Parkinson's disease). Some medications cause urinary retention either by inhibiting bladder contractility or by increasing bladder outlet resistance (AUA, 2019b; Wooldridge, 2017).

Assessment and Diagnostic Findings

The assessment of a patient for urinary retention is multifaceted because the signs and symptoms are challenging to detect. The following questions serve as a guide in assessment:

- What was the time of the last voiding, and how much urine was voided?
- Is the patient voiding small amounts of urine frequently?
- Is the patient dribbling urine?
- Does the patient complain of pain or discomfort in the lower abdomen? (Discomfort may be relatively mild if the bladder distends slowly.)
- Is the pelvic area rounded and swollen (could indicate urine retention and a distended bladder)?
- Does percussion of the suprapubic region elicit dullness (possibly indicating urine retention and a distended bladder)?
- Are other indicators of urinary retention present, such as restlessness and agitation?
- Does a postvoid bladder ultrasound test reveal residual urine?

The patient may verbalize an awareness of bladder fullness and a sensation of incomplete bladder emptying. Signs and symptoms of UTI (hematuria, urgency, frequency, and nocturia) may be present. A series of urodynamic studies (described in Chapter 47) may be performed to identify the type of bladder dysfunction and to aid in determining appropriate treatment. A voiding diary can be used to provide a written record of the amount of urine voided and the frequency of voiding. Postvoid residual urine may be assessed by using either straight catheterization or an ultrasound bladder scanner (see Chapter 47, Fig. 47-8) and is considered diagnostic of urinary retention. Normally, residual urine amounts to no more than 50 mL in the middle-aged adult and less than 50 to 100 mL in the older adult (Weber & Kelley, 2018).

Complications

The retention of urine can lead to chronic infections that, if unresolved, predispose the patient to renal calculi (urolithiasis or nephrolithiasis), pyelonephritis, sepsis, or hydronephrosis. In addition, urine leakage can lead to perineal skin breakdown, especially if regular hygiene measures are neglected.

Nursing Management

Strategies are instituted to prevent overdistention of the bladder and to treat infection or correct obstruction. However, many complications can be prevented with careful assessment and appropriate nursing interventions. The nurse explains to the patient why normal voiding is not occurring and monitors urine output closely. The nurse also provides reassurance about the temporary nature of retention and successful management strategies.

Promoting Urinary Elimination

Nursing measures to encourage normal voiding patterns include providing privacy, ensuring an environment and body position conducive to voiding, and assisting the patient with the use of the bathroom or bedside commode, rather than a bedpan, to provide a more natural setting for voiding. If his condition allows, the male patient may stand beside the bed to use the urinal; most men find this position more comfortable and natural.

Additional measures include applying warmth to relax the sphincters (e.g., sitz baths, warm compresses to the perineum, showers), giving the patient hot caffeine-free beverage and offering encouragement and reassurance. Simple trigger techniques, such as turning on the water faucet while the patient is trying to void, may also be used. Other examples of trigger techniques are stroking the abdomen or inner thighs, tapping above the pubic area, and dipping the patient's hands in warm water. After surgery or childbirth, prescribed analgesic agents should be given because pain in the perineal area can make voiding difficult. A combination of techniques may be necessary to initiate voiding.

When the patient cannot void, bladder scanning is used to assess for distention, then straight catheterization (as prescribed) is used to prevent overdistention of the bladder (see later discussion of neurogenic bladder and catheterization). In the case of prostatic obstruction, attempts at catheterization (by the urologist) may not be successful, requiring insertion of a **suprapubic catheter** (catheter inserted through a small abdominal incision into the bladder) (see Fig. 49-4, below). After urinary drainage is restored, bladder retraining is initiated for the patient who cannot void spontaneously.

Promoting Home, Community-Based, and Transitional Care

In addition to the strategies listed for promoting urinary continence found in Chart 49-8, modifications to the home environment can provide simple and effective ways to assist in treating urinary incontinence and retention. For example, the patient may need to remove obstacles, such as throw rugs or other objects, to provide easy, safe access to the bathroom. Other modifications that the nurse may recommend include installing support bars in the bathroom; placing a bedside commode, bedpan, or urinal within easy reach; leaving lights on in the bedroom and bathroom; and wearing clothing that is easy to remove quickly.

Neurogenic Bladder

Neurogenic bladder is a dysfunction that results from a disorder or dysfunction of the nervous system and leads to urinary incontinence. It may be caused by spinal cord injury, spinal tumor, herniated vertebral disc, multiple sclerosis, congenital disorders (spina bifida or myelomeningocele), infection, or complications of diabetes (Alley, 2017) (see Chapters 63 and 64).

Pathophysiology

The two types of neurogenic bladder are spastic (or reflex) bladder and flaccid bladder. Spastic bladder is the more common type and is caused by any spinal cord lesion above the voiding reflex arc (upper motor neuron lesion) (Hickey & Strayer, 2020). The result is a loss of conscious sensation and cerebral motor control. A spastic bladder empties on reflex, with minimal or no controlling influence to regulate its activity.

Flaccid bladder is caused by a lower motor neuron lesion, commonly resulting from trauma. This form of neurogenic bladder is also increasingly being recognized in patients with diabetes. The bladder continues to fill and becomes greatly distended, and overflow incontinence occurs. The bladder muscle does not contract forcefully at any time. Because sensory loss may accompany a flaccid bladder, the patient feels no discomfort.

Assessment and Diagnostic Findings

Evaluation for neurogenic bladder involves measurement of fluid intake, urine output, and residual urine volume; urinalysis; and assessment of sensory awareness of bladder fullness and degree of motor control. Comprehensive urodynamic studies are also performed.

Complications

The most common complication of neurogenic bladder is infection resulting from urinary stasis and catheterization. Other complications include renal calculi, impaired skin integrity, and urinary incontinence or retention.

Medical Management

The problems resulting from neurogenic bladder disorders vary considerably from patient to patient and are a major challenge to the health care team. Several long-term objectives appropriate for all types of neurogenic bladders include preventing overdistention of the bladder, emptying the bladder regularly and completely, maintaining urine sterility with no stone formation, and maintaining adequate bladder capacity with no reflux.

Specific interventions include continuous, intermittent, or self-catheterization (discussed later in this chapter); the use of an external condom-type catheter; a diet low in calcium (to prevent calculi); and encouragement of mobility and ambulation. A liberal fluid intake is encouraged to reduce the urinary bacterial count, reduce stasis, decrease the concentration of calcium in the urine, and minimize the precipitation of urinary crystals and subsequent stone formation.

A bladder retraining program may be effective in treating a spastic bladder or urine retention. The use of a timed, or habit, voiding schedule may be established. To further enhance emptying of a flaccid bladder, the patient may be taught to "double void." After each voiding, the patient is instructed to remain on the toilet, relax for 1 to 2 minutes, and then attempt to void again in an effort to further empty the bladder.

Pharmacologic Therapy

Parasympathomimetic medications, such as bethanechol, may help to increase the contraction of the detrusor muscle.

Surgical Management

Surgery may be carried out to correct bladder neck contractures or vesicoureteral reflux, or to perform a urinary diversion procedure.

Urinary Catheters

In patients with a urologic disorder or with marginal kidney function, care must be taken to ensure that urinary drainage is adequate and that kidney function is preserved. When urine cannot be eliminated naturally and must be drained artificially, catheters may be inserted directly into the bladder, the ureter, or the renal pelvis.

Catheterization is performed to achieve the following (Gould et al., 2019; Taylor, 2018):

- Assist with postoperative drainage in urologic and other surgeries
- Provide a means to monitor accurate urine output in patients who are critically ill
- Promote urinary drainage in patients with neurogenic bladder dysfunction, urine retention, or at end-of-life care
- Prevent urinary leakage in patients with stage III to IV pressure injuries (see Chapter 56)
- Relieve urinary tract obstruction

An indwelling urinary catheter should be placed only if necessary because catheterization commonly leads to CAUTI. Figure 49-3 summarizes the pathophysiology of CAUTI.

Indwelling Catheters

If an indwelling catheter is necessary, the following specific nursing interventions are initiated to prevent CAUTI (McCoy et al., 2017; Taylor, 2018):

- Use strict aseptic technique during insertion of the smallest catheter possible
- Secure the catheter to prevent movement
- Frequently inspect urine color, odor, and consistency
- Perform daily perineal care with soap and water
- Maintain a closed system
- Follow the manufacturer's instructions when using the catheter port to obtain urine specimens
- Discontinue use as soon as feasible

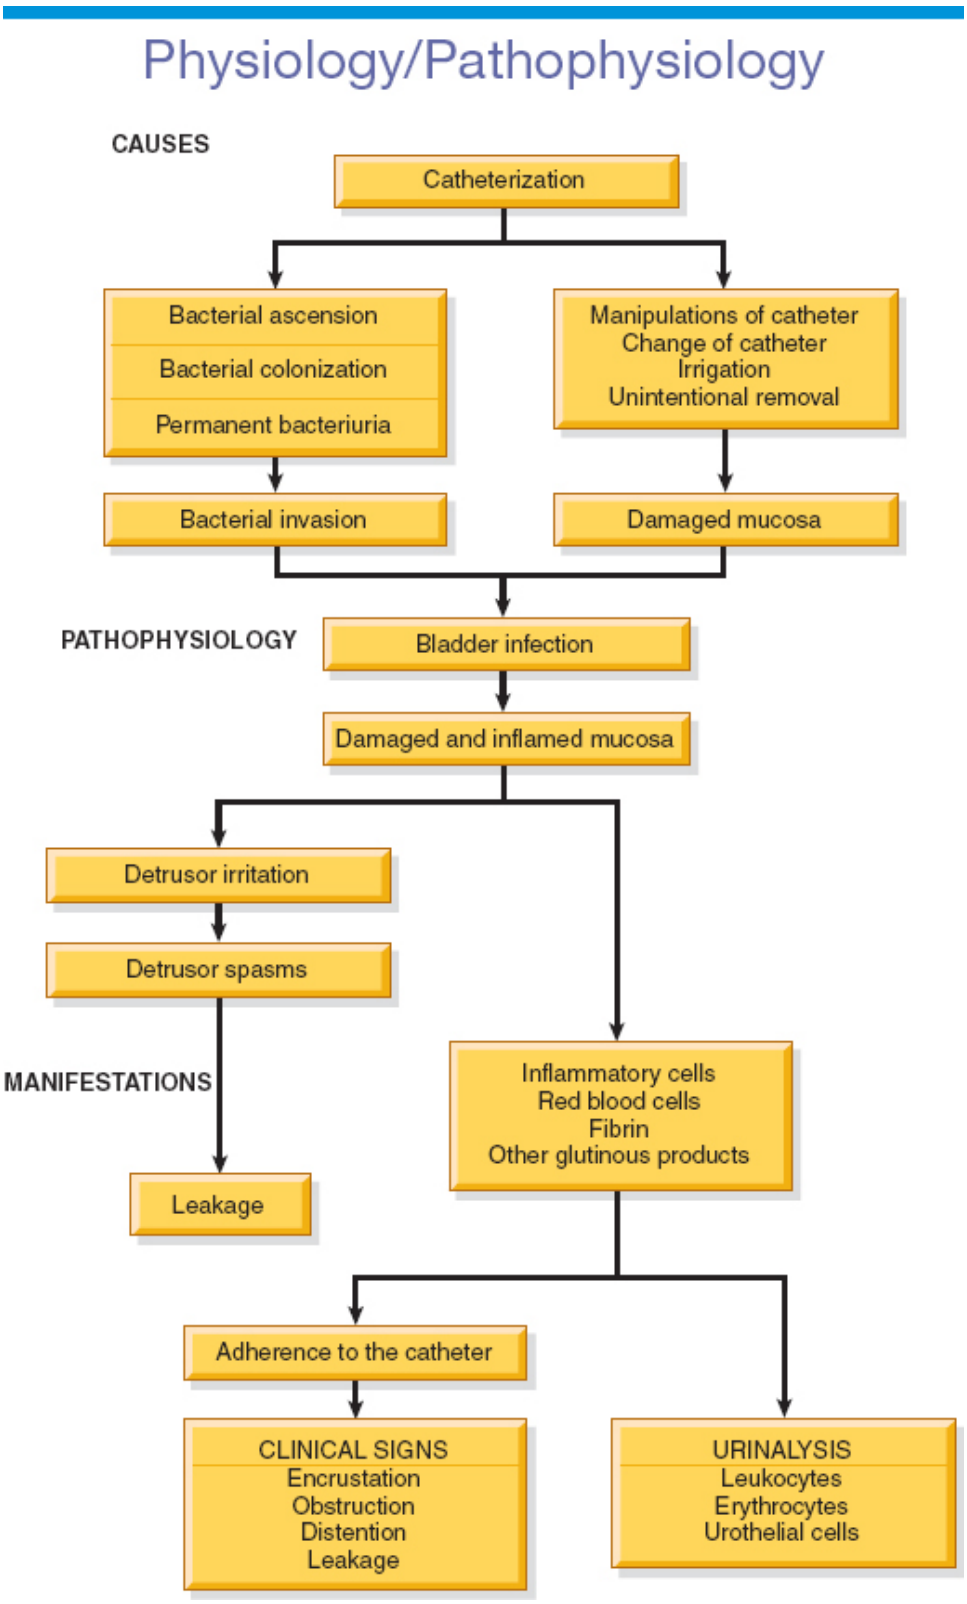

Figure 49-3 • Pathophysiology of CAUTI.

Suprapubic Catheters

Suprapubic catheterization allows bladder drainage by inserting a catheter or tube into the bladder through a suprapubic (above the pubis) incision or puncture (see Fig. 49-4). The catheter or suprapubic drainage tube is then threaded into the bladder and secured with sutures or tape, and the area around the catheter is covered with a sterile dressing. The catheter is connected to a sterile closed drainage system, and the tubing is secured to prevent tension on the catheter. This may be a temporary measure to divert the flow of urine from the urethra when the urethral route is impassable (because of injuries, strictures, prostatic obstruction), after gynecologic or other abdominal surgery when bladder dysfunction is likely to occur, and occasionally after pelvic fractures. A permanent indwelling suprapubic catheter may be needed in the patient who is incontinent following a spinal cord injury (Hickey & Strayer, 2020).

Suprapubic bladder drainage may be maintained continuously for several weeks. When the patient's ability to void is to be tested, the catheter is clamped for 4 hours, during which time the patient attempts to void. After the patient voids, the catheter is unclamped, and the residual urine is measured. If the amount of residual urine is less than 100 mL on two separate occasions (morning and evening), the catheter is usually removed. However, if the patient complains of pain or discomfort, the suprapubic catheter is usually left in place until the patient can void successfully.

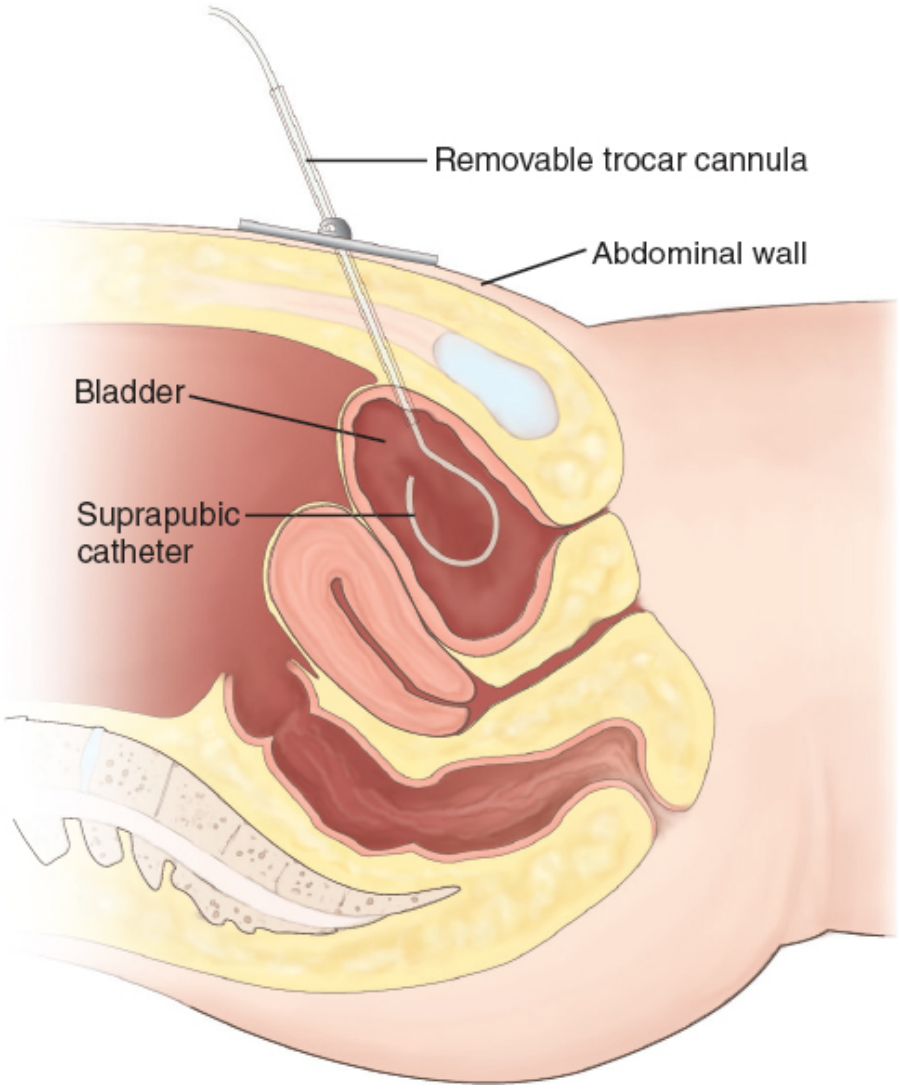

Figure 49-4 • Suprapubic bladder drainage. A trocar cannula is used to puncture the abdominal and bladder walls. The catheter is threaded through the trocar cannula, which is then removed, leaving the catheter in place. The catheter is secured by tape or sutures to prevent unintentional removal.

Suprapubic drainage offers certain advantages. Patients can usually void sooner after surgery than those with urethral catheters, and they may be more comfortable. The catheter allows greater mobility, permits measurement of residual urine without urethral instrumentation, and presents less risk of bladder infection. The suprapubic catheter is removed when it is no longer required, and a sterile dressing is placed over the site.

The patient requires liberal amounts of fluid to prevent encrustation around the catheter. Other potential problems include the formation of bladder stones, acute and chronic infections, and problems collecting urine. A wound-ostomy-continence (WOC) nurse may be consulted to assist the patient and family in

selecting the most suitable urine collection system and to educate them about its use and care.

Nursing Management

Assessing the Patient and the System

Patients at high risk for CAUTI need to be identified and monitored carefully. These include women; older adults; and patients who are debilitated, malnourished, chronically ill, immunosuppressed, or have diabetes (Newman, 2017). They are observed for signs and symptoms of CAUTI: cloudy malodorous urine, hematuria, fever, chills, anorexia, and malaise. Any drainage and excoriation in the area around the urethral orifice is noted. Urine cultures provide the most accurate means of assessing a patient for infection.

Preventing Infection

Certain principles of care are essential to prevent infection in patients with a closed urinary drainage system (see Chart 49-9). The catheter is an object foreign to the body and produces a reaction in the urethral mucosa with some urethral discharge. Cleansing should be done on a daily basis and after bowel movements/contamination. A clean washcloth or wipe is used, cleansing from the catheter along its length from the meatus away from the patient. Disinfectants or antibacterial lubricants have not been found to decrease infections. Water in the wash basin used for daily cleansing is avoided as it may harbor microbes. Using disposable wipes that contain purified water, aloe, and vitamin E has been shown to decrease the incidence of CAUTIs (Newman, 2017). Vigorous cleansing of the meatus while the catheter is in place is discouraged because the cleansing action can move the catheter back and forth, increasing the risk of infection. The catheter is anchored as securely as possible to prevent it from moving in the urethra (Gould et al., 2019). Special care should be taken to ensure that any patient who is confused does not remove the catheter with the retention balloon still inflated, because this could cause bleeding and considerable injury to the urethra.

Chart 49-9

Preventing Infection in the Patient with an Indwelling Urinary Catheter

- Avoid contamination of the drainage spout. A receptacle in which to empty the bag is provided for each patient.
- Avoid routine catheter changes. The catheter is changed only to correct problems such as leakage, blockage, or encrustations.
- Avoid unnecessary handling or manipulation of the catheter by the patient or staff.
- Carry out hand hygiene before and after handling the catheter, tubing, or drainage bag.
- Ensure a free flow of urine to prevent infection. Improper drainage occurs when the tubing is kinked or twisted, allowing pools of urine to collect in the tubing loops.
- Evaluate the benefit of placing an indwelling urinary catheter versus the risk of the patient developing a catheter-associated urinary tract infection (CAUTI).
- If the collection bag *must* be raised above the level of the patient's bladder, clamp the drainage tube. This prevents backflow of contaminated urine into the patient's bladder from the bag.
- Monitor the patient's voiding when the catheter is removed. The patient must void within 8 hours; if unable to void, the patient may require catheterization with a straight catheter.
- Never disconnect the tubing to obtain urine samples, to irrigate the catheter, or to ambulate or transport the patient.
- Never irrigate the catheter routinely. If the patient is prone to obstruction from clots or large amounts of sediment, use a three-way system with continuous irrigation.
- Never leave the catheter in place longer than is necessary to decrease the risk of CAUTI.
- Obtain a urine specimen for culture at the first sign of infection.
- To prevent contamination of the closed system, *never* disconnect the tubing. The drainage bag must *never* touch the floor. The bag and collecting tubing are changed if contamination occurs, if urine flow becomes obstructed, or if tubing junctions start to leak at the connections.
- To reduce the risk of bacterial proliferation, empty the collection bag at least every 8 hours through the drainage spout—more frequently if there is a large volume of urine.
- Use scrupulous aseptic technique during insertion of the catheter. Use a preassembled, sterile, closed urinary drainage system of the smallest catheter size possible to minimize trauma.
- Wash the perineal area with soap and water at least twice a day; avoid a to-and-fro motion of the catheter. Dry the area well, but avoid applying powder because it may irritate the perineum.

Adapted from McCoy, C., Paredes, M., Allen, S., et al. (2017). Catheter-associated urinary tract infections. *Clinical Journal of Oncology Nursing*, *21*(4), 460–465; Gould, C. V., Umscheid, C. A., Agarwal, R. K., et al. (2019). Guideline for prevention of catheter-associated urinary tract infections 2009. Retrieved on 5/13/2020 at: www.cdc.gov/infectioncontrol/guidelines/cauti/

A liberal fluid intake, within the limits of the patient's cardiac and renal reserve, and an increased urine output must be ensured to flush the catheter and to dilute urinary substances that might form encrustations (Newman, 2017).

Urine cultures are obtained as prescribed or indicated when monitoring the patient for infection; many catheters have an aspiration (puncture) port from which a specimen can be obtained.

Bacteriuria is considered inevitable in patients with indwelling catheters; therefore, controversy remains about the usefulness of taking cultures and treating asymptomatic bacteriuria, because overtreatment may lead to resistant strains of bacteria. Continual observation for fever, chills, and other signs and symptoms of systemic infection is necessary. Infections are treated aggressively.

Retraining the Bladder

When an indwelling urinary catheter is in place, the detrusor muscle does not actively contract the bladder wall to stimulate emptying because urine is continuously draining from the bladder. As a result, the detrusor may not immediately respond to bladder filling when the catheter is removed, resulting in either urine retention or urinary incontinence. This condition, known as postcatheterization detrusor instability, can be managed with bladder retraining (see Chart 49-10).

Immediately after the indwelling catheter is removed, the patient is placed on a timed voiding schedule, usually every 2 to 3 hours. At the given time interval, the patient is instructed to void. The bladder is then scanned using a portable ultrasonic bladder scanner, and if the bladder has not emptied completely, straight catheterization may be performed (Newman, 2017). After a few days, as the nerve endings in the bladder wall become resensitized to the bladder filling and emptying, bladder function usually returns to normal. If the patient has had an indwelling catheter in place for an extended period (e.g., greater than 1 month), bladder retraining will take longer; in some cases, function may never return to normal, and long-term intermittent catheterization may become necessary.

Assisting with Intermittent Self-Catheterization

Intermittent self-catheterization provides periodic drainage of urine from the bladder. By promoting drainage and eliminating excessive residual urine, intermittent catheterization protects the kidneys, reduces the incidence of UTIs, and improves continence. It is the treatment of choice in some patients with spinal cord injury and other neurologic disorders, such as multiple sclerosis, when the ability to empty the bladder is impaired. Self-catheterization promotes independence, results in few complications, and enhances self-esteem and quality of life.

Chart 49-10

Bladder Retraining After Indwelling Catheterization

- Instruct the patient to drink a measured amount of fluid from 8 AM to 10 PM to avoid bladder overdistention. Offer no fluids (except sips) after 10 PM.
- At specific times, ask the patient to void by applying pressure over the bladder, tapping the abdomen, or running water to trigger the bladder.
- Immediately after the voiding attempt, perform a bladder scan to determine the amount of residual urine (see Chapter 47, Fig. 47-8).
- Measure the volumes of urine voided.
- Palpate the bladder at repeated intervals to assess for distention.
- Instruct the patient who has no voiding sensation to be alert to any signs that indicate a full bladder, such as perspiration, cold hands or feet, or feelings of anxiety.
- Perform straight catheterization, as prescribed, usually for residual urine of >300 mL.
- Lengthen the intervals between catheterizations as the volume of residual urine decreases. Catheterization is usually discontinued when the volume of residual urine is <100 mL.

Adapted from Newman, D. (2017). Catheters, devices, products, and catheter-associated urinary tract infections. In D. K. Newman, J. F. Wyman, & V. W. Welch (Eds.). *Core curriculum for urologic nursing*. Pitman, NJ: Society of Urologic Nurses and Associates.

When educating the patient about how to perform self-catheterization, the nurse often teaches the patient to use a "clean technique" (nonsterile) at home (Hickey & Strayer, 2020). Antibacterial liquid soap is recommended for cleaning urinary catheters at home. The catheter is thoroughly rinsed with warm tap water and must be dried before reuse. It should be kept in its own container, such as a plastic food storage bag.

In educating the patient, the nurse emphasizes the importance of frequent catheterization and emptying the bladder at the prescribed time. The average daytime clean intermittent catheterization schedule is every 4 to 6 hours and

just before bedtime. If the patient is awakened at night with an urge to void, catheterization may be performed after an attempt is made to void normally.

The female patient assumes a Fowler position and uses a mirror to help locate the urinary meatus. She lubricates the catheter and inserts it 7.5 cm (3 inches) into the urethra, in a downward and backward direction. The male patient assumes a Fowler or sitting position, lubricates the catheter, and retracts the foreskin of the penis with one hand while grasping the penis and holding it at a right angle to the body. (This maneuver straightens the urethra and makes it easier to insert the catheter.) He inserts the catheter 15 to 25 cm (6 to 10 inches) until urine begins to flow. After removal, the catheter is cleaned, rinsed, dried, and placed in a plastic bag or case. Patients who follow an intermittent catheterization routine should consult a primary provider at regular intervals to assess urinary function and to detect complications. If the patient cannot perform intermittent self-catheterization, a family member or caregiver may be taught to carry out the procedure at regular intervals during the day.

An alternative to self-catheterization is creation of the Mitrofanoff umbilical appendicovesicostomy, which provides easy access to the bladder but requires an extensive surgical procedure (King, 2017). In this procedure, the bladder neck is closed and the appendix is used to create access to the bladder from the skin surface through a submucosal tunnel created with the appendix. One end of the appendix is brought to the skin surface and used as a stoma, and the other end is tunneled into the bladder. The appendix serves as an artificial urinary sphincter when an alternative is necessary to empty the bladder. A surgically prepared continent urine reservoir with a sphincter mechanism is required in cases of bladder cancer and severe interstitial cystitis. Various types of urinary diversions may be used when a radical **cystectomy** (surgical removal of the bladder) is necessary (see discussion later in chapter).

UROLITHIASIS AND NEPHROLITHIASIS

Urolithiasis and nephrolithiasis refer to stones (calculi) in the urinary tract and kidney, respectively. Urinary stones predominantly occur in the third to fifth decades of life and affect men twice as often as women (Norris, 2019). The prevalence of renal calculi is 10.6% for males and 7.1% for females; however, recent studies show that rates are increasing among women with estimates that the ratio of affected males-to-females is 1.3 to 1 (Flagg & Joiner, 2017). Stones may develop in one or both kidneys (Norris, 2019).

Pathophysiology

Stones are formed in the urinary tract when urinary concentrations of substances such as calcium oxalate, calcium phosphate, and uric acid increase. Referred to as supersaturation, this depends on the amount of the substance, ionic strength, and pH of the urine. Stones may be found anywhere from the kidney to the bladder and may vary in size from minute granular deposits, called *sand* or *gravel,* to bladder stones as large as an orange. The different sites of calculi formation in the urinary tract are shown in Figure 49-5.

Certain factors favor the formation of stones, including infection, urinary stasis, and periods of immobility, all of which slow kidney drainage and alter calcium metabolism (Norris, 2019). In addition, increased calcium concentrations in the blood and urine promote precipitation of calcium and formation of stones (the most common are calcium based) (Norris, 2019). Causes of hypercalcemia (high serum calcium) and hypercalciuria (high urine calcium) may include the following (Norris, 2019):

- Hyperparathyroidism
- Renal tubular acidosis
- Cancers (e.g., leukemia, multiple myeloma)
- Dehydration
- Granulomatous diseases (e.g., sarcoidosis, tuberculosis), which may cause increased vitamin D production by the granulomatous tissue
- Excessive intake of vitamin D
- Excessive intake of milk and alkali
- Myeloproliferative diseases such as polycythemia vera, which produce an unusual proliferation of blood cells from the bone marrow
- Intestinal bypass surgery

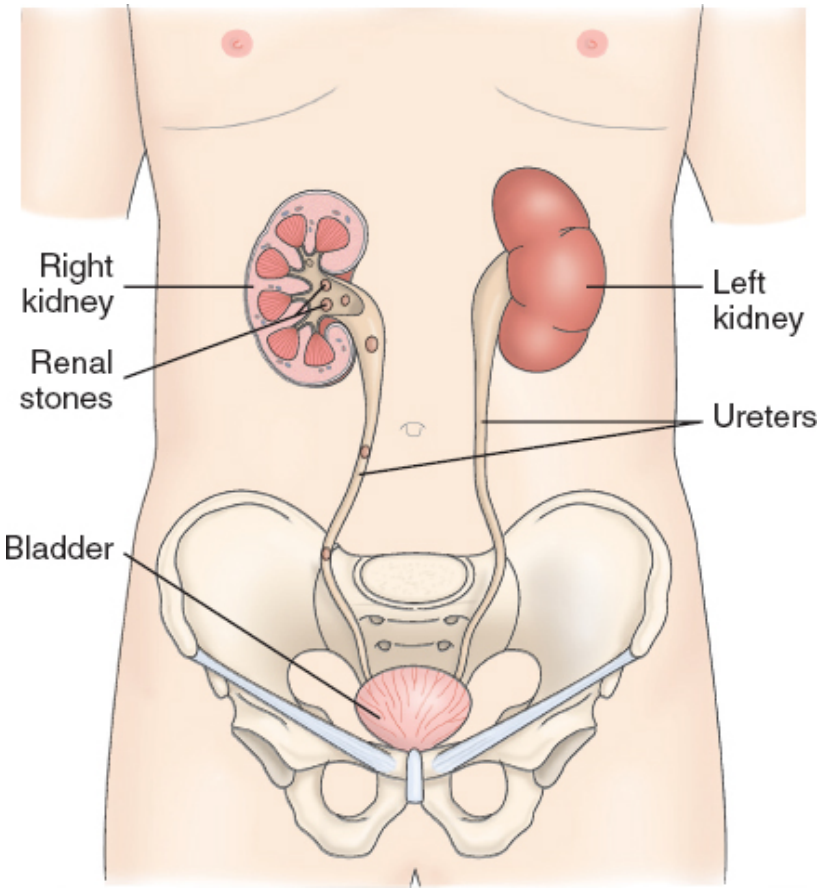

Figure 49-5 • Examples of potential sites of calculi formation in the urinary tract (urolithiasis) and kidney (nephrolithiasis).

For patients with stones containing uric acid, struvite, or cystine, a thorough physical examination and metabolic workup are indicated because of associated disturbances contributing to the stone formation. Uric acid stones account for 72% of stones in men (Flagg & Joiner, 2017). These may be seen in patients with gout or myeloproliferative disorders. Seventy-two percent of stones diagnosed in women are struvite stones (Flagg & Joiner, 2017) which form in persistently alkaline, ammonia-rich urine caused by the presence of bacteria such as *Proteus, Pseudomonas, Klebsiella, Staphylococcus,* or *Mycoplasma*. Predisposing factors for struvite stones include neurogenic bladder, foreign bodies, and recurrent UTIs (Norris, 2019).

Several conditions, as well as certain metabolic risk factors, predispose patients to stone formation. These include anatomic derangements such as polycystic kidney disease, horseshoe kidneys, chronic strictures, and medullary sponge disease. Urinary stone formation can occur in patients with inflammatory bowel disease and in those with an ileostomy or bowel resection because these patients absorb more oxalate. Medications known to cause stones in some patients include antacids, acetazolamide, vitamin D, laxatives, and high doses of aspirin (Comerford & Durkin, 2020). However, in many patients, no cause may be found.

Clinical Manifestations

Signs and symptoms of stones in the urinary system depend on the presence of obstruction, infection, and edema. When stones block the flow of urine, obstruction develops, producing an increase in hydrostatic pressure and distending the renal pelvis and proximal ureter (Norris, 2019). Infection (pyelonephritis and UTI with chills, fever, and frequency) can be a contributing factor with struvite stones. Some stones cause few, if any, symptoms while slowly destroying the functional units (nephrons) of the kidney; others cause excruciating pain and discomfort (Flagg & Joiner, 2017). Stones in the renal pelvis may be associated with an intense, deep ache in the costovertebral region. Hematuria is often present; pyuria may also be noted. Pain originating in the renal area radiates anteriorly and downward toward the bladder in the female and toward the testes in the male. If the pain suddenly becomes acute, with tenderness over the costovertebral area, and nausea and vomiting occur, the patient is having an episode of renal colic. Diarrhea and abdominal discomfort are due to renointestinal reflexes and the anatomic proximity of the kidneys to the stomach, pancreas, and large intestine.

Stones lodged in the ureter (ureteral obstruction) cause acute, excruciating, colicky, wavelike pain that radiates down the thigh and to the genitalia. Often, the patient has a desire to void, but little urine is passed, and it usually contains blood because of the abrasive action of the stone. This group of symptoms is called *ureteral colic.* Colic is mediated by prostaglandin E, a substance that increases ureteral contractility and renal blood flow and that leads to increased intraureteral pressure and pain. In general, the patient is able to pass stones 0.5 cm in diameter (Norris, 2019). Stones larger than 1 cm in diameter usually must be removed or fragmented (broken up by lithotripsy) so that they can be removed or passed spontaneously.

Stones lodged in the bladder usually produce symptoms of irritation and may be associated with UTI and hematuria. If the stone obstructs the bladder neck, urinary retention occurs. If infection is associated with a stone, the condition is far more serious, with the potential for urosepsis developing.

Assessment and Diagnostic Findings

The diagnosis is confirmed by a noncontrast CT scan (Flagg & Joiner, 2017). Blood chemistries and a 24-hour urine test for measurement of calcium, uric acid, creatinine, sodium, pH, and total volume may be part of the diagnostic workup. Dietary and medication histories and family history of renal calculi are obtained to identify factors predisposing the patient to the formation of stones.

When stones are recovered (whether freely passed by the patient or removed through special procedures), chemical analysis is carried out to

determine their composition. Stone analysis can provide a clear indication of the underlying disorder. For example, calcium oxalate or calcium phosphate stones usually indicate disorders of oxalate or calcium metabolism, whereas urate stones suggest a disturbance in uric acid metabolism (Flagg & Joiner, 2017).

Medical Management

The goals of management are to eradicate the stone, determine the stone type, prevent nephron destruction, control infection, and relieve any obstruction that may be present. The immediate objective of treatment of renal or ureteral colic is to relieve the pain until its cause can be eliminated. Opioid analgesic agents are given to prevent shock and syncope that may result from the excruciating pain. Nonsteroidal anti-inflammatory drugs (NSAIDs) are effective in treating renal calculus pain because they provide specific pain relief. They also inhibit the synthesis of prostaglandin E, reducing swelling and facilitating passage of the stone. Generally, once the stone has passed, the pain is relieved. Unless the patient is vomiting or has heart failure or any other condition requiring fluid restriction, fluids are encouraged. This increases the hydrostatic pressure behind the stone, assisting it in its downward passage. A high, around-the-clock fluid intake reduces the concentration of urinary crystalloids, dilutes the urine, and ensures a high urine output.

Chart 49-11 PATIENT EDUCATION

Preventing Renal Calculi

The nurse instructs the patient to:

- Avoid protein intake to decrease urinary excretion of calcium and uric acid.
- Limit sodium intake to 3 to 4 g/day. Table salt and high-sodium foods should be reduced, because sodium competes with calcium for reabsorption in the kidneys.
- Be aware that low-calcium diets are not generally recommended, except for true absorptive hypercalciuria. Evidence shows that limiting calcium, especially in women, can lead to osteoporosis and does not prevent calculi.
- Avoid intake of oxalate-containing foods (e.g., spinach, Swiss chard, chocolate, peanuts, pecans).
- Drink fluids (ideally water) every 1 to 2 hours during the day and one glass of cranberry juice per day.
- Drink two glasses of water at bedtime and an additional glass at each nighttime awakening to prevent urine from becoming too concentrated during the night.
- Avoid activities leading to sudden increases in environmental temperatures that may cause excessive sweating and dehydration.
- Contact the primary provider at the first sign of a urinary tract infection.

Adapted from Norris, T. L. (2019). *Porth's pathophysiology: Concepts of altered health state* (10th ed.). Philadelphia, PA: Wolters Kluwer.

Nutritional Therapy

Nutritional therapy plays an important role in preventing renal calculi (Flagg & Joiner, 2017) (see Chart 49-11). Fluid intake is the mainstay of most medical therapy for renal calculi. Unless fluids are contraindicated, patients with renal calculi should drink eight to ten 8-oz glasses of water daily or have IV fluids prescribed to keep the urine dilute. A urine output exceeding 2 L/day is advisable.

Calcium Stones

Historically, patients with calcium-based renal calculi were advised to restrict calcium in their diet. However, evidence has questioned this practice, except for patients with type 2 absorptive hypercalciuria (half of all patients with calcium stones), as stones in these patients are clearly the result of excess dietary calcium. Liberal fluid intake is encouraged. Medications such as ammonium chloride may be used, and if increased parathormone production (resulting in increased serum calcium levels in blood and urine) is a factor in the formation of stones, therapy with thiazide diuretics may be beneficial in

reducing the calcium loss in the urine and lowering the elevated parathormone levels (Cahill & Haras, 2017).

Uric Acid Stones

For uric acid stones, the patient is placed on a low-purine diet to reduce the excretion of uric acid in the urine. Foods high in purine (shellfish, anchovies, asparagus, mushrooms, and organ meats) are avoided, and other proteins may be limited. Allopurinol may be prescribed to reduce serum uric acid levels and urinary uric acid excretion, and to dissolve or reduce the size of existing stones (Cahill & Haras, 2017).

Cystine Stones

A low-protein diet may be prescribed, the urine is alkalinized with potassium alkali salts, and fluid intake is increased (Norris, 2019).

Oxalate Stones

A dilute urine is maintained through increasing fluid intake, and the intake of oxalate is limited. Many foods contain oxalate including spinach, Swiss chard, chocolate, peanuts, and pecans (Norris, 2019).

Interventional Procedures

If the stone does not pass spontaneously or if complications occur, common interventions include endoscopic or other procedures. For example, ureteroscopy, extracorporeal shock wave lithotripsy (ESWL), or endourologic (percutaneous) stone removal may be necessary (Norris, 2019).

Ureteroscopy (see Fig. 49-6A) involves first visualizing the stone and then destroying it. Access to the stone is accomplished by inserting a ureteroscope into the ureter and then inserting a laser, electrohydraulic lithotripter, or ultrasound device through the ureteroscope to fragment and remove the stones. A stent may be inserted and left in place for 48 hours or more after the procedure to keep the ureter patent. Length of hospital stay is generally brief, and some patients can be treated as outpatients.

ESWL, commonly referred to as lithotripsy, is a noninvasive procedure used to break up stones in the calyx of the kidney (see Fig. 49-6B). After the stones are fragmented to the size of grains of sand, the remnants of the stones are spontaneously voided. In ESWL, a high-energy amplitude of pressure, or shock wave, is generated by the abrupt release of energy and transmitted through water and soft tissues. When the shock wave encounters a substance of different intensity (a renal calculus), a compression wave causes the surface of the stone to fragment. Repeated shock waves focused on the stone eventually reduce it to many small pieces that are excreted in the urine.

Discomfort from the multiple shocks may occur, although the shock waves usually do not cause damage to other tissue. The patient is observed for obstruction and infection resulting from blockage of the urinary tract by stone fragments. All urine is strained after the procedure; voided gravel or sand is sent to the laboratory for chemical analysis. Several treatments may be necessary to ensure disintegration of stones.

Endourologic methods of stone removal (see Fig. 49-6C) may be used to extract kidney calculi that cannot be removed by other procedures. A percutaneous nephrostomy or a percutaneous nephrolithotomy (which are similar procedures) may be performed. A nephroscope is introduced through a percutaneous route into the renal parenchyma. Depending on its size, the stone may be extracted with forceps or by a stone retrieval basket. If the stone is too large to initially be removed, an ultrasound probe inserted through a nephrostomy tube is used to pulverize the stone. Small stone fragments and stone dust are then removed.

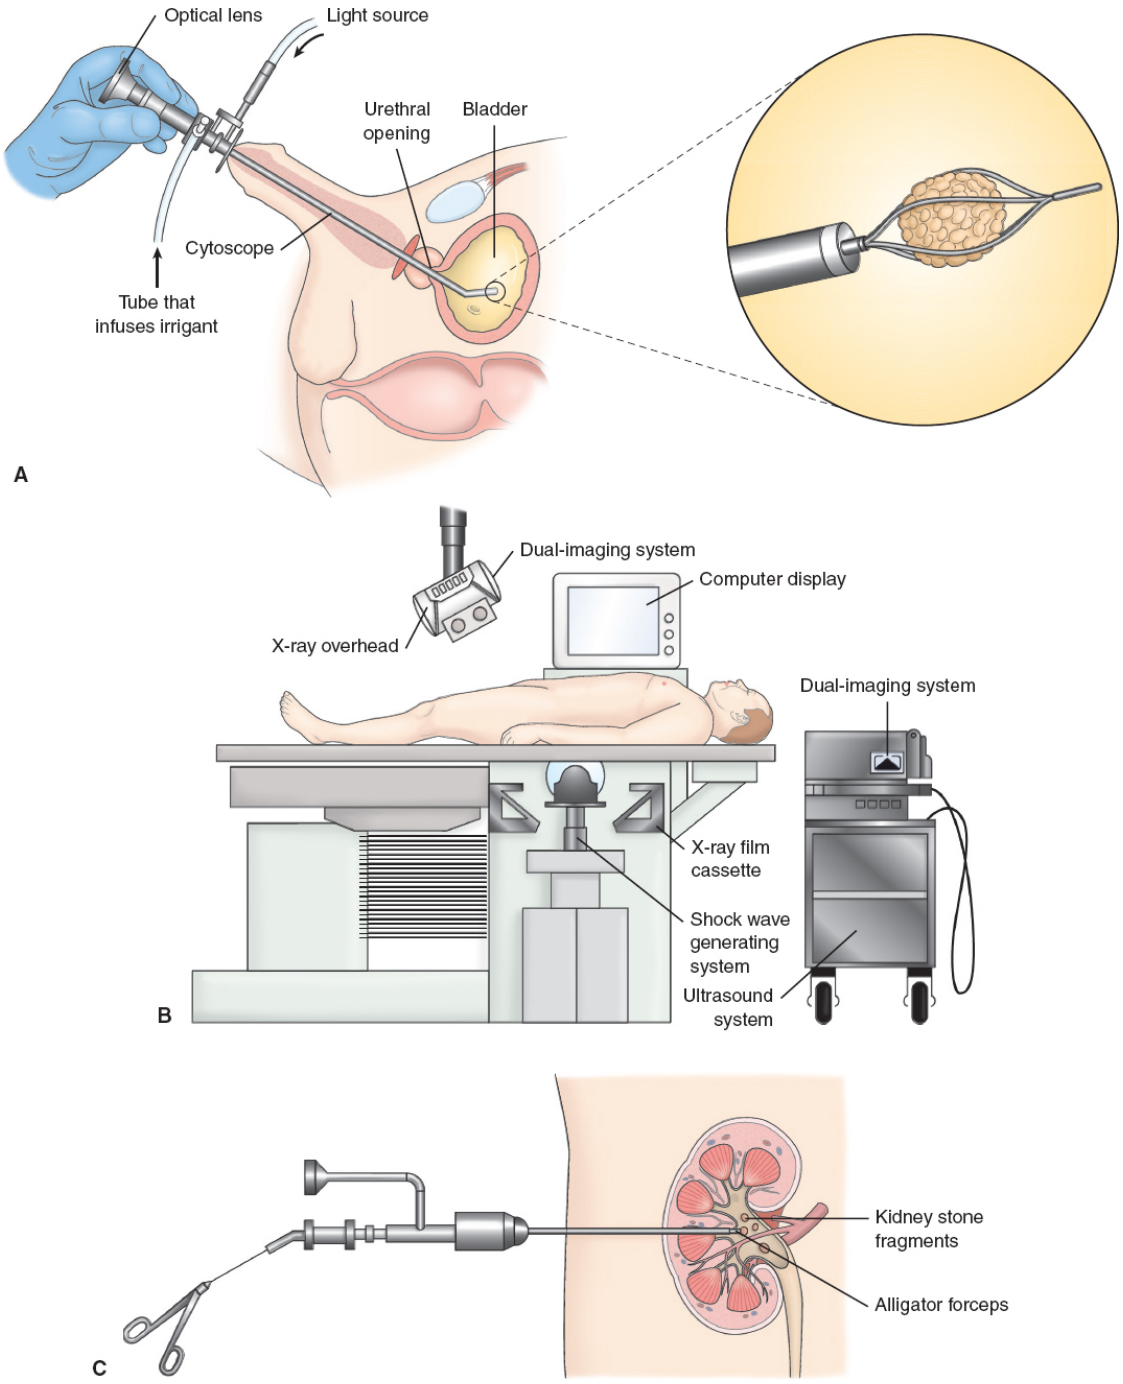

Figure 49-6 • Methods of treating renal calculi. **A.** During ureteroscopy, which is used for removing small stones located in the ureter close to the bladder, a ureteroscope is inserted into the ureter to visualize the stone. The stone is then fragmented or captured and removed. **B.** Extracorporeal shock water lithotripsy is used for most symptomatic, nonpassable upper urinary stones. Electromagnetically generated shock waves are focused over the area of the renal calculus. The high-energy dry shock waves pass through the skin and fragment the stone. **C.** Percutaneous nephrolithotomy is used to treat larger stones. A percutaneous tract

is formed, and a nephroscope is inserted through it. Then, the stone is extracted or pulverized.

Electrohydraulic lithotripsy is a similar method in which an electrical discharge is used to create a hydraulic shock wave to break up the stone. A probe is passed through the cystoscope, and the tip of the lithotripter is placed near the stone. The strength of the discharge and pulse frequency can be varied. This procedure is performed under topical anesthesia. After the stone is extracted, the percutaneous nephrostomy tube may be left in place for a time to ensure that the ureter is not obstructed by edema, blood clots, or fragmented calculi (Norris, 2019). The most common complications are hemorrhage, infection, and urinary extravasation. After the tube is removed, the nephrostomy tract usually closes spontaneously.

Chemolysis, stone dissolution using infusions of chemical solutions (e.g., alkylating agents, acidifying agents) for the purpose of dissolving the stone, is an alternative treatment sometimes used in patients who are at risk for complications with other types of therapy, who refuse to undergo other methods, or who have stones (struvite) that dissolve easily. A percutaneous nephrostomy is performed, and the warm chemical solution is allowed to flow continuously onto the stone. The solution exits the renal collecting system by means of the ureter or the nephrostomy tube. The pressure inside the renal pelvis is monitored during the procedure.

Several of these treatment modalities may be used in combination to ensure removal of the stones.

Surgical Management

Surgical intervention may be indicated if the stone does not respond to other forms of treatment. It may also be performed to correct anatomic abnormalities within the kidney to improve urinary drainage. If the stone is in the kidney, the surgery performed may be a nephrolithotomy (incision into the kidney with removal of the stone) or a nephrectomy, if the kidney is nonfunctional secondary to infection or hydronephrosis. Stones in the kidney pelvis are removed by a pyelolithotomy, those in the ureter by ureterolithotomy, and those in the bladder by cystotomy. If the stone is in the bladder, an instrument may be inserted through the urethra into the bladder, and the stone crushed. Such a procedure is called a cystolitholapaxy. Nursing management following kidney surgery is discussed in Chapter 48.

NURSING PROCESS

The Patient with Renal Calculi

Assessment

The patient with suspected renal calculi is assessed for pain and discomfort as well as associated symptoms, such as nausea, vomiting, diarrhea, and abdominal distention. The severity and location of pain are determined, along with any radiation of the pain. Nursing assessment also includes observing for signs and symptoms of UTI (chills, fever, frequency, and hesitancy) and obstruction (frequent urination of small amounts, oliguria, or anuria). The urine is inspected for blood and is strained for stones or gravel.

The history focuses on factors that predispose the patient to urinary tract stones or that may have precipitated the current episode of renal or ureteral colic. The patient's knowledge about renal calculi and measures to prevent their occurrence or recurrence is also assessed.

Diagnosis

Nursing Diagnoses

Based on the assessment data, nursing diagnoses may include the following:

- Acute pain associated with inflammation, obstruction, and abrasion of the urinary tract
- Lack of knowledge regarding prevention of recurrence of renal calculi

Collaborative Problems/Potential Complications

Potential complications may include the following:

- Infection and urosepsis (from UTI and pyelonephritis)
- Obstruction of the urinary tract by a stone or edema with subsequent acute kidney injury

Planning and Goals

The major goals for the patient may include relief of pain and discomfort, prevention of recurrence of renal calculi, and absence of complications.

Nursing Interventions

Relieving Pain

Severe acute pain is often the presenting symptom of a patient with kidney and urinary calculi and requires immediate attention. Opioid analgesic agents may be prescribed and given to provide rapid relief along with an IV NSAID. The patient is encouraged and assisted to assume a position of comfort. If activity brings pain relief, the patient is assisted to ambulate. The pain level is monitored closely, and an increase in severity is reported

promptly to the primary provider so that relief can be provided and additional treatment initiated.

Monitoring and Managing Potential Complications

Increased fluid intake is encouraged to prevent dehydration and increase hydrostatic pressure within the urinary tract to promote passage of the stone. If the patient cannot take adequate fluids orally, IV fluids are prescribed. The total urine output and patterns of voiding are monitored. Ambulation is encouraged as a means of moving the stone through the urinary tract.

All urine is strained as it be necessary to determine the type of calculi the patient has formed (Flagg & Joiner, 2017). Any blood clots passed in the urine should be crushed and the sides of the urinal and bedpan inspected for clinging calculi. Renal calculi increase the risk of infection, sepsis, and obstruction of the urinary tract. Therefore, the patient is instructed to report decreased urine volume, bloody or cloudy urine, fever, and pain to the primary provider.

Patients with calculi require frequent nursing observation to detect the spontaneous passage. The patient is instructed to immediately report any sudden increases in pain intensity because of the possibility of a stone fragment obstructing a ureter. Vital signs, including temperature, are monitored closely to detect early signs of infection. UTIs may be associated with renal calculi due to an obstruction from the stone or from the stone itself. All infections should be treated with the appropriate antibiotic agent before efforts are made to dissolve the stone.

Promoting Home, Community-Based, and Transitional Care

Educating Patients About Self-Care. Because the risk of recurring renal calculi is high, the nurse provides education about the causes of renal calculi and recommendations to prevent their recurrence (see Chart 49-11).

The patient is encouraged to follow a regimen to avoid further stone formation, including maintaining a high fluid intake because stones form more readily in concentrated urine. A patient who has shown a tendency to form stones should drink enough fluid to excrete greater than 2000 mL (preferably 3000 to 4000 mL) of urine every 24 hours (Flagg & Joiner, 2017).

Urine cultures may be performed every 1 to 2 months in the first year and periodically thereafter. Recurrent UTI is treated promptly. Because prolonged immobilization slows renal drainage and alters calcium metabolism, increased mobility is encouraged whenever possible. In addition, excessive ingestion of vitamins (especially vitamin D) and minerals is discouraged.

If lithotripsy, percutaneous stone removal, ureteroscopy, or other surgical procedures for stone removal have been performed, the nurse educates the patient about the signs and symptoms of complications (e.g., urinary retention, infection) that need to be reported to the primary provider. The importance of follow-up is to assess kidney function and to ensure the eradication or removal of all renal calculi is emphasized to the patient and family.

If ESWL has been performed, the nurse must provide instructions for home care and necessary follow-up. The patient is encouraged to increase fluid intake to assist in the passage of stone fragments, which may occur for 6 weeks to several months after the procedure. The patient and family are educated about signs and symptoms of complications. It is also important to inform the patient to expect hematuria (it is anticipated in all patients), but it should disappear within 4 to 5 days. If the patient has a stent in the ureter, hematuria may be expected until the stent is removed. The patient is instructed to check their temperature daily and notify the primary provider if the temperature is greater than 38°C (about 101°F) or the pain is unrelieved by the prescribed medication. The patient is also informed that a bruise may be observed on the treated side of the back.

Continuing and Transitional Care. Close monitoring of the patient in follow-up care is essential to ensure that treatment has been effective and that no complications develop. The nurse has the opportunity to assess the patient's understanding of ESWL and possible complications. In addition, the nurse has the opportunity to assess the patient's understanding of factors that increase the risk of recurrence of renal calculi and strategies to reduce those risks.

The nurse must assess the patient's ability to monitor urinary pH and interpret the results during follow-up visits. Because of the high risk of recurrence, the patient with renal calculi needs to understand the signs and symptoms of stone formation, obstruction, and infection and the importance of reporting these signs promptly. If medications are prescribed for the prevention of stone formation, the nurse explains their actions, importance, and side effects to the patient.

Evaluation

Expected patient outcomes may include:

1. Reports relief of pain
2. States increased knowledge of health-seeking behaviors to prevent recurrence
    a. Consumes increased fluid intake (at least eight 8-oz glasses of fluid per day)
    b. Participates in appropriate activity

c. Consumes diet prescribed to reduce dietary factors predisposing to stone formation
d. Recognizes symptoms (fever, chills, flank pain, hematuria) to be reported to primary provider
e. Monitors urinary pH as directed
f. Takes prescribed medication as directed to reduce stone formation

3. Experiences no complications
   a. Reports no signs or symptoms of infection or urosepsis
   b. Voids 200 to 400 mL per voiding of clear urine without evidence of bleeding
   c. Experiences absence of urgency, frequency, and hesitancy
   d. Maintains normal body temperature

GENITOURINARY TRAUMA

Various types of injuries to the flank, back, or upper abdomen may result in trauma to the ureters, bladder, or urethra. Blunt trauma is responsible for approximately 85% of all genitourinary trauma and another 15% is from penetrating trauma (Blair, 2017). Kidney trauma is discussed in Chapter 48.

Specific Injuries

Ureteral Trauma

The main causes of ureteral trauma are motor vehicle crashes, sports injuries, falls, and assaults. Penetrating trauma, such as gunshot wounds, is the most frequent etiology, accounting for 90% of ureteral injuries (Blair, 2017). Injuries range from contusions to complete transection. Unintentional injury to the ureter may occur during gynecologic or urologic surgery. There are no specific signs or symptoms of ureteral injury; many traumatic injuries are discovered during exploratory surgery. Surgical repair with placement of stents (to divert urine away from an anastomosis) is usually necessary. If the ureteral trauma is not detected and urine leakage continues, fistulas can develop (Norris, 2019).

Bladder Trauma

Injury to the bladder may occur with pelvic fractures, multiple trauma, or from a blow to the lower abdomen when the bladder is full. Blunt trauma may result

in contusion evident as an ecchymosis—a large bruise resulting from escape of blood into the tissues and involving a segment of the bladder wall—or in rupture of the bladder extraperitoneally, intraperitoneally, or both. Because of the bladder's protected location within the bony pelvis, bladder trauma is relatively uncommon (Blair, 2017). Complications from these injuries include hemorrhage, shock, sepsis, and extravasation of blood into the tissues, which must be treated promptly.

Urethral Trauma

Urethral injuries usually occur with blunt trauma to the lower abdomen or pelvic region. Many patients with urethral injuries also have associated pelvic fractures. The classic triad of symptoms include blood at the urinary meatus, inability to void, and a distended bladder. Complete rupture is seen more often in children because their urethras are less elastic and tear more easily than the adult urethra. Men have five times the risk of urethral injury than women because of the exposed nature of the male urethra (Blair, 2017).

Medical Management

The goals of management in patients with genitourinary trauma are to control hemorrhage, pain, and infection and to maintain urinary drainage. Genitourinary trauma is frequently associated with kidney trauma (see Chapter 48). Hematocrit and hemoglobin levels are monitored closely; decreasing values can indicate hemorrhage within the genitourinary system. The patient is also monitored for oliguria, signs of hemorrhagic shock, and signs and symptoms of acute peritonitis.

Surgical Management

In urethral trauma, a patient whose condition is unstable and who needs monitoring of urine output may need a suprapubic catheter inserted. The patient is catheterized after urethrography has been performed to minimize the risk of urethral disruption and extensive, long-term complications, such as stricture, incontinence, and impotence. Surgical repair may be performed using either open or laparoscopic approaches (Blair, 2017). After surgery, an indwelling urinary catheter may remain in place for 1 to 2 months to allow the system to heal.

Nursing Management

The patient with genitourinary trauma should be assessed frequently during the first few days after injury to detect flank and abdominal pain, muscle spasm, and swelling over the flank.

During this time, patients are educated about care of the incision and the importance of adequate fluid intake. In addition, instructions about changes that should be reported to the primary provider, such as fever, hematuria, flank pain, or any signs and symptoms of decreasing kidney function, are provided (Blair, 2017). The patient with a ruptured bladder may have gross bleeding for several days after repair. Guidelines for increasing activity gradually, lifting, and driving are also provided.

Follow-up nursing care includes monitoring the blood pressure to detect hypertension and advising the patient to restrict activities for about 1 month after trauma to minimize the incidence of delayed or secondary bleeding.

URINARY TRACT CANCERS

Urinary tract cancers include those of the urinary bladder; kidney and renal pelvis; ureters; and other urinary structures, such as the prostate. Kidney cancer is discussed in Chapter 48, and prostate cancer is discussed in Chapter 53.

Cancer of the Bladder

Twenty-five percent of cancers of the urinary bladder occur in adults older than 65 years (Caruso, Tyler, & Wolkowicz, 2017). It is the sixth most common cancer with a much higher incidence in men than women for reasons that are still not well understood (National Cancer Institute [NCI], 2020). Bladder cancer is a leading cause of death, accounting for more than 15,000 deaths in the United States annually (NCI, 2020). Cancers arising from the prostate, colon, and rectum in males and from the lower gynecologic tract in females may metastasize to the bladder.

Tobacco use, especially cigarettes, continues to be a leading risk factor for all urinary tract cancers (NCI, 2020) (see Chart 49-12).

Clinical Manifestations

Bladder tumors usually arise at the base of the bladder and involve the ureteral orifices and bladder neck. Visible, painless hematuria is the most common symptom of bladder cancer. Infection of the urinary tract is a common complication, producing frequency and urgency. However, any alteration in voiding or change in the urine may indicate cancer of the bladder. Pelvic or back pain may occur with metastasis.

Assessment and Diagnostic Findings

The diagnostic evaluation includes cystography, excretory urography, CT and MRI scans, ultrasonography, and bimanual examination with the patient anesthetized. Noninvasive detection using molecular markers is currently under investigation (Caruso et al., 2017). Biopsies of the tumor and adjacent mucosa are the definitive diagnostic procedures (NCI, 2020; Norris, 2019). Transitional cell carcinomas and carcinomas in situ shed recognizable cancer cells. Cytologic examination of fresh urine and saline bladder washings provides information about the prognosis and staging, especially for patients at high risk for recurrence of primary bladder tumors. See Chapter 12 for more information on cancer grading and staging.

Chart 49-12 RISK FACTORS

Bladder Cancer

- Certain genetic mutations including:
  - *HRAS* mutation (Costello syndrome, Facio-cutaneous-skeletal syndrome).
  - *Rb1* mutation.
  - *PTEN/MMAC1* mutation (Cowden syndrome).
  - *NAT2* slow acetylator phenotype.
  - *GSTM1* null phenotype.
- Exposure to arsenic
- Occupational exposure to chemicals in processed paint, dye, metal, and petroleum products
- Positive family history of bladder cancer
- Pelvic radiation therapy or treatment for other cancers
- Tobacco use, cigarette smoking in particular

Adapted from National Cancer Institute (NCI). (2020). Bladder cancer treatment (PDQ®)—Health professional version. Retrieved on 01/11/2020 at: www.cancer.gov/types/bladder/hp/bladder-treatment-pdq#section/all

Medical Management

Treatment of bladder cancer depends on the grade of the tumor (the degree of cellular differentiation) and the stage of tumor growth (the degree of local invasion and the presence or absence of metastasis) (NCI, 2020). The patient's age and physical, mental, and emotional status are considered when determining treatment modalities.

Surgical Management

Transurethral resection or fulguration (cauterization) may be performed for simple papillomas (benign epithelial tumors) (Caruso et al., 2017). These procedures eradicate the tumors through surgical incision or electrical current with the use of instruments inserted through the urethra. After this bladder-sparing surgery, intravesical administration of bacille Calmette–Guérin (BCG) is the treatment of choice. BCG Live is an attenuated live strain of *Mycobacterium bovis,* the causative agent in tuberculosis; treatment is recommended for a minimum of 1 year (NCI, 2020). The exact action of BCG is unknown, but it is thought to produce a local inflammatory and a systemic immunologic response.

Management of superficial bladder cancers presents a challenge because there are usually widespread abnormalities in the bladder mucosa. The entire lining of the urinary tract, or urothelium, is at risk because carcinomatous changes can occur in the mucosa of the bladder, kidney pelvis, ureter, and urethra.

A simple cystectomy or a radical cystectomy is performed for invasive or multifocal bladder cancer. Radical cystectomy in men involves removal of the bladder, prostate, and seminal vesicles and immediate adjacent perivesical tissues. In women, radical cystectomy involves removal of the bladder, lower ureter, uterus, fallopian tubes, ovaries, anterior vagina, and urethra. It may include removal of pelvic lymph nodes. Removal of the bladder requires a urinary diversion procedure, which is described later in this chapter.

Although radical cystectomy remains the standard of care for invasive bladder cancer in the United States, clinical trials continue to explore other options in an effort to spare patients the need for radical cystectomy (NCI, 2020). Other options for managing transitional cell bladder cancer mandate lifelong surveillance with periodic cystoscopy. Although most patients respond completely and their bladders remain free from invasive relapse, one fourth develop a relapse of noninvasive disease. This may be managed with transurethral resection of the bladder tumor and intravesical therapies but carries an additional risk that a late cystectomy may be required.

Pharmacologic Therapy

Chemotherapy with a combination of methotrexate, 5-fluorouracil, vinblastine, doxorubicin, and cisplatin has been effective in producing partial remission of transitional cell carcinoma of the bladder in some patients. IV chemotherapy may be accompanied by radiation therapy (NCI, 2020). Topical chemotherapy (intravesical chemotherapy or instillation of antineoplastic agents into the bladder, resulting in contact of the agent with the bladder wall) is considered when there is a high risk of recurrence, when cancer in situ is present, or when tumor resection has been incomplete. Topical chemotherapy delivers a high

concentration of medication (thiotepa, doxorubicin, mitomycin, and BCG Live) to the tumor to promote tumor destruction. Bladder cancer may also be treated by direct infusion of the cytotoxic agent through the bladder's arterial blood supply to achieve a higher concentration of the chemotherapeutic agent with fewer systemic toxic effects (Blair, 2017; NCI, 2020).

BCG Live is now considered the most predominant and conservative intravesical agent for recurrent bladder cancer, especially superficial transitional cell carcinoma, because it is an immunotherapeutic agent that enhances the body's immune response to cancer. BCG Live has a 43% advantage in preventing tumor recurrence, a significantly better rate than the 16% to 21% advantage of intravesical chemotherapy. In addition, BCG Live is particularly effective in the treatment of carcinoma in situ, eradicating it in more than 80% of cases. In contrast to intravesical chemotherapy, BCG Live has also been shown to decrease the risk of tumor progression. Although BCG Live treatment is the current standard of care, this treatment is most effective when some form of maintenance therapy is utilized (Caruso, et al., 2017; NCI, 2020).

The optimal course of BCG Live appears to be a 6-week course of weekly instillations, followed by a 3-week course at 3 months for tumors that do not respond. In high-risk cancers, maintenance BCG Live given in a 3-week course at 6, 12, 18, and 24 months may limit recurrence and prevent progression. However, the adverse effects associated with this prolonged therapy may limit its widespread applicability.

The patient is allowed to eat and drink before the instillation procedure. Once the bladder is full, the patient must retain the intravesical solution for 2 hours before voiding. At the end of the procedure, the patient is encouraged to void and to drink liberal amounts of fluid to flush the medication from the bladder.

Radiation Therapy

Radiation of the tumor may be performed preoperatively to reduce microextension of the neoplasm and viability of tumor cells, thus decreasing the chances that the cancer may recur in the immediate area or spread through the circulatory or lymphatic systems. Radiation therapy is also used in combination with surgery or to control the disease in patients with inoperable tumors.

For more advanced bladder cancer or for patients with intractable hematuria (especially after radiation therapy), a large, water-filled balloon placed in the bladder produces tumor necrosis by reducing the blood supply of the bladder wall (hydrostatic therapy). The instillation of formalin, phenol, or silver nitrate relieves hematuria and strangury (slow and painful discharge of urine) in some patients.

URINARY DIVERSIONS

Urinary diversion procedures are performed to divert urine from the bladder to a new exit site, usually through a surgically created opening (stoma) in the skin. These procedures are primarily performed when a bladder tumor necessitates cystectomy (NCI, 2020) and are most commonly associated with a high-grade or muscle-invasive bladder cancer (Caruso et al., 2017). Urinary diversion has also been used in managing pelvic malignancy, birth defects, strictures, trauma to the ureters and urethra, neurogenic bladder, chronic infection causing severe ureteral and kidney damage, and intractable interstitial cystitis. It may also be used as a last resort in managing incontinence.

Controversy exists about the best method of establishing permanent diversion of the urinary tract. New techniques are frequently introduced in an effort to improve patient outcomes and quality of life (Shi, Yu, Bellmont, et al., 2018). The age of the patient, condition of the bladder, body build, presence of obesity, degree of ureteral dilation, status of kidney function, and the patient's learning ability, and willingness to participate in postoperative care are all taken into consideration when determining the appropriate surgical procedure.

The types of urinary diversions are an ileal conduit, an orthotopic neobladder reconstruction, or various other continent urinary diversions (Chang & Lawrentschuk, 2015; Yang, Bai, Wang, et al., 2019). The choice of a urinary diversion surgical procedure depends on the patient's and surgeon's preferences, the extent of comorbidity, and the quality of life goal in the postoperative period (Chang & Lawrentschuk, 2015). Variations in urinary diversion surgical procedures are devised frequently in an effort to identify and perfect procedures that will improve patient outcomes and reduce the incidence of postoperative problems (Yang et al., 2019).

Ileal Conduit

The **ileal conduit** (ileal loop) is the oldest and most common of the urinary diversion procedures in use because of the low number of complications and the simplicity of the procedure (Chang & Lawrentschuk, 2015; Shi et al., 2018) (Fig 49-7). Additional advantages include that it is well known to health care professionals, there is no need for bladder retraining, and no nocturnal incontinence (Chang & Lawrentschuk, 2015).

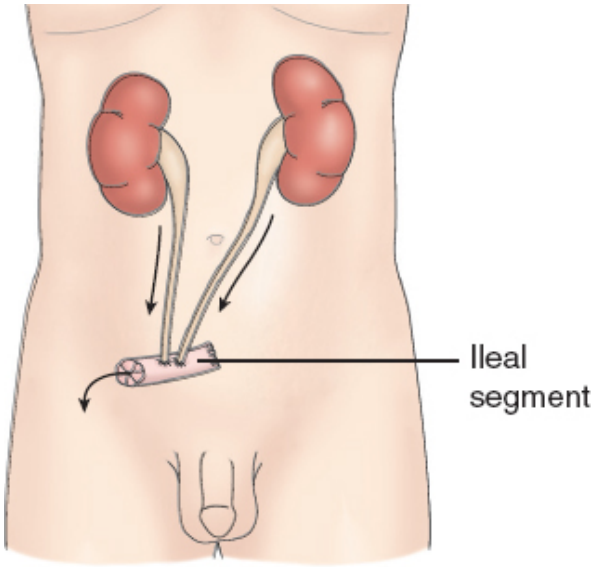

Figure 49-7 • Conventional ileal conduit. The surgeon transplants the ureters to an isolated section of the terminal ileum (ileal conduit), bringing one end to the abdominal wall. The ureter may also be transplanted into the transverse sigmoid colon (colon conduit) or proximal jejunum (jejuna conduit).

When an ileal conduit surgical procedure is performed, the urine is diverted by implanting the ureter into a 12-cm loop of ileum that is led out through the abdominal wall. This loop of ileum is a simple conduit (passageway) for urine from the ureters to the surface. A loop of the sigmoid colon may also be used. An ileostomy bag is used to collect the urine. The resected (cut) ends of the remaining intestine are anastomosed (connected) to provide an intact bowel (Wound Ostomy Continence Nurses [WOCN] Society, 2018).

Stents, usually made of thin, pliable tubing, are placed in the ureters to prevent occlusion secondary to postsurgical edema (Yang et al., 2019). The bilateral ureteral stents allow urine to drain from the kidney to the stoma and provide a method for accurate measurement of urine output. They may be left in place 10 to 21 days postoperatively. Jackson–Pratt drains or other types of drains are inserted to prevent the accumulation of fluid in the space created by removal of the bladder.

The outcome for a patient with an ileal conduit depends to a large degree on the location or position of the stoma, whether the drainage device (bag) establishes a watertight seal to the skin, and the patient's ability to manage the appliance.

After surgery, a skin barrier and a transparent, disposable urinary drainage bag are applied around the conduit and connected to drainage. A custom-cut appliance is used until the edema subsides and the stoma shrinks to normal size. The clear bag allows the stoma to be inspected and the patency of the stent and the urine output to be monitored. The ileal bag drains urine (not

feces) continuously. The appliance (bag) usually remains in place as long as it is watertight; it is changed when necessary to prevent leakage of urine.

Complications

Complications that may follow placement of an ileal conduit include wound infection or wound dehiscence, urinary leakage, ureteral obstruction, hyperchloremic acidosis, small bowel obstruction, ileus, and gangrene of the stoma. Delayed complications include ureteral obstruction, contraction or stenosis (narrowing) of the stoma, kidney deterioration due to chronic reflux, peristomal hernia, retraction, pyelonephritis, renal calculi, and cancer recurrence (WOCN Society, 2018).

Nursing Management

During the preoperative period, the nurse helps facilitate the marking of the stoma on the abdominal wall as this is associated with decreased complications postoperatively, fewer problems with the fitting of the appliance, and increased quality of life and independence postoperatively (WOCN Society, 2018). Preoperative education is initiated about basic self-care skills for managing the ileal conduit (WOCN Society, 2018). Because the patient requires specialized care, a consultation is initiated with a WOC nurse.

In the immediate postoperative period, urine volumes are monitored hourly. Throughout the patient's hospitalization, the nurse monitors closely for complications, reports signs and symptoms of them promptly, and intervenes quickly to prevent their progression.

A urine output below 0.5 mL/kg/h may indicate dehydration or an obstruction in the ileal conduit, with possible backflow or leakage from the ureteroileal anastomosis. A catheter may be inserted through the urinary conduit to monitor the patient for possible stasis or residual urine from a constricted stoma. Urine may drain through the bilateral ureteral stents as well as around the stents. If the ureteral stents are not draining, the nurse may be instructed to carefully irrigate with 5 to 10 mL sterile normal saline solution, being careful not to exert tension that could dislodge the stent. Hematuria may be noted in the first 48 hours after surgery but usually resolves spontaneously.

Providing Stoma and Skin Care

The stoma is inspected frequently for color and viability. A healthy stoma is pink or red. A change from this normal color to purple, brown, or black suggests that the vascular supply may be compromised. If cyanosis and a compromised blood supply persist, surgical intervention may be necessary. The stoma is not sensitive to touch, but the skin around the stoma becomes sensitive if urine or the appliance causes irritation. The skin is inspected for

signs of irritation and bleeding of the stoma mucosa, encrustation and skin irritation around the stoma (from alkaline urine coming in contact with exposed skin), rashes, redness, pruritus, or other signs of impairment and wound infections (WOCN Society, 2018).

Caring for the Ostomy

Moisture in bed linens or clothing or the odor of urine around the patient should alert the nurse to the possibility of leakage from the appliance, potential infection, or a problem in hygienic management. A properly fitted appliance is essential to prevent exposure of the skin around the stoma to urine (WOCN Society, 2018). If the urine smells foul, the stoma is catheterized, if prescribed, to obtain a urine specimen for culture and sensitivity testing.

Encouraging Fluids and Relieving Anxiety

Because mucous membrane is used in forming the conduit, the patient may excrete a large amount of mucus mixed with urine. This causes anxiety in many patients. To help relieve this anxiety, the nurse reassures the patient that this is a normal occurrence after an ileal conduit procedure. The nurse encourages adequate fluid intake to flush the ileal conduit and decrease the accumulation of mucus.

Selecting the Ostomy Appliance

The nurse is instrumental (often with consultation with a WOC nurse) in selecting an appropriate ostomy appliance. The urinary appliance may consist of one or two pieces and may be disposable (usually used once and discarded) or reusable. The choice of appliance is determined by the location of the stoma and by the patient's normal activity, manual dexterity, visual function, body build, economic resources, and preference.

Promoting Home, Community-Based, and Transitional Care

Educating Patients About Self-Care

Patient education begins in the hospital but continues in the home setting because patients are usually discharged within days of surgery. The nurse educates the patient how to assess and manage the urinary diversion as well as how to deal with changes in body image. A WOC nurse is invaluable in consulting with the nurse on various aspects of care and patient education (WOCN Society, 2018).

Changing the Appliance

The patient and family are educated about how to apply and change the appliance so that they are comfortable carrying out the procedure and can do so proficiently. Ideally, the appliance system is changed before the system leaks and at a time that is convenient for the patient. Many patients find that early morning is most convenient because the urine output is reduced. A variety of appliances are available (WOCN Society, 2018).

Regardless of the type of appliance used, a skin barrier is essential to protect the skin from irritation and excoriation (WOCN Society, 2018). To maintain skin integrity, a skin barrier or leaking pouch is never patched with tape to prevent accumulation of urine under the skin barrier or faceplate. The patient is instructed to avoid moisturizing soaps and body washes when cleaning the area because they interfere with the adhesion of the pouch. The degree to which the stoma protrudes is not the same in all patients; thus, there are various accessories and custom-made appliances to solve individual problems. Patient guidelines for applying reusable and disposable systems are presented in Chart 49-13.

Controlling Odor

The patient is instructed to avoid foods that give the urine a strong odor (e.g., asparagus, cheese, eggs). Most appliances contain odor barriers, but, if needed, a few drops of liquid deodorizer or diluted white vinegar may be introduced through the drain spout into the bottom of the pouch with a syringe or eyedropper to reduce odors. The patient is reminded that odor will develop if the pouch is worn longer than recommended and not cared for properly (WOCN Society, 2018).

Managing the Ostomy Appliance

The patient is instructed to empty the pouch by means of a drain valve when it is one third full because the weight of more urine will cause the pouch to separate from the skin. Some patients prefer wearing a leg bag attached with an adapter to the drainage apparatus. To promote uninterrupted sleep, a collecting bottle and tubing (one unit) are snapped onto an adapter that connects to the ileal appliance. A small amount of urine is left in the bag when the adapter is attached to prevent the bag from collapsing against itself. The tubing may be threaded down the pajama or pants leg to prevent kinking. The collecting bottle and tubing are rinsed daily with cool water and once a week with a 3:1 solution of water and white vinegar.

Cleaning and Deodorizing the Appliance

Usually, the reusable appliance is rinsed in warm water and soaked in a 3:1 solution of water and white vinegar or a commercial deodorizing solution for 30 minutes. It is rinsed with tepid water and air-dried away from direct sunlight as hot water and exposure to direct sunlight dry the pouch and increase the incidence of cracking. After drying, the appliance may be

powdered with cornstarch and stored. Two appliances are necessary—one to be worn while the other is air-drying.

Chart 49-13  **PATIENT EDUCATION**

Using Urinary Diversion Collection Appliances

Applying a Reusable Pouch System

The nurse instructs the patient to:

1. Gather all necessary supplies. Perform hand hygiene.
2. Prepare new appliance according to the manufacturer's directions:
   - Apply double-faced adhesive disc that has been properly sized to fit the reusable pouch faceplate.
   - Remove paper backing and set pouch aside, or apply thin layer of contact cement to one side of the reusable pouch faceplate.
   - Set pouch aside.
3. Remove soiled pouch gently. Lay aside to clean later.
4. Clean peristomal skin (skin around stoma) with small amount of soap and water. Rinse thoroughly and dry. If a film of soap remains on the skin and the site does not dry, the appliance will not adhere adequately.
5. Use a wick (rolled gauze pad or tampon) over the stoma to absorb urine and keep the skin dry throughout the appliance change.
6. Inspect peristomal skin for irritation.
7. Note that a skin protector wipe or barrier ring may be applied before centering the faceplate opening directly over the stoma.
8. Position appliance over stoma, and press gently into place.
9. If desired, use a pouch cover or apply cornstarch under the pouch to prevent perspiration and skin irritation.
10. Clean soiled pouch, and prepare for reuse.

Applying a Disposable Pouch System

The nurse instructs the patient to:

1. Gather all necessary supplies. Perform hand hygiene.
2. Measure stoma, and prepare an opening in the skin barrier about 1/8-inch larger than the stoma and the same shape as the stoma.
3. Remove paper backing from skin barrier, and set aside.
4. Gently remove old appliance, and set aside.
5. Clean peristomal skin with warm water, and dry thoroughly.
6. Inspect peristomal skin (skin around stoma) for irritation.
7. Use a wick (rolled gauze pad or tampon) over the stoma to absorb urine, and keep the skin dry during the appliance change.
8. Center opening of skin barrier over stoma, and apply with firm, gentle pressure to attain a watertight seal.
9. If using a two-piece system, snap pouch onto the flanged wafer that adheres to skin.
10. Close drainage tap or spout at bottom of pouch.
11. Note that a pouch cover can be used or cornstarch applied under pouch to prevent perspiration and skin irritation.

12. Apply hypoallergenic tape around the skin barrier in a picture-frame manner.
13. Dispose of soiled appliance.

Adapted from Wound Ostomy Continence Nurses (WOCN) Society. (2018). WOCN Society Clinical Guideline: Management of the adult patient with a fecal or urinary ostomy—An executive summary. *Journal of Wound Ostomy Continence Nursing*, *45*(1), 50–58.

Continuing and Transitional Care

Follow-up care is essential to determine how the patient has adapted to the altered body image and lifestyle changes. Referral for home health is indicated to determine how well the patient and family are coping with the urinary drainage diversion. The nurse assesses the patient's physical status and emotional response. In addition, the nurse assesses the ability of the patient and family to manage the urinary diversion and appliance, reinforces previous education, and provides additional information (e.g., community resources, sources of ostomy supplies, insurance coverage for supplies).

As the postoperative edema subsides, the nurse assists in determining the appropriate changes needed in the ostomy appliance. The size of the stoma is measured every 3 to 6 weeks for the first few months postoperatively. The correct appliance size is determined by measuring the widest part of the stoma with a ruler. The permanent appliance should be no more than 1.6 mm (1/8 inch) larger than the diameter of the stoma and the same shape as the stoma to prevent contact of the skin with drainage.

The nurse educates the patient and family about resources (see the Resources section at the end of this chapter). Local chapters of the American Cancer Society (ACS) can provide medical equipment and supplies and other resources for the patient who has undergone ostomy surgery for cancer.

The home health nurse assesses the patient for potential long-term complications such as ureteral obstruction, strictures, hernias, or deterioration of kidney function (Yang et al., 2019). The nurse also reinforces previous education about potential complications and self-care management (WOCN Society, 2018).

Orthotopic Neobladder

An orthotopic neobladder reconstruction is performed in approximately 38% of patients who have undergone cystectomy for invasive bladder cancer (Shi et al., 2018). During this surgery, a new bladder is constructed from segments of the intestine (Chang & Lawrentschuk, 2015) (see Fig. 49-8). There are several advantages of this type of urinary diversion compared to the more common ileal conduit including that the newly reconstructed bladder is attached to the

urethra, achieving functional and anatomical restoration (Shi et al., 2018). The new voiding system is similar to the natural preoperative state, and researchers have reported a higher quality of life in patients who undergo this procedure compared to patients with an ileal conduit (Chang & Lawrentschuk, 2015; Shi et al., 2018; Yang et al., 2019).

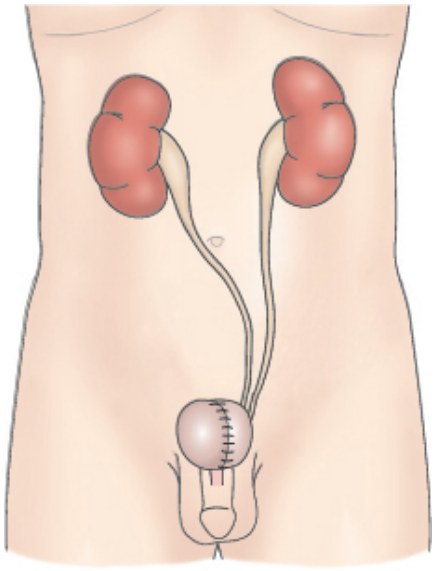

Figure 49-8 • Orthotopic neobladder. The surgeon constructs a new bladder from segments of intestine.

There are several disadvantages to orthotopic neobladder reconstruction as well. Not all patients are suitable for the surgery (see later discussion). Other disadvantages include the need for bladder retraining and the potential for incontinence postoperatively (Chang & Lawrentschuk, 2015). The intestine used to create the neobladder does not have the stimulation to contract that the natural bladder had, leading to the need for bladder retraining. Even with bladder retraining, only 80% of patients achieve full continence (Shi et al., 2018).

Surgical Management

In the preoperative period, the patient undergoes careful evaluation as not all patients are suitable for this surgery. Major contraindications include renal and liver impairment, intestinal disease, and cancer in specific parts of the bladder (Chang & Lawrentschuk, 2015). See Chart 49-14 for a list of patient characteristics that contraindicate performing an orthotopic neobladder reconstruction. However, this surgery is a viable alternative to an ileal conduit in the patient who is free of these contraindications, does not want a stoma, and is willing to adhere to the neobladder training (Chang & Lawrentschuk, 2015).

When the surgery is performed, the surgeon constructs a sphere-shaped neobladder, also referred to as a pouch, from intestinal segments to replace the bladder that has been removed. The most common intestinal segments used are the ileum, colon, and sigmoid portions of the intestine (Chang & Lawrentschuk, 2015).

Complications

This is a more complex surgery than the creation of an ileal conduit; therefore, there is a higher risk of several complications including fluid and electrolyte imbalances, postoperative ileus, and incontinence. The patient is at risk for metabolic acidosis as the wall of the neobladder is now made of intestinal mucosa that is more permeable to urinary electrolytes compared to the original bladder wall (Chang & Lawrentschuk, 2015). The shift in electrolytes also leads to the urine being more concentrated, which can lead to dehydration (Chang & Lawrentschuk, 2015). Patients are at higher risk of postoperative ileus at the fifth postoperative day and later compared to those undergoing an ileal conduit procedure (Chang & Lawrentschuk, 2015).

Chart 49-14

Contraindications to Orthotopic Neobladder Reconstruction Surgery

- Acute kidney injury with a serum creatinine of >150 umol/L
- Lack of motivation or intellectual ability to follow a strict postoperative voiding regimen
- Impaired liver function
- Inability to accept incontinence postoperatively (mainly nocturnal) in the short term and possibly long term
- Intestinal disease due to radiation or inflammatory bowel disease
- Histologically confirmed cancer at the prostatic apex (males) or bladder neck (females)
- Physical limitations preventing the performance of self-catheterization
- Presence of metastatic cancer

Adapted from Chang, D. T. S., & Lawrentschuk, N. (2015). Orthotopic neobladder reconstruction. *Urology Annals*, *7*(1), 1–7.

Nursing Management

In the preoperative period, the nurse assists in the assessment of the suitability of the patient to undergo an orthotopic neobladder reconstruction. In conjunction with the surgeon the nurse assesses for potential patient contraindications to the surgery (see Chart 49-14). It is important to begin

education about what the patient can expect in the postoperative period, especially the time and effort that will be needed for bladder retraining. The patient needs to clearly understand the risk for incontinence both in the short term postoperatively and possibly on a long-term basis.

Postoperative nursing care of the patient with an orthotopic neobladder reconstruction is similar to nursing care of the patient with an ileal conduit. In addition to the usual postoperative care (see Chapter 16), the patient will have an indwelling and subrapubic catheter (Chang & Lawrentschuk, 2015). Procedures may vary between surgical centers that perform this procedure, but commonly an irrigation of 100 mL normal saline every 6 to 8 hours is prescribed to prevent catheter blockage due to an increase in the amount of mucous discharged from the intestine compared to a regular bladder wall (Chang & Lawrentschuk, 2015).

Monitoring Fluid and Electrolytes

Fluid and electrolyte balance is maintained in the immediate postoperative period by closely monitoring the serum electrolyte levels and administering appropriate IV fluids. The patient is monitored for signs and symptoms of metabolic acidosis and dehydration. Electrolyte replacement may be required to return values to within normal limits.

Encouraging Adequate Nutrition

The patient has additional carbohydrate and protein needs in order to heal from the complex surgery (Chang & Lawrentschuk, 2015). Dietary instructions include increasing the fiber content in the diet to decrease the risk of postoperative ileus, particularly on the fifth postoperative day and following discharge. Increased dietary fiber and other measures are needed to prevent constipation as the intestine is now shorter.

Promoting Home, Community-Based, and Transitional Care

Patient education begins in the hospital but continues in the home setting because patients are usually discharged within days of surgery. The neobladder needs 2 to 3 weeks to heal and therefore the patient is discharged home with an indwelling and subrapubic catheter (Chang & Lawrentschuk, 2015). The nurse instructs the patient how to assess and manage the indwelling catheters and irrigate as needed. Once it is determined that the neobladder is watertight, neobladder retraining begins.

Chart 49-15 PATIENT EDUCATION

Neobladder Training

The nurse instructs the patient to:

- Void in a sitting position using the Valsalva maneuver to empty the neobladder
- Perform all pelvic floor muscle exercises as prescribed, every day.
- Take steps to avoid constipation: Drink adequate fluids, eat a well-balanced diet high in fiber, exercise regularly, and take stool softeners if recommended.
- Void regularly, five to eight times a day (about every 2 to 3 hours):
  - First thing in the morning
  - Before each meal
  - Before retiring to bed
  - Once during the night if necessary

Adapted from Chang, D. T. S., & Lawrentschuk, N. (2015). Orthotopic neobladder reconstruction. *Urology Annals*, *7*(1), 1–7.

Educating Patients About Self-Care

Patient education is important and should be provided verbally and in writing (see Chart 49-15). The patient should be educated to develop and use a log or diary to record timing of pelvic floor muscle exercises, frequency of voiding and intermittent catheterization, any changes in bowel function, and any episodes of incontinence.

Continuing and Transitional Care

Follow-up care is essential to determine how the patient has adapted to the changes needed to manage the neobladder. Referral for home health is indicated to continue the neobladder training and determine how well the patient and family are coping with the urinary drainage diversion. The nurse assesses the patient's physical status and emotional response. In addition, the nurse assesses the ability of the patient and family to manage the urinary diversion, reinforces previous education, and provides additional information (e.g., community resources, insurance coverage for supplies).

Other Continent Urinary Diversion Procedures

Another type of continent urinary diversion is the Indiana pouch, created for the patient whose bladder is removed (Chang & Lawrentschuk, 2015). The Indiana pouch uses a segment of the ileum and cecum to form the reservoir for urine (see Fig. 49-9). The ureters are tunneled through the muscular bands of

the intestinal pouch and anastomosed. The reservoir is made continent by narrowing the efferent portion of the ileum and sewing the terminal ileum to the subcutaneous tissue, forming a continent stoma flush with the skin. The pouch is sewn to the anterior abdominal wall around a cecostomy tube. Urine collects in the pouch until a catheter is inserted and the urine is drained.

The pouch must be drained at regular intervals by a catheter to prevent absorption of metabolic waste products from the urine, reflux of urine to the ureters, and UTI. Postoperative nursing care of the patient with a continent ileal urinary pouch is similar to nursing care of the patient with an ileal conduit. However, these patients usually have additional drainage tubes (cecostomy catheter from the pouch, stoma catheter exiting from the stoma, ureteral stents, and Penrose drain, as well as a urethral catheter). All drainage tubes must be carefully monitored for patency and amount and type of drainage. In the immediate postoperative period, the cecostomy tube is irrigated two or three times daily to remove mucus and prevent blockage.

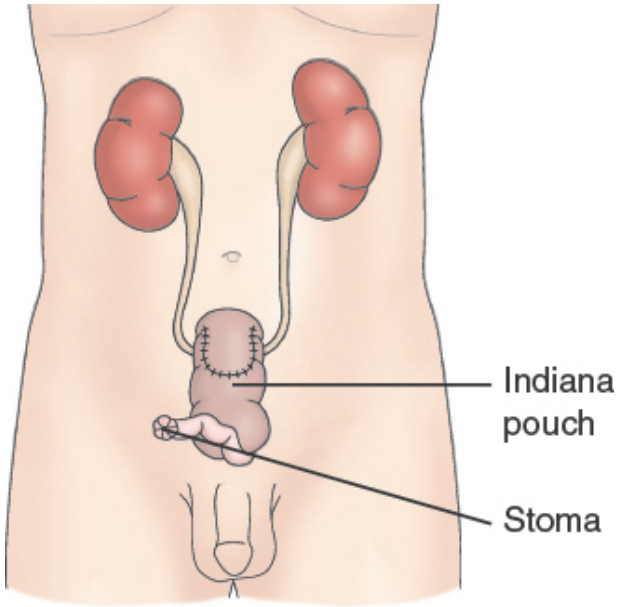

Figure 49-9 • Indiana pouch. The surgeon introduces the ureters into a segment of ileum and cecum. Urine is drained periodically by inserting a catheter into the stoma.

Other variations of continent urinary reservoirs are used occasionally (Chang & Lawrentschuk, 2015). With these methods, the pouch must be drained at regular intervals by inserting a catheter.

NURSING PROCESS

The Patient Undergoing Urinary Diversion Surgery

Preoperative Assessment

The following are key preoperative nursing assessment concerns:

- Cardiopulmonary function assessments are performed because patients undergoing cystectomy are often older adults who may be at greater risk for cardiac and respiratory complications.
- A nutritional status assessment is important because of possible poor nutritional intake related to underlying health problems.
- Learning needs are assessed in consultation with a WOC nurse to evaluate the patient's and the family's understanding of the procedure as well as the changes in physical structure and function that result from the surgery. The patient's self-concept and self-esteem are assessed in addition to methods for coping with stress and loss. The patient's mental status, manual dexterity and coordination, vision, and preferred method of learning are noted because they affect postoperative self-care.

Preoperative Diagnosis

Nursing Diagnoses

Based on the assessment data, preoperative nursing diagnoses may include the following:

- Anxiety associated with anticipated losses associated with the surgical procedure
- Impaired nutritional intake associated with inadequate nutritional ingestion
- Lack of knowledge about the surgical procedure and postoperative care

Preoperative Planning and Goals

The major goals for the patient may include relief of anxiety; improved preoperative nutritional status; and increased knowledge about the surgical procedure, expected outcomes, and postoperative care.

Preoperative Nursing Interventions

Relieving Anxiety

The threat of cancer and removal of the bladder create anxiety related to changes in body image. Patients may face problems adapting to an external appliance, a stoma, a surgical incision, and altered toileting habits. Men must also adapt to sexual impotency; a penile implant is considered if the patient is a candidate for the procedure. Women also have anxiety related to

altered appearance, body image, and self-esteem. A supportive approach, both physical and psychosocial, is needed and includes assessing the patient's self-concept and manner of coping with stress and loss; helping the patient to identify ways to maintain their lifestyle and independence with as few changes as possible; and encouraging the patient to express fears and anxieties about the ramifications of the upcoming surgery. Support services are available through ostomy societies and agencies, and can provide emotional support and make adaptation easier both before and after surgery (see Resources section at the end of this chapter).

Ensuring Adequate Nutrition

A low-residue diet is prescribed to cleanse the bowel to minimize fecal stasis, decompress the bowel, and minimize postoperative ileus. In addition, antibiotic medications are given to reduce pathogenic flora in the bowel and to reduce the risk of infection. Because the patient undergoing a urinary diversion procedure for cancer may be severely malnourished due to the tumor, previous treatments, and anorexia, enteral or parenteral nutrition may be prescribed to promote healing. Adequate preoperative hydration is imperative to ensure urine flow during surgery and to prevent hypovolemia during the prolonged surgical procedure.

Explaining Surgery and Its Effects

Participation of a WOC nurse in patient education and care is invaluable for informed preoperative education and postoperative planning. Explanations of the surgical procedure, the appearance of the stoma, the rationale for preoperative bowel preparation, the reasons for wearing a collection device, and the anticipated effects of the surgery on sexual functioning are part of patient education. The placement of the stoma site is planned preoperatively with the patient standing, sitting, and lying down to locate the stoma away from bony prominences, skin creases, and folds. The stoma should also be placed away from old scars, the umbilicus, and the belt line.

For ease of self-care, the patient must be able to see and reach the site comfortably. The site is marked with indelible ink so that it can be located easily during surgery. The patient is assessed for allergies or sensitivity to tape or adhesives. Patch testing of certain appliances may be necessary before the ostomy equipment is selected. This is particularly important if the patient is or may be allergic to latex (see Chapter 14, Fig. 14-2).

Preoperative Evaluation

To measure the effectiveness of care, the nurse evaluates the patient's preoperative anxiety level and nutritional status as well as preexisting knowledge and expectations of surgery.

Expected patient outcomes may include:

1. Exhibits reduced anxiety about surgery and expected losses

a. Verbalizes fears with health care team and family
b. Expresses positive attitude about outcome of surgery

2. Exhibits adequate nutritional status
   a. Maintains adequate intake before surgery
   b. Maintains body weight
   c. States rationale for enteral or parenteral nutrition if needed
   d. Exhibits normal skin turgor, moist mucous membranes, adequate urine output, and absence of excessive thirst
3. Demonstrates knowledge about the surgical procedure and postoperative course
   a. Identifies limitations expected after surgery
   b. Discusses expected immediate postoperative environment (tubes, equipment, nursing surveillance)
   c. Practices deep-breathing, coughing, and foot exercises

Postoperative Assessment

The role of the nurse in the immediate postoperative period is to prevent complications and to assess the patient carefully for any signs and symptoms of complications. The catheters and any drainage devices are monitored closely. Urine volume, patency of the drainage system, and color of the drainage are assessed. A sudden decrease in urine volume or increase in drainage is reported promptly to the primary provider, because these may indicate obstruction of the urinary tract, inadequate blood volume, or bleeding. In addition, the patient's need for pain control is assessed regularly, as with all postoperative patients.

Postoperative Diagnosis

Nursing Diagnoses

Based on the assessment data, major postoperative nursing diagnoses may include the following:

- Risk for impaired skin integrity associated with problems in managing the urine collection appliance
- Acute pain associated with surgical incision
- Disturbed body image associated with urinary diversion
- Impaired sexual functioning associated with structural and physiologic alterations
- Lack of knowledge about management of urinary function

Collaborative Problems/Potential Complications

Potential complications may include the following:

- Peritonitis due to disruption of anastomosis

- Stoma ischemia and necrosis due to compromised blood supply to stoma
- Stoma retraction and separation of mucocutaneous border due to tension or trauma

Postoperative Planning and Goals

The major goals for the patient may include maintaining skin integrity, relieving pain, increasing self-esteem, developing appropriate coping mechanisms to accept and deal with altered urinary function and sexuality, increasing knowledge about management of urinary function, and preventing potential complications.

Postoperative Nursing Interventions

Postoperative management focuses on monitoring urinary function, preventing postoperative complications (infection and sepsis, respiratory complications, fluid and electrolyte imbalances, fistula formation, and urine leakage), and promoting patient comfort. Catheters or drainage systems are monitored, and urine output is monitored carefully. A nasogastric tube is inserted during surgery to decompress the GI tract and to relieve pressure on the intestinal anastomosis. It is usually kept in place for several days after surgery. As soon as bowel function resumes—as indicated by bowel sounds, the passage of flatus, and a soft abdomen—oral fluids are permitted. Until that time, IV fluids and electrolytes are given. The patient is assisted to ambulate as soon as possible to prevent complications of immobility.

Maintaining Skin Integrity

Strategies to promote skin integrity begin with reducing and controlling those factors that increase the patient's risk of poor nutrition and poor healing. Meticulous skin care and management of the drainage system are provided by the nurse until the patient can manage them and is comfortable doing so. Care is taken to keep the system intact to protect the skin from exposure to drainage. Supplies must be readily available to manage the drainage in the immediate postoperative period. Consistency in implementing the skin care program throughout the postoperative period results in maintenance of skin integrity and patient comfort. In addition, maintenance of skin integrity around the stoma enables the patient and family to adjust more easily to the alterations in urinary function and helps them learn skin care techniques.

Relieving Pain

Analgesic medications are administered liberally postoperatively to relieve pain and promote comfort, thereby allowing the patient to turn, cough, and perform deep-breathing exercises. Patient-controlled analgesia and regular administration of analgesic agents around the clock are two options that

may be used to ensure adequate pain relief. A pain intensity scale is used to evaluate the adequacy of the medication and the approach to pain management. See Chapter 9 for further discussion of pain management.

Improving Body Image

The patient's ability to cope with the changes associated with the surgery depends to some degree on their body image and self-esteem before the surgery and the support and reaction of others. Allowing the patient to express concerns and anxious feelings can help, especially in adjusting to the changes in toileting habits. The nurse can also help improve the patient's self-concept by educating about skills needed to be independent in managing the urinary drainage devices. Education about ostomy care is conducted in a private setting to encourage the patient to ask questions without fear of embarrassment. Explaining why the nurse must wear gloves when performing ostomy care can prevent the patient from misinterpreting the use of gloves as a sign of aversion to the stoma.

Exploring Sexuality Issues

Patients who experience altered sexual function as a result of the surgical procedure may mourn this loss. Encouraging the patient and partner to share their feelings about this loss with each other and acknowledging the importance of sexual function and expression may encourage the patient and partner to seek sexual counseling and to explore alternative ways of expressing sexuality. Using the support and expertise from another patient with an ostomy who is functioning fully in society and family life may also assist the patient and family in recognizing that full recovery is possible.

Monitoring and Managing Potential Complications

Complications are not unusual because of the complexity of the surgery, the underlying reason (cancer, trauma) for the urinary diversion procedure, and the patient's frequently less-than-optimal nutritional status. Complications may include respiratory disorders (e.g., atelectasis, pneumonia), fluid and electrolyte imbalances, breakdown of any anastomosis, sepsis, fistula formation, fecal or urine leakage, and skin irritation. If these occur, the patient will remain hospitalized for an extended length of time and will probably require parenteral nutrition, GI decompression by means of nasogastric suction, and further surgery. The goals of management are to establish drainage, provide adequate nutrition for healing to occur, and prevent sepsis.

Peritonitis. Peritonitis can occur postoperatively if urine leaks at the anastomosis. Signs and symptoms include abdominal pain and distention, muscle rigidity with guarding, nausea and vomiting, paralytic ileus (absence of bowel sounds), fever, and leukocytosis.

Urine output must be monitored closely, because a sudden decrease in output with a corresponding increase in drainage from the incision or drains

may indicate urine leakage. In addition, the urine drainage device is observed for leakage. The pouch is changed if a leak is observed. Small leaks in the anastomosis may seal themselves, but surgery may be needed for larger leaks.

Vital signs (blood pressure, pulse and respiratory rates, temperature) are monitored. Changes in vital signs, as well as increasing pain, nausea and vomiting, and abdominal distention, are reported and may indicate peritonitis.

Stoma Ischemia and Necrosis. The stoma is monitored because ischemia and necrosis of the stoma can result from tension on the mesentery blood vessels, twisting of the bowel segment (conduit) during surgery, or arterial insufficiency. The new stoma must be inspected at least every 4 hours to assess the adequacy of its blood supply. The stoma should be red or pink. If the blood supply to the stoma is compromised, the color changes to purple, brown, or black. These changes are reported immediately. The surgeon or WOC nurse may insert a small, lubricated tube into the stoma and shine a flashlight into the lumen of the tube to assess for superficial ischemia or necrosis. A necrotic stoma requires surgical intervention. If the ischemia is superficial, the dusky stoma is observed and may slough its outer layer in several days.

Stoma Retraction and Separation. Stoma retraction and separation of the mucocutaneous border can occur as a result of trauma or tension on the internal bowel segment used for creation of the stoma. In addition, mucocutaneous separation can occur if the stoma does not heal as a result of accumulation of urine on the stoma and mucocutaneous border. Using a collection drainage pouch with an antireflux valve is helpful because the valve prevents urine from pooling on the stoma and mucocutaneous border. Meticulous skin care to keep the area around the stoma clean and dry promotes healing. If a separation of the mucocutaneous border occurs, surgery is not usually needed. The separated area is protected by applying karaya powder, stoma adhesive paste, and a properly fitted skin barrier and pouch. By protecting the separation, healing is promoted. If the stoma retracts into the peritoneum, surgical intervention is mandatory.

If surgery is needed to manage these complications, the nurse provides explanations to the patient and family. The need for additional surgery is usually perceived as a setback by the patient and family. Emotional support of the patient and family is provided along with physical preparation of the patient for surgery.

Promoting Home, Community-Based, and Transitional Care

Educating Patients About Self-Care. A major postoperative objective is to assist the patient to achieve the highest level of independence and self-care possible. The nurse and WOC nurse work closely with the patient and family to educate and assist them in all

phases of managing the ostomy. Adequate supplies and complete instruction are necessary to enable the patient and a family member to develop competence and confidence in their skills. Written and verbal instructions are provided, and the patient is encouraged to contact the nurse or primary provider with follow-up questions. Follow-up telephone calls from the nurse to the patient and family after discharge may provide added support and provide another opportunity to answer their questions. Follow-up visits and reinforcement of correct skin care and appliance management techniques also promote skin integrity. Specific techniques for managing the appliance are described in Chart 49-13.

The patient is encouraged to participate in decisions regarding the type of collecting appliance and the time of day to change the appliance. The patient is assisted and encouraged to look at and touch the stoma early to overcome any fears. The patient and family need to know the characteristics of a normal stoma:

- Pink or red and moist, like the inside of the mouth
- Insensitive to pain because it has no nerve endings
- Vascular, which means it may bleed when cleaned

In addition, if a segment of the GI tract was used to create the urinary diversion, mucus may be visible in the urine. By learning what is normal, the patient and family become familiar with what signs and symptoms they should report and what problems they can handle themselves.

Information provided to the patient and the extent of involvement in self-care are determined by the patient's physical recovery and ability to accept and acquire the knowledge and skill needed for independence. Verbal and written instructions are provided, and the patient is given the opportunity to practice and demonstrate the knowledge and skills needed to manage urinary drainage.

Continuing and Transitional Care. Follow-up care is essential to determine how the patient has adapted to the changes in body image and lifestyle adjustments. Visits from a nurse are important to assess the patient's adaptation to the home setting and management of the ostomy. Education and reinforcement may assist the patient and family to cope with altered urinary function. It is important to assess for long-term complications that may occur, such as pouch leakage or rupture, stone formation, stenosis of the stoma, deterioration in kidney function, or incontinence.

Long-term monitoring for anemia is performed to identify vitamin B_{12} deficiency, which may occur when a significant portion of the terminal ileum is removed. This may take several years to develop and can be treated with vitamin B_{12} injections. The patient and family are informed about the United Ostomy Associations of America (UOAA) and any local

ostomy support groups to provide ongoing support, assistance, and education (see Resources section at the end of this chapter).

Postoperative Evaluation

Expected patient outcomes may include:

1. Maintains skin integrity
   a. Maintains intact skin and demonstrates skill in managing drainage system and appliance
   b. States actions to take if skin excoriation occurs
2. Reports relief of pain
3. Exhibits improved body image as evidenced by the following:
   a. Voices acceptance of urinary diversion, stoma, and appliance
   b. Demonstrates increasingly independent self-care, including hygiene and grooming
   c. States acceptance of support and assistance from family members, health care providers, and another patient with an ostomy
4. Copes with sexuality issues
   a. Verbalizes concern about possible alterations in sexuality and sexual function
   b. Reports discussion of sexual concerns with partner and appropriate counselor
5. Demonstrates knowledge needed for self-care
   a. Performs self-care and proficient management of urinary diversion and appliance
   b. Asks questions relevant to self-management and prevention of complications
   c. Identifies signs and symptoms needing care from primary provider, nurse, or other health care providers
6. Absence of complications as evidenced by the following:
   a. Reports absence of pain or tenderness in abdomen
   b. Has temperature within normal range
   c. Reports no urine leakage from incision or drains
   d. Has urine output within desired volume limits
   e. Maintains stoma that is red or pink, moist, and appropriate in size without edema
   f. Has intact and healed border of the stoma

CRITICAL THINKING EXERCISES

1 ipc You are caring for a 53-year-old woman in the outpatient clinic where you work; she is newly diagnosed with urinary incontinence. What type of referrals might be appropriate for this patient? What members of the interprofessional health care team do you anticipate as being integral to the care of this patient?

2 ebp You notice an increase in the number of CAUTIs among patients on the medical-surgical unit where you work. What are the evidence-based management techniques used in CAUTI prevention? Identify the criteria used to evaluate the strength of the evidence for these practices. How will you individualize these techniques for your unit?

3 pq A 65-year-old man is admitted to the medical-surgical nursing unit where you work with bladder cancer. He is scheduled for a radical cystectomy with an orthotopic neobladder reconstruction. Identify the priorities, approach, and techniques you would use to provide care for this patient in the preoperative phase of care. How will your priorities, approach, and techniques differ in the postoperative phase of care?

UNIT 12 Reproductive Function

Case Study

IMPLEMENTING ALTERNATIVE, COMPLEMENTARY, AND SPIRITUAL PRACTICES

You work on an oncology unit and are caring for a 37-year-old woman from Brazil who reported a growing lump on her right breast after it became painful to touch. She is positive for metastatic breast cancer and is admitted for bilateral mastectomy.

She is married with two children, ages 6 and 10. The oncologist, radiologist, surgical oncologist, and oncology nurse meet with her to discuss the plan of care. She will need radiation and chemotherapy following the mastectomy. The patient states that she wants "everything done," including the use of alternative and complementary therapies her family is sending from her home country. She also states that maintaining her spiritual practices is imperative as part of her healing process. The team discusses how to implement these requests into the plan of care.

QSEN Competency Focus: Patient-Centered Care

The complexities inherent in today's health care system challenge nurses to demonstrate integration of specific interdisciplinary core competencies. These competencies are aimed at ensuring the delivery of safe, quality patient care (Institute of Medicine, 2003). The Quality and Safety Education for Nurses project (Cronenwett, Sherwood, Barnsteiner, et al., 2007; QSEN, 2020) provides a framework for the knowledge, skills, and attitudes (KSAs) required for nurses to demonstrate competency in these key areas, which include ***patient-centered care***, ***interdisciplinary teamwork and collaboration***, ***evidence-based practice***, ***quality improvement***, ***safety***, and ***informatics.***

Patient-Centered Care Definition: Recognize the patient or designee as the source of control and full partner in providing compassionate and coordinated care based on respect for patient's preferences, values, and needs.

SELECT PRE-LICENSURE KSAs	APPLICATION AND REFLECTION
Knowledge	
Integrate understanding of multiple dimensions of patient-centered care: • patient/family/community preferences, values • coordination and integration of care • information, communication, and education • physical comfort and emotional support • involvement of family and friends • transition and continuity Describe how diverse cultural, ethnic and social backgrounds function as sources of patient, family, and community values	Describe how you can integrate the patient's preferences and values into her treatment regimen for metastatic breast cancer. How does the involvement of the patient's family impact the plan of care? What are the cultural implications for a patient from Brazil in terms of traditional medicine, spirituality, and care?
Skills	
Elicit patient values, preferences and expressed needs as part of clinical interview, implementation of care plan and evaluation of care	Identify the skills needed by members of the health care team to incorporate patient-centered care and consideration for this patient. How can you be more culturally aware and sensitive to the patient's requests for alternative and complementary therapy?
Attitudes	
Respect and encourage individual expression of patient values, preferences, and expressed needs	Reflect on your attitudes toward use of alternative and complementary therapy by patients who have cancer. Do you feel that these alternative treatment methods are beneficial or harmful? How might your attitude encourage or discourage trust between you and

your patients who are managing a serious disease process?

50 Assessment and Management of Patients with Female Physiologic Processes

LEARNING OUTCOMES

On completion of this chapter, the learner will be able to:

1. Describe the structures and functions of the female reproductive system as well as approaches to assessment of female physiologic processes.
2. Identify the diagnostic examinations and tests used to determine alterations in female reproductive function, and describe the nurse's role before, during, and after these examinations and procedures.
3. Compare and contrast the different methods of contraception and the causes of infertility; describe implications for nursing care and education for the patient who wishes to practice contraception or to conceive.
4. Use the nursing process as a framework for care of the patient with an ectopic pregnancy.
5. Develop an education plan for women who are approaching or have completed menopause.

GLOSSARY

adnexa: the fallopian tubes and ovaries

amenorrhea: absence of menstrual flow

cervix: bottom (inferior) part of the uterus that is located in the vagina

corpus luteum: site within a follicle that changes after ovulation

cystocele: a bulge caused by the bladder protruding into the vagina

dysmenorrhea: painful menstruation

dyspareunia: difficult or painful penile-vaginal intercourse

endometrial ablation: procedure performed through a hysteroscope in which the lining of the uterus is burned away or ablated to treat abnormal uterine bleeding

endometrium: mucous membrane lining of the uterus

estrogens: several hormones produced in the ovaries that develop and maintain the female reproductive system

follicle-stimulating hormone (FSH): hormone released by the pituitary gland to stimulate estrogen production and ovulation

fornix: upper part of the vagina

fundus: the rounded upper portion of the uterus

graafian follicle: cystic structure that develops on the ovary as ovulation begins

hymen: tissue that covers the vaginal opening partially or completely before vaginal penetration

hysteroscopy: an endoscopic procedure performed using a long telescope like instrument inserted through the cervix to diagnose uterine problems

introitus: perineal opening to the vagina

luteal phase: stage in the menstrual cycle in which the endometrium becomes thicker and more vascular

luteinizing hormone (LH): hormone released by the pituitary gland that stimulates progesterone production

menarche: beginning of menstrual function

menopause: permanent cessation of menstruation resulting from the loss of ovarian follicular activity

menstruation: sloughing and discharge of the lining of the uterus if conception does not take place

ovaries: almond-shaped reproductive organs that produce eggs at ovulation and play a major role in hormone production

ovulation: discharge of a mature ovum from the ovary

perimenopause: the period around menopause

progesterone: hormone produced by the corpus luteum that prepares the uterus for receiving the fertilized ovum

proliferative phase: stage in the menstrual cycle before ovulation when the endometrium increases

rectocele: bulging of the rectum into the vagina

secretory phase: stage of the menstrual cycle in which the endometrium becomes thickened, becomes more vascular, and ovulation occurs

uterine prolapse: the cervix and uterus descend into the lower vagina

Nurses who work with women need an understanding of the physical, developmental, psychological, and sociocultural influences on women's health, as well as health practices. It is necessary to consider how medications and diseases specifically affect women. In addition, women's sexuality is complex and often affected by many factors, and related issues need careful evaluation and treatment.

CHALLENGES IN WOMEN'S HEALTH

Women face unique challenges in their roles, lifestyles, and family patterns. Furthermore, they encounter increasing environmental hazards and stress, prompting greater attention to health and health-promoting practices. As a result, many women are taking a greater interest in and responsibility for their own health and health care. Nurses encounter women with health care needs in all settings and they need a solid understanding of the unique issues related to women's health to provide optimal care. The Affordable Care Act (ACA) had made major changes to the health insurance market, and millions of women have gained coverage since its implementation (Kaiser Family Foundation, 2018).

The ACA expands coverage to the uninsured through a combination of Medicaid expansions, private insurance reforms, and tax credits (Kaiser Family Foundation, 2018). The affordability of health coverage and care is a problem that affects both sexes; however, women consistently are more likely than men to report cost-related barriers to care (Lee, Monuteaux, & Galbraith, 2019). Among the 97.4 million American women ages 19 to 64, most had some form of insurance coverage in 2017. However, gaps in private sector and publicly funded programs still leave almost one in ten women uninsured. Women with low incomes, women of color, and those who are immigrants are still at greater risk of being uninsured. Single mothers are much more likely to be uninsured (13%) than women in two-parent households (10%) (Kaiser Family Foundation, 2018).

The ACA set new standards for the scope of benefits offered in private plans. In addition to the broad categories of essential health benefits (EHBs)

offered by the state-based marketplace plans, the law also requires that new private plans cover preventive services without copayments or other cost sharing. This includes Pap tests, mammograms, bone density tests, as well as the human papilloma virus (HPV) vaccine. New plans are required to cover additional preventive services for women, including prescribed contraceptives, breast-feeding supplies, and resources such as breast pumps, screening for intimate partner violence, well woman visits, and several counseling and screening services (Kaiser Family Foundation, 2018; Lee et al., 2019).

ASSESSMENT OF THE FEMALE REPRODUCTIVE SYSTEM

Anatomic and Physiologic Overview

The female reproductive system is complex because it involves many external and internal structures that are under hormonal control.

Anatomy of the Female Reproductive System

The female reproductive system consists of external and internal pelvic structures. Other anatomic structures that affect the female reproductive system include the hypothalamus and pituitary gland of the endocrine system. The female breast is covered in Chapter 52.

External Genitalia

The female external genitalia are composed of a variety of tissue types starting with the mons pubis, which is a thick pad of adipose tissue that covers the symphysis pubis and cushions it during penile-vaginal intercourse (see Fig. 50-1). Moving downward are two thick folds of connective tissue covered with pubic hair known as the labia majora, which extend from the mons pubis to the perineum. The labia majora cover the oval-shaped area known as the vestibule, where the labia minora originate. The labia minora are two narrow folds of hairless skin, beginning at the clitoris and extending to the fourchette. This area is highly vascular and rich in nerve supply and glands that lubricate the vulva, the collective name for the external genitalia. The labia minora join at the top to form the prepuce, a hoodlike structure that partially covers the clitoris. The clitoris, an erectile organ located beneath the pubic arch, consists of a shaft and glans. It secretes smegma, a pheromone (olfactory erotic stimulant), and is sensitive to touch and temperature. Below the clitoris is the urinary meatus, the external opening of the female urethra that has a slit

appearance. Below the meatus is the **introitus** (vaginal opening). On each side of the introitus are Bartholin glands, which secrete mucus through tiny ducts that lie within the labia minora and are external to the **hymen** (membrane that encircles the introitus). The vestibule is bounded by the clitoris, fourchette, and labia minora and contains the urethral meatus. Skene glands, located within the urethral meatus, produce mucus for lubrication (Ball, Dains, Flynn, et al., 2019). The Bartholin glands on either side of the entrance to the vagina also produce mucus for lubrication (Ball et al., 2019).

The hymen opening varies widely among women, and the size of the opening is an unreliable indicator of sexual experience (Ball et al., 2019). The fourchette is located in the midline below the vaginal opening where the labia majora and labia minora merge. The perineum is the area between the vagina and the rectum or anus; it is a skin-covered muscular tissue (Ball et al., 2019).

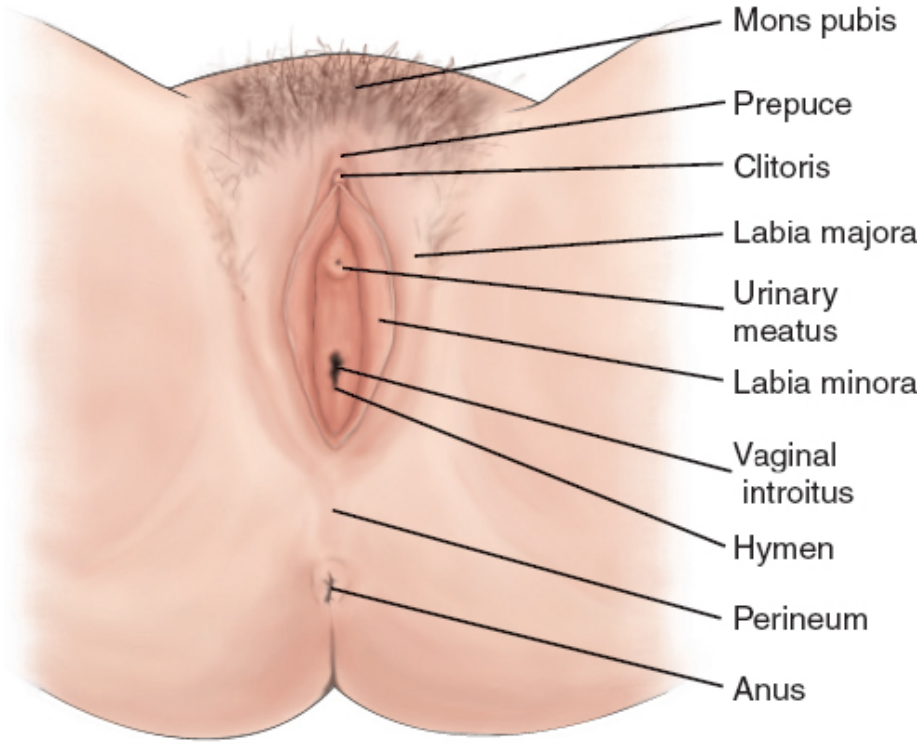

Figure 50-1 • External female genitalia.

A number of muscles support the external genitalia. Support for the pelvic organs is from the deep muscle layer known as the levator ani. This muscle, which forms most of the pelvic diaphragm, is composed of the iliococcygeus, pubococcygeus, and the puborectalis muscles. It supports the organs of reproduction and provides elasticity of the pelvic floor. When viewed from above, it looks like joined cupped hands. Its main function is to provide support to the organs of the pelvis when increased pressure from coughing and sneezing occurs. When this muscle group is contracted, the pelvic floor is lifted upward, supporting continence (Eickmeyer, 2017). Muscles that

contribute to the strength of the pelvic floor may be damaged during childbirth (Eickmeyer, 2017). The bulbocavernosus, ischiocavernosus, and transverse perineal muscles encircle and support the vagina and urethra as well as the anal sphincter.

Internal Reproductive Structures

The internal structures consist of the vagina, uterus, ovaries, and fallopian or uterine tubes (see Fig. 50-2).

Vagina

The vagina, a tubular-shaped canal lined with glandular mucous membrane, is 7.5 to 10 cm (3 to 4 inches) long and extends upward and backward from the vulva to the cervix. It is thin walled and can be distended during birth. It is highly vascular and has little sensation. Anterior to it are the bladder and the urethra, and posterior to it lies the rectum. The anterior and posterior walls of the vagina normally touch each other. The **fornix** (the upper part of the vagina) surrounds the **cervix** (the inferior part of the uterus) (Ball et al., 2019).

Uterus

The uterus, a pear-shaped, muscular organ, is about 7.5 cm (3 inches) long and 5 cm (2 inches) wide at its upper part. Its walls are about 1.25 cm (0.5 inch) thick. The size of the uterus varies, depending on parity (number of pregnancies), size of the infants, and uterine abnormalities (e.g., fibroids, which are a type of tumor that may distort the uterus). A woman who is nulliparous (one who has not completed a pregnancy to the stage of fetal viability) usually has a smaller uterus than a woman who is multiparous (one who has completed two or more pregnancies to the stage of fetal viability). The uterus lies posterior to the bladder and is held in position by several ligaments. The round ligaments extend anteriorly and laterally to the internal inguinal ring and down the inguinal canal, where they blend with the tissues of the labia majora. The broad ligaments are folds of peritoneum extending from the lateral pelvic walls and enveloping the fallopian tubes. The uterosacral ligaments extend posterior to the sacrum (Eickmeyer, 2017).

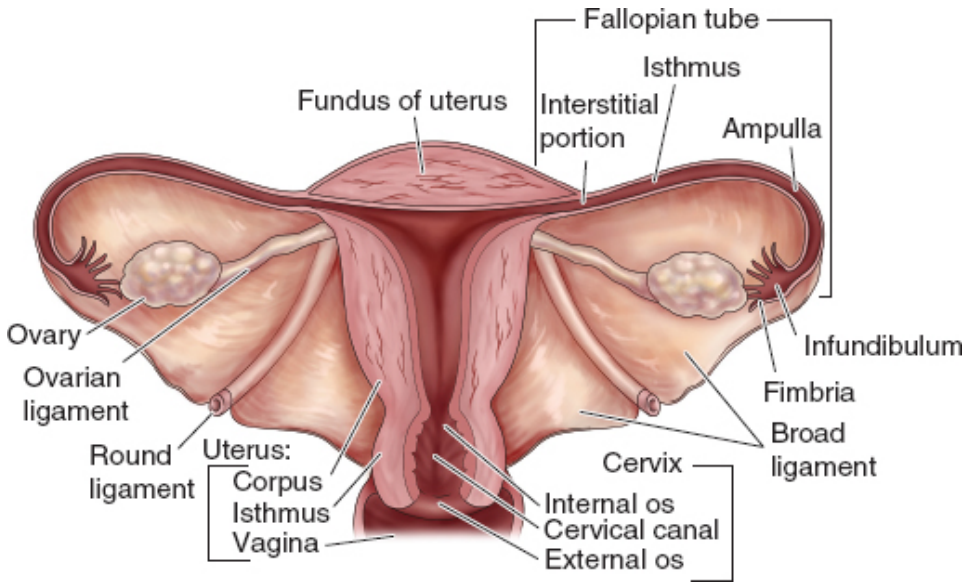

Figure 50-2 • Internal female reproductive structures.

The uterus has four parts: the cervix, fundus, corpus, and isthmus. The cervix is the opening to the uterus and projects into the vagina. A larger upper part, the **fundus**, is the rounded portion above the insertion of the fallopian tubes. The corpus or body is the main portion of the uterus located between the fundus and the isthmus. The isthmus is referred to as the lower uterine segment during pregnancy and joins the corpus to the cervix.

The cervix is divided into two portions. The portion above the site of attachment of the cervix to the vaginal vault is known as the supravaginal portion; the portion below the attachment site that protrudes into the vagina is known as the vaginal portion. The cervix is composed of fibrous connective tissue. The diameter varies from 2 to 5 cm depending on the childbearing history. The length is usually 2.5 to 3 cm in the woman who is not pregnant. The vaginal portion is smooth, firm, and doughnut shaped with a visible central opening referred to as the external os. The external os is round before the first birth and is often slitlike in shape after childbirth. The internal os is the opening in the cervix to the uterine cavity. In response to cyclic hormones, the cervix produces mucus, which is an important factor in fertility awareness. The vaginal surface of the cervix is covered with squamous epithelium, a rapid cellular growth site of cervical cancer and precancerous changes.

The uterine wall has three layers. The **endometrium**, the innermost layer, is highly vascular and responds to hormone stimulation to prepare to receive the developing ovum. It sloughs if pregnancy does not occur, resulting in menstruation; if pregnancy occurs, it sloughs after delivery. The myometrium, the middle layer, is made up of several smooth muscle layers. The outer layer of the myometrium is composed of longitudinal fibers, chiefly in the fundus, which provide the power to expel the fetus. The middle layer of the myometrium is composed of fibers interlaced with blood vessels in a figure-

eight pattern called a *living ligature* because it contracts after childbirth to help control blood loss (Eickmeyer, 2017). The inner layer of the myometrium is composed of circular fibers that are concentrated around the internal cervical os to help keep the cervix closed during pregnancy. The outer layer of the uterus is composed of parietal peritoneum, which covers most of the uterus. From here, the oviducts or fallopian (or uterine) tubes extend outward, and their lumina are internally continuous with the uterine cavity (Ball et al., 2019). The fallopian tubes or oviducts are the passageway for eggs from the ovary to the uterus. They curve around each ovary and are attached to the uterine fundus. Fallopian tubes are about 10 cm in length and are comprised of four parts. The infundibulum, the most distal portion, is covered in fimbriae, whose wavelike motion helps to pull the egg into the tube. The ampulla is usually the site of fertilization of the egg or ovum. The fallopian tube then narrows from its 0.6 cm diameter in the isthmus, ending in the narrowest part of the interstitial portion, which opens into the uterine cavity. The fallopian tube also secretes nutrients for growth and development of the ovum after fertilization while it passes down the tube to the uterus.

Ovaries

The **ovaries** lie behind the broad ligaments and behind and below the fallopian tubes. They are almond-shaped bodies about 3 cm (1.2 inches) long. At birth, they contain thousands of tiny egg cells, or ova. The ovaries and the fallopian tubes together are referred to as the **adnexa**.

Function of the Female Reproductive System

Ovulation

At puberty (usually between 11 and 13 years of age), the ova begin to mature and menstrual cycles begin. In the follicular phase, an ovum enlarges into a cystic structure called a **graafian follicle** until it reaches the surface of the ovary, where transport occurs. The ovum (or oocyte) is discharged into the peritoneal cavity. This periodic discharge of matured ovum is referred to as **ovulation**. The ovum usually finds its way into the fallopian tube, where it is carried to the uterus. If it is penetrated by a spermatozoon, the male reproductive cell, a union occurs, and conception takes place. After the discharge of the ovum, the cells of the graafian follicle undergo a rapid change. Gradually, they become yellow and produce **progesterone**, a hormone that prepares the uterus for receiving the fertilized ovum. Ovulation usually occurs 2 weeks prior to the next menstrual period (Casanova, Chuang, Goepfert, et al., 2019).

Menstrual Cycle

The menstrual cycle is a complex process involving the reproductive and endocrine systems. The ovaries produce steroid hormones, predominantly estrogens and progesterone. Several different estrogens are produced by the ovarian follicle, which consists of the developing ovum and its surrounding cells. The most potent of the ovarian estrogens is estradiol. **Estrogens** are responsible for developing and maintaining the female reproductive organs and the secondary sex characteristics associated with the adult female. Estrogens play an important role in breast development and in monthly cyclic changes in the uterus (Casanova et al., 2019).

Progesterone is also important in regulating the changes that occur in the uterus during the menstrual cycle. It is secreted by the **corpus luteum** (site within a follicle that changes after ovulation) or the ovarian follicle after the ovum has been released. Progesterone is the most important hormone for conditioning the endometrium (the mucous membrane lining of the uterus) in preparation for implantation of a fertilized ovum. If pregnancy occurs, the progesterone secretion becomes largely a function of the placenta and is essential for maintaining a normal pregnancy. In addition, progesterone, working with estrogen, prepares the breast for producing and secreting milk. Androgens are hormones produced by the ovaries and adrenal glands in small amounts. These hormones affect many aspects of female health, including follicle development, libido, oiliness of hair and skin, and hair growth (Casanova et al., 2019).

Two gonadotropic hormones are released by the pituitary gland: **follicle-stimulating hormone (FSH)** and **luteinizing hormone (LH)**. FSH is primarily responsible for stimulating the ovaries to secrete estrogen. LH is primarily responsible for stimulating progesterone production. Feedback mechanisms, in part, regulate FSH and LH secretion. For example, elevated estrogen levels in the blood inhibit FSH secretion but promote LH secretion, whereas elevated progesterone levels inhibit LH secretion. In addition, gonadotropin-releasing hormone (GnRH) from the hypothalamus affects the rate of FSH and LH release (Casanova et al., 2019).

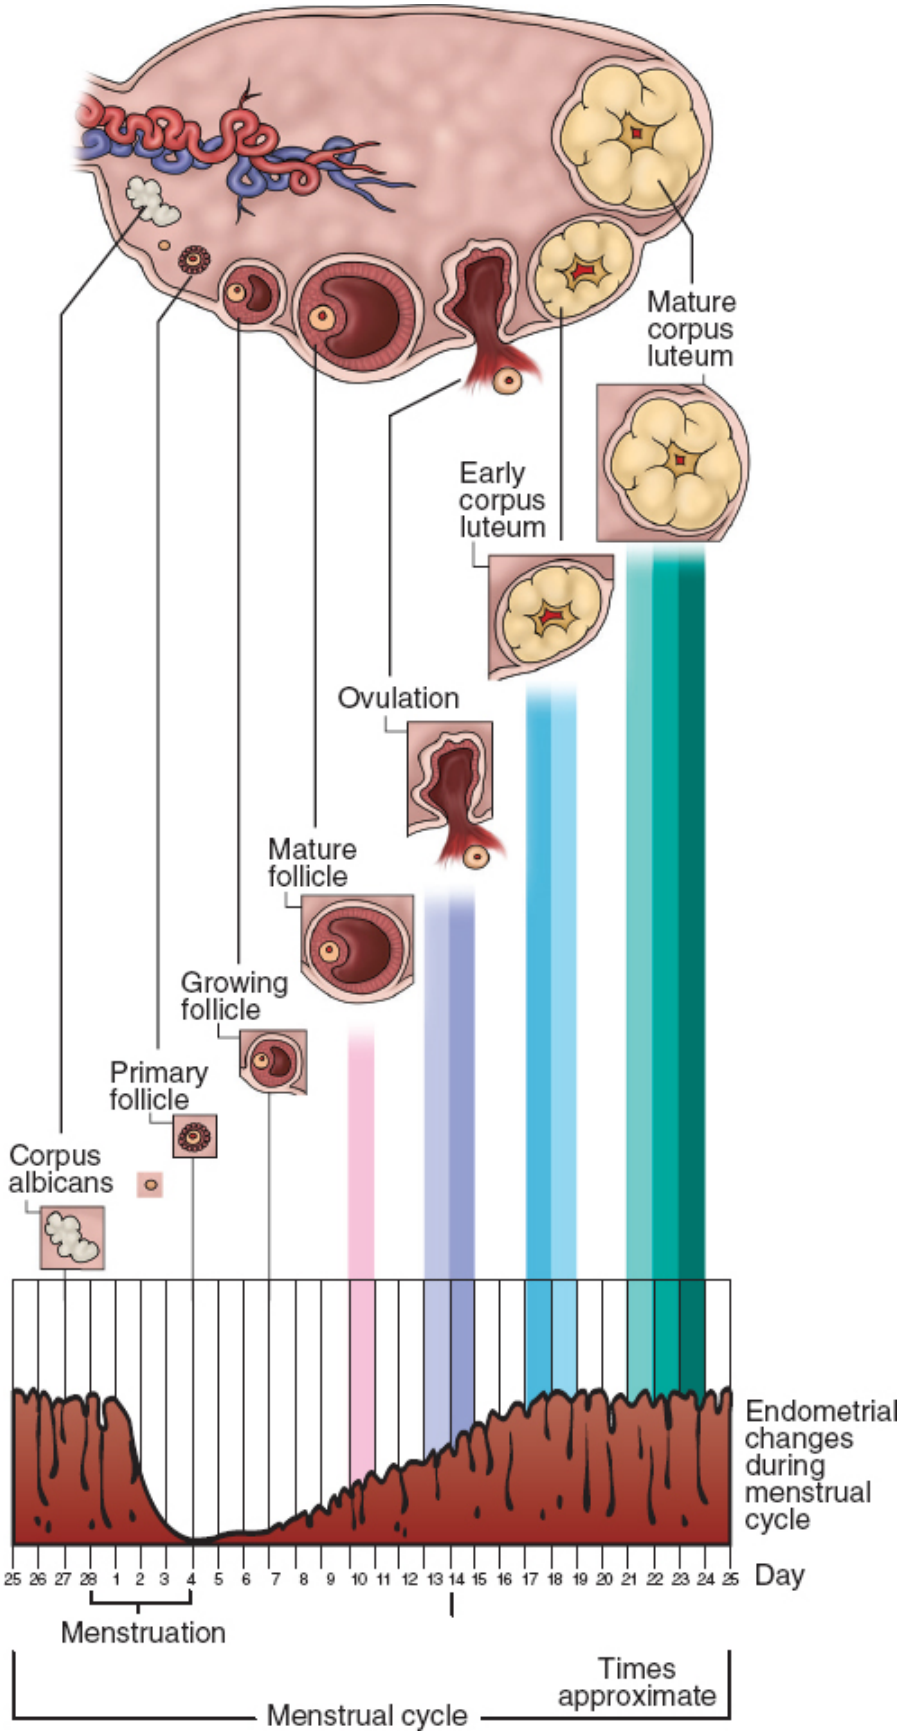

Figure 50-3 • The menstrual cycle and corresponding changes in the endometrium.

The secretion of ovarian hormones follows a cyclic pattern that results in changes in the uterine endometrium and in menstruation (see Fig. 50-3 and Table 50-1). This cycle is typically 28 days in length, but there are many normal variations (from 21 to 42 days). In the **proliferative phase** at the beginning of the cycle (just after menstruation), FSH output increases, and estrogen secretion is stimulated. This causes the endometrium to thicken and become more vascular. In the **secretory phase** near the middle portion of the cycle (day 14 in a 28-day cycle), LH output increases, and ovulation occurs. Under the combined stimulus of estrogen and progesterone, the endometrium reaches the peak **luteal phase**, in which the endometrium is thick and highly vascular. In the luteal phase, which begins after ovulation, progesterone is secreted by the corpus luteum.

TABLE 50-1 Hormonal Changes during the Menstrual Cycle

Times Approximate Phase	Menstrual	Follicular	Ovulation	Luteal	Premenstrual
Days	1 2 3 4 5 6 7 8 9	10 11 12 13 14	15 16 17 18 19	20 21 22 23 24	25 26 27 28 1 2
Ovary	Degenerating corpus luteum; beginning follicular development	Growth and maturation of follicle	Ovulation	Active corpus luteum	Degenerating corpus luteum
Estrogen production	Low	Increasing	High	Declining, then a secondary rise	Decreasing
Progesterone production	None	Low	Low	Increasing	Decreasing
FSH production	Increasing	High, then declining	Low	Low	Increasing
LH production	Low	Low, then increasing	High	High	Decreasing
Endometrium	Degeneration and shedding of superficial layer. Coiled arteries dilate, then constrict again.	Reorganization and proliferation of superficial layer	Continued growth	Active secretion and glandular dilation; highly vascular; edematous	Vasoconstriction of coiled arteries; beginning degeneration

FSH, follicle-stimulating hormone; LH, luteinizing hormone.

If the ovum is fertilized, estrogen and progesterone levels remain high, and the complex hormonal changes of pregnancy follow. If the ovum has not been fertilized, FSH and LH output diminishes; estrogen and progesterone secretion falls; the ovum disintegrates; and the endometrium, which has become thick and congested, becomes hemorrhagic. The product, menstrual flow, consisting of old blood, mucus, and endometrial tissue, is discharged through the cervix and into the vagina. After the menstrual flow stops, the cycle begins again; the endometrium proliferates and thickens from estrogenic stimulation, and ovulation recurs (Ball et al., 2019).

TABLE 50-2 Age-Related Changes in the Female Reproductive System

The age-related changes described below pertain to women ages 41 yrs and older.

Changes	Physiologic Effects	Signs and Symptoms
Cessation of ovarian function and decreased estrogen production	Decreased ovulation Onset of menopause	Decreased/loss of ability to conceive; increased infertility Irregular menses with eventual cessation of menses
	Vasomotor instability and hormonal fluctuations	Hot flashes or flushing; night sweats, sleep disturbances; mood swings; fatigue
	Decreased bone formation	Bone loss and increased risk for osteoporosis and osteoporotic fractures; loss of height
	Decreased vaginal lubrication	Dyspareunia, resulting in lack of interest in sex
	Thinning of urinary and genital tracts	Increased risk for urinary tract infection
	Increased pH of vagina Thinning of pubic hair and shrinking of labia	Increased incidence of inflammation (atrophic vaginitis) with discharge, itching, and vulvar burning
Relaxation of pelvic musculature	Prolapse of uterus, cystocele, rectocele	Dyspareunia, incontinence, feelings of perineal pressure

Adapted from Casanova, R., Chuang, A., Goepfert, A. R., et al. (2019). *Beckman and Ling's obstetrics and gynecology* (8th ed.). Philadelphia. PA: Wolters Kluwer.

Menopausal Period

The menopausal period marks the end of a woman's reproductive capacity. It usually occurs between 41 and 59 years of age (Ball et al., 2019). Perimenopause precedes this and can begin as early as 35 years of age. Physical, emotional, and menstrual changes may occur, and this transition offers another opportunity for health promotion and disease prevention education and counseling. Menopause is a normal part of aging and maturation. Menstruation ceases, and because the ovaries are no longer active, the reproductive organs become smaller. No more ova mature; therefore, no ovarian hormones are produced. (An earlier menopause may occur if the ovaries are surgically removed or are destroyed by radiation or chemotherapy or because of an unknown etiology.) Multifaceted changes also occur throughout the woman's body. These changes are neuroendocrine,

biochemical, and metabolic and are related to normal maturation or aging (see Table 50-2).

Chart 50-1

Select Health Screening and Counseling Issues for Women

Ages 19–39 Years

Sexuality and Reproductive Issues

Annual pelvic examination to begin at 21 years of age
Annual clinical breast examination
Contraceptive options
High-risk sexual behaviors

Health and Risk Behaviors

Hygiene
Injury prevention
Nutrition
Exercise patterns
Risk for abuse, maltreatment, and neglect
Use of tobacco, drugs, and alcohol
Life stresses
Immunizations

Diagnostic Testing[a]

Cervical cytology (Pap smear) alone every 3 years from ages 21 to 29. From ages 30 to 64: cervical cytology alone every 3 years; or cytology and HPV testing every 5 years.
Sexually transmitted infection screening as indicated

Ages 40–64 Years

Sexuality and Reproductive Issues

Annual pelvic examination
Annual clinical breast examination
Contraceptive options
High-risk sexual behaviors
Menopausal concerns

Health and Risk Behaviors

Hygiene
Bone loss and injury prevention
Nutrition
Exercise patterns
Risk for abuse, maltreatment, and neglect
Use of tobacco, drugs, and alcohol
Life stresses
Immunizations

Diagnostic Testing[a]

Cervical cytology (Pap smear) every 3 years; or cytology and HPV testing every 5 years.

Annual mammography for women ages 45 to 54 years, women ages 40 to 44 years have the option to begin yearly screening.

- Women 55 and older may continue yearly screening or transition to every 2 years.
- Screening should continue as long as a woman is in good health and is expected to live 10 more years or longer.

Cholesterol and lipid profile
Colorectal cancer screening beginning at age 50 years
Bone mineral density testing
Thyroid-stimulating hormone testing
Hearing and eye examinations

Age 65 Years and Older

Sexuality and Reproductive Issues

Annual pelvic examination
Annual clinical breast examination
High-risk sexual behaviors

Health and Risk Behaviors

Hygiene
Injury prevention, falls
Nutrition
Exercise patterns
Risk for abuse, maltreatment, and neglect
Use of tobacco, drugs, and alcohol
Life stresses
Immunizations

Diagnostic Testing[a]

No cervical cytology (Pap smear) following adequate negative prior screenings
Mammography
Cholesterol and lipid profile
Colorectal cancer screening
Bone mineral density testing
Thyroid-stimulating hormone testing
Hearing and eye examinations

HPV, human papilloma virus.

[a] Each person's risks (family history, personal history) influence the need for specific assessments and their frequency.

Adapted from American Cancer Society (ACS). (2019). Breast cancer facts & figures 2019–2020. Retrieved on 9/9/2019 at: www.cancer.org/content/dam/cancer-org/research/cancer-facts-and-statistics/breast-cancer-facts-and-figures/breast-cancer-facts-and-figures-2019-2020.pdf; Eliopoulos, C. (2018). *Gerontological nursing* (9th ed.). Philadelphia, PA: Lippincott Williams & Wilkins.

Assessment

A nurse who is obtaining information from a woman for the health history and performing physical assessment is in an ideal position to discuss the woman's general health issues, health promotion, and health-related concerns. Relevant topics include fitness, nutrition, cardiovascular risks, health screening, sexuality, menopause, abuse, health risk behaviors, emotional well-being, and immunizations. Select health screening and counseling issues are summarized in Chart 50-1.

Health History

In addition to the general health history, the nurse asks about past illnesses and experiences specific to a woman's health. Data should be collected about the following:

- Menstrual history (including onset, length of cycles, duration and amount of flow, presence of cramps or pain, bleeding between periods or after penile-vaginal intercourse, bleeding after menopause)
- Pregnancies (number of pregnancies, outcomes of pregnancies)
- Exposure to medications (diethylstilbestrol, immunosuppressive agents, others)
- **Dysmenorrhea** (pain with menses), **dyspareunia** (pain with penile-vaginal intercourse), pelvic pain
- Symptoms of vaginitis (i.e., odor or itching)
- Problems with urinary function, including frequency, urgency, and incontinence
- Bowel problems
- Sexual history
- Sexually transmitted infections (STIs) and methods of treatment
- Current or previous sexual abuse or physical abuse
- Past surgery or other procedures on reproductive tract structures (including female genital mutilation [FGM] or female circumcision)
- Chronic illness or disability that may affect health status, reproductive health, need for health screening, or access to health care
- Presence or family history of a genetic disorder. Chart 50-2 presents information about genetic reproductive disorders.

Chart 50-2 GENETICS IN NURSING PRACTICE

Female Reproductive Processes

Various female reproductive disorders are influenced by genetic factors. Some examples include:

- Hereditary breast or ovarian cancer syndromes
- Hereditary nonpolyposis colon cancer syndrome (risk for uterine cancer)
- Kallmann syndrome
- Müllerian aplasia
- 21-Hydroxylase deficiency (female masculinization)
- Turner syndrome (45, XO)

Nursing Assessments

Refer to Chapter 4, Chart 4-2: Genetics in Nursing Practice: Genetic Aspects of Health Assessment

Family History Assessment Specific to Female Reproductive Processes

- Assess family history for other family members with similar reproductive problems/abnormalities. If the female is a carrier of fragile X, she may be at risk for premature ovarian failure.
- Ask about age at the start and completion of puberty. Failure to complete puberty can lead to infertility.
- The absence of the sense of smell is noted with Kallmann syndrome which, if untreated, can lead to infertility.
- Inquire about ethnic background (e.g., Ashkenazi Jewish populations and hereditary breast/ovarian cancer mutations).
- Inquire about relatives with other cancers, including early-onset ovarian, uterine, renal, prostate cancers.
- Obtain family history that includes a thorough review of reproductive history which addresses spontaneous abortions (miscarriages), infant deaths, or difficulties during pregnancy.
- If possible, obtain ages of the parents during pregnancy.

Patient Assessment Specific to Female Reproductive Processes

- In females with delayed puberty or primary amenorrhea, assess for clinical features of Turner syndrome (short stature, webbing of the neck, widely spaced nipples).
- Assess for other congenital anomalies in females with Müllerian defect, including renal and vertebral anomalies.
- Assess for exposure to toxic chemicals, radiation, or medications during pregnancy.
- Obtain prior reproductive history.
- Inquire about use and frequency of alcohol or tobacco during pregnancy.

In collecting data related to reproductive health, the nurse can educate the patient about normal physiologic processes, such as menstruation and menopause, and assess possible abnormalities. Many problems experienced by young or middle-aged women can be corrected easily. However, if they are not treated, they may result in anxiety and health problems. Issues related to sexuality and sexual function are typically more often brought to the attention of the gynecologic or women's health care provider than other health care providers; however, nurses caring for all women should consider these issues part of routine health assessment.

Sexual History

A sexual assessment includes both subjective and objective data and should be included in care of people from adolescence through advanced age. Health and sexual histories, physical examination findings, and laboratory results are all part of the database. The purpose of a sexual history is to obtain information that provides a picture of a woman's sexuality and sexual practices and to promote sexual health. It may lead to discussion about sexually transmitted illnesses, unintended pregnancies, and ways of reducing high-risk sexual behaviors (Herbert, 2018). The sexual history may enable a patient to discuss sexual matters openly and to discuss sexual concerns with an informed health professional. Due to the sensitive nature of the subject matter, excellent communication skills are essential when taking a sexual history (Herbert, 2018). This information can be obtained after the gynecologic–obstetric or genitourinary history is completed. By incorporating the sexual history into the general health history, the nurse can move from areas of lesser sensitivity to areas of greater sensitivity after establishing initial rapport.

Taking the sexual history becomes a dynamic process reflecting an exchange of information between the patient and the nurse and provides the opportunity to clarify myths and explore areas of concern that the patient may not have felt comfortable discussing in the past. In obtaining a sexual history, the nurse must not assume the patient's sexual orientation until clarified. When asking about sexual health, the nurse also cannot assume that the patient is married or unmarried. Asking a patient to label herself as single, married, widowed, or divorced may be considered by some women as inappropriate. Asking about a partner or about current meaningful relationships may be a less offensive way to initiate a sexual history.

The PLISSIT (*p*ermission, *l*imited *i*nformation, *s*pecific *s*uggestions, *i*ntensive *t*herapy) model of sexual assessment and intervention may be used to provide a framework for nursing interventions (Annon, 1976). The assessment begins by introducing the topic and asking the woman for permission to discuss issues related to sexuality with her. See Chapter 53 for further discussion of sexual history.

The nurse can begin by explaining the purpose of obtaining a sexual history (e.g., "I ask all my patients about their sexual health. May I ask you some questions about this?"). History taking continues by inquiring about gender identity and sexual orientation (see Chapter 54, Chart 54-1 for further discussion about how to assess for personal information), followed by inquiring about sexual activity (e.g., "Are you currently having sex? With a man, woman, both, or a gender questioning or nonconforming person?"). Inquiries about possible sexual dysfunction may include, "Are you having any problems related to your current sexual performance?" Such problems may be related to medication, life changes, disability, or the onset of physical or emotional illness. A patient can be asked about her thoughts on what is causing the current problem (Weber & Kelley, 2018).

Information about sexual function can be introduced during the health history (see Chapter 4). By initiating an assessment about sexual concerns, the nurse communicates to the patient that issues about changes or problems in sexual functioning are valid health issues, which provides a safe environment for discussing these sensitive topics. Young women may be apprehensive about having irregular periods, may be concerned about STIs, or may need contraception. They may want information about using tampons, emergency contraception, or issues related to pregnancy. Women who are perimenopausal may have concerns about irregular menses. Women who are menopausal may be concerned about vaginal dryness and discomfort with penile-vaginal intercourse. Women of any age may have concerns about relationships, sexual satisfaction, orgasm, or masturbation.

Risk of STIs can be assessed by asking about the number of sexual partners in the past year or in the patient's lifetime. An open-ended question related to the patient's need for further information should be included (e.g., "Do you have any questions or concerns about your sexual health?"). Women can be advised that sexual activity should never be painful; pain should be investigated by a care provider. They should also be encouraged to talk openly about their sexual feelings with their partner; in an intimate relationship, feelings are facts.

Female Genital Mutilation or Cutting

Female genital mutilation (FGM) comprises all procedures that involve partial or total removal of the external female genitalia, or other injuries to the female genital organs for nonmedical reasons. FGM is recognized internationally as a

violation of the human rights of girls and women. It reflects deep-rooted inequality between the sexes and constitutes an extreme form of discrimination against women. It is nearly always carried out on minors and is a violation of the rights of children. The practice also violates a person's rights to health, security and physical integrity, the right to be free from torture and cruel, inhuman or degrading treatment, and the right to life when the procedure results in death (World Health Organization [WHO], 2018).

Complications for patients who have undergone FGM can include infertility, childbirth complications, impaired bladder function, and urinary complications. The practice is most common in the western, eastern, and north-eastern regions of Africa, in some countries in Asia and the Middle East, and among migrants from these areas (WHO, 2018).

Nurses caring for patients who have undergone FGM need to be sensitive, empathetic, knowledgeable, culturally competent, and nonjudgmental. Respect for others' health beliefs, practices, and behaviors, as well as recognition of the complexity of issues involved, is crucial. The nurse should use terminology with which the woman is familiar; *cutting* is usually a more acceptable term than *mutilation.* Speculums are not used in some developing countries; the function of this instrument should be explained, and an appropriately sized speculum used to examine women who have experienced FGM.

Intimate Partner Violence

Intimate partner violence (IPV) is a preventable public health problem affecting more than 32 million Americans (Weil, 2019). IPV involves four main types of violence: physical violence, sexual violence, stalking, and psychological aggression (Centers for Disease Control and Prevention [CDC], 2019a).

Approximately one in four women in the United States has experienced one or more of the four forms of IPV, with lifetime costs of more than $6.3 trillion (CDC, 2019a). Violence is rarely a one-time occurrence in a relationship; it usually continues and escalates in severity. This is an important point to emphasize when a woman states that her partner has hurt her but has promised to change. Perpetrators can change their behavior, although not without extensive counseling and motivation. Sixteen percent of homicide victims are killed by an intimate partner (CDC, 2019a). If a woman states that she is being hurt, sensitive care is required (see Chart 50-3).

By knowing about this major public health problem, being alert to abuse-related problems, and learning how to elicit information from women about abuse, maltreatment, and neglect in their lives, nurses can intervene to assist the patient in addressing a problem that might otherwise go undetected and thus save lives by making women safer through education and support. As part of a comprehensive assessment, the nurse should ensure a safe environment (i.e., a private room with the door closed) and ask each woman about violence

in her life. More information on family violence, abuse, and neglect, including sexual assault and rape, can be found in Chapter 67.

No specific signs or symptoms are diagnostic of abuse; however, nurses may see an injury that does not fit the account of how it happened (e.g., a bruise on the side of the upper arm after "I walked into a door"). Manifestations of abuse, maltreatment, and neglect may involve suicide attempts, drug and alcohol abuse, frequent emergency department visits, vague pelvic pain, somatic complaints, and depression. However, there may be no obvious signs or symptoms. Women in abusive situations have higher levels of depression (CDC, 2019a) and often report that they "do not feel well," possibly due to the stress or fear and anticipation of impending abuse.

Incest and Childhood Sexual Abuse

Nurses may encounter women who have been sexually traumatized. Female survivors of sexual abuse are reported to have more mental and physical health problems than women who were not victims of abuse (Hailes, Yu, Danese, et al., 2019). Victims of childhood sexual abuse are reported to experience more depression (Hailes et al., 2019), posttraumatic stress disorder, morbid obesity, marital instability, gastrointestinal problems, and headaches, as well as use health care services more frequently than people who were not victims. In women, chronic pelvic pain is often associated with physical violence, emotional neglect, and sexual abuse in childhood (Harris, Wieser, Vitonis, et al., 2018). Women who have experienced rape or sexual abuse may be very anxious about pelvic examinations, labor, pelvic or breast irradiation, or any treatment or examination that involves hands-on treatment or requires removal of clothing. Nurses should be prepared to offer support and referral to psychologists, community resources, and self-help groups.

Chart 50-3

Strategies for Providing Sensitive Care Following Intimate Partner Violence, Maltreatment, and Neglect

Strategy	Rationale
Reassure the woman that she is not alone	Women often believe that they are alone in experiencing abuse, maltreatment, and neglect at the hands of their partners.
Express your belief that no one should be hurt, that abuse is the fault of the batterer and is against the law.	Doing so lets the woman know that no one deserves to be abused and that she has not caused the abuse.
Assure the woman that her information is confidential, although it does become part of her medical record. *If children are suspected of being abused or are being abused, the law requires that this be reported to the authorities.* Some states require reporting of spousal or partner abuse. Domestic violence agencies and medical and nursing groups disagree with this policy and are trying to have it changed. Serious opposition is based on the fact that reporting does not and cannot currently guarantee a woman's safety and may place her in more danger. It may also interfere with a patient's willingness to discuss her personal life and concerns with health care providers. This places a serious barrier in the way of comprehensive nursing care. If nurses are in doubt about laws on reporting abuse, they need to check with their local or state domestic violence agency.	Women are often afraid that their information will be reported to the police or protective services and their children may be taken away.
Document the woman's statement of abuse and take photographs of any visible injuries if written formal consent has been obtained. (Emergency departments usually have a camera available if one is not on the nursing unit.)	Doing so provides documentation of injuries that may be needed for later legal or criminal proceedings.
Provide education that includes the following: • Inform the woman that shelters are available to ensure safety for her and her children. (Lengths of stay in shelters vary by state but are often up to 2 months. Staff often assists with housing, jobs, and the emotional distress that accompanies the breakup of the family.) Provide list of shelters. • Inform the woman that violence gets worse, not better.	Options may be lifesaving for the woman and her children.

- If the woman chooses to go to a shelter, let her make the call.
- If the woman chooses to return to the abuser, remain nonjudgmental and provide information that will make her safer than she was before disclosing her situation.
- Make sure that the woman has a 24-hour hotline telephone number that provides information and support (Spanish translation and a device for the deaf are also available), police number, and 911.
- Assist her to set up a safety plan in case she decides to return home. (A safety plan is an organized plan for departure with packed bags and important papers hidden in a safe spot.)

Health Issues in Women with Disability

Approximately 20% of women have disability and encounter physical, architectural, and attitudinal barriers that may limit their full participation in society (Okoro, Hollis, Cyrus, et al., 2018). Women with disability may experience stereotyping and increased risk of abuse, maltreatment, and neglect. They have reported that others, including health care providers, often equate them with their disability. Studies have reported that women with disability receive less primary health care and preventive health screening than other women, often because of access problems and health care providers who focus on the causes of disability rather than on health issues that are of concern to all women (Horner-Johnson, 2019; Okoro et al., 2018). To address these issues, the health history must include questions about barriers to health care encountered by women with disability and the effect of their disability on their health status and health care.

The CDC and the Association of Maternal Child Health Programs partnered to develop a central resource tool made of existing resources for nurses, physicians, physician assistants, and nurse practitioners who work with women with disability. The Toolbox provides links to existing tools to help facilitate preventive services (such as routine physical examinations, teeth cleanings, hepatitis B vaccinations, cervical cancer and breast cancer screenings, and family planning services) to women with disability (CDC, 2019b). Other issues to be addressed regarding the care of women with disability are identified in Chart 50-4.

Chart 50-4 ASSESSMENT

Assessing a Woman with a Disability

Health History

Address questions directly to the woman herself rather than to people accompanying her. Ask about:

- Self-care limitations resulting from her disability (ability to feed and dress self, the use of assistive devices, transportation requirements, other assistance needed)
- Sensory limitations (lack of sensation, low vision, deaf or hard of hearing)
- Accessibility issues (ability to get to health care provider, transfer to examination table, accessibility of office/clinic of health care provider, previous experiences with health care providers, health screening practices, her understanding of physical examination)
- Cognitive or developmental changes that affect understanding
- Limitations secondary to disability that affect general health issues and reproductive health and health care
- Sexual function and concerns (those of all women and those that may be affected by the presence of a disabling condition)
- Menstrual history and menstrual hygiene practices
- Physical, sexual, or psychological abuse (including abuse by care providers; abuse by neglect, withholding or withdrawing assistive devices or personal or health care) (see Chart 50-3)
- Presence of secondary disability (i.e., those resulting from the patient's primary disability: pressure injuries, spasticity, osteoporosis, etc.)
- Health concerns related to aging with a disability

Physical Assessment

Provide instructions directly to the woman herself rather than to people accompanying her; provide written or audiotaped instructions.

Ask the woman what assistance she needs for the physical examination and provide assistance if needed:

- Undressing and dressing
- Providing a urine specimen
- Standing on scale to be weighed (provide alternative means of obtaining weight if she is unable to stand on scale)
- Moving on and off the examination table
- Assuming, changing, and maintaining positions

Consider the fatigue experienced by the woman during a lengthy examination and allow rest.

Provide assistive devices and other aids/methods needed to allow adequate communication with the patient (interpreters, signers, large-print written materials).

Complete examination that would be indicated for any other woman; having a disability is *never* justification for omitting parts of the physical examination, including the pelvic examination.

Adapted from Konig-Bachman, M., Zenzmaier, C., & Schildberger, B. (2019). Health professionals' views on maternity care for women with physical disabilities: A qualitative study. *BMC Health Services Research*, *19*(1), 551.

People Who Identify as Lesbian, Gay, Bisexual, Transgender, or Queer (LGBTQ)

As the nature of family changes in our society, so must the health care providers' understanding of the people who make up the family unit (Gregg, 2018). Many health assessments presume a heterosexual orientation. Many health care providers are insufficiently prepared to meet the health needs of patients who identify as lesbian, gay, bisexual, transgender, or queer (LGBTQ) (see Chapter 54) (Wingo, Ingraham, & Roberts, 2018).

Those who identify themselves as LGBTQ may have concerns about disclosure and confidentiality, discriminatory attitudes, and treatment (Gregg, 2018; Wingo et al., 2018) (see Chart 50-5). Some research has reported that transgender people abuse alcohol and drugs to a greater degree than their nontransgender counterparts because their social venues may contribute to alcohol and drug use.

Youth who identify as LGBTQ are at higher risk of human immune deficiency virus (HIV) and STIs (Wingo et al., 2018). In addition, youth who self-identify as lesbian, gay, or bisexual or who lack support from parents and families may experience increased physical and mental health issues (e.g., depression, obesity) as well as isolation (Lapinski, Covas, Perkins, et al., 2018). Nurses need to understand the unique needs of this population and provide appropriate and sensitive care.

Chart 50-5

Health Care for Those Who Identify as LGBTQ

Nurses working with those who identify as LGBTQ should consider that these people:

- Are found in every ethnic group and socioeconomic class.
- Are seen in all age groups, including teens and seniors.
- Can be single, celibate, or divorced.
- Have often encountered insensitivity in health care encounters.
- Are typically offered contraception when asked if they are sexually active and respond affirmatively, as health care providers may assume incorrectly that they practice heterosexual intercourse.
- Have lower health screening rates than other women.
- Often feel invisible and underuse health care, similar to many other marginalized groups of women.

Nurses need to:

- Use gender-neutral questions and terms that are nonjudgmental and accepting.
- Recognize that lesbian teens are at risk for suicide and screen for those at risk.
- Recognize that many lesbians do participate in heterosexual activity but consider themselves at low risk for STIs. Because human papilloma virus, herpes infections, and other organisms implicated in STIs are transmitted by secretions and contact, lesbians may need information on STIs and contraception. If sex toys are used and not cleaned, pelvic infections can occur.

Women who identify as LGBTQ are at high risk for cancer, heart disease, depression, and alcohol abuse. They may have a higher body mass index, may bear fewer or no children, and often have fewer health preventive screenings than women who are heterosexual. These factors may increase the risk of colon, endometrial, ovarian, and breast cancer, as well as cardiovascular disease and diabetes. Adolescents are at risk for smoking and suicide/depression.

Adapted from Gregg, I. (2018). The health care experiences of lesbian women becoming mothers. *Nursing for Women's Health*, *22*(1), 40–50; Wingo, E., Ingraham, N., & Roberts, S. (2018). Reproductive health care priorities and barriers to effective care for LGBTQ people assigned female at birth: A qualitative study. *Women's Health Issues*, *28*(4), 350–357.

Gerontologic Considerations

Older women function at various levels across the health spectrum; some function at a high level in their jobs or families, whereas others may be very ill. Nurses need to be prepared to care for older women who may be bright,

energetic, and ambitious or who are coping with multiple family crises, including their own health issues, as well as for those who are experiencing a life-altering or life-threatening health problem. Older women are at risk for several conditions, including diabetes, dyslipidemia, hypertension, and thyroid disease, all of which have symptoms that may be dismissed as typical aging. Nurses can help prevent morbidity and mortality from these conditions by encouraging women to obtain regular health screenings (Eliopoulos, 2018). Knowledge about heart disease prevention, pharmacology, diet, signs of dementia or cognitive decline, fall prevention, osteoporosis prevention, gynecologic and breast cancers, and sexuality are important for providing high-level nursing care. Health disparities, cultural competency, and end-of-life issues also need to be considered.

Physical Assessment

Periodic examinations and routine cancer screening are important for all women (Bibbins-Domingo, 2017). Patients need understanding and support due to the emotional and physical considerations associated with gynecologic examinations. Women may be embarrassed by the usual questions asked by a gynecologist or women's health care provider. Because gynecologic conditions are of a personal and private nature to most women, such information is shared only with those directly involved in patient care.

The approach to the gynecologic examination needs to be systematic and thorough (Weber & Kelley, 2018). The nurse can alleviate feelings of anxiety with explanations and education (see Chart 50-6). It may be helpful to emphasize that a pelvic examination should not usually be uncomfortable. Before the examination begins, the patient is asked to empty her bladder and to provide a urine specimen if urine tests are part of the assessment. Voiding ensures patient comfort and eases the examination because a full bladder can make palpation of pelvic organs uncomfortable for the patient and difficult for the examiner.

Positioning

The supine lithotomy position is used most commonly (Weber & Kelley, 2018). If the patient chooses, alternative positions are sometimes used (Ball et al., 2019). The lithotomy position offers several advantages:

- It is more comfortable for some women.
- It allows better eye contact between patient and examiner.
- It may provide an easier means for the examiner to carry out the bimanual examination.
- It enables the woman to use a mirror to see her anatomy (if she chooses) to visualize any conditions that require treatment or to learn

about using certain contraceptive methods.

Chart 50-6 PATIENT EDUCATION

The Pelvic Examination

A pelvic examination includes assessment of the appearance of the vulva, vagina, and cervix and the size and shape of the uterus and ovaries to ensure reproductive health and absence of illness. Providing education for the patient should make the examination proceed more smoothly.

The nurse instructs the patient to:

- Expect to have a feeling of fullness or pressure during the examination, but you should not feel pain. It is important to relax, because if you are very tense, you may feel discomfort.
- Recognize that it is normal to feel uncomfortable and apprehensive.
- Be aware that a narrow, warmed speculum will be inserted to visualize the cervix and a Papanicolaou (Pap) smear will be obtained, if indicated, and should not be uncomfortable.
- Note that you may watch the examination with a mirror if you choose; the examination usually takes no longer than 5 minutes.
- Understand that draping will be used to minimize exposure and reduce embarrassment.

Adapted from Weber, J., & Kelley, J. (2018). *Health assessment in nursing* (6th ed.). Philadelphia, PA: Lippincott Williams & Wilkins.

Inspection

After the patient is prepared, the examiner inspects the external genitalia by looking at the labia majora and minora, noting the epidermal tissue of the labia majora; the skin fades to the pink mucous membrane of the vaginal introitus. Lesions of any type (e.g., genital warts, pigmented lesions [melanoma]) are evaluated. In the woman who is nulliparous, the labia minora come together at the opening of the vagina. In a woman who has delivered children vaginally, the labia minora may gape and vaginal tissue may protrude.

Trauma to the anterior vaginal wall during childbirth may have resulted in incompetency of the musculature, and **cystocele** (a bulge caused by the bladder protruding into the submucosa of the anterior vaginal wall) may be seen. Childbirth trauma may also have affected the posterior vaginal wall, producing a **rectocele** (a bulge caused by rectal cavity protrusion). **Uterine prolapse**, in which the cervix and uterus descend under pressure through the vaginal canal and may be seen at the introitus, may also occur. To identify such protrusions, the examiner asks the patient to "bear down."

The introitus should be free of superficial mucosal lesions. The labia minora may be separated by the fingers of the gloved hand and the lower part of the vagina palpated. In women who have not had penile-vaginal intercourse, a hymen of variable thickness may be felt circumferentially within the vaginal opening. The hymenal ring usually permits the insertion of one finger. Rarely, the hymen totally occludes the vaginal entrance (imperforate hymen).

Examination

Examination techniques include the speculum examination and several palpation methods.

Speculum Examination

The bivalve speculum, either metal or plastic, is available in many sizes (Ball et al., 2019). Metal specula are cleaned and sterilized between patients; plastic specula are for one-time use. Water-soluble lubricant or warm water is used to lubricate the speculum (Ball et al., 2019).

The speculum is gently inserted into the posterior portion of the introitus and slowly advanced to the top of the vagina; this should not be painful or uncomfortable for the woman. The speculum is then slowly opened. In the metal types, a setscrew of the thumb rest is tightened; in the plastic types, a clip is locked to hold the blades in place (Ball et al., 2019).

Inspecting the Cervix

The cervix is inspected for color, position, size, surface characteristics, discharge, and size and shape of the cervical os (Ball et al., 2019). In women who are nulliparous, the cervix usually is 2 to 3 cm wide and smooth. In women who have borne children, the cervix may have a laceration, usually transverse, giving the cervical os a "fishmouth" appearance. Epithelium from the endocervical canal may have grown onto the surface of the cervix, appearing as beefy-red surface epithelium circumferentially around the os. Occasionally, the cervix of a woman whose mother took diethylstilbestrol during pregnancy has a hooded appearance (a peaked aspect superiorly or a ridge of tissue surrounding it); this is evaluated by colposcopy when identified.

Malignant changes may not be obviously differentiated from the rest of the cervical mucosa. Small, benign cysts may appear on the cervical surface. Called *nabothian (retention) cysts,* these are usually bluish or white and are a normal finding after childbirth (Ball et al., 2019). A polyp of endocervical mucosa may protrude through the os and usually is dark red. Polyps can cause irregular bleeding; they are rarely malignant and usually are removed easily in an office or clinic setting. A carcinoma may appear as a cauliflowerlike growth (Ball et al., 2019). Bluish coloration of the cervix is a sign of early pregnancy (Chadwick sign).

Obtaining Pap Smears and Other Samples

A Papanicolaou (Pap) smear is a screening test for abnormal cells of the cervix. Usually, a Pap test is obtained using liquid-based cytology. A cytobrush collection device is rotated in the cervical os. The nurse or provider should be sure to follow the manufacturer's instructions to collect and preserve the specimen appropriately. The liquid sample is also used to test for the presence of HPV (Ball et al., 2019). Immediately after the Pap smear, DNA testing for organisms or a wet mount and potassium hydroxide procedures can be completed before the speculum is removed (Ball et al., 2019).

TABLE 50-3 Characteristics of Vaginal Discharge

Cause of Discharge	Symptoms	Odor	Consistency/Color
Physiologic	None	None	Mucus/white
Candida species infection	Itching, irritation	Yeast odor or none	Thin to thick, curdlike/white
Bacterial vaginosis	Odor	Fishy, often noticed after penile-vaginal intercourse	Thin/grayish or yellow
Trichomonas species infection	Irritation, odor	Malodorous	Copious, often frothy/yellow-green
Atrophic	Vulvar or vaginal dryness	Occasional mild malodor	Usually scant and mucoid/may be blood tinged

For the procedural guidelines for obtaining an optimal Pap smear, go to thepoint.lww.com/Brunner15e.

A specimen of any purulent material appearing at the cervical os is obtained for culture. A sterile applicator is used to obtain the specimen, which is immediately placed in an appropriate medium for transfer to a laboratory. In a patient who has a high risk for infection, routine cultures for gonococcal and chlamydial organisms are recommended because of the high incidence of both diseases and the complications of pelvic infection, fallopian tube damage, and subsequent infertility (Ball et al., 2019).

Vaginal discharge, which may be normal or may result from vaginitis, may be present. Table 50-3 summarizes the characteristics of vaginal discharge found in different conditions.

Inspecting the Vagina

The vagina is inspected as the examiner withdraws the speculum. It is smooth in young girls and thickens after puberty, with many rugae (folds) and redundancy in the epithelium. In women who are menopausal, the vagina thins and has fewer rugae because of decreased estrogen.

Bimanual Palpation

To complete the pelvic examination, the examiner performs a bimanual examination. The examiner should inform the woman that she will be examined internally with the examiners' fingers. The gloved fingers are then advanced vertically along the vaginal canal, and the vaginal wall is palpated. Any firm part of the vaginal wall may represent old scar tissue from childbirth trauma but may also require further evaluation (Ball et al., 2019).

Cervical Palpation

The cervix is palpated and assessed for its consistency, mobility, size, and position. The normal cervix is uniformly firm but not hard. Softening of the cervix is a finding in early pregnancy. Hardness and immobility of the cervix may reflect invasion by a neoplasm. Pain on gentle movement of the cervix is called a *positive chandelier sign* (positive cervical motion tenderness; recorded as + CMT) and usually indicates a pelvic infection.

Uterine Palpation

To palpate the uterus, the examiner places the opposite hand on the abdominal wall halfway between the umbilicus and the pubis and presses firmly toward the vagina. Movement of the abdominal wall causes the body of the uterus to descend, and the organ becomes freely movable between the hand used to examine the abdomen and the fingers of the hand used to examine the pelvis. Uterine size, mobility, and contour can be estimated through palpation. Fixation of the uterus in the pelvis may be a sign of endometriosis or malignancy.

The body of the uterus is normally twice the diameter and twice the length of the cervix, curving anteriorly toward the abdominal wall. Some women have a retroverted or retroflexed uterus, which tips posteriorly toward the sacrum, whereas others have a uterus that is neither anterior nor posterior and is described as midline.

Adnexal Palpation

The right and left adnexal areas are palpated to evaluate the fallopian tubes and ovaries. The fingers of the hand examining the pelvis are moved first to one side, then to the other, while the hand palpating the abdominal area is moved correspondingly to either side of the abdomen and downward. The adnexa

(ovaries and fallopian tubes) are trapped between the two hands and palpated for an obvious mass, tenderness, and mobility. Commonly, the ovaries are slightly tender, and the patient is informed that slight discomfort on palpation is normal.

Vaginal and Rectal Palpation

Bimanual palpation of the vagina and cul-de-sac is accomplished by placing the index finger in the vagina and the middle finger in the rectum. To prevent cross-contamination between the vaginal and rectal orifices, the examiner puts on new gloves. A gentle movement of these fingers toward each other compresses the posterior vaginal wall and the anterior rectal wall and assists the examiner in identifying the integrity of these structures. During this procedure, the patient may sense an urge to defecate. The nurse assures the patient that this is unlikely to occur. Ongoing explanations are provided to reassure and educate the patient about the procedure.

Gerontologic Considerations

Yearly examinations aid early identification of reproductive system disorders in aging women (Eliopoulos, 2018). Nurses play an important role in encouraging all women to have an annual gynecologic examination. Women older than 65 years may stop cervical cancer screening if they have had a hysterectomy or have had three normal cytology tests and no abnormal test in the past 10 years (U.S. Preventive Services Task Force [USPSTF], 2018).

Perineal pruritus is abnormal in older women and should be evaluated because it may indicate a disease process (diabetes or malignancy). Vulvar dystrophy (a thickened or whitish discoloration of tissue) may be visible, and biopsy is needed to rule out abnormal cells. Topical cortisone and hormone creams may be prescribed for symptomatic relief.

With relaxing pelvic musculature, uterine prolapse and relaxation of the vaginal walls can occur (Eliopoulos, 2018). Appropriate evaluation and surgical repair can relieve the discomfort and pressure of the prolapse if the patient is a candidate for surgery. The patient should be informed that tissue repair and healing after surgery may require more time with aging. A pessary (rubber or plastic device that provides support) is often used before surgery to see if surgery can be avoided. It is fitted by a gynecologic health care provider and may reduce the patient's discomfort and pressure. Pessaries also are used if surgery is contraindicated. The use of a pessary requires the patient to have routine gynecologic examinations to monitor for irritation or infection. The patient must be assessed for allergy prior to insertion of a latex pessary. See Chapter 51, Figure 51-4, for details about pessaries.

Diagnostic Evaluation

A wide range of diagnostic studies may be performed in the management of female physiologic processes. The nurse should educate the patient about the purpose, what to expect, and any possible side effects related to these examinations prior to testing. The nurse should be aware of contraindications, potential complications, and trends in results. Trends provide information about disease progression as well as the patient's response to therapy.

Cytologic Test for Cancer (Pap Smear)

The Pap smear is used to detect cervical cancer. Cervical secretions are gently removed from the cervical os and may be transferred to a glass slide and fixed immediately by spraying with a fixative or immersed in solution. If the Pap smear reveals atypical cells, the liquid method allows for HPV testing. See Chapter 51 for further discussion of HPV.

Terminology used to describe findings includes the following categories:

- No abnormal or atypical cells
- Atypical squamous cells of undetermined significance
- Inflammatory reactions and microbes identified
- Positive deoxyribonucleic acid (DNA) test for HPV
- Precancerous and cancerous lesions of the cervix identified

The patient may incorrectly assume that an abnormal Pap smear signifies cancer. If the Pap smear (liquid immersion method) shows atypical cells and no high-risk HPV types, the next Pap smear is performed in 1 year. If a specific infection is causing inflammation, it is treated appropriately, and the Pap smear is repeated. If the repeat Pap smear reveals atypical squamous cells with high-risk HPV types, colposcopy may be indicated. Pap smears that indicate precancerous lesions should be repeated in 4 to 6 months and colposcopy performed if the lesion has not resolved. Patients with Pap smears that indicate cancerous lesions require prompt colposcopy (Casanova et al., 2019).

If the Pap smear results are abnormal, prompt notification, evaluation, and treatment are crucial. Notification of patients is often the responsibility of nurses in a women's health care practice or clinic. Pap smear follow-up is essential because it can provide early detection of cervical cancer. Interventions are tailored to meet the needs and health beliefs of the particular patient. Intensive telephone counseling, tracking systems, brochures, videos, and financial incentives have all been used to encourage follow-up. The nurse provides clear explanations and emotional support along with a carefully designed setting-specific follow-up protocol designed to meet the needs of the patient.

Colposcopy and Cervical Biopsy

If the cervical cytology screening result requires evaluation, a colposcopy is performed. The colposcope is an instrument with a magnifying lens that allows the examiner to visualize the cervix and obtain a sample of abnormal tissue for analysis (Casanova et al., 2019). Nurse practitioners and gynecologists require special training in this diagnostic technique.

After inserting a speculum and visualizing the cervix and vaginal walls, the examiner applies acetic acid to the cervix. Subsequent abnormal findings that indicate the need for biopsy include leukoplakia (white plaque visible before applying acetic acid), acetowhite tissue (white epithelium after applying acetic acid), punctation (dilated capillaries occurring in a dotted or stippled pattern), mosaicism (a tilelike pattern), and atypical vascular patterns. If biopsy specimens show precancerous cells, the patient usually requires cryotherapy, laser therapy, or a cone biopsy (excision of an inverted tissue cone from the cervix).

Cryotherapy and Laser Therapy

Cryotherapy (freezing cervical tissue with nitrous oxide) and laser treatment are used in the outpatient setting. Cryotherapy may result in cramping and occasional feelings of faintness (vasovagal response). A watery discharge is normal for a few weeks after the procedure as the cervix heals; however, excessive bleeding, pain, or fever should be reported to the primary provider (Casanova et al., 2019).

Cone Biopsy and Loop Electrosurgical Excision Procedure

If endocervical curettage findings indicate abnormal changes or if the lesion extends into the canal, the patient may undergo a cone biopsy. This can be performed surgically or with a procedure called *loop electrosurgical excision procedure* (LEEP), which uses a laser beam (Casanova et al., 2019).

Usually performed in the outpatient setting, LEEP is associated with a high success rate in removal of abnormal cervical tissue. The gynecologist excises a small amount of cervical tissue, and the pathologist examines the borders of the specimen to determine if disease is present. A patient who has received anesthesia for a surgical cone biopsy is advised to rest for 24 hours after the procedure and to leave any vaginal packing in place until it is removed (usually the next day). The patient is instructed to report any excessive bleeding.

The nurse or primary provider provides guidelines regarding postoperative sexual activity, bathing, and other activities. Because open tissue may be

potentially exposed to HIV and other pathogens, the patient is cautioned to avoid penile-vaginal intercourse until healing is complete and verified at follow-up.

Endometrial (Aspiration) Biopsy

Endometrial biopsy, a method of obtaining endometrial tissue, is performed as an outpatient procedure. This procedure is usually indicated in cases of midlife irregular bleeding, postmenopausal bleeding, and irregular bleeding while taking hormone therapy or tamoxifen. A tissue sample obtained through biopsy permits diagnosis of cellular changes in the endometrium. The only absolute contraindication to an endometrial biopsy is the presence of a viable and desired pregnancy (Del Priore, 2019).

Women who undergo endometrial biopsy may experience slight discomfort. The examiner may apply a tenaculum (a clamplike instrument that stabilizes the uterus) after the pelvic examination and then inserts a thin, hollow, flexible suction tube (Pipelle or sampler) through the cervix into the uterus.

Findings on aspiration may include normal endometrial tissue, hyperplasia, or endometrial cancer. Simple hyperplasia is an overgrowth of the uterine lining and is usually treated with progesterone. Complex hyperplasia, which refers to overgrowth of cells with abnormal features, is a risk factor for uterine cancer and is treated with progesterone and careful follow-up. Women who are overweight, who are older than 45 years, who have a history of nulliparity and infertility, or who have a family history of colon cancer seem to be at higher risk for hyperplasia. See Chapter 51 for discussion of endometrial cancer.

Dilation and Curettage

Dilation and curettage (D&C) may be diagnostic (identifies the cause of irregular bleeding) or therapeutic (often temporarily stops irregular bleeding). The cervical canal is widened with a dilator, and the uterine endometrium is scraped with a curette. The purpose of the procedure is to secure endometrial or endocervical tissue for cytologic examination, to control abnormal uterine bleeding, and as a therapeutic measure for incomplete abortion.

Because D&C is usually carried out under anesthesia and requires surgical asepsis, it is usually performed in the operating room (Casanova et al., 2019). However, it may take place in the outpatient setting with the patient receiving a local anesthetic supplemented with diazepam or midazolam.

The nurse explains the procedure, preparation, and expectations regarding postoperative discomfort and bleeding. The patient is instructed to void before the procedure. The patient is placed in the lithotomy position, the cervix is dilated with a dilating instrument, and endometrial scrapings are obtained by a curette. A perineal pad is placed over the perineum after the procedure, and

excessive bleeding is reported. No restrictions are placed on dietary intake. If pelvic discomfort or low back pain occurs, mild analgesic medications usually provide relief. The primary provider indicates when sexual activity may be safely resumed. To reduce the risk of infection and bleeding, most gynecologists advise no vaginal penetration or use of tampons for 2 weeks.

Endoscopic Examinations

Laparoscopy (Pelvic Peritoneoscopy)

A laparoscopy, minimally invasive surgery, involves inserting a laparoscope (a tube about 10 mm wide and similar to a small periscope) into the peritoneal cavity through a 2-cm (0.75-inch) incision below the umbilicus to allow visualization of the pelvic structures (see Fig. 50-4). Laparoscopy may be used for diagnostic purposes (e.g., in cases of pelvic pain when no cause can be found) or treatment. Laparoscopy facilitates many surgical procedures, such as tubal ligation, ovarian biopsy, myomectomy, hysterectomy, and lysis of adhesions (scar tissue that can cause pelvic discomfort) (Sharp, 2019). A surgical instrument (intrauterine sound or cannula) may be positioned inside the uterus to permit manipulation or movement during laparoscopy, affording better visualization. The pelvic organs can be visualized after the injection of carbon dioxide intraperitoneally into the cavity. Called *insufflation,* this technique separates the intestines from the pelvic organs (Sharp, 2019). If a patient is undergoing sterilization, the fallopian or uterine tubes may be electrocoagulated, sutured, or ligated and a segment removed for histologic verification (clips are an alternative device for occluding the tubes).

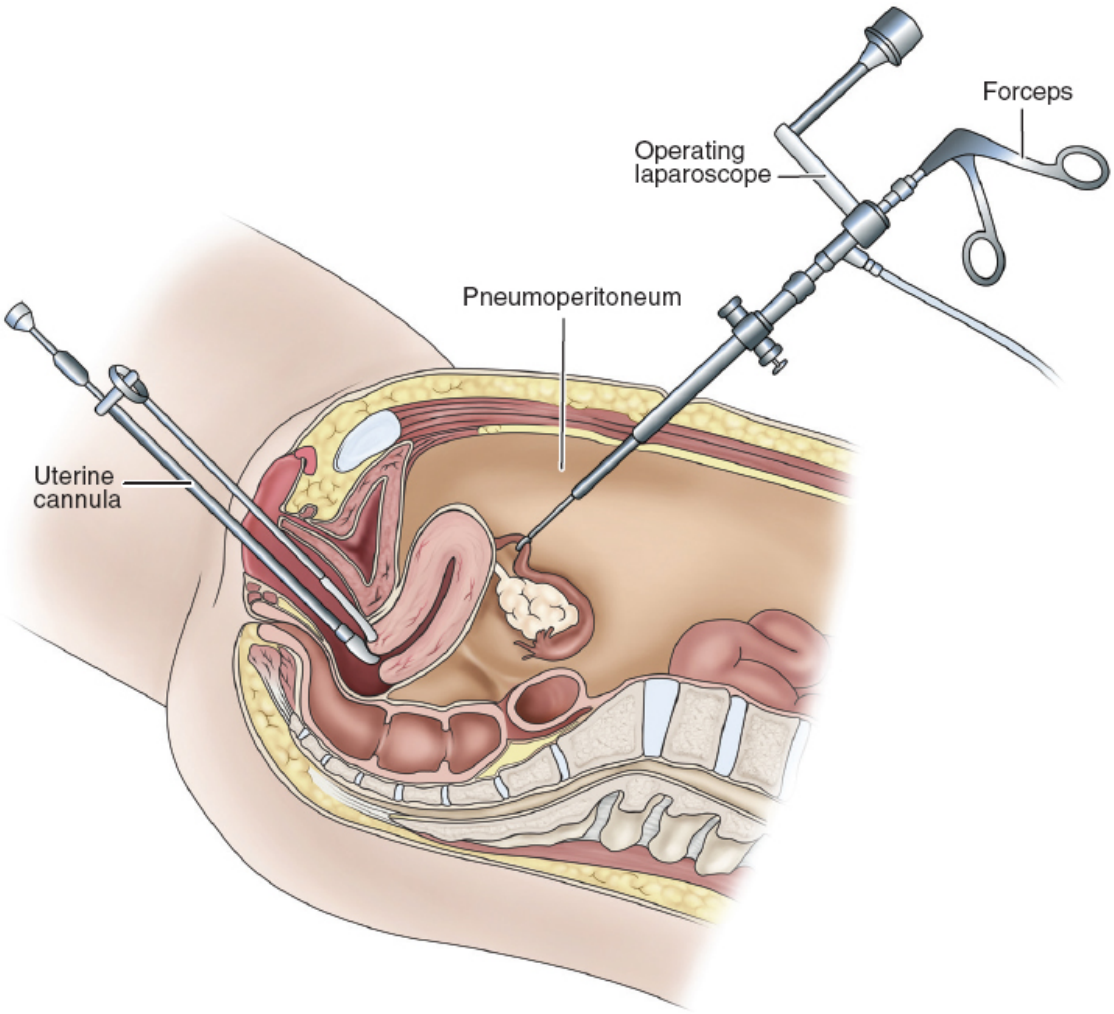

Figure 50-4 • Laparoscopy. The laparoscope (*right*) is inserted through a small incision in the abdomen. A forceps is inserted through the scope to grasp the fallopian tube. To improve the view, a uterine cannula (*left*) is inserted into the vagina to push the uterus upward. Insufflation of gas creates an air pocket (pneumoperitoneum), and the pelvis is elevated (note the angle), which forces the intestines higher in the abdomen.

After the laparoscopy is completed, the laparoscope is withdrawn, carbon dioxide is allowed to escape through the outer cannula, the small skin incision is closed with sutures or a clip, and the incision is covered with an adhesive bandage. The patient is carefully monitored for several hours to detect any untoward signs indicating bleeding (most commonly from vascular injury to the hypogastric vessels), bowel or bladder injury, or burns from the coagulator. These complications are rare, making laparoscopy a cost-effective and safe short-stay procedure. The patient may experience abdominal or shoulder pain related to the use of carbon dioxide gas (Casanova et al., 2019).

Hysteroscopy

Hysteroscopy (transcervical intrauterine endoscopy) allows direct visualization of all parts of the uterine cavity by means of a lighted optical instrument. The procedure is best performed about 5 days after menstruation ceases, in the estrogenic phase of the menstrual cycle. The vagina and vulva are cleansed, and a paracervical anesthetic block is performed or lidocaine spray is used. The instrument used for the procedure, a hysteroscope, is passed into the cervical canal and advanced 1 or 2 cm under direct vision. Uterine-distending fluid (normal saline solution or dextrose 5% in water) is infused through the instrument to dilate the uterine cavity and enhance visibility. Hysteroscopy, which has few complications, is useful for evaluating endometrial pathology or for evaluating and treating retained products of conception (Bradley, 2018).

Hysteroscopy may be indicated as an adjunct to a D&C and laparoscopy in cases of infertility, unexplained bleeding, retained intrauterine device (IUD), and recurrent early pregnancy loss (Bradley, 2018). Treatment for some conditions (e.g., fibroid tumors) can be accomplished during this procedure, and sterilization may also be performed. Hysteroscopy is contraindicated in patients with cervical or endometrial carcinoma or acute pelvic inflammation.

An **endometrial ablation** (destruction of the uterine lining) procedure is performed with a hysteroscope and resector (cutting loop), roller ball (a barrel-shaped electrode), or laser beam in cases of severe bleeding not responsive to other therapies. Completed in an outpatient setting under general, regional, or local anesthesia, this rapid procedure is an alternative to hysterectomy for some patients. Following uterine distention with fluid infusion, the lining of the uterus is destroyed. Hemorrhage, perforation, and burns can occur.

Other Diagnostic Procedures

Additional diagnostic procedures may be helpful in evaluating pelvic conditions; these include x-rays, barium enemas, gastrointestinal x-ray series, intravenous (IV) urography, and cystography studies. In addition, because the uterus, ovaries, and fallopian tubes are near the structures of the urinary tract, urologic diagnostic studies, such as x-ray study of the kidney, ureters, and bladder (KUB) and pyelography are used, as are angiography and radioisotope scanning, if needed. Other diagnostic procedures include hysterosalpingography (HSG) and computed tomography (CT) scanning.

Hysterosalpingography or Uterotubography

HSG is an x-ray study of the uterus and the fallopian tubes after injection of a contrast agent. The diagnostic procedure is performed to evaluate infertility or tubal patency and to detect any abnormal condition in the uterine cavity. Sometimes, the procedure is therapeutic because the flowing contrast agent flushes debris or loosens adhesions.

Prior to HSG, laxatives and an enema may be given to evacuate the intestinal tract so that gas shadows do not distort the x-ray findings. A mild sedative or an analgesic agent, such as ibuprofen, may be prescribed. The patient is placed in the lithotomy position and the cervix is exposed with a bivalve speculum. A cannula is inserted into the cervix, and the contrast agent is injected into the uterine cavity and the fallopian tubes. X-rays are taken to show the path and the distribution of the contrast agent.

Some patients experience nausea, vomiting, cramps, and faintness. After the test, the patient is advised to wear a perineal pad for several hours, because the radiopaque contrast agent may stain clothing.

Computed Tomography

CT scans have several advantages over ultrasonography, but they involve radiation exposure and are more costly. They are more effective than ultrasonography for patients with obesity or for patients with a distended bowel. CT scans can also demonstrate a tumor and any extension into the retroperitoneal lymph nodes and skeletal tissue, although they have limited value in diagnosing other gynecologic abnormalities (Casanova et al., 2019).

Ultrasonography

Ultrasonography (or ultrasound) is a useful adjunct to the physical examination, particularly in patients receiving obstetric care or in patients with abnormal pelvic examination findings. It is a simple procedure based on sound wave transmission that uses pulsed ultrasonic waves at frequencies exceeding 20,000 Hz (formerly cycles per second) by way of a transducer placed in contact with the abdomen (abdominal scan) or a vaginal probe (vaginal ultrasound). Mechanical energy is converted into electrical impulses, which in turn are amplified and recorded on an oscilloscope screen while a photograph or video recording of the patterns is taken. The entire procedure takes 15 to 30 minutes and involves no ionizing radiation and no discomfort other than a full bladder, which is necessary for good visualization during an abdominal scan. A vaginal ultrasound or sonogram does not require a full bladder; however, the vaginal probe may cause mild discomfort in some women (Casanova et al., 2019).

Magnetic Resonance Imaging

Magnetic resonance imaging (MRI) produces patterns that are finer and more definitive than other imaging procedures, and it does not expose patients to radiation. However, MRI is more costly.

Quality and Safety Nursing Alert

All metal devices, including medication skin patches with foil backing, must be removed before MRI is performed to avoid burns.

MANAGEMENT OF FEMALE PHYSIOLOGIC PROCESSES

Many health concerns of women are related to normal changes or abnormalities of the menstrual cycle and may result from women's lack of understanding of the menstrual cycle, developmental changes, and factors that may affect the pattern of the menstrual cycle. Educating women about the menstrual cycle and changes over time is an important aspect of the nurse's role in providing quality care to women. Education should begin early so that menstruation and the lifelong changes in the menstrual cycle can be anticipated and accepted as a normal part of life.

Menstruation

Menstruation, the sloughing and discharge of the lining of the uterus that takes place if conception does not occur, happens about every 28 days during the reproductive years, although normal cycles can vary from 25 to 35 days (Welt, 2019) (see Fig. 50-3). The flow usually lasts 4 to 5 days, during which time 50 to 60 mL of blood is lost.

A perineal pad or tampon is generally used to absorb menstrual discharge. Tampons are used extensively. There is no significant evidence of untoward effects from their use, provided that there is no difficulty in inserting them. However, a tampon should not be used for more than 4 to 8 hours, and the lowest absorbency should be used to prevent toxic shock syndrome (Mayo Clinic, 2017). If a tampon is difficult to remove or shreds when removed, less absorbent tampons should be used. If the string breaks or retracts, the woman should squat in a comfortable position, insert one finger into the vagina, try to locate the tampon, and remove it. If she feels uncomfortable attempting this maneuver or cannot remove the tampon, she should consult a gynecologic health care provider promptly.

Psychosocial Considerations

Girls who are approaching **menarche** (the onset of menstruation) should be educated about the normal process of the menstrual cycle before it occurs. Psychologically, it is much healthier and appropriate to refer to this event as a "period" rather than as "being sick." With adequate nutrition, rest, and

exercise, most women feel little discomfort, although some report breast tenderness and a feeling of fullness 1 or 2 days before menstruation begins. Others report fatigue and some discomfort in the lower back, legs, and pelvis on the first day and temperament or mood changes. Slight deviations from a usual pattern of daily living are considered normal, but excessive deviation may require evaluation. Regular exercise and a healthy diet have been found to decrease discomfort for some women. Heating pads or nonsteroidal anti-inflammatory drugs (NSAIDs) may be very effective for cramps. For women with excessive cramping or dysmenorrhea, referral to a women's health care provider is appropriate; following evaluation, providers may prescribe oral contraceptive agents.

Cultural Considerations

Cultural views and beliefs about menstruation differ. Some women believe that it is detrimental to change a pad or tampon too frequently; they think that allowing the discharge to accumulate increases the flow, which is considered desirable. Some women believe they are vulnerable to illness during menstruation. Others believe it is harmful to swim, shower, have their hair permed, have their teeth filled, or eat certain foods during menstruation. They may also avoid using contraception during menstruation.

In such situations, nurses are in a position to provide women with facts in an accepting and culturally sensitive manner. The objective is to be mindful of these unexpressed, deep-rooted beliefs and to provide the facts with care. Aspects of gynecologic problems cannot always be expressed easily. The nurse needs to convey confidence and openness and to offer facts to facilitate communication. Suggestions to improve care include overcoming language barriers, providing appropriate materials in the patient's language, asking about traditional beliefs and dietary practices, and asking about fears regarding care. Patience, sensitivity, and a desire to learn about other cultures and groups will enhance the nursing care of all women.

Menstrual Disorders

Menstrual disorders may include premenstrual syndrome (PMS); dysmenorrhea; amenorrhea; and excessive bleeding, irregular bleeding, or bleeding between cycles or unrelated to cycles. These disorders need to be discussed with a health care provider and managed individually.

Premenstrual Syndrome

PMS is a cluster of physical, emotional, and behavioral symptoms that are usually related to the luteal phase of the menstrual cycle. PMS is very common, affecting many women at some time in their lives (Gnanasambanthan & Datta, 2019) (see Chart 50-7).

Clinical Manifestations

Major symptoms of PMS include physical symptoms such as headache, fatigue, low back pain, painful breasts, and a feeling of abdominal fullness. Behavioral and emotional symptoms may include general irritability, mood swings, fear of losing control, binge eating, and crying spells. Symptoms vary widely from one woman to another and from one cycle to the next in the same woman. Great variability is found in the degree of symptoms. Many women are affected to some degree, but some are severely affected. Premenstrual dysphoric disorder (PMDD) is a severe form of PMS with significant severity of symptoms (Casper & Yonkers, 2019; Gnanasambanthan & Datta, 2019).

Chart 50-7

Causes, Manifestations, and Treatment of Premenstrual Syndrome

Cause

- Unknown; may be related to hormonal changes combined with other factors (diet, stress, and lack of exercise)
- Many women have some symptoms related to menses, but premenstrual syndrome affects 75% to 95% of women at some point and is a complex of symptoms that result in dysfunction.

Physical Symptoms

- Fluid retention (e.g., bloating, breast tenderness)
- Headache
- Low back pain

Affective Symptoms

- Depression
- Anger
- Irritability
- Anxiety
- Confusion
- Withdrawal
- Symptoms begin in the 5 days preceding menses, and relief occurs within 4 days of onset of menses. Dysfunction usually occurs in relationships, parenting, work, or school.

Treatment

- The use of social support and family resources
- Nutritious diet consisting of whole grains, fruits, and vegetables; increased water intake may help.
- Selective serotonin reuptake inhibitors
- Alprazolam has been effective, but risk of physical and psychological dependence is high
- Spironolactone, a diuretic agent, may be effective in treating fluid retention
- Initiation/maintenance of exercise program
- Stress reduction techniques

Treatment of premenstrual syndrome and premenstrual dysphoric disorder. *UpToDate.* Retrieved on 11/17/2019 at: www.uptodate.com/contents/treatment-of-premenstrual-syndrome-and-premenstrual-dysphoric-disorder; Gnanasambanthan, S., & Datta, S. (2019). Premenstrual syndrome. *Obstetrics, Gynaecology and Reproductive Medicine*, *29*(10), 281–285.

Medical Management

Because there is no single treatment or known cure for PMS, it is helpful for women to keep a record of their symptoms so they can anticipate and therefore cope with them. Regular exercise may be helpful. Although women have been advised to avoid caffeine, high-fat foods, and refined sugars, little research demonstrates the efficacy of dietary changes. Alternative therapies that have been used include vitamins B_6 (pyridoxine) and E, calcium, magnesium, and oil of primrose capsules (Casper & Yonkers, 2019; Gnanasambanthan & Datta, 2019).

Pharmacologic treatments include selective serotonin reuptake inhibitors (e.g., fluoxetine), prostaglandin inhibitors (e.g., ibuprofen and naproxen), diuretic agents, antianxiety agents, and calcium supplements. Oral contraceptives containing drospirenone (a synthetic progestin) and extended regimens also may be effective (Gnanasambanthan & Datta, 2019).

Nursing Management

The nurse obtains a health history, noting the time when symptoms began and their nature and intensity. The nurse then determines whether symptoms occur before or shortly after the menstrual flow begins. In addition, the nurse can show the patient how to record the timing and intensity of symptoms. A nutritional history is also elicited to determine if the diet is high in salt, caffeine, or alcohol or low in essential nutrients.

The patient's goals may include reduction of anxiety, mood swings, crying, binge eating, fear of losing control, improved coping with day-to-day stressors, improved relationships with family and coworkers, and increased knowledge about PMS. Positive coping measures are promoted. This may involve encouraging the woman's partner to offer support and assistance with childcare. The patient can try to plan her working time to accommodate the days she is less productive because of PMS. The nurse encourages the patient to use exercise, meditation, imagery, and creative activities to reduce stress. The nurse also encourages the patient to take medications as prescribed and provides instructions about the desired effects of the medications. Contact details for PMS support services should also be provided.

If the patient has severe symptoms of PMS or PMDD, the nurse assesses her for suicidal, uncontrollable, and violent behavior. An immediate psychiatric evaluation is necessary for women with any suggestions of suicidal tendencies. In rare cases, uncontrollable behavior may lead to violence toward family members. If abuse, maltreatment, and neglect of any member of a patient's family are suspected, it is important to implement and follow reporting protocols.

Dysmenorrhea

Primary dysmenorrhea is painful menstruation, with no identifiable pelvic pathology. It occurs at the time of menarche or shortly thereafter. It is characterized by crampy pain that begins before or shortly after the onset of menstrual flow and continues for 48 to 72 hours. Pelvic examination findings are normal. Dysmenorrhea is thought to result from excessive production of prostaglandins, which causes painful contraction of the uterus. In secondary dysmenorrhea, pelvic pathology such as endometriosis, tumors such as leiomyomata or malignancies, polyps, or pelvic inflammatory disease (PID) contributes to symptoms. Patients frequently have pain that occurs several days before menses, with ovulation, and occasionally with penile-vaginal intercourse. It may be accompanied by nausea, diarrhea, dizziness, and backache (Kulkarni & Deb, 2019).

Assessment and Diagnostic Findings

A pelvic examination is performed to rule out possible disorders, such as endometriosis, PID, adenomyosis, and uterine fibroids. A laparoscopy may be performed to identify organic causes (see Fig. 50-4).

Management

In primary dysmenorrhea, the reason for the discomfort is explained, and the patient is assured that menstruation is a normal function of the reproductive system. If the patient is young and accompanied by her mother, the mother may also need reassurance. Many young women expect to have painful periods if their mothers did. The discomfort of cramps can be treated once anxiety and concern about its cause are dispelled by adequate explanation. Symptoms usually subside with appropriate medication. Useful medications include prostaglandin antagonists such as NSAIDs (e.g., ibuprofen, naproxen, and mefenamic acid, or aspirin). If one medication does not provide relief, another may be recommended. Usually, these medications are well tolerated, but some women experience gastrointestinal side effects. Contraindications include allergy, peptic ulcer history, sensitivity to aspirin-containing medications, asthma, and pregnancy. Low-dose oral contraceptives may be prescribed for women with dysmenorrhea who are sexually active but do not desire pregnancy (Kulkarni & Deb, 2019).

Continuous low-level local heat, such as a heating pad, may be effective in relieving primary dysmenorrhea. Heat therapy and medication have been found to work well in combination. The patient is encouraged to continue her usual activities and to increase physical exercise if possible because this

relieves discomfort for some women. Taking analgesic agents before cramps start, in anticipation of discomfort, is advised.

Management of secondary dysmenorrhea is directed at diagnosis of and treatment for the underlying cause (e.g., endometriosis, PID) (see Chapter 51).

Amenorrhea

Amenorrhea, or the absence of menstrual flow, is a symptom of a variety of disorders and dysfunctions. Primary amenorrhea (delayed menarche) refers to the situation in which a young woman who by age 15 years has not begun developing secondary sex characteristics or who by age 16 years or older has developed secondary sex characteristics but has not started menstruation (Welt & Barbieri, 2018). There are many reasons for primary amenorrhea, including genetic and anatomical disorders, Turner syndrome, anorexia, and polycystic ovarian syndrome (Welt & Barbieri, 2018).

The nurse encourages the patient to express her concerns and anxiety about this problem because the patient may feel that she is different from her peers. A complete physical examination, careful health history, and laboratory tests help rule out possible causes, such as metabolic or endocrine disorders and systemic diseases. Treatment is directed toward correcting any abnormalities.

Secondary amenorrhea (an absence of menses for three cycles or 6 months after a normal menarche) may be caused by functional hypothalamic amenorrhea, pituitary disease, primary ovarian failure, pregnancy, breast-feeding, menopause, too little body fat (about 22% required for menses), eating disorder, thyroid disease, or polycystic ovary syndrome (Welt & Barbieri, 2018). In adolescents, secondary amenorrhea can be caused by minor emotional upset related to being away from home, attending college, tension due to schoolwork, or interpersonal problems.

Secondary nutritional disturbances may also be factors. Obesity can result in anovulation and subsequent amenorrhea. Eating disorders, such as anorexia and bulimia, often result in lack of menses because the decrease in body fat and caloric intake affects hormonal function. Intense exercise can induce menstrual disturbances. Females who are competitive athletes often experience amenorrhea. Oligomenorrhea (infrequent periods) may be related to thyroid disorders, polycystic ovarian syndrome, or premature ovarian failure. Women who are HIV positive are apt to miss menstrual periods and need to be evaluated for pregnancy, thyroid disorders, hyperprolactinemia, and menopause.

Abnormal Uterine Bleeding

Dysfunctional uterine bleeding is defined as irregular, painless bleeding of endometrial origin that may be excessive, prolonged, or without pattern.

Dysfunctional uterine bleeding can occur at any age but is most common at opposite ends of the reproductive lifespan. It is usually secondary to anovulation (lack of ovulation) and is common in adolescents and women approaching menopause.

Adolescents account for many cases of abnormal uterine bleeding; they often do not ovulate regularly as the pituitary–ovarian axis matures. Women who are perimenopausal also experience this condition because of irregular ovulation secondary to decreasing ovarian hormone production. Other causes may include fibroids, obesity, and hypothalamic dysfunction.

Abnormal or unusual vaginal bleeding that is atypical in time or amount must be evaluated because it could possibly be a manifestation of a major disorder. A physical examination is performed, and the patient is evaluated for conditions such as pregnancy, neoplasm, infection, anatomic abnormalities, endocrine disorders, trauma, blood dyscrasias, platelet dysfunction, and hypothalamic disorders.

Menorrhagia

Menorrhagia is prolonged or excessive bleeding at the time of the regular menstrual flow. In young women, the cause is usually related to endocrine disturbance; in later life, it usually results from inflammatory disturbances, tumors of the uterus, or hormonal imbalance.

Women with menorrhagia are urged to see a primary provider and to describe the amount of bleeding by pad count and saturation (i.e., absorbency of perineal pad or tampon and number saturated hourly). Persistent heavy bleeding can result in anemia. It can also be a sign of a bleeding disorder or a result of anticoagulant therapy. Treatment may involve endometrial ablation or hysterectomy.

Metrorrhagia

Metrorrhagia (vaginal bleeding between regular menstrual periods) is probably the most significant form of menstrual dysfunction because it may signal cancer, benign tumors of the uterus, or other gynecologic problems. This condition warrants prompt evaluation and treatment. Although bleeding between menstrual periods by women taking oral contraceptive agents is usually not serious, irregular bleeding by women taking hormone therapy should be evaluated (Goodman, 2020).

Menometrorrhagia is heavy vaginal bleeding between and during periods. It, too, requires evaluation.

Dyspareunia

Dyspareunia (difficult or painful penile-vaginal intercourse) can be superficial, deep, primary, or secondary and may occur at the beginning of, during, or after penile-vaginal intercourse. Dyspareunia may be related to many factors, including injury during childbirth; lack of vaginal lubrication; a history of incest, sexual abuse, or assault; endometriosis; pelvic or vaginal infection; vaginal dryness due to breast-feeding or menopause; gastrointestinal disorders; fibroids; urinary tract infection; STIs; or vulvodynia (vulvar pain that affects women of all ages without any discernible physical cause). Depending on the cause of dyspareunia, counseling, extra lubrication, or antidepressant medications may be prescribed (Mayo Clinic, 2018). Women's health issues related to sexuality may be affected by many factors. Thus, these issues need to be taken seriously, carefully assessed, and treated.

Contraception

Approximately 61 million women in the United States are in their childbearing years (i.e., between the ages of 15 and 44 years). Those who are sexually active and do not want to become pregnant but could become pregnant if they and their partners fail to use a contraceptive method, are at risk of unintended pregnancy. Thus, approximately 43 million women of childbearing age are at risk for unintended pregnancy (Alan Guttmacher Institute, 2018). Approximately 45% of the pregnancies each year in the United States are unintended and can result in negative health consequences and are an enormous financial burden to the health care system (American College of Obstetricians and Gynecologists [ACOG], 2019). Family planning benefits mothers, newborns, families, and communities.

Nurses who are involved in helping patients make contraceptive choices need to listen, take time to answer questions, and educate and assist patients in choosing the contraceptive method they prefer (see Chart 50-8). It is important for women to receive unbiased and nonjudgmental information, understand the benefits and risks of each contraceptive method, learn about alternatives and how to use them, and receive positive reinforcement and acceptance of their choice. Nurses also have the opportunity to dispel myths and misinformation surrounding contraception. Figure 50-5 provides an overview of the effectiveness of family planning methods.

Contraindications

Coexisting medical disorders may make contraception a complex issue. Contraception needs to be addressed individually in women with preexisting conditions. With the aid of a thorough history, nurses are well positioned to aid

patients in choosing the safest, most effective method of contraception to meet their individual needs.

Chart 50-8 PATIENT EDUCATION

Using Contraceptives

The nurse provides education to enhance the chosen method of contraception.

The nurse instructs patients who have chosen male or female sterilization to:

- Use another contraceptive method for the first 3 months.
- Use condoms to protect against sexually transmitted infections.

The nurse instructs women who have chosen an injectable method to:

- Use condoms to protect against sexually transmitted infections.
- Obtain repeat injections on time.

The nurse instructs women who have chosen pills to:

- Use condoms to protect against sexually transmitted infections.
- Take the pill at exactly the same time every day.

The nurse instructs women who have chosen the patch to:

- Use condoms to protect against sexually transmitted infections.
- Change the patch once a week.

The nurse instructs women who have chosen a ring to:

- Use condoms to protect against sexually transmitted infections.
- Remove the vaginal ring after 3 weeks.

The nurse instructs women who have chosen a diaphragm to:

- Use correctly each time you have sex.

The nurse instructs women who have chosen condoms, a sponge, withdrawal, or spermicides to:

- Use correctly each time you have sex.

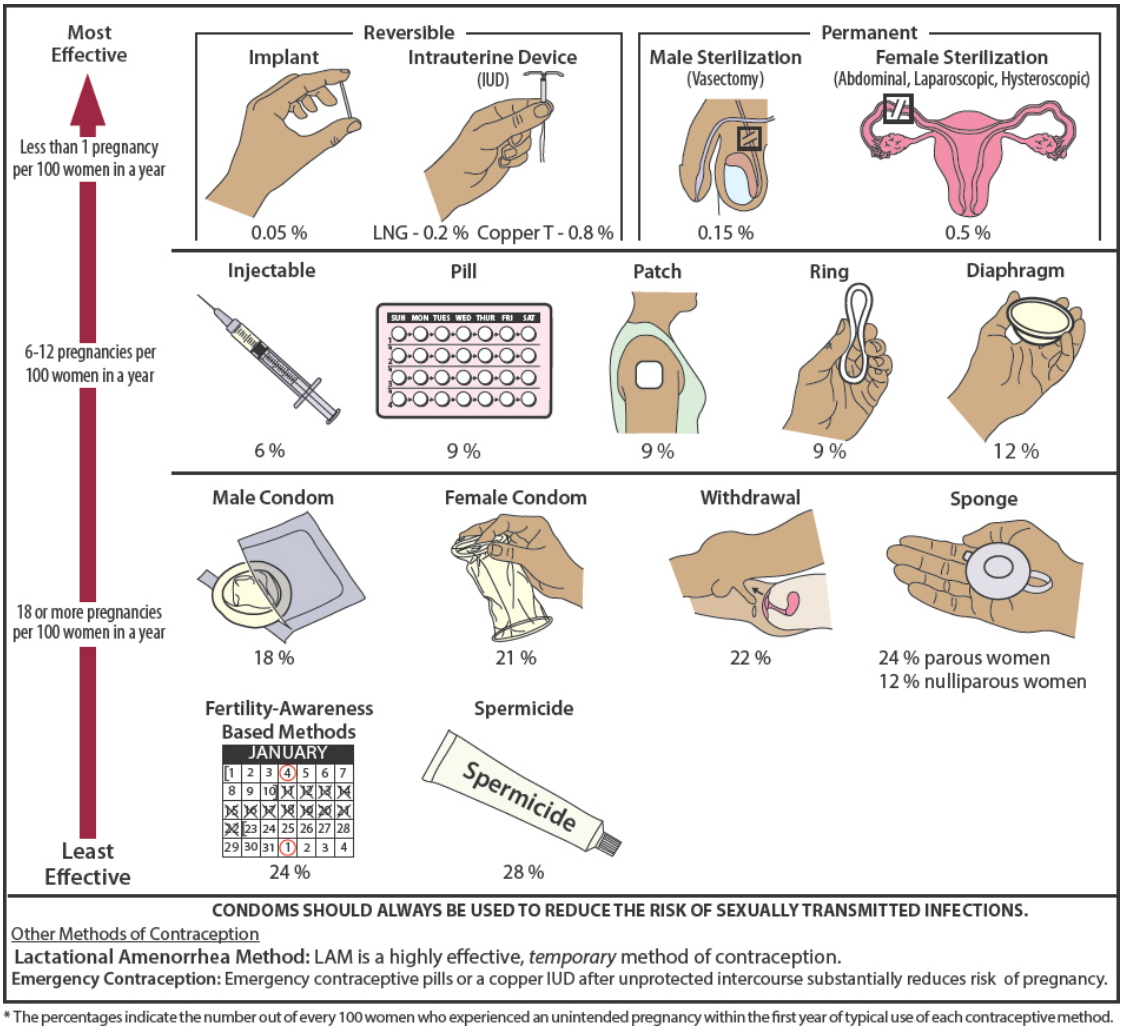

Figure 50-5 • Overview of the effectiveness of select family planning methods. Adapted from Centers for Disease Control and Prevention (CDC). (2016). U.S. selected practice recommendations for contraceptive use, 2016. *Morbidity and Mortality Weekly Report*, *65*(4), 1–72.

Abstinence

Abstinence, or celibacy, is the only completely effective means of preventing pregnancy. Abstinence may not be a desired or available option for many women because of cultural expectations and their own and their partner's values and sexual needs.

Long-Acting Reversible Contraceptive (LARC) Methods

Long-acting reversible contraception (LARC) methods are the most effective reversible methods for pregnancy prevention with a failure rate of less than 1% (Moore, Edie, Johnson, et al., 2019). Encouraging the use of LARC methods for appropriate candidates may help lower unintended pregnancy rates in the

United States. With few contraindications, the LARC methods should be offered as first-tier contraception to most women (ACOG, 2015 reaffirmed 2018; Moore et al., 2019). LARC methods include the IUD and the single-rod implant (ACOG, 2017).

Intrauterine Device

An IUD is a small device, usually T shaped that is inserted into the uterine cavity to prevent pregnancy. A string attached to the IUD is visible and palpable at the cervical os. Two types of IUDs are the hormonal and nonhormonal. The hormonal IUD releases progestin; a 3-year type and a 5-year are approved for use (ACOG, 2017). The nonhormonal IUD is effective for up to 10 years (ACOG, 2017).

Advantages include effectiveness over a long period of time, few if any systemic effects, and reduction of patient error. Almost all women are able to use an IUD. This reversible method of birth control is as effective as female sterilization and more effective than barrier methods (ACOG, 2017).

Disadvantages include possible excessive bleeding, cramps, and backaches; a slight risk of tubal pregnancy; slight risk of pelvic infection on insertion; displacement of the device; and, rarely, perforation of the cervix and uterus. If a pregnancy occurs with an IUD in place, the device is removed immediately to avoid infection. Spontaneous abortion (miscarriage) may occur on removal (ACOG, 2017).

Implants

One type of single-rod subdermal implant, effective for 3 years, is approved for use in the United States and is usually placed inside the upper arm using a small incision (ACOG, 2017). After implant insertion, changes in menstrual bleeding are common and include amenorrhea or frequent, infrequent, or prolonged bleeding (ACOG, 2017). Women should be warned about possible discomforts that can be treated with NSAIDs. Heavy or prolonged bleeding should be evaluated for an underlying gynecologic problem, such as interactions with other medications, an STI, pregnancy, or new pathologic uterine conditions (e.g., polyps, fibroids) (ACOG, 2017).

Almost all women are able to use the implant, even those who are lactating. The implant is very convenient as once it is in place the patient does not have to do anything else to prevent pregnancy.

Sterilization

Among women who practice contraception, approximately 22% rely on female and 7% on male sterilization (Alan Guttmacher Institute, 2018). Women and men who choose sterilization should be certain that they no longer wish to

have children, no matter how the circumstances in their life may change. Vasectomy (male sterilization) and tubal ligation (female sterilization) are compared in Table 50-4. See Chapter 53 for discussion of vasectomy.

Hormonal Contraception

Oral contraceptives block ovarian stimulation by preventing the release of FSH from the anterior pituitary gland. In the absence of FSH, a follicle does not ripen, and ovulation does not occur. Progestins (synthetic forms of progesterone) suppress the LH surge, prevent ovulation, and also render the cervical mucus impenetrable to sperm. Hormonal contraceptive agents may be intrauterine, implantable, injectable, oral, transdermal, or intravaginal. (See previous discussion of LARC methods.) These methods contain either a combination of estrogen and progestin or progestin-only. The combined methods include combination oral contraceptives, the transdermal patch, and the intravaginal ring. The progestin-only methods include the intrauterine system, the implant, the injectable, and the “mini-” pill. Hormonal contraception methods work by inhibiting ovulation (with the exception of the mini-pill and the intrauterine system).

TABLE 50-4 Comparison of Sterilization Methods

Sterilization Method	Advantages	Disadvantages
Vasectomy	• Highly effective • Relieves female of contraceptive burden • Inexpensive in long run • Permanent • Highly acceptable procedure to most patients • Very safe • Quickly performed	• Expensive in short term • Serious long-term effects suggested (although currently unproved) • Permanent (Although reversal is possible, it is expensive and requires highly technical and major surgery, and results cannot be guaranteed.) • Regret in 5–10% of patients • No protection against STIs, including HIV • Not effective until sperm remaining in reproductive system are ejaculated
Hysteroscopic and laparoscopic tubal sterilization	• Low incidence of complications • Short recovery • Leaves small or no scar • Quickly performed	• Permanent • Reversal difficult and expensive • Sterilization procedures technically difficult • Requires surgeon, operating room (aseptic conditions), trained assistants, medications, surgical equipment. (Essure [insertion of coil or spring in fallopian tubes] requires hysteroscopy rather than surgery.) • Expensive at the time performed • If failure, high probability of ectopic pregnancy • No protection against STIs, including HIV

HIV, human immune deficiency virus; STIs, sexually transmitted infections.

Chart 50-9 PHARMACOLOGY

Benefits and Risks of Hormonal Contraceptives

Benefits

- Highly effective at preventing unintended pregnancy
- Decreased cramps and bleeding
- Decreased incidence of anemia
- Decreased incidence of ectopic pregnancy
- Decreased incidence of pelvic infection
- Protection from benign breast disease
- Protection from uterine and ovarian cancer
- Regular bleeding cycle

Risks

- Bothersome side effects (e.g., breakthrough bleeding, breast tenderness)
- Nausea, weight gain, mood changes
- No protection from sexually transmitted infections (possible increased risk with unsafe sex)
- Possible increased incidence of benign liver tumors and gallbladder disorders
- Small increased risk of developing blood clots, stroke, or heart attack, related more to smoking than to oral contraceptive use alone
- Rare in women who are healthy

Adapted from Casanova, R., Chuang, A., Goepfert, A. R., et al. (Eds.). (2019). *Beckman and Ling's obstetrics and gynecology* (8th ed.). Philadelphia, PA: Wolters Kluwer.

Chart 50-9 describes the benefits and risks of hormonal contraceptive use.

Methods of Hormonal Contraception

A wide variety of hormonal methods of birth control are available. Combination methods include the combination of oral contraceptive pills, vaginal ring, and transdermal patch. Progestin-only methods include the progestin-only pills or "mini-pills," once-every-3-month injection, levonorgestrel-releasing intrauterine system, and single-rod subdermal implant (Casanova et al., 2019).

Quality and Safety Nursing Alert

Patients need to be aware that hormonal contraceptives protect them from pregnancy but not from STIs or HIV infection. In addition, sex with multiple partners or sex without a condom may also result in chlamydial and other infections, including HIV infection.

Oral Contraceptives

Many women use oral contraceptive preparations of synthetic estrogens and progestins. A variety of formulations are available. Extended regimens of oral hormonal contraceptive agents are an option for women who have heavy or uncomfortable menstrual bleeding or who wish to have fewer periods. With the use of these regimens, women may have an increased occurrence of breakthrough bleeding; the blood may be dark brown rather than red. It may be more difficult to tell if a pregnancy occurs with this method, although pregnancy is unlikely if pills are taken as prescribed (Casanova et al., 2019).

Transdermal Contraceptives

Transdermal contraception is done through a thin, beige, matchbook-size skin patch that releases an estrogen and a progestin continuously. It is changed every week for 3 weeks, and no patch is used during the fourth week, resulting in withdrawal bleeding. The effectiveness of transdermal contraception is comparable to that of oral contraceptives. Its risks are similar to those of oral contraceptives and include an increased risk of venous thromboemboli formation. The patch may be applied to the torso, chest, arms, or thighs; it should not be applied to the breasts. The patch is convenient and more easily remembered than a daily pill but is not as effective for women who weigh more than 90 kg (198 lb). One additional side effect with the patch includes possible skin reaction such as irritation, redness, pigment changes, or rash at the site of the patch (Casanova et al., 2019).

Vaginal Contraceptives

An etonogestrel/ethinyl estradiol vaginal ring is a combination hormonal contraceptive that releases estrogen and progestin. It is as effective as oral contraceptive agents and results in lower hormone blood levels than oral contraceptives. The ring is flexible, does not require sizing or fitting, and is effective when placed anywhere in the vagina. Patients are occasionally reluctant to consider vaginal methods of contraception unless discussed openly and as a convenient alternative to other routes of administration. Some women are uncomfortable with this method and may fear that the ring may migrate or be uncomfortable or be noticed by a partner. The ring is usually more expensive than oral contraceptives as well.

Injectable Contraceptives

An intramuscular injection of a long-acting progestin every 13 weeks inhibits ovulation and provides a reliable, private, and convenient contraceptive method (Casanova et al., 2019). A subcutaneous formulation is also available. It can be used by women who are lactating and those with hypertension, liver disease, migraine headaches, heart disease, and hemoglobinopathies. With continued use, women must be prepared for irregular bleeding episodes and spotting decrease, or amenorrhea.

Advantages of long-acting progestin include reduction of menorrhagia, dysmenorrhea, and anemia due to heavy menstrual bleeding. It may reduce the risk of pelvic infection, has been associated with improvement in hematologic status in women with sickle cell disease, and does not interfere with the efficacy of seizure agents. It decreases the risk of endometrial cancer, PID, endometriosis, and uterine fibroids (Casanova et al., 2019).

Possible side effects of long-acting progestin include irregular menstrual bleeding, bloating, headaches, hair loss, decreased sex drive, bone loss, and weight loss or weight gain. The contraceptive does not protect against STIs. Although bone loss may occur while using the injections, when the injections are stopped, sometimes all of the bone loss is regained. Use of this method should be limited to 2 years of use because of loss of bone mineral density (Casanova et al., 2019).

Long-acting progestin is contraindicated in women who are pregnant and those who have abnormal vaginal bleeding of unknown cause, breast or pelvic cancer, or sensitivity to synthetic progestin.

Mechanical Barriers

Diaphragm

The diaphragm is an effective contraceptive device that consists of a round, flexible spring (50 to 90 mm wide) covered with a domelike latex rubber cup. A spermicidal (contraceptive) jelly or cream is used to coat the concave side of the diaphragm before it is inserted deep into the vagina, covering the cervix completely. The spermicide inhibits spermatozoa from entering the cervical canal. The diaphragm is not felt by the user or her partner when properly fitted and inserted. Because women vary in size, the diaphragm must be sized and fitted by an experienced clinician. The woman is instructed in using and caring for the device. A return demonstration ensures that the woman can insert the diaphragm correctly and that it covers the cervix.

Each time the woman uses the diaphragm, she should examine it carefully. By holding it up to a bright light, she should ensure that it has no pinpoint holes, cracks, or tears; if any are present, the diaphragm should not be used. She then applies spermicidal jelly or cream and inserts the diaphragm. The diaphragm should remain in place at least 6 hours after coitus (no more than 12

hours). Additional spermicide is necessary if more than 6 hours have passed before penile-vaginal intercourse occurs and before each act of repeated penile-vaginal intercourse. On removal, the diaphragm should be cleansed thoroughly with mild soap and water, rinsed, and dried before being stored in its original container.

Disadvantages include allergic reactions in those who are sensitive to latex and an increased incidence of urinary tract infections. Toxic shock syndrome has been reported in some diaphragm users but is rare.

Quality and Safety Nursing Alert

The nurse must assess the woman for possible latex allergy because the use of latex barrier methods (e.g., diaphragm, cervical cap, male condoms) may cause severe allergic reactions, including anaphylaxis, in patients with latex allergy.

Cervical Cap

The cervical cap is much smaller (22 to 35 mm) than the diaphragm and covers only the cervix. If a woman can feel her cervix, she can usually learn to use a cervical cap. The chief advantage is that the cap may be left in place for 2 days after coitus. Although convenient to use, the cervical cap may cause cervical irritation; therefore, before fitting a cap, most primary providers obtain a Pap smear and repeat the smear after 3 months. The cap is used with a spermicide and does not require additional spermicide for repeated penile-vaginal intercourse.

Female Condom

The female condom was developed to give control of barrier protection to women—to provide them with protection from STIs and HIV as well as pregnancy. The female condom consists of a cylinder of polyurethane enclosed at one end by a closed ring that covers the cervix and at the other end by an open ring that covers the perineum (see Fig. 50-6). Advantages include some degree of protection from STIs (i.e., HPV, herpes simplex virus, and HIV) (Casanova et al., 2019). Disadvantages are that female condoms are more costly than male condoms and the inability to use the female condom with some positions (i.e., standing).

Spermicides

Spermicides are made from nonoxynol-9 or octoxynol and are available over the counter as foams, gels, films, suppositories, and sponges and also on condoms. Spermicides do not protect women from HIV or other STIs

(Casanova et al., 2019). Advantages of spermicides include they are nonhormonal, are user controlled, do not cause systemic side effects, and are immediately effective (Casanova et al., 2019).

Male Condom

The male condom is an impermeable, snug-fitting cover applied to the erect penis before it enters the vaginal canal. The tip of the condom is pinched while being applied to leave space for ejaculate. If no space is left, ejaculation may cause a tear or hole in the condom and reduce its effectiveness. The penis, with the condom held in place, is removed from the vagina while still erect to prevent the ejaculate from leaking. Condoms are available in large and small sizes.

The latex condom also creates a barrier against transmission of STIs (gonorrhea, chlamydial infection, and HIV) by body fluids and may reduce the risk of herpes virus transmission. However, natural condoms (those made from animal tissue) do not protect against HIV infection. Nurses need to reassure women that they have a right to insist that their male partners use condoms and a right to refuse sex without condoms, although women in abusive relationships may increase their risk of abuse, maltreatment, and neglect by doing so. Some women carry condoms with them to be certain that one is available. Nurses should be familiar and comfortable with instructions about using condoms because many women need to know about this way of protecting themselves from HIV and other STIs. Condoms do not provide complete protection from STIs, however, because HPV may be transmitted by skin-to-skin contact. Other STIs may be transmitted if any abraded skin is exposed to body fluids. This information should be included in patient education.

The nurse needs to consider the possibility of latex allergy. Swelling and itching can also occur. Possible warning signs of latex allergy include oral itching after blowing up a balloon or eating kiwis, bananas, pineapples, passion fruit, avocados, or chestnuts. Because many contraceptives are made of latex, patients who experience burning or itching while using latex contraceptives are instructed to see their primary provider. Alternatives to latex condoms include the female condom (Reality) and the male condom (Avanti), made of polyurethane.

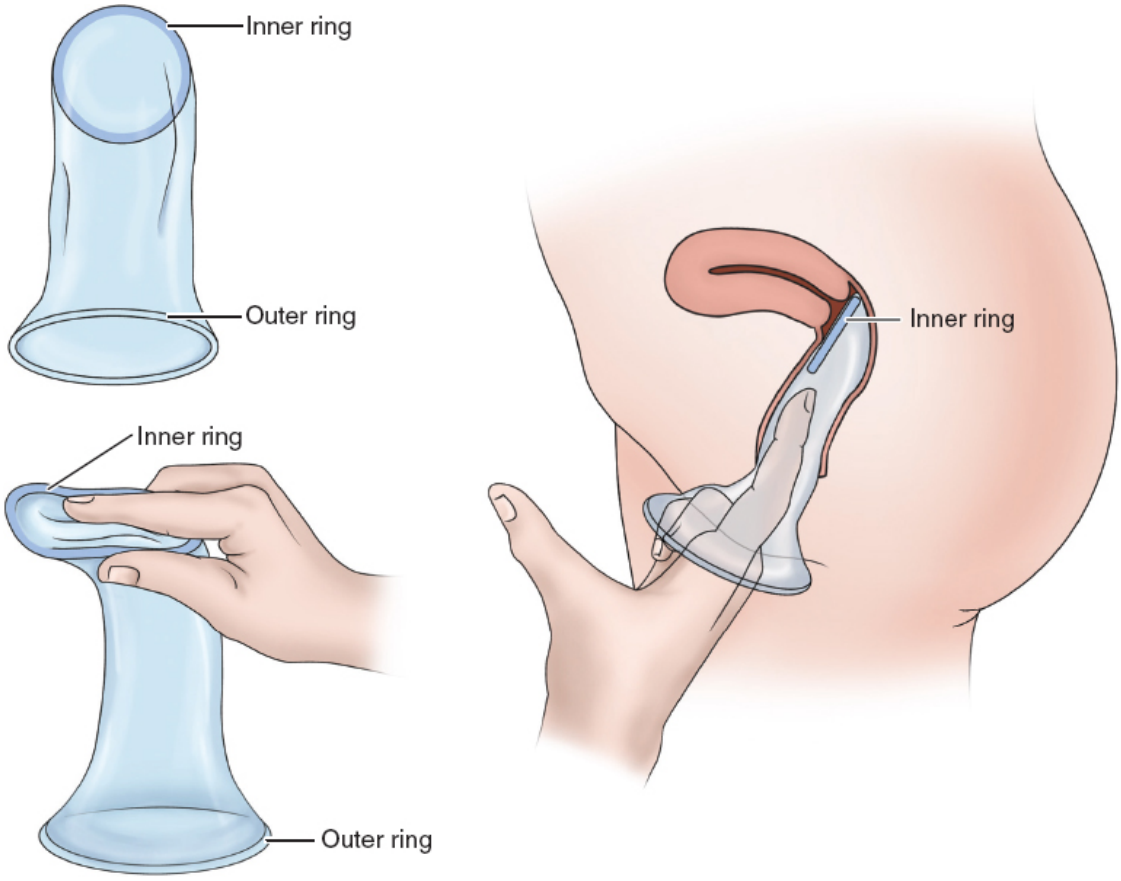

Figure 50-6 • Female condom. To insert the female condom, hold the inner ring between the thumb and middle finger. Put the index finger on the pouch between the thumb and other fingers and squeeze the ring. Slide the condom into the vagina as far as it will go. The inner ring keeps the condom in place.

Coitus Interruptus or Withdrawal

Coitus interruptus (removing the penis from the vagina before ejaculation) requires careful control by the male partner. Although it is a frequently used method of preventing pregnancy and better than no method, it is considered an unreliable method of contraception.

Fertility Awareness–Based Methods

Fertility awareness is knowing and recognizing when the fertile time occurs in the menstrual cycle. If a couple is practicing fertility awareness as a birth control method to prevent pregnancy, the couple needs to avoid having penile-vaginal intercourse or use a barrier method during the fertile period. If the woman would like to get pregnant, the couple should have penile-vaginal intercourse during the women's fertile days. When used to prevent pregnancy,

during the first year of typical use, up to 24 women out of 100 will become pregnant (Alan Guttmacher Institute, 2018).

The most common fertility awareness–based method is the Standard Days method. With this method, users must avoid unprotected penile-vaginal intercourse on days 8 to 19 of the menstrual cycle. The Standard Days method requires the woman to determine the fertile days of her cycle. This method works best if the woman has a regular menstrual cycle.

The advantages of using fertility awareness–based methods to prevent pregnancy are that they are safe, inexpensive, and approved by some religions that do not approve of other methods of contraception. The disadvantage is that they require discipline by the couple, who must monitor the menstrual cycle and abstain from penile-vaginal intercourse during the fertile phase.

Ovulation detection methods are available in most pharmacies. The presence of the enzyme guaiacol peroxidase in cervical mucus signals ovulation 6 days beforehand and also affects mucosal viscosity. Over-the-counter test kits are easy to use and reliable but can be expensive. Ovulation prediction kits are more effective for planning conception than for avoiding it.

Emergency Contraception

Emergency contraception are methods that can be used by women after unprotected penile-vaginal intercourse to prevent pregnancy (Casanova et al., 2019). Nurses need to be aware of emergency contraception as an option for women and the indications for its use. It is clearly not suitable for long-term avoidance of pregnancy because it is not as effective as oral contraceptives or other reliable methods used regularly. However, it is valuable following penile-vaginal intercourse when a pregnancy is not intended and in emergency situations such as rape, a defective or torn condom or diaphragm, or other situations that may result in unintended conception.

Methods of Emergency Contraception

Emergency Contraceptive Pills

Three kinds of emergency contraceptive pills are available in the United States. A properly timed, adequate dose of medication after penile-vaginal intercourse without effective contraception, or when a method has failed, can prevent pregnancy by inhibiting or delaying ovulation. Emergency contraceptive pills should be taken as soon as possible and within 5 days of unprotected penile-vaginal intercourse (Casanova et al., 2019).

Nausea, a common side effect, can be minimized by taking the medication with meals and with an antiemetic agent. Other side effects, such as breast soreness and irregular bleeding, may occur but are transient. Patients who use emergency contraceptive pills should be advised of the potential failure rate

and also counseled about other contraceptive methods. There are no known contraindications to the use of this method, except an established pregnancy (Casanova et al, 2019).

The nurse reviews with the patient instructions for emergency contraception based on the medication regimen prescribed. If the woman is breast-feeding, a progestin-only formulation is prescribed. To avoid exposing infants to synthetic hormones through breast milk, the patient can manually express milk and bottle-feed for 24 hours after treatment. The patient should be informed that her next menstrual period may begin a few days earlier or a few days later than expected. She is instructed to return for a pregnancy test if she has not had a menstrual period in 3 weeks and should be offered another visit to provide a regular method of contraception if she does not have one currently.

Postcoital Intrauterine Device Insertion

Postcoital IUD insertion, another form of emergency contraception, involves insertion of a copper-bearing IUD within 5 days of coitus (Casanova et al., 2019). The copper-bearing IUD prevents fertilization by causing a chemical change in sperm and egg before they can meet. The patient may experience discomfort on insertion and may have heavier menstrual periods and increased cramping. Contraindications include a confirmed or suspected pregnancy or any contraindication to regular IUD use. The patient must be informed that there is a risk that insertion of an IUD may disrupt a pregnancy that is already present.

Nursing Management

Patients who use emergency contraception may be anxious, embarrassed, and lacking information about birth control. The nurse must be supportive and nonjudgmental and provide facts and appropriate patient education. If the patient repeatedly uses this method of birth control, she should be informed that the failure rate with this method is higher than with a regularly used method. Nurses can educate and inform women about emergency contraception options to reduce unintended pregnancies and abortions. See the Resources section at the end of this chapter for more information.

Abortion

Interruption of pregnancy or expulsion of the product of conception before the fetus is viable is called *abortion.* The fetus is generally considered to be viable any time after the fifth to sixth month of gestation.

Spontaneous Abortion

It is estimated that 1 of every 5 to 10 conceptions ends in spontaneous abortion. Most of these occur because an abnormality in the fetus makes survival impossible. Other causes may include systemic diseases, hormonal imbalance, or anatomic abnormalities. If a woman who is pregnant experiences bleeding and cramping, a threatened abortion is diagnosed because an actual abortion is usually imminent. Spontaneous abortion occurs most commonly in the second or third month of gestation.

There are various types of spontaneous abortion, depending on the nature of the process (threatened, inevitable, incomplete, or complete). In a threatened abortion, the cervix does not dilate. With bed rest and conservative treatment, the abortion may be prevented. If not, an abortion is imminent. If only some of the tissue is passed, the abortion is referred to as incomplete. An emptying or evacuation procedure (D&C, or dilation and evacuation [D&E]) or administration of oral misoprostol is usually required to remove the remaining tissue. If the fetus and all related tissue are spontaneously evacuated, the abortion is termed *complete,* and no further treatment is required.

Habitual Abortion

Habitual or recurrent abortion is defined as successive, repeated, spontaneous abortions of unknown cause. As many as 60% of abortions may result from chromosomal anomalies (Casanova et al., 2019). After two consecutive abortions, the patient is referred for genetic counseling and testing, and other possible causes are explored.

If bleeding occurs in a woman who is pregnant with a past history of habitual abortion, conservative measures, such as bed rest and administration of progesterone to support the endometrium, are attempted to save the pregnancy. Supportive counseling is crucial in this stressful condition. Bed rest, sexual abstinence, a light diet, and no straining on defecation may be recommended in an effort to prevent spontaneous abortion. If infection is suspected, antibiotic agents may be prescribed.

In the condition known as incompetent or dysfunctional cervix, the cervix dilates painlessly in the second trimester of pregnancy, often resulting in a spontaneous abortion. In such cases, a surgical procedure called *cervical cerclage* may be used to prevent the cervix from dilating prematurely. It involves placing a purse-string suture around the cervix at the level of the internal os (Casanova et al., 2019). Bed rest is usually advised to keep the weight of the uterus off the cervix. About 2 to 3 weeks before term or at the onset of labor, the suture is cut. Delivery is usually by cesarean section.

Medical Management

After a spontaneous abortion, all tissue passed vaginally is saved for examination, if possible. The patient and all personnel who care for her are alerted to save any discharged material. In the rare case of heavy bleeding, the patient may require blood component transfusions and fluid replacement. An estimate of the bleeding volume can be determined by recording the number of perineal pads and the degree of saturation over 24 hours. When an incomplete abortion occurs, oxytocin may be prescribed to cause uterine contractions before D&E or uterine suctioning.

Nursing Management

Because patients experience loss and anxiety, emotional support and understanding are important aspects of nursing care. Women may be grieving or relieved, depending on their feelings about the pregnancy. Providing opportunities for the patient to talk and express her emotions is helpful and also provides clues for the nurse in planning more specific care.

Induced Abortion

A voluntary induced termination of pregnancy is performed by skilled health care providers. Decisions about abortion reside with a woman and her primary provider in the first trimester. During the second trimester, the state may regulate practice in the interest of a woman's health and during the final weeks of pregnancy may choose to protect the life of the fetus, except when necessary to preserve the life or health of the woman.

In the United States, 42% of all unintended pregnancies were terminated by abortion (Allan Guttmacher Institute, 2018). These numbers indicate the need for effective contraceptive education, information about emergency contraception, and counseling.

Chart 50-10

Types of Induced Abortions

Vacuum Aspiration

- The cervix is dilated manually with instrumentation or by laminaria (small suppositories made of seaweed that swells as it absorbs water).
- A uterine aspirator is introduced.
- Suction is applied, and tissue is removed from the uterus.

This is the most common type of termination procedure and is used early in pregnancy, up to 14 weeks. Laminaria may be used to soften and dilate the cervix prior to the procedure.

Dilation and Evacuation

Cervical dilation with laminaria followed by vacuum aspiration

Labor Induction

These procedures account for fewer than 1% of all terminations and generally take place in an inpatient setting.

1. Installation of normal saline or urea results in uterine contractions.
    - Although rare, serious complications can occur, including cardiovascular collapse, cerebral edema, pulmonary edema, kidney disease, and disseminated intravascular coagulopathy.
2. Prostaglandins
    - Prostaglandins are introduced into the amniotic fluid or by vaginal suppository or intramuscular injection in later pregnancy.
    - Strong uterine contractions begin within 4 hours and usually result in abortion.
    - Gastrointestinal side effects (e.g., nausea, vomiting, diarrhea, and abdominal cramping) and fever can occur.
3. IV oxytocin
    - Used for later abortions for genetic indications. Requires patient to go through labor.

Medical Abortion

Mifepristone

- Mifepristone is a progesterone antagonist that prevents implantation of the ovum.
- Given orally within 10 days of an expected menstrual period, mifepristone produces a medical abortion in most patients.
- Combined with a prostaglandin suppository, mifepristone causes abortion in up to 95% of patients.
- Prolonged bleeding may occur. Other side effects may include abdominal pain, nausea, vomiting, and diarrhea. This method may not be used in women with adrenal failure, asthma, long-term

corticosteroid therapy, an intrauterine device in place, porphyria, or a history of allergy to mifepristone or other prostaglandins. It is less effective when used in pregnancies more than 49 days from the beginning of the last menstrual period.

Methotrexate

- Methotrexate has also been used to terminate pregnancy because it is lethal to the fetus. It has been found to have minimal risk and few side effects in the woman. Its low cost may provide an alternative for some women.

Misoprostol

- Misoprostol is a synthetic prostaglandin analog that produces cervical effacement and uterine contractions.
- Inserted vaginally, misoprostol is effective in terminating a pregnancy in about 75% of cases.
- When combined with methotrexate or mifepristone, misoprostol's effectiveness rate is high.

Medical Management

Before the abortion procedure is performed (see Chart 50-10), a nurse or counselor trained in pregnancy counseling should talk with the patient and explore her fears, feelings, and options. The nurse then identifies the patient's choice (i.e., continuing pregnancy and parenthood, continuing pregnancy followed by adoption, or terminating pregnancy by abortion). If abortion is chosen, the patient has a pelvic examination to determine uterine size. A pelvic ultrasound may also be performed. Laboratory studies before an abortion must include a pregnancy test to confirm the pregnancy, hematocrit to rule out anemia, and Rh determination. Patients with anemia will require an iron supplement, and patients who are Rh negative may require Rho(D) immune globulin (RhoGAM) to prevent isoimmunization. Before the procedure, all patients should be screened for STIs to prevent introducing pathogens upward through the cervix during the procedure.

Quality and Safety Nursing Alert

Women who have resorted to unskilled attempts to end a pregnancy may become critically ill because of infection, hemorrhage, or uterine rupture. If a woman has undergone such efforts to end a pregnancy, prompt medical attention, broad-spectrum antibiotics, and replacement of fluids and blood components may be required before careful attempts are made to evacuate the uterus.

Surgical terminations include D&C or vacuum aspiration of uterine contents. Medications can also be used. Mifepristone is used only in early pregnancy (up to 49 days from the last menstrual period). It works by blocking progesterone. Cramping and bleeding similar to a heavy menstrual period occur. After counseling and consent and often a sonogram to confirm the pregnancy, mifepristone is given. This is followed by a dose of misoprostol orally or vaginally. If the pregnancy persists, a suction aspiration is performed. Contraindications include ectopic pregnancy, adrenal failure, allergy to the medications, bleeding disorder, irritable bowel syndrome, or uncontrolled seizure disorders. Several deaths from sepsis have occurred following medical abortion; researchers and the FDA are closely monitoring the morbidity and mortality associated with medical abortion. Medical and surgical abortions used in the first trimester are both highly effective with low complication rates (Bartz & Blumenthal, 2019).

Nursing Management

Patient education is an important aspect of care for women who elect to terminate a pregnancy. A patient undergoing induced abortion is informed about what the procedure entails and the expected course after the procedure. The patient is scheduled for a follow-up appointment 2 weeks after the procedure and is instructed about signs and symptoms (i.e., fever, heavy bleeding, or pain) that should be reported.

Available contraceptive methods are reviewed with the patient. Effectiveness depends on the method used and the extent to which the woman and her partner follow the instructions for use. A woman who has used any method of birth control should be assessed for her understanding of the method and its potential side effects as well as her satisfaction with the method. If the woman has not been using contraception, the nurse explains all methods and their benefits and risks and helps the patient make a contraceptive choice for use after abortion. Related education issues, such as the need to use barrier contraceptive devices (i.e., condoms) for protection against transmission of

STIs and HIV infection and the availability of emergency contraception, are also important.

Psychological support is another important aspect of nursing care. The nurse needs to be aware that women terminate pregnancies for many reasons. Some women terminate pregnancies because of severe genetic defects. Women who have been raped or impregnated in incestuous relationships or by an abusive partner may elect to terminate their pregnancies. The care of a woman undergoing termination of pregnancy is stressful, and assistance needs to be provided in a safe and nonjudgmental way. Nurses have the right to refuse to participate in a procedure that is against their religious beliefs but are professionally obligated not to impose their beliefs or judgments on their patients.

Infertility

In the United States, infertility affects approximately 1 in 8 couples between ages 15 and 44 (over 7 million women) and is defined as a couple's inability to achieve pregnancy after 1 year of unprotected penile-vaginal intercourse (Lee, 2019). Primary infertility refers to a couple who has never had a child. Secondary infertility means that at least one conception has occurred, but currently the couple cannot achieve a pregnancy. It is often a complex physical problem and causes are related to endometriosis, uterine factors, anovulation, tubal obstruction, and male factors.

Diagnostic Findings

Ovarian and Ovulation Factors

Diagnostic studies performed to determine if ovulation is regular and whether the progestational endometrium is adequate for implantation may include a serum progesterone level and an ovulation index. The ovulation index involves a urine dipstick test to determine whether the surge in LH that precedes follicular rupture has occurred.

Tubal and Uterine Factors

HSG is used to rule out uterine or tubal abnormalities. A contrast agent injected into the uterus through the cervix produces an outline of the shape of the uterine cavity and the patency of the tubes. This process sometimes removes mucus or tissue that is lodged in the tubes. Laparoscopy permits direct visualization of the tubes and other pelvic structures and can assist in identifying conditions that may interfere with fertility (e.g., endometriosis).

Fibroids, polyps, and congenital malformations are possible causative factors affecting the uterus. Their presence may be determined by pelvic examination, hysteroscopy, saline sonogram (a variation of a sonogram), and HSG. Endometriosis, even if mild, is associated with reduced fertility (Schenken, 2019).

Male Factors

An analysis of semen provides information about the number of sperm (density), percentage of moving forms, quality of forward movement (forward progression), and morphology (shape and form). From 2 to 6 mL of watery alkaline semen is normal. A normal count has 60 to 100 million sperm/mL. However, the incidence of impregnation is lessened only when the count decreases to fewer than 15 million sperm/mL (Anawat & Page, 2019).

Men may also be affected by varicoceles (varicose veins around the testicle), which decrease semen quality by increasing testicular temperature. Retrograde ejaculation or ejaculation into the bladder is assessed by urinalysis after ejaculation. Blood tests for male partners may include measuring testosterone, FSH, and LH (both of which are involved in maintaining testicular function), and prolactin levels (Anawat & Page, 2019).

Medical Management

The treatment of infertility is complex and often requires advanced technology. The specific type of treatment depends on the cause of the problem, if it can be identified. Many couples with infertility have normal test results for ovulation, sperm production, and fallopian tube patency.

Ovulatory dysfunction is complex, but many women with ovulation disorders have polycystic ovary syndrome (see Chapter 51) and may be treated with 5 days of clomiphene to induce ovulation (Comerford & Durkin, 2020). Insulin sensitizing agents are sometimes used, and once insulin levels are normalized, ovulation often occurs. Some women have high prolactin levels, which inhibit ovulation, and they are treated with dopaminergic drugs after a pituitary adenoma is ruled out by MRI. If a woman has premature ovarian failure, oocyte donation may be considered.

Pharmacologic Therapy

Pharmacologically induced ovulation is undertaken when women do not ovulate on their own or ovulate irregularly. These couples are often treated with clomiphene to stimulate ovulation. Gonadotropin treatment may also be used if conception does not occur. Various other medications are used, depending on the main cause of infertility (see Chart 50-11).

Blood tests and ultrasounds are used to monitor ovulation. Multiple pregnancies (i.e., twins, triplets, or more) may occur with the use of these medications. Ovarian hyperstimulation syndrome (OHSS) may also occur. This condition is characterized by enlarged multicystic ovaries and is complicated by a shift of fluid from the intravascular space into the abdominal cavity. The fluid shift can result in ascites, pleural effusion, and edema; hypovolemia may also occur. Risk factors include younger age, history of polycystic ovarian syndrome, high serum estradiol levels, a larger number of follicles, and pregnancy.

Artificial Insemination

Artificial insemination is the deposit of semen into the female genital tract by artificial means. If the sperm cannot penetrate the cervical canal normally, artificial insemination using a partner's or husband's semen or that of a donor may be considered. When the sperm of the woman's partner is defective or absent (azoospermia) or when there is a risk of transmitting a genetic disease, donor sperm may be used. Safeguards are put in place to address legal, ethical, emotional, and religious issues. Written consent is obtained to protect all parties involved, including the woman, the donor, and the resulting child. The donor's semen is frozen, and the donor is evaluated to ensure that he is free of genetic disorders and STIs, including HIV infection (Ginsburg & Srouji, 2019).

Conditions must be optimal for conception before semen is transferred to the vagina or uterus. The woman must have no abnormalities of the genital system, the fallopian tubes must be patent, and ova must be available. In the male, sperm need to be normal in shape, amount, motility, and endurance. The time of ovulation should be determined as accurately as possible so that the 2 or 3 days during which fertilization is possible each month can be targeted for the treatment.

Ultrasonography and blood studies of varying hormone levels are used to pinpoint the best time for insemination and to monitor for OHSS. Fertilization seldom occurs from a single insemination. Usually, insemination is attempted between days 10 and 17 of the cycle; three different attempts may be made during one cycle. The woman may have received clomiphene or other medications to stimulate ovulation before insemination. The recipient is placed in the lithotomy position on the examination table, a speculum is inserted, and the vagina and cervix are swabbed with a cotton-tipped applicator to remove any excess secretions. The sperm are washed before insertion to remove biochemicals and to select the most active sperm. Semen is drawn into a sterile syringe, and a cannula is attached. The semen is then directed to the external os. In intrauterine insemination, semen is placed into the uterine cavity.

Chart 50-11 PHARMACOLOGY

Medications That Induce Ovulation

- Clomiphene citrate is an estrogen antagonist that increases gonadotropin release, resulting in follicular rupture or ovulation. Clomiphene is used when the hypothalamus is not stimulating the pituitary gland to release follicle-stimulating hormone (FSH) and luteinizing hormone (LH). This medication stimulates follicles in the ovary. It is usually taken for 5 days beginning on the 5th day of the menstrual cycle. Ovulation should occur 4 to 8 days after the last dose. Patients receive instructions about timing penile-vaginal intercourse to facilitate fertilization.
- Menotropins, a combination of FSH and LH, may be used to stimulate the ovaries to produce eggs. These agents are used for women with deficiencies in FSH and LH. When followed by administration of human chorionic gonadotropin, menotropins stimulates the ovaries, so monitoring by ultrasound and hormone levels is essential because overstimulation may occur.
- Follitropin alfa, follitropin beta, and urofollitropin may be used to treat ovulation disorders or to stimulate a follicle and egg production for intrauterine insemination or in vitro fertilization or other assisted reproductive technologies.
- Gonadotropin-releasing hormone agonists (leuprolide, nafarelin acetate) suppress FSH, prevent premature egg release, and shrink fibroids.
- Bromocriptine may be used in treatment for infertility due to elevated prolactin levels.
- Progesterone vaginal suppositories help improve the uterine lining after ovulation.
- Urofollitropin, which contains FSH with a small amount of LH, is used in some disorders (e.g., polycystic ovarian syndrome) to stimulate follicle growth. Clomiphene is then used to stimulate ovulation.
- Chorionic gonadotropin, which mimics LH, releases an egg after hyperstimulation and supports the corpus luteum.
- Metformin may be used in polycystic ovarian syndrome to induce regular ovulation.
- Aspirin and heparin may be used to prevent recurrent pregnancy loss in patients with elevated antiphospholipid antibodies.

Assisted Reproductive Technologies

Assisted reproductive technologies include in vitro fertilization (IVF) and its modifications. Currently, between 1% and 3% of all live births each year in the United States are achieved through assisted technology (Paulson, 2019).

IVF refers to a set of procedures that, if successful, results in a pregnancy. These procedures involve ovarian stimulation, egg retrieval, fertilization, and embryo transfer. The ovaries are stimulated to produce multiple eggs or ova, usually with medications, because success rates are greater with more than one embryo. Many different protocols exist for inducing ovulation with one or more agents (Paulson, 2019). Patients are carefully selected and evaluated, and cycles are carefully monitored using ultrasound and monitoring hormone levels. At the appropriate time, the ova are recovered by transvaginal ultrasound retrieval. Sperm and eggs are coincubated for up to 36 hours, and the embryos are transferred about 48 hours after retrieval. Implantation should occur in 3 to 5 days.

Gamete intrafallopian transfer (GIFT), a variation of IVF, is the treatment of choice for patients with ovarian failure. GIFT is considered in unexplained infertility and when there is religion-based discomfort with IVF. The most common indications for IVF and GIFT are irreparable tubal damage, endometriosis (see Chapter 51), unexplained infertility, inadequate sperm, and exposure to diethylstilbestrol. Success rates for GIFT are similar to those for IVF (Paulson, 2019).

Additional Assisted Reproductive Technologies

In intracytoplasmic sperm injection (ICSI), an ovum is retrieved, and a single sperm is injected through the zona pellucida, through the egg membrane, into the cytoplasm of the oocyte. The fertilized egg is then transferred back to the donor. ICSI is the treatment of choice in severe male factor infertility.

Women who cannot produce their own eggs (i.e., premature ovarian failure) have the option of using the eggs of a donor after stimulation of the donor's ovaries. The recipient also receives hormones in preparation for these procedures. Couples may also choose this modality if the female partner has a genetic disorder that may be passed on to children.

Tubal embryo transfer (TET) involves the placement of fertilized eggs or embryos into the fallopian tube. A laparoscopic procedure is needed to place the embryos in the fallopian tubes. Some women choose TET after IVF failure (Paulson, 2019).

Chart 50-12  **NURSING RESEARCH PROFILE**

Stress and Anxiety in Couples Who Conceive via In Vitro Fertilization

Stevenson, E. L., Cebert, M., & Silva, S. (2019). Stress and anxiety in couples who conceive via In Vitro fertilization compared with those who conceive spontaneously. *Journal of Obstetric, Gynecologic and Neonatal Nursing*, *48*(6), 635–644.

Purpose

Infertility, which impacts roughly 15% of couples worldwide, is a stressful event for couples. Few studies have examined the continued stress and anxiety experienced after successful in vitro fertilization (IVF). Even less investigated is the partners' experience during infertility and IVF. The aim of this pilot study was to examine the levels of stress and anxiety of women and their partners who conceived via IVF compared with each other, as well as compared to couples who conceived spontaneously.

Design

The longitudinal, descriptive pilot study enrolled 48 women and their partners (n = 96). The 22 couples (n = 44) who conceived by IVF and 26 (n = 52) couples who conceived spontaneously were recruited from 2 fertility clinics and a well women clinic throughout the northeast and southeast United States. Participants were asked to complete three instruments during each trimester of pregnancy to measure the perceptual and emotional response components of stress and anxiety.

Results

The analysis of the instruments across the 3 trimesters showed significant differences between women and their male partners. All women showed greater levels of stress and anxiety during each trimester compared to their male partners. Anxiety was not consistent throughout the pregnancy, showing a gradual decline as the pregnancy progressed. The study also reported no significant difference in the levels of stress and anxiety between couples who conceived by IVF and those who conceived spontaneously.

Nursing Implications

It is imperative that nurses and other professionals recognize the impact infertility can have on a couple's level of stress and anxiety. In addition to care of the couple, nurses need to care for the individual, taking into full account the differences in experiences of the woman and her partner during the pregnancy.

Nursing Management

Nursing interventions when working with couples during infertility evaluations include assisting in reducing stress in the relationship, encouraging cooperation, protecting privacy, fostering understanding, and referring the

couple to appropriate resources when necessary. Because infertility evaluations and treatments are expensive, time-consuming, invasive, stressful, and not always successful, couples need support in working together to deal with this process (Stevenson, Cebert, & Silva, 2019) (see the Nursing research Profile in Chart 50-12).

Smoking cessation is encouraged because smoking, smokeless tobacco, electronic nicotine delivery systems (ENDS) including e-cigarettes, e-pens, e-pipes, e-hookah, and e-cigars, have an adverse effect on the success of assisted reproduction (Rodriguez, 2020). Diet, exercise, stress reduction techniques, folic acid supplementation, health maintenance, and disease prevention are emphasized in many infertility programs. Couples may also consider adoption, child-free living, and gestational carriers (the use of a surrogate to carry the fetus for the couple with infertility). Nurses can be helpful listeners and information resources in these deliberations.

Preconception/Periconception Health Care

Nurses can be instrumental in encouraging all women of childbearing age, including those with chronic illness or disabilities, to consider issues that may affect health during pregnancy (Lammers, Hulme, Wey, et al., 2017). Preconception health care is a concept that expands on the definition of prenatal care to include the time before conception (Lammers et al., 2017). Women who plan their pregnancies and are healthy and well informed tend to have better outcomes. There are currently nine consensus recommendations for advancing preconception health (see Chart 50-13).

Chart 50-13

Preconception Wellness Strategies

Nurses can help advance pre- and periconception care of women by establishing the following:

- Pregnancy intention
- Absence of sexually transmitted infections
- Access to care
- Healthy weight
- Optimal glycemic control in women with pregestational diabetes
- Preconception multivitamin with folic acid
- Teratogenic medication avoidance
- Tobacco avoidance

Adapted from Lammers, C. R., Hulme, P. A., Wey, H., et al. (2017). Understanding women's awareness and access to preconception health care in rural population: A cross-sectional study. *Journal of Community Health*, *42*(3), 489–499.

Nurses can make a difference in preconception health through education and counseling. Women who use tobacco products, by smoking or ENDS, should be encouraged to stop their use; it may help to offer cessation classes. Women should take folic acid supplements to prevent neural tube defects. Women with diabetes should have good glycemic control prior to conception. It is necessary to assess rubella immunity and other immunizations as well as a family history of genetic defects; genetic counseling may be appropriate. Women taking teratogenic medications and women concerned about genetic disorders should be encouraged to discuss effective contraception and childbearing plans with their primary provider (see Chart 50-2).

Ectopic Pregnancy

The incidence of ectopic pregnancy and the risk of death due to ectopic pregnancy are decreasing. However, ectopic pregnancy remains the leading cause of pregnancy-related death in the first trimester (ACOG, 2018). Ectopic pregnancy occurs when a fertilized ovum (a blastocyst) becomes implanted on any tissue other than the uterine lining, most commonly along the fallopian tube (ACOG, 2018) (see Fig. 50-7).

Possible causes of ectopic pregnancy include salpingitis, peritubal adhesions (after pelvic infection, endometriosis, appendicitis), structural abnormalities of the fallopian tube, previous ectopic pregnancy, previous tubal surgery, multiple previous induced abortions, and tumors that distort the tube (ACOG, 2018). Additional risk factors include use of tobacco products, IUD

use, history of PID, and use of fertility drugs to induce ovulation (ACOG, 2018).

Risk factors are important, but all women need to be educated about early treatment and have a high index of suspicion in the case of a period that does not seem normal, the presence of pain, or pain with a suspected pregnancy. Women may have fatal hemorrhage with ruptured ectopic pregnancies if they delay seeking attention or if their primary providers are not alert to the possibility of this diagnosis.

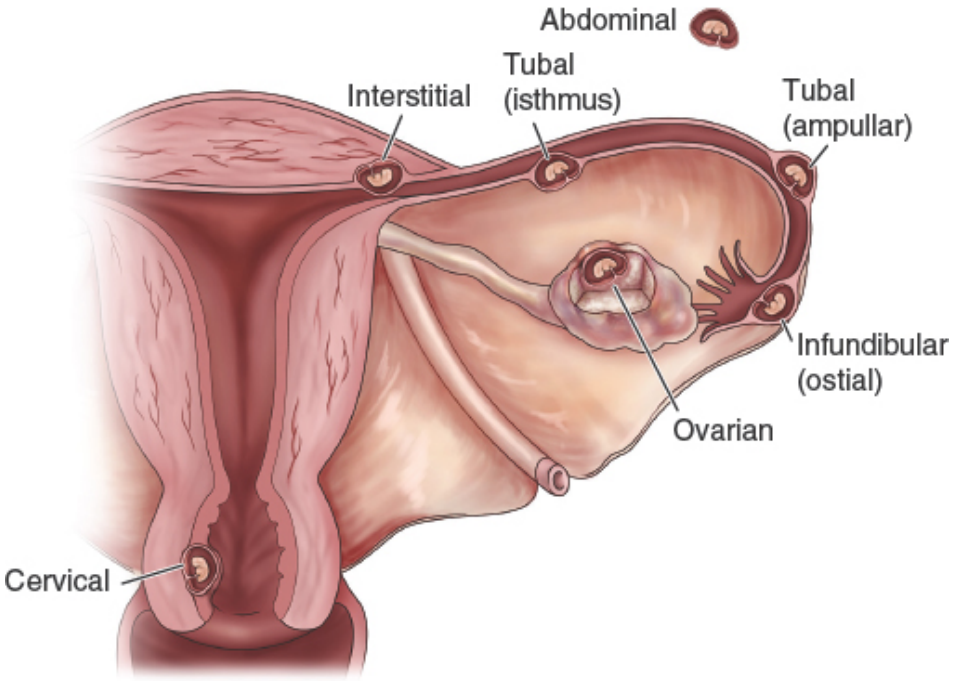

Figure 50-7 • Sites of ectopic pregnancy.

Clinical Manifestations

Signs and symptoms vary depending on whether tubal rupture has occurred. Delay in menstruation from 1 to 2 weeks followed by slight bleeding (spotting) or a report of a slightly abnormal period suggests the possibility of an ectopic pregnancy. Symptoms may begin late, with vague soreness on the affected side (probably due to uterine contractions and distention of the tube), and may proceed to sharp, colicky pain. Most patients experience some pelvic or abdominal pain and some spotting or bleeding. Gastrointestinal symptoms, dizziness, or lightheadedness may occur. Patients may think the abnormal bleeding is a menstrual period, especially if a recent period occurred and was normal.

If implantation occurs in the fallopian tube, the tube becomes more and more distended and can rupture if the ectopic pregnancy remains undetected for 4 to 6 weeks or longer after conception. When the tube ruptures, the ovum

is discharged into the abdominal cavity, and the woman experiences agonizing pain, dizziness, faintness, and nausea and vomiting due to the peritoneal reaction to blood escaping from the tube. Dyspnea and symptoms of shock may occur, and the signs of hemorrhage—rapid and thready pulse, decreased blood pressure, subnormal temperature, restlessness, pallor, and sweating—are evident. Later, the pain becomes generalized in the abdomen and radiates to the shoulder and neck because of accumulating intraperitoneal blood that irritates the diaphragm.

Assessment and Diagnostic Findings

Ectopic pregnancies must be diagnosed promptly to prevent life-threatening hemorrhage, which is the major complication of rupture. During vaginal examination, a large mass of clotted blood that has collected in the pelvis behind the uterus or a tender adnexal mass may be palpable, although there are often no abnormal findings. If an ectopic pregnancy is suspected, the patient is evaluated by sonography and human chorionic gonadotropin (hCG) levels. Serial hCG tests may be needed (Tulandi, 2019). The levels of hCG (the diagnostic hormone of pregnancy) double in early normal pregnancies every 3 days but are reduced in abnormal or ectopic pregnancies. A less-than-normal increase is cause for suspicion. Transvaginal ultrasound, the usual method of diagnosis, can detect a pregnancy between 5 and 6 weeks from the time of the last menstrual period. Detectable fetal heart movement outside the uterus on ultrasound is firm evidence of an ectopic pregnancy.

Occasionally, the clinical picture makes the diagnosis relatively easy. However, when the clinical signs and symptoms are inconclusive, laparoscopy may be required for definitive diagnosis (Tulandi, 2019).

Medical Management

Surgical Management

When surgery is performed early, almost all patients recover rapidly; if tubal rupture occurs, mortality increases. The type of surgery is determined by the size and extent of local tubal damage. Resection of the involved fallopian tube with end-to-end anastomosis may be effective. Some surgeons attempt to salvage the tube with a salpingotomy, which involves opening and evacuating the tube and controlling bleeding. More extensive surgery includes salpingectomy (removing the tube alone) or salpingo-oophorectomy (removing the tube and ovary).

Pharmacologic Therapy

Another option is the use of methotrexate without surgery (ACOG, 2018). Because methotrexate stops the pregnancy from progressing by interfering with DNA synthesis and the multiplication of cells, it interrupts early, small, unruptured ectopic pregnancies. The patient must be hemodynamically stable; have no active renal or hepatic disease; have no evidence of thrombocytopenia or leukopenia; and have a very small, unruptured ectopic pregnancy on ultrasound. Other indications may include no fetal cardiac activity and no active abdominal bleeding. Methotrexate is occasionally used to eliminate residual ectopic pregnancy tissue following a laparoscopy (ACOG, 2018).

NURSING PROCESS

The Patient with an Ectopic Pregnancy

Assessment

The health history includes the menstrual pattern and any (even slight) bleeding since the last menstrual period. The nurse elicits the patient's description of pain and its location. The nurse asks the patient whether any sharp, colicky pains have occurred and whether pain radiates to the shoulder and neck (possibly caused by rupture and pressure on the diaphragm).

In addition, the nurse monitors vital signs, level of consciousness, and the nature and amount of vaginal bleeding. If possible, the nurse assesses how the patient is coping with the abnormal pregnancy and likely loss.

Diagnosis

Nursing Diagnoses

Based on the assessment data, major nursing diagnoses may include the following:

- Acute pain associated with the progression of the ectopic pregnancy
- Grief associated with the loss of pregnancy and anticipatory effect on future pregnancies
- Lack of knowledge associated with the treatment and effect on future pregnancies

Collaborative Problems/Potential Complications

Potential complications may include:

- Hemorrhage
- Hemorrhagic shock

Planning and Goals

The major goals may include relief of pain; acceptance and resolution of grief and pregnancy loss; increased knowledge about ectopic pregnancy, its treatment, and its outcome; and absence of complications.

Nursing Interventions

Relieving Pain

The abdominal pain associated with ectopic pregnancy may be described as cramping or severe continuous pain. If the patient is to have surgery, preanesthetic medications may provide pain relief. Postoperatively, analgesic agents are given liberally; this promotes early ambulation and enables the patient to cough and take deep breaths.

Supporting the Grieving Process

Patients experience varying levels of distress. If the pregnancy was desired, loss may or may not be expressed verbally by the patient and her partner. The impact may not be fully realized until much later. The nurse should be available to listen and provide support. The patient's partner, if appropriate, should participate in this process. Even if the pregnancy was unintended, a loss has been experienced, and a grief reaction may occur.

Monitoring and Managing Potential Complications

Potential complications of ectopic pregnancy are hemorrhage and shock. Careful assessment is essential to detect the development of these complications. Continuous monitoring of vital signs, level of consciousness, amount of bleeding, and intake and output provide information about the possibility of hemorrhage and the need to prepare for IV therapy. Bed rest is indicated. Hematocrit, hemoglobin, and blood gases are monitored to assess hematologic status and adequacy of tissue perfusion. Significant deviations in these laboratory values are reported immediately, and the patient is prepared for possible surgery. Blood component therapy may be required if blood loss has been rapid and extensive. If hypovolemic shock occurs, the treatment is directed toward reestablishing tissue perfusion and adequate blood volume. See Chapter 11 for a discussion of the IV fluids and medications used in treating shock.

The nurse has an important role in prevention by being alert to patients with abnormal bleeding who may be at risk for an ectopic pregnancy and referring them immediately for care. It is necessary to keep a high index of suspicion in daily practice when a woman of childbearing age, particularly one who is not using an effective method of contraception consistently, reports abdominal discomfort or abnormal bleeding.

Promoting Home, Community-Based, and Transitional Care

Educating Patients About Self-Care. If the patient has experienced life-threatening hemorrhage and shock, these complications are addressed and treated before education can begin. At this time, the patient's and the nurse's attention is focused on the crisis, not on learning. Once hemodynamically stable, the patient begins to ask questions about what happened and why certain procedures were performed. Procedures are explained in terms that are understandable to a patient who is distressed and apprehensive. The patient's partner is included in education when possible. After the patient recovers from postoperative discomfort, it may be more appropriate to address any questions and concerns that she and her partner have, including the effect of this pregnancy or its treatment on future pregnancies. The patient should be advised that ectopic pregnancies may recur. The patient is educated about possible complications and instructed to report early signs and symptoms. It

is important to review signs and symptoms with the patient and instruct her to report an abnormal menstrual period promptly.

Continuing and Transitional Care. Because of the risk of subsequent ectopic pregnancies, the patient is advised to seek preconception counseling before considering future pregnancies and to seek early prenatal care. Follow-up contact allows the nurse to answer questions and clarify information for the patient and her partner.

Evaluation

Expected patient outcomes may include:

1. Experiences relief of pain
   a. Reports a decrease in pain and discomfort
   b. Ambulates as prescribed; performs coughing and deep breathing
2. Begins to accept loss of pregnancy and expresses grief by verbalizing feelings and reactions to loss
3. Verbalizes an understanding of the causes of ectopic pregnancy
4. Experiences no complications
   a. Exhibits no signs of bleeding, hemorrhage, or shock
   b. Has decreased amounts of discharge (on perineal pad)
   c. Has normal skin color and turgor
   d. Exhibits stable vital signs and adequate urine output
   e. Levels of beta-hCG return to normal

Perimenopause

Perimenopause is the menstrual transition period before menopause that begins on average 4 years before the last menstrual period (Casper, 2019). Perimenopause is characterized by marked hormonal fluctuations and irregular menstrual cycles (Casper, 2019). Women often have varied beliefs about aging, and these must be considered when caring for or educating patients who are perimenopausal.

Nursing Management

Women who are perimenopausal often benefit from information about the subtle physiologic changes they are experiencing. Perimenopause has been described as an opportune time for educating women about health promotion and disease prevention strategies. When discussing health-related concerns with women who are in midlife, nurses should consider the following issues:

- Sexuality, fertility, contraception, and STIs

- Unintended pregnancy (if contraception is not used correctly and consistently)
- Oral contraceptive use. Oral contraceptives provide women with protection against uterine cancer, ovarian cancer, anemia, pregnancy, and fibrocystic breast changes as well as relief from perimenopausal symptoms (Casanova et al., 2019). This option should be discussed with women who are perimenopausal. Women who smoke and are 35 years or older should not take oral contraceptive agents because of an increased risk of cerebrovascular disease. Contraception is discussed in detail earlier in this chapter.
- Breast health. About 16% of cases of breast cancer occur in women who are perimenopausal, so breast self-examination, routine physical examinations, and mammograms are essential.

Menopause

Menopause is the permanent physiologic cessation of menses associated with declining ovarian function evidenced by 12 consecutive months with no menstrual bleeding (Casanova et al., 2019). Most women stop menstruating between 41 and 59 years of age. Postmenopause is the period beginning from about 1 year after menses cease. Due to a decrease in estrogen levels, menopause may be associated with some atrophy of breast tissue and genital organs, loss in bone density, and vascular changes.

Menopause starts gradually and is usually signaled by changes in menstruation. The monthly flow may increase or decrease, become irregular, and finally cease. Often, the interval between periods is longer; a lapse of several months between periods is not uncommon. Ovulation occurs less frequently, estrogen levels fluctuate, and FSH levels increase in an attempt to stimulate estrogen production (Casanova et al., 2019).

Postmenopausal Bleeding

Bleeding 1 year after menses cease at menopause must be investigated, and a malignant condition must be considered until proven otherwise. A transvaginal ultrasound can be used to measure the thickness of the endometrial lining (Goodman, 2020). The uterine lining in women who are postmenopausal should be thin because of low estrogen levels. A thicker lining warrants further evaluation by endometrial biopsy or a D&C.

Clinical Manifestations

Menopause has systemic effects that include an increase in body fat and intra-abdominal deposition of body fat. Also, levels of total and LDL cholesterol increase. Hot flashes occur in many women going through menopause due to alterations in thermoregulation. Because of these hormonal changes, some women notice irregular menses, breast tenderness, and mood changes long before menopause occurs (Casanova et al., 2019). The hot or warm flashes and night sweats reported by some women are thought to be caused by hormonal changes and denote vasomotor instability. They may vary in intensity from a barely perceptible warm feeling to a sensation of extreme warmth accompanied by profuse sweating, causing discomfort, sleep disturbances, and subsequent fatigue. Other physical changes may include increased bone loss (see Chapter 36).

Chart 50-14 HEALTH PROMOTION

Strategies for Women Approaching Menopause

- An annual physical examination can help screen for problems and promote general health.
- Changes in lifestyle (e.g., diet, activity) to promote health and wellness.
  - A nutritious diet (decrease fat and calories, increase fiber and whole grains) and weight control will enhance physical and emotional well-being.
  - Exercise for at least 30 minutes 3 or 4 times a week to maintain good health.
  - Involvement in outside activities is beneficial in reducing anxiety and tension.
- Recognize the following about sexual activity:
  - Sexual functioning may be enhanced at midlife.
  - Frequent sexual activity helps to maintain the elasticity of the vagina.
  - Contraception is advised until 1 year passes without menses.
  - Safer sex is important at any age.
- Strategies and methods to prevent or manage potential problems:
  - *Hot flashes:* See primary provider to discuss hormone replacement therapy indications (lowest dose for shortest period of time) and alternative therapy (e.g., vitamin therapy, black cohosh, and other herbal preparations). Fatigue and stress may worsen hot flashes.
  - *Itching or burning of vulvar areas:* See primary provider to rule out dermatologic abnormalities and, if appropriate, to obtain a prescription for a lubricating or hormonal cream.
  - *Dyspareunia due to vaginal dryness:* Use a water-soluble lubricant, hormone cream, or contraceptive foam.
  - *Decreased perineal muscle tone and bladder control:* Practice Kegel exercises daily (contract the perineal muscles as though stopping urination; hold for 5 to 10 seconds and release; repeat frequently during the day).
  - *Dry skin:* Use mild emollient skin cream and lotions to prevent dry skin.
  - *Weight control:* Join a weight reduction support group such as Weight Watchers or a similar group if appropriate or consult a registered dietitian for guidance about the tendency to gain weight, particularly around the hips, thighs, and abdomen.
  - *Osteoporosis:* Observe recommended calcium and vitamin D intake, including calcium supplements, if indicated, to slow the process of osteoporosis; avoid smoking, alcohol, and excessive caffeine, all of which increase bone loss. Perform weight-bearing exercises. Undergo bone density testing when appropriate.

- *Risk for urinary tract infection (UTI):* Drink 6 to 8 glasses of water daily as a possible way to reduce the incidence of UTI related to atrophic changes of the urethra.
- *Vaginal bleeding:* Report any bleeding after 1 year of no menses to the primary provider *immediately, no matter how minimal.*

The entire genitourinary system is affected by the reduced estrogen level. Changes in the vulvovaginal area may include a gradual thinning of pubic hair and a gradual shrinkage of the labia. Vaginal secretions decrease, and women may report dyspareunia. The vaginal pH increases during menopause, predisposing women to bacterial infections and atrophic vaginitis. Discharge, itching, and vulvar burning may result.

Some women report fatigue, forgetfulness, weight gain, irritability, trouble sleeping, feeling "blue," and feelings of panic. Menopausal complaints need to be evaluated carefully because they may indicate other disorders. Most women have few problems and are relieved to be free from menstrual periods. Nurses should provide women with education and health promotion strategies appropriate for those approaching menopause (see Chart 50-14).

Psychological Considerations

Women's reactions and feelings related to loss of reproductive capacity may vary. Some women may experience role confusion, whereas others experience a sense of sexual and personal freedom. Women may be relieved that the childbearing phase of their lives is over. Each woman's personal views about menopause and circumstances affect her response and must be considered on an individual basis. Nurses need to be sensitive to all possibilities and take their cues from the patient.

Medical Management

Women approaching menopause often have many concerns about their health. Some have concerns based on a family history of heart disease, osteoporosis, or cancer. Each woman needs to be as knowledgeable as possible about her health options and should be encouraged to discuss her concerns with her primary provider so that she can make an informed decision about managing menopausal symptoms and maintaining her health.

Hormone Therapy

HT or menopausal hormonal therapy (previously referred to as hormone replacement therapy [HRT]) is medication that contains estrogen or estrogen and progestin together, to replace the ones the body is no longer making. HT is controversial but it is prescribed to treat moderate to severe menopause-related

vasomotor symptoms (hot flashes and night sweats) in women without contraindications to estrogen and progesterone whose quality of life is being affected (Martin & Barbieri, 2019). The current recommendation for treatment of hot flashes with HT is to use the lowest dose possible for the shortest time possible (Martin & Barbieri, 2019).

Methods of Administration

Both estrogen and progestin are prescribed for women who have not had a hysterectomy; progestin prevents proliferation of the uterine lining and hyperplasia. Women who no longer have a uterus because of hysterectomy can take estrogen without progestin (i.e., unopposed estrogen) because there is no longer a risk of estrogen-induced hyperplasia of the uterine lining. Although there is a slight increase of risk of stroke in women taking estrogen alone following hysterectomy, the risk of breast cancer is unchanged (Martin & Barbieri, 2019).

Some women take both estrogen and progestin daily; others take estrogen for 25 consecutive days each month, with progestin taken in cycles (e.g., 10 to 14 days of the month). Women who take HT for 25 days often experience bleeding after completing the progestin. Other women take estrogen and progestin every day and usually experience no bleeding. They occasionally have irregular spotting, which should be evaluated by their primary provider. Progestin administration may be oral, transdermal, vaginal, or intrauterine.

Estrogen patches, which are replaced once or twice weekly, are another option but require a progestin along with them if the woman still has a uterus. Another type of patch provides estrogen and progestin treatment (Comerford & Durkin, 2020). Skin should be dry at the area of application and cleansing the site with alcohol may improve adhesiveness. Vaginal treatment with an estrogen cream, suppository, or a vaginal ring may be used for vasomotor symptoms, vaginal dryness, or atrophy (Comerford & Durkin, 2020).

Risks and Benefits

HT is contraindicated in women with a history of breast cancer, vascular thrombosis, impaired liver function, uterine cancer, and undiagnosed abnormal vaginal bleeding. The risk of venous thromboembolism is increased with HT (Martin & Barbieri, 2019). Women who elect to take HT should be educated about the signs and symptoms of deep vein thrombosis (DVT) and pulmonary embolism (PE) and instructed to report these signs and symptoms (i.e., leg redness, tenderness, chest pain, shortness of breath) immediately. Women who take HT need to be informed about the importance of regular follow-up care, including a yearly physical examination and mammograms as needed and age appropriate. An endometrial biopsy is indicated for any irregular bleeding. Because the risk of complications increases the longer HT is used, HT should be used for the shortest time possible (Martin & Barbieri, 2019). Estrogen

alone or in combination with a progestin does not reduce the risk of dementia or cognitive impairment.

Alternative Therapy for Hot Flashes

Because women often seek information about alternatives to the use of HT, nurses must be knowledgeable about other approaches that women can use to promote their health in the peri- and postmenopausal periods. Problematic hot flashes have been treated with low-dose venlafaxine, psychoeducational approaches, and diet and lifestyle changes (Santen, Loprinzi, & Casper, 2019). Similarly, vitamin B_6 and vitamin E may be effective. Some women have expressed interest in other alternative treatments (e.g., natural estrogens and progestins, black cohosh, ginseng, dong quai, soy products, and several other herbal preparations); however, scant data exist about their safety or effectiveness. A few studies have shown some improvement in vasomotor symptoms (hot flashes and night sweats) with the use of complementary therapies. These include reflexology, aromatherapy, yoga, hypnotherapy, breathing exercises, and meditation (Santen et al., 2019). When taking a medical history of a patient who is perimenopausal or menopausal, the nurse should always address their use of complementary and alternative therapies and supplements.

Maintaining Bone Health

Acceleration of bone loss resulting in osteoporosis and microarchitectural deterioration of bone tissue occurs at menopause and leads to increased bone fragility and risk of fracture (see Chapter 36).

Maintaining Cardiovascular Health

A variety of strategies can help to lower the risk of heart disease in women, including lifestyle changes and behavioral strategies (see Chapter 21).

Behavioral Strategies

As stated previously, regular physical exercise is beneficial. It may also reduce stress, enhance well-being, and improve self-image. In addition, weight-bearing exercise may prevent loss of muscle tissue and bone tissue.

Women are also encouraged to participate in other health-promoting activities. These include regular health screening recommended for women at the time of menopause: gynecologic examinations, mammograms, colonoscopy, fecal occult blood testing, and bone mineral density testing if at risk for osteoporosis.

Nutritional Therapy

Women are encouraged to decrease their fat and caloric intake and increase their intake of whole grains, fibers, fruits, and vegetables.

Nursing Management

Nurses can encourage women to view menopause as a natural change resulting in freedom from symptoms related to menses. No relationship exists between menopause and mental health problems; however, social circumstances (e.g., adolescent children, ill partners, and dependent or ill parents) that may coincide with menopause can be stressful.

Measures should be taken to promote general health. The nurse explains to the patient that cessation of menses is a normal occurrence that is rarely accompanied by nervous symptoms or illness. The current expected lifespan after menopause for the average woman is 30 to 35 years, which may encompass as many years as the childbearing phase of her life. Normal sexual urges continue, and women retain their usual response to sex long after menopause. Many women enjoy better health after menopause than before, especially those who have experienced dysmenorrhea. The individual woman's evaluation of herself and her worth, now and in the future, is likely to affect her emotional reaction to menopause. Patient education and counseling regarding healthy lifestyles, health promotion, and health screening are of paramount importance (Santen et al., 2019).

CRITICAL THINKING EXERCISES

1 ebp During an outpatient visit, your 33-year-old female patient and her spouse mention they are interested in infertility evaluation. What information will you need to determine if infertility treatment is an option? What is the evidence base for infertility methods for this couple? Specify the criteria used to evaluate the strength of the evidence for the practices that you identify.

2 ipc A 40-year-old woman was admitted to your unit for complications from a recent induced abortion. You notice bruising in various stages of healing and suspect she may be a victim of intimate partner violence. What type of referrals might be appropriate for this patient? What members of the interprofessional health care team do you anticipate as being integral to the care of this patient?

3 pq During her annual physical examination, a 21-year-old woman is anxious about her first pelvic examination. What are the immediate nursing priorities in providing care to this patient? How will your priorities and approach differ if the patient were older adult or from a different culture than your own?

51 Management of Patients with Female Reproductive Disorders

LEARNING OUTCOMES

On completion of this chapter, the learner will be able to:

1. Compare the various types of vaginal infections and the signs, symptoms, and treatments of each.
2. Discuss the signs and symptoms, management, and nursing care of patients with inflammatory processes, structural disorders, and benign and malignant conditions of the female reproductive tract.
3. Use the nursing process as a framework for care of the patient with a vulvovaginal infection or with genital herpes, or who is undergoing a hysterectomy.
4. Describe the nursing management of the patient undergoing radiation therapy for cancer of the female reproductive tract.

NURSING CONCEPTS

Comfort
Family
Infection
Reproduction
Sexuality

GLOSSARY

abscess: a collection of purulent material

Bartholin cyst: a cyst in a paired Bartholin or vestibular gland in the vulva

brachytherapy: delivery of radiation therapy through internal implants to a localized area of tissue

candidiasis: infection caused by *Candida* species or yeast; also referred to as monilial vaginitis or yeast infection

condylomata: warty growths indicative of the human papillomavirus

cryotherapy: destruction of tissue by freezing (e.g., with liquid nitrogen)

cystocele: displacement of the bladder downward into the vagina

douche: rinsing the vaginal canal with fluid

dysplasia: term related to abnormal cell changes; may be found on Pap smear and cervical biopsy reports

endocervicitis: inflammation of the mucosa and the glands of the cervix

endometriosis: endometrial tissue in abnormal locations; causes pain with menstruation, scarring, and possible infertility

enterocele: a protrusion of the intestinal wall into the vagina

fibroid tumor: usually benign tumor arising from the muscle tissue of the uterus

fistula: abnormal opening between two organs or sites (e.g., vesicovaginal, between bladder and vagina; rectovaginal, between rectum and vagina)

hyphae: long, branching filamentous structures characteristic of fungi such as *Candida* seen under microscopic examination

hysterectomy: surgical removal of the uterus

loop electrocautery excision procedure (LEEP): procedure in which a laser is used to remove a thin layer of cervical tissue after abnormal biopsy findings

myomectomy: surgical removal of uterine fibroids

oophorectomy: surgical removal of an ovary

pelvic exenteration: major surgical procedure in which the pelvic organs are removed

pelvic inflammatory disease (PID): inflammatory condition of the pelvic cavity, usually from a sexually transmitted infection

polycystic ovary syndrome (PCOS): complex endocrine condition resulting in chronic anovulation, androgen excess, and multiple ovarian cysts

rectocele: bulging of the rectum into the vagina

salpingitis: inflammation of the fallopian tube

salpingo-oophorectomy: removal of the ovary and its fallopian tube (removal of the fallopian tube alone is a salpingectomy)

vaginitis: inflammation of the vagina, usually secondary to infection

vulvar dystrophy: thickening or lesions of the vulva; usually causes itching and may require biopsy to exclude malignancy

vulvectomy: removal of the tissue of the vulva

vulvitis: inflammation of the vulva, usually secondary to infection or irritation

vulvodynia: painful condition that affects the vulva

Disorders of the female reproductive system can be minor or serious but are often anxiety producing and distressing. Some disorders are self-limited and cause only minor inconvenience; others are life-threatening and require immediate attention and long-term therapy. Many disorders are managed by the patient at home, whereas others require hospitalization and surgical intervention. Nurses not only need to be knowledgeable about these disorders but need to be sensitive to patient concerns and possible discomfort in discussing and managing these disorders.

VULVOVAGINAL INFECTIONS

Vulvovaginal infections are common, and nurses have an important role in providing information that may prevent their occurrence. To help prevent these infections, women need to understand their anatomy and normal vulvovaginal health.

The Bartholin glands on either side of the entrance to the vagina can become blocked (cyst formation) or infected (abscess formation) (Ball, Dains, Flynn, et al., 2019). Treatment is different for both cyst and abscess formation, but pain is common with both. Pain can interfere with sitting and walking.

The vagina is protected against infection by its normally low pH (3.5 to 4.5), which is maintained in part by the actions of *Lactobacillus acidophilus,* the dominant bacteria in a healthy vaginal ecosystem. These bacteria suppress the growth of anaerobes and produce lactic acid, which maintains normal pH. They also produce hydrogen peroxide, which is toxic to anaerobes (Paavonen & Brunham, 2018). The risk of infection increases if a woman's resistance is reduced by stress or illness, if the pH is altered, or if a pathogen is introduced (see Chart 51-1). Continued research into causes and treatments is needed, along with better ways to encourage growth of lactobacilli.

Chart 51-1 RISK FACTORS

Vulvovaginal Infections

- Allergies
- Diabetes
- Frequent douching
- HIV infection
- Long-term or repeated use of broad-spectrum antibiotics
- Low estrogen levels
- Oral–genital contact (yeast can inhabit the mouth and intestinal tract)
- Perimenopause/Menopause
- Poor personal hygiene
- Pregnancy
- Premenarche
- Sex with infected partner
- Synthetic clothing
- Tight undergarments
- Use of oral contraceptives

HIV, human immune deficiency virus.

Adapted from Singh, J., Kalia, N., & Kaur, M. (2018). Recurrent vulvovaginal infections: Etiology, diagnosis, treatment and management. In P. Sing (Ed.). *Infectious diseases and your health*. Singapore: Springer; Zapata, M. R. (2017). Diagnosis and treatment of vulvovaginitis. In D. Shoupe (Ed.). *Handbook of gynecology*. Switzerland: Springer.

The epithelium of the vagina is highly responsive to estrogen, which induces glycogen formation. The subsequent breakdown of glycogen into lactic acid assists in producing a low vaginal pH. When estrogen decreases during lactation and menopause, glycogen also decreases. With reduced glycogen formation, infections may occur. In addition, as estrogen production ceases during the peri- and postmenopausal periods, the vagina and labia may atrophy (thin), making the vaginal area more susceptible to infection. When patients are treated with antibiotic agents, the normal vaginal flora is reduced. This results in altered pH and growth of fungal organisms. Other factors that may initiate or predispose to infections include contact with an infected partner and wearing tight, nonabsorbent, and heat- and moisture-retaining clothing.

Vaginitis (inflammation of the vagina) is a group of conditions that cause vulvovaginal symptoms such as itching, irritation, burning, and abnormal discharge. Bacterial vaginitis is the most common cause, followed by trichomoniasis and vulvovaginal candidiasis (Paladine & Desai, 2018) (see Table 51-1). Other types include desquamative vaginitis, atrophic vaginitis, various vulvar dermatologic conditions, and vulvodynia. Normal vaginal discharge, which may occur in slight amounts during ovulation or just before

the onset of menstruation, is clear to white, odorless, and viscous. It becomes more profuse when vaginitis occurs. Urethritis may accompany vaginitis because of the proximity of the urethra to the vagina. Discharge that occurs with vaginitis may produce itching, odor, redness, burning, or edema, which may be aggravated by voiding and defecation. After the causative organism has been identified, appropriate treatment (discussed later) is prescribed. This may include an oral medication or a local medication that is inserted into the vagina using an applicator.

Candidiasis

Vulvovaginal **candidiasis** is a fungal or yeast infection caused by strains of *Candida* (see Table 51-1). It is the second most common type of vaginal infection and accounts for an estimated 1.4 million outpatient visits annually in the United States (Centers for Disease Control and Prevention [CDC], 2019a). An estimated 75% of women will experience at least one yeast infection, and 40% to 45% will experience two or more in their lifetime (CDC, 2019a). *Candida albicans* accounts for approximately 90% of the cases, but other strains, such as *Candida glabrata,* may also be implicated (Casanova, Chuang, Goepfert, et al., 2019). Many women with a healthy vaginal ecosystem harbor *Candida* but are asymptomatic. Certain conditions favor the change from an asymptomatic state to colonization with symptoms. For example, the use of antibiotic agents decreases bacteria, thereby altering the natural protective organisms usually present in the vagina. Although infections can occur at any time, they occur more commonly in pregnancy or with a systemic condition such as diabetes or human immune deficiency virus (HIV) infection, or when patients are taking medications such as corticosteroids or oral contraceptive agents (Casanova et al., 2019).

Clinical Manifestations

Clinical manifestations include a vaginal discharge that causes pruritus (itching) and subsequent irritation. The discharge may be watery or thick but usually has a white, cottage cheese–like appearance. Symptoms are usually more severe just before menstruation and may be less responsive to treatment during pregnancy. Diagnosis is made by microscopic identification of spores and **hyphae** (long, branching filamentous structures) on a glass slide prepared from a discharge specimen mixed with potassium hydroxide. With candidiasis, the pH of the discharge is 4 to 5 (Casanova et al., 2019). Manifestations may be uncomplicated, occurring sporadically in women who are healthy, or recurrent and complicated in women who have diabetes, are pregnant, have a compromised immune system, or have obesity.

TABLE 51-1 Vaginal Infections and Vaginitis

Infection	Cause	Clinical Manifestations	Management Strategies
Candidiasis	*Candida albicans, C. glabrata,* or *C. tropicalis*	Inflammation of vaginal epithelium, producing itching, reddish irritation White, cheeselike discharge clinging to epithelium	Eradicate the fungus by administering an antifungal agent. Some more frequently used vaginal creams and suppositories are miconazole and clotrimazole. Review other causative factors (e.g., antibiotic therapy, nylon underwear, tight clothing, pregnancy, oral contraceptive agents). Assess for diabetes and HIV infection in patients with recurrent monilia.
Gardnerella-associated bacterial vaginosis	*Gardnerella vaginalis* and vaginal anaerobes	Usually no edema or erythema of vulva or vagina Gray-white to yellow-white discharge clinging to external vulva and vaginal walls	Administer metronidazole, with instructions about avoiding alcohol while taking this medication. If infection is recurrent, may treat partner.
Trichomonas vaginalis vaginitis	*Trichomonas vaginalis*	Inflammation of vaginal epithelium, producing burning and itching Frothy yellow-white or yellow-green vaginal discharge	Relieve inflammation, restore acidity, and reestablish normal bacterial flora; provide oral metronidazole for patient and partner.
Bartholinitis (infection of the greater vestibular gland)	*Escherichia coli* *T. vaginalis* Staphylococcus Streptococcus Gonococcus	Erythema around vestibular gland Swelling and edema Abscessed vestibular gland	Drain the abscess; provide antibiotic therapy; excise gland of patients with chronic bartholinitis.
Cervicitis—acute and chronic	Chlamydia Gonococcus Streptococcus Many pathogenic	Profuse purulent discharge Backache Urinary frequency and urgency	Determine the cause—perform cytologic examination of cervical smear and appropriate cultures. Eradicate the gonococcal organism, if present: penicillin (as directed)

	bacteria		or spectinomycin or tetracycline, if patient is allergic to penicillin. Tetracycline, doxycycline to eradicate chlamydia. Eradicate other causes.
Atrophic vaginitis	Lack of estrogen; glycogen deficiency	Discharge and irritation from alkaline pH of vaginal secretions	Provide topical vaginal estrogen therapy; improve nutrition if necessary; relieve dryness through the use of moisturizing medications.

HIV, human immune deficiency virus.

Adapted from Paladine, H. L., & Desai, U. A. (2018). Vaginitis: Diagnosis and treatment. *American Family Physician*, *97*(5), 321–329.

Medical Management

The goal of management is to eliminate symptoms. Treatments include antifungal agents such as miconazole, nystatin, clotrimazole, and terconazole cream. These agents are inserted into the vagina with an applicator at bedtime. There are 1-, 3-, and 7-night treatment courses available (Paladine & Desai, 2018). Oral medication (fluconazole) is also available in a one-pill dose. Relief should be noted within 3 days.

Some vaginal creams are available without a prescription; however, patients are cautioned to use these creams only if they are certain that they have a yeast or monilial infection. Patients often use these remedies for problems other than yeast infections. If a woman is uncertain about the cause of her symptoms or if relief has not been obtained after using these creams, she should be instructed to seek health care promptly. Yeast infections can become recurrent or complicated. Women may have more than four infections in a year and severe symptoms due to preexisting conditions such as diabetes or immunosuppression. Cell-mediated immunity may be a factor. Women with recurrent yeast infections benefit from a comprehensive gynecologic assessment.

Bacterial Vaginosis

Bacterial vaginosis is caused by an overgrowth of anaerobic bacteria and *Gardnerella vaginalis* normally found in the vagina and an absence of lactobacilli (see Table 51-1). Risk factors include douching after menses, smoking, multiple sex partners, and other sexually transmitted infections (STIs) (also referred to as sexually transmitted diseases [STDs]). Bacterial vaginosis is not considered an STI but is associated with sexual activity, and

incidence is increased in female same-sex partners (Paavonen & Brunham, 2018).

Clinical Manifestations

Bacterial vaginosis can occur throughout the menstrual cycle and does not produce local discomfort or pain. More than half of patients with bacterial vaginosis do not notice any symptoms. Discharge, if noticed, is heavier than normal and gray to yellowish white in color. It is characterized by a fishlike odor that is particularly noticeable after penile–vaginal intercourse or during menstruation as a result of an increase in vaginal pH. The pH of the discharge is usually greater than 4.7 because of the amines that result from enzymes from anaerobes. The fishlike odor can be detected readily by adding a drop of potassium hydroxide to a glass slide with a sample of vaginal discharge, which releases amines; this is referred to as a positive "whiff" test. Under the microscope, vaginal cells are coated with bacteria and are described as "clue cells." Lactobacilli, which serve as a natural host defense, are usually absent. Bacterial vaginosis is not usually considered a serious condition, although it can be associated with premature labor, premature rupture of membranes, endometritis, and pelvic infection (Casanova et al., 2019; Paavonen & Brunham, 2018).

Medical Management

Metronidazole, given orally twice a day for 1 week, is effective; a vaginal gel is also available. Clindamycin vaginal cream or ovules (oval suppositories) are also effective. Treatment of patients' partners does not seem to be effective, but the use of condoms may be helpful. Bacterial vaginosis is highly persistent and tends to recur after treatment; therefore, women are encouraged to seek follow-up care if symptoms recur (CDC, 2015; Paladine & Desai, 2018).

Trichomoniasis

Trichomonas vaginalis is a flagellated protozoan that causes a common STI often called *trich.* About 3.7 million cases occur each year in the United States; however, only about 30% of those will exhibit symptoms of the disease (CDC, 2017a). Trichomoniasis may be transmitted by an asymptomatic carrier who harbors the organism in the urogenital tract (see Table 51-1). It may increase the risk of contracting HIV from an infected partner and may play a role in development of cervical neoplasia, postoperative infections, adverse pregnancy outcomes, pelvic inflammatory disease (PID), and infertility.

Clinical Manifestations

Clinical manifestations include a vaginal discharge that is thin (sometimes frothy), yellow to yellow-green, malodorous, and very irritating. An accompanying vulvitis may result, with vulvovaginal burning and itching. Diagnosis is made most often by microscopic detection of the motile causative organisms or less frequently by culture. Inspection with a speculum often reveals vaginal and cervical erythema (redness) with multiple small petechiae ("strawberry spots") (Casanova et al., 2019). Testing of a trichomonal discharge demonstrates a pH greater than 4.5.

Medical Management

The most effective treatment for trichomoniasis is metronidazole or tinidazole. All partners receive a one-time loading dose or a smaller dose twice a day for 7 days (CDC, 2015). The one-time dose is more convenient; consequently, adherence tends to be greater. The week-long treatment has occasionally been noted to be more effective. Some patients complain of an unpleasant but transient metallic taste when taking metronidazole. Nausea and vomiting, as well as a hot, flushed feeling can occur when this medication is taken with an alcoholic beverage. Patients are strongly advised to abstain from alcohol during treatment and for 24 hours after taking metronidazole or 72 hours after completion of a course of tinidazole (CDC, 2015). About 1 in 5 people will be reinfected with trichomoniasis within 3 months of treatment. All sexual partners should be treated, and patients are encouraged to abstain from sexual activity for 7 to 10 days after treatment (CDC, 2017a).

Gerontologic Considerations

After menopause, the vaginal mucosa becomes thinner and may atrophy. While vulvovaginal atrophy can occur at any time in a woman's life, it is most common in women who are postmenopausal, with an incidence of nearly 50% (Naumova & Castelo-Branco, 2018). This condition can be complicated by infection from phylogenic bacteria, resulting in atrophic vaginitis (see Table 51-1). Leukorrhea (vaginal discharge) may cause itching and burning. Management is similar to bacterial vaginosis. Estrogenic hormones, either taken orally or inserted into the vagina in a cream form, can also be effective in restoring the epithelium.

Desquamative inflammatory vaginitis is an uncommon but severe purulent form of vaginal infection that occurs mostly in Caucasian women who are perimenopausal. It results in vaginal inflammation, burning, discharge, and

dyspareunia (pain with penile–vaginal intercourse). Topical anti-inflammatory and antibiotic treatment is usually effective (Mills, 2017).

NURSING PROCESS

The Patient with a Vulvovaginal Infection

Assessment

The woman with vulvovaginal symptoms should be examined as soon as possible after the onset of symptoms. She should be instructed not to **douche** (rinse the vaginal canal), because doing so removes the discharge needed to make the diagnosis. The area is observed for erythema, edema, excoriation, and discharge. Each of the infection-producing organisms produces its own characteristic discharge and effect (see Table 51-1). The patient is asked to describe any discharge and other symptoms, such as odor, itching, or burning. Dysuria often occurs as a result of local irritation of the urinary meatus. A urinary tract infection may need to be ruled out by obtaining a urine specimen for culture and sensitivity testing.

The patient is asked about the occurrence of factors that may contribute to vulvovaginal infection:

- Physical and chemical factors, such as constant moisture from tight or synthetic clothing, perfumes and powders, soaps, bubble bath, poor hygiene, and the use of feminine hygiene products
- Psychogenic factors (e.g., stress, fear of STIs, intimate partner violence [IPV])
- Medical conditions or endocrine factors, such as a predisposition to *Monilia* in a patient who has diabetes
- The use of medications such as antibiotics, which may alter the vaginal flora and allow an overgrowth of monilial organisms
- New sex partner, multiple sex partners, previous vaginal infection

The patient is also asked about factors that could contribute to infection, including hygiene practices (douching) and the use or nonuse of condoms.

The nurse may prepare a vaginal smear (wet mount) to assist in diagnosing the infection. A common method for preparing the smear is to collect vaginal secretions with an applicator and place the secretions on two separate glass slides. A drop of saline solution is added to one slide and a drop of 10% potassium hydroxide is added to another slide for examination under a microscope. If bacterial vaginosis is present, the slide with normal saline solution added shows epithelial cells dotted with bacteria (clue cells). If *Trichomonas* species is present, small motile cells are seen. In the presence of yeast, the potassium hydroxide slide reveals branching hyphae (Casanova et al., 2019). Discharge associated with bacterial vaginosis produces a strong odor when mixed with potassium hydroxide. Testing the pH of the discharge with Nitrazine paper assists in proper diagnosis (Casanova et al., 2019).

Diagnosis

Nursing Diagnoses

Based on the assessment data, major nursing diagnoses may include the following:

- Discomfort associated with distressing symptoms and feelings of discomfort from the infectious process
- Anxiety associated with worry about symptoms
- Risk for infection or spread of infection
- Lack of knowledge about proper hygiene and preventive measures

Planning and Goals

Major goals may include increased comfort, reduction of anxiety related to symptoms, prevention of reinfection or infection of sexual partner, and acquisition of knowledge about methods for preventing vulvovaginal infections and managing self-care.

Nursing Interventions

Relieving Impaired Comfort

Treatment with the appropriate medication usually relieves discomfort. Sitz baths may be occasionally recommended and may provide temporary relief of symptoms.

Reducing Anxiety

Vulvovaginal infections are upsetting and require treatment. The patient who experiences such an infection may be very anxious about the significance of the symptoms and possible causes. Explaining the cause of symptoms may reduce anxiety related to fear of a more serious illness. Discussing ways to help prevent vulvovaginal infections may help patients adopt specific strategies to decrease infection and the related symptoms.

Preventing Reinfection or Spread of Infection

Patient education should include the fact that vulvovaginal candidiasis is not an STI and incidence can be decreased by completing treatment, avoiding unnecessary antibiotic agents, wearing cotton underwear, and not douching.

The patient needs to be informed about the importance of adequate treatment for herself and her partner, if indicated. Other strategies to prevent persistence or spread of infection include abstaining from penile–vaginal intercourse when infected, treatment for sexual partners, and minimizing irritation of the affected area. When medications such as antibiotic agents are prescribed for any infection, the nurse instructs the patient about the usual precautions related to using these agents. If vaginal itching occurs several days after use, the patient can be reassured that this is usually not an allergic reaction but may be a yeast or monilial infection

resulting from altered vaginal bacteria. Treatment for monilial infection is prescribed if indicated.

Another goal of treatment is to reduce tissue irritation caused by scratching or wearing tight clothing. The area needs to be kept clean by daily bathing and adequate hygiene after voiding and defecation. The use of a hair dryer on a cool setting will dry the area, and application of topical corticosteroids may decrease irritation.

When educating the patient about medications such as suppositories and devices such as applicators to dispense cream or ointment, the nurse may demonstrate the procedure by using a plastic model of the pelvis and vagina. The nurse should also stress the importance of hand hygiene before and after each administration of medication. To prevent the medication from escaping from the vagina, the patient should recline for 30 minutes after it is inserted, if possible. The patient is informed that seepage of medication may occur, and the use of a perineal pad may be helpful.

PROMOTING HOME, COMMUNITY-BASED, AND TRANSITIONAL CARE

Educating Patients About Self-Care. Vulvovaginal conditions are treated on an outpatient basis unless a patient has other medical problems. Patient education, tact, and reassurance are important aspects of nursing care. Women may express embarrassment, guilt, or anger and may be concerned that the infection could be serious or that it may have been acquired from a sex partner. In some instances, treatment plans include the partner.

The nurse assesses the patient's learning needs about the immediate problem. The patient needs to know the characteristics of normal as opposed to abnormal discharge. Questions often arise about douching. Normally, douching and the use of feminine hygiene sprays are unnecessary because daily baths or showers and proper hygiene after voiding and defecating keep the perineal area clean. Douching tends to eliminate normal flora, reducing the body's ability to ward off infection. In addition, repeated douching may result in vaginal epithelial breakdown and chemical irritation and has been associated with other pelvic disorders. In the case of recurrent yeast infections, the perineum should be kept as dry as possible. Loose-fitting cotton instead of tight-fitting synthetic, nonabsorbent, heat-retaining underwear is recommended.

Vulvar self-examination is a good health practice for all women. Becoming familiar with one's own anatomy and reporting anything that seems new or different may result in early detection and treatment of any new disorders. Nurses can also play a role in educating women about the risks of unprotected penile–vaginal intercourse, particularly with partners who have had sex with others.

Evaluation

Expected patient outcomes may include:

1. Experiences increased comfort
   a. Cleans the perineum as instructed
   b. Reports that itching is relieved
   c. Maintains urine output within normal limits and without dysuria
2. Experiences relief of anxiety
3. Remains free from infection
   a. Has no signs of inflammation, pruritus, odor, or dysuria
   b. Notes that vaginal discharge appears normal (thin, clear, not frothy)
4. Participates in self-care
   a. Takes medication as prescribed
   b. Wears absorbent underwear
   c. Avoids unprotected penile–vaginal intercourse
   d. Douches only as prescribed
   e. Performs vulvar self-examination regularly and reports any new findings to primary provider

Human Papillomavirus

Human papillomavirus (HPV) is the most common STI in the United States, affecting 79 million Americans and about 14 million newly acquired infections each year. Most adults who are sexually active will be infected with at least one type of HPV during their lifetime (CDC, 2019b). Most infections are self-limiting and without symptoms, and others can cause cervical and anogenital cancers. Infections can be latent (asymptomatic and detected only by deoxyribonucleic acid [DNA] hybridization tests for HPV), subclinical (visualized only after application of acetic acid followed by inspection under magnification), or clinical (visible condylomata acuminata).

Pathophysiology

HPV can be found in lesions of the skin, cervix, vagina, anus, penis, and oral cavity. Of the more than 100 genotypes of HPV that exist, about 40 genotypes affect the anogenital tract (Casanova et al., 2019). Some are low risk in that they are unlikely to cause cancerous changes. These include types 6, 11, 42, 43, 44, 54, 61, 70, and 72. The most common strains of HPV, 6 and 11, usually cause **condylomata** (warty growths) that can appear on the vulva, vagina, cervix, and anus. These are often visible or may be palpable by patients. Condylomata are rarely premalignant but are an outward manifestation of the virus (Casanova et al., 2019). High-risk oncogenic types, including 16, 18, 31,

33, 45, and 52 affect the cervix, causing abnormal cell changes or **dysplasia** (found on a Papanicolaou [Pap] smear). HPV types 16 and 18 account for 66% of cervical cancer cases, while types 31, 33, 45, and 52 account for another 15% (American College of Obstetricians and Gynecologists [ACOG], 2017a). The incidence of HPV in young women who are sexually active is high. The infection often disappears as the result of an effective immune system response. It is thought that two proteins produced by high-risk types of HPV interfere with tumor suppression by normal cells. Risk factors include being young, being sexually active, having multiple sex partners, and having sex with a partner who has or has had multiple partners. It can be transmitted by other means, however, as it has been found in young girls who have not been sexually active.

Medical Management

Options for the treatment of external genital warts by a primary provider include topical application of trichloroacetic acid, podophyllin, cryotherapy, as well as surgical removal. Topical agents that can be applied by patients to external lesions include podofilox and imiquimod. Because the safety of podophyllin, imiquimod, and podofilox during pregnancy has not been determined, these agents should not be used during pregnancy. Electrocautery and laser therapy are alternative therapies that may be indicated for patients with a large number or area of genital warts.

Treatment usually eradicates perineal warts or condylomata. However, they may resolve spontaneously without treatment and may also recur even with treatment. Genital warts are more resistant to treatment in patients with diabetes, those who are pregnant, who smoke, or are immunocompromised (Casanova et al., 2019).

If the treatment includes application of a topical agent by the patient, she needs to be carefully instructed in the use of the agent prescribed and must be able to identify the warts and be able to apply the medication to them. The patient is instructed to anticipate mild pain or local irritation with the use of these agents.

Women with HPV should have annual Pap smears because of the potential of HPV to cause dysplasia.

For the procedural guidelines for obtaining an optimal Pap smear, go to thepoint.lww.com/Brunner15e.

Much remains unknown about subclinical and latent HPV disease. Women are often exposed to HPV by partners who are unknowing carriers. The use of condoms can reduce the likelihood of transmission, but transmission can also occur during skin-to-skin contact in areas not covered by condoms.

In many cases, patients are angry about having warts or HPV and do not know who infected them because the incubation period can be long, and partners may have no symptoms. Acknowledging the emotional distress that occurs when an STI is diagnosed and providing support and facts are important nursing actions.

Prevention

The best strategy is prevention of HPV. The Advisory Committee on Immunization Practices (ACIP) of the CDC recommends routine vaccination of boys and girls 11 to 12 years of age, before they become sexually active. Vaccination is also recommended for females aged 13 through 26 years and males aged 13 through 21 years for those who were not previously vaccinated (Meites, Szilagyi, Chesson, et al., 2019). The ACIP recommends the 9-valent human papillomavirus (9vHPV) vaccine for routine vaccinations. In addition to the four noninfectious virus–like particles (VLPs) HPV 6, 11, 16, and 18 found in 4vHPV, 9vHPV also contains HPV 31, 33, 45, 52, and 58 VLPs (Meites et al., 2019). The vaccination is given in two intramuscular doses, with the initial dose followed by a second dose 6 to 12 months after the first dose. Completion of both doses of the vaccine is important for immunity to develop. If the doses are less than 5 months apart a third dose is required. The vaccination is contraindicated for use in women who are pregnant (National Cancer Institute [NCI], 2018).

Although this vaccine is considered an important medical breakthrough with the potential to decrease the impact of HPV-related disease in men and women, it does not replace other strategies important in prevention of HPV. Women still need cervical cancer screening (CDC, 2019b).

Herpes Virus Type 2 Infection (Herpes Genitalis, Herpes Simplex Virus)

Herpes simplex virus 2 (HSV-2) is a recurrent, lifelong viral infection that causes herpetic lesions (blisters) on the external genitalia and occasionally the vagina and cervix. It is an STI but possibly may also be transmitted asexually from wet surfaces or by self-transmission (i.e., touching a cold sore and then touching the genital area). The initial infection is usually very painful, and blisters may take 2 to 4 weeks to heal, but it can also be asymptomatic. Over 87% of infected individuals are unaware of their infection; most HSV

transmission occurs from asymptomatic viral shedding (CDC, 2017b). Recurrences are less painful, self-limited, and usually produce less severe symptoms. Some patients have few or no recurrences, whereas others have frequent bouts (CDC, 2017b). Recurrences can be associated with stress, sunburn, dental work, or inadequate rest or poor nutrition, or any situations that tax the immune system.

There are more than 400 million people affected by HSV-2 worldwide (Cohen, 2017). The prevalence of other STIs has decreased slightly, possibly because of increased condom use, but herpes can be transmitted by contact with skin that is not covered by a condom. Transmission is possible even when a carrier does not have symptoms (subclinical shedding). Lesions increase vulnerability to HIV infection and other STIs.

Pathophysiology

Herpes simplex virus (HSV) is a double-stranded DNA virus that is differentiated into two types of HSV infection (Casanova et al., 2019). These include herpes simplex type 1 (HSV-1), usually associated with cold sores of the lips (herpes labialis) and gingivostomatitis as well as herpes simplex type 2 (HSV-2), usually associated with genital herpes.

Close human contact by the mouth, oropharynx, mucosal surface, vagina, or cervix appears necessary to acquire the infection. Other susceptible sites are skin lacerations and conjunctivae. Usually, the virus is killed at room temperature by drying. When viral replication diminishes, the virus ascends the peripheral sensory nerves and remains inactive in the nerve ganglia. Another outbreak may occur when the host is subjected to stress. In women who are pregnant and have active herpes, infants delivered vaginally may become infected with the virus. There is a risk of fetal morbidity and mortality if this occurs; therefore, a cesarean delivery may be performed if the virus recurs near the time of delivery.

Clinical Manifestations

Itching and pain occur as the infected area becomes red and edematous. Infection may begin with macules and papules and progress to vesicles and ulcers. The vesicular state often appears as a blister, which later coalesces, ulcerates, and encrusts. In women, the labia are the usual primary site, although the cervix, vagina, and perianal skin may be affected. In men, the glans penis, foreskin, or penile shaft is typically affected. Influenzalike symptoms may occur 3 or 4 days after the lesions appear. Inguinal lymphadenopathy (enlarged lymph nodes in the groin), minor temperature elevation, malaise, headache, myalgia (aching muscles), and dysuria (pain on

urination) are often noted. Pain is evident during the first week and then decreases. The lesions last 2 to 12 days before crusting over (CDC, 2017b).

Rarely, complications may arise from extragenital spread, such as to the buttocks, upper thighs, or even the eyes, as a result of touching lesions and then touching other areas. Patients should be advised to wash their hands after contact with lesions. Other potential problems are aseptic meningitis, neonatal transmission, and severe emotional stress related to the diagnosis.

Medical Management

Currently, there is no cure for genital herpes infection, but treatment is aimed at relieving the symptoms. Management goals include preventing the spread of infection, making patients comfortable, decreasing potential health risks, and initiating a counseling and education program. Three oral antiviral agents—acyclovir, valacyclovir, and famciclovir—can suppress symptoms and shorten the course of the infection (King, 2017). These agents are effective at reducing the duration of lesions and preventing recurrences. Antispasmodic agents and a saline compress can provide additional relief of symptoms. Resistance and long-term side effects do not appear to be major problems. Recurrent episodes are often milder than the initial episode. Prophylactic vaccine and topical gel development for genital herpes continues to be investigated in clinical trials (King, 2017).

NURSING PROCESS

The Patient with a Genital Herpes Infection

Assessment

The health history and a physical and pelvic examination are important in establishing the nature of the infectious condition. In addition, patients are assessed for risk of STIs. The perineum is inspected for painful lesions. Inguinal nodes are assessed and are often enlarged and tender during an occurrence of genital herpes.

Diagnosis

NURSING DIAGNOSES

Based on the assessment data, major nursing diagnoses may include the following:

- Acute pain associated with the genital lesions
- Risk for infection or spread of infection
- Anxiety associated with worry about the diagnosis
- Lack of knowledge about the disease and its management

Planning and Goals

Major goals may include relief of pain and discomfort, control of infection and its spread, relief of anxiety, knowledge of and adherence to the treatment regimen and self-care, and knowledge about implications for the future.

Nursing Interventions

RELIEVING PAIN

The lesions should be kept clean, and proper hygiene practices are advocated. Sitz baths may ease discomfort. Additional strategies for relieving pain during a herpes outbreak can be found in Chart 51-2.

Chart 51-2  **HEALTH PROMOTION**

Strategies for the Patient with Genital Herpes

Herpes is transmitted mainly by direct contact. Sexual activity during a herpes outbreak not only increases the risk of transmission but also increases the likelihood of contracting HIV and other STIs. The patient therefore takes the following measures:

- Abstains from sexual activity during treatment for active disease (other options such as hand-holding and kissing are acceptable).
- Avoids exposure to the sun, which can cause recurrences (and skin cancer).
- Avoids self-infection by not touching lesions during an outbreak.
- Uses barrier methods when engaging in sexual activity to provide protection against viral transmission.
- Informs sexual partners of herpes diagnosis as transmission is possible even in the absence of active lesions.
- Informs obstetric care provider about the history of genital herpes. In cases of recurrence at time of delivery, cesarean section may be considered.
- Utilizes available support services (see Resources section).
- Keeps follow-up appointments with health care provider, and reports repeated recurrences (may not be as severe as the initial episode).
- Takes medication prescribed for outbreaks and avoids occlusive ointments, strong perfumed soaps, or bubble bath.
- Takes aspirin and other analgesic agents to control pain during outbreaks.
- Uses the appropriate hygiene practices including hand hygiene, perineal cleanliness, gentle washing of lesions with mild soap and running water and lightly drying lesions (i.e., lesions can become infected from germs on the hand, and the virus from the lesion can be transmitted from the hand to another area of the body or another person).
- Wears loose, comfortable clothing; eats a balanced diet; ingests adequate fluids gets adequate rest during outbreaks.

HIV, human immune deficiency virus; STIs, sexually transmitted infections.

The patient is encouraged to increase fluid intake, to be alert for possible bladder distention, and to contact her primary provider immediately if she cannot void because of discomfort. Painful voiding may occur if urine comes in contact with the herpes lesions. Discomfort with urination can be reduced by pouring warm water over the vulva during voiding. When oral antiviral agents are prescribed, the patient is instructed about when to take the medication and what side effects to note, such as rash and headache.

Preventing Infection and Its Spread

The risk of reinfection and spread of infection to others or to other structures of the body can be reduced by proper hand hygiene, the use of barrier methods with sexual contact, and adherence to prescribed medication regimens. Avoidance of contact when obvious lesions are present does not eliminate the risk because the virus can be shed in the absence of symptoms, and lesions may not be visible.

Relieving Anxiety

Concern about the presence of herpes infection, future occurrences of lesions, and the impact of the infection on future relationships and childbearing may cause considerable patient anxiety. Nurses serve as important sources of support by listening to patients' concerns and providing information and education. The patient may be angry with her partner if the partner is the probable source of the infection. The patient may need assistance in discussing the infection and its implications with her current sexual partners and in future sexual relationships. The nurse can provide the patient with contact details for support services to assist in coping with the diagnosis (see the Resources section).

Increasing Knowledge About the Disease and Its Treatment

Patient education is an essential part of nursing care of the patient with a genital herpes infection. This includes an adequate explanation about the infection and how it is transmitted, management and treatment strategies, strategies to minimize spread of infection, the importance of adherence to the treatment regimen, and self-care strategies. Because of the increased risk of HIV and other STIs in the presence of skin lesions, an important part of education involves informing the patient of strategies to protect herself from exposure to HIV and other STIs.

Promoting Home, Community-Based, and Transitional Care

Educating Patients About Self-Care. Health promotion strategies and self-care measures for the patient with genital herpes are described in Chart 51-2.

Evaluation

Expected patient outcomes may include:

1. Experiences a reduction in pain and discomfort
2. Keeps infection under control
    a. Demonstrates proper hygiene techniques
    b. Takes medication as prescribed
    c. Consumes adequate fluids
    d. Assesses own current lifestyle (diet, adequate fluid intake, safer sex practices, stress management)
3. Uses strategies to reduce anxiety
    a. Verbalizes issues and concerns related to genital herpes infection
    b. Discusses strategies to deal with issues and concerns with current and future sexual partners
    c. Utilizes available support services if indicated
4. Demonstrates knowledge about genital herpes and strategies to control and minimize recurrences
    a. Identifies methods of transmission of herpes infection and strategies to prevent transmission to others
    b. Discusses strategies to reduce recurrence of lesions
    c. Takes medications as prescribed
    d. Reports no recurrence of lesions

Endocervicitis and Cervicitis

Endocervicitis is an inflammation of the mucosa and the glands of the cervix that may occur when organisms gain access to the cervical glands after penile–vaginal intercourse and, less often, after procedures such as abortion, intrauterine manipulation, or vaginal delivery. If untreated, the infection may extend into the uterus, fallopian tubes, and pelvic cavity. Inflammation can irritate the cervical tissue, resulting in spotting or bleeding and mucopurulent cervicitis (inflammation of the cervix with exudate).

Chlamydia and Gonorrhea

Chlamydia and gonorrhea are the most common causes of endocervicitis, although *Mycoplasma* may also be involved. Chlamydia causes about 2.86 million infections every year in the United States; it is most commonly found in young people who are sexually active with more than one partner and is transmitted through sexual contact (CDC, 2016). Untreated chlamydia infections can spread to the fallopian tubes and uterus leading to serious complications including PID, an increased risk of ectopic pregnancy, and infertility (CDC, 2016). Chlamydial infections of the cervix often produce no

symptoms, but cervical discharge, dyspareunia, dysuria, and bleeding may occur. Other complications include conjunctivitis and perihepatitis (Fitz-Hugh–Curtis syndrome) (CDC, 2016). Gonorrhea is the second most commonly reported STI, with over a million new infections each year (CDC, 2019). The inflamed cervix that results from infection may leave a woman more vulnerable to HIV transmission from an infected partner. Gonorrhea is often asymptomatic and a major cause of PID, tubal infertility, ectopic pregnancy, and chronic pelvic pain (CDC, 2019). Diagnosis can be confirmed by urine culture or other methods such as using a swab to obtain a sample of cervical or penile discharge from the patient's partner (CDC, 2019).

Medical Management

The CDC recommends treating chlamydia with doxycycline for 1 week or with a single dose of azithromycin (CDC, 2016). Antimicrobial resistance to fluoroquinolones in the treatment of gonorrhea has left cephalosporins as the remaining recommended treatment (ACOG, 2018a; CDC, 2019). Dual therapy with azithromycin and ceftriaxone given simultaneously on the same day is the recommended first-line treatment for gonorrhea infection (ACOG, 2018a; CDC, 2019). Partners must also be treated. Women who are pregnant are cautioned not to take tetracycline because of potential adverse effects on the fetus. In these cases, erythromycin may be prescribed. Results are usually good if treatment begins early. Possible complications from delayed or no treatment are tubal disease, ectopic pregnancy, PID, and infertility.

Cultures for chlamydia and other STIs should be obtained from all patients who have been sexually assaulted when they first seek medical attention; patients are treated prophylactically. Cultures should then be repeated in 2 weeks. Annual screening for chlamydia is recommended for all young women who are sexually active and older women with new sex partners or multiple partners (CDC, 2016).

Nursing Management

All women who are sexually active may be at risk for chlamydia, gonorrhea, and other STIs, including HIV. Nurses can assist patients in assessing their own risk. Recognition of risk is a first step before changes in behavior occur. Patients should be discouraged from assuming that a partner is "safe" without open, honest discussion. Nonjudgmental attitudes, educational counseling, and role-playing may be helpful.

Because chlamydia, gonorrhea, and other STIs may have a serious effect on future health and fertility, and because many of these disorders can be prevented by the use of condoms and spermicides and careful choice of partners, nurses can play a major role in counseling patients about safer sex

practices. Exploring options with patients, addressing knowledge deficits, and correcting misinformation may reduce morbidity and mortality.

Patients should be advised to refer partners for evaluation and treatment. All women aged 25 and younger who are sexually active should be screened annually. Those older than 25 years should be screened if risk factors are present. Repeat testing should occur 3 months after treatment (CDC, 2016).

Promoting Home, Community-Based, and Transitional Care

Educating Patients About Self-Care

Nurses can educate women and help them improve communication skills and initiate discussions about sex with their partners. Communicating with partners about sex, risk, postponing penile–vaginal intercourse, and using safer sex behaviors, including the use of condoms, may be lifesaving. Some young women report having sex but not being comfortable enough to discuss sexual risk issues. Nurses can help women to advocate for their own health by discussing safety with partners prior to sexual activity.

Reinforcing the need for annual screening for chlamydia and other STIs is an important part of patient education. Instructions also include the need for the patient to abstain from penile–vaginal intercourse until all her sex partners are treated (CDC, 2016).

Pelvic Inflammatory Disease

Pelvic inflammatory disease (PID) is an inflammatory condition of the pelvic cavity that may begin with cervicitis and involve the uterus (endometritis), fallopian tubes (salpingitis), ovaries (oophoritis), pelvic peritoneum, or pelvic vascular system. Infection, which may be acute, subacute, recurrent, or chronic and localized or widespread, is usually caused by bacteria but may be attributed to a virus, fungus, or parasite. Gonorrheal and chlamydial organisms are common causes, but most cases of PID are polymicrobial. While incidence has been declining over the past decades, data from a recent survey indicates the rate of PID in sexually experienced women of reproductive age (18 to 44 years of age) is 4.4% or 2.5 million women (CDC, 2017c; Curry, Williams, & Penny, 2019).

Short- and long-term consequences can occur. The fallopian tubes become narrow and scarred, which increases the risk of ectopic pregnancy (fertilized eggs trapped in the tube), infertility, recurrent pelvic pain, tubo-ovarian **abscess** (a collection of purulent material), and recurrent disease (Curry et al., 2019).

Pathophysiology

The exact pathogenesis of PID has not been determined, but it is presumed that organisms usually enter the body through the vagina, pass through the cervical canal, colonize the endocervix, and move upward into the uterus. Under various conditions, the organisms may proceed to one or both fallopian tubes and ovaries and into the pelvis. In bacterial infections that occur after childbirth or abortion, pathogens are disseminated directly through the tissues that support the uterus by way of the lymphatics and blood vessels (see Fig. 51-1A). In pregnancy, the increased blood supply required by the placenta provides a wider pathway for infection. These postpartum and postabortion infections tend to be unilateral. Infections can cause perihepatic inflammation when the organism invades the peritoneum.

In gonorrheal infections, the gonococci pass through the cervical canal and into the uterus, where the environment, especially during menstruation, allows them to multiply rapidly and spread to the fallopian tubes and into the pelvis (see Fig. 51-1B). The infection is usually bilateral.

In rare instances, organisms (e.g., tuberculosis) gain access to the reproductive organs by way of the bloodstream from the lungs (see Fig. 51-1C). One of the most common causes of **salpingitis** (inflammation of the fallopian tube) is chlamydia, possibly accompanied by gonorrhea.

Pelvic infection is most often sexually transmitted but can also occur with invasive procedures such as endometrial biopsy, abortion, hysteroscopy, or insertion of an intrauterine device. Bacterial vaginosis (a vaginal infection) may predispose women to pelvic infection. Risk factors include early age at first sexual experience multiple sexual partners, frequent penile–vaginal intercourse, penile–vaginal intercourse without condoms, sex with a partner with an STI, and a history of STIs or previous pelvic infection.

Clinical Manifestations

Symptoms of pelvic infection usually begin with vaginal discharge, dyspareunia, dysuria, pelvic or lower abdominal pain, tenderness that occurs after menses, and postcoital bleeding. Other symptoms include fever, general malaise, anorexia, nausea, headache, and possibly vomiting (Norris, 2019). On pelvic examination, intense tenderness may be noted on palpation of the uterus or movement of the cervix (cervical motion tenderness). Symptoms may be acute and severe or low grade and subtle (CDC, 2017c; Curry et al., 2019).

Complications

Pelvic or generalized peritonitis, abscesses, strictures, and fallopian tube obstruction may develop. Obstruction may cause an ectopic pregnancy in the

future if a fertilized egg cannot pass a tubal stricture, or scar tissue may occlude the tubes, resulting in sterility. Adhesions are common and often result in chronic pelvic pain; they eventually may require removal of the uterus, fallopian tubes, and ovaries.

Medical Management

Broad-spectrum antibiotic therapy is prescribed, usually a combination of ceftriaxone, doxycycline, and metronidazole. Women are most often treated as outpatients and monitored carefully. Indications for hospitalization include surgical emergencies, pregnancy, no clinical response to outpatient oral antimicrobial therapy, inability to follow or tolerate an outpatient oral regimen, severe illness (i.e., nausea, vomiting, or high fever), and tubo-ovarian abscess (Curry et al., 2019; Norris, 2019). Treatment of sexual partners is necessary to prevent reinfection.

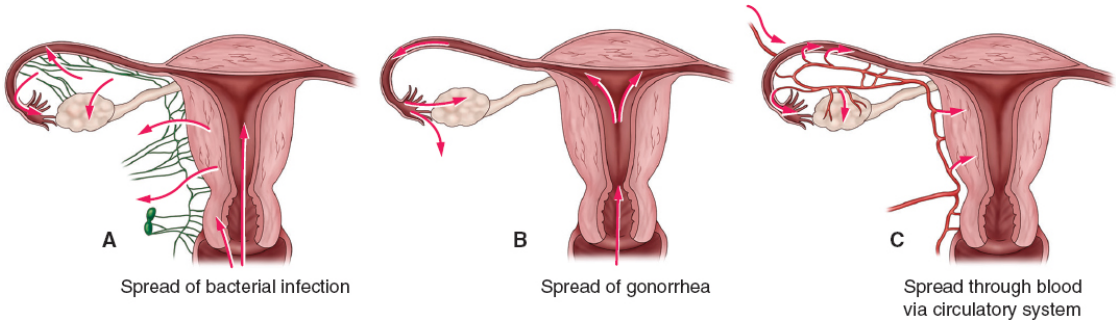

Figure 51-1 • Pathway by which microorganisms spread in pelvic infections. **A.** Bacterial infection spreads up the vagina into the uterus and through the lymphatics. **B.** Gonorrhea spreads up the vagina into the uterus and then to the tubes and ovaries. **C.** Bacterial infection can reach the reproductive organs through the bloodstream (hematogenous spread).

Chart 51-3 HOME CARE CHECKLIST

The Patient with Pelvic Inflammatory Disease

At the completion of education, the patient and/or caregiver will be able to:

- State the impact of pelvic inflammatory disease on physiologic functioning, ADLs, IADLs, roles, relationships, and spirituality.
- Identify the name, dose, side effects, frequency, and schedule for all medications.
  - State the importance of completing the course of antibiotic therapy.
- Understand interventions that may prevent reoccurrence:
  - Describe proper perineal care procedures (wiping from front to back after defecation or urination).
  - Take full course of antibiotic agents, if prescribed, after insertion of intrauterine devices.
  - Recognize that sexual partners may need treatment.
- Discuss the importance of following health practices (e.g., proper nutrition, exercise, weight control), and safer sex practices (e.g., avoiding multiple sexual partners, consistent use of condoms before penile–vaginal intercourse or any penile–vaginal contact if there is any chance of transmitting infection).
- State symptoms which require evaluation by a health care provider:
  - Pelvic pain or abnormal discharge, particularly after sexual exposure, childbirth, or pelvic surgery.
  - Unusual vaginal discharge or odor.
  - Pain, abnormal bleeding, delayed menses, faintness, dizziness, and shoulder pain (symptoms may indicate ectopic pregnancy).
- Relate how to reach primary provider with questions or complications.
- State time and date of follow-up medical appointments, therapy, and testing.
  - State that a gynecologic examination should be performed at least once a year.
- Identify sources of support (e.g., friends, relatives, faith community).
- Identify the contact details for support services for patients and their caregivers/families.
- Identify the need for health promotion, disease prevention, and screening activities.

ADLs, activities of daily living; IADLs, instrumental activities of daily living.

Nursing Management

The nurse assesses for both the physical and emotional effects of PID. The patient may feel well one day and experience vague symptoms and discomfort

the next. She may also suffer from constipation and menstrual difficulties.

If the patient is hospitalized, the nurse prepares the patient for further diagnostic evaluation and surgical intervention as prescribed. Accurate recording of vital signs, intake and output, and the characteristics and amount of vaginal discharge is necessary as a guide to therapy.

The nurse administers analgesic agents as prescribed for pain relief. Adequate rest and a healthy diet are encouraged. In addition, the nurse minimizes the transmission of infection by adhering to appropriate infection control practices and performing meticulous hand hygiene.

Promoting Home, Community-Based, and Transitional Care

Educating Patients About Self-Care

The patient must be informed of the need for precautions and must be encouraged to take part in procedures to prevent infecting others and protect herself from reinfection. The use of condoms is essential to prevent infection and sequelae. If reinfection occurs or if the infection spreads, symptoms may include abdominal pain, nausea and vomiting, fever, malaise, malodorous purulent vaginal discharge, and leukocytosis. Patient education consists of explaining how pelvic infections occur, how they can be controlled and avoided, and the associated signs and symptoms. Guidelines and instructions provided to the patient are summarized in Chart 51-3.

All patients who have had PID need to be informed of the signs and symptoms of ectopic pregnancy (pain, abnormal bleeding, delayed menses, faintness, dizziness, and shoulder pain), because they are prone to this complication. See Chapter 50 for a discussion of ectopic pregnancy.

Human Immune Deficiency Virus Infection and Acquired Immune Deficiency Syndrome

Any discussion of vulvovaginal infections and STIs must include the topic of HIV and acquired immune deficiency syndrome (AIDS). Although the incidence of HIV diagnosis among women has declined in recent years, more than 7000 (19%) of all new HIV diagnoses are adolescent and adult women (CDC, 2019c). Because HIV infection may be detected during prenatal testing and screening for STIs, nurses and other women's health care clinicians may be the first professionals to provide care for a woman with HIV infection. Thus, clinicians need to be knowledgeable about this disorder and sensitive to women's issues and concerns.

After informed consent is obtained, women who are at risk for HIV are offered testing by a nurse or counselor. Because patients may be reluctant to

discuss risk-taking behavior, routine screening should be offered to all women between the ages of 13 and 64 years in all health care settings (CDC, 2019d). Early detection permits early treatment to delay progression of the disease. The nurse needs to remember that many women do not see themselves as at risk for acquiring HIV infection. See Chapter 32 for further discussion of HIV infection and AIDS.

STRUCTURAL DISORDERS

Fistulas of the Vagina

A **fistula** is an abnormal opening between two internal hollow organs or between an internal hollow organ and the exterior of the body. The name of the fistula indicates the two areas that are connected abnormally—for example, a vesicovaginal fistula is an opening between the bladder and the vagina, and a rectovaginal fistula is an opening between the rectum and the vagina (see Fig. 51-2). Fistulas may be congenital in origin but are most common in developing countries due to obstructed labor complications. In developed countries, they occur most often as a result of injury during pelvic surgery, vaginal delivery, radiation therapy, complications from surgical insertion of vaginal mesh, or disease processes such as carcinoma (El-Azab, Abolella, & Farouk, 2019).

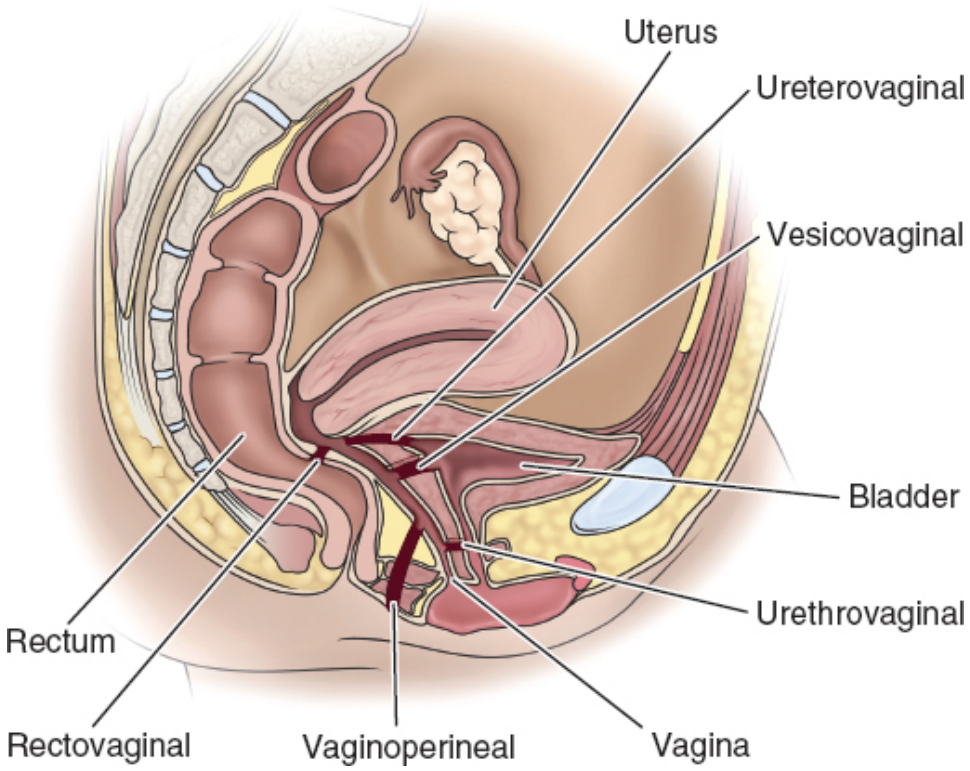

Figure 51-2 • Common sites for vaginal fistulas. *Vesicovaginal*—bladder and vagina. *Urethrovaginal*—urethra and vagina. *Vaginoperineal*—vagina and perineal area. *Ureterovaginal*—ureter and vagina. *Rectovaginal*—rectum and vagina.

Clinical Manifestations

Symptoms depend on the specific defect. For example, in a patient with a vesicovaginal fistula, urine escapes continuously into the vagina. With a rectovaginal fistula, there is fecal incontinence, and flatus is discharged through the vagina. The combination of fecal discharge with leukorrhea results in malodor that is difficult to control.

Assessment and Diagnostic Findings

A history of the symptoms experienced by the patient is important to identify the structural alterations and to assess the impact of the symptoms on the patient's quality of life. Although there is no reported specificity for its use, methylene blue dye is commonly used to help delineate the course of the fistula (El-Azab et al., 2019). In a vesicovaginal fistula, the dye is instilled into the bladder along with placement of vaginal packing known as the "tampon test"; stained vaginal packing can be indicative of a fistula (El-Azab et al., 2019). Cystourethroscopy is useful in identifying fistula while cystoscopy or IV pyelography may then be used to determine the exact location.

Medical Management

The goal is to eliminate the fistula and to treat infection and excoriation. A fistula may heal without surgical intervention, but surgery is often required. If the primary provider determines that a fistula will heal without surgical intervention, care is planned to relieve discomfort, prevent infection, and improve the patient's self-concept and self-care abilities. Measures to promote healing include proper nutrition, cleansing douches and enemas, rest, and administration of prescribed intestinal antibiotic agents. A rectovaginal fistula heals faster when the patient eats a low-residue diet and when the affected tissue drains properly. Warm perineal irrigations promote healing.

Sometimes, a fistula does not heal and cannot be surgically repaired. In this situation, care must be planned and implemented on an individual basis. Cleanliness, frequent sitz baths, and deodorizing douches are required, as are perineal pads and protective undergarments. Meticulous skin care is necessary to prevent excoriation. Applying bland creams or lightly dusting with cornstarch may be soothing. In addition, attending to the patient's social and psychological needs is an essential aspect of care.

If the patient is to have a fistula repaired surgically, preoperative treatment of any existing vaginitis is important to ensure success. Usually, the vaginal approach is used to repair vesicovaginal and urethrovaginal fistulas; the abdominal approach is used to repair fistulas that are large or complex. Fistulas that are difficult to repair or very large may require surgical repair with a urinary or fecal diversion. Tissue transfer techniques (skin or tissue grafting) may be used (El-Azab et al., 2019).

Because fistulas usually are related to obstetric, surgical, or radiation trauma, occurrence in a patient without previous vaginal delivery or a history of surgery must be evaluated carefully. Crohn's disease and lymphogranuloma venereum are other possible causes.

Despite the best surgical intervention, fistulas may recur. After surgery, medical follow-up continues for at least 2 years to monitor for a possible recurrence.

Pelvic Organ Prolapse: Cystocele, Rectocele, Enterocele

Age and parity can put strain on the ligaments and structures that make up the female pelvis and pelvic floor. Childbirth can result in tears of the levator sling musculature, resulting in structural weakness. Hormone deficiency also may play a role. Some degree of prolapse (weakening of the vaginal walls allowing the pelvic organs to descend and protrude into the vaginal canal) may be found in older women. Risk factors include age, parity (particularly vaginal

delivery), menopause, previous pelvic surgery, and possibly a genetic predisposition (ACOG, 2017b; Casanova et al., 2019).

Cystocele is a downward displacement of the bladder toward the vaginal orifice (see Fig. 51-3) from damage to the anterior vaginal support structures. It usually results from injury and strain during childbirth. The condition usually appears years later when genital atrophy associated with aging occurs, but younger women who are multiparous and premenopausal may also be affected.

Rectocele is an upward pouching of the rectum that pushes the posterior wall of the vagina forward. Both rectoceles and perineal lacerations, which occur because of muscle tears below the vagina, may affect the muscles and tissues of the pelvic floor and may occur during childbirth. Sometimes, the lacerations may completely sever the fibers of the anal sphincter (complete tear). An **enterocele** is a protrusion of the intestinal wall into the vagina. Prolapse results from a weakening of the support structures of the uterus itself; the cervix drops and may protrude from the vagina. If complete prolapse occurs (cervix descending beyond vulva), it may also be referred to as procidentia.

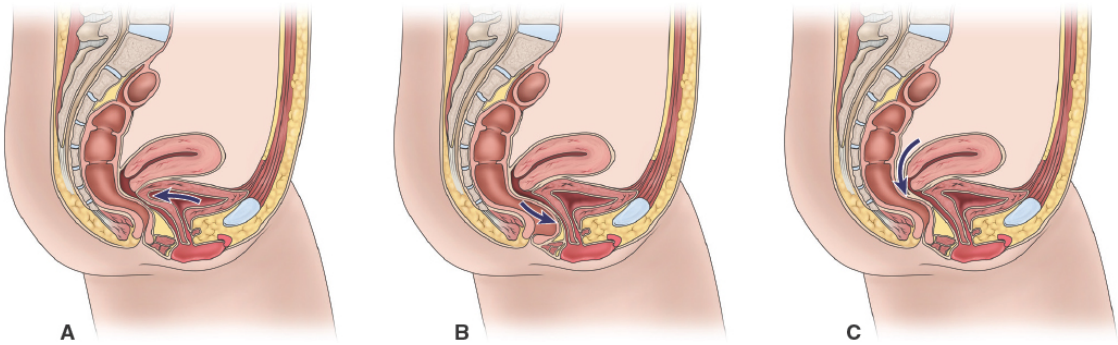

Figure 51-3 • Diagrammatic representation of the three most common types of pelvic floor relaxation. **A.** Cystocele. **B.** Rectocele. **C.** Enterocele. *Arrows* depict sites of maximum protrusion.

Clinical Manifestations

Because a cystocele causes the anterior vaginal wall to bulge downward, the patient may report a sense of pelvic pressure and urinary problems such as incontinence, frequency, and urgency. Back pain and pelvic pain may occur as well. The symptoms of rectocele resemble those of cystocele, with one exception: Instead of urinary symptoms, patients may experience rectal pressure. Constipation, uncontrollable gas, and fecal incontinence may occur in patients with complete tears. Prolapse can result in feelings of pressure and ulcerations and bleeding. Dyspareunia may occur with these disorders.

Medical Management

Kegel exercises, which involve contracting or tightening the vaginal muscles, are prescribed to help strengthen these weakened muscles (Good & Solomon, 2019). The exercises are more effective in the early stages of a cystocele. Kegel exercises are easy to perform and are recommended for all women, including those with strong pelvic floor muscles (see Chart 51-4). Pelvic floor PT is another treatment option for early-stage pelvic organ prolapse. It often requires multiple visits and use of manometers and internal examinations, which can be distressing to some (Good & Solomon, 2019).

Chart 51-4 PATIENT EDUCATION

Performing Kegel (Pelvic Muscle) Exercises

Purposes: To strengthen and maintain the tone of the pubococcygeal muscle, which supports the pelvic organs; reduce or prevent stress incontinence and uterine prolapse; enhance sensation during penile–vaginal intercourse; and hasten postpartum healing.

The nurse instructs the patient to:

1. Become aware of pelvic muscle function by "drawing in" the perivaginal muscles and anal sphincter as if to control urine or defecation, but not contracting the abdominal, buttock, or inner thigh muscles.
2. Sustain contraction of the muscles for up to 10 seconds, followed by at least 10 seconds of relaxation.
3. Perform these exercises 30–80 times a day.

A pessary can be used alone or in conjunction with other treatments to avoid surgery (ACOG, 2017b; Good & Solomon, 2019). This device is inserted into the vagina and positioned to keep an organ, such as the bladder, uterus, or intestine, properly aligned when a cystocele, rectocele, or prolapse has occurred. Pessaries are usually ring- or doughnut shaped and are made of various materials, such as rubber or plastic (see Fig. 51-4). Rubber pessaries must be avoided in women with latex allergy. The size and type of pessary are selected and fitted by a gynecologic health care provider. The patient should have the pessary removed, examined, and cleaned by her health care provider at prescribed intervals. At these checkups, vaginal walls should be examined for pressure points or signs of irritation. Normally, the patient experiences no pain, discomfort, or discharge with a pessary, but if chronic irritation, excessive discharge, or bleeding occur, alternative measures may be needed (ACOG, 2017b; Good & Solomon, 2019).

A Colpexin Sphere is another nonsurgical device used to treat pelvic organ prolapse. This intravaginal device is similar to a pessary, but it supports the pelvic floor muscles and facilitates exercise of these muscles. It is removed daily for cleaning.

Surgical Management

In many cases, surgery helps correct structural abnormalities. The procedure to repair the anterior vaginal wall is called anterior colporrhaphy, repair of a rectocele is referred to as a posterior colporrhaphy, and repair of perineal lacerations is called a perineorrhaphy. These repairs are frequently performed laparoscopically, resulting in short hospital lengths of stay and good outcomes. A laparoscope is inserted through a small abdominal incision, the pelvis is visualized, and surgical repairs are performed. Transvaginal surgical mesh as a treatment option has been associated with the complications of vaginal erosion, pain and infection leading to the U.S. Food and Drug Administration (FDA) ordering manufacturers of surgical mesh to stop selling and distributing these products (FDA, 2019).

Uterine Prolapse

Usually, the uterus and the cervix lie at right angles to the long axis of the vagina with the body of the uterus inclined slightly forward. The uterus is normally freely movable on examination. Individual variations may result in an anterior, middle, or posterior uterine position. A backward positioning of the uterus, known as retroversion and retroflexion, is not uncommon (see Fig. 51-5).

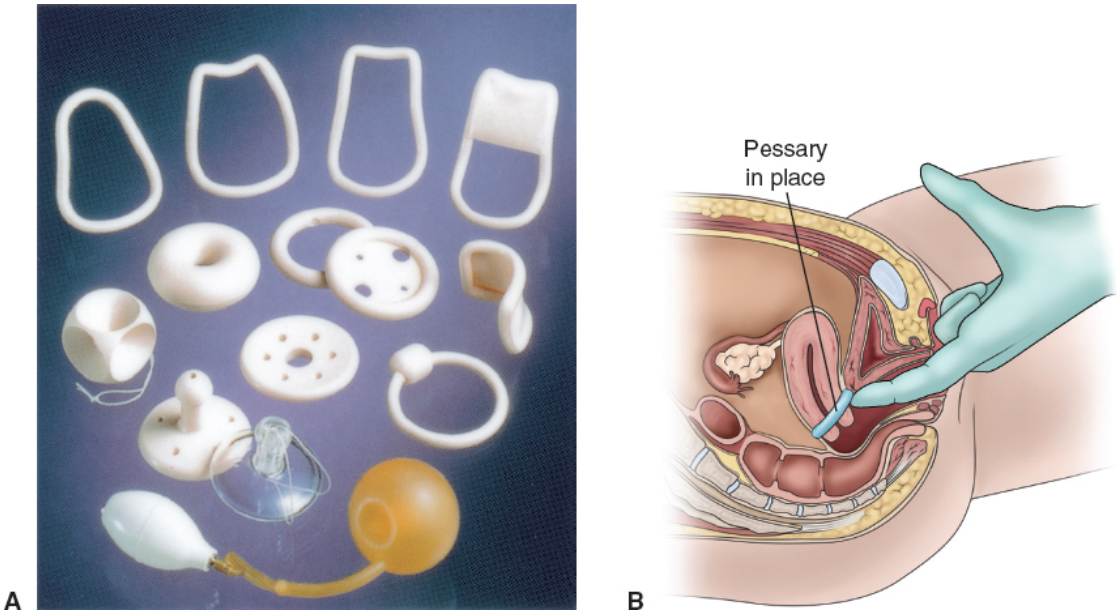

Figure 51-4 • Examples of pessaries. **A.** Various shapes and sizes of pessaries available. **B.** Insertion of one type of pessary.

If the structures that support the uterus weaken (typically from childbirth), the uterus may prolapse, or move down the vaginal canal; in severe prolapse, called procidentia, the uterus may appear outside the vaginal orifice (see Fig. 51-6). As the uterus descends, it may pull the vaginal walls and even the bladder and rectum with it. Symptoms include pressure and urinary problems (incontinence or retention) from displacement of the bladder. The symptoms are aggravated when a woman coughs, lifts a heavy object, or stands for a long time. Normal activities, even walking up stairs, may aggravate the symptoms.

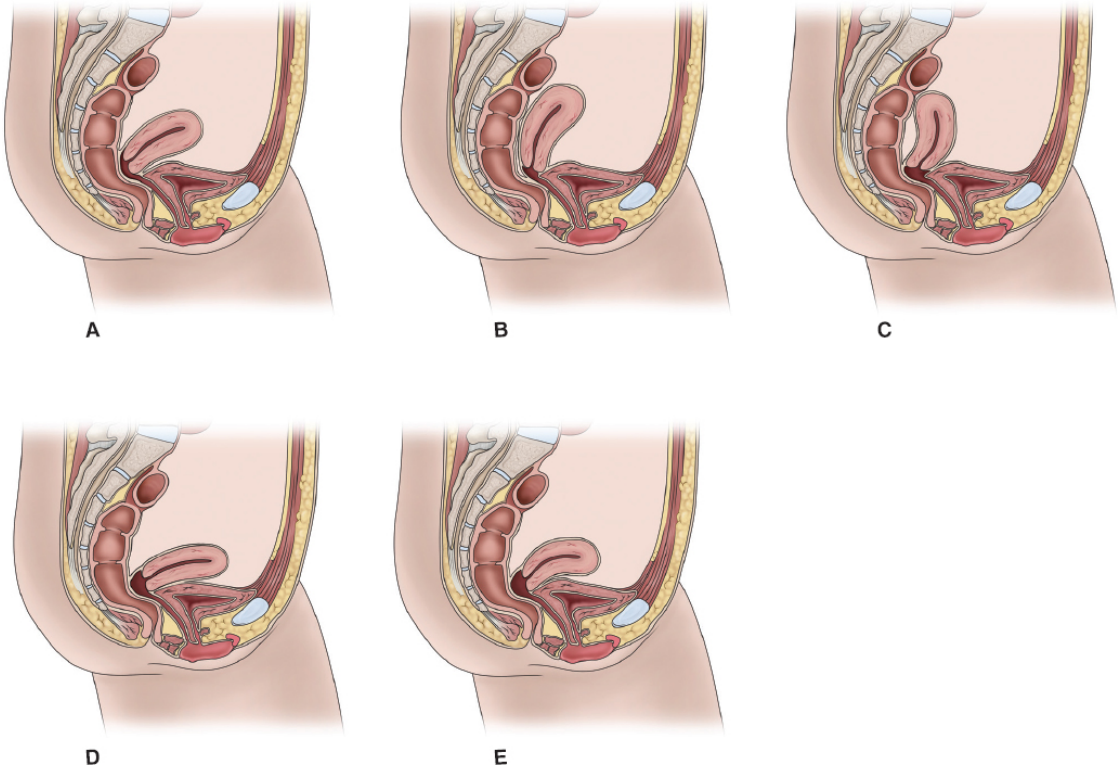

Figure 51-5 • Positions of the uterus. **A.** The most common position of the uterus detected on palpation. **B.** In *retroversion,* the uterus turns posteriorly as a whole unit. **C.** In *retroflexion,* the fundus bends posteriorly. **D.** In *anteversion,* the uterus tilts forward as a whole unit. **E.** In *anteflexion,* the uterus bends anteriorly.

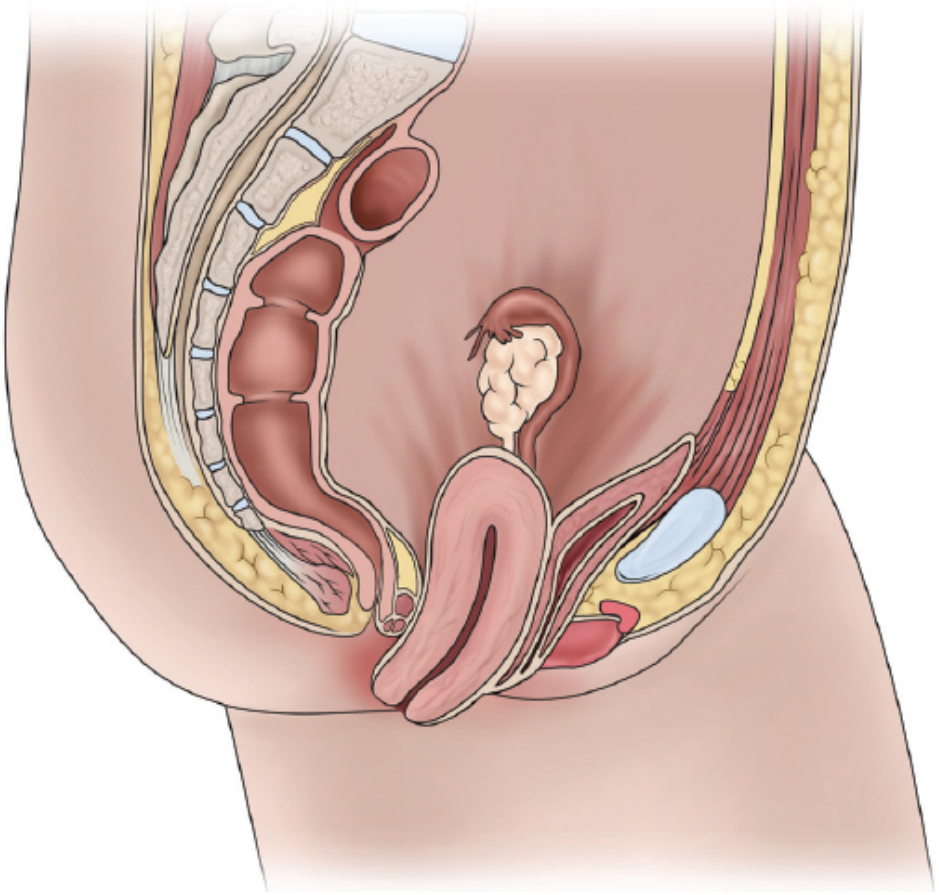

Figure 51-6 • Complete prolapse of the uterus through the introitus.

Medical Management

There are surgical and nonsurgical options for treatment. With surgery, the uterus is sutured back into place and repaired to strengthen and tighten the muscle bands. In women who are postmenopausal, the uterus may be removed by hysterectomy or repaired by colpopexy. Colpocleisis, or vaginal closure, may be an option for women who do not wish to have penile–vaginal intercourse or to bear children. Conservative treatments and mechanical options, including lifestyle changes, pessaries, and pelvic floor muscle training, can usually result in symptomatic improvement. These options may be the treatment of choice for women with a mild prolapse, who desire additional children, or who are unable to tolerate surgery (Meriwether, Antosh, Olivera, et al., 2018).

Nursing Management

Implementing Preventive Measures

Some disorders related to "relaxed" pelvic muscles (cystocele, rectocele, and uterine prolapse) may be prevented. During pregnancy, early visits to the primary provider permit early detection of problems. During the postpartum period, the woman can be educated to perform pelvic muscle exercises (see Chart 51-4) to increase muscle mass and strengthen the muscles that support the uterus and then to continue them as a preventive action (Good & Solomon, 2019).

Delays in obtaining evaluation and treatment may result in complications such as infection, cervical ulceration, cystitis, and hemorrhoids. The nurse encourages the patient to obtain prompt treatment for these structural disorders.

Implementing Preoperative Nursing Care

Before surgery, the patient needs to know the extent of the proposed surgery, the expectations for the postoperative period, and the effect of surgery on future sexual function. In addition, the patient having a rectocele repair needs to know that before surgery, a laxative and a cleansing enema may be prescribed. She may be asked to administer these at home the day before surgery. The patient is usually placed in a lithotomy position for surgery, with special attention given to moving both legs in and out of the stirrups simultaneously to prevent muscle strain and excess pressure on the legs and thighs. Other preoperative interventions are similar to those described in Chapter 14.

Initiating Postoperative Nursing Care

Immediate postoperative goals include preventing infection and pressure on any existing suture line. This may require perineal care and may preclude using dressings. The patient is encouraged to void within a few hours after surgery for cystocele and complete tear. If the patient does not void within this period and reports discomfort or pain in the bladder region after 6 hours, catheterization is needed. An indwelling catheter may be indicated for 2 to 4 days, so some women may return home with a catheter in place. Various other bladder care methods are described in Chapter 49. After each voiding or bowel movement, the perineum may be cleaned with warm, sterile saline solution and dried with sterile absorbent material if a perineal incision has been made.

After an external perineal repair, the perineum is kept as clean as possible. Commercially available sprays containing combined antiseptic and anesthetic solutions are soothing and effective, and an ice pack applied locally may relieve discomfort. However, the weight of the ice bag must rest on the bed, not on the patient.

Routine postoperative care is similar to that given after abdominal surgery. The patient is positioned in bed with the head and knees elevated slightly. The

patient may go home the day of or the day after surgery; the length of hospital stay depends on the surgical approach used.

After surgery for a complete perineal laceration (through the rectal sphincter), special care and attention are required. The bladder is drained through the catheter to prevent strain on the sutures. Throughout recovery, stool-softening agents are given nightly after the patient begins a soft diet.

Promoting Home, Community-Based, and Transitional Care

Educating Patients About Self-Care

Prior to discharge, education is provided about cleanliness, prevention of constipation, recommended exercises, and avoiding lifting heavy objects or standing for prolonged periods. The patient is instructed to report any pelvic pain, unusual discharge, inability to carry out personal hygiene, and vaginal bleeding.

Continuing and Transitional Care

The patient is advised to continue with perineal exercises, which are recommended to improve muscle strength and tone. She is reminded to return to the gynecologist for a follow-up visit and to consult with the primary provider about when it is safe to resume sexual activity.

BENIGN DISORDERS

Vulvitis and Vulvodynia

Vulvitis (an inflammation of the vulva) may occur with other disorders, such as diabetes, dermatologic problems, or poor hygiene, or it may be secondary to irritation from a vaginal discharge related to a specific vaginitis.

Vulvodynia is a chronic vulvar pain syndrome. Symptoms may include burning, stinging, irritation, or stabbing pain. The syndrome has been described as primary, with onset at first tampon insertion or sexual experience, or secondary, beginning months or years after first tampon insertion or sexual experience. Women affected by this are usually between 18 and 25 years of age. The cause of vulvodynia is not well understood; many believe it is multifactorial. Future research is critical to understanding the pathophysiology and cause of vulvodynia. It can be chronic or unremitting, intermittent or episodic, or may occur only in response to contact (Stenson, 2017). The pathophysiology is unknown. Vestibulodynia is the most frequent type of vulvodynia, producing sharp pain on pressure on the vestibule or posterior aspect of the vaginal opening.

Medical Management

Treatment methods for vulvodynia vary and depend on cause. Topical treatments, self-management care (strict vulvar care/hygiene), surgery, as well as biofeedback and dietary changes, have been used. Some cases seem to be similar to peripheral neuralgia and may respond to treatment with tricyclic antidepressant agents. Patients with dyspareunia may benefit from referral to a behavioral or mental health professional. Psychotherapy is a validated noninvasive treatment option (Stenson, 2017).

Vulvar Cysts

Bartholin cyst results from the obstruction of a duct in one of the paired Bartholin or vestibular mucous-secreting glands located in the posterior third of the vulva, near the vestibule. This cyst is the most common vulvar disorder. A simple cyst may be asymptomatic, but an infected cyst or abscess may cause discomfort. Infection may be due to a gonococcal organism, *Escherichia coli,* or *Staphylococcus aureus* and can cause an abscess with or without involving the inguinal lymph nodes. Skene duct cysts may result in pressure, dyspareunia, altered urinary stream, and pain, especially if infection is present. Vestibular cysts, located inferior to the hymen, may also occur. Cysts can be treated by resection or with laser, ablation with silver nitrate, and puncture. Asymptomatic cysts do not require treatment. Malignancy can occur, usually in women older than 40 years, so drainage and biopsy may be considered (Mahonski & Hu, 2019).

Medical Management

The usual treatment for a symptomatic Bartholin cyst or abscess is drainage. If a cyst is asymptomatic, treatment is unnecessary. Moist heat or sitz baths may promote drainage and resolution.

If drainage is necessary, several techniques are available. The simplest technique is incision and drainage. Using a Word catheter provides another method. This catheter, which is a short latex stem with an inflatable bulb at the distal end, creates a tract that preserves the gland and allows for drainage. A nonopioid analgesic agent may be given before this outpatient procedure. A local anesthetic agent is injected, and the cyst is incised or lanced and irrigated with normal saline; the catheter is inserted and inflated with 2 to 3 mL of water. The catheter stem is then tucked into the vagina to allow freedom of movement. The catheter is left in place for 4 to 6 weeks (Mahonski & Hu, 2019). The patient is informed that discharge should be expected because the catheter allows drainage of the cyst. She is instructed to contact her primary provider if pain occurs, in which case the bulb may be too large for the cavity

and fluid may need to be removed. Routine hygiene is encouraged. Marsupialization (creation of small pouch) and gland removal are additional treatment options (Mahonski & Hu, 2019).

Vulvar Dystrophy

Vulvar dystrophy is a condition found in older women that causes dry, thickened skin on the vulva or slightly raised, whitish papules, fissures, or macules. Symptoms usually consist of varying degrees of itching, but some patients have no symptoms. A few patients with vulvar cancer have associated dystrophy (vulvar cancer is discussed later in this chapter). Biopsy with careful follow-up is the standard intervention. Benign dystrophies include lichen planus, lichen simplex chronicus, lichen sclerosus (benign disorder of the vulva), squamous cell hyperplasia, vulvar **vestibulitis** (inflammation of the vulvar vestibule), and other dermatoses (Chibnall, 2017).

Medical Management

Topical corticosteroids (i.e., hydrocortisone creams) are the usual treatment. Petrolatum jelly may relieve pruritus. Use is decreased as symptoms resolve. Topical corticosteroids are effective in treating squamous cell hyperplasia. Treatment is often complete in 2 to 3 weeks, but ongoing assessment for vulvar atrophy should occur at least annually (Chibnall, 2017).

If malignant cells are detected on biopsy, local excision, laser therapy, local chemotherapy, and immunologic treatment are used. Vulvectomy is avoided, if possible, to spare the patient from the stress of disfigurement and possible sexual dysfunction.

Nursing Management

Key nursing responsibilities for patients with vulvar dystrophies focus on education. Important topics include hygiene and self-monitoring for signs and symptoms of complications.

Promoting Home, Community-Based, and Transitional Care

Educating Patients About Self-Care

Education for patients with benign vulvar dystrophies includes the importance of maintaining good personal hygiene and keeping the vulva dry. Lanolin or hydrogenated vegetable oil is recommended for relief of dryness. Sitz baths may help but should not be overused because dryness may result or increase.

The patient is instructed to notify the primary provider about any change or ulceration because biopsy may be necessary to rule out squamous cell carcinoma.

By encouraging all patients to perform genital self-examinations regularly and have any itching, lesions, or unusual symptoms assessed by a primary provider, nurses can help prevent complications and progression of vulvar lesions. Ongoing assessment should occur at least annually.

Ovarian Cysts

The ovary is a common site for cysts, which may be simple enlargements of normal ovarian constituents, the graafian follicle, or the corpus luteum, or they may arise from abnormal growth of the ovarian epithelium. Ovarian cysts are often detected on routine pelvic examination. Although these cysts are typically benign, they nevertheless should be evaluated to exclude ovarian cancer, particularly in women who are postmenopausal (Casanova et al., 2019).

The patient may or may not report acute or chronic abdominal pain. Symptoms of a ruptured cyst mimic various acute abdominal emergencies, such as appendicitis or ectopic pregnancy. Larger cysts may produce abdominal swelling and exert pressure on adjacent abdominal organs.

Postoperative nursing care after surgery to remove an ovarian cyst is similar to that after abdominal surgery, with one exception. The marked decrease in intra-abdominal pressure resulting from removal of a very large cyst usually leads to considerable abdominal distention. This may be prevented to some extent by applying a snug-fitting abdominal binder.

Some surgeons discuss the option of a hysterectomy when a woman is undergoing bilateral ovary removal because of a suspicious mass; it may increase life expectancy and avoid a later second surgery. Patient preference is a priority in determining its appropriateness.

Polycystic ovary syndrome (PCOS) is a type of hormonal imbalance or cystic disorder that affects the ovaries. This complex endocrine condition involves a disorder in the hypothalamic-pituitary and ovarian network or axis, resulting in chronic anovulation and hyperandrogenism, often along with multiple small ovarian cysts. It is common and occurs in approximately 6% to 20% of women of childbearing age (Pfieffer, 2019). Features can include obesity, insulin resistance, glucose intolerance, dyslipidemia, sleep apnea, and infertility. Symptoms are related to androgen excess. Irregular menstrual periods, resulting from lack of regular ovulation, infertility, obesity, and hirsutism, may be a presenting complaint. Cysts form in the ovaries because the hormonal milieu cannot cause ovulation on a regular basis.

Diagnosis is based on clinical criteria, including hyperandrogenism, chronic anovulation, and polycystic ovaries on ultrasound examination. Two out of three of these criteria must be present to make the diagnosis (ACOG, 2018b; Pfieffer, 2019). Women with PCOS are at increased risk for diabetes, increased blood lipids, cardiovascular disease, nonalcoholic fatty liver disease as well as anxiety and depression (Pfieffer, 2019).

Medical Management

The treatment of polycystic ovary syndrome consists of lifestyle changes including weight loss and pharmacotherapy. Oral contraceptive agents are often prescribed to treat PCOS (ACOG, 2018b; Pfieffer, 2019). When pregnancy is desired, medications to stimulate ovulation (clomiphene citrate) are often effective. Lifestyle modification is critical, and weight management is part of the treatment plan.

Weight loss as little as 5% to 10% of total body weight can help with hormone imbalance and infertility. Metformin often regulates periods and can help with weight loss (ACOG, 2018b; Pfieffer, 2019). Women with this diagnosis are at increased risk for endometrial cancer due to anovulation.

Benign Tumors of the Uterus: Fibroids (Leiomyomas, Myomas)

Most women will develop myomatous or **fibroid tumors** of the uterus at some point in their life. It is estimated that by the age of 50, up to 70% of White women and 80% of African American women will experience uterine fibroids (National Institutes of Health [NIH], 2018). It is thought that women are genetically predisposed to develop this condition, which is almost always benign. Fibroids arise from the muscle tissue of the uterus and can be solitary or multiple, intracavitary (in the lining of the uterus), intramural (in the muscle wall), and serosal (in the outside surface). They usually develop slowly in women between 25 and 40 years of age and may become quite large. A growth spurt with enlargement of the fibroid tumor may occur in the decade before menopause, possibly related to anovulatory cycles and high levels of unopposed estrogen. Fibroids are a common reason for hysterectomy because they often result in menorrhagia, which can be difficult to control.

Clinical Manifestations

Fibroids may cause no symptoms, or they may produce abnormal vaginal bleeding. Other symptoms result from pressure on the surrounding organs and include pain, backache, pressure, bloating, constipation, and urinary problems.

Menorrhagia (excessive bleeding) and metrorrhagia (irregular bleeding) may occur because fibroids may distort the uterine lining (see Fig. 51-7). Fibroids may interfere with fertility.

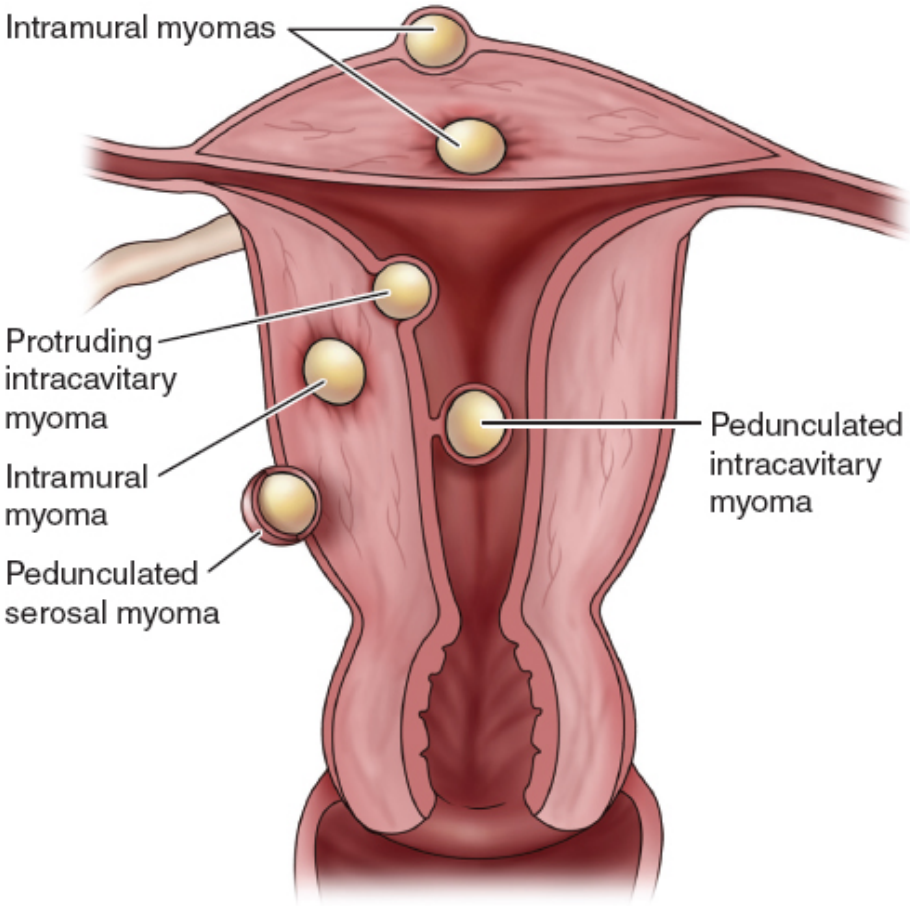

Figure 51-7 • Myomas (fibroids). Those that impinge on the uterine cavity are called *intracavitary myomas.*

Medical Management

Treatment of uterine fibroids may include medical or surgical intervention and depends to a large extent on the size, symptoms, and location, as well as the woman's age and her reproductive plans. Fibroids usually shrink and disappear during menopause, when estrogen is no longer produced. Simple observation and follow-up may be all the management that is necessary. The patient with minor symptoms is closely monitored. If she plans to have children, treatment is as conservative as possible. As a rule, **myomectomy** (surgical removal of uterine fibroids) is performed for large tumors that produce pressure symptoms. A hysterectomy may be performed if symptoms are severe and childbearing is completed (see later discussion of nursing care for a patient having a hysterectomy).

Several alternatives to hysterectomy have been developed for the treatment of excessive bleeding due to fibroids (Fortin, Flyckt, & Falcone, 2017). These include the following:

- *Hysteroscopic resection of myomas:* A laser is used through a hysteroscope passed through the cervix; no incision or overnight stay is needed.
- *Laparoscopic myomectomy:* Removal of a fibroid through a laparoscope inserted through a small abdominal incision.
- *Laparoscopic myolysis:* The use of a laser or electrical needles to cauterize and shrink the fibroid.
- *Laparoscopic cryomyolysis:* Electric current is used to coagulate the fibroid.
- *Uterine artery embolization (UAE):* Polyvinyl alcohol or gelatin particles are injected into the blood vessels that supply the fibroid via the femoral artery, resulting in infarction and resultant shrinkage. This percutaneous image-guided therapy offers an alternative to hormone therapy or surgery. UAE may result in infrequent but serious complications such as pain, infection, amenorrhea, necrosis, and bleeding. Although rare, deaths and ovarian failure may occur. Women need to weigh the risks and benefits carefully, especially if they have not completed childbearing.
- *Magnetic resonance–guided focused ultrasound surgery (MRgFUS):* Ultrasonic energy is passed through the abdominal wall to target and destroy the fibroid. This noninvasive procedure is approved by the FDA for women who are premenopausal with bothersome symptoms due to fibroids and who do not want more children. It is an outpatient treatment.

Medications (e.g., leuprolide) or other gonadotropin-releasing hormone (GnRH) analogues, which induce a temporary menopause like environment, may be prescribed to shrink the fibroids. This treatment consists of monthly injections, which may cause hot flashes and vaginal dryness. Treatment is usually short term (i.e., before surgery) to shrink the fibroids, allowing easier surgery, and to alleviate anemia, which may occur as a result of heavy menstrual flow. This treatment is used on a temporary basis because it leads to vasomotor symptoms and loss of bone density.

Antifibrotic agents are under investigation for long-term treatment of fibroids. Mifepristone, a progesterone antagonist, is also utilized.

Endometriosis

Endometriosis is a chronic disease affecting between 7% and 10% of women of reproductive age, occurring more frequently in women who have never had children (Casanova et al., 2019). **Endometriosis** consists of a benign lesion or lesions that contain endometrial tissue (similar to that lining the uterus) found in the pelvic cavity outside the uterus. Extensive endometriosis may cause few symptoms, or an isolated lesion may produce severe symptoms. It is a major cause of chronic pelvic pain and infertility.

Endometriosis has been diagnosed more frequently as a result of the increased use of laparoscopy. There is a high incidence among patients who bear children late and among those who have fewer children. In countries where tradition favors early marriage and early childbearing, endometriosis is rare. There also appears to be a familial predisposition to endometriosis; it is more common in women whose close female relatives are affected. Other factors that may suggest increased risk include a shorter menstrual cycle (less than every 27 days), flow longer than 7 days, outflow obstruction, and younger age at menarche.

Pathophysiology

Misplaced endometrial tissue responds to and depends on ovarian hormonal stimulation. During menstruation, this ectopic tissue bleeds, mostly into areas having no outlet, which causes pain and adhesions. The lesions are typically small and puckered, with a blue/brown/gray powder-burn appearance and brown or blue-black appearance, indicating concealed bleeding.

Endometrial tissue contained within an ovarian cyst has no outlet for the bleeding; this formation is referred to as a pseudocyst or chocolate cyst. Adhesions, cysts, and scar tissue may result, causing pain and infertility (Casanova et al., 2019). Endometriosis may increase the risk of ovarian cancer.

Currently, the best-accepted theory regarding the origin of endometrial lesions is the transplantation theory, which suggests that a backflow of menses (retrograde menstruation) transports endometrial tissue to ectopic sites through the fallopian tubes. Why some women with retrograde menstruation develop endometriosis and others do not is unknown. Endometrial tissue can also be spread by lymphatic or venous channels.

Clinical Manifestations

Symptoms vary but include dysmenorrhea (menstrual pain), dyspareunia, and pelvic discomfort or pain. Dyschezia (pain with bowel movements) and radiation of pain to the back or leg may occur. Depression, loss of work due to pain, and relationship difficulties may result. Infertility may occur because of fibrosis and adhesions or because of a variety of substances (prostaglandins,

cytokines, other factors) produced by the implants of endometriosis and scar tissue on anatomic sites.

Assessment and Diagnostic Findings

A health history, including an account of the menstrual pattern, is necessary to elicit specific symptoms. On bimanual pelvic examination, fixed tender nodules are sometimes palpated, and uterine mobility may be limited, indicating adhesions. Laparoscopic examination confirms the diagnosis and helps stage the disease. In stage 1, patients have superficial or minimal lesions; stage 2, mild involvement; stage 3, moderate involvement; and stage 4, extensive involvement and dense adhesions, with obliteration of the cul-de-sac. Ultrasonography, magnetic resonance imaging (MRI), and CT scans may also be useful to visualize endometriosis (Casanova et al., 2019).

Medical Management

Treatment depends on the symptoms, the patient's desire for pregnancy, and the extent of the disease. If the woman does not have symptoms, routine examination may be all that is required. Other therapy for varying degrees of symptoms may be NSAIDs, oral contraceptive agents, GnRH agonists, or surgery. Pregnancy often alleviates symptoms, because neither ovulation nor menstruation occurs.

Pharmacologic Therapy

Palliative measures include the use of medications, such as analgesic agents and prostaglandin inhibitors, for pain. Hormonal therapy is effective in suppressing endometriosis and relieving dysmenorrhea. Oral contraceptive agents provide effective pain relief and may prevent disease progression (Casanova et al., 2019). Infrequently, side effects may occur with oral contraceptives, such as fluid retention, weight gain, and nausea. These can usually be managed by changing brands or formulations.

Several types of hormonal therapy are also available in addition to oral contraceptive agents. A synthetic androgen, danazol, causes atrophy of the endometrium and subsequent amenorrhea. The medication inhibits the release of gonadotropin with minimal overt sex hormone stimulation. The drawbacks of this medication are that it is expensive and may cause troublesome side effects such as fatigue, depression, weight gain, oily skin, decreased breast size, mild acne, hot flashes, and vaginal atrophy (Casanova et al., 2019; Comerford & Durkin, 2020). GnRH agonists decrease estrogen production and cause subsequent amenorrhea. Side effects are related to low estrogen levels (e.g., hot flashes and vaginal dryness). Loss of bone density is often offset by concurrent use of estrogen. If side effects from GnRH develop, treatment is

needed long term or repeated treatments are necessary, additional therapy should be considered. Norethindrone acetate (low-dose hormone) given along with GnRH agonist will mitigate the bone density side effects as well as not affect the drug's control of pelvic pain. Aromatase inhibitor therapy is emerging as an alternative therapy (Casanova et al., 2019). Most women continue treatment despite side effects, and symptoms diminish for 80% to 90% of women with mild to moderate endometriosis. Hormonal medications are not used in patients with a history of abnormal vaginal bleeding or liver, heart, or kidney disease. Bone density is followed carefully because of the risk of bone loss; hormone therapy is usually short term.

Surgical Management

If conservative measures are not helpful, surgery may be necessary to relieve pain and improve the possibility of pregnancy. Surgery may be combined with the use of medical therapy. The procedure selected depends on the patient. Laparoscopy may be used to fulgurate (cut with high-frequency current) endometrial implants and to release adhesions. Laser surgery is another option made possible by laparoscopy. Laser therapy vaporizes or coagulates the endometrial implants, thereby destroying this tissue. Other surgical options include endocoagulation and electrocoagulation, laparotomy, abdominal hysterectomy, **oophorectomy** (removal of the ovary), bilateral **salpingo-oophorectomy** (removal of the ovary and its fallopian tube), and appendectomy. Many women need further intervention following conservative surgeries; therefore, total hysterectomy is the definitive procedure (Casanova et al., 2019).

Nursing Management

The health history and physical examination focus on specific symptoms (e.g., pelvic pain), the effect of prescribed medications, and the woman's reproductive plans. This information helps in determining the treatment plan. Explaining the various diagnostic procedures may help to alleviate the patient's anxiety. Patient goals include relief of pain, dysmenorrhea, dyspareunia, and avoidance of infertility.

As the treatment progresses, the woman with endometriosis and her partner may find that pregnancy is not easily possible, and the psychosocial impact of this realization must be recognized and addressed. Alternatives, such as assisted reproductive technologies or adoption, may be discussed at an appropriate time and referrals offered.

The nurse's role in patient education is to dispel myths and encourage the patient to seek care if dysmenorrhea or dyspareunia occur. The Endometriosis Association (see the Resources section) is a helpful resource for patients

seeking further information and support for this condition, which can cause disabling pain and severe emotional distress.

Chronic Pelvic Pain

Chronic pelvic pain is a common disorder of women that may be related to several of the previously discussed gynecologic disorders. Chronic pelvic pain is defined as noncyclic pain concentrated in the pelvis, anterior abdominal wall, and buttock or lumbosacral region for a period greater than 6 months (Andrew & Pickett, 2019). Causes may be of reproductive, genitourinary, or gastrointestinal origin. A history of sexual abuse, IPV, PID, endometriosis, interstitial cystitis, musculoskeletal disorders, irritable bowel syndrome, and previous surgery resulting in abdominal adhesions may be associated with chronic pelvic pain. Dysmenorrhea, dyspareunia, and lower abdominal pain may also be associated with sexual abuse and IPV.

Chronic pelvic pain is often difficult to treat. Treatment depends on physical and diagnostic test results and may include antidepressant, analgesic, anxiolytic, and oral contraceptive agents; GnRH agonists; exercise; diet modification; and various surgical procedures (Andrew & Pickett, 2019).

Adenomyosis

In adenomyosis, the tissue that lines the endometrium invades the uterine wall. Symptoms include hypermenorrhea (excessive and prolonged bleeding), dysmenorrhea, polymenorrhea (abnormally frequent bleeding), and pelvic pain. Physical examination findings on palpation include a symmetrically enlarged, tender, and boggy uterus (Casanova et al., 2019). Treatment depends on the severity of bleeding and pain. Hysterectomy may be the best option in providing relief of symptoms.

Endometrial Hyperplasia

Endometrial hyperplasia (a buildup of endometrial tissue) is the most common precursor to endometrial cancer and often results from unopposed estrogen from any source. Estrogen therapy alone without progesterone in a woman with a uterus can cause this condition. Women with anovulatory cycles, PCOS, or obesity may have high circulating levels of estrogen. Tamoxifen may also be a causative factor. Diagnosis is by biopsy or ultrasound findings of thickness of the endometrium. Hyperplasia with atypia on a pathology or biopsy report indicates risk of progression. Progestin treatment may be

effective, but hysterectomy may be advised if pathology from an endometrial biopsy shows atypia. Abnormal bleeding is the most common symptom.

MALIGNANT CONDITIONS

Gynecologic cancer is any cancer that starts in a woman's reproductive organs (CDC, 2019e). According to the American Cancer Society (ACS, 2019a), the projected incidence for female reproductive cancers in the United States includes about 61,880 new cases of uterine cancer; 22,530 new cases of ovarian cancer; 13,170 new cases of cervical cancer; 6070 new cases of vulvar cancer; and 5350 new cases of vaginal cancer per year. Ovarian cancer is responsible for 5% of all cancer deaths in women and is the leading cause of death in female reproductive cancers.

Although some cancers are difficult to detect or prevent, annual pelvic examination with a Pap smear is a painless and relatively inexpensive method of early detection (CDC, 2019e). Primary providers can encourage women to follow this health practice by providing examinations that are educational and supportive and offer women an opportunity to ask questions and clarify misinformation.

Women diagnosed with gynecologic malignancies experience anxiety related to their prognosis. The occurrence of physical symptoms may cause more psychological distress. Intervention directed toward physical and psychological symptoms requires a multidisciplinary approach.

Nurses should be aware of ongoing clinical trials to identify options for many conditions. They are often able to answer questions about clinical trials and to encourage patients to consider participation if appropriate. Women's participation in cancer research may not occur in part because women are unaware of ongoing relevant research (see ClinicalTrials.gov in the Resources section).

Cancer of the Cervix

Death from cervical cancer is less common due to early detection of cell changes by Pap smear (ACS, 2019b). However, it is still the third most common female reproductive cancer in the United States (ACS, 2019b). Risk factors are presented in Chart 51-5.

Preventive measures include regular pelvic examinations and Pap tests for all women, especially older women past childbearing age. Preventive counseling should encourage delaying first penile–vaginal intercourse, avoiding HPV infection, engaging only in safer sex, ceasing smoking, and receiving HPV immunization.

Chart 51-5 RISK FACTORS

Cervical Cancer

Chronic cervical infection

- Early childbearing
- Exposure to diethylstilbestrol in utero
- Exposure to human papillomavirus, types 16 and 18
- Family history of cervical cancer
- HIV infection and other causes of immune deficiency
- Low socioeconomic status (may be related to early marriage and early childbearing)
- Nutritional deficiencies (folate, beta-carotene, and vitamin C levels are lower in women with cervical cancer than in women without it)
- Overweight status
- Prolonged use of oral contraceptives
- Sexual activity:
  - Multiple sex partners
  - Early age (<20 years) at first coitus (exposes the vulnerable young cervix to potential viruses from a partner)
- Sexual contact with men whose partners have had cervical cancer
- Sex with uncircumcised men
- Smoking and exposure to secondhand smoke

HIV, human immune deficiency virus.

Adapted from American Cancer Society. (2019b). *Cervical cancer*. Retrieved on 10/28/2019 at: www.cancer.org/cancer/cervical-cancer/about/key-statistics.html; Casanova, R., Chuang, A., Goepfert, A. R., et al. (Eds.). (2019). *Beckman and Ling's obstetrics and gynecology* (8th ed.). Philadelphia, PA: Wolters Kluwer.

There are several different types of cervical cancer. Most of these cancers are squamous cell carcinomas, and the rest are adenocarcinomas or mixed adenosquamous carcinomas. Adenocarcinomas begin in mucous-producing glands and are often due to HPV infection. Most cervical cancers, if not detected and treated, spread to regional pelvic lymph nodes, and local recurrence is not uncommon (ACS, 2019b).

Clinical Manifestations

Early cervical cancer rarely produces symptoms. If symptoms are present, they may go unnoticed as a thin, watery vaginal discharge often noticed after penile–vaginal intercourse or douching. When symptoms such as discharge, irregular bleeding, or pain or bleeding after penile–vaginal intercourse occur, the disease may be advanced. Advanced disease should not occur if all women

have access to gynecologic care and avail themselves to it. The nurse's role in access to care and its utilization is crucial.

In advanced cervical cancer, the vaginal discharge gradually increases and becomes watery and, finally, dark and foul smelling from necrosis and infection. The bleeding, which occurs at irregular intervals between periods (metrorrhagia) or after menopause, may be slight (just enough to spot the undergarments) and occurs usually after mild trauma or pressure (e.g., penile–vaginal intercourse, douching, or bearing down during defecation). As the disease continues, the bleeding may persist and increase. Leg pain, dysuria, rectal bleeding, and edema of the extremities signal advanced disease.

As the cancer advances, it may invade the tissues outside the cervix, including the lymph glands anterior to the sacrum. In one third of patients with invasive cervical cancer, the disease involves the fundus. The nerves in this region may be affected, producing excruciating pain in the back and the legs that is relieved only by large doses of opioid analgesic agents. If the disease progresses, it often produces extreme emaciation and anemia that usually is accompanied by fever (due to secondary infection and abscesses in the ulcerating mass) and by fistula formation. Because the survival rate for in situ cancer is 100% and the rate for women with more advanced stages of cervical cancer decreases dramatically, early detection is essential.

Assessment and Diagnostic Findings

Diagnosis may be made on the basis of abnormal Pap smear results, followed by biopsy results identifying severe dysplasia (cervical intraepithelial neoplasia type III [CIN III], high-grade squamous intraepithelial lesions [HGSILs, also referred to as HSILs], or carcinoma in situ). HPV infections are usually implicated in these conditions. Carcinoma in situ is technically classified as severe dysplasia and is defined as cancer that has extended through the full thickness of the epithelium of the cervix, but not beyond. This is often referred to as preinvasive cancer.

In its very early stages, cervical cancer is found microscopically by Pap smear. In later stages, pelvic examination may reveal a large, reddish growth or a deep, ulcerating lesion. The patient may report spotting or bloody discharge.

When the patient has been diagnosed with invasive cervical cancer, clinical staging estimates the extent of the disease so that treatment can be planned more specifically, and prognosis reasonably predicted. Staging is based on the International Federation of Gynecology and Obstetrics (FIGO) Staging Classification (Casanova et al., 2019):

- Stage I, the carcinoma is strictly confined to the cervix.
- Stage II, the carcinoma invades beyond the uterus but not the pelvic wall or vagina.

- Stage III, the tumor spreads to the pelvic wall and/or the vagina, and/or causes hydronephrosis of the kidneys.
- Stage IV, the tumor has extended beyond the pelvis and involves the bladder or rectum.

Signs and symptoms are evaluated, and x-rays, laboratory tests, and special examinations, such as biopsy and colposcopy, are performed (Casanova et al., 2019). Depending on the stage of the cancer, other tests and procedures may be performed to determine the extent of disease and appropriate treatment. These tests may include dilation and curettage (D&C), CT scan, MRI scan, IV urography, cystography, positron emission tomography (PET) scan, and barium x-ray studies. Treatment depends on the stage of the disease.

Medical Management

Precursor or Preinvasive Lesions

When precursor lesions, such as low-grade squamous intraepithelial lesions (LGSILs, also referred to as LSILs; CIN I and II or mild to moderate dysplasia), are found by colposcopy and biopsy, careful monitoring by frequent Pap smears or conservative treatment is possible. Conservative treatment may consist of monitoring, **cryotherapy** (freezing with liquid nitrogen), or laser therapy. A **loop electrocautery excision procedure (LEEP)** may also be used to remove abnormal cells. In this procedure, a thin wire loop with laser is used to cut away a thin layer of cervical tissue. LEEP is an outpatient procedure that usually is performed in a gynecologist's office; it takes only a few minutes. Analgesia is given before the procedure, and a local anesthetic agent is injected into the area. This procedure allows the pathologist to examine the removed tissue sample to determine if the borders of the tissue are disease free. Another procedure referred to as a cone biopsy or conization (removing a cone-shaped portion of the cervix) is performed when biopsy findings demonstrate CIN III or HGSIL (equivalent to severe dysplasia) and carcinoma in situ.

If preinvasive cervical cancer (carcinoma in situ) occurs when a woman has completed childbearing, a simple hysterectomy (removal of the uterus only) is usually recommended (Casanova et al., 2019). If a woman is pregnant or wishes to have children and invasion is less than 1 mm, conization may be sufficient. Frequent follow-up examinations are necessary to monitor for recurrence (Casanova et al., 2019).

Patients who have precursor or premalignant lesions need reassurance that they do not have invasive cancer. However, the importance of close follow-up is emphasized because the condition, if untreated for a long time, may progress to cancer. Patients with cervical cancer in situ also need to know that this is

usually a slow-growing and nonaggressive type of cancer that is not expected to recur after appropriate treatment.

Invasive Cancer

Treatment of invasive cervical cancer depends on the stage of the lesion, the patient's age and general health. Surgery and radiation treatment (intracavitary and external) are most often used. Surgical procedures that may be used to treat cervical cancer are summarized in Chart 51-6. Robot-assisted technology for the treatment of cervical cancer is a rapidly growing alternative to more invasive surgical options with decreased length of stay, recovery time, decreased blood loss, and increase in total number of retrievable lymph nodes (ACOG, 2017c).

Chart 51-6

Surgical Procedures for Cervical Cancer

- Total hysterectomy—removal of the uterus, cervix, and ovaries
- Radical hysterectomy—removal of the uterus, ovaries, fallopian tubes, proximal vagina, and bilateral lymph nodes through an abdominal incision (*Note:* "Radical" indicates that an extensive area of the paravaginal, paracervical, parametrial, and uterosacral tissues is removed with the uterus.)
- Radical vaginal hysterectomy—vaginal removal of the uterus, ovaries, fallopian tubes, and proximal vagina
- Bilateral pelvic lymphadenectomy—removal of the common iliac, external iliac, hypogastric, and obturator lymphatic vessels and nodes
- Pelvic exenteration—removal of the pelvic organs, including the bladder or rectum and pelvic lymph nodes, and construction of diversional conduit, colostomy, and vagina
- Radical trachelectomy—removal of the cervix and selected nodes to preserve childbearing capacity in a woman of reproductive age with cervical cancer

Adapted from American Cancer Society. (2019b). *Cervical cancer*. Retrieved on 10/28/2019 at: www.cancer.org/cancer/cervical-cancer/about/key-statistics.html; Casanova, R., Chuang, A., Goepfert, A. R., et al. (Eds.). (2019). *Beckman and Ling's obstetrics and gynecology* (8th ed.). Philadelphia PA: Wolters Kluwer.

Frequent follow-up after surgery is imperative because the risk of recurrence is high and usually occurs within the first 2 years. Recurrences are often in the upper quarter of the vagina, and ureteral obstruction may be a sign. Weight loss, leg edema, and pelvic pain may be signs of lymphatic obstruction and metastasis.

Radiation, which is often part of treatment to reduce recurrent disease, may be delivered by an external beam or by **brachytherapy** (method by which the radiation source is placed near the tumor in a sealed source) or both. The field to be irradiated as well as the dose and method of radiation are determined by stage, volume of tumor, and lymph node involvement (Casanova et al., 2019).

A variety of chemotherapeutic approaches are used to treat advanced cervical cancer. They are often used in combination with surgery and radiation. Vaginal stenosis is a frequent side effect of radiation. Preventive therapy (i.e., vaginal dilator) can be used to avoid severe permanent vaginal stenosis.

Some patients with recurrences of cervical cancer are considered for **pelvic exenteration**, in which several pelvic organs are removed. This is a complex, extensive surgical procedure that is reserved for women with a high likelihood of cure. Unilateral leg edema, sciatica, and ureteral obstruction indicate likely disease progression. Patients with these symptoms have advanced disease and are not considered candidates for this major surgical procedure. Surgery is complex because it is performed close to the bowel, bladder, ureters, and great vessels. Possible complications include pulmonary embolism (PE), pulmonary edema, myocardial infarction, cerebrovascular disease, hemorrhage, sepsis, small bowel obstruction, fistula formation, obstruction of the ileal conduit, bladder dysfunction, and pyelonephritis, most often in the first 18 months postoperatively. Vein constriction must be avoided postoperatively. Patients with varicose veins or a history of thromboembolic disease may be treated prophylactically with heparin. Anti-embolism stockings are prescribed to reduce the risk of deep vein thrombosis (DVT). Nursing care of these patients is complex and requires coordination and care by experienced health care professionals. Pelvic exenteration is discussed in further detail later in this chapter.

Cancer of the Uterus (Endometrium)

Over the last decade there has been an increase in both the incidence and death rates of cancer of the uterine endometrium (fundus or corpus), possibly because of increased lifespan and coexisting comorbidities. This cancer is the most frequently occurring gynecologic cancer in the United States. After breast, lung, and colorectal cancer, endometrial cancer is the fourth most common cancer in women. Most women are diagnosed after menopause, with only 15% diagnosed before age 50 (ACOG, 2019). Many women with endometrial cancer have obesity, which increases the risk of morbidity and mortality from this disease. Cumulative exposure to estrogen is considered the major risk factor (see Chart 51-7). This exposure occurs with the use of estrogen therapy without the use of progestin, early menarche, late menopause, nulliparity, and anovulation. Other risk factors include infertility, diabetes, and

the use of tamoxifen. Tamoxifen, which is taken for treatment or prevention of breast cancer, may cause proliferation of the uterine lining (ACOG, 2019). Women who take tamoxifen should be monitored by their oncologists and/or gynecologic health care providers.

Chart 51-7 RISK FACTORS

Uterine Cancer

- Age—usually >50 years; average age, 63 years
- Obesity that results in increased estrone levels (related to excess weight) resulting from conversion of androstenedione to estrone in body fat, which exposes the uterus to unopposed estrogen
- Unopposed estrogen therapy (estrogen used without progesterone, which offsets the risk of unopposed estrogen)
- Other—nulliparity, truncal obesity, early menarche, late menopause (after 52 years of age) and the use of tamoxifen

Adapted from American College of Obstetricians and Gynecologists. (2015, reaffirmed 2019). Practice Bulletin No. 149: Endometrial cancer. *Obstetrics and Gynecology*, *125*(4), 1006–1026.

Pathophysiology

Most uterine cancers are endometrioid (i.e., originating in the lining of the uterus). There are two types. Type 1, which accounts for about 90% of cases, is estrogen dependent. It is usually low grade with a favorable prognosis. Type 2, which occurs in about 10% of cases, is high grade and usually serous cell or clear cell. Type 2 is considered to be estrogen independent. Older and African American women are at higher risk for type 2 (ACOG, 2019; Casanova et al., 2019).

Assessment and Diagnostic Findings

All women should be encouraged to have annual checkups, including a gynecologic examination. Any woman who is experiencing irregular bleeding should be evaluated promptly. If a menopausal woman experiences bleeding, an endometrial aspiration or biopsy is performed to rule out hyperplasia, which is a possible precursor of endometrial cancer. The procedure is quick and usually not painful. Transvaginal ultrasound can also be used to measure the thickness of the endometrium (ACOG, 2019). (Women who are postmenopausal should have a very thin endometrium due to low levels of estrogen; a thicker lining warrants further investigation.) A biopsy or aspiration for tissue pathology is diagnostic.

Medical Management

Treatment for endometrial cancer consists of surgical staging, total or radical hysterectomy (discussed later in this chapter), and bilateral salpingo-oophorectomy and lymph node sampling. Laparoscopy or a robot-assisted laparoscopic surgery is less invasive than abdominal surgery (ACOG, 2019). Lymph node sampling and visualization of the peritoneum can be accomplished in many women in this manner. Cancer antigen 125 (CA-125) levels must be monitored, because elevated levels are a significant predictor of extrauterine disease or metastasis. Depending on the stage, the therapeutic approach is individualized and is based on stage, type, differentiation, degree of invasion, and node involvement. Radiation may be used in the form of external-beam radiation or vaginal brachytherapy (ACOG, 2019). Whole pelvis radiotherapy may be used if there is any spread beyond the uterus. Recurrent cancer usually occurs inside the vaginal vault or in the upper vagina, and metastasis usually occurs in lymph nodes or the ovary. Recurrent lesions in the vagina are treated with surgery and radiation. Recurrent lesions beyond the vagina are treated with hormonal therapy or chemotherapy. Progestin therapy is used frequently. Patients should be prepared for such side effects as nausea, depression, rash, or mild fluid retention with progestin therapy.

Cancer of the Vulva

Primary cancer of the vulva is rare, representing less than 1% of all cancers (Weinberg & Gomez-Martinez, 2019). It is most common in women who are postmenopausal, although its incidence in younger women is increasing. Possible risk factors include smoking, HPV infection, HIV infection, and immunosuppression. Squamous cell carcinoma accounts for most primary vulvar tumors. Less common are Bartholin gland cancer, vulvar sarcoma, and malignant melanoma. Little is known about what causes this disease; however, increased risk may be related to chronic vulvar irritation. In younger women, HPV infection may be implicated, especially types 16, 18, and 31. Prevention includes delaying onset of sexual activity to avoid early exposure to HPV, administration of the HPV vaccine, and avoidance of smoking. Regular pelvic examinations, Pap smears, and vulvar self-examination are helpful in early detection. Women with persistent irritation or itching should be encouraged to seek evaluation.

Clinical Manifestations

Vulvar cancers are rarely asymptomatic (Weinberg & Gomez-Martinez, 2019). Long-standing pruritus and soreness are the most common symptoms of vulvar cancer. Itching occurs in half of all patients with vulvar malignancy. Bleeding,

dysuria, foul-smelling discharge, and pain may also be present and are usually signs of advanced disease. Cancerous lesions of the vulva are visible and accessible and grow relatively slowly. Early lesions appear as a chronic dermatitis; later, patients may note a lump that continues to grow and becomes a hard, ulcerated, cauliflowerlike growth. Biopsy should be performed on any vulvar lesion that persists, ulcerates, or fails to heal quickly with proper therapy. Vulvar malignancies may appear as a lump or mass, redness, or a lesion that fails to heal.

Medical Management

Vulvar intraepithelial lesions are preinvasive and are also called *vulvar carcinoma in situ.* They may be treated by local excision, laser ablation, application of chemotherapeutic creams, or cryosurgery.

When invasive vulvar carcinoma exists, treatment may include wide excision of the vulva and **vulvectomy** (removal of the vulva). An effort is made to individualize treatment, depending on the extent of the disease. A wide excision is performed only if lymph nodes are normal. More pervasive lesions require vulvectomy with deep pelvic node dissection. Vulvectomy is very effective at prolonging life but is frequently followed by complications (i.e., scarring, wound breakdown, leg swelling, vaginal stenosis, or rectocele). To reduce complications, only necessary tissue is removed. External-beam radiation may be used, resulting in sunburnlike irritation that usually resolves in 6 to 12 months. Laser therapy and chemotherapy are other possible treatment options.

If a widespread area is involved or the disease is advanced, a radical vulvectomy with bilateral groin dissection may be performed. Antibiotic and heparin prophylaxis may be prescribed preoperatively and continued postoperatively to prevent infection, DVT, and PE. Sequential compression devices (SCDs) are applied to reduce the risk of venous thromboembolism (VTE).

Although the role of systemic chemotherapy in the treatment of vulvar cancer remains to be determined, chemotherapy may be helpful when used in combination with radiation therapy in treatment for advanced disease. The combination of radiation and chemotherapy may reduce the size of the cancer, resulting in less extensive subsequent surgery (Weinberg & Gomez-Martinez, 2019).

Clinical trials to determine the most effective treatment are difficult to conduct because there are few patients with this condition. Morbidity with recurrence of the disease is high, and patterns of recurrence vary. Reconstruction after vulvectomy is performed by plastic surgeons when appropriate and desired.

Nursing Management

Obtaining the Health History

The health history is a valuable tool for establishing rapport with the patient. The reason the patient is seeking health care is apparent. What the nurse can tactfully elicit is the reason a delay, if any, occurred in seeking health care—for example, because of modesty, economics, denial, neglect, or fear (partners who are abusive sometimes prevent women from seeking health care). Factors involved in any delay in seeking health care and treatment may also affect recovery. The patient's health habits and lifestyle are assessed, and her receptivity to education is evaluated. Psychosocial factors are also assessed. Preoperative preparation and psychological support begin at this time.

Providing Preoperative Care

Relieving Anxiety

Prior to surgery, the patient must be allowed time to talk and ask questions. Fear often decreases when a woman who is to undergo wide excision of the vulva or vulvectomy learns that the possibility for subsequent sexual relations is good. The nurse reinforces the information the surgeon has given to the patient and addresses the patient's questions and concerns.

Preparing Skin for Surgery

Skin preparation may include cleansing the lower abdomen, inguinal areas, upper thighs, and vulva with chlorhexidine for several days before the surgical procedure. The patient may be instructed to do this at home.

Providing Postoperative Care

Relieving Pain

Because of the wide excision, the patient may experience severe pain and discomfort even with minimal movement. Therefore, analgesic agents are given preventively (i.e., around the clock at designated times) to relieve pain, increase the patient's comfort level, and allow mobility. Patient-controlled analgesia (see Chapter 9) may be used to relieve pain and promote patient comfort. Careful positioning using pillows usually increases comfort, as do soothing backrubs. A low Fowler position or, occasionally, a pillow placed under the knees reduces pain by relieving tension on the incision; however, efforts must be made to avoid pressure behind the knees, which increases the risk of DVT. Positioning the patient on her side, with pillows between her legs and against the lumbar region, provides comfort and reduces tension on the surgical wound.

Improving Skin Integrity

A pressure-reducing mattress may be used to prevent pressure injuries. Moving from one position to another requires time and effort; the use of an overbed trapeze bar may help the patient move herself more easily. The extent of the surgical incision and the type of dressing are considered when choosing strategies to promote skin integrity. Intact skin needs to be protected from drainage and moisture. Dressings are changed as needed to ensure patient comfort, to perform wound care and irrigation (if prescribed), and to permit observation of the surgical site.

The wound is usually cleansed daily with warm, normal saline irrigations or other antiseptic solutions as prescribed, or a transparent dressing may be in place over the wound to minimize exposure to the air and subsequent pain. The appearance of the surgical site and the characteristics of drainage are assessed and documented. After the dressings are removed, a bed cradle may be used to keep the bed linens away from the surgical site.

Supporting Positive Sexuality and Sexual Function

The patient who undergoes vulvar surgery usually experiences concerns about body image, sexual attractiveness, and functioning. Establishing a trusting nurse–patient relationship is important for the patient to feel comfortable with expressing her concerns and fears. The patient is encouraged to discuss her concerns with her sexual partner as well.

Because alterations in sexual sensation and functioning depend on the extent of surgery, the nurse needs to know about any structural and functional changes resulting from the surgery. Referral of the patient and her partner to a sex counselor may help them address these changes and resume satisfying sexual activity.

Monitoring and Managing Potential Complications

Location, extent, and exposure of the surgical site and incision put the patient at risk for contamination of the site, infection, and sepsis. The patient is monitored closely for local and systemic signs and symptoms of infection: purulent drainage, redness, increased pain, fever, and increased white blood cell count. The nurse assists in obtaining specimens for culture if infection is suspected and administers antibiotic agents as prescribed. Hand hygiene—always a crucial infection-preventing measure—is of particular importance along with wearing masks whenever there is an extensive area of exposed tissue. Catheters, drains, and dressings are handled carefully with gloves on to avoid cross-contamination. A low-residue diet prevents straining on defecation and wound contamination.

The patient is at risk for complications of VTE, which include DVT and PE, because of the positioning required during surgery, postoperative edema, and the immobility needed to promote healing. SCDs are applied, and other

prophylactic measures may be prescribed for patients at high risk. The patient is encouraged and reminded to perform ankle exercises to minimize venous pooling, which leads to VTE. The patient is encouraged and assisted in changing positions by using the overbed trapeze bar. Pressure behind the knees is avoided when positioning the patient, because this may increase venous pooling. The patient is assessed for signs and symptoms of DVT (leg pain, redness, warmth, edema) and PE (chest pain, tachycardia, dyspnea). Fluid intake is encouraged to prevent dehydration, which also increases the risk of DVT.

The extent of the surgical incision and possibly wide excision of tissue increase the risk of postoperative bleeding and hemorrhage. Pressure dressings are applied after surgery to minimize this risk.

Quality and Safety Nursing Alert

The patient must be monitored closely for signs of hemorrhage and resulting hypovolemic shock. These signs may include decreased blood pressure; increased pulse rate; decreased urine output; decreased mental status; and cold, clammy skin.

If hemorrhage and shock occur, interventions include fluid replacement, blood component therapy, and vasopressor medications. Laboratory results (e.g., hematocrit and hemoglobin levels) and hemodynamic monitoring are used to assess the patient's response to treatment. Depending on the specific cause of hemorrhage, the patient may be returned to the operating room. See Chapter 11 for a detailed discussion of shock.

Promoting Home, Community-Based, and Transitional Care

Educating Patients About Self-Care

Preparing the patient for hospital discharge begins before hospital admission. The patient and family are informed about what to expect during the immediate postoperative and recovery periods. Depending on the changes resulting from the surgery, the patient and her family may need education about wound care, urinary catheterization, and possible complications. The patient is encouraged to share her concerns and to assume increasing responsibility for her own care. She is encouraged and assisted in learning to care for the surgical site. A referral for transitional, home, or community-based care is made as indicated.

Nurses are in an ideal position to educate women about performing regular vulvar self-examinations. Using a mirror, patients can see what constitutes

normal female anatomy and learn about changes that should be reported (e.g., lesions, ulcers, masses, persistent itching). Nurses must urge women to seek health care if they notice anything abnormal, because vulvar cancer is one of the most curable of all malignant conditions.

Continuing and Transitional Care

Patients may be discharged early in their postoperative recovery to home or a subacute facility. During this phase, the patient's physical status and psychological responses to the surgery are assessed. In addition, the patient is assessed for complications and healing of the surgical site. During home visits, the nurse assesses the home to determine if modifications are needed to facilitate care. The home visit is used to reinforce previous education and to assess the patient's and the family's understanding of and adherence to the prescribed treatment strategies. Follow-up phone calls by the nurse to the patient between home visits are usually reassuring to the patient and family, who may be responsible for performing complex care procedures. Attention to the patient's psychological responses is important because the patient may become discouraged and depressed because of alterations in body image and a slow recovery. Communication between the nurse involved in the patient's immediate postoperative care and the home health nurse is essential to ensure continuity of care.

Cancer of the Vagina

Cancer of the vagina is uncommon, representing 1% to 3% of gynecologic cancers; it is usually squamous in origin (Casanova et al., 2019). Malignant melanoma and sarcomas can occur. Most vaginal cancers are secondary and invasive at the time of diagnosis. Risk factors include previous cervical cancer, in utero exposure to diethylstilbestrol, previous vaginal or vulvar cancer, previous radiation therapy, history of HPV, or pessary use. Any patient with previous cervical cancer should be examined regularly for vaginal lesions.

Vaginal pessaries, which are used to support prolapsed tissues, can be a source of chronic irritation. As such, they have been associated with vaginal cancer, but only when the devices were not cared for properly (i.e., the device was not cleaned regularly or the patient did not return to the primary provider regularly for vaginal examinations).

Patients often do not have symptoms but may report slight bleeding after penile–vaginal intercourse, spontaneous bleeding, vaginal discharge, pain, and urinary or rectal symptoms (or both). Diagnosis is often by Pap smear. Encouraging close follow-up is the focus of nursing interventions with women who were exposed to diethylstilbestrol in utero. Emotional support for mothers

who received diethylstilbestrol before its risks were discovered and their daughters who were exposed to diethylstilbestrol in utero is essential.

Medical Management

Treatment of early lesions may include local excision, topical chemotherapy, or laser. Laser therapy is a common treatment option in early vaginal and vulvar cancer. Surgery for more advanced lesions depends on the size and the stage of the cancer. If radical vaginectomy is required, a vagina can be reconstructed with tissue from the intestine, muscle, or skin grafts. After vaginal reconstructive surgery and radiation, regular penile–vaginal intercourse may be helpful in preventing vaginal stenosis. Water-soluble lubricants are helpful in reducing dyspareunia.

Following surgery, radiation therapy may be given by a variety of methods, including external-beam radiation, which is usually an outpatient procedure, or brachytherapy, which is internal radiation therapy. Internal radiation may be given with intracavitary radioactive material contained in a seed, wire, needle, or tube, which is placed into a cavity such as the uterus or vagina. Interstitial radiation is another type of internal radiation treatment in which the radioactive material is placed in or near the cancer but not into a body cavity and is used in cervical and ovarian malignancies. These treatments may be high dose for a short period or low dose, which may take longer. Treatment during hospitalization or during outpatient therapy depends on several factors, including the status of the patient and the mode of delivery.

Cancer of the Fallopian Tubes

Malignancies of the fallopian tube are the least common type of genital cancer (ACS, 2019a). Although this type of cancer can occur at any age, it is most common in women who are postmenopausal. Symptoms are often minimal, causing diagnosis to be made at an advanced stage (Casanova et al., 2019). Symptoms include abdominal pain, abnormal bleeding, and vaginal discharge. An enlarged fallopian tube may be found on sonogram if dilated and fluid filled, or it may appear or be palpated as a mass. Surgery followed by radiation therapy is the usual treatment.

Cancer of the Ovary

Ovarian cancer is the leading cause of gynecologic cancer deaths in the United States, and the fifth deadliest cancer for women following lung, breast, colorectal, and pancreatic (Casanova et al., 2019; Stewart, Ralyea, &

Lockwood, 2019). Despite careful physical examination, ovarian tumors are often difficult to detect because they are usually deep in the pelvis. Often called the "Silent Killer," about 70% of ovarian cancers are not diagnosed until stage III or IV. Tumor-associated antigens are helpful in determining follow-up care after diagnosis and treatment and to evaluate for recurrent disease but are not useful in early general screening (Casanova et al., 2019).

Epidemiology

One in 70 women will develop ovarian cancer in her lifetime. The incidence of this type of cancer increases with age until 70 years, with most cases diagnosed by age 60 (Stewart et al., 2019). The frequency of ovarian cancer is highest in industrialized countries and affects women of all races and ethnic backgrounds.

Family history is the most significant risk factor. Most cases are random, but 8% to 13% of ovarian cancers are familial (Casanova et al., 2019). In most cases, the mutations are in the *BRCA1* gene and sometimes in the *BRCA2* gene. A family history in a first-degree relative (mother, daughter, or sister), older age, early menarche, late menopause, and obesity may increase the risk of ovarian cancer. However, most women who develop ovarian cancer have no known risk factors, and no definitive causative factors have been determined.

Patients with concerns about their family history should be referred to a cancer genetics center to obtain information and testing, if indicated (see Chapter 6). Women with inherited types of ovarian cancer tend to be younger when the diagnosis is made than the average age at the time of diagnosis. Hereditary non-polyposis colorectal cancer (HNPCC, also known as Lynch syndrome) increases the risk of ovarian cancer by 5% to 10% (Casanova et al., 2019). Lifetime risk of developing ovarian cancer has been shown to be decreased by 40% to 50% with long-term suppression (greater than 5 years) of ovulation through use of oral contraceptives (Stewart et al., 2019).

Pathophysiology

Types of tumors include germ cell tumors, which arise from the cells that produce eggs and are the most common cause of ovarian cancer in women younger than 20 years (Casanova et al., 2019); stromal cell tumors, which arise in connective tissue cells that produce hormones; and epithelial tumors, which originate from the outer surface of the ovary. Most ovarian cancers are epithelial in origin. Of the many different cell types in ovarian cancer, epithelial tumors constitute 90%. Germ cell and stromal tumors make up the other 10% (Casanova et al., 2019).

Primary peritoneal carcinoma is closely related to ovarian cancer. Extraovarian primary peritoneal carcinoma (EOPPC) resembles ovarian cancer

histologically and can occur in women with and without ovaries. Symptoms and treatment are similar. Because of the possibility of EOPPC, oophorectomy lessens the chance but does not guarantee that the patient will not develop carcinoma.

Clinical Manifestations

Symptoms of ovarian cancer are nonspecific and may include increased abdominal girth, pelvic pressure, bloating, back pain, constipation, abdominal pain, urinary urgency, indigestion, flatulence, increased waist size, leg pain, and pelvic pain. Symptoms are often vague, so many women tend to ignore them. Ovarian cancer is often silent, but enlargement of the abdomen from an accumulation of fluid is a common sign. All women with gastrointestinal symptoms without a known cause must be evaluated for potential ovarian cancer. Vague, undiagnosed, persistent gastrointestinal symptoms should alert the nurse to the possibility of an early ovarian malignancy. A palpable ovary in a woman who has gone through menopause is investigated immediately, because ovaries normally become smaller and less palpable after menopause.

Assessment and Diagnostic Findings

Any enlarged ovary must be investigated. Pelvic examination often does not detect early ovarian cancer, and pelvic imaging techniques are not always definitive. Ovarian tumors are classified as benign if there is no proliferation or invasion, borderline if there is proliferation but no invasion, and malignant if there is invasion. Of all new cases of ovarian tumors, 20% are classified as borderline and have low malignancy potential. However, by the time of diagnosis, most ovarian cancers are advanced (Casanova et al., 2019; Stewart et al., 2019).

Diagnostic test may include an MRI scan, transvaginal and pelvic ultrasound, chest x-rays, and a blood test for CA-125. An abdominal CT scan with and without contrast may be used to rule out metastasis (Casanova et al., 2019).

Medical Management

Surgical Management

Surgical staging, exploration, and reduction of tumor mass are the basics of treatment. Surgical removal is the treatment of choice. Staging the tumor by the FIGO staging system is performed to guide treatment (see Chart 51-8). Likely treatment involves a total abdominal hysterectomy with removal of the fallopian tubes and ovaries and possibly the omentum (bilateral salpingo-oophorectomy and omentectomy), tumor debulking, para-aortic and pelvic

lymph node sampling, diaphragmatic biopsies, random peritoneal biopsies, and cytologic washings. Postoperative management may include taxanes or platinum-based chemotherapy (discussed in the next section).

Chart 51-8

Main Stages of Ovarian Cancer

I. Cancer is contained within the ovary (or ovaries).
II. Cancer is in one or both ovaries and has involved other organs (i.e., uterus, fallopian tubes, bladder, the sigmoid colon, or the rectum) within the pelvis.
III. Cancer involves one or both ovaries, and one or both of the following are present: (1) cancer has spread beyond the pelvis to the lining of the abdomen; (2) cancer has spread to lymph nodes.
IV. The most advanced stage of ovarian cancer. Cancer is in one or both ovaries. There is distant metastasis to the liver, lungs, or other organs outside the peritoneal cavity; ovarian cancer cells in the pleural cavity are evidence of stage IV disease.

Adapted from Casanova, R., Chuang, A., Goepfert, A. R., et al. (Eds.). (2019). *Beckman and Ling's obstetrics and gynecology* (8th ed.). Philadelphia, PA: Wolters Kluwer.

Borderline tumors resemble ovarian cancer but have much more favorable outcomes. Women diagnosed with this type of cancer tend to be younger (early 40s). A conservative surgical approach is used. The affected ovary is removed, but the uterus and the contralateral ovary may remain in place. Adjuvant therapy may not be warranted.

Pharmacologic Therapy

Chemotherapy is usually administered IV on an outpatient basis using a combination of platinum and taxane agents. Paclitaxel plus carboplatin are most often used because of their excellent clinical benefits and manageable toxicity. Leukopenia, neurotoxicity, and fever may occur.

Because paclitaxel often causes leukopenia, patients may need to take granulocyte colony-stimulating factor as well. Paclitaxel is contraindicated in patients with hypersensitivity to medications formulated in polyoxyethylated castor oil and in patients with baseline neutropenia. Because of possible adverse cardiac effects, paclitaxel is not used in patients with cardiac disorders. Hypotension, dyspnea, angioedema, and urticaria indicate severe reactions that usually occur soon after the first and second doses are given. Nurses who administer chemotherapy are prepared to assist in treating anaphylaxis. Patients should be prepared for inevitable hair loss.

Carboplatin may be used in the initial treatment and in patients with recurrence. It is used with caution in patients with renal impairment. Usually,

six cycles are given. A positive clinical response is normalization of the tumor marker CA-125, negative CT results, and a normal physical and gynecologic examination.

Liposomal therapy, delivery of chemotherapy in a liposome, allows the highest possible dose of chemotherapy to the tumor target with a reduction in adverse effects. Liposomes are used as drug carriers because they are nontoxic, biodegradable, easily available, and relatively inexpensive. This encapsulated chemotherapy allows increased duration of action and better targeting. The encapsulation of doxorubicin lessens the incidence of nausea, vomiting, and alopecia. Patients must be monitored for bone marrow suppression and gastrointestinal and cardiac effects.

Combination IV and intraperitoneal chemotherapy is an option for some patients. However, this treatment is more toxic and side effects are more severe than regular chemotherapy (ACS, 2018). Intraperitoneal chemotherapy is reserved for women with good kidney function (ACS, 2018).

Genetic engineering and identification of cancer genes may make gene therapy a future possibility; gene therapy is under investigation. Emerging proteomic technologies (tissue-based protein analysis) look promising; they may allow earlier diagnosis and treatment decision making. New biomarkers need further validation, but protein signature patterns are now being tested. These technologies may result in individualized treatment strategies for epithelial ovarian cancer (ACS, 2018).

Recurrence of ovarian cancer is common, and many patients may require treatment with multiple agents. Treatment is directed toward control of the cancer, maintenance of quality of life, and palliation. Liposomal preparations, intraperitoneal drug administration, anticancer vaccines, monoclonal antibodies directed against cancer antigens, gene therapy, and antiangiogenic treatments (to prevent formation of new blood vessels in an effort to halt growth of ovarian cancer) may be used in the treatment for recurrence.

Nursing Management

Nursing measures involve those related to the patient's treatment plan, which may include surgery, chemotherapy, palliative care, or a combination of these. Nursing interventions after pelvic surgery to remove the tumor are similar to those after other abdominal surgeries. If ovarian cancer occurs in a young woman and the tumor is unilateral, it is removed. Childbearing, if desired, is encouraged in the near future. After childbirth, surgical re-exploration may be performed, and the remaining ovary may be removed. If both ovaries are involved, bilateral oophorectomy is performed and chemotherapy follows.

Patients with advanced ovarian cancer may develop ascites and pleural effusion. Nursing care may include administering IV fluids prescribed to alleviate fluid and electrolyte imbalances, administering parenteral nutrition to

provide adequate nutrition, providing postoperative care after intestinal bypass to alleviate any obstruction, controlling pain, and managing drainage tubes. Comfort measures for women with ascites may include providing small frequent meals, decreasing fluid intake, administering diuretic agents, and providing rest. Patients with pleural effusion may experience shortness of breath, hypoxia, pleuritic chest pain, and cough. Thoracentesis is usually performed to relieve these symptoms. The patient with ovarian cancer often has complex needs and benefits from the assistance and support of an oncology clinical nurse specialist.

Hysterectomy

Hysterectomy is the surgical removal of the uterus to treat cancer, dysfunctional uterine bleeding, endometriosis, nonmalignant growths, persistent pain, pelvic relaxation and prolapse, and previous injury to the uterus. Hysterectomies have been steadily declining over the last decade as the number of other therapeutic options (i.e., laser therapy, endometrial ablation, UAE, medications to shrink fibroid tumors) has increased (Morgan, Kamdar, Swenson, et al., 2017). Despite the decline in hysterectomies, it is still the second most common gynecologic procedure; 90% of all hysterectomies are for benign causes (ACOG, 2017d).

A total hysterectomy involves removal of the uterus and the cervix. Hysterectomy can be supracervical or subtotal, in which the uterus is removed but the cervix is spared. Radical hysterectomy involves removal of the uterus as well as the surrounding tissue, including the upper third of the vagina and pelvic lymph nodes. The procedure can be performed through the vagina, through an abdominal incision, or laparoscopically (in which the uterus is removed in sections through small incisions using a laparoscope). Malignant conditions usually require a total abdominal hysterectomy and bilateral salpingo-oophorectomy.

A laparoscopically assisted approach can also be used for vaginal hysterectomy. This procedure is performed as a short-stay procedure or ambulatory surgery in patients who are carefully selected. Robot-assisted hysterectomies are performed in more than 20% of cases, with similar outcomes compared to laparoscopic and vaginal methods at a higher cost (ACOG, 2017d).

Preoperative Management

Patients are advised to discontinue anticoagulant medications, NSAIDs such as aspirin, and vitamin E prior to surgery to reduce the risk of bleeding. Pregnancy is ruled out on the day of surgery. Prophylactic antibiotic agents

may be given prior to surgery and discontinued the next day. Prevention of thromboembolic events is critical, and methods depend on the risk profile of the patient.

Postoperative Management

The principles of general postoperative care for abdominal surgery apply. Major risks are infection and hemorrhage. In addition, because the surgical site is close to the bladder, voiding problems may occur, particularly after a vaginal hysterectomy. Edema or nerve trauma may cause temporary bladder atony (loss of bladder tone), and an indwelling catheter may be inserted.

NURSING PROCESS

The Patient Undergoing a Hysterectomy

Assessment

The health history and the physical and pelvic examination are completed, and laboratory tests are performed. Additional assessment data include the patient's psychosocial responses, because the need for a hysterectomy may elicit strong emotional reactions. If the hysterectomy is performed to remove a malignant tumor, anxiety related to fear of cancer and its consequences adds to the stress of the patient and her family. Women who have had a hysterectomy may be at risk for psychological and physical symptoms. Alternatively, women may note improved physical and mental health after hysterectomy as troublesome symptoms may be alleviated.

Diagnosis

Nursing Diagnoses

Based on the assessment data, major nursing diagnoses may include the following:

- Anxiety associated with the diagnosis of cancer, fear of pain, possible perception of loss of femininity or childbearing potential
- Disturbed body image associated with altered body function
- Acute pain associated with surgery and other adjuvant therapy
- Lack of knowledge of the perioperative aspects of hysterectomy and postoperative self-care

Collaborative Problems/Potential Complications

Potential complications may include the following:

- Hemorrhage
- VTE
- Bladder dysfunction
- Infection

Planning and Goals

The major goals may include relief of anxiety, acceptance of loss of the uterus, absence of pain or discomfort, increased knowledge of self-care requirements, and absence of complications.

Nursing Interventions

Relieving Anxiety

Anxiety stems from several factors: unfamiliar environment; the effects of surgery on body image and reproductive ability; fear of pain and other discomfort; and, possibly, feelings of embarrassment about exposure in the perioperative period. The nurse determines what the experience means to

the patient and encourages her to verbalize her concerns. Throughout the preoperative, postoperative, and recovery periods, explanations are given about physical preparations and procedures that are performed.

Improving Body Image

The patient may have strong emotional reactions to having a hysterectomy and personal feelings related to the diagnosis, views of significant others who may be involved (family, partner), religious beliefs, and fears about prognosis. Concerns such as the inability to have children and the effect on femininity may surface, as may questions about the effects of surgery on sexual relationships, function, and satisfaction. The patient needs reassurance that she will still have a vagina and that she can experience sexual activity after temporary postoperative abstinence while tissues heal. Information that sexual satisfaction and orgasm arise from clitoral stimulation rather than from the uterus reassures many women. Most women note some change in sexual feelings after hysterectomy, but they vary in intensity. In some cases, the vagina is shortened by surgery, and this may affect sensitivity or comfort.

When hormonal balance is upset, as often occurs with reproductive system disorders, the patient may experience depressed mood and heightened emotional sensitivity to people and situations. The nurse needs to approach and evaluate each patient individually in light of these factors. A nurse who exhibits interest, concern, and willingness to listen to the patient's fears will help the patient progress through the surgical experience.

Relieving Pain

Postoperative pain and discomfort are common. Therefore, the nurse assesses the intensity of the patient's pain and assists the patient with analgesia as prescribed. If the patient has abdominal distention or flatus, a rectal tube and application of heat to the abdomen may be prescribed. When abdominal auscultation reveals return of bowel sounds and peristalsis, additional fluids and a soft diet are permitted. Early ambulation facilitates the return of normal peristalsis.

Addressing Learning Needs

Patient education should address learning needs specific to the surgical procedure being performed. Research indicates that women undergoing robotic or laparoscopic surgeries have different learning needs (Kurt, Loerzel, Hines, et al., 2018). See the Nursing Research Profile in Chart 51-9.

Chart 51-9 NURSING RESEARCH PROFILE

Gynecologic Surgery Learning Needs

Kurt, G., Loerzel, V. W., Hines, R. B., et al. (2018). Learning needs of women who undergo robotic versus open gynecologic surgery. *Journal of Obstetric, Gynecologic, and Neonatal Nursing: JOGNN*, *47*(4), 490–497.

Purpose

The purpose of this study was to determine and compare the specific learning needs of women who undergo open gynecologic surgery via laparotomy or robotic surgery.

Design

The study used a descriptive exploratory design. The sample consisted of 226 women who underwent laparotomy (n = 71) or robotic surgery (n = 155) in one hospital. Participants were 18 years of age or older, able to speak, understand and read English or Spanish and scheduled for a laparotomy or robotic surgical procedure. Learning needs were measured using a 50-item patient learning needs scale (PLNS).

Findings

Study findings reported that at the time of discharge, participants in the robotic surgery group had significantly more learning needs overall on the PLNS, with means of 179.67 in the group that had robotic surgery compared to 159.66 in the group that had laparotomy ($p < 0.001$). Specifically, learning needs were greater in the topics of medications, activities of daily living, feelings related to condition, treatment and complications, skin care, and enhancing quality of life.

Nursing Implications

Nurses need to be proactive in educating women about postoperative care following robotic surgery for gynecologic conditions. Nurses caring for these women should consider providing education earlier in the surgical process, ideally prior to surgery. A learning needs assessment done prior to surgery will help the nurse develop an individualized education plan.

Patient education also addresses the outcomes of surgery, possible feelings of loss, and options for management of any symptoms that occur. Women vary in their preferences for information and participation in decision making, including choice of treatment options, accurate and useful information at the appropriate time, support from their health care providers, and access to professional and lay support systems.

Monitoring and Managing Potential Complications

HEMORRHAGE

Vaginal bleeding and hemorrhage may occur after hysterectomy. To detect these complications early, the nurse counts the perineal pads used or checks the incision site, assesses the extent of saturation with blood, and monitors vital signs. Abdominal dressings are monitored for drainage if an abdominal surgical approach has been used. In preparation for hospital discharge, the nurse gives prescribed guidelines for activity restrictions to promote healing and to prevent postoperative bleeding. Because many women may go home the day of surgery or within a day or two, they are instructed to contact the nurse or surgeon if bleeding is beyond what is expected, which should be minimal.

Venous Thromboembolism

Because of positioning during surgery, postoperative edema, and decreased activity postoperatively, the patient is at risk for DVT and PE. To minimize the risk, anti-embolism stockings are applied. In addition, the patient is encouraged and assisted to change positions frequently, although pressure under the knees is avoided, and to exercise her legs and feet while in bed. The nurse helps the patient ambulate early in the postoperative period. The nurse also assesses for DVT (leg pain, redness, warmth, edema) and PE (chest pain, tachycardia, dyspnea). If the patient is being discharged home soon after surgery, she is instructed to avoid prolonged sitting in a chair with pressure at the knees, sitting with crossed legs, and inactivity. Furthermore, she is instructed to contact her primary provider if symptoms of DVT or PE occur.

Bladder Dysfunction

Because of possible difficulty in voiding postoperatively, occasionally an indwelling catheter may be inserted before or during surgery and is left in place in the immediate postoperative period. If a catheter is in place, it is usually removed shortly after the patient begins to ambulate. After the catheter is removed, urinary output is monitored; additionally, the abdomen is assessed for distention. If the patient does not void within a prescribed time, measures are initiated to encourage voiding (e.g., assisting the patient to the bathroom, pouring warm water over the perineum). If the patient cannot void, catheterization may be necessary. On rare occasions, the patient may be discharged home with the catheter in place and is instructed in its management.

Promoting Home, Community-Based, and Transitional Care

Educating Patients About Self-Care. The information provided to the patient is tailored to her needs. She must know what limitations or restrictions, if any, to expect. She is instructed to check the surgical incision daily and to contact her primary provider if redness or purulent drainage or discharge occurs. She is reminded that her periods are now over but that she may have a slightly

bloody discharge for a few days; if bleeding recurs after this time, it should be reported immediately. The patient is educated about the importance of an adequate oral intake and of maintaining bowel and urinary tract function. The patient is informed that she is likely to recover quickly but that postoperative fatigue is not unusual.

The patient should resume activities gradually. This does not mean sitting for long periods, because doing so may cause blood to pool in the pelvis, increasing the risk of VTE. The nurse explains that showers are preferable to tub baths to reduce the possibility of infection and to avoid the dangers of injury that may occur when getting in and out of the bathtub. The patient is instructed to avoid straining, lifting, having penile–vaginal intercourse, or driving until permitted. Vaginal discharge, foul odor, excessive bleeding, any leg redness or pain, or an elevated temperature should be reported, and the nurse reinforces education regarding activities and restrictions.

Continuing and Transitional Care. Follow-up telephone contact provides the nurse with the opportunity to determine whether the patient is recovering without problems and to answer any questions that may have arisen. The patient is reminded about postoperative follow-up appointments. If the patient's ovaries were removed and she finds vasomotor symptoms troublesome, hormone therapy may be considered at a low dose for a short amount of time. The patient is reminded to discuss risks and benefits of hormone therapy and alternative therapies with her primary provider and gynecologic care provider. Decisions about use of hormone therapy need to be made individually in consultation with these providers.

Evaluation

Expected patient outcomes may include:

1. Experiences decreased anxiety
   a. Has improved body image
   b. Discusses changes resulting from surgery with her partner
   c. Verbalizes understanding of her disorder and the treatment plan
2. Displays minimal depression or anxiety
3. Experiences minimal pain and discomfort
   a. Reports relief of abdominal pain and discomfort
   b. Ambulates without pain
4. Verbalizes knowledge and understanding of self-care
   a. Practices deep-breathing, turning, and leg exercises as instructed
   b. Increases activity and ambulation daily
   c. Reports adequate fluid intake and adequate urinary output
   d. Identifies reportable symptoms

e. Schedules and keeps follow-up appointments

5. Absence of complications
   a. Has minimal vaginal bleeding and exhibits normal vital signs
   b. Ambulates early
   c. Notes no chest or calf pain and no redness, tenderness, or swelling in the extremities
   d. Reports no urinary problems or abdominal distention

Unfolding Patient Stories: Doris Bowman • Part 2

Recall from Chapter 12 Doris Bowman, who is undergoing a total abdominal hysterectomy with bilateral salpingo-oophorectomy. What are potential postoperative complications that the nurse should consider? What assessments and interventions are done by the nurse to monitor for early detection or to prevent these complications? Describe the discharge education provided by the nurse on self-care monitoring required of the patient at home and what should be reported to the health care provider.

Care for Doris and other patients in a realistic virtual environment: *vSim* (**thepoint.lww.com/vSimMedicalSurgical**). Practice documenting these patients' care in DocuCare (**thepoint.lww.com/DocuCareEHR**).

Radiation Therapy

Radiation may be used in the treatment of cervical, uterine, and less frequently in ovarian cancers either alone or in combination with surgery and chemotherapy. Several approaches are used to deliver radiation to the female reproductive system: external radiation, intraoperative radiation therapy (IORT), and internal (intracavitary) irradiation or brachytherapy (Smith & Jhingran, 2017). The cervix and uterus can serve as a receptacle for radioactive sources for internal radiation therapy.

Methods of Radiation Therapy

External Radiation Therapy

This method of delivering radiation destroys cancerous cells at the skin surface or deeper in the body. Other methods of delivering radiation therapy are more

commonly used to treat cancer of the female reproductive system than this method.

Intraoperative Radiation Therapy

IORT allows radiation to be applied directly to the affected area during surgery. An electron beam is directed at the disease site. This direct-view irradiation may be used when para-aortic nodes are involved or for unresectable (inoperable) or partially resectable neoplasms. Benefits include accurate beam direction (which precisely limits the radiation to the tumor) and the ability during treatment to block sensitive organs from radiation. IORT is usually combined with external-beam irradiation pre- or postoperatively.

Internal (Intracavitary) Irradiation

After the patient receives an anesthetic agent and an examination, specially prepared applicators are inserted into the endometrial cavity and vagina. These devices are not loaded with radioactive material until the patient returns to her room. X-rays are obtained to verify the precise relationship of the applicator to the normal pelvic anatomy and to the tumor. When this step is completed, the radiation oncologist loads the applicators with predetermined amounts of radioactive material. This procedure, called *afterloading,* allows for precise control of the radiation exposure received by the patient, with minimal exposure of physicians, nurses, and other health care personnel. A patient undergoing internal radiation treatment remains isolated in a private room until the application is completed. Adjacent rooms may need to be evacuated and a lead shield placed at the doorway to the patient's room.

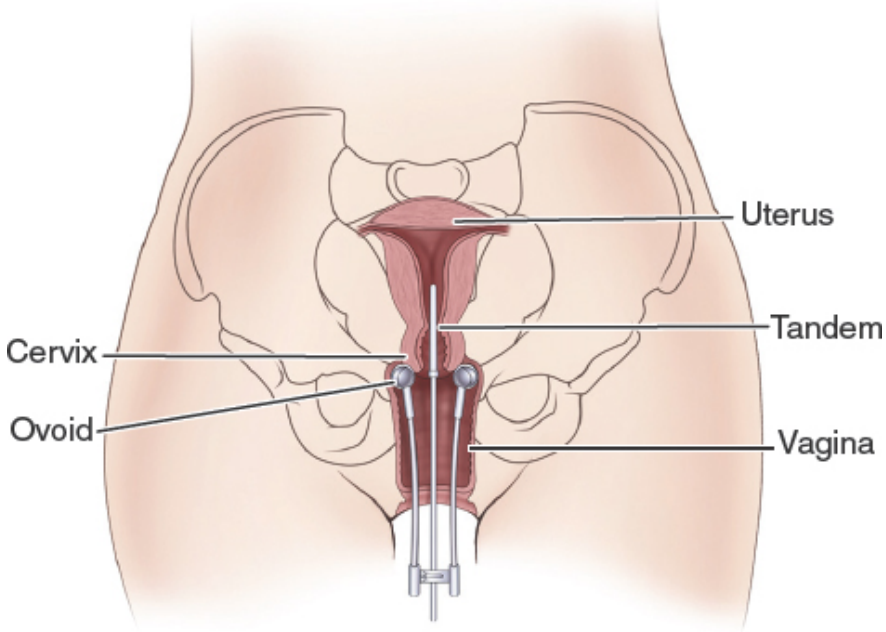

Figure 51-8 • Placement of tandem and ovoids for internal radiation therapy.

Of the various applicators developed for intracavitary treatment, some are inserted into the endometrial cavity and endocervical canal as multiple small irradiators (e.g., Heyman capsules). Others consist of a central tube (a tandem or intrauterine "stem") placed through the dilated endocervical canal into the uterine cavity, which remains in a fixed relationship with the irradiators placed in the upper vagina on each side of the cervix (vaginal ovoids) (see Fig. 51-8).

When the applicator is inserted, an indwelling urinary catheter is also inserted. Vaginal packing is inserted to keep the applicator in place and to keep other organs, such as the bladder and rectum, as far from the radioactive source as possible. The objective of the internal treatment is to maintain the distribution of internal radiation at a fixed dosage throughout the application, which may last 24 to 72 hours, depending on dose calculations made by the radiation physicist.

Automated high-dose rate intracavitary brachytherapy systems have been developed that allow outpatient radiation therapy. Treatment time is shorter, thereby decreasing patient discomfort. Staff exposure to radiation is also avoided. Isotopes of radium and cesium are used for intracavitary irradiation.

Nursing Considerations for Radiation Safety

Special precautions for the safety of the patient and the nurse are important considerations when the patient is receiving radiation therapy. The radiation safety department will identify specific safety precautions to those people who will be in contact with the patient, including health care providers and family.

Nursing concerns include providing the patient with emotional support and physical comfort. Further details about nursing management are provided in Chapter 12.

CRITICAL THINKING EXERCISES

1 ebp A 48-year-old woman with a diagnosis of fibroid tumors presents to the outpatient clinic with increased pain. What is the evidence base for medical and surgical treatment of fibroids? Specify the criteria used to evaluate the strength of the evidence for the practices you have identified.

2 pq Identify the priorities, approach, and techniques you would use to provide care for a 20-year-old woman who is being seen in an outpatient clinic for a new diagnosis of vulvovaginal infection. How will your priorities, approach, and techniques differ if the patient says she is not in a monogamous relationship? If the patient is from a culture with very different values from your own? Describe your priorities, approach, and techniques to prevent reinfection or spread of the infection.

3 ipc A 32-year-old woman has been admitted to your unit for a radical vulvectomy after a new diagnosis of vulvar cancer. Describe the preoperative education for her and the postoperative care that can be anticipated. What modifications in postoperative education and discharge planning may be necessary if the patient tells you she is a newlywed and is anxious about future sexual experiences? Describe how you will collaborate with her physician during her recovery process. What other professionals might you wish to include as part of her interdisciplinary care team?

52 Assessment and Management of Patients with Breast Disorders

LEARNING OUTCOMES

On completion of this chapter, the learner will be able to:

1. Describe the anatomy and physiology of the breast as well as identify the assessment and diagnostic studies used to diagnose breast disorders.
2. Compare and contrast the pathophysiology of benign and malignant breast disorders.
3. Summarize evidence-based guidelines for the early detection of breast cancer and develop a plan for educating patients and consumer groups about breast self-awareness.
4. Use the nursing process as a framework for care of the patient undergoing surgery for the treatment of breast cancer.
5. Recognize the physical, psychosocial, and rehabilitative needs of the patient who has had breast surgery for the treatment of breast cancer.

NURSING CONCEPTS

Assessment
Cellular Regulation
Comfort
Family
Infection
Inflammation
Mobility
Patient Education
Reproduction
Sexuality

GLOSSARY

adjuvant chemotherapy: the use of anticancer medications in addition to other treatments to delay or prevent a recurrence of the disease

adjuvant hormonal therapy: the use of synthetic hormones or other medications given after primary treatment to increase the chances of a cure by stopping or slowing the growth of certain cancers that are affected by hormone stimulation, also called endocrine or antiestrogen therapy

aromatase inhibitors: medications that block the production of estrogens by the adrenal glands

atypical hyperplasia: abnormal increase in the number of cells in a specific area within the ductal or lobular areas of the breast; this abnormal proliferation increases the risk for cancer

benign proliferative breast disease: various types of atypical, yet noncancerous, breast tissue that increase the risk of breast cancer

brachytherapy: delivery of radiation therapy through internal implants placed inside or adjacent to a tumor

***BRCA1* and *BRCA2*:** genes on chromosome 17 that, when damaged or mutated, increase a person's risk for breast or ovarian cancer compared with people without the mutation

breast conservation treatment: surgery to remove a breast tumor and a margin of tissue around the tumor without removing any other part of the breast; may or may not include lymph node removal and radiation therapy

dose-dense chemotherapy: administration of chemotherapeutic agents at standard doses with shorter time intervals between each cycle of treatment

ductal carcinoma in situ (DCIS): cancer cells starting in the ductal system of the breast but not penetrating surrounding tissue

fibrocystic breast changes: term used to describe certain benign changes in the breast, typically palpable nodularity, lumpiness, swelling, or pain

fine-needle aspiration (FNA): removal of fluid for diagnostic analysis from a cyst or cells from a mass using a needle and syringe

gynecomastia: firm, overdeveloped breast tissue typically seen in adolescent boys

HER-2/neu: a protein that, when found in larger amounts, indicates an aggressive tumor

lobular carcinoma in situ (LCIS): atypical change and proliferation of the lobular cells of the breast

lymphedema: chronic swelling of an extremity due to interrupted lymphatic circulation, typically from an axillary lymph node dissection

mammoplasty: surgery to reconstruct or change the size or shape of the breast; can be performed for reduction or augmentation

mastalgia: breast pain, usually related to hormonal fluctuations or irritation of a nerve

mastectomy: removal of the breast tissue and nipple–areola complex

mastitis: inflammation or infection of the breast

modified radical mastectomy: removal of the breast tissue, nipple–areola complex, and a portion of the axillary lymph nodes

Paget disease: form of breast cancer that begins in the ductal system and involves scaly changes in the nipple, areola, and surrounding skin

sentinel lymph node: first lymph node(s) in the lymphatic basin that receives drainage from the primary tumor in the breast; identified by a radioisotope or blue dye

stereotactic core biopsy: computer-guided method of core needle biopsy that is useful when masses or calcifications in the breast cannot be felt but can be visualized using mammography

surgical biopsy: surgical removal of all or a portion of a mass for microscopic examination by a pathologist

transverse rectus abdominal myocutaneous (TRAM) flap: method of breast reconstruction in which a flap of skin, fat, and muscle from the lower abdomen, with its attached blood supply, is rotated to the mastectomy site

Nurses care for patients with breast disorders in many settings. To care for these patients effectively, nurses require an understanding of the assessment, diagnostic testing, nursing management, and rehabilitation needs of patients with multiple processes that affect the breasts. A breast disorder, whether benign or malignant, can cause great anxiety and fear of potential disfigurement, loss of sexual attractiveness, and even death. Nurses, therefore, must have expertise in the assessment and management of not only the physical symptoms but also the psychosocial symptoms associated with various breast disorders.

BREAST ASSESSMENT

Anatomic and Physiologic Overview

Male and female breasts mature comparably until puberty, when estrogen and other hormones initiate breast development in females. This development usually occurs from 10 to 16 years of age, although the range can vary from 9 to 18 years. Stages of breast development are described as Tanner stages 1 through 5:

- Stage 1 describes a prepuberty breast.
  - Stage 2 is breast budding, the first sign of puberty in a female.
  - Stage 3 involves further enlargement of breast tissue and the areola (a darker tissue ring around the nipple).
  - Stage 4 occurs when the nipple and areola form a secondary mound on top of the breast tissue.
  - Stage 5 is the continued development of a larger breast with a single contour.

The breasts are located between the second and sixth ribs over the pectoralis muscle from the sternum to the midaxillary line. An area of breast tissue, called the *tail of Spence,* extends into the axilla (Bland, Copeland, & Klimberg, 2018). Fascial bands, called *Cooper ligaments,* support the breast on the chest wall. The inframammary fold (or crease) is a ridge of fat at the bottom of the breast.

Each breast contains 12 to 20 cone-shaped lobes, which are made up of glandular elements (lobules and ducts) and separated by fat and fibrous tissue that binds the lobes together. Milk is produced in the lobules and then carried through the ducts to the nipple. Figure 52-1 shows the anatomy of the fully developed breast.

Assessment

Breast assessment includes a targeted health history and physical examination.

Health History

When a patient presents with a breast problem, the nurse conducts a general health assessment, including history of medical disorders and previous surgery; family history of diseases, particularly cancer; gynecologic and obstetric history; present medications (including prescriptions, vitamins, and herbals); past and present use of hormonal contraceptives, hormone therapy (HT) (formerly referred to as hormone replacement therapy [HRT]), or fertility treatments; and social habits (e.g., smoking, drinking alcohol, illicit drug use). Psychosocial information, such as the patient's marital status, occupation, and availability of resources and support people, is obtained. Any recent x-rays or other diagnostic tests are noted. Focused questions pertaining to the breast disorder are asked concerning the onset of the disorder and the length of time it has been present. In addition, the patient is asked if any masses are palpable and if there is any associated pain, swelling, redness, nipple discharge, or change in the skin. Knowledge and comfort related to breast self-awareness, which can include breast self-examination (BSE), should also be ascertained from the patient.

Physical Assessment: Female Breast

A female breast examination can be conducted during any general physical or gynecologic examination or whenever the patient reports an abnormality. While the American Cancer Society (ACS) no longer recommends regular clinical breast examinations for average-risk women, this doesn't mean that the examination should never be performed. Providers may still examine women's breasts, offer education about breast awareness to all women, and women should get screening imaging based upon their risks (see later discussion) (American Cancer Society [ACS], 2019).

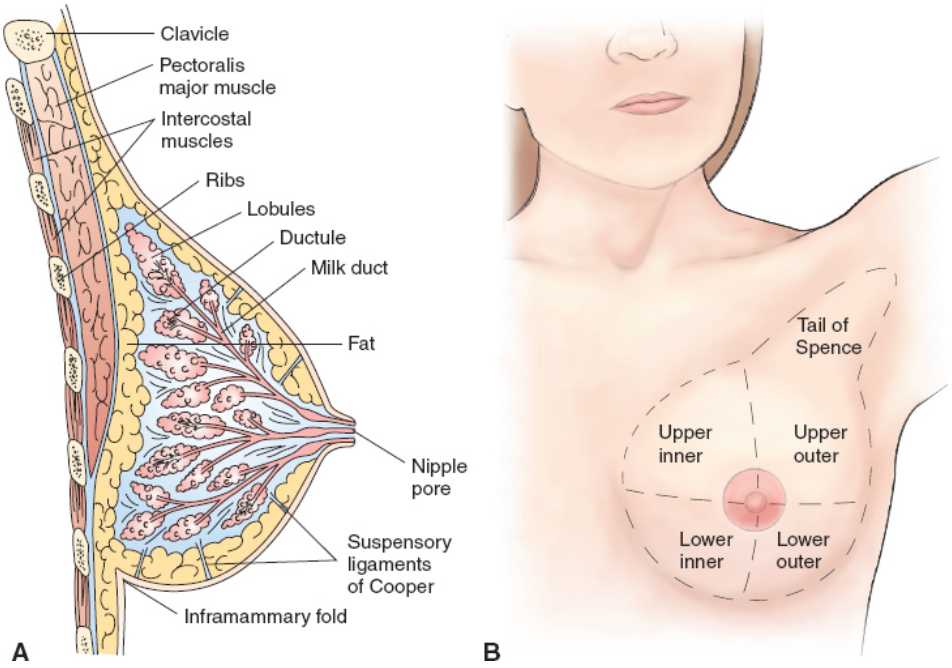

Figure 52-1 • **A.** Anatomy of the breast. **B.** Areas of breast, including the tail of Spence.

Inspection

Examination begins with inspection. The patient is asked to disrobe to the waist and sit in a comfortable position facing the examiner. The breasts are inspected for size and symmetry. A slight variation in the size of each breast is common and generally normal. The skin is

inspected for color, venous pattern, thickening, or edema. Erythema (redness) may indicate benign local inflammation or superficial lymphatic invasion by a neoplasm. A prominent venous pattern can signal increased blood supply required by a tumor. Edema and pitting of the skin may result from a neoplasm blocking lymphatic drainage, giving the skin an orange peel appearance; this is called peau d'orange—a classic sign of advanced breast cancer. Nipple inversion of one or both breasts is not uncommon and is significant only when of recent origin. Ulceration, rashes, or spontaneous nipple discharge requires evaluation. Examples of abnormal breast findings on inspection can be found in Chart 52-1.

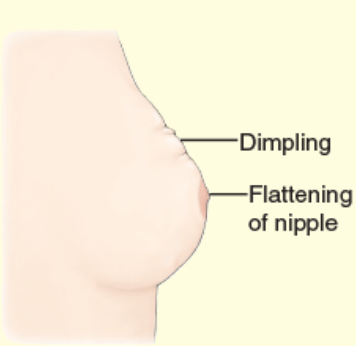
To elicit skin dimpling or retraction that may otherwise go undetected, the examiner instructs the patient to raise both arms overhead. This maneuver normally elevates both breasts equally. The patient is then instructed to place her hands on her waist and push in. These movements, which cause contraction of the pectoral muscles, do not normally alter the breast contour or nipple direction. Any dimpling or retraction during these position changes suggests an underlying mass. The clavicular and axillary regions are inspected for swelling, discoloration, lesions, or enlarged lymph nodes (Mallory & Golshan, 2018).

Palpation

The breasts are palpated with the patient upright (sitting up) and supine (lying down). In the supine position, the patient's shoulder is first elevated with a small pillow to help balance the breast on the chest wall. Failure to do this allows the breast tissue to slip laterally and a breast mass may be missed. The entire surface of the breast and the axillary tail is systematically palpated using the flat part (pads) of the second, third, and fourth fingertips, held together, making dime-size circles. The examiner may choose to proceed in a clockwise direction, following imaginary concentric circles from the outer limits of the breast toward the nipple. Other acceptable methods are to palpate from each number on the face of the clock toward the nipple in a clockwise fashion or along imaginary vertical lines on the breast (see Fig. 52-2).

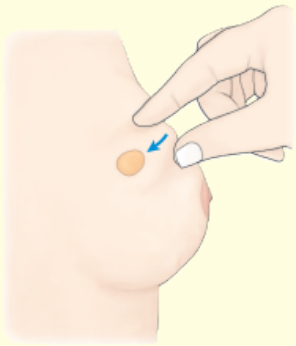
Palpation of the axillary and clavicular areas is easily performed with the patient seated (see Fig. 52-3). To examine the axillary lymph nodes, the examiner gently abducts the patient's arm from the thorax. With the left hand, the patient's right forearm is grasped and supported. The right hand is then free to palpate the axilla. Any lymph nodes that may be lying against the thoracic wall are noted. Normally, these lymph nodes are not palpable, but if they are enlarged, their location, size, mobility, and consistency are noted. During palpation, the examiner notes any patient-reported tenderness or masses. If a mass is detected, it is described by its location (e.g., right breast, 2 cm from the nipple at 2 o'clock position). Size, shape, consistency, border delineation, and mobility are included in the description (Mallory & Golshan, 2018). The examiner then modifies these steps to use the right hand to grasp the patient's left forearm, and then uses the left hand to palpate the axilla of the left breast.

The breast tissue of the adolescent is usually firm and lobular, whereas that of the postmenopausal woman is more likely to feel thinner and fattier. During pregnancy and lactation, the breasts are firmer and larger with lobules that are more distinct. Hormonal changes cause the areola to darken.



Obesity may have a proinflammatory effect on the breast that can contribute to increased rates of atypia. Atypia in breast ductal lavage and C-reactive protein levels in the nipple are significantly correlated with body mass index (BMI). Excessive body weight, as reflected by a BMI of 25 kg/m^2 or higher, is associated with postmenopausal breast cancer and increases the risk of dying of this disease; conversely, being overweight or having obesity seems to provide protection to women aged 40 to 49 (ACS, 2019).

Chart 52-1  ASSESSMENT



Abnormal Assessment Findings during Inspection of the Breasts

Retraction Signs

- Signs include skin dimpling, creasing, or changes in the contour of the breast or nipple
- They may be secondary to contraction of fibrotic tissue that can occur with underlying malignancy
- They may be secondary to scar tissue formation after breast surgery
- Retraction signs may appear only with position changes

Retraction signs

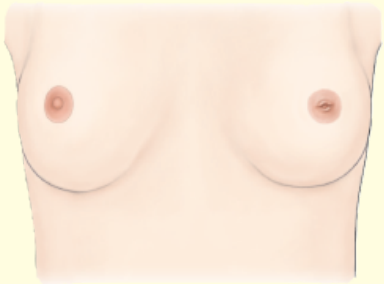
Retraction with compression

Increased Venous Prominence

- Unilateral localized increase in venous pattern associated with malignant tumors
- Normal with bilateral and symmetrical breast enlargement associated with pregnancy and lactation

Increased venous prominence

Peau d'Orange (Edema)

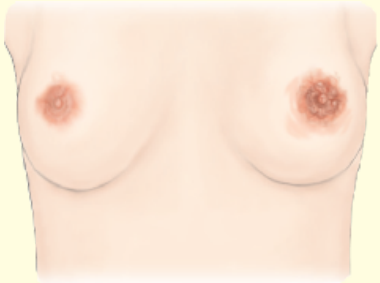


- Associated with inflammatory breast cancer
- Caused by interference with lymphatic drainage
- Breast skin has orange peel appearance
- Skin pores enlarge
- May be noted on the areola
- Skin becomes thick, hard, and immobile

Peau d'orange

Nipple Inversion

- Considered normal if long-standing
- Associated with fibrosis and malignancy if recent development



Nipple inversion

Acute Mastitis (Inflammation of the Breasts)

- Associated with lactation but may occur at any age
- Nipple cracks or abrasions noted
- Breast skin reddened and warm to touch
- Tenderness
- Systemic signs include fever and increased pulse

Paget Disease (Malignancy of Mammary Ducts)

- Early signs—erythema of nipple and areola
- Late signs—thickening, scaling, and erosion of the nipple and areola

Paget's disease

Adapted from Stanford Medicine 25. (2020). Breast exam. Retrieved on 5/13/2020 at: www.stanfordmedicine25.stanford.edu/the25/BreastExam.html and Newton, E., & Grethlein, S. (2018). Breast examination. Retrieved on 5/13/2020 at: https://emedicine.medscape.com/article/1909276-overview.

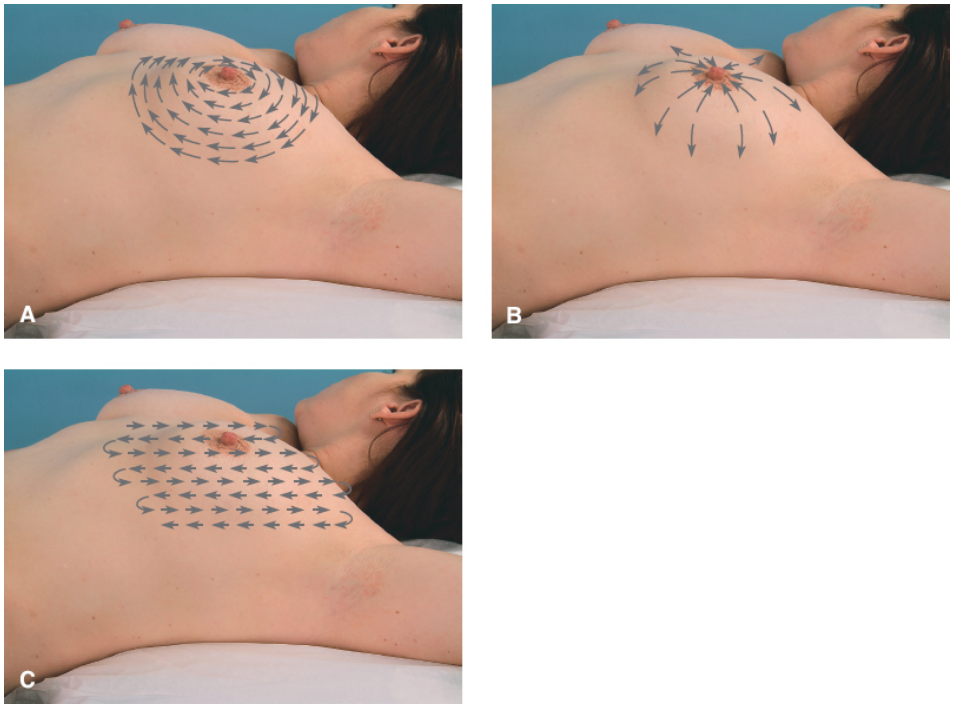


Figure 52-2 • Breast examination with the woman in a supine position. The entire surface of the breast is palpated from the outer edge of the breast to the nipple; palpation patterns are circular or clockwise (**A**), wedge (**B**), and vertical strip (**C**).

Cysts are commonly found in women who are menstruating and are usually well defined and freely movable. In the premenstrual period, cysts may be larger and more tender. Malignant tumors, on the other hand, tend to be hard, poorly defined, and nontender. A clinician should further evaluate any abnormalities detected during inspection and palpation.

Physical Assessment: Male Breast

Breast cancer can occur in men. Assessment of the male breast and axilla is brief but important and should be included in a physical examination. The nipple and areola are inspected for swelling, nodules, ulcerations, and nipple discharge. The flat disc of undeveloped breast tissue under the nipple is palpated. The same procedure for palpating the female breast is used to assess the male breast (Canadian Cancer Society, 2020).

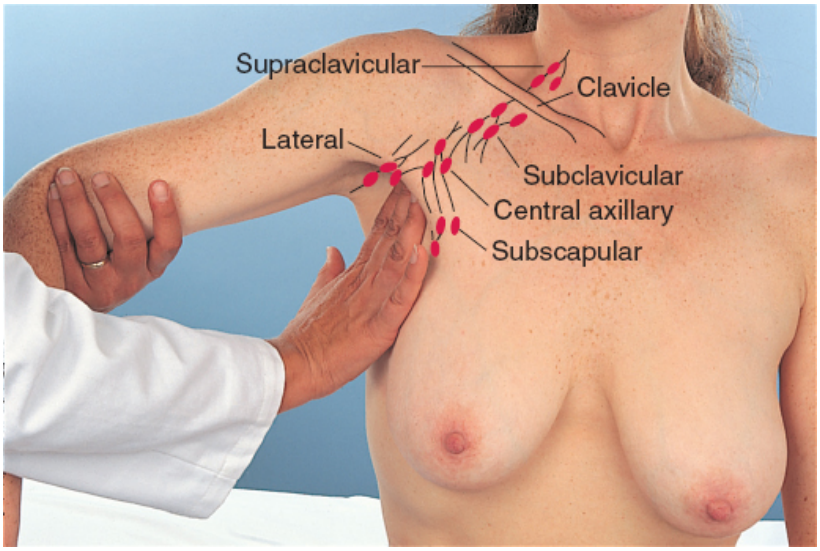

Figure 52-3 • Palpating axillary nodes in breast examination.

Gynecomastia is the firm enlargement of glandular tissue beneath and immediately surrounding the areola of the male (see later discussion). This is different from the enlargement of soft, fatty tissue, which is caused by obesity.

Diagnostic Evaluation

A wide range of diagnostic studies may be performed in patients with breast conditions. The nurse should educate the patient about the purpose, what to expect, and any possible side effects related to these examinations prior to testing. The nurse should note trends in the patient's test results, because they often provide information about disease progression as well as the patient's response to therapy.

Breast Self-Examination

The nurse plays a critical role in breast awareness education—a modality used for the early detection of breast cancer. BSE can be taught in a variety of settings, either on a one-to-one basis or in a group. It can also be initiated by a health care provider during a patient's routine physical examination. Regular self-examinations may result in early identification of problems and may also result in more diagnostic workups for benign or malignant problems.

Variations in breast tissue occur during the menstrual cycle, pregnancy, and the onset of menopause. Women on HT can also experience fluctuations. Normal changes must be distinguished from those that may signal disease. Most women notice increased tenderness and lumpiness before their menstrual periods; therefore, BSE is best performed after menses (day 5 to day 7, counting the first day of menses as day 1). In addition, many women have grainy-textured breast tissue, but such areas are usually less nodular after menses. Younger women may find BSE particularly difficult because of the density of their breast tissue. As women age, their breasts become fattier and may be easier to examine.

Current practice is shifting from educating about BSE to promoting breast self-awareness, which is a woman's attentiveness to the normal appearance and feel of her breasts. However, self-examination still may be appropriate for some women who are at high risk and for those who prefer it. Breast self-awareness can include self-examination. For every woman, knowing how her breasts normally feel helps detect any changes or signs of a problem. BSE

may play an important role in screening, especially for women who develop cancer in the interval after a negative result on mammography or clinical breast examination or who have a false-negative imaging or clinical examination result. It can also promote detection in women who have not been screened. The goal, with or without BSE, is to report any breast changes to a primary provider.

Family history can increase the risk of breast cancer in men, particularly if other men in the family have had breast cancer. The risk is also higher if there is a breast cancer gene abnormality in the family. *BRCA2* mutations are much more common than *BRCA1* mutations in males (Jain & Gradishar, 2018). Instructions about BSE should be provided to men if they have a family history of breast cancer.

Patients who elect to perform BSE should receive proper instruction on technique (see Chart 52-2). They should be informed that routine, monthly BSE will help them become familiar with their "normal abnormalities." If a change is detected, they should seek medical attention.

Patients should be instructed about optimal timing for BSE (5 to 7 days after menses begin for women who are premenopausal and once monthly for women who are postmenopausal or not menstruating). When demonstrating examination techniques, the feel of normal breast tissue should be reviewed and ways to identify breast changes discussed. Patients should then perform a BSE demonstration on themselves or on a breast model. Patients who have had breast cancer surgery should be instructed to examine their breast or chest wall for any new changes or nodules that may indicate a recurrence of the disease.

Mammography

The ACS has changed the mammography recommendations to state that healthy women should have mammography every year beginning at age 45; women aged 40 to 44 have the option to begin yearly screening early (ACS, 2019). Women 55 and older may continue yearly screening or transition to every 2 years. This change was based on calculations that starting annual screening mammography later and getting it less often would cause less harm and be as safe as starting it earlier and getting it more often. Screening every other year may, however, result in a missed diagnosis and a small increase in the probability of being diagnosed with later-stage cancer.

Mammography is a breast imaging technique using a low-dose x-ray system to visualize the anatomy of the breasts; this aids in the early detection and diagnosis of malignant or benign disease (American College of Radiology [ACR], 2019). The procedure takes about 30 minutes and can be performed in a hospital radiology department or independent imaging center. Two views are taken of each breast. The breast is mechanically compressed from top to bottom (craniocaudal view) (see Fig. 52-4) and side to side (mediolateral oblique view). Women may experience some discomfort because maximum compression is necessary for proper visualization. The new mammogram is compared with previous mammograms, and any changes may indicate a need for further investigation. Mammography may detect a breast tumor before it is clinically palpable. Younger women, or those taking HTs, may have dense breast tissue, making it more difficult to detect lesions with mammography.

Patients scheduled for a mammogram may voice concern about exposure to radiation. The radiation exposure is equivalent to about 7 weeks of natural background radiation exposure (ACR, 2019), so patients would have to have many mammograms in a year to increase their cancer risk. To ensure that a mammogram is reliable, it is important that a woman find a reputable facility. Mammographic facilities are certified by the U.S. Food and Drug Administration (FDA), and the machines are accredited by either the American College of Radiology or the States of Arkansas, Iowa or Texas (U.S. Food and Drug Administration [FDA], 2018).

Additional techniques for breast screening include digital mammography and 3D mammography. Digital mammography records x-ray images on a computer instead of on film, thus allowing radiologists to adjust the contrast and focus on an image without having to take additional x-rays. Although the accuracy of both film and digital screening mammography is similar for most women, digital mammography has been shown to be better at detecting estrogen receptor–negative tumors and cancer in extremely dense breasts. Both of these subgroups are more common in younger women, who may therefore choose digital mammography if they wish to have screening mammography. The 3D mammography obtains multiple projections of the compressed breast and results in lower false-positive interpretation rates and improved cancer detection rates (Bassett & Lee-Felker, 2018). Computer-aided detection (CAD) is an option for radiologists and can be helpful in finding abnormal areas that should be checked more closely for early cancers. Refinements and improvements have been made to CAD software with a focus on increasing sensitivity for masses and reducing false-positive rates.

Contrast Mammography

A contrast mammography (i.e., ductogram, galactogram) is a diagnostic procedure that involves injection of less than 1 mL of radiopaque material through a cannula inserted into a ductal opening on the areola, which is followed by a mammogram (Bassett & Lee-Felker, 2018). It is performed to evaluate an abnormality within the duct when the patient has bloody nipple discharge on expression, spontaneous nipple discharge, or a solitary dilated duct noted on mammography.

Ultrasonography

Ultrasonography (ultrasound) is used as a diagnostic adjunct to mammography to help distinguish fluid-filled cysts from other lesions. A thin coating of lubricating jelly is spread over the area to be imaged. A transducer is then placed on the breast. The transducer transmits high-frequency sound waves through the skin toward the area of concern. The sound waves are reflected back from a two-dimensional image, which is then displayed on a computer screen. No radiation is emitted during the procedure. Ultrasound is also used as an adjunct to mammography in women with dense breast tissue. Ultrasound may be used as an aid for interventional procedures.

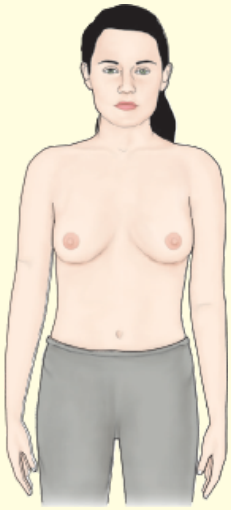

Chart 52-2  **PATIENT EDUCATION**

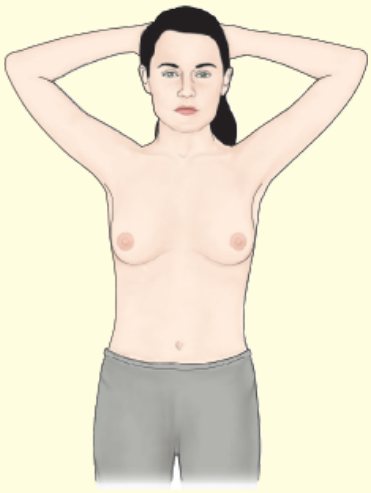
Breast Self-Examination

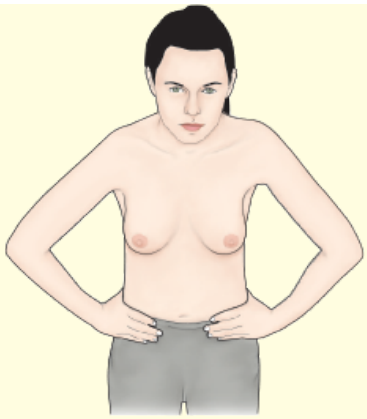
The nurse instructs the patient to perform the following steps:

Step 1



1. Stand in front of a mirror.
2. Check both breasts for anything unusual.
3. Look for discharge from the nipple, puckering, dimpling, or scaling of the skin.

Step 2



Steps 2 and 3 are done to check for any changes in the contour of your breasts. As you do them, you should be able to feel your muscles tighten.

1. Watch closely in the mirror as you clasp your hands behind your head and press your hands forward.
2. Note any change in the contour of your breasts.

Step 3

1. Next, press your hands firmly on your hips and bow slightly toward the mirror as you pull your shoulders and elbows forward.
2. Note any change in the contour of your breasts.

Step 4

Some women do step 4 of the examination in the shower. Your fingers will glide easily over soapy skin, so you can concentrate on feeling for changes inside the breast.

1. Raise your left arm.
2. Use three or four fingers of your right hand to feel your left breast firmly, carefully, and thoroughly.
3. Beginning at the outer edge, press the flat part of your fingers in small circles, moving the circles slowly around the breast.
4. Gradually work toward the nipple.
5. Be sure to cover the whole breast.
6. Pay special attention to the area between the breast and the underarm, including the underarm itself.
7. Feel for any unusual lumps or masses under the skin.
8. If you have any spontaneous discharge during the month—whether or not it is during your breast self-examination—see your primary provider.
9. Repeat the examination on your right breast.

Step 5

Step 4 should be repeated lying down.

1. Lie flat on your back with your left arm over your head and a pillow or folded towel under your left shoulder. (This position flattens your breast and makes it easier to check.)
2. Use the same circular motion described earlier.
3. Repeat on your right breast.

Adapted from Boraas, M., & Gupta, S. (2019). Breast self-exam. Retrieved on 5/14/2020 at: www.breastcancer.org/symptoms/testing/types/self_exam

Ultrasonography has advantages and disadvantages. Although it can diagnose cysts with great accuracy, it cannot definitively rule out malignant lesions. Microcalcifications, which are detectable on mammography, cannot be identified on ultrasonography. Finally, examination techniques and interpretation criteria are not standardized.

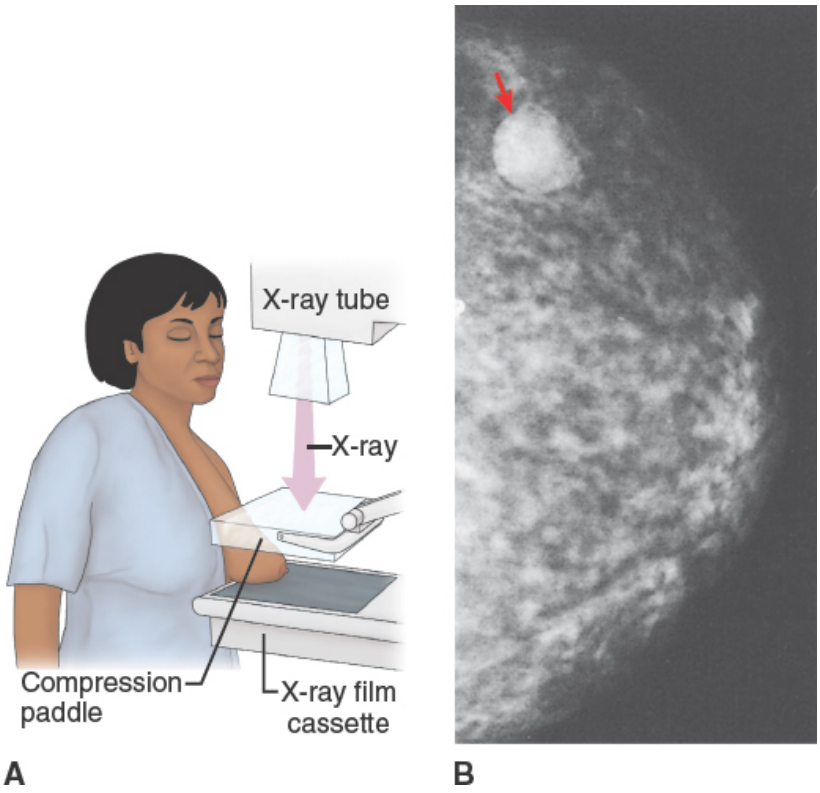


Figure 52-4 • The mammography procedure (**A**) relies on x-ray imaging to produce the mammogram (**B**), which in this case reveals a breast lump (see *arrow*).

Magnetic Resonance Imaging

Magnetic resonance imaging (MRI) of the breast is a highly sensitive test that has become a useful diagnostic adjunct to mammography. A magnet is linked to a computer that creates detailed images of the breast without exposure to radiation. An intravenous (IV) injection of gadolinium, a contrast dye, is given to improve visibility. The patient lies face down, and the breast is placed through a depression in the table. A coil is placed around the breast, and the patient is placed inside the MRI machine. The entire procedure takes about 30 to 40 minutes.

Breast MRI is useful for evaluation of contralateral disease, invasive lobular carcinoma, and assessment of chemotherapeutic response. Additionally, screening guidelines provided by the National Comprehensive Cancer Network (NCCN) recommend an annual MRI scan in addition to mammography in women at high risk for breast cancer (i.e., those with greater than 20% lifetime risk). Candidates include women who have a *BRCA1* or *BRCA2* mutation, a first-degree relative with either of these mutations, certain rare genetic syndromes, or radiation to the chest between 10 and 30 years of age (National Comprehensive Cancer Network [NCCN], 2019). MRI should be used in addition to mammography, not instead of it.

Some disadvantages of MRI include high cost, variations in technique and interpretation, and the potential for patient claustrophobia. The procedure cannot always accurately distinguish between malignant and benign breast conditions, so false-positive results may occur. MRI is contraindicated in patients with implantable metal devices (e.g., aneurysm clips, ports of tissue expanders). Patients with any type of cardiac implantable electronic device need to be screened to see if it is safe for them to undergo an MRI (Indik, Gimbel, Abe, et al., 2017). Foil-backed medication patches (e.g., nicotine, nitroglycerin, fentanyl) must be removed prior to MRI to avoid burns to the skin.

Procedures for Tissue Analysis

Percutaneous Biopsy

Percutaneous biopsy is performed on an outpatient basis to sample palpable and nonpalpable lesions. Less invasive than a surgical biopsy, percutaneous biopsy is a needle or core biopsy that obtains tissue by making a small puncture in the skin. Table 52-1 outlines the different types of biopsies that can be performed to obtain a tissue diagnosis.

Concept Mastery Alert

It is important to understand the differences between common procedures used for patients with breast disorders. Mammography is used to detect breast abnormalities, whereas biopsy is performed to confirm a diagnosis of breast cancer.

TABLE 52-1 Types of Breast Biopsies

Procedure	Palpable Mass	Health Professional Who Performs Procedure	Nature of Breast Tissue Removed
Fine-needle aspiration	Yes	Surgeon	Cellular material
Core needle biopsy	Yes	Surgeon	Tissue core
Stereotactic core biopsy	No	Radiologist	Tissue core
Ultrasound-guided core biopsy	No	Radiologist	Tissue core
Magnetic resonance imaging (MRI)-guided core biopsy	No	Radiologist	Tissue core
Excisional biopsy	Yes	Surgeon	Entire mass
Incisional biopsy	Yes	Surgeon	Tissue core
Wire needle localization biopsy; may be guided by mammogram, ultrasound, or MRI	No	Radiologist inserts wire; surgeon performs biopsy	Entire mass

Fine-Needle Aspiration

Fine-needle aspiration (FNA) is a biopsy technique that is generally well tolerated by most women. A local anesthetic may or may not be used. A small-gauge needle (20- to 27-gauge) attached to a syringe is inserted into the mass or area of nodularity. Suction is applied to the syringe, and multiple passes are made through the mass. A simple cyst often disappears on aspiration, and the fluid is usually discarded if it is nonbloody. If the material is bloody, however, it most likely indicates malignancy and should be sent for cytology; this is performed either directly as a smear or after the fluid is centrifuged (Obeng-Gyasi, Grimm, Hwang, et al., 2018). For nonpalpable masses, the same procedure can be performed by a radiologist using ultrasound guidance (ultrasound-guided FNA).

FNA is less expensive than other diagnostic methods, and results are usually available quickly. However, false-negative or false-positive results are possible, and appropriate follow-up depends on the clinical judgment of the treating physician.

Core Needle Biopsy

Core needle biopsy is similar to FNA, except that a larger-gauge needle is used (usually 11- to 18-gauge). A local anesthetic is applied, and tissue cores are removed via a spring-loaded device. This procedure allows for a more definitive diagnosis than FNA, because actual tissue, not just cells, is removed. It is often performed for relatively large tumors that are close to the skin surface, but is also utilized for smaller, deeper lesions that are visible on ultrasound.

Stereotactic Core Biopsy

Stereotactic core biopsy is performed on nonpalpable lesions detected by mammography. The patient lies prone on the stereotactic table. The breast is suspended through an opening in the table and compressed between two x-ray plates. Images are then obtained using digital mammography. The exact coordinates of the lesion to be sampled are located with the aid of a computer. Next, a local anesthetic is injected into the entry site on the breast. A small nick is made in the skin, a core needle is inserted, and samples of the tissue are taken for pathologic examination. Often, several passes are taken to ensure that the lesion is well sampled. Postbiopsy images are then taken to check that sampling has been adequate. A small titanium clip is almost always placed at the biopsy site so that the site can easily be located if further treatment is indicated (Obeng-Gyasi et al., 2018). Stereotactic biopsy is quite accurate and often allows the patient to avoid a surgical biopsy. However, there is a small false-negative rate. Appropriate follow-up depends on the final pathologic diagnosis and the clinical judgment of the primary provider. The use of a titanium clip does not preclude subsequent MRIs.

Ultrasound-Guided Core Biopsy

The principles for ultrasound-guided core biopsy are similar to those of stereotactic core biopsy, but by using ultrasound guidance, computer coordination and mammographic compression are not necessary. An ultrasound-guided core biopsy does not use radiation and is also usually faster and less expensive than stereotactic core biopsy.

Magnetic Resonance Imaging–Guided Core Biopsy

MRI-guided core biopsy can be performed by a radiologist and technologist when the abnormal area in the breast is too small to be felt but is visible on MRI.

Surgical Biopsy

Surgical biopsy is usually performed using local anesthesia and IV sedation. After an incision is made, the lesion is excised and sent to a laboratory for pathologic examination.

Surgical biopsy is usually preceded by a core biopsy or stereotactic biopsy for pathologic determination.

Types of Surgical Breast Biopsy

There are several types of procedures used for a surgical breast biopsy including an excisional or incisional biopsy, and a wire needle localization.

Excisional Biopsy

Excisional biopsy is the standard procedure for complete pathologic assessment of a palpable breast mass. The entire mass, plus a margin of surrounding tissue, is removed. This type of biopsy may also be referred to as a lumpectomy. Depending on the clinical situation, a frozen-section analysis of the specimen may be performed at the time of the biopsy by the pathologist, who does an immediate reading intraoperatively and provides a provisional diagnosis. This can help confirm a diagnosis in a patient who has had no previous tissue analysis performed.

Incisional Biopsy

Incisional biopsy surgically removes a portion of a mass. This is performed to confirm a diagnosis and to conduct special studies (e.g., ER/PR, HER-2/neu [also referred to as ERBB2]; see later discussion for explanation of these terms) that will aid in determining treatment, which is discussed later in this chapter. Complete excision of the area may not be possible or immediately beneficial to the patient, depending on the clinical situation. This procedure is often performed on women with locally advanced breast cancer or on women with suspected cancer recurrence, whose treatment may depend on the results of these special studies. However, pathologic information may be easily obtained from core needle biopsy, and incisional biopsy is becoming less common.

Wire Needle Localization

Wire needle localization is a technique used to locate nonpalpable masses or suspicious calcium deposits detected on a mammogram, ultrasound, or MRI that require an excisional biopsy. The radiologist inserts a long, thin wire through a needle, which is then inserted into the area of abnormality using x-ray or ultrasound guidance (whichever imaging technique originally identified the abnormality). The wire remains in place after the needle is withdrawn to ensure the precise location. The patient is then taken to the operating room, where the surgeon follows the wire to the tip and excises the area.

Nursing Implications

During the preoperative or preprocedure visit, the nurse assesses the patient for any specific educational, physical, or psychosocial needs. This can be accomplished by reviewing the medical and psychosocial history and encouraging the patient to verbalize fears, concerns, and questions. Patients are often worried not only about the procedure but also about the potential implications of the pathology results. Providing a thorough explanation about what to expect in a supportive manner can help alleviate anxiety. Patients often have difficulty absorbing all the information given to them; therefore, written materials to take home are often provided to reinforce and clarify education.

The nurse instructs the patient to discontinue any agents that can increase the risk of bleeding, including products containing aspirin, nonsteroidal anti-inflammatory drugs, vitamin E supplements, herbal substances (such as ginkgo biloba and garlic supplements). Patients on prescription anticoagulants need to check with the prescriber prior to temporary cessation for the procedure, as biopsies done without cessation of these drugs can result in prolonged bleeding and hematomas. The patient may be instructed not to eat or drink for several hours prior to the procedure or after midnight the night before the procedure,

depending on the type of biopsy and anesthesia planned. Most breast biopsy procedures are performed with the use of the combination of sedation and local anesthesia.

Immediate assessment after the procedure includes monitoring the effects of the anesthesia and inspecting the surgical dressing for any signs of bleeding. Once the sedation has worn off, the nurse reviews the care of the biopsy site, pain management, and activity restrictions with the patient. Prior to discharge from the ambulatory surgical center or the office, the patient must be able to tolerate fluids, ambulate, and void. The patient must be accompanied home by an adult. The dressing covering the incision is usually removed after 48 hours, but the Steri-Strips, which are applied directly over the incision, should remain in place for approximately 7 to 10 days or until they fall off. The use of a supportive bra following surgery is encouraged to limit movement of the breast and reduce discomfort. A follow-up telephone call from the nurse 24 to 48 hours after the procedure can provide the patient with the opportunity to ask any questions and can be a source of great comfort and reassurance.

Most women return to their usual activities the day after the procedure but are encouraged to avoid jarring or high-impact activities for 1 week to promote healing of the biopsy site. Discomfort is usually minimal, and most women find acetaminophen sufficient for pain relief, although a mild opioid analgesic agent may be prescribed if needed.

Follow-up after the biopsy includes a return visit to the surgeon for discussion of the final pathology report and assessment of the healing of the biopsy site. Depending on the results of the biopsy, the nurse's role varies. If the pathology report is benign, the nurse reviews incision care and explains what the patient should expect as the biopsy site heals (i.e., changes in sensation may occur weeks or months after the biopsy due to nerve injury within the breast tissue). If a diagnosis of cancer is made, the nurse's role changes dramatically. This is discussed in depth later in this chapter.

CONDITIONS AFFECTING THE NIPPLE

Nipple Discharge

Nipple discharge in a woman who is not lactating may be related to many causes, such as carcinoma, papilloma, pituitary adenoma, cystic breasts, and various medications. Oral contraceptives, pregnancy, HT, chlorpromazine, and frequent breast stimulation may be contributing factors. In some women, nipple discharge may occur during running or aerobic exercises. Nipple discharge should be evaluated by a health care provider, but it is not often a cause for alarm. One in three women has clear discharge on expression, which is usually normal. A green discharge could indicate an infection. Any discharge that is spontaneous, persistent, or unilateral is of concern. Although bloody discharge can indicate a malignancy, it is often caused by a benign wartlike growth on the lining of the duct called an *intraductal papilloma.*

Nipple discharge should be evaluated for the presence of occult (hidden) blood by performing a guaiac test. A negative test can be reassuring as it indicates that there is no blood, but it does not prove there is no malignancy. A galactogram can also be performed to detect abnormalities within the duct that may be causing the discharge. If there is a high level of suspicion, an excisional biopsy may be indicated. (See procedures for tissue analysis earlier in this chapter.)

Fissure

A fissure is a longitudinal ulcer that may develop in women who are breast-feeding. If the nipple becomes irritated, a painful, raw area may form and become a site of infection. Daily washing with water, massage with breast milk or lanolin, and exposure to air are helpful. Breast-feeding can continue with the use of a nipple shield. However, if the fissure is severe or extremely painful, the woman may be advised to stop breast-feeding. A breast pump can be used until breast-feeding can be resumed. Persistent ulceration requires further diagnosis and therapy. Guidance from a nurse or lactation consultant may be helpful, because nipple irritation can result from improper positioning or poor latching on (i.e., the infant has not grasped the areola fully) during breast-feeding.

BREAST INFECTIONS

Mastitis

Mastitis, an inflammation or infection of breast tissue, occurs most commonly in women who are breast-feeding, although it may also occur in women who are nonlactating. The infection may result from a transfer of microorganisms to the breast by the patient's hands or from a breast-fed infant with an oral, eye, or skin infection. Mastitis may also be caused by bloodborne organisms. As inflammation progresses, the breast texture becomes tough or doughy, and the patient complains of dull to severe pain in the infected region. A nipple that is discharging purulent material, serum, or blood should be investigated promptly.

Treatment consists of antibiotics and local application of cold compresses to relieve discomfort. A broad-spectrum antibiotic agent may be prescribed for 7 to 10 days. The patient should wear a snug bra and perform personal hygiene carefully. Adequate rest and hydration are important aspects of management.

Lactational Abscess

A breast abscess may develop as a consequence of acute mastitis. The area affected becomes tender and red. Purulent matter can usually be aspirated with a needle, but incision and drainage may be required. Specimens of the aspirated material are obtained for culture so that an organism-specific antibiotic agent can be prescribed.

BENIGN CONDITIONS OF THE BREAST

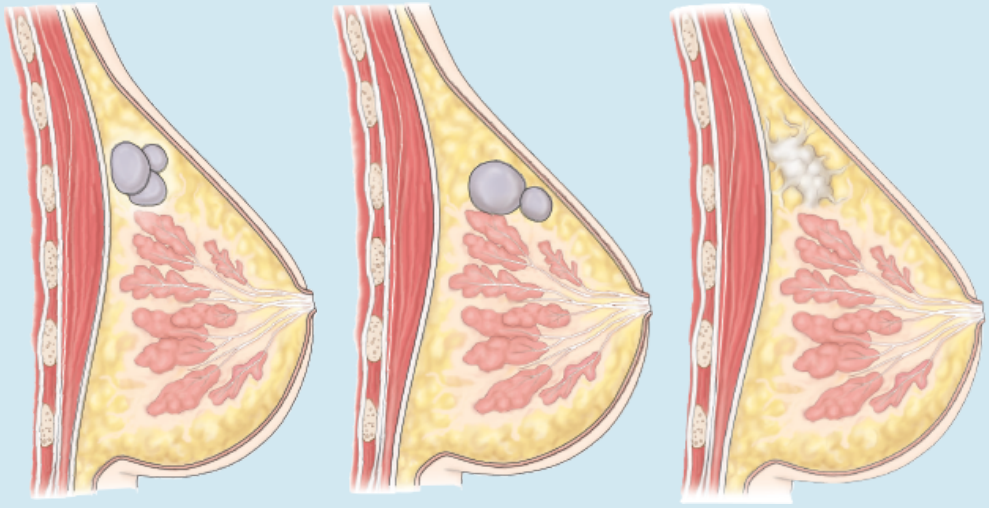
Breast Pain

Mastalgia (breast pain) may be cyclical or noncyclical. Cyclical pain is usually related to hormonal fluctuations, usually during the menstrual cycle, and accounts for the majority of complaints. Noncyclical pain is far less common and does not vary with the menstrual cycle. Women who experience injury or trauma to the breast or those who have had a breast biopsy may experience noncyclical pain. Patients should be reassured that breast pain is rarely indicative of cancer. However, if the pain persists after menses begin, the patient should see her primary provider.

Nursing Management

The nurse may recommend that the patient wear a supportive bra both day and night for a week, avoiding the use of underwire bras, decrease her salt and caffeine intake, and take

ibuprofen as needed for its anti-inflammatory actions. Vitamin E supplements may also be helpful.



Cysts

Cysts are fluid-filled sacs that develop as breast ducts dilate. Cysts occur most commonly in women 30 to 55 years of age and may be exacerbated during perimenopause. Although their cause is unknown, cysts usually disappear after menopause, suggesting that estrogen is a factor. Cystic areas often fluctuate in size and are usually larger premenstrually. They may be painless or may become very tender premenstrually. Occasionally, a patient may report an intermittent shooting sensation or a dull ache. Various breast masses are compared in Table 52-2. Cysts that are confirmed on an ultrasound and are not bothersome can often be left alone. To confirm a diagnosis or to relieve pain, FNA can be performed. Cysts are rarely malignant (Sasaki, Geletzke, Kass, et al., 2018).

Fibrocystic breast changes, often incorrectly called *fibrocystic breast disease,* is a nonspecific term used to describe an array of benign findings including palpable nodularity, lumpiness, swelling, or pain. The changes do not necessarily indicate a cystic or disease process.

TABLE 52-2 Comparison of Various Breast Masses

The most common breast masses are due to cysts, fibroadenomas, or malignancy. Biopsy is usually needed for confirmation, but the following characteristics are diagnostic clues:

Characteristics	Cysts	Fibroadenomas	Malignancy
			
Age	30–55 yrs, regress after menopause except with use of estrogen therapy	Puberty to menopause	30–90 yrs; most common, 40–80 yrs
Number	Single or multiple	Usually single	Usually single
Shape	Round	Round, disc, or lobular	Irregular or stellate
Consistency	Soft to firm, usually elastic	Usually firm	Firm or hard
Mobility	Mobile	Mobile	May be fixed to skin or underlying tissues
Tenderness	Usually tender	Usually nontender	Usually nontender
Retraction signs	Absent	Absent	May be present

Adapted from Bland, K., Copeland, E., Klimberg, V., et al. (Eds.). *The breast: Comprehensive management of benign and malignant diseases* (5th ed.). Philadelphia, PA: Elsevier.

Fibroadenomas

Fibroadenomas are firm, round, movable, benign tumors. They can occur from puberty to menopause with a peak incidence at 30 years of age. These masses are nontender and are sometimes biopsied or removed for definitive diagnosis.

Benign Proliferative Breast Disease

The two most common types of **benign proliferative breast disease** (atypical, yet noncancerous, breast tissue) found on biopsy are atypical hyperplasia and lobular carcinoma in situ (LCIS). These diagnoses increase a woman's risk of breast cancer.

Atypical Hyperplasia

Atypical hyperplasia can be ductal or lobular and is a premalignant lesion of the breast. It is recognized as a precursor lesion to both noninvasive and invasive breast cancer. Imbalance in the normal regulation of cell proliferation is a defining feature. Women with atypical hyperplasia have a fourfold increased risk of breast cancer compared to women in the general population (Sasaki et al., 2018).

Lobular Carcinoma In Situ

Lobular carcinoma in situ (LCIS) is an incidental microscopic finding of abnormal tissue growth in the lobules of the breast. Many types of LCIS have been identified; some types are associated with a 4- to 10-fold increased risk of invasive breast cancer (Klimberg & Bland, 2018). Affected women should undergo rigorous breast cancer surveillance that consists of annual mammography and clinical breast examination every 6 months (NCCN, 2019). Patients should be offered information about chemoprevention with selective estrogen receptor modulators (SERMs), such as tamoxifen. See the discussion of chemoprevention later in this chapter.

Other Benign Conditions

Cystosarcoma phyllodes is a rare fibroepithelial tumor that tends to grow rapidly. It is rarely malignant and is treated with surgical excision. If it is malignant, mastectomy may follow. Lymph node removal is usually not performed, because metastasis is rare.

Fat necrosis is a condition of the breast that is often associated with a history of trauma. Surgical procedures such as a breast biopsy, lumpectomy, or mastectomy can cause fat necrosis. It may be indistinguishable from carcinoma, and the entire mass may be excised or biopsied. If excision is not indicated, it is followed with regular breast imaging.

Intraductal papilloma is a wartlike growth that often involves the large milk ducts near the nipple, causing bloody nipple discharge. Surgery usually involves removal of the papilloma and a segment of the duct where the papilloma is found.

Superficial thrombophlebitis of the breast (Mondor disease) is an uncommon condition that is usually associated with pregnancy, trauma, or breast surgery. Pain and redness occur as a result of a superficial thrombophlebitis in the vein that drains the outer part of the breast. The mass is usually linear, tender, and erythematous. Treatment consists of analgesic agents and heat.

MALIGNANT CONDITIONS OF THE BREAST

Breast cancer is a major health problem in the United States. Current statistics indicate that over a lifetime (birth to death), a woman's risk of developing breast cancer is about 12%, or one in eight. Currently, about 268,600 new cases of invasive breast cancer are diagnosed in women each year. Risk of developing breast cancer increases with increasing age. About two of three invasive breast cancers are found in women 55 years or older. About 5% to 10% of breast cancer cases are thought to be hereditary, resulting directly from gene defects (cell mutations) inherited from a biologic parent (ACS, 2019). Female breast cancer incidence rates vary substantially by race and ethnicity. Non-Hispanic African American women have higher incidence of breast cancer than non-Hispanic Caucasian women before the age of 40 and are more likely to die from breast cancer at every age. Higher death rates in African Americans have been attributed to later stage at diagnosis and poorer stage-specific survival (ACS, 2019).

Types of Breast Cancer

Ductal Carcinoma In Situ

Ductal carcinoma in situ (DCIS) is characterized by the proliferation of malignant cells inside the milk ducts without invasion into the surrounding tissue. Unlike invasive breast cancer, DCIS does not metastasize and a woman generally does not die of DCIS unless it develops into invasive breast cancer. DCIS can develop into invasive breast cancer if left untreated. The best estimates are that 14% to 53% of untreated DCIS progresses to invasive breast cancer over a period of 10 years or more. However, the natural history of DCIS is not well understood, and it is currently not possible to accurately predict which women with DCIS will go on to develop invasive breast cancer (ACS, 2019). DCIS is frequently manifested on a mammogram with the appearance of calcifications and is considered breast cancer stage 0.

Medical Management

Current management takes into account the assurance of an accurate diagnosis, assessment of DCIS size and grade, and careful margin evaluation. The pathologist analyzes the piece of breast tissue removed to determine the type and grade of the DCIS or how abnormal the cells look when compared with normal breast cells and how fast they are growing. Grade III (high-grade DCIS) cells tend to grow more quickly than grade I (low-grade) and grade II (moderate-grade) cells and look very different from normal breast cells. Accurate grading of DCIS is critical, because high nuclear grade and the presence of necrosis (the premature death of cells in living tissue) are highly predictive of the inability to achieve adequate margins or borders of healthy tissue around the cancer, of local recurrence, and of the probability of missed areas of invasion. The pros and cons of irradiating patients with DCIS who are treated conservatively should be carefully weighed on a case-by-case basis, considering recent trials have shown that radiation has a beneficial effect on distant recurrence, breast cancer–specific mortality, and overall survival. Breast conservation (treatment of a breast cancer without the loss of the breast) can be curative for well-defined subsets of women with DCIS, especially if the area of concern is very small (ACS, 2019).

Invasive Cancer

Invasive breast cancer includes several types of carcinoma and Paget disease.

Infiltrating Ductal Carcinoma

Infiltrating ductal carcinoma—the most common histologic type of breast cancer—accounts for 70% to 80% of all cases (Komen, 2019b). The tumors arise from the duct system and invade the surrounding tissues. They often form a solid irregular mass in the breast (Komen, 2019b).

Micropapillary invasive ductal carcinoma is a rare type of aggressive ductal cancer characterized by a high rate of axillary node metastasis and skin involvement (Komen, 2019b).

Infiltrating Lobular Carcinoma

Infiltrating lobular carcinoma accounts for 10% to 15% of breast cancers (Komen, 2019b). The tumors arise from the lobular epithelium and typically occur as an area of ill-defined thickening in the breast. They are often multicentric and can be bilateral (Komen, 2019b).

Medullary Carcinoma

Medullary carcinoma accounts for less than 1% of breast cancers (Komen, 2019b), and it tends to be diagnosed more often in women younger than 50 years. The tumors grow in a capsule inside a duct. They can become large and may be mistaken for a fibroadenoma. The prognosis is often favorable (Komen, 2019b).

Mucinous Carcinoma

Mucinous carcinoma accounts for about 2% of breast cancers and often presents in women who are postmenopausal and are 75 years and older (Komen, 2019b). A mucin producer, the tumor is also slow growing; thus, the prognosis is more favorable than in many other types (Komen, 2019b).

Tubular Carcinoma

Tubular carcinoma accounts for 1% to 5% of breast cancers (Komen, 2019b). Because axillary metastases are uncommon with this histology, prognosis is usually excellent.

Inflammatory Carcinoma

Inflammatory carcinoma is a rare (1% to 5%) (ACS, 2019; Komen, 2019b) and aggressive type of breast cancer that has unique symptoms. The cancer is characterized by diffuse edema and erythema of the skin, often referred to as peau d'orange. This is caused by malignant cells blocking the lymph channels in the skin. An associated mass may or may not be present; if there is a mass, it is often a large area of indiscrete thickening. Inflammatory carcinoma can be confused with an infection because of its presentation (Komen, 2019b). The disease can spread to other parts of the body rapidly. Chemotherapy often plays an initial role in controlling disease progression, but radiation and surgery may also follow (Komen, 2019b).

Paget Disease

Paget disease of the breast accounts for 1% to 4% of diagnosed cases of breast cancer; it is more common in men than in women (Komen, 2019b). Symptoms typically include a scaly, erythematous, pruritic lesion of the nipple. Paget disease often represents DCIS of the nipple but may have an invasive component. If no lump can be felt in the breast tissue and the biopsy shows DCIS without invasion, the prognosis is very favorable (Komen, 2019b).

Risk Factors

There is no single, specific cause of breast cancer. A combination of genetic, hormonal, and possibly environmental factors may increase the risk of its development (see Table 52-3). More than 80% of all cases of breast cancer are sporadic, meaning that patients have no known family history of the disease. The remaining cases are either familial (there is a family history of breast cancer, but it is not passed on genetically) or genetically acquired. Research suggests that obesity, alcohol use, and smoking (especially when started before the first pregnancy) may increase risk (ACS, 2019). There is some evidence that late-in-life weight gain, a sedentary lifestyle, and night shift work may increase the risk for breast cancer (ACS, 2019). There is no evidence that silicone breast implants, the use of antiperspirants, underwire bras, or abortion (induced or spontaneous) increases the risk of the disease (ACS, 2019).

As stated previously, breast cancer can be genetically inherited, resulting in significant risk. Approximately 5% to 10% of breast cancer cases have been linked to specific genetic mutations. Factors that may indicate a genetic link include multiple first-degree relatives with early-onset breast cancer, breast and ovarian cancer in the same family, male breast cancer, and Ashkenazi Jewish background. ***BRCA1* and *BRCA2*** are tumor suppressor genes that normally function to identify damaged deoxyribonucleic acid (DNA) and thereby restrain abnormal cell growth (O'Donnell, Axilbund, & Euhus, 2018). Mutations in these genes on chromosome 17 are responsible for the majority of hereditary breast cancer in the United States. *BRCA* mutations in women have been associated with an overall risk of breast cancer up to 70% (ACS, 2019). Currently, women who are *BRCA* positive are counseled to start screening, typically using mammography, once a year and then MRI 6 months after the yearly mammography by 25 years of age, or 5 to 10 years earlier than their youngest affected family member. Mutations in the *PALB2* gene confer similar risk. Males who carry the *BRCA2* mutation may have a lifetime risk of 6% to 7% of developing breast cancer (Jain & Gradishar, 2018).

Protective Factors

Certain factors may be protective against the development of breast cancer. Breast-feeding for at least 1 year, regular or moderate physical activity, and maintaining a healthy body weight are cited as protective (ACS, 2019). Some research suggests that the use of extra virgin olive oil, as is found in a Mediterranean diet, might be preventive, but recent research is inconclusive (Mayo Clinic, 2018).

TABLE 52-3 Risk Factors for Breast Cancer

Risk Factor	Comments
Female gender	99% of cases occur in women.
Increasing age	Increasing age is associated with an increased risk.
Personal history of breast cancer	Once treated for breast cancer, the risk of developing breast cancer in same or opposite breast is significantly increased.
Family history of breast cancer	Having first-degree relative with breast cancer (mother, sister, daughter) increases the risk twofold; having two first-degree relatives increases the risk fivefold. The risk is higher if the relative was premenopausal at the time of diagnosis. The risk is increased if a father or brother had breast cancer (exact risk is unknown).
Genetic mutation	*BRCA1* and *BRCA2* mutations account for majority of inherited cases of breast cancer (see additional information in text).
Hormonal Factors	
• Early menarche	Before 12 yrs of age
• Late menopause	After 55 yrs of age
• Nulliparity	No full-term pregnancies
• Late age at first full-term pregnancy	After 30 yrs of age
• Hormone therapy (formerly referred to as hormone replacement therapy)	Current or recent use of combined postmenopausal hormone therapy (estrogen and progesterone) Long-term use (several years or more)
Exposure to ionizing radiation during adolescence and early adulthood	The risk is highest if breast tissue was exposed while still developing (during adolescence), such as women who received mantle radiation (to the chest area) for treatment of Hodgkin lymphoma in their younger years.
History of benign proliferative breast disease	Having had atypical ductal or lobular hyperplasia or lobular carcinoma in situ increases the risk.
Obesity	Obesity and weight gain during adulthood increases the risk of postmenopausal breast cancer. During menopause, estrogen is primarily produced in fat tissue. More fat tissue can increase estrogen levels, thereby increasing breast cancer risk.
High-fat diet	More research is needed.
Alcohol intake (beer, wine, or liquor)	Two to five drinks daily increases the risk about one and a half times.

Breast Cancer Prevention Strategies in the Patient Who Is at High Risk

Patients often over- or underestimate their risk of developing breast cancer. A consultation with a breast specialist is of paramount importance prior to embarking on any of the prevention strategies that follow. Once patients have an accurate assessment of their risk, along with the knowledge of the pros and cons of each prevention strategy, they can make a decision that is most appropriate for their situation.

Long-Term Surveillance

Long-term surveillance focuses on early detection. As recommended by the NCCN (2019), women at high risk for breast cancer benefit from additional screening using MRI along with a yearly mammogram. Clinical breast examinations may be performed twice a year starting as early as 25 years of age. Mammograms may also be performed as early as 25 years of age. Data concerning the effectiveness of BSE are limited. In addition to yearly mammography and MRI, other screening tests, including ultrasonography, may be useful.

Chemoprevention

Chemoprevention is the main modality that aims to prevent the disease. Several national, randomized clinical trials have led to FDA approval of tamoxifen and raloxifene as effective chemopreventive agents for use in women who are at high risk (Mayo Clinic, 2019a). Tamoxifen has been shown to reduce risk by up to 50% even in women in whom up to three first-degree relatives are also affected (O'Donnell et al., 2018). Because tamoxifen is associated with an increased risk for endometrial cancer and thromboembolic events, especially in postmenopausal women, it is more frequently recommended for premenopausal women. In women previously diagnosed with LCIS, who are at risk for developing invasive cancer, tamoxifen has been approved for use premenopausally, while raloxifene is recommended postmenopausally (Calhoun & Anderson, 2018). Postmenopausally, anastrozole and exemestane are also now used for chemoprevention (Mayo Clinic, 2019a). Nurses can help women who are considering chemoprevention by providing them with information about the benefits, risks, and possible side effects of these medications.

Prophylactic Mastectomy

Prophylactic mastectomy is another primary prevention modality that can reduce the risk of breast cancer by 90% to 95% (Mayo Clinic, 2019b) and is sometimes referred to as a "risk-reducing" mastectomy. The procedure consists of a total **mastectomy** (removal of breast tissue) and is usually accompanied by immediate breast reconstruction. Possible candidates include women with a strong family history of breast cancer, a diagnosis of LCIS or atypical hyperplasia, a mutation in a *BRCA* gene, and previous cancer in one breast. Because of physical and psychological ramifications including anxiety, depression, and altered body image, this procedure should be undertaken only after extensive counseling related to its risks and benefits. The procedure does not confer 100% protection against the development of breast cancer (Mayo Clinic, 2019b).

A multidisciplinary approach is used to help the patient arrive at a decision that is best for her. Consultation with a genetic counselor, plastic surgeon, medical oncologist, and psychiatrist can be invaluable. The patient needs to understand that this surgery is elective and not emergent. The nurse can play a valuable role in providing the patient with information, clarification, and support during the decision-making process.

Clinical Manifestations

Breast cancers can occur anywhere in the breast but are usually found in the upper outer quadrant, where the most breast tissue is located. In general, the lesions are nontender, fixed rather than mobile, and hard with irregular borders. Complaints of diffuse breast pain and tenderness with menstruation are usually associated with benign breast disease.

Because of mammography, more women are seeking treatment at earlier stages of the disease. These women often have no signs or symptoms other than a mammographic abnormality. Some women with advanced disease seek initial treatment after ignoring symptoms. Advanced signs may include skin dimpling, nipple retraction, or skin ulceration.

Assessment and Diagnostic Findings

Techniques to determine the diagnosis of breast cancer include various types of biopsy, which have been described previously. Tumor staging and analysis of additional prognostic factors are used to determine the prognosis and optimal treatment regimen (see below).

Staging

Staging involves classifying the cancer by the extent of the disease in the body. It is based on whether the cancer is invasive or noninvasive, the size of the tumor, how many lymph nodes are involved, and if it has spread to other parts of the body. The stage of a cancer is one of the most important factors in determining prognosis and treatment options. The most common system used to describe the stages of breast cancer is the American Joint Committee on Cancer (AJCC) TNM (tumor, nodes, metastasis) system (see Chapter 12, Chart 12-3). Other factors considered in staging include hormone receptors and genetic mutations.

Other diagnostic tests may be performed before or after surgery to help in the staging of the disease. The extent of testing often depends on the clinical presentation of the disease and may include chest x-rays, computed tomography (CT) scan, MRI scan, positron emission tomography (PET) scan, bone scans, and blood work (complete blood count, comprehensive metabolic panel, and tumor markers [i.e., carcinoembryonic antigen, cancer antigen 15-3]).

Prognosis

Several different factors must be taken into consideration when determining the prognosis of a patient with breast cancer. Two of the most important factors are tumor size and whether the tumor has spread to the axillary (underarm) lymph nodes.

In general, the smaller the tumor appears, the better the prognosis. A tumor starts with a genetic alteration in a single cell and takes time to divide and double in size. A carcinoma may double in size 30 times to become 1 cm or larger, at which point it becomes clinically apparent. Doubling time varies, but breast tumors are often present for several years before they become palpable. Nurses can reassure patients that once breast cancer is diagnosed, they have a safe period of several weeks to make decisions regarding treatment; however, a lengthy delay is not advisable.

Prognosis also depends on the extent of spread of the breast cancer. The 5-year survival rate is approximately 88% for a stage I breast cancer and 15% for a stage IV breast cancer (ACS, 2019). The most common route of regional spread is to the axillary lymph nodes. Other sites of lymphatic spread include the internal mammary and supraclavicular nodes (see Fig. 52-5). Distant metastasis can affect any organ, but the most common sites are bone, lung, liver, and brain (Breastcancer.org, 2018).

In addition to the type of breast cancer and the stage, other factors may help determine prognosis (see Chart 52-3). Amplification (excessive number of copies of certain genes) or overexpression (excessive amounts of their protein product) may represent a poorer prognosis. The HER-2/neu (also known as *ERBB2*) oncogene is the classic example; approximately 20% of invasive breast cancers, which typically involve the more aggressive tumors, have amplification or overexpression of this gene (Mayo Clinic, 2020). The proliferative rate or rapidity in growth rate (S-phase fraction) and DNA content (ploidy) of a tumor are factors that are also associated with overall survival rate.

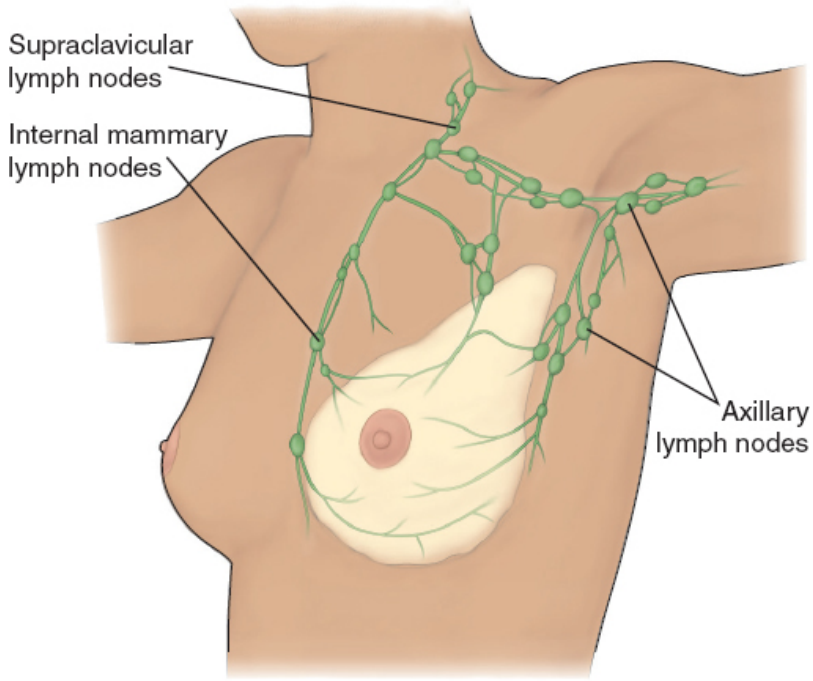

Figure 52-5 • Lymphatic drainage of the breast.

Chart 52-3

Factors Associated with Favorable Prognosis for Breast Cancer

- Noninvasive tumors or invasive tumors <1 cm
- Negative axillary lymph nodes
- Estrogen receptor (ER) and progesterone receptor (PR) proteins
- Well-differentiated tumors
- Low expression of HER-2/neu oncogene (also known as *ERBB2*)
- No vascular or lymphatic invasion
- Diploid tumors with low S-phase fraction

Surgical Management

The main goal of surgery is to gain local control of the disease. With breast cancer being diagnosed today at earlier stages, options for less invasive, breast conserving surgical procedures are available. Surgical treatment options for noninvasive and invasive breast cancer are summarized in Table 52-4.

Modified Radical Mastectomy

Modified radical mastectomy is performed to treat invasive breast cancer. The procedure involves removal of breast tissue, including the nipple–areola complex. In addition, a portion of the axillary lymph nodes are also removed in axillary lymph node dissection (ALND). If immediate breast reconstruction is desired, the patient is referred to a plastic surgeon prior to the mastectomy so that the patient has the opportunity to explore all available options (see

Chart 52-4). In modified radical mastectomy, the pectoralis major and pectoralis minor muscles are left intact, unlike in radical mastectomy, in which the muscles are removed.

TABLE 52-4 Surgical Treatment Options for Noninvasive and Invasive Breast Cancer

Noninvasive Breast Cancer	Invasive Breast Cancer
Breast conservation[a] alone	Breast conservation[a] with one of the following: Sentinel lymph node biopsy Axillary lymph node dissection
Total mastectomy alone	Total mastectomy with sentinel lymph node biopsy or Modified radical mastectomy

[a]Breast conservation treatment includes lumpectomy, wide excision, partial or segmental mastectomy, and quadrantectomy. These are relatively synonymous terms that describe removal of varying amounts of breast tissue.

Total Mastectomy

Like modified radical mastectomy, total mastectomy (i.e., simple mastectomy) also involves removal of the breast and nipple–areola complex but does not include ALND. Total mastectomy may be performed in patients with noninvasive breast cancer (e.g., DCIS), which does not have a tendency to spread to the lymph nodes. It may also be performed prophylactically in patients who are at high risk for breast cancer (e.g., LCIS, *BRCA* mutation). A total mastectomy may also be performed in conjunction with sentinel lymph node biopsy (SLNB) for patients with invasive breast cancer.

Breast Conservation Treatment

The goal of **breast conservation treatment** (i.e., lumpectomy, wide excision, partial or segmental mastectomy, quadrantectomy) is to excise the tumor in the breast completely and obtain clear margins while achieving an acceptable cosmetic result. If the procedure is being performed to treat a noninvasive breast cancer, lymph node removal is not necessary. For an invasive breast cancer, lymph node removal (SLNB or ALND) is indicated. The lymph nodes are removed through a separate semicircular incision in the axilla.

Sentinel Lymph Node Biopsy

The status of the lymph nodes is the most important prognostic factor in breast cancer. The SLNB is a less invasive alternative to ALND and is considered a standard of care for the treatment of early-stage breast cancer. ALND is associated with potential morbidity, including lymphedema, cellulitis, decreased arm mobility, and sensory changes. Studies suggest that SLNB is highly accurate and is associated with a low axillary recurrence rate (Prati, Chang, & Chung, 2018). Table 52-5 compares SLNB and ALND.

The **sentinel lymph node**, which is the first node (or nodes) in the lymphatic basin that receives drainage from the primary tumor in the breast, is identified by injecting a radioisotope or blue dye into the breast; the radioisotope or dye then travels via the lymphatic pathways to the node. In SLNB, the surgeon uses a handheld probe to locate the sentinel lymph node, excises it, and sends it for pathologic analysis, which is often performed immediately during the surgery using frozen-section analysis. If the sentinel lymph node is positive, the surgeon can proceed with an immediate ALND, thus sparing the patient a return trip to the operating room and additional anesthesia. (The patient could also return for additional surgery at a later time.) If the sentinel lymph node is negative, a standard ALND is not needed, thus sparing the patient the possible complications of the procedure. After the procedure is complete, all specimens are sent to pathology for more thorough analysis.

Nursing Management

Patients who undergo SLNB in conjunction with breast conservation treatments are generally discharged the same day. Patients who undergo SLNB with total mastectomy usually stay in the hospital overnight, possibly longer if breast reconstruction is being performed. The patient must be informed that although frozen-section analysis is highly accurate, false-negative results can occur. A negative sentinel lymph node on frozen-section analysis may show metastatic disease on subsequent analysis, indicating that ALND is still necessary. The patient should also be reassured that the radioisotope and blue dye are generally safe. The nurse informs patients that they may notice a blue-green discoloration in the urine or stool for the first 24 hours as the blue dye is excreted. The incidence of lymphedema, decreased arm mobility, and seroma formation (collection of serous fluid) in the axilla is generally low, but the patient should be prepared for these possibilities. Women who have SLNB alone have neuropathic sensations similar to those who undergo ALND, although the prevalence and severity of these sensations and the resulting distress are lower with SLNB.

Chart 52-4  **ETHICAL DILEMMA**

What Is Acceptable Treatment for a Patient with Breast Cancer during a Pandemic?

Case Scenario

You work as a staff nurse on an oncology surgery unit. K.M. is a 37-year-old woman who is one day postoperative for a mastectomy for an invasive ductal carcinoma of her left breast. There is an outbreak of coronavirus disease 2019 (COVID-19) within your community. K.M. does not have COVID-19 and the surgical unit where you work has been designated to manage patients without COVID-19; nonetheless, a no visitor policy is enforced throughout your hospital and K.M. may not receive any visitors. When you enter K.M.'s room to perform your baseline assessment, you find her crying. She says to you, "This is terrible. When my sister had a mastectomy 3 years ago, she was able to have breast reconstruction done at the same time. I did not have that choice because only the mastectomy was considered essential—the reconstruction was considered elective! I have to wait before I can have that done and go through surgery all over again! It is so unfair! And it is so unfair that my husband had to drop me off at the curb and cannot be with me! He is worried sick!" K.M. is not the only patient you have cared for during this pandemic who has faced obstacles receiving what had previously been considered standard care. Additionally, many of your patients have voiced anger, frustration, anxiety, and fear because their loved ones are barred from being able to visit them postoperatively.

Discussion

Access to health care resources can drastically change during a pandemic. Resources may be scarce not only for patients who are directly infected by the pathogen responsible for the pandemic, but for all patients. For instance, access to the services rendered by health care personnel (e.g., surgeons), facilities (e.g., surgical centers, operating rooms), pharmacologic agents, medical devices, to name a few, may all be disrupted or delayed because of societal needs to divert maximum resources to mitigate the effects of the pandemic. Diversion of these resources can result in a scarcity of resources considered as standard therapy during other times. The COVID-19 pandemic has caused disruptions to and delays in access to care for many patients with breast cancer, as well as patients with other cancers.

Analysis

- Describe the ethical principles that are in conflict in this case (see Chapter 1, Chart 1-7). K.M. feels that she should have been eligible to have reconstruction done at the same time as her mastectomy. Her availability of choices and her personhood were arguably threatened by not being able to select her preferred surgical procedure. She might have elected to wait to have her mastectomy until such time as the breast reconstruction could have also been done; however, her risk of an adverse outcome related to her cancer would have been greater. Is it just to enforce these types of resource delays during a pandemic?
- K.M. expresses frustration at not being able to see her husband postoperatively. Are visitor prohibitions during a pandemic so much a threat to beneficence that they should not be enforced? Or are these types of universal prohibitions justifiable?
- What resources might be mobilized to assist you in caring for K.M. and other patients on your unit? How can you assure that your professional need to deliver quality care to your patients is not threatened? How can you preserve your own sense of self-worth?

Resources

See Chapter 1, Chart 1-10 for Steps of an Ethical Analysis and Ethics Resources.

The nurse must not overlook the psychosocial needs of the patient who has undergone SLNB. Although SLNB is a less invasive procedure than ALND and results in a shorter recovery period, a patient who has undergone SLNB also has many difficult issues surrounding her breast cancer diagnosis and treatment. The nurse must listen, provide emotional support, and refer the patient to appropriate specialists when indicated.

TABLE 52-5 Comparison of Sentinel Lymph Node Biopsy and Axillary Lymph Node Dissection

Sentinel Lymph Node Biopsy	Axillary Lymph Node Dissection
Shorter operating room time (~15–30 mins)	Longer operating room time (~60–90 mins)
No surgical drain	Surgical drain
Local anesthesia with IV moderate sedation as outpatient surgery (unless being performed in conjunction with total mastectomy)	General anesthesia; usually overnight admission (sometimes done as outpatient surgery)
Lymphedema risk minimal	Lymphedema risk higher
Presence of neuropathic sensations postoperatively (prevalence lower than after axillary lymph node dissection)	Presence of neuropathic sensations postoperatively
Decreased range of motion in affected arm unlikely postoperatively but may occur	Decreased range of motion likely postoperatively
Seroma (collection of serous fluid in the axilla) may occur postoperatively, but less likely	Seroma may occur postoperatively

NURSING PROCESS

The Patient Undergoing Surgery for Breast Cancer

Assessment

The health history is a valuable tool to assess the patient's reaction to the diagnosis and her ability to cope with it. Pertinent questions include the following:

- How is the patient responding to the diagnosis?
- What coping mechanisms does she find most helpful?
- What psychological or emotional supports does she have and use?
- Is there a partner, family member, or friend available to assist her in making treatment choices?
- What are her educational needs?
- Is she experiencing any discomfort?

Diagnosis

Preoperative Nursing Diagnoses

Based on the assessment data, major preoperative nursing diagnoses may include the following:

- Lack of knowledge about the planned surgical treatments
- Anxiety associated with the diagnosis of cancer
- Fear associated with specific treatments and body image changes
- Risk for difficulty with coping associated with the diagnosis of breast cancer and related treatment options
- Decisional conflict associated with treatment options

Postoperative Nursing Diagnoses

Based on the assessment data, major postoperative nursing diagnoses may include the following:

- Acute pain and discomfort associated with surgical procedure
- Risk for impaired peripheral neurovascular function associated with nerve irritation in affected arm, breast, or chest wall
- Disturbed body image associated with loss or alteration of the breast
- Risk for difficulty with coping associated with the diagnosis of cancer and surgical treatment
- Impaired ability to perform hygiene, impaired ability to dress, impaired self feeding, and impaired self toileting associated with partial immobility of upper extremity on operative side
- Lack of knowledge: drain management after breast surgery, arm exercises to regain mobility of affected extremity, hand and arm care after ALND

Collaborative Problems/Potential Complications

Potential complications may include the following:

- Lymphedema
- Hematoma/Seroma formation
- Infection
- Changes in sexual function

Planning and Goals

The major goals may include increased knowledge about the disease and its treatment; reduction of preoperative and postoperative fear, anxiety, and emotional stress;

improvement of decision-making ability; pain management; neurovascular function management; maintenance of a positive body image; improvement in coping abilities; increased self-care abilities; improvement in sexual function; and the absence of complications.

Preoperative Nursing Interventions

Providing Education and Preparation About Surgical Treatments

Many cancer centers have coordinators to help patients navigate appointments, decision-making, and care-paths. Nurses can encourage patients and their support persons to establish and maintain contact with these coordinators and utilize available resources as needed along their journeys. The nurse will reinforce a coordinator's support, if available; if no coordinator is available, nurses assume much of this responsibility.

Patients with newly diagnosed breast cancer are expected to absorb an abundance of new information during a very emotionally difficult time, and this may lead to difficulty in making treatment decisions. The nurse plays a key role in reviewing treatment options by reinforcing information provided to the patient and answering any questions. The nurse fully prepares the patient for what to expect before, during, and after surgery. Patients undergoing breast conservation with ALND, or a total or modified radical mastectomy, generally remain in the hospital overnight (or longer if they have immediate reconstruction). Surgical drains will be inserted in the mastectomy incision and in the axilla if the patient undergoes ALND. A surgical drain is generally not needed after SLNB. The patient should be informed that she will go home with the drain(s) and that complete instructions about drain care will be provided prior to discharge. In addition, the patient should be informed that she will often have decreased arm and shoulder mobility after ALND and that she will be shown range-of-motion exercises prior to discharge. The patient should also be reassured that appropriate analgesia and comfort measures will be provided to alleviate any postoperative discomfort.

Reducing Fear and Anxiety and Improving Coping Ability

The nurse helps the patient cope with the physical and emotional effects of surgery. Many fears may emerge during the preoperative phase. These can include fear of pain, mutilation (after mastectomy), and loss of sexual attractiveness; concern about inability to care for oneself and one's family; concern about taking time off from work; and coping with an uncertain future. Providing the patient with realistic expectations about the healing process and expected recovery can help alleviate fears. Maintaining open communication and assuring the patient that she can contact the nurse at any time with questions or concerns can be a source of comfort. The patient should also be made aware of available resources at the treatment facility as well as in the breast cancer community such as social workers, psychiatrists, and support groups. Some women find it helpful and reassuring to talk to a survivor of breast cancer who has undergone similar treatments.

Promoting Decision-Making Ability

The patient may be eligible for more than one therapeutic approach; she may be presented with treatment options and then asked to make a choice. This can be very frightening for some patients, and they may prefer to have someone else make the decision for them (e.g., surgeon, family member). The nurse can be instrumental in ensuring that the patient and family members truly understand their options. The nurse can then help the patient weigh the risks and benefits of each option. The patient may be presented with the option of having breast conservation treatment followed by radiation or a mastectomy. The nurse can explore the issues with the patient by asking questions such as the following:

- How do you think you might feel about losing your breast?
- Are you considering breast reconstruction?

- If you choose to retain your breast, would you consider undergoing radiation treatments 5 days a week for 5 to 6 weeks?

Questions such as these can help the patient focus. Once the patient's decision is made, it is very important to support it.

Postoperative Nursing Interventions

Relieving Pain and Discomfort

Many patients tolerate breast surgery well and have minimal pain during the postoperative period. This is particularly true of less invasive procedures such as breast conservation treatment with SLNB. However, all patients must be carefully assessed, because individual patients can have varying degrees of pain. Patients who have had more invasive procedures, such as a modified radical mastectomy with immediate reconstruction, may have considerably more pain. All patients are discharged home with analgesic medication (e.g., oxycodone and acetaminophen) and are encouraged to take it if needed. An over-the-counter analgesic agent such as acetaminophen may provide sufficient relief. Patients sometimes complain of a slight increase in pain after the first few days of surgery; this may occur as patients regain sensation around the surgical site and become more active. However, patients who report more than moderate pain must be evaluated to rule out any potential complications such as infection or hematoma. Postoperative pain may be more common in patients who have had axillary dissection: the amount of discomfort may increase with each additional node removed. (Komen, 2019a). Alternative methods of pain management, such as taking warm showers (if permitted by the surgeon) and using distraction methods (e.g., guided imagery), may also be helpful. See Chapter 9 for further discussion of methods that relieve pain.

Managing Postoperative Sensations

Because nerves in the skin and axilla are often ligated or injured during breast surgery, patients experience a variety of sensations. Common sensations include tenderness, soreness, numbness, tightness, pulling, and twinges. These sensations may occur along the chest wall, in the axilla, and along the inside aspect of the upper arm. After mastectomy, some patients experience phantom sensations and report a feeling that the breast or nipple is still present. Overall, patients do not find these sensations severe or distressing. Sensations usually persist for several months and then begin to diminish, although some may persist for as long as 5 years and possibly longer. Patients should be reassured that this is a normal part of healing and that these sensations are not indicative of a problem.

Promoting Positive Body Image

Patients who have undergone mastectomy may find it difficult to view the surgical site for the first time. No matter how prepared the patient may think she is, the appearance of an absent breast can be very emotionally distressing. Ideally, the patient sees the incision for the first time when she is with the nurse or another health care provider who is available for support.

The nurse first assesses the patient's readiness and provides gentle encouragement. It is important to maintain the patient's privacy while assisting her as she views the incision; this allows her to express feelings safely to the nurse. Asking the patient what she perceives, acknowledging her feelings, and allowing her to express her emotions are important nursing actions. Reassuring the patient that her feelings are a normal response to breast cancer surgery may be comforting. If the patient has not had immediate reconstruction, providing her with a temporary breast form or soft padding to place in her bra on discharge can help alleviate feelings of embarrassment or self-consciousness.

Promoting Positive Adjustment and Coping

Providing ongoing assessment of how the patient is coping with her diagnosis of breast cancer and her surgical treatment is important in determining her overall adjustment. Assisting the patient in identifying and mobilizing her support systems can be beneficial to her well-being. The patient's spouse or partner may also need guidance, support, and education. The patient and partner may benefit from a wide network of available community resources, including the Reach to Recovery program of the ACS, advocacy groups, social worker, or a spiritual advisor. Encouraging the patient to discuss issues and concerns with other patients who have had breast cancer may help her to understand that her feelings are normal and that other women who have had breast cancer can provide invaluable support and understanding.

The patient may also have considerable anxiety about the treatments that will follow surgery (i.e., chemotherapy and radiation) and their implications. Providing her with information about the plan of care and referring her to the appropriate members of the health care team also promote coping during recovery. Some women require additional support to adjust to their diagnosis and the changes that it brings. If a woman displays difficulty coping, consultation with a mental health provider may be indicated. Nurse navigators can help those undergoing breast biopsy to cope.

Monitoring and Managing Potential Complications

Lymphedema. **Lymphedema** is a complication characterized by a chronic swelling of an extremity due to interrupted lymphatic circulation. The swelling is due to the accumulation of protein-rich fluid in the interstitial space and is a somewhat common postoperative complication after ALND. It often affects both the breast and ipsilateral limb. It is associated with a painful swelling of the arm as well as weakness, shoulder pain, and tingling sensations in the arm and shoulder. After ALND, the risk of developing lymphedema may be as low as 11% or as high as 57% (Rivere & Klimberg, 2018). Because sentinel lymph node dissection (SLND) involves more focused surgery and less disruption of the axilla, the risk is only up to 7% within 5 years (Rivere & Klimberg, 2018). Risk factors for lymphedema in mixed-age groups include ALND, concomitant radiation therapy, increased age, presence of a concomitant infection, preexisting cardiovascular conditions, and obesity (Rivere & Klimberg, 2018).

Lymphedema results if functioning lymphatic channels are inadequate to ensure a return flow of lymph fluid to the general circulation. After axillary lymph nodes are removed, collateral circulation must assume this function. Transient edema in the postoperative period occurs until collateral circulation has completely taken over this function, which generally occurs within a month. Performing prescribed exercises, elevating the arm above the heart several times a day, and gentle muscle pumping (making a fist and releasing) can help reduce the transient edema. The patient needs reassurance that this transient swelling is not lymphedema.

Once lymphedema develops, it tends to be chronic, so preventive strategies are vital. After ALND, the patient is taught hand and arm care to prevent injury or trauma to the affected extremity, thus decreasing the likelihood for development of lymphedema (see Chart 52-5). The patient is instructed to follow these guidelines for the rest of her life. She is also instructed to contact her primary provider immediately if she suspects that she has lymphedema, because early intervention provides the best chance for control. If allowed to progress without treatment, the swelling can become more difficult to manage. Treatment may consist of a course of antibiotic agents if an infection is present. A referral to a rehabilitation specialist (e.g., occupational or physical therapist) may be necessary for a compression sleeve or glove, exercises, manual lymph drainage, and a discussion of ways to modify daily activities to avoid worsening lymphedema. Ongoing research is seeking to identify which lymph nodes drain the arm before surgery so that they can be

preserved when possible, helping to prevent the development of lymphedema. The practice of yoga may result in improved shoulder range of motion and upper extremity strength in women with postoperative lymphedema (Mazor, Lee, Peled, et al., 2018). See the Nursing Research Profile in Chart 52-6.

Chart 52-5 PATIENT EDUCATION

Hand and Arm Care After Axillary Lymph Node Dissection

The nurse instructs the patient to:

- Avoid blood pressures, injections, and blood draws in affected extremity.
- Use sunscreen (higher than 15 SPF) for extended exposure to sun.
- Apply insect repellent to avoid insect bites.
- Wear gloves for gardening.
- Use cooking mitt for removing objects from oven.
- Avoid cutting cuticles; push them back during manicures.
- Use electric razor for shaving armpit.
- Avoid lifting objects heavier than 5 to 10 lb.
- If a trauma or break in the skin occurs, wash the area with soap and water, and apply an over-the-counter antibacterial ointment. Observe the area and extremity for 24 hours; if redness, swelling, or a fever occurs, call the surgeon or nurse.

Hematoma or Seroma Formation. Hematoma formation (collection of blood inside a cavity) may occur after either mastectomy or breast conservation and usually develops within the first 12 hours after surgery. The nurse assesses for signs and symptoms of hematoma at the surgical site, which may include swelling, tightness, pain, and bruising of the skin. The surgeon should be notified immediately if there is gross swelling or increased bloody output from the drain. Depending on the surgeon's assessment, a compression wrap may be applied to the incision for approximately 12 hours, or the patient may be returned to the operating room so that the incision may be reopened to identify the source of bleeding. Some hematomas are small, and the body absorbs the blood naturally. The patient may take warm showers (if permitted by the surgeon) or apply warm compresses to help increase the absorption. A hematoma usually resolves in 4 to 5 weeks.

Chart 52-6 NURSING RESEARCH PROFILE

Effect of Yoga on Lymphedema

Mazor, M., Lee, J. Q., Peled, A., et al. (2018). The effect of yoga on arm volume, strength, and range of motion in women at risk for breast cancer-related lymphedema. *Journal of Alternative and Complementary Medicine*, *24*(2), 154–160.

Purpose

Breast cancer-related lymphedema (BCRL) is a complication of breast cancer that causes considerable morbidity. The intent of this study was to assess the feasibility, safety, and initial estimates of efficacy of a yoga program in the postoperative care of women at increased risk for BCRL.

Design

Twenty-one women were recruited at a breast care center in California. All participants were over 18 years of age, had undergone surgical intervention for breast cancer, and were at high risk for lymphedema. Women participated in an 8-week regimen of Ashtanga yoga, taking one instructor-led class weekly and also completing one self-led session weekly. Poses focused on upper-body strength and flexibility, while also avoiding placing the affected arm in a dependent position. Measurements of upper extremity volume, range of motion, and strength were assessed.

Findings

Twenty of the 21 participants finished the 8-week intervention and 17 completed the final assessment. The mean age was 52 years and body mass index was 24.8 kg/m^2. Postintervention mean upper extremity volumes were slightly decreased in the at-risk arm ($p = 0.397$). Range of motion in both shoulder flexion ($p < 0.01$) and external rotation ($p < 0.05$) improved significantly. After the intervention, strength also improved on the affected side for shoulder abduction, grip strength, and bilaterally for elbow flexion ($p < 0.05$ for all).

Nursing Implications

Nurses should know that yoga is feasible and safe to recommend for women at risk for BCRL and may result in small improvements in shoulder range of motion and upper extremity strength. Many women may have already been exposed to yoga or similar exercises prior to their cancer diagnosis and nurses can encourage these women to facilitate integration of this intervention into their postoperative care. The added benefits of yoga in providing stress reduction, mindfulness, breathing practices, and meditation may also contribute to a woman's sense of well-being and self-care.

A seroma, a collection of serous fluid, may accumulate under the breast incision after mastectomy or breast conservation or in the axilla. Signs and symptoms may include swelling, heaviness, discomfort, and a sloshing of fluid. Seromas may develop temporarily after the drain is removed or if the drain is in place and becomes obstructed. Seromas rarely pose a threat and may be treated by unclogging the drain or manually aspirating the fluid with a needle and syringe. Large, long-standing seromas that have not been aspirated may lead to infection. Small seromas that are not bothersome to the patient usually resolve on their own.

Infection. Although infection is rare, it is a risk after any surgical procedure. This risk may be higher in patients with conditions such as diabetes, immune disorders, and advanced age, as well as in those with poor hygiene. Patients are taught to monitor for signs and symptoms of infection (redness, warmth around incision, tenderness, foul-smelling drainage, temperature greater than 38°C [100.4°F], chills) and to contact the

surgeon or nurse for evaluation. Treatment consists of oral or IV antibiotics (for more severe infections) for 1 or 2 weeks. Cultures are taken of any foul-smelling discharge.

Changes in Sexual Function. Once discharged from the hospital and feeling well, most patients are physically allowed to engage in sexual activity, if interested. However, any change in the patient's body image, self-esteem, or the response of her partner may increase her anxiety level and affect sexual function. Some partners may have difficulty looking at the incision, whereas others may be completely unaffected. Encouraging the patient to openly discuss how she feels about herself and about possible reasons for a decrease in libido (e.g., fatigue, anxiety, self-consciousness) may help clarify issues for her. Helpful suggestions for the patient may include varying the time of day for sexual activity (when the patient is less tired), assuming positions that are more comfortable, and expressing affection using alternative measures (e.g., hugging, kissing, manual stimulation).

Most patients and their partners adjust with minimal difficulty if they openly discuss their concerns. However, if issues cannot be resolved, a referral for counseling (e.g., psychologist, psychiatrist, psychiatric clinical nurse specialist, social worker, sex therapist) may be helpful. The ambulatory care nurse in the outpatient clinic or hospital should inquire whether the patient who was sexually active prior to surgery has resumed activities, because many patients are reluctant or embarrassed to bring this topic up themselves.

Promoting Home, Community-Based, and Transitional Care

Educating Patients About Self-Care. Patients who undergo breast cancer surgery receive a tremendous amount of information both pre- and postoperatively. It is often difficult for the patient to absorb all of the information, partly because of the emotional distress that often accompanies the diagnosis and treatment. Prior to discharge, the nurse must assess the patient's readiness to assume self-care responsibilities and identify any gaps in knowledge. A review of education provided in written and oral forms, with reinforcement, may be required to ensure that the patient and family are prepared to manage the necessary care at home. The nurse reiterates symptoms that the patient should report, such as infection, seroma, hematoma, or arm swelling. All instruction should be reinforced during office visits and by telephone.

Most patients are discharged 1 or 2 days after ALND or mastectomy (possibly later if they have had immediate reconstruction) with surgical drains in place. Initially, the drainage fluid appears bloody, but it gradually changes to a serosanguineous and then a serous fluid over the next several days. The patient is given instructions about drainage management at home (see Chart 52-7). If the patient lives alone and drainage management is difficult, a referral for a home health nurse should be made. The drains are usually removed when the output is less than 30 mL in two consecutive 24-hour periods (approximately 7 to 10 days) (Grobmyer & Bland, 2018). The home health nurse also reviews pain management and incision care.

Chart 52-7  **HOME CARE CHECKLIST**

Patient with a Drainage Device Following Breast Surgery

At the completion of education, the patient and/or caregiver will be able to:

- Name the procedure that was performed and identify changes in anatomic structure or function as well as changes in ADLs, IADLs, roles, relationships, and spirituality.
- Identify interventions and strategies (e.g., prosthesis) used in adapting to any permanent changes in structure or function.
- Describe ongoing postoperative therapeutic regimen, including diet and activities to perform (e.g., when to shower, arm exercises) and to limit or avoid (e.g., lifting weights, driving a car, contact sports).
- State the name, dose, side effects, frequency, and schedule for all medications.
  - Describe approaches to controlling pain (e.g., take analgesics as prescribed; use nonpharmacologic interventions).
- State how to obtain medical supplies and carry out dressing changes, wound care, and other prescribed regimens.
  - Care for the drain site and incision as per surgeon's recommendation.
  - Demonstrate how to empty and measure fluid from the drainage device.
  - Demonstrate how to milk clots through the tubing of the drainage device.
  - Identify when the drain is ready for removal (usually when draining <30 mL for 24 to 48 hours).
- Describe signs and symptoms of complications.
  - State observations that require contacting the primary provider or nurse (e.g., sudden change in color of drainage, sudden cessation of drainage, signs or symptoms of an infection).
- Relate how to reach primary provider with questions or complications.
- State time and date of follow-up appointments, therapy, and testing.
- Identify sources of support (e.g., friends, relatives, faith community).
- Identify the contact details for support services (for patients and their caregivers/families).
- Identify the need for health promotion, disease prevention, and screening activities (e.g., gynecologic examination, mammogram).

ADL, activities of daily living; IADL, instrumental activities of daily living.

In general, the patient may shower on the second postoperative day and wash the incision and drain site with soap and water to prevent infection. Some surgeons do not permit showers until 48 hours after drains are removed. If immediate reconstruction has been performed, showering may be contraindicated until the drain is removed. A dry dressing may be applied to the incision each day for 7 days. The patient should realize that sensation may be decreased in the operative area because the nerves were disrupted during surgery, and she should be informed that gentle care is needed to avoid injury. After the incision has completely healed (usually after 4 to 6 weeks), lotions or creams may be applied to the area to increase skin elasticity. The patient can begin to use deodorant on the affected side, although many women note that they no longer perspire as much as before the surgery.

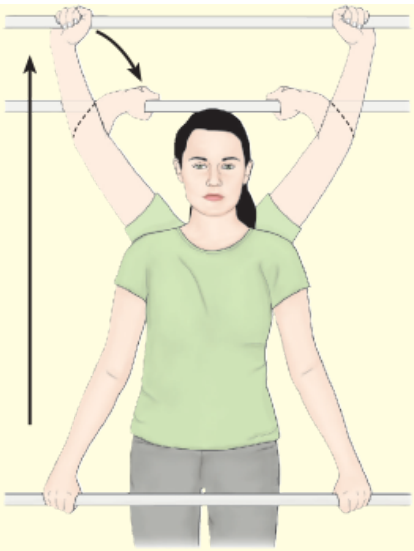
After ALND, patients are taught arm exercises on the affected side to restore range of motion (see Chart 52-8). After SLNB, patients may also benefit from these exercises, although they are less likely to have decreased range of motion than those who have undergone ALND. Range-of-motion exercises are initiated on the second postoperative day; however, instruction often occurs on the first postoperative day. The goals of the

exercise regimen are to increase circulation and muscle strength, prevent joint stiffness and contractures, and restore full range of motion. The patient is instructed to perform range-of-motion exercises at home three times a day for 20 minutes at a time until full range of motion is restored (generally 4 to 6 weeks). Most patients find that after the drain is removed, range of motion returns quickly if they have adhered to their exercise program.

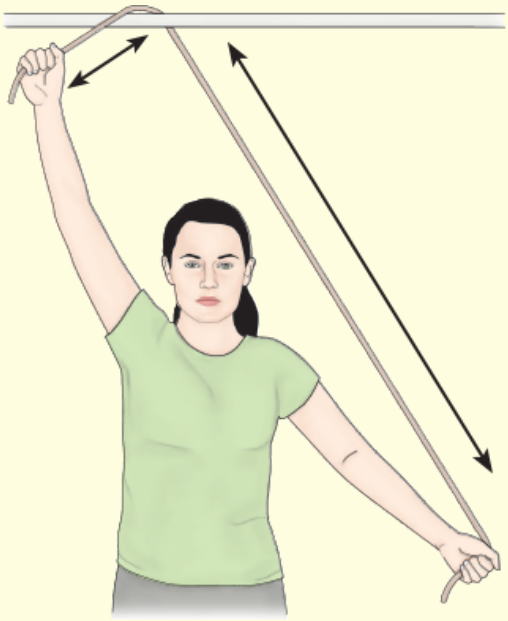
Chart 52-8  **PATIENT EDUCATION**

Exercise After Breast Surgery

The nurse instructs the patient to perform the following exercises:



1. *Wall hand climbing.* Stand facing the wall with feet apart and toes as close to the wall as possible. With elbows slightly bent, place the palms of the hand on the wall at shoulder level. By flexing the fingers, work the hands up the wall until arms are fully extended. Then reverse the process, working the hands down to the starting point.



2. *Rope turning.* Tie a light rope to a doorknob. Stand facing the door. Take the free end of the rope in the hand on the side of surgery. Place the other hand on the hip. With the rope-holding arm extended and held away from the body (nearly parallel with the floor), turn the rope, making as wide swings as possible. Begin slowly at first; speed up later.

3. *Rod or broomstick lifting.* Grasp a rod with both hands, held about 2 feet apart. Keeping the arms straight, raise the rod over the head. Bend elbows to lower the rod behind the head. Reverse maneuver, raising the rod above the head, then return to the starting position.

4. *Pulley tugging.* Toss a light rope over a shower curtain rod or doorway curtain rod. Stand as close to the rope as possible. Grasp an end in each hand. Extend the arms straight and away from the body. Pull the left arm up by tugging down with the right arm, then the right arm up and the left down in a see-sawing motion.

If the patient is having any discomfort, taking an analgesic agent 30 minutes before beginning the exercises can be helpful. Taking a warm shower before exercising can also loosen stiff muscles and provide comfort. When exercising, the patient is encouraged to use the muscles in both arms and to maintain proper posture. Specific exercises may need to be prescribed and introduced gradually if the patient has had skin grafts; has a tense, tight surgical incision; or has had immediate reconstruction. Self-care activities, such as brushing the teeth, washing the face, and brushing the hair, are physically and emotionally therapeutic because they aid in restoring arm function and provide a sense of normalcy for the patient.

The patient is instructed about postoperative activity limitation. In general, heavy lifting (more than 5 to 10 lb) is avoided for about 4 to 6 weeks, although normal household and work-related activities are promoted to maintain muscle tone. Brisk walking, the use of stationary bikes and stepping machines, and stretching exercises may

begin as soon as the patient feels comfortable. Once the drain is removed, the patient may begin to drive if she has full arm range of motion and is no longer taking opioid analgesic agents. General guidelines for activity focus on the gradual introduction of previous activities (e.g., bowling, weight training) once fully healed.

Continuing and Transitional Care. Patients who have difficulty managing their postoperative care at home may benefit from a referral for home health, transitional, or community-based care. The nurse making a home visit assesses the patient's incision and surgical drain(s), adequacy of pain management, adherence to the exercise plan, and overall physical and psychological functioning. In addition, the home health nurse reinforces previous education and communicates important physiologic findings and psychosocial issues to the patient's primary provider, nurse, or surgeon.

The frequency of follow-up visits after surgery may vary but generally should occur every 3 to 6 months for the first several years. These visits may occur with the surgeon, medical oncologist or radiation oncologist, depending on the treatment regimen. The ambulatory care nurse can also be a great source of education for the patient and family and should encourage them to telephone if they have any questions or concerns. It is common for people to ignore routine health care when a major health issue arises, so women who have been treated for breast cancer should be reminded of the importance of participating in routine health screening.

Evaluation

Expected preoperative patient outcomes may include:

1. Exhibits knowledge about diagnosis and surgical treatment options
   a. Asks relevant questions about diagnosis and available surgical treatments
   b. States rationale for surgery
   c. Describes advantages and disadvantages of treatment options
2. Verbalizes willingness to deal with anxiety and fears related to the diagnosis and the effects of surgery on self-image and sexual functioning
3. Demonstrates ability to cope with diagnosis and treatment
   a. Verbalizes feelings appropriately and recognizes normalcy of mood lability
   b. Proceeds with treatment in timely fashion
   c. Discusses impact of diagnosis and treatment on family and work
4. Makes decisions regarding treatment options in timely fashion

Expected postoperative patient outcomes may include:

1. Reports that pain has decreased and states pain and discomfort management strategies are effective
2. Identifies postoperative sensations and recognizes that they are a normal part of healing
3. Exhibits clean, dry, and intact surgical incisions without signs of inflammation or infection
4. Lists the signs and symptoms of infection to be reported to the nurse or surgeon
5. Verbalizes feelings regarding change in body image
6. Discusses meaning of the diagnosis, surgical treatment, and fears appropriately
7. Participates actively in self-care measures
   a. Performs exercises as prescribed
   b. Participates in self-care measures as prescribed
8. Discusses issues of sexuality and resumption of sexual relations
9. Demonstrates knowledge of post discharge recommendations and restrictions
   a. Describes follow-up care and activities
   b. Demonstrates appropriate care of incisions and drainage system

c. Demonstrates arm exercises, and describes exercise regimen and activity limitations during postoperative period
d. Describes care of affected arm and hand, and lists indications to contact the surgeon or nurse

10. Experiences no complications
a. Identifies signs and symptoms of reportable complications (e.g., fever, redness, heat, pain, edema)
b. Explains how to contact appropriate providers in case of complications

Radiation Therapy

Radiation therapy is used to decrease the chance of a local recurrence in the breast by eradicating residual microscopic cancer cells. Breast conservation treatment followed by radiation therapy for stages I and II breast cancer results in a survival rate equal to that of a mastectomy (Freedman, 2018a). If radiation therapy, which is part of breast conservation treatment (see Chart 52-9), is contraindicated, a mastectomy would then be indicated.

Chart 52-9

Contraindications to Breast Conservation Treatment

Note: Breast-conservation treatment includes both surgery and radiation.

Absolute Contraindications

- First or second trimester of pregnancy
- Prior radiation to the breast or chest region
- Patient preference for mastectomy

Relative Contraindications

- History of collagen vascular disease
- Large tumor-to-breast ratio
- High probability of recurrence
- High probability of problems with radiation therapy
- Two or more tumors in different quadrants of the breast

Adapted from Rivere, A., & Klimberg, V. (2018). Lymphedema in the postmastectomy patient: Pathophysiology, prevention, and management. In K. Bland, E. Copeland, V. Klimberg, et al. (Eds.). *The breast: comprehensive management of benign and malignant diseases* (5th ed.). Philadelphia, PA: Elsevier.

External-beam radiation (the most common type) typically begins about 6 weeks after breast conservation to allow the surgical site to heal. If systemic chemotherapy is indicated, radiation therapy usually begins after its completion. Before radiation begins, the patient undergoes a planning session called a *simulation,* in which the anatomic areas to be treated are mapped out and then identified with small permanent ink markings (National Cancer Institute, 2018b). External-beam radiation, which delivers high-energy photons from a linear accelerator, is given to the entire breast region (whole breast radiation). Each treatment lasts only a few minutes and is generally given 5 days a week for 5 to 6 weeks. After completion of radiation to the entire breast, many patients receive a "boost"—a dose of radiation to the

lumpectomy site where the cancer cells were located. The boost consists of the same dose of radiation but is less penetrating and directed to a smaller area. The treatments are not painful.

Because most breast cancer recurrences appear at or near the lumpectomy site, the need for whole breast radiation has been questioned. Partial breast radiation (radiation to the lumpectomy site alone) continues be evaluated at some institutions in patients who have been carefully selected. One approach is **brachytherapy**, in which radiation is delivered by an internal device that is placed inside or adjacent to the tumor within the breast. This technique can lead to an improved quality of life because the treatments are given over 4 to 5 days instead of 5 to 6 weeks. After mastectomy, postoperative radiation may be indicated for women at high risk for cancer recurrence (i.e., chest wall involvement, four or more positive lymph nodes, tumors larger than 5 cm, positive surgical margins).

Side Effects

In general, radiation therapy is well tolerated. Acute side effects consist of mild to moderate erythema, breast edema, and fatigue. Occasionally, skin breakdown may occur in the inframammary fold or near the axilla toward the end of treatment; breakdown may be managed by application of topical medications between treatments (Freedman, 2018b). Fatigue can be depressing, as can the frequent trips to the radiation oncology unit for treatment. The patient needs to be reassured that the fatigue is normal and not a sign of recurrence. Side effects usually resolve within a few weeks to a few months after treatment is completed. Some long-term effects of radiation therapy include lung disease, dental disease, osteoporosis, and heart and vascular disease (Pedersen & Klemp, 2018).

Nursing Management

Nurses play a significant role in supporting patients throughout their treatment with radiation therapy. During brachytherapy, the radiation source will give off radiation. Patients must be educated about safety measures, including any restrictions to visitors, especially young children and pregnant women (National Cancer Institute, 2018a). See Chapter 12 for discussion of radiation therapy.

Self-care instructions for patients receiving radiation are provided to assist in the maintenance of skin integrity during the treatments and for several weeks after completion. They pertain only to the area being treated and not to the rest of the body. Instructions from the National Cancer Institute (2018c) include:

- Use mild soap with minimal rubbing.
  - Avoid perfumed soaps or deodorants.
  - Use hydrophilic lotions for dryness.
  - Use a nondrying, antipruritic soap if pruritus occurs.
  - Avoid tight clothes, underwire bras, excessive temperatures, and ultraviolet light.

Follow-up care includes educating the patient to minimize sun exposure to the treated area (i.e., using sunblock with sun protection factor [SPF] of 15 or higher) and reassuring the patient that short-term minor twinges and pain in the breast are normal after radiation treatment.

Systemic Treatments

Chemotherapy

Adjuvant chemotherapy involves the use of anticancer agents in addition to other treatments (i.e., surgery, radiation) to delay or prevent a recurrence of breast cancer. It is generally recommended for patients who have positive lymph nodes or who have invasive tumors greater than 1 cm in size, regardless of nodal status. It is considered in patients with smaller tumors; involvement of lymph nodes affects the decision-making process (NCCN, 2019). Table 52-6 outlines general indications for adjuvant chemotherapy. A survival benefit has been shown in both women who are pre- and postmenopausal and who have received chemotherapy, although data are limited in women older than 70 years. Chemotherapy is most commonly initiated after breast surgery and before radiation. Preoperative therapy may be considered in order to shrink tumor size to support breast conservation (Telli, 2018). Patients with triple-negative breast cancer (cancer that tests negative for estrogen receptors, progesterone receptors, and excess HER2 protein) who delay initiation of chemotherapy beyond 30 days postsurgery have an increased risk of recurrence (DePolo, 2018). Nurses encourage and assist in facilitating timely treatment to optimize outcomes.

TABLE 52-6 General Indications for Adjuvant Chemotherapy for Breast Cancer

Nodal Status, Tumor Size	Adjuvant Chemotherapy
Node negative, ≤0.5 cm	None
Node negative 0.6–1 cm (well differentiated)	None
Node negative, 0.6–1 cm (moderately or poorly differentiated and unfavorable features)	Consider chemotherapy
Node negative, >1 cm	Chemotherapy
Node positive, any tumor size	Chemotherapy

- In addition to chemotherapy, patients with HER-2/neu-positive tumors will receive trastuzumab if they have node-positive disease; or node-negative disease with a tumor >1 cm. Trastuzumab is a monoclonal antibody that targets and inactivates the HER-2/neu protein. HER-2/neu is overproduced in 25–30% of tumors and is associated with rapid growth and poor prognosis.
- Following chemotherapy, patients with hormone receptor positive (ER+/PR+) tumors will receive hormonal therapy (tamoxifen or aromatase inhibitor) if they have either node-positive disease; node-negative disease with a tumor >1 cm; or node-negative disease with a tumor 0.6–1 cm and moderately or poorly differentiated and unfavorable features.

Note: These are only general guidelines. Recommendations may vary depending on factors such as prognostic variables, patient age, and comorbid conditions.

Adapted from National Comprehensive Cancer Network (NCCN). (2019). Clinical practice guidelines: Breast. Retrieved on 9/9/2019 at: www.nccn.org/professionals/physician_gls/pdf/breast_risk.pdf

Chemotherapy regimens for breast cancer combine several agents (polychemotherapy), generally given over a period of 3 to 6 months. Decisions regarding the optimal regimen are based on a variety of factors, including tumor characteristics (i.e., tumor size, lymph node status, hormone receptor status, HER-2/neu status) and the patient's age, physical status, and existing comorbid conditions. A regimen that includes ***c***yclophosphamide, ***m***ethotrexate, and ***f***luorouracil (collectively referred to as CMF) has been the most widely used adjuvant therapy. It is usually well tolerated and may be considered for patients with a low risk of recurrence. CMF also may be considered for use in patients who have a high risk of cardiac toxicity or who have other limiting comorbidities. Anthracycline-based regimens (e.g., doxorubicin, epirubicin) have shown longer survival in patients. However, the benefit relative to CMF is modest and is accompanied by increased toxicity, especially to the bone marrow (Santa-Maria & Gradishar, 2018). Selection of patients most likely to benefit from anthracycline therapy would allow better use of current cytotoxic agents and reduce the risk of patients receiving toxicity with little or no effect. ***C***yclophosphamide, ***d***oxorubicin (trade

name ***A***driamycin), and **f**luorouracil (CAF) and ***d***oxorubicin and ***c***yclophosphamide (AC) are examples of the trade names of combination regimens often given to patients who are at high risk. Identifying biomarkers that can accurately predict benefit from specific chemotherapeutic agents will also highlight key resistance/susceptibility pathways that can then be exploited clinically to further increase efficacy and ensure timely treatment (Korourian, Kumarapeli, & Klimberg, 2018).

The taxanes (paclitaxel, docetaxel) are generally incorporated into treatment regimens for patients with larger, node-negative cancers and for those with positive axillary lymph nodes. The addition of four cycles of paclitaxel after a standard course of AC has been found to increase the disease-free period and improve overall survival in patients with operable breast cancer and positive lymph nodes (NCCN, 2019).

Much attention has been focused on **dose-dense chemotherapy**, which is the administration of chemotherapeutic agents at standard doses with shorter time intervals between each cycle of treatment. Cells are more sensitive to chemotherapy during rapid growth phase, so more frequent doses kill more cancer cells than increased doses (Santa-Maria & Gradishar, 2018). Dose density is standard of care with some breast cancers, but is still controversial with estrogen-receptor positive disease.

Side Effects

Many of the side effects of adjuvant chemotherapy can be managed well, allowing patients to maintain their daily routines and work schedules. In large part, this is the result of the meticulous educational and psychological preparation provided to patients and their families by oncology nurses, oncologists, social workers, and other members of the health care team. In addition, strides have been made in the effectiveness of antiemetic agents used to alleviate nausea and vomiting and the use of hematopoietic growth factors to treat neutropenia and anemia.

Common physical side effects of chemotherapy for breast cancer may include nausea, vomiting, bone marrow suppression, taste changes, alopecia (hair loss), mucositis, neuropathy, skin changes, and fatigue. A weight gain of more than 10 lb occurs in about half of all patients; the cause is unknown. Women who are premenopausal may also experience temporary or permanent amenorrhea.

Specific side effects vary with the type of chemotherapeutic agent used. In general, CMF and the taxanes are better tolerated than the anthracyclines. However, the taxanes can cause peripheral neuropathy, arthralgias, and myalgias, particularly at high doses. During taxane administration, hypersensitivity reactions may occur; therefore, the patient must be premedicated with corticosteroids and antihistamines. Alopecia is also common. The side effects of the anthracyclines may be severe and include cardiotoxicity in addition to nausea and vomiting, bone marrow suppression, and alopecia. Their vesicant properties can lead to tissue necrosis if infiltration of the medication infusion occurs.

Nursing Management

Nurses play an important role in helping patients manage the physical and psychosocial sequelae of chemotherapy. (Chapter 12 provides an in-depth discussion of side effect management.) Educating the patient about the use of antiemetic agents and reviewing the optimal dosage schedule can help minimize nausea and vomiting. The different classes of antiemetic agents include serotonin (5-HT_3) receptor antagonists (palonosetron, granisetron, ondansetron); neurokinin-1 receptor antagonists (aprepitant); dopamine receptor antagonists (prochlorperazine, metoclopramide); benzodiazepines (lorazepam); and corticosteroids (dexamethasone). Measures to ease the symptoms of mucositis may include rinsing with

normal saline or sodium bicarbonate solution, avoiding hot and spicy foods, and using a soft toothbrush.

Chart 52-10 HOME CARE CHECKLIST

Self-Administration of Hematopoietic Growth Factors

At the completion of education, the patient and/or caregiver will be able to:

- State the impact of treatment on physiologic functioning, ADLs, IADLs, roles, relationships, and spirituality.
- Identify the benefits and expected outcome of hematopoietic growth factors.
- Locate list of names and telephone numbers of resource personnel involved in care (e.g., health care professionals, home health nurse, hematopoietic growth factor and supply vendor).
- Identify the equipment necessary for self-injection and how to obtain hematopoietic growth factor and supplies.
- Demonstrate how to give an injection properly, including:
  - How to draw up the solution in a syringe if indicated. (*Note:* Darbepoetin and pegfilgrastim come in prefilled syringes; pegfilgrastim also comes in an on-body injector placed by a nurse and monitored by the patient or caregiver.)
  - Identify appropriate body sites for self-injection.
  - Demonstrate correct disposal of sharps.
  - Describe proper storage of supplies.
- State what types of lifestyle and environmental changes are needed (if any) to maintain a clean home environment and prevent infection.
- State the name, dose, side effects, frequency, and schedule for all medications.
- List complications of medications/therapeutic regimen necessitating a call to the nurse or primary provider (e.g., excessive pain, fever).
- List complications of medications/therapeutic regimen necessitating a visit to the emergency department.
- Explain treatment plan and importance of follow-up care to all health care providers.
  - State time and date of follow-up appointments, therapy, and testing.
- Identify community resources for peer and caregiver/family support:
  - Identify sources of support (e.g., friends, relatives, faith community).
  - Identify the contact details for support services for patients and their caregivers/families.
- Identify the need for health promotion, disease prevention, and screening activities.

ADL, activities of daily living; IADL, instrumental activities of daily living.

Some patients may require hematopoietic growth factors to minimize the effects of chemotherapy-induced neutropenia and anemia. Granulocyte colony-stimulating factors boost the white blood cell count, helping to reduce the incidence of neutropenic fever and infection. The short-acting form, filgrastim, is injected subcutaneously or IV for 7 to 10 days after chemotherapy administration. The long-acting form, pegfilgrastim, is injected once, no earlier than 24 hours after chemotherapy (Vallerand & Sanoski, 2018). Erythropoietin growth factor increases the production of red blood cells, thus decreasing the symptoms of anemia. The short-acting form, epoetin alfa is usually given weekly. The long-acting form, darbepoetin alfa, can be given every 2 to 3 weeks. The nurse instructs the patient and family

on proper injection technique of hematopoietic growth factors and about symptoms that require follow-up with a primary provider (see Chart 52-10).

To prevent some of the emotional trauma associated with alopecia, it often helps to have a patient obtain a wig before hair loss begins to occur. The nurse may provide a list of wig suppliers in the patient's geographic region. Familiarity with creative ways to use scarves and turbans may also help minimize the patient's distress. The patient needs reassurance that new hair will grow back when treatment is completed, although the color and texture may be different. The ACS offers the Look Good Feel Better program, which provides useful tips for applying cosmetics during the period a patient is receiving chemotherapy (see Resources section).

Chemotherapy may negatively affect the patient's self-esteem, sexuality, and sense of well-being. This, combined with the stress of a potentially life-threatening disease, can be acute. Providing support and promoting open communication are important aspects of nursing care. Referring the patient to the dietitian, social worker, psychiatrist, or spiritual advisor can provide additional support. Numerous community support and advocacy groups are available for patients and their families. Complementary therapies, such as guided imagery, meditation, and relaxation exercises, can also be used in conjunction with conventional treatments.

Hormonal Therapy

The use of **adjuvant hormonal therapy**, with or without the addition of chemotherapy, is considered in women who have hormone receptor–positive tumors. Its use can be determined by the results of an estrogen and progesterone receptor assay (a test to determine whether the breast tumor is nourished by hormones). About two thirds of breast cancers depend on estrogen for growth and express a nuclear receptor that binds to the estrogen; thus, they are estrogen receptor positive (ER+). Similarly, tumors that express the progesterone receptor are progesterone receptor positive (PR+). Hormonal therapy involves the use of synthetic hormones or other medications that compete with estrogen by binding to the receptor sites (SERMs), or the use of **aromatase inhibitors**, which block estrogen production by the adrenal glands. In general, tumors that are ER+/PR+ have the greatest likelihood of responding to hormonal therapy and have a more favorable prognosis than those that are ER−/PR−. Women who are pre- and perimenopausal are more likely to have non–hormone-dependent lesions, whereas women who are postmenopausal are more likely to have hormone-dependent lesions.

Traditionally, the SERM tamoxifen has been the main hormonal agent used in treatment of pre- and postmenopausal breast cancer and remains the mainstay in women who are premenopausal. As an SERM, tamoxifen has estrogen antagonistic (estrogen-blocking) and agonistic (estrogenlike) effects on certain tissues. Its antagonistic effects in the breast prevent estrogen from binding to the receptor sites, thus preventing tumor growth. Tamoxifen has positive agonistic effects on blood lipid profiles and bone mineral density in women who are postmenopausal. It also has agonistic effects on endometrial tissue and blood coagulation processes, leading to an increased incidence of endometrial cancer and thromboembolic events (e.g., deep vein thrombosis [DVT], superficial phlebitis, pulmonary embolism). Nevertheless, the benefits in most women with breast cancer outweigh the risks.

The aromatase inhibitors anastrozole, letrozole, and exemestane are important components in the hormonal management of women who are postmenopausal. Most of the circulating estrogens in women who are postmenopausal are derived from the conversion of the adrenal androgen androstenedione to estrone and the conversion of testosterone to estradiol. Aromatase inhibitors work by blocking the enzyme aromatase from performing the conversion, thereby decreasing the level of circulating estrogen in peripheral tissues. Clinical

trials have demonstrated that the aromatase inhibitors are superior to tamoxifen in terms of overall response rate and clinical benefit and that inhibitors appear to be effective and feasible compared with tamoxifen as first-line hormonal therapy in women who are postmenopausal with advanced breast cancer (Santa-Maria & Gradishar, 2018). These data ensure that aromatase inhibitors will play an increasingly central role in the long-term management of breast cancer. Trials are ongoing to determine the optimal treatment regimen and the timing of the treatment; possible eligibility for a clinical trial should be discussed between the patient and the care team. Table 52-7 outlines the adverse effects of adjuvant hormonal therapy. Chart 52-11 outlines appropriate patient education to manage the adverse effects.

TABLE 52-7 Adverse Reactions Associated with Adjuvant Hormonal Therapy Used to Treat Breast Cancer

Therapeutic Agent	Adverse Reactions/Side Effects
Selective Estrogen Receptor Modulator	
tamoxifen	Hot flashes, vaginal dryness/discharge/bleeding, irregular menses, nausea, mood disturbances, rashes; increased risk for endometrial cancer; increased risk for thromboembolic events (deep vein thrombosis, pulmonary embolism, superficial phlebitis)
Aromatase Inhibitors	
anastrozole letrozole exemestane	Musculoskeletal symptoms (arthritis, arthralgia, myalgia), increased risk of osteoporosis/fractures, nausea/vomiting, hot flashes, fatigue, mood disturbances, rashes

Adapted from Vallerand, A., & Sanoski, C. (2018). *Davis's drug guide for nurses* (15th ed.). Philadelphia, PA: Davis.

Targeted Therapy

An exciting area of research in the systemic treatment of breast cancer involves the use of targeted therapies. Trastuzumab is a monoclonal antibody that binds specifically to the **HER-2/neu** protein. This protein, which regulates cell growth, is present in small amounts on the surface of normal breast cells and in most breast cancers. Approximately 20% of tumors overexpress (overproduce) the HER-2/neu protein and are associated with rapid growth and poor prognosis (Mayo Clinic, 2020). Trastuzumab targets and inactivates the HER-2/neu protein, thus slowing tumor growth.

Unlike chemotherapy, trastuzumab spares the normal cells and has limited adverse reactions, which may include fever, chills, nausea, vomiting, diarrhea, and headache. However, when trastuzumab is given to patients who have previously been treated with an anthracycline, the risk of cardiac toxicity is increased. The medication has been shown to improve survival rates in women with HER-2/neu–positive metastatic breast cancer and is now regarded as standard therapy. Recently, three other HER2-targeting agents have entered routine clinical practice. These include a small molecule receptor tyrosine kinase inhibitor (lapatinib) and two novel HER2-targeting monoclonal antibodies (pertuzumab and ado-trastuzumab emtansine). Assessing the benefits and risks of these medications is complex, and medical oncologists often use a variety of aids in their decision making (Sledge, 2018).

Chart 52-11  **PATIENT EDUCATION**

Managing Side Effects of Adjuvant Hormonal Therapy in Breast Cancer

The nurse instructs the patient in strategies to manage the following side effects:

Hot Flashes

- Wear breathable, layered clothing.
- Avoid caffeine and spicy foods.
- Perform breathing exercises (paced respirations).
- Consider medications (vitamin E, antidepressants) or acupuncture.

Vaginal Dryness

- Use vaginal moisturizers for everyday dryness (e.g., Replens, vitamin E suppository).
- Apply vaginal lubrication during penile–vaginal intercourse (e.g., Astroglide, K-Y Jelly).

Nausea and Vomiting

- Consume a bland diet.
- Try to take medication in the evening.

Musculoskeletal Symptoms

- Take nonsteroidal analgesic agents as recommended.
- Take warm baths.

Risk of Endometrial Cancer

- Report any irregular bleeding to a gynecologist for evaluation.

Risk for Thromboembolic Events

- Report any redness, swelling, or tenderness in the lower extremities, or any unexplained shortness of breath.

Risk for Osteoporosis or Fractures

- Undergo a baseline bone density scan.
- Perform regular weight-bearing exercises.
- Take calcium supplements with vitamin D.
- Take bisphosphonates (e.g., alendronate) or calcitonin as prescribed.

Treatment of Recurrent and Metastatic Breast Cancer

Despite the advances made in the treatment of breast cancer, it may recur locally (on the chest wall or in the conserved breast), regionally (in the remaining lymph nodes), or systemically (in distant organs). In metastatic disease, the bone, usually the hips, spine, ribs, skull, or pelvis, is the most common site of spread. Other sites of metastasis include the lungs, liver, pleura, and brain.

The overall prognosis and optimal treatment are determined by a variety of factors such as the site and extent of recurrence, the time to recurrence from the original diagnosis, history of prior treatments, the patient's performance status, and any existing comorbid conditions.

Patients with bone metastases generally have a longer overall survival compared with metastases in visceral organs.

Local recurrence in the absence of systemic disease is treated aggressively with surgery, radiation, and hormonal therapy. Chemotherapy may also be used for tumors that are not hormonally sensitive. Identifying a local recurrence may be an indicator of occult systemic disease (Wapnir, Tsai, & Aebi, 2018).

Metastatic breast cancer involves control of the disease rather than cure, individualized to location of the metastasis (NCCN, 2019). Treatment includes hormonal therapy, chemotherapy, and targeted therapy. Surgery or radiation may be indicated in select situations. Women who are premenopausal and who have hormonally dependent tumors may eliminate the production of estrogen by the ovaries through oophorectomy (removal of the ovaries) or suppression of estrogen production by medications such as leuprolide or goserelin.

Patients with advanced breast cancer are monitored closely for signs of disease progression. Baseline studies are obtained at the time of recurrence. These may include complete blood count; comprehensive metabolic panel; tumor markers (i.e., carcinoembryonic antigen, cancer antigen 15-3); bone scan; CT of the chest, abdomen, and pelvis; and MRI of symptomatic areas. Additional x-rays may be performed to evaluate areas of pain or abnormal areas seen on bone scan (e.g., long bones, pelvis). These studies are repeated at regular intervals to assess for effectiveness of treatment and to monitor progression of disease.

Nursing Management

Nurses play an important role in not only educating patients and managing their symptoms but also in providing emotional support. Many patients find that recurrence of the disease is more distressing than the initial cancer diagnosis. They not only have to contend with another round of treatments but are also faced with a greater uncertainty about their future and long-term survival. The nurse can help the patient identify coping strategies and set priorities to optimize quality of life. Family members and significant others should be included in the treatment plan and follow-up care. Referrals to support groups, as well as psychiatry or psychiatric clinical nurse specialist, social work, and complementary medicine programs (e.g., guided imagery, meditation, yoga), should be made as indicated.

Nurses can also be instrumental in providing palliative care, if indicated. The highest priorities include alleviating pain and providing comfort measures. A frank discussion with the patient and family regarding their preferences for end-of-life care should occur before the need arises to ensure a smooth transition without disruption of care. Referrals to hospice and home health care should be initiated as necessary (see Chapters 12 and 13).

Reconstructive Procedures After Mastectomy

Breast reconstruction can provide a significant psychological benefit for women who are already struggling with the emotional distress of losing a breast. A consultation with a plastic surgeon can help the patient understand procedures for which she is a candidate and the pros and cons of each. Factors to consider include body size and shape, comorbid conditions (e.g., hypertension, diabetes, obesity), personal habits such as smoking, and patient preference. The patient must be informed that although breast reconstruction can provide a good cosmetic result, it will never precisely duplicate the natural breast. Realistic preparation can help the patient avoid unrealistic expectations. Once reconstruction is complete, the opposite breast may require augmentation, reduction, or mastopexy to achieve symmetry on both sides. The

patient must also be informed that breast reconstruction will not affect the risk of cancer recurrence. Reconstruction is considered an integral component in the surgical treatment of breast cancer and is usually covered by insurance companies.

Many women elect immediate reconstruction at the time of the mastectomy operation. This can be beneficial in that it saves the woman from undergoing general anesthesia a second time and saves the cost and stress of future hospitalizations. However, it does increase the length of the surgical procedure. Delayed reconstruction is preferable in women who are having a difficult time deciding on the type of reconstruction that they desire. It may also be preferable in patients with advanced disease such as inflammatory breast cancer, where the breast cancer treatments should begin without delay; delayed reconstruction may also be beneficial if radiation is planned, as radiation therapy is technically less complicated on an unreconstructed chest wall (Fayanju, Garvey, Karuturi, et al., 2018). Any delays in healing after immediate reconstruction may interfere with the initiation of treatment.

Tissue Expander Followed by Permanent Implant

Breast reconstruction using a tissue expander followed by a permanent implant is the simplest and most common method in use (see Fig. 52-6). To accommodate an implant, the skin remaining after a mastectomy and the underlying muscle must gradually be stretched by a process called *tissue expansion.* The surgeon places a tissue expander (a balloonlike device) through the mastectomy incision underneath the pectoralis muscle. A small amount of saline is injected through a metal port intraoperatively to partially inflate the expander. Then, for about 6 to 8 weeks, at weekly intervals, the patient receives additional saline injections through the port until the expander is fully inflated. It remains fully expanded for about 6 weeks to allow the skin to loosen. The expander is then exchanged for a permanent implant. This is usually performed as an outpatient surgical procedure.

Advantages of the expansion procedure are a shorter operating time and a shorter recuperation period than for autologous reconstruction (see the Tissue Transfer Procedures section). A disadvantage is a tendency for the implant to feel firm and round, with little natural ptosis (sag). Women with a small to medium opposite breast with little ptosis are good candidates for this procedure. Women who have had radiation or who have connective tissue disease are not good candidates because of the decreased elasticity of the skin.

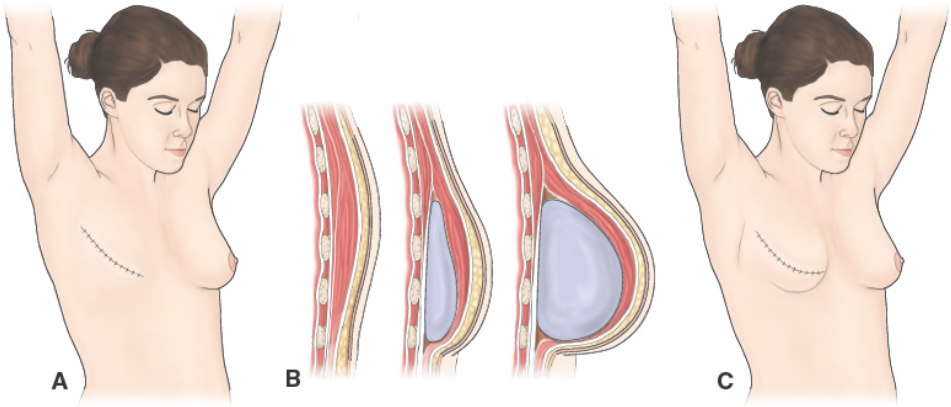


Figure 52-6 • Breast reconstruction with tissue expander. **A.** Mastectomy incision line prior to tissue expansion. **B.** The expander is placed under the pectoralis muscle and is gradually filled with saline solution through a port to stretch the skin enough to accept a permanent implant. **C.** The breast mound is restored. Although permanent, scars will fade with time. The nipple and areola are reconstructed later. Adapted from American Society of Plastic Surgeons.

Quality and Safety Nursing Alert

The patient must be cautioned not to have an MRI while the tissue expander is in place because the port contains metal. This is not an issue once the permanent implant is in place because it does not contain any metal.

The patient should be informed that for the rest of her life she should not engage in any exercises that will develop the pectoralis muscle, because this can result in distortion of the reconstructed breast.

Tissue Transfer Procedures

Autologous reconstruction is the use of the patient's own tissue to create a breast mound. A flap of skin, fat, and muscle with its attached blood supply is rotated to the mastectomy site to create a mound that simulates the breast. Donor sites may include the **transverse rectus abdominal myocutaneous (TRAM) flap** (abdominal muscle) (see Fig. 52-7), gluteal flap (buttock muscle), or the latissimus dorsi flap (back muscle) (see Fig. 52-8). The results more closely resemble a real breast because the skin and fat from the donor sites are similar in consistency to a natural breast. These procedures avoid the use of synthetic material. However, they involve longer recuperation than a tissue expander procedure. The risk of potential complications (e.g., infection, bleeding, flap necrosis) is also greater. Therefore, patients must be in relatively good health, and those with medical conditions (e.g., atherosclerosis, pulmonary disease, heart failure) that affect circulation or compromise oxygen delivery are not good candidates. Other candidates who are poor risks include those with poorly controlled diabetes or morbid obesity and those who smoke.

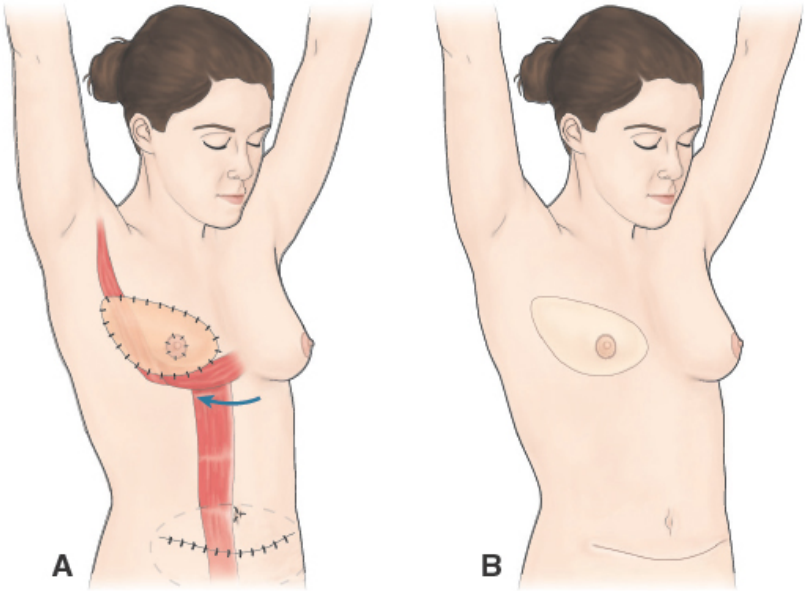

Figure 52-7 • Breast reconstruction: transverse rectus abdominal myocutaneous flap. **A.** A breast mound is created by tunneling abdominal skin, fat, and muscle to the mastectomy site. **B.** Final location of scars. Adapted from American Society of Plastic Surgeons.

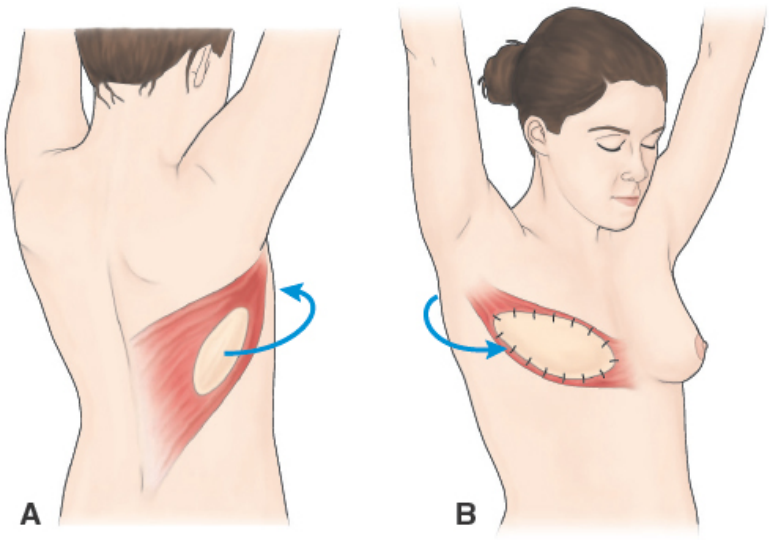

Figure 52-8 • Breast reconstruction: latissimus dorsi flap. **A.** The latissimus muscle with an ellipse of skin is rotated from the back to the mastectomy site. **B.** Because the flap is usually not bulky enough to provide an adequate breast mound, an implant is often also required. Adapted from American Society of Plastic Surgeons.

The TRAM flap is the most commonly performed tissue transfer procedure. A free TRAM procedure may also be performed; in this case, the skin, fat, muscle, and blood supply are completely detached from the body and then transplanted to the mastectomy site using microvascular surgery (the use of a microscope to reconnect the vessels). Postoperatively, patients who have undergone TRAM procedures often face a lengthy recovery (often 6 to 8 weeks) and have incisions both at the mastectomy site and at the donor site in the abdomen. Other free flap procedures include deep inferior epigastric perforator (DIEP) flap and superficial inferior epigastric artery (SIEA) flap depending on whether the superior gluteal artery perforator or the inferior one is utilized. Free flaps involve microsurgery for blood vessel transfer.

Deep breathing and leg exercises are essential because the patient is more limited in her activity and is at greater risk for respiratory complications and DVT. Measures to help the patient reduce tension on the abdominal incision during the first postoperative week include elevating the head of the bed 45 degrees and flexing the patient's knees.

Once the patient is able to ambulate, she can protect the surgical incision by splinting it and will gradually achieve a more upright position. The patient is instructed to avoid high-impact activities and lifting (more than 5 to 10 lb for 6 to 8 weeks after surgery) to prevent stress on the incision.

Nipple–Areola Reconstruction

After the breast mound has been created and the site has healed, some women choose to have nipple–areola reconstruction. This is a minor surgical procedure carried out either in the physician's office or at an outpatient surgical facility. The most common method of creating a nipple is with the use of local flaps (skin and fat from the center of the new breast mound), which are wrapped around each other to create a projecting nipple. The areola is created using a skin graft. The most common donor site is the upper inner thigh, because this skin has darker pigmentation than the skin on the reconstructed breast. After the nipple graft has healed, micropigmentation (tattooing) can be performed to achieve a more natural color. The

surgeon can usually match the reconstructed nipple–areola complex with that of the contralateral breast for an acceptable cosmetic result.

Prosthetics

Not all patients desire or are candidates for reconstructive surgery. A breast prosthesis—an external form that simulates the breast—is another option. Prostheses are available in different shapes, sizes, colors, and materials, although they are most often made of silicone. They can be placed inside a pocket in a bra or can adhere directly to the chest wall. The nurse can provide the patient with the names of shops where she can be fitted for a prosthesis, or the patient can call the Reach to Recovery program of the ACS for appropriate referrals. The patient should be encouraged to find a shop with a comfortable, supportive atmosphere that employs a certified prosthetics consultant. In general, medical supply shops are not recommended because often they do not have the appropriate resources to ensure the proper fitting of a prosthesis.

Prior to discharge from the hospital, the nurse usually provides the patient with a temporary, lightweight, cotton-filled form that can be worn until the surgical incision is well healed (4 to 6 weeks). After that, the patient can be fitted for a prosthesis. Insurance companies generally cover the cost of the prosthesis and the special bras that hold it in place. A breast prosthesis can provide a psychological benefit and assist the woman in resuming proper posture because it helps balance the weight of the remaining breast.

Special Issues in Breast Cancer Management

Implications of Genetic Testing

The rapid advancement in genetics not only has brought new knowledge about inherited breast cancer, but it has also raised potential ethical and psychosocial issues. Although the actual testing for the *BRCA1* and *BRCA2* and several other genes that increase risk involves a simple blood or saliva test, ethical and psychosocial issues must first be addressed. Before undergoing genetic testing, a person should meet either with a clinician who has expertise in this area or with a certified genetic counselor to discuss risk factors as well as the benefits, sequelae, and limitations of testing.

How people react when they receive their actual test results is not always easy to predict. A negative test in a person who comes from a family with a known mutation may lead to enormous relief. However, a negative test in a family with no known mutation may be a source of undue reassurance; the possibility of existing genes that cannot yet be detected remains. A negative test may also lead to feelings of guilt in a person whose family members did not receive favorable test results; this is known as survivor's guilt. A positive test could act as a motivator in a person to pursue appropriate screening or treatment, or it could cause tremendous anxiety, depression, and worry.

In addition, test results may be ambiguous, leading to feelings of confusion and uncertainty. People must be informed that not all gene carriers develop breast cancer (incomplete penetrance) and that not all noncarriers are protected or immune.

People must be well informed of all issues and potential implications prior to undergoing genetic testing (see Chapter 6). Nurses play a role in educating and counseling patients and their family members about the implications of genetic testing. Nurses provide support and clarification and make referrals to appropriate specialists when indicated.

Pregnancy and Breast Cancer

Breast cancer during pregnancy is defined as breast cancer diagnosed during gestation or within 1 year of childbirth. According to the NCCN, in a California registry study, 1.3 breast cancers are diagnosed in 10,000 live births (NCCN, 2019). Because of increased levels of hormones produced during pregnancy and subsequent lactation, the breast tissue becomes tender and swollen, making it more difficult to detect a mass. If a mass is found during pregnancy, ultrasound is the preferred diagnostic method because it involves no exposure to radiation. If indicated, mammography with appropriate shielding, FNA, and biopsy can be performed. Modified radical mastectomy remains the most common form of surgical treatment. SLNB is typically not offered under 30-week gestation because of the unknown effects of the radioisotope and the blue dye on the fetus (NCCN, 2019). Breast conservation treatment may be considered if the breast cancer is diagnosed during the third trimester. Radiation can then be delayed until after delivery because it is contraindicated during pregnancy. If a woman is close to term, a cesarean section may be performed as soon as maturation of the fetus allows and then treatment is initiated. If aggressive disease is detected early in pregnancy and chemotherapy is advised, termination of the pregnancy may be considered. If a mass is found while a woman is breast-feeding, she is urged to stop to allow the breast to involute (return to its baseline state) before any type of surgery is performed. Endocrine therapy is also contraindicated during pregnancy and should be postponed until the postpartum period.

Fertility issues and the future desire for children are major concerns of young women who are survivors of breast cancer. Most cancer therapies have a substantial morbidity on reproductive function, not only because they increase the risk of early menopause but also because they are associated with a decreased ovarian reserve and a loss of fertility. It is estimated that physiologic age of the ovaries in a survivor of cancer may be 10 years older than the actual chronologic age.

Chemotherapy causes a progressive dose-related depletion of ovarian follicles and granulosa cells that translates into oligomenorrhea and subsequent premature ovarian failure, ultimately leading to what is known as chemotherapy-induced amenorrhea (CIA). Regardless of the beneficial effects that hormonal changes can have as part of the adjuvant endocrine strategy, CIA is an adverse event to consider when selecting the best adjuvant treatment. Patients with cancer need to be informed about their reproductive future and options to preserve fertility before treatment (Petersen, Moravek, Woodruff, et al., 2018). SaveMyFertility, a national nonprofit organization, can also provide updated information on reproduction (see the Resources section).

Quality of Life and Survivorship

With increased early detection and improved treatment modalities, women with breast cancer have become the largest group of cancer survivors. Ninety-nine percent of women diagnosed with early-stage cancer localized to the breast will survive beyond 5 years (Mehra, Berkowitz, & Sanft, 2018). However, the treatment or simply the diagnosis of breast cancer may have long-term effects that negatively affect the patient and her family. The patient should be prepared early on for the potential long-term effects of the disease so that she has realistic expectations and can make informed decisions.

Survivors of breast cancer may experience a variety of issues as a result of their diagnosis and treatment. Estrogen withdrawal from chemotherapy-induced menopause and hormonal treatments can lead to a variety of symptoms, including hot flashes, vaginal dryness, urinary tract infections, weight gain, decreased sex drive, and increased risk of osteoporosis. HT to alleviate symptoms is contraindicated in women with breast cancer. Certain chemotherapeutic

agents can cause long-term cardiac effects and neuropathy. In addition, patients may experience impaired cognitive functioning, such as difficulty concentrating (often referred to as "chemo brain"). Studies have shown some correlation between levels of post-chemotherapy cognitive dysfunction and chemotherapy dosing; higher doses increase dysfunction (Shahpar, Mhatre, & Oza, 2018). Rare long-term effects of radiation can include pneumonitis, rib fractures, heart disease, and breast fibrosis or necrosis (Pederson & Klemp, 2018). Long-term sequelae after breast surgery may include lymphedema (mainly after ALND), pain, and sensory disturbances. Once lymphedema develops, it tends to be a chronic problem, so prevention strategies (discussed earlier) are vital. Weight gain and infections are risk factors for lymphedema (Makhoul, Banderudrappagari, & Pennisi, 2018). Nurses need to encourage patients to maintain an active lifestyle and avoid weight gain.

Long-term psychosocial sequelae may include fears of recurrence; mood changes (e.g., worry, sadness, anger, frustration); an increased sense of vulnerability, uncertainty, feelings of loss (e.g., fertility); concerns about body image, self-concept, and sexuality; emotional distress related to role adjustments and family response; and concerns about finances and employment. Depression and anxiety have been documented in 20% to 30% of women with breast cancer. Interventions should be targeted to meet informational needs, manage uncertainty, control symptoms, address cultural differences, and enhance social and emotional support (Makhoul et al., 2018).

Gerontologic Considerations

Breast cancer reconstruction in older women with breast cancer is a feasible option that should be offered to patients. Most women tolerate the procedure well and have good cosmetic outcomes. Patients can be offered both implant-based reconstruction and autologous tissue transfer with minimal complications as long as appropriate preoperative selection criteria are used. The safety of reconstruction, together with increase in perceived quality of life, life expectancy, and healthier lifestyles, makes breast reconstruction after mastectomy desirable at any age (van Ee, Smits, Honkoop, et al., 2019).

A thorough assessment must be performed before any treatment is initiated, and careful monitoring must occur throughout the course of treatment to avoid complications. The physical and psychosocial assessment of the older woman should include general health, currently existing comorbidities, performance status, cognitive status, current medications, available resources, and support systems.

Breast Health of Women with Disability

Disparities in obtaining a mammogram at recommended screening intervals persist for many women, including those with disability. Prevalence of self-reported use of mammography is lower for women with a disability. Thirty-six million women in the United States are disabled (Centers for Disease Control and Prevention [CDC], 2019a). Efforts to reduce disparities in breast cancer screening might be more effective if all segments of the population are targeted. Possible barriers to the use of mammography in women with disability include physical inaccessibility of office space and medical equipment; limited transportation and parking options; and time and assistance constraints associated with undressing, transferring, and positioning for medical examinations. People who are lesbian, gay, bisexual, transgender, and those questioning their gender may also be uncomfortable with the health care system and avoid screening (Kates, Ranji, Beamesderfer, et al., 2018). To promote health and wellness, health agencies, providers, and health care plans must promote cancer prevention and educational programs that are inclusive and responsive to the special needs of women with disability (CDC, 2019b).

An essential role of the nurse is to assist all women, including those with disability, to identify accessible health screening and to advocate for greater accessibility of imaging centers and other health care facilities. Reminding women of the need for recommended clinical breast examinations and mammograms is an important part of nursing care.

RECONSTRUCTIVE BREAST SURGERY

Breast reconstruction surgery, called **mammoplasty**, is an elective procedure that can enhance a woman's self-image and sense of well-being. Women desire reconstruction for a variety of physical and psychological reasons. Therefore, it is important for the health care team to conduct a thorough assessment prior to reconstructive surgery to evaluate the woman's underlying desire, motivation, and expectations. Preparing a woman realistically could help her to avoid potential disappointment. A variety of reconstructive options are available today for women who desire a correction in the size or the shape of the breast, including reduction mammoplasty (breast reduction), augmentation mammoplasty (breast enlargement), and mastopexy (breast lift). Several options are also available to reconstruct the breast after a mastectomy.

Reduction Mammoplasty

Reduction mammoplasty is usually performed on women who have breast hypertrophy (excessively large breasts). The weight of the enlarged breasts can cause discomfort, fatigue, embarrassment, and poor posture.

Reduction mammoplasty is an outpatient procedure that is performed under general anesthesia. Most commonly, an anchor-shaped incision that circles the areola is made, extending downward and following the natural curve of the inframammary fold. Depending on the size of the breast, the nipple may be moved up to a higher position while still attached to the breast tissue, or it may be separated and transplanted to a new location. Drains are placed in the incision and remain for 2 to 5 days.

During the preoperative consultation, the patient should be informed that there is a possibility that sensory changes of the nipple (such as numbness) may occur. These sensations are normal and usually resolve after several months but can sometimes persist. The procedure may also make breast-feeding impossible, although some women have breast-fed successfully. The patient must also be aware that if she gains weight (usually more than 10 lb), her breasts may also enlarge.

After reduction mammoplasty, many women verbalize feelings of extreme satisfaction, possibly because of the relief they experience. The patient is instructed to wear a supportive bra 24 hours a day for 2 weeks to prevent tension on the swollen breast and incision line. Vigorous exercise (e.g., jumping, jogging) should be avoided for about 6 weeks after surgery.

Augmentation Mammoplasty

Augmentation mammoplasty is requested by women who desire larger or fuller breasts. The procedure is performed by placing a breast implant either under the pectoralis muscle (subpectoral) or under the breast tissue (subglandular). The subpectoral approach is preferred because it interferes less with clinical breast examinations and mammograms. The incision line can be placed in the inframammary fold, in the axilla, or around the areola. The

procedure is performed as an outpatient procedure under general anesthesia. A drain is not necessary. Postoperative instructions are the same as for reduction mammoplasty.

Saline implants are typically used for augmentation mammoplasty. The FDA has approved the use of silicone gel–filled implants manufactured by three companies. FDA approval for use of these implants applies to women of all ages for breast reconstruction, and women 22 years and older for breast augmentation (FDA, 2019). Women with breast implants should be aware that mammograms may be more difficult to read, so they should seek experienced breast radiologists.

Mastopexy

Mastopexy is performed when the patient is happy with the size of her breasts but wishes to have the shape improved and a lift performed. This is also an outpatient surgical procedure, and postoperative instructions are the same as for reduction mammoplasty.

DISEASES OF THE MALE BREAST

Gynecomastia

Gynecomastia is the most common breast condition in the male. Adolescent boys can be affected because of hormones secreted by the testes. This type of gynecomastia is virtually always benign and resolves spontaneously in 1 to 2 years. Gynecomastia can also occur in older men and usually presents as a firm, tender mass underneath the areola. In these patients, gynecomastia may be diffuse and related to the use of certain medication (e.g., digitalis). It may also be associated with certain conditions, including feminizing testicular tumors, infection in the testes, and liver disease resulting from factors such as alcohol abuse or a parasitic infection.

Patients in their late teens to late 40s presenting with idiopathic (unknown cause) gynecomastia should have a testicular examination and possibly a testicular ultrasound. Treatment of the enlarged breast tissue is based on patient preference and is usually reserved for those men who cannot tolerate the cosmetic appearance of the breast or who have severe pain associated with the condition. Mammography and ultrasound are utilized if there is a concern about malignancy. Observation is acceptable in most cases because gynecomastia may resolve on its own. Surgical removal of the tissue through a small incision around the areola is the best treatment option. Liposuction performed by a plastic surgeon is another possibility, although this does not allow for pathologic examination of the tissue.

Male Breast Cancer

The lifetime risk of breast cancer in men is about 1 in 1000. The number of breast cancer cases in men relative to the population has been fairly stable over the past 30 years. Nearly 2670 new cases of invasive breast cancer were expected to be diagnosed in men in 2019 (ACS, 2019). The ratio of women to men diagnosed with breast cancer worldwide is 122:1 (Jain & Gradishar, 2018). Although breast carcinoma in both genders share certain characteristics, notable differences have emerged. Familial cases in men usually have *BRCA2* rather than *BRCA1* mutations. Klinefelter syndrome, a chromosomal condition reflecting decreased testosterone levels, is the strongest risk factor for developing male breast carcinoma. Presentation is usually a painless lump, but is often late, with more than 40% of

individuals having stage III or IV disease. When survival is adjusted for age at diagnosis and stage of disease, outcomes for male and female patients with breast cancer is similar (Jain & Gradishar, 2018).

Early detection is uncommon in male breast cancer because of the rare nature of the disease. Often, neither patient nor provider suspects male breast cancer early in its development. There is no role for screening mammogram in males, but biopsies may be performed to determine hormone receptor status (Jain & Gradishar, 2018). Treatment generally consists of a total mastectomy with either SLNB or ALND. As in women with breast cancer, prognosis depends on the stage of disease at presentation. Involvement of the axillary lymph nodes is the most important prognostic indicator. Male breast cancers are very likely to be ER+, and tamoxifen, although it has several side effects, is a mainstay of treatment.

Because breast cancer is primarily a disease of women, men may feel that a certain stigma is attached to their diagnosis. This may cause poor adherence to treatment plans, especially long-term medication management. Health care professionals must be sensitive to their needs and provide information and support to improve survivorship.

CRITICAL THINKING EXERCISES

1 ebp A 34-year-old woman calls the breast clinic where you work in a panic. She explains that her mom was recently diagnosed with breast cancer. She is convinced that she also has cancer, because she woke up this morning with unilateral breast inflammation. After further questioning, you learn that she is breast-feeding her 10-day-old infant. What evidence-based recommendation would you make for genetic testing for this patient?

2 pq A 45-year-old woman arrives to the medical-surgical unit where you work after having a mastectomy this morning. She plans a delayed implant and has a tissue expander in place. How do you prioritize her physical care and her education?

3 ipc A 70-year-old woman who had a mastectomy without reconstruction 7 years ago comes to the clinic where you work. She intermittently wears her compression garment and is faithful about her follow-up care. What members of the health care team should be included in the care of this patient?

53 Assessment and Management of Patients with Male Reproductive Disorders

LEARNING OUTCOMES

On completion of this chapter, the learner will be able to:

1. Describe structures and function of the male reproductive system.
2. Discuss nursing assessment of the male reproductive system, identifying diagnostic tests used and their related nursing implications.
3. Explain the causes and management of male sexual dysfunction.
4. Compare the types of prostatectomy with regard to advantages and disadvantages.
5. Use the nursing process as a framework for care of the patient with male reproductive disorders and conditions, including prostate, testicular, and penis disorders.

NURSING CONCEPTS

Assessment
Family
Infection
Inflammation
Mobility
Reproduction
Sexuality
Stress

GLOSSARY

androgen deprivation therapy: surgical (orchiectomy) or medical castration (e.g., with luteinizing hormone–releasing hormone agonists)

benign prostatic hyperplasia (BPH): noncancerous enlargement or hypertrophy of the prostate; the most common pathologic condition in older men

brachytherapy: delivery of radiation therapy through internal implants placed inside or adjacent to a tumor

circumcision: excision of the foreskin, or prepuce, of the glans penis

cystostomy: surgical creation of an opening into the urinary bladder

epididymitis: infection of the epididymis that usually descends from an infected prostate or urinary tract; also may develop as a complication of gonorrhea, chlamydia, or *Escherichia coli*

erectile dysfunction: the inability to either achieve or maintain an erection sufficient to accomplish sexual intercourse (*synonym*: impotence)

hydrocele: a collection of fluid, generally in the tunica vaginalis of the testis, although it also may collect within the spermatic cord

orchiectomy: surgical removal of one or both testes

orchitis: acute inflammation of the testes (testicular congestion) caused by pyogenic, viral, spirochetal, parasitic, traumatic, chemical, or unknown factors

phimosis: condition in which the foreskin is constricted so that it cannot be retracted over the glans; can occur congenitally or from inflammation and edema

priapism: an uncontrolled, persistent erection of the penis from either neural or vascular causes, including medications, sickle cell thrombosis, leukemic cell infiltration, spinal cord tumors, and tumor invasion of the penis or its vessels

prostatectomy: surgical removal of the entire prostate, the prostate urethra, and the attached seminal vesicles plus the ampulla of the vas deferens

prostate-specific antigen (PSA): substance that is produced by the prostate gland; is used in combination with digital rectal examination to screen for prostate cancer

prostatitis: inflammation of the prostate gland caused by infectious agents (bacteria, fungi, mycoplasma) or various other problems (e.g., urethral stricture, prostatic hyperplasia)

retrograde ejaculation: during ejaculation, semen travels to the urinary bladder instead of exiting through the penis

spermatogenesis: production of sperm in the testes

testosterone: male sex hormone secreted by the testes; induces and preserves the male sex characteristics

transurethral resection of the prostate (TURP): resection of the prostate through endoscopy; the surgical and optical instrument is introduced

directly through the urethra to the prostate, and the gland is then removed in small chips with an electrical cutting loop

varicocele: an abnormal dilation of the veins of the pampiniform venous plexus in the scrotum (the network of veins from the testis and the epididymis, which constitute part of the spermatic cord)

vasectomy: ligation and transection of part of the vas deferens, with or without removal of a segment of the vas, to prevent the passage of the sperm from the testes (*synonym*: male sterilization)

Disorders of the male reproductive system include a wide variety of conditions that usually affect both urinary and reproductive systems. Because these disorders involve the genitalia and often affect sexuality, the patient may experience anxiety and embarrassment. The nurse must be aware of the patient's need for privacy as well as the need for education and support. This requires an openness to discuss critical and sensitive issues with the patient, including a partner when appropriate, as well as effective assessment, management, and communication. Nurses must be comfortable when examining male genitalia and must recognize their own attitudes and perceptions about male reproductive disorders. Education of the patient and partner about treatment and self-care strategies is essential (Tabloski, 2019).

ASSESSMENT OF THE MALE REPRODUCTIVE SYSTEM

Anatomic and Physiologic Overview

In the male, several organs serve as parts of both the urinary tract and the reproductive system. Disorders in the male reproductive organs may interfere with the functions of one or both of these systems. As a result, diseases of the male reproductive system are usually treated by a urologist. The structures in the male reproductive system include the (1) external male genitalia, consisting of the testes, epididymis, scrotum, and penis, and the (2) internal male genitalia, consisting of the vas deferens (ductus deferens), ejaculatory duct, and prostatic and membranous sections of the urethra, seminal vesicles, and certain accessory glands, such as the prostate gland and Cowper glands (bulbourethral glands) (see Fig. 53-1).

The testes have a dual function: **spermatogenesis** (production of sperm) and secretion of the male sex hormone **testosterone**, which induces and preserves the male sex characteristics. The testes are formed in the embryo, within the abdominal cavity near the kidney. During the last month of fetal life, they descend posterior to the peritoneum and pierce the abdominal wall in the groin. Later, they progress along the inguinal canal into the scrotal sac. In this descent, they are accompanied by blood vessels, lymphatics, nerves, and ducts, which support the tissue and make up the spermatic cord. This cord extends from the internal

inguinal ring through the abdominal wall and the inguinal canal to the scrotum. As the testes descend into the scrotum in the final 2 to 3 months of gestation, a tubular extension of peritoneum accompanies them (Rhoades & Bell, 2017). Normally, this tissue is obliterated during fetal development; only the tunica vaginalis, which covers the testes, remains. If the peritoneal process remains open into the abdominal cavity, a potential sac remains into which abdominal contents may enter to form an indirect inguinal hernia.

The testes, or ovoid sex glands, are encased in the scrotum, which keeps them at a slightly lower temperature than the rest of the body to facilitate spermatogenesis (Rhoades & Bell, 2017). The testes consist of numerous seminiferous tubules in which the spermatozoa form. Collecting tubules transmit the spermatozoa into the epididymis, a hoodlike structure lying on the testes and containing winding ducts that lead into the vas deferens. This firm, tubular structure passes upward through the inguinal canal to enter the abdominal cavity behind the peritoneum. It then extends downward toward the base of the bladder. An outpouching from this structure is the seminal vesicle, which acts as a reservoir for testicular secretions. The tract is continued as the ejaculatory duct, which passes through the prostate gland to enter the urethra. Testicular secretions take this pathway when they exit the penis during ejaculation.

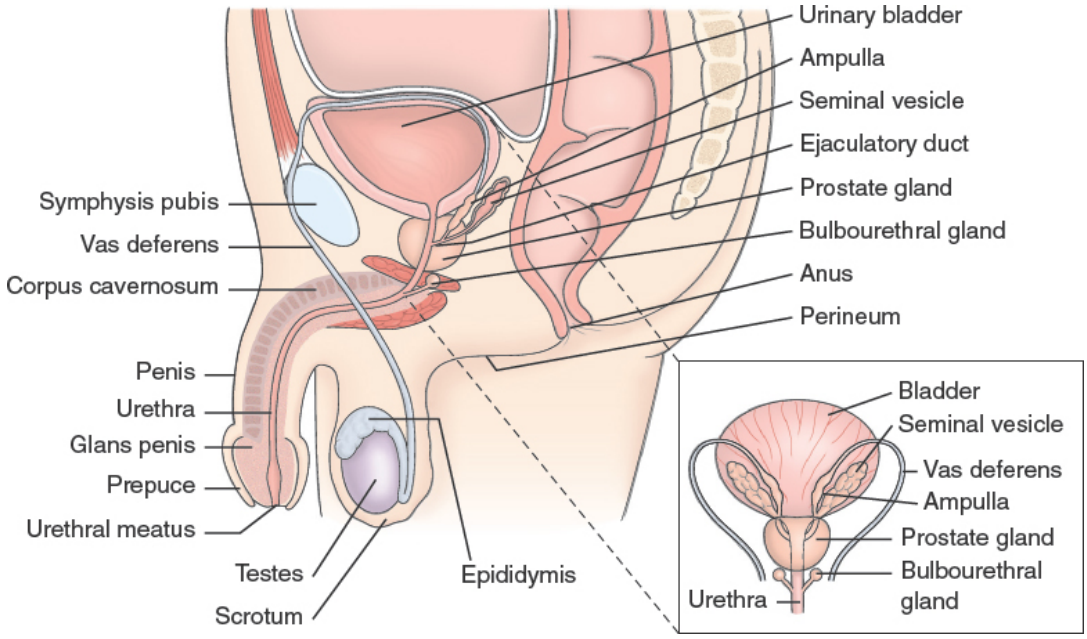

Figure 53-1 • Structures of the male reproductive system.

The penis is the organ for both copulation and urination. It consists of the glans penis, the body, and the root. The glans penis is the soft, rounded portion at the distal end of the penis. The urethra (the tube that carries urine) opens at the tip of the glans. The glans is naturally covered by elongated penile skin—the foreskin—which may be retracted to expose the glans. However, many men as newborns have undergone circumcision, which is a procedure to remove the foreskin. The body of the penis is composed of erectile tissues containing numerous blood

vessels that become dilated, leading to an erection during sexual excitement. The urethra, which passes through the penis, extends from the bladder through the prostate to the distal end of the penis.

The prostate gland, lying just below the neck of the bladder, is composed of four zones and four lobes. It surrounds the urethra and is traversed by the ejaculatory duct, a continuation of the vas deferens. This gland produces a secretion that is chemically and physiologically suitable to the needs of the spermatozoa in their passage from the testes. Cowper glands lie below the prostate, within the posterior aspect of the urethra. This gland empties its secretions into the urethra during ejaculation, providing lubrication.

Gerontologic Considerations

As men age, the prostate gland enlarges; prostate secretion decreases; the scrotum hangs lower; the testes decrease in weight, atrophy, and become softer; and pubic hair becomes sparser and stiffer. Changes in gonadal function include a decline in plasma testosterone levels and reduced production of progesterone (see Table 53-1). Libido and potency often decrease in as many as two thirds of men older than 70 years (Tabloski, 2019). Vascular problems cause about half of the cases of erectile dysfunction in men older than 50 years.

However, male reproductive capability is maintained with advancing age. Although degenerative changes occur in the seminiferous tubules and sperm production decreases, spermatogenesis continues, allowing men to produce viable sperm throughout their lives (McCance, Huether, Braskers, et al., 2018).

Male hypogonadism (decreased function of the testes) starts gradually at approximately 50 years of age, resulting in decreased testosterone production. The older man notices that the sexual response slows, erection takes longer, full erections may not be attained, ejaculation takes longer to occur, and control or resolution may occur without orgasm. Sexual function can be affected by psychological problems, illnesses, and medications (Sikka & Hellstrom, 2017). In general, the entire sexual act takes longer. Sexual activity is closely correlated with the man's sexual activity in his earlier years; if he was more active than average as a young man, he will most likely continue to be more active than average in his later years.

Men older than 50 years are at increased risk for genitourinary tract cancers, including those of the kidney, bladder, prostate, and penis. The digital rectal examination (DRE), prostate-specific antigen (PSA) test, and urinalysis, which screens for hematuria, may uncover a higher percentage of malignancies at earlier stages and lead to lower treatment-associated morbidity as well as a lower mortality.

Urinary incontinence occurs in one fifth of community-dwelling older men and rises to nearly 50% in men in long-term care settings (Tabloski, 2019). Older adults admitted to acute care settings should be screened for this problem. Urinary incontinence may have many causes, including medications, neurologic disease,

or benign prostatic hyperplasia (BPH). Incontinence may also be linked to erectile dysfunction when there is damage to the neural pathways that initiate an erection (Rantell, Apostolidis, Anding, et al., 2017). Diagnostic tests are performed to exclude reversible causes. New-onset urinary incontinence is a nursing priority that requires evaluation.

Assessment

Assessing the male reproductive system includes a targeted health history and physical examination.

Health History

Male sexuality is a complex phenomenon that is strongly influenced by personal, cultural, religious, and social factors. Sexuality and male reproductive function become concerns in the presence of illness and disability (Kaufman, Lapauw, Mahmoud, et al., 2019). Throughout the assessment process, the nurse must recognize the significance of sexuality to the patient. Assessment of male reproductive function begins with an evaluation of urinary function and symptoms. The patient is asked about his usual state of health and any recent change in general physical and sexual activity. Any symptoms or changes in function are explored fully and described in detail. Symptoms related to bladder function and urination, collectively referred to as prostatism, are explored further. Symptoms may occur with an obstruction caused by an enlarged prostate gland and may include increased urinary frequency, decreased force of urine stream, and “double” or “triple” voiding (the patient needs to urinate two or three times over a period of several minutes to completely empty his bladder). The patient is also assessed for dysuria (painful urination), hematuria (blood in the urine), nocturia (urination during the night), and hematospermia (blood in the ejaculate).

TABLE 53-1 Age-Related Changes in the Male Reproductive System

Age-Related Changes	Physiologic Changes	Manifestations
Decrease in sex hormone secretion, especially testosterone	Decreased muscle strength and sexual energy	Changes in sexual response—prolonged time to reach full erection, rapid penile detumescence, and prolonged refractory period
	Decrease in number of viable sperm	
	Shrinkage and loss of firmness of testes; thickening of seminiferous tubules	Smaller testes
	Fibrotic changes of corpora cavernosa	Erectile dysfunction
		Weakening of prostatic contractions
	Enlargement of prostate gland	Hyperplasia of prostate gland
		Signs and symptoms of obstruction of lower urinary tract (urgency, frequency, nocturia)

Adapted from Tabloski, P. A. (2019). *Gerontological nursing: The essential guide to clinical practice* (4th ed.). New York: Pearson.

Assessment also involves addressing sexual function, including manifestations of sexual dysfunction. The extent of the history depends on the patient's presenting symptoms and the presence of factors that may affect sexual function such as chronic illnesses or disability (e.g., diabetes, multiple sclerosis, stroke, cardiac disease), the use of medications that affect sexual function (e.g., antihypertensive and anticholesterolemic medications, psychotropic agents), stress, the use of alcohol, and the patient's willingness to discuss sexual issues.

By initiating an assessment about sexual concerns, the nurse conveys the message that changes in sexual functioning are valid topics and provides a safe environment for discussing these sensitive topics. Several models are available to assist in assessing patient's problems and concerns. The PLISSIT (*p*ermission, *l*imited *i*nformation, *s*pecific *s*uggestions, *i*ntensive *t*herapy) model of sexual assessment and intervention may be used to provide a framework for nursing interventions (Annon, 1976; Messelis, Kazer, & Gelmetti, 2019). It provides a graded counseling approach that allows health care professionals to deal with sexual issues with a level of comfort and expertise. The model begins by asking the patient's permission (P) to discuss sexual functioning. Limited information (LI) about sexual function may then be provided to the patient. As the discussion progresses, the nurse may offer specific suggestions (SS) for interventions. A professional who specializes in sex therapy may provide more intensive therapy (IT) as needed. The BETTER (*b*ringing up the topic, *e*xplaining, *t*elling, *t*iming, *e*ducate about treatment-related sexual side effects, *r*ecording) model was

developed more recently to assist health care professionals to include sexuality in the assessment of patients with cancer (Campbell, 2020).

Patients may find it difficult to express their feelings and concerns regarding their sexuality, especially after a body image change (e.g., after major surgery such as amputation). Discussing sexuality with patients who have an illness or disability can be uncomfortable for nurses and other health care providers; this, in turn, makes discussion of these issues more difficult and uncomfortable for patients. Some health care professionals may unconsciously have stereotypes about the sexuality of people who are ill or have a disability (e.g., the belief that people with disability are asexual or should be sexually inactive). In addition, patients are often embarrassed to initiate a discussion about sexual issues with their health care providers (Campbell, 2020; Katz, Cherven, Ballard, et al., 2019).

Physical Assessment

In addition to the usual aspects of the physical examination, two essential components address disorders of the male genital or reproductive system: the DRE and the testicular examination.

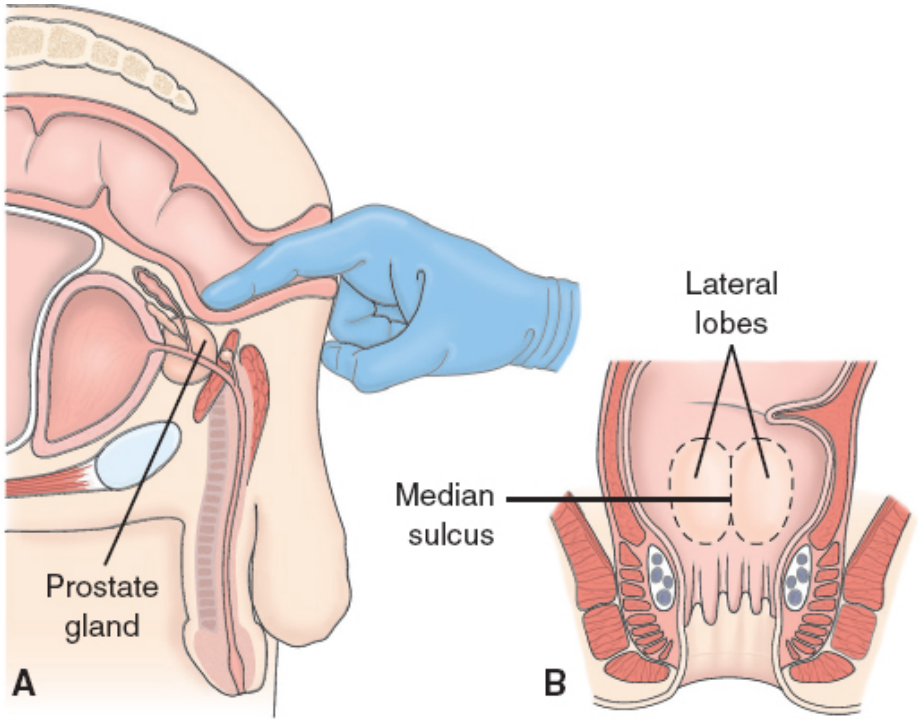

Figure 53-2 • **A.** Palpation of the prostate gland during digital rectal examination enables the examiner to assess the size, shape, and texture of the gland. **B.** The prostate is round, with a palpable median sulcus or groove separating the lateral lobes. It should feel rubbery and free of nodules and masses.

Digital Rectal Examination

The DRE is used to screen for prostate cancer and is recommended annually for every man older than 50 years (45 years for men at high risk [African American men and men with a family history of prostate cancer in first-degree relatives]) (American Cancer Society [ACS], 2020). The DRE enables the skilled examiner, using a lubricated, gloved finger placed in the rectum, to assess the size, symmetry, shape, and consistency of the posterior surface of the prostate gland (see Fig. 53-2). The clinician assesses for tenderness of the prostate gland on palpation and for the presence and consistency of any nodules. The DRE may be performed with the patient leaning over an examination table or positioning the man in a side-lying position with legs flexed toward the abdomen or supine with legs resting in stirrups. To minimize discomfort and relax the anal sphincter during the rectal examination, the patient is instructed to take a deep breath and exhale slowly as the practitioner inserts a finger. If possible, he should turn his feet inward, so that his toes are touching. Although this examination may be uncomfortable and embarrassing for the patient, it is an important screening tool.

Testicular Examination

The male genitalia are inspected for abnormalities and palpated for masses. The scrotum is palpated carefully for nodules, masses, or inflammation. Examination of the scrotum can reveal such disorders as hydrocele, inguinal hernia, testicular torsion, orchitis, epididymitis, or a tumor of the testis. The penis is inspected and palpated for ulcerations, nodules, inflammation, discharge, and curvature. If the patient is uncircumcised, the foreskin should be retracted for visualization of the glans penis. The testicular examination provides an excellent opportunity to educate the patient on how to perform a testicular self-examination (TSE) and its importance in early detection of testicular cancer. TSE should begin during adolescence. For more details on TSE, see later discussion in the chapter.

Diagnostic Evaluation

A wide range of diagnostic studies may be performed in men with reproductive disorders. The nurse should educate the patient about the purpose, what to expect, and any possible side effects related to these tests and examinations prior to testing. The nurse should note trends in results because they provide information about disease progression as well as the patient's response to therapy.

Prostate-Specific Antigen Test

The cells within the prostate gland produce a protein that can be measured in the blood called the **prostate-specific antigen (PSA)**. It is a sensitive but not specific test for prostate cancer. In the absence of prostate cancer, serum PSA levels vary with age, race, and prostate volume. Increased levels may indicate prostate cancer. However, a number of other conditions such as BPH, acute urinary retention, and acute prostatitis may cause high PSA levels. Values of PSA may

also increase after ejaculation. PSA levels are measured in nanograms per milliliter (ng/mL). In most laboratories, values less than 4 ng/mL are generally considered normal, and values greater than 4 ng/mL are considered elevated in men 60 years of age or younger (Law, Nguyen, Barkin, et al., 2020; Pagana & Pagana, 2018). The use of age-specific reference ranges is encouraged to help minimize unnecessary biopsies (see Appendix A on thePoint).

A serum PSA level and a DRE, which are recommended by the ACS (2020), are used to screen for prostate cancer for men with at least a 10-year life expectancy and for men at high risk, including those with a strong family history of prostate cancer and of African American ethnicity. The perceptions of some African American men and women reflect the belief that PSA screening saves lives and needs to be done despite recommendations against screening due to false positives potentially resulting in unnecessary treatment (Arace, Flores, Monaghan, et al., 2020; Kearns, Adeyemi, Anderson, et al., 2020). The PSA test is also used to monitor patients for recurrence after treatment for cancer of the prostate, based on evidence-based guidelines (National Comprehensive Cancer Network [NCCN], 2020b). Neither the DRE nor PSA is 100% accurate, but when used together, their accuracy increases.

Ultrasonography

Transrectal ultrasound (TRUS) may be performed in patients with abnormalities detected by DRE and in those with elevated PSA levels. After DRE has been completed, a lubricated, condom-covered, rectal probe transducer is inserted into the rectum (Lim, Jun, Chang, et al., 2019). Water may be introduced into the condom to help transmit sound waves to the prostate. TRUS may be used in detecting nonpalpable prostate cancers and in staging localized prostate cancer. Needle biopsies of the prostate are commonly guided by TRUS.

Prostate Fluid or Tissue Analysis

Specimens of prostate fluid or tissue may be obtained for culture if disease or inflammation of the prostate gland is suspected. A biopsy of the prostate gland may be necessary to obtain tissue for histologic examination. This may be performed at the time of prostatectomy or by means of a perineal or transrectal needle biopsy. Six to 12 biopsies from all four prostate zones may be obtained during a TRUS-guided biopsy.

Tests of Male Sexual Function

If the patient cannot engage in sexual activity to his satisfaction, a detailed history is obtained. Nocturnal erections occur in healthy males of all ages. Nocturnal penile tumescence tests may be conducted in a sleep laboratory to monitor changes in penile circumference during sleep using various methods to determine number, duration, rigidity, and circumference of penile erections; the results help

identify whether the erectile dysfunction is caused by physiologic or psychological factors. Additional tests, including psychological evaluations, are also part of the diagnostic workup and are usually conducted by a specialized team of health care providers.

DISORDERS OF MALE SEXUAL FUNCTION

Erectile Dysfunction

Erectile dysfunction, also called *impotence,* is the inability to achieve or maintain an erect penis (Norris, 2019). The man may report decreased frequency of erections, inability to achieve a firm erection, or rapid detumescence (subsiding of erection). In the United States, 30 million men experience erectile dysfunction; more than half of men 40 to 70 years of age are unable to attain or maintain an erection sufficient for satisfactory sexual performance (Smith, Howards, Preminger, et al., 2019). The physiology of erection and ejaculation is complex and involves parasympathetic and sympathetic components. Erection involves the release of nitric oxide into the corpus cavernosum during sexual stimulation. Its release activates cyclic guanosine monophosphate (cGMP), causing smooth muscle relaxation. This allows flow of blood into the corpus cavernosum, resulting in erection (Cheng, MacLennan, & Bostwick, 2019; Norris, 2019).

Erectile dysfunction has both psychogenic and organic causes. Psychogenic causes include anxiety, fatigue, depression, pressure to perform sexually, negative body image, absence of desire, and privacy, as well as trust and relationship issues. Organic causes include cardiovascular disease, endocrine disease (diabetes, pituitary tumors, testosterone deficiency, hyperthyroidism, and hypothyroidism), cirrhosis, chronic kidney injury, genitourinary conditions (radical pelvic surgery), hematologic conditions (Hodgkin lymphoma, leukemia), neurologic disorders (neuropathies, parkinsonism, spinal cord injury [SCI], multiple sclerosis), trauma to the pelvic or genital area, smoking, medications (see Chart 53-1), and substance use disorder.

Assessment and Diagnostic Findings

The diagnosis of erectile dysfunction requires a sexual and medical history; an analysis of presenting symptoms; a physical examination, including a neurologic examination; a detailed assessment of all medications, alcohol, and drugs used; and various laboratory studies. Nocturnal penile tumescence tests are conducted to monitor changes in penile circumference. This test can help to determine if erectile dysfunction has an organic or a psychological cause. In healthy men, nocturnal penile erections closely parallel rapid eye movement (REM) sleep in occurrence and duration. Organically, men with erectile dysfunction show inadequate sleep-related erections that correspond to their waking performance. Arterial blood flow to the penis is measured using a Doppler probe. In addition,

nerve conduction tests and extensive psychological evaluations may be carried out. Figure 53-3 describes the evaluation and treatment of erectile dysfunction.

Chart 53-1 PHARMACOLOGY

Select Medications Associated with Erectile Dysfunction

- *Antiadrenergics and antihypertensives:* guanethidine, clonidine, hydralazine
- *Anticholinergics and phenothiazines:* prochlorperazine, trihexyphenidyl
- *Anticonvulsant agents:* carbamazepine
- *Antidepressants:* tricyclic antidepressants: amitriptyline, desipramine; selective serotonin reuptake inhibitors: fluoxetine, sertraline
- *Antifungals:* ketoconazole
- *Antihistamines:* diphenhydramine, dimenhydrinate
- *Antihormone (prostate cancer treatment):* flutamide, leuprolide
- *Antipsychotics:* haloperidol, chlorpromazine
- *Antispasmodics:* oxybutynin
- *Anxiolytics, sedative–hypnotics, tranquilizers:* lorazepam, triazolam
- *Beta-blockers:* nadolol, metoprolol
- *Calcium channel blockers:* nifedipine
- *Carbonic anhydrase inhibitors:* acetazolamide
- *Chemotherapeutic agents:* busulfan, cyclophosphamide
- *Diuretics:* hydrochlorothiazide, furosemide, spironolactone, verapamil
- *Histamine-2 antagonists:* nizatidine
- *Nonsteroidal anti-inflammatory drugs:* naproxen, indomethacin
- *Other substances:* alcohol, amphetamines, barbiturates, cocaine, marijuana, methadone, nicotine, opioids
- *Parkinson's disease medications:* carbidopa/levodopa, benztropine

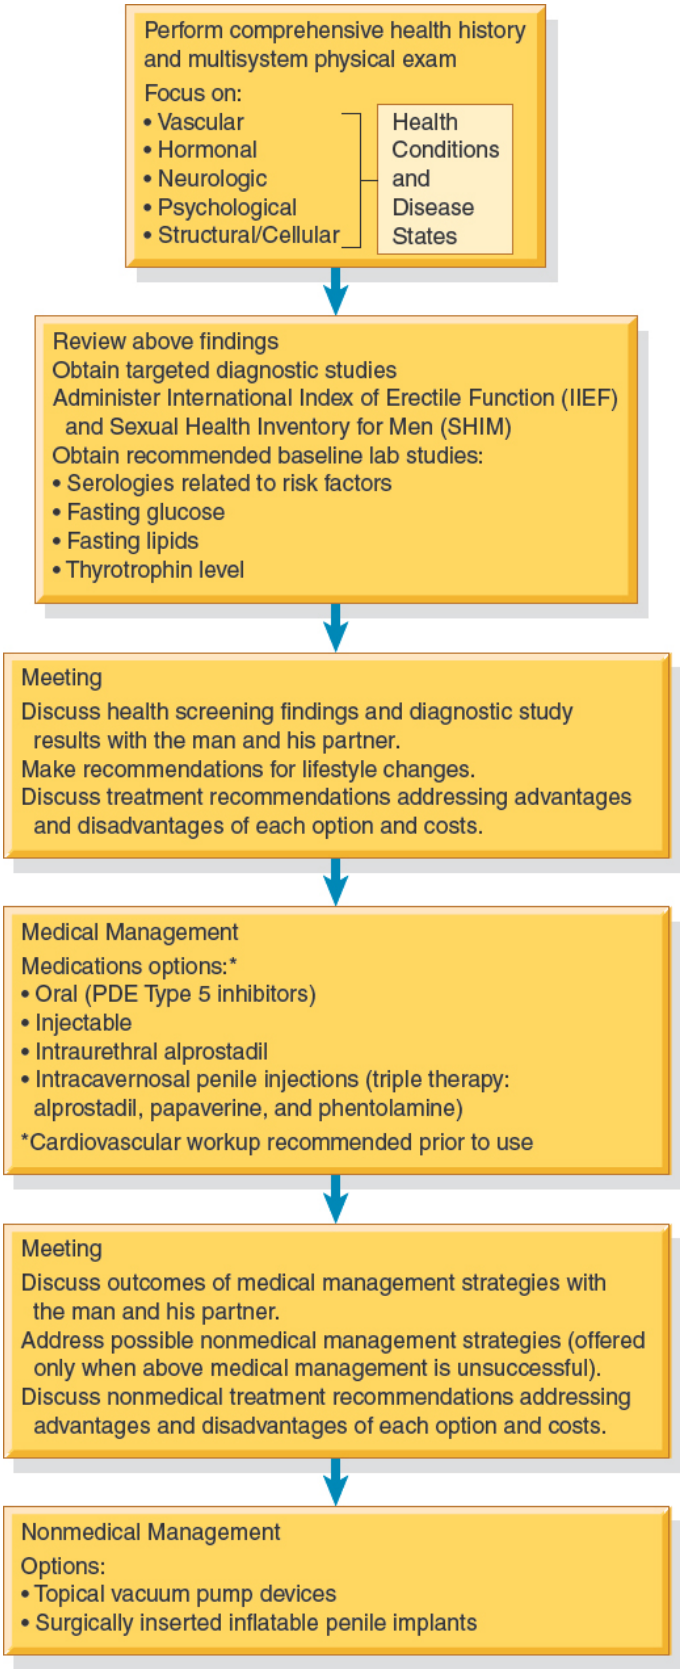
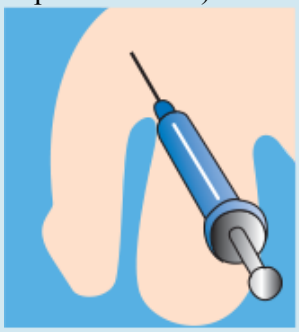
Medical Management

Treatment can be medical, surgical, or both, depending on the cause. Treatment of erectile dysfunction includes therapy for associated disorders (e.g., alcoholism, diabetes) or adjustment of medications (McMahon, 2019). Endocrine therapy instituted to treat erectile dysfunction secondary to hypothalamic–pituitary–gonadal dysfunction may reverse the condition. Insufficient penile blood flow may be treated with vascular surgery. Patients with erectile dysfunction from psychogenic causes are referred to a health care provider or therapist who specializes in sexual dysfunction. Patients with erectile dysfunction secondary to organic causes may be candidates for penile implants.





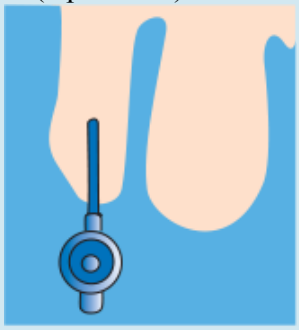


Figure 53-3 • Evaluation and treatment of erectile dysfunction.

Currently available therapies for the treatment of erectile dysfunction include pharmacologic therapy (including urethral suppositories), penile implants, and vacuum constriction devices (see Table 53-2). These options should be considered in a stepwise fashion, with increasing invasiveness and risk balanced against the likelihood of efficacy. The patient and, if possible, his partner, should be informed of the relevant treatment options and their associated risks and benefits. The choice of treatment is made jointly by the primary provider, patient, and partner, taking into consideration patient preferences and expectations.

TABLE 53-2 Treatments for Erectile Dysfunction

Method	Description	Advantages and Disadvantages	Duration
Pharmacologic Therapy Oral medications (sildenafil, vardenafil, tadalafil)  Oral medication	Smooth muscle relaxant causing blood to flow into penis	Can cause headache, flushing, dyspepsia, diarrhea, nasal congestion, and lightheadedness See contraindications in Table 53-3	Taken orally before sexual activity. Stimulation is required to achieve erection. Erection can last up to 1 h.
Injection (alprostadil, papaverine, phentolamine)  Penile injection	Smooth muscle relaxant causing blood to flow into penis	Firm erections are achievable in >50% of cases Pain at injection site; plaque formation, risk of priapism	Injection 20 min before sexual activity. Erection can last up to 1 h.
Urethral suppository (alprostadil)  Penile suppository	Smooth muscle relaxant causing blood to flow into penis	May be used twice a day Urethral and genital pain; risk of hypertension and syncope Not recommended with pregnant partners	Inserted 10 min before sexual activity. Erection can last up to 1 h.
Penile Implants • Semirigid rod • Inflatable • Soft silicone	Surgically implanted into corpus cavernosum	Reliable Requires surgery Healing takes up to 3 wks Subsequent cystoscopic surgery is difficult	Indefinite Inflatable prosthesis—saline returns from penile receptacle to reservoir.

 Penile implant		Semirigid rod results in permanent semierection	
Negative-Pressure (Vacuum) Devices  Penile vacuum pump	Induction of erection with vacuum; maintained with constriction band around base of penis	Few side effects Cumbersome to use before sexual activity Vasocongestion of penis can cause pain or numbness	To prevent penile injury, constriction band must not be left in place >1 h.

Pharmacologic Therapy

Phosphodiesterase type 5 (PDE-5) inhibitors (oral medications that are used to treat erectile dysfunction) are first-line therapy (Allen, 2019). Currently available PDE-5 inhibitors include sildenafil, vardenafil, and tadalafil. Each of these agents has a similar mechanism of action but a different pharmacologic action and clinical use. Erection involves the release of nitric oxide in the vasculature of the corpus cavernosum as a result of sexual stimulation. This subsequently leads to smooth muscle relaxation in blood vessels supplying the corpus cavernosum, resulting in increased blood flow and an erection. During sexual stimulation, PDE-5 inhibitors increase blood flow to the penis (Norris, 2019).

When PDE-5 inhibitors are taken about 1 hour before sexual activity, they are effective in producing an erection with sexual stimulation; the erection can last about 1 to 2 hours. The most common side effects of these medications include headache, flushing, dyspepsia, diarrhea, nasal congestion, and lightheadedness. These agents are contraindicated in men who take organic nitrates (e.g., isosorbide, nitroglycerin), because taken together, these medications can cause side effects such as severe hypotension (Cheng et al., 2019; Norris, 2019). In addition, PDE-5 inhibitors must be used with caution in patients with retinopathy, especially in those with diabetic retinopathy. Patient education about the use of these medications and their side effects is summarized in Table 53-3.

For patients in whom PDE-5 inhibitors are contraindicated or ineffective, other pharmacologic measures to induce erections include injecting vasoactive agents, such as alprostadil, papaverine, and phentolamine, directly into the penis. Complications include **priapism** (a persistent abnormal erection) and

development of fibrotic plaques at the injection sites. Alprostadil is also formulated in a gel pellet that can be inserted into the tip of the urethra with an applicator to create an erection.

Penile Implants

Two general types of penile implants are available: the malleable, noninflatable, nonhydraulic prosthesis (also called the *semirigid rod*) and the inflatable, hydraulic prostheses (Lindsey, Lue, & Shindel, 2020). The semirigid rod (e.g., the Small–Carrion prosthesis) results in a permanent semierection but can be bent into an unnoticeable position when appropriate. The inflatable prosthesis simulates natural erections and natural flaccidity. Complications after implantation include infection, erosion of the prosthesis through the skin (more common with the semirigid rod than with the inflatable prosthesis), and persistent pain, which may require removal of the implant. Subsequent cystoscopic surgery is more difficult with a semirigid rod than with the inflatable prosthesis.

TABLE 53-3  Pharmacologic Treatment of Erectile Dysfunction

	Sildenafil	Vardenafil	Tadalafil
When to take	Take the medication 30 min to 4 h before penile-vaginal intercourse. *There must be sexual stimulation to produce an erection.*	Take the medication 1 h before penile-vaginal intercourse. The peak action occurs in 30–120 min. *There must be sexual stimulation to produce an erection.*	Take the medication before sexual activity. Effect peaks at 30 min to 6 h; effect may last up to 36 h. *There must be sexual stimulation to produce an erection.*
Frequency of use	If you take this medication more than once a day, it will not have an increased effect. You may take it 7 days per week if you wish, but only once in 24 h. It does not build up in your bloodstream. Remember to take it only when you want to have penile-vaginal intercourse.	The recommended frequency for this medication is 10 mg in 24 h.	The effects of this medication may last up to 36 h. This allows for increased spontaneity in the sexual experience.
Side effects	Side effects include headache, flushing, indigestion, nasal congestion, abnormal vision, diarrhea, dizziness, and rash. You may also have low blood sugar and abnormal liver function tests; your primary provider can determine this.	Side effects include headache, flushing, runny nose, indigestion, sinusitis, flulike syndrome, dizziness, nausea, back pain, and joint pain. Tell your primary provider if you experience any of these effects. You may also have abnormally elevated liver enzymes; your primary provider can determine this.	Side effects are similar to those of sildenafil and vardenafil. Tadalafil may also cause back pain and muscle aches. Tell your primary provider if you experience any of these side effects.
Contraindications	Do not take if you are taking nitrate medications such as nitroglycerin or isosorbide mononitrate. Do not take if you have high uncontrolled blood pressure, coronary artery disease, or have had a heart attack within the past 6 mo. Do not take if you have been diagnosed with a cardiac arrhythmia or		

	kidney or liver dysfunction.
Drug interactions	This medication can react with other medications that you may be taking. Provide your primary provider and pharmacist with a complete list of all prescribed and over-the-counter medications that you are using.
Use of PDE-5 inhibitors with penile injections or urethral suppositories	The use of PDE-5 inhibitors with other forms of therapy for erectile dysfunction has not been tested and should be avoided.

PDE-5, phosphodiesterase type 5.

Adapted from McMahon, C. G. (2019). Current diagnosis and management of erectile dysfunction. *Medical Journal of Australia*, *2*(10), 469–476.

Factors to consider in choosing a penile prosthesis are the patient's activities of daily living, social activities, and the expectations of the patient and his partner. Ongoing counseling for the patient and his partner is usually necessary to help them adapt to the prosthesis.

Penis Transplants

In the United States, a few medical centers have protocols for penis transplants. Candidates for transplantation include military veterans and other men who have suffered traumatic penile injuries. It is believed that men undergoing this surgery will have their ability to urinate and their sexual functioning restored (Ngaage, Elegbede, Sugarman, et al., 2020). For more details on organ transplantation, see discussion in Chapter 48.

Negative-Pressure Devices

Negative-pressure (vacuum) devices may also be used to induce an erection. A plastic cylinder is placed over the flaccid penis, and negative pressure is applied. When an erection is attained, a constriction band is placed around the base of the penis to maintain the erection. To avoid penile injury, the patient is instructed not to leave the constricting band in place for longer than 1 hour. Only devices with a vacuum limiter are recommended for use (Sikka & Hellstrom, 2017). Although many men find this method satisfactory, others experience premature loss of penile rigidity or pain when applying suction or during sexual activity.

Nursing Management

Personal satisfaction and the ability to sexually satisfy a partner are common concerns of patients. Men with illnesses and disability may need the assistance of a sex therapist to identify, implement, and integrate their sexual beliefs and behaviors into a healthy and satisfying lifestyle. The nurse can inform patients about support groups for men with erectile dysfunction and their partners.

Disorders of Ejaculation

Premature ejaculation is defined as the occurrence of ejaculation sooner than desired, either before or shortly after penetration, causing distress to either one or both partners. It is one of the most common complaints of men or couples, affecting 20% to 30% of men (Cheng et al., 2019; Smith et al., 2019). The spectrum of responses ranges from occasional ejaculation with penile-vaginal intercourse or self-stimulation to complete inability to ejaculate under any circumstances. Various forms have been identified including lifelong premature ejaculation caused by neurobiologic or genetic conditions, acquired (medical or psychological), natural variable (normal variation), and premature like ejaculatory dysfunction (psychological). In young men aged 18 to 25 years, factors associated with premature ejaculation and erectile dysfunction include smoking, use of illegal drugs or medications without prescriptions, poor physical and mental health, lack of physical activity, and lack of sexual experience (Barbonetti, D'Andrea, Cavallo, et al., 2019). Other ejaculatory problems may include inhibited (delayed or retarded) ejaculation, which is the involuntary inhibition of the ejaculatory reflex (see Chart 53-2). **Retrograde ejaculation** occurs when semen travels toward the bladder instead of exiting through the penis, resulting in infertility. This form of premature ejaculation may occur after prior prostate or urethral surgery, with diabetes, or with the use of medications such as antihypertensive agents.

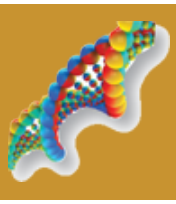

Chart 53-2 GENETICS IN NURSING PRACTICE

Male Reproductive Disorders

Various male reproductive disorders are influenced by genetic factors. Some examples are:

- 21-Hydroxylase deficiency
- Congenital absence of the vas deferens, prostate gland, or seminal vesicles
- Kallmann syndrome
- Klinefelter syndrome (47, XXY)
- Prostate cancer
- Y chromosome deletions

Nursing Assessments

Refer to Chapter 4, Chart 4-2: Genetics in Nursing Practice: Genetic Aspects of Health Assessment

Family History Assessment Specific to Male Reproductive Disorders

- Collect a three-generation family history on both maternal and paternal sides of the family.
- Assess family history for other family members with similar reproductive problems/abnormalities.

Patient Assessment Specific to Male Reproductive Disorders

- In males with delayed puberty or infertility, assess for clinical features of Klinefelter syndrome (tall stature, gynecomastia, learning disability).
- Assess males with delayed or absent puberty for clinical features of Kallmann syndrome (cleft lip with or without cleft palate, abnormal eye movements, hearing loss, and abnormalities of tooth development).
- Assess males for history of early growth spurt, which is a symptom of 21-hydroxylase deficiency.
- Inquire about history of prostate inflammation, genital infections, medication use (steroids), or prior history of mumps.
- Assess for physical abnormalities of the genitalia.

Genetics Resources

Association for X and Y Chromosome Variations, www.genetic.org
Klinefelter Syndrome Support Group, www.klinefeltersyndrome.org
See Chapter 6, Chart 6-7 for components of genetic counseling.

Evaluation of premature ejaculation involves a thorough sexual history focusing on the duration of symptoms, time to ejaculation, degree of voluntary control over ejaculation, frequency of occurrence, and course of the problem since the first sexual encounter (Cheng et al., 2019; Smith et al., 2019). Treatment, which depends on the nature, severity, and perceived distress that it causes, includes behavioral and psychological approaches, as well as

pharmacologic therapy that attempts to alter the sensory input or retard the ejaculatory response. Behavioral therapy (e.g., counseling, sex therapy, psychoeducation, and couples therapy) often involves both the man and his sexual partner. The couple is encouraged to identify their sexual needs and to communicate those needs to each other. Pharmacologic management involves selective serotonin reuptake inhibitors, dapoxetine, alpha$_1$ adrenoceptor antagonists, the tricyclic antidepressant clomipramine, and topical anesthetic agents. In some cases, a combination of pharmacologic and behavioral therapy may be effective.

Inhibited ejaculation is most often caused by psychological factors, neurologic disorders (e.g., SCI, multiple sclerosis, neuropathy secondary to diabetes), surgery (prostatectomy), and medications. Chemical, vibratory, and electrical methods of stimulation have been used with some success. Treatment usually addresses the physical and psychological factors involved in inhibited ejaculation (Bartlik, Espinosa, & Mindes, 2019). Although outpatient therapy may involve numerous sessions (12 to 18), it often results in a success rate of 70% to 80%. The outcome depends on a previous satisfying sexual experience history, a short duration of the ejaculatory problem, communication about feelings of sexual desire and attraction to one's sexual partner, motivation for treatment, and absence of serious psychological problems.

For men with retrograde ejaculation, the urine may be collected shortly after ejaculation, revealing a large amount of sperm in the urine. This urine may also be collected to obtain adequate viable sperm for use in artificial insemination. In men with SCI, techniques that may be used to obtain sperm for artificial insemination include self-stimulation, vibratory stimulation, or electroejaculation. Electroejaculation involves the use of a specially designed probe that is inserted into the rectum next to the prostate. The probe delivers a current that stimulates the nerves and produces contraction of the pelvic muscles and ejaculation. However, spontaneous or stimulated ejaculation may cause autonomic dysreflexia (overstimulation of the autonomic nervous system) in patients with SCI at T6 or higher, creating a life-threatening situation (see Chapter 63). If this disorder is not treated promptly, it may lead to seizures, stroke, and even death.

INFECTIONS OF THE MALE GENITOURINARY TRACT

Acute uncomplicated cystitis in adult men is uncommon but occasionally occurs. Asymptomatic bacteriuria may also result from genitourinary manipulation, catheterization, or instrumentation. Urinary tract infections (UTIs) are discussed in Chapter 49.

According to the Centers for Disease Control and Prevention (CDC, 2019), more than 20 million people develop sexually transmitted infections (STIs) annually in the United States; almost half of all STIs occur in people 15 to 24 years of age. The CDC (2019) also reported that the incidence of STIs has

increased over the past several years from 2013 through 2017, except in specific populations, such as men who have sex with men. Routine human papillomavirus (HPV) vaccination for all males has become the standard of preventative care since 2011, as recommended by the Advisory Committee on Immunization Practices (ACIP) (Meites, Szilagyi, Chesson, et al., 2019).

STIs affect people from all walks of life—from all social, educational, economic, and racial backgrounds. The single greatest risk factor for contracting an STI is the number of sexual partners. As the number of partners increases, so does the risk of exposure to a person infected with an STI. For men who have sex with men, the CDC recommends annual testing for human immune deficiency virus (HIV), syphilis, *Chlamydia,* gonorrhea, hepatitis B viral infection, and herpes simplex virus type 2, along with counseling (An, Bernstein, & Balaji, 2020; CDC, 2019). Additionally, it is now encouraged that primary providers screen for STI at extragenital sites such as the oropharyngeal and anal areas (Keenan, Thomas, & Cotler, 2020).

There are many causes of urethritis (gonococcal and nongonococcal), genital ulcers (genital herpes infections, primary syphilis, chancroid, granuloma inguinale, and lymphogranuloma venereum), genital warts (HPV), scabies, pediculosis pubis, molluscum contagiosum, hepatitis and enteric infections, proctitis, and acquired immune deficiency syndrome (AIDS). Trichomoniasis and STIs characterized by genital ulcers are thought to increase susceptibility to HIV infection. Trichomoniasis is associated with nonchlamydial, nongonococcal urethritis.

Current treatment guidelines for STIs are available from the CDC (2019; Kuehn, 2019). Treatment must target the patient as well as his sexual partners and sometimes an unborn child. A thorough history, including a sexual history, is crucial to identify patients at risk and to direct care and education. It is essential for patient education to focus on partner safety as people can misjudge partner safety with known acquaintances, thus causing individuals to be at greater risk of STI/HIV transmission (Dennin & Sinn, 2020).

Partners of men with STIs must also be examined, treated, and counseled to prevent reinfection and complications in both partners and to limit the spread of the disease. Sexual abstinence during treatment and recovery is advised to prevent the transmission of STIs. The use of synthetic condoms for at least 6 months after completion of treatment is recommended to decrease transmission of HPV infection as well as other STIs. It is important to assess and test for other STIs because patients who have one STI may also have another. The use of spermicides with nonoxynol-9 (known as N-9) is discouraged; these agents do not protect against HIV infection and may increase the risk of transmission of the virus. See Chapters 32 and 66 for more detailed discussions of HIV infection, AIDS, and other STIs.

PROSTATIC DISORDERS

Prostatitis

Prostatitis is an inflammation of the prostate gland that is often associated with lower urinary tract symptoms and symptoms of sexual discomfort and dysfunction. The condition affects 5% to 10% of men. It is the most common urologic diagnosis in men younger than 50 years and the third most common such diagnosis in men older than 50 years (Cheng et al., 2019). Prostatitis may be caused by infectious agents (bacteria, fungi, mycoplasma) or other conditions (e.g., urethral stricture, BPH). *Escherichia coli* is the most commonly isolated organism, although *Klebsiella* and *Proteus* species are also found (Wu, Jiang, Tan, et al., 2020). The microorganisms colonize the urinary tract and ascend to the prostate, ultimately causing infection. The causal pathogen is usually the same in recurrent infections.

There are four types of prostatitis: acute bacterial prostatitis (type I), chronic bacterial prostatitis (type II), chronic prostatitis/chronic pelvic pain syndrome (CP/CPPS) (type III), and asymptomatic inflammatory prostatitis (type IV). Type III, which occurs in more than 90% of cases, is further classified as type IIIA or type IIIB, depending on the presence (type IIIA) or absence (type IIIB) of white blood cells in semen after prostate massage (Rhoades & Bell, 2017).

Clinical Manifestations

Acute prostatitis is characterized by the sudden onset of fever, dysuria, perineal prostatic pain, and severe lower urinary tract symptoms including dysuria, frequency, urgency, hesitancy, and nocturia. Approximately 5% of cases of type I prostatitis (acute bacterial prostatitis) progress to type II prostatitis (chronic bacterial prostatitis) (Cheng et al., 2019). Patients with type II disease are typically asymptomatic between episodes. Patients with type III prostatitis often have no bacteria in the urine in the presence of genitourinary pain. Patients with type IV prostatitis are usually diagnosed incidentally during a workup for infertility, an elevated PSA test, or other disorders.

Medical Management

The goal of treatment is to eradicate the causal organisms. Hospital admission may be necessary for patients with unstable vital signs, sepsis, or intractable pelvic pain; those who are frail or immunosuppressed; or those who have diabetes or renal insufficiency. Specific treatment is based on the type of prostatitis and on the results of culture and sensitivity testing of the urine (Farmer, Johnston, Milica, et al., 2019). If bacteria are cultured from the urine, antibiotic agents, including trimethoprim-sulfamethoxazole or a fluoroquinolone (e.g., ciprofloxacin), may be prescribed, and continuous therapy with low-dose antibiotic agents may be used. If the patient is afebrile and has a normal urinalysis, anti-inflammatory agents may be used. Alpha-adrenergic blocker therapy (e.g., tamsulosin) may be prescribed to promote bladder and prostate relaxation.

Factors contributing to prostatitis, including stress, neuromuscular factors, and myofascial pain, are also addressed. Supportive, nonpharmacologic therapies may be prescribed. These include biofeedback, pelvic floor training, physical therapy, reduction of prostatic fluid retention by ejaculation through penile-vaginal intercourse or masturbation, sitz baths, stool softeners, and evaluation of sexual partners to reduce the possibility of cross-infection.

Nursing Management

If the patient experiences symptoms of acute prostatitis (fever, severe pain and discomfort, inability to urinate, malaise), he may be hospitalized for intravenous (IV) antibiotic therapy. Nursing management includes administration of prescribed antibiotic agents and provision of comfort measures, including prescribed analgesic agents and sitz baths.

The patient with chronic prostatitis is usually treated on an outpatient basis and needs to be educated about the importance of continuing antibiotic therapy and recognizing recurrent signs and symptoms of prostatitis.

Promoting Home, Community-Based, and Transitional Care

Educating Patients About Self-Care

The nurse educates the patient about the importance of completing the prescribed course of antibiotic therapy. If IV antibiotic agents are to be given at home, the nurse educates the patient and family about correct and safe administration. Arrangements for a home health nurse to oversee administration may be needed. Warm sitz baths (10 to 20 minutes) may be taken several times daily. Fluids are encouraged to satisfy thirst but are not "forced," because an effective medication level must be maintained in the urine. Foods and liquids with diuretic action or that increase prostatic secretions, such as alcohol, coffee, tea, chocolate, cola, and spices, should be avoided. A suprapubic catheter may be necessary for severe urinary retention. During periods of acute inflammation, any sexual activity should be avoided. To minimize discomfort, the patient should avoid sitting for long periods. Medical follow-up is necessary for at least 6 months to 1 year, because prostatitis caused by the same or different organisms can recur. The patient is advised that the UTI may recur and is educated to recognize its symptoms.

Benign Prostatic Hyperplasia (Enlarged Prostate)

Benign prostatic hyperplasia (BPH), a noncancerous enlargement or hypertrophy of the prostate, is one of the most common diseases in aging men. It can cause bothersome lower urinary tract symptoms that affect quality of life by interfering with normal daily activities and sleep patterns (Cheng et al., 2019).

BPH typically occurs in men older than 40 years. By the time they reach 60 years, 50% of men will have BPH. It affects as many as 90% of men by 85 years of age. BPH is the second most common cause of surgical intervention in men older than 60 years.

Pathophysiology

The cause of BPH is not well understood, but testicular androgens have been implicated. Dihydrotestosterone (DHT), a metabolite of testosterone, is a critical mediator of prostatic growth. Estrogens may also play a role in the cause of BPH; BPH generally occurs when men have elevated estrogen levels and when prostate tissue becomes more sensitive to estrogens and less responsive to DHT. Smoking, heavy alcohol consumption, obesity, reduced activity level, hypertension, heart disease, diabetes, and a Western diet (high in animal fat and protein and refined carbohydrates, low in fiber) are risk factors for BPH (Cheng et al., 2019; El Jalby, Thomas, Elterman, et al., 2019).

BPH develops over a prolonged period; changes in the urinary tract are slow and insidious. BPH is a result of complex interactions involving resistance in the prostatic urethra to mechanical and spastic effects, bladder pressure during voiding, detrusor muscle strength, neurologic functioning, and general physical health (McCance et al., 2018). The hypertrophied lobes of the prostate may obstruct the bladder neck or urethra, causing incomplete emptying of the bladder and urinary retention. As a result, hydroureter (dilation of the ureters) and hydronephrosis (dilation of the kidneys) can gradually occur. Urinary retention may result in UTIs because urine that remains in the urinary tract serves as a medium for infective organisms.

Clinical Manifestations

BPH may or may not lead to lower urinary tract symptoms; if symptoms occur, they may range from mild to severe. Severity of symptoms increases with age, and half of men with BPH report having moderate to severe symptoms. Obstructive and irritative symptoms may include urinary frequency, urgency, nocturia, hesitancy in starting urination, decreased and intermittent force of stream and the sensation of incomplete bladder emptying, abdominal straining with urination, a decrease in the volume and force of the urinary stream, dribbling (urine dribbles out after urination), and complications of acute urinary retention and recurrent UTIs. Normally, residual urine amounts to no more than 50 mL in the middle-aged adult and less than 50 to 100 mL in the older adult (Weber & Kelley, 2018). Ultimately, chronic urinary retention and large residual volumes can lead to azotemia (accumulation of nitrogenous waste products) and kidney failure.

Generalized symptoms may also be noted, including fatigue, anorexia, nausea, vomiting, and pelvic discomfort. Other disorders that produce similar symptoms

include urethral stricture, prostate cancer, neurogenic bladder, and urinary bladder stones.

Assessment and Diagnostic Findings

The health history focuses on the urinary tract, previous surgical procedures, general health issues, family history of prostate disease, and fitness for possible surgery (DeNunzio, Lombardo, Cicione, et al., 2020). A voiding diary is used by the patient to record voiding frequency and urine volume. A DRE often reveals a large, rubbery, and nontender prostate gland. A urinalysis to screen for hematuria and UTI is recommended. A PSA level is obtained if the patient is without a terminal disease and for whom knowledge of the presence of prostate cancer would change management. The American Urological Association (AUA) Symptom Index or International Prostate Symptom Score (IPSS) can be used to assess the severity of symptoms (Smith et al., 2019).

Other diagnostic tests may include recording urinary flow rate and the measurement of postvoid residual urine. If invasive therapy is considered, urodynamic studies, urethrocystoscopy, and ultrasound may be performed. Complete blood studies are performed. Cardiac status and respiratory function are assessed because a high percentage of patients with BPH have cardiac or respiratory disorders due to their age.

Medical Management

The goals of medical management of BPH are to improve quality of life, improve urine flow, relieve obstruction, prevent disease progression, and minimize complications. Treatment depends on the severity of symptoms, the cause of disease, the severity of the obstruction, and the patient's condition.

If a patient is admitted on an emergency basis because he is unable to void, he is immediately catheterized. The ordinary catheter may be too soft and pliable to advance through the urethra into the bladder. In such cases, a stylet (thin wire) is introduced (by a urologist) into the catheter to prevent the catheter from collapsing when it encounters resistance. A metal catheter with a pronounced prostatic curve may be used if obstruction is severe. A **cystostomy** (incision into the bladder) may be needed to provide urinary drainage.

Discussion of all treatment options by the primary provider enables the patient to make an informed decision based on symptom severity, the effect of BPH on his quality of life, and preference. Patients with mild symptoms and those with moderate or severe symptoms, who are not bothered by them and have not developed complications, may be managed with "watchful waiting." With this approach, the patient is monitored and reexamined annually but receives no active intervention (DeNunzio et al., 2020). Other therapeutic choices include pharmacologic treatment, minimally invasive procedures, and surgery.

Pharmacologic Therapy

Pharmacologic treatment for BPH includes the use of alpha-adrenergic blockers and 5-alpha-reductase inhibitors (Cheng et al., 2019). Alpha-adrenergic blockers, which include alfuzosin, terazosin, doxazosin, and tamsulosin, relax the smooth muscle of the bladder neck and prostate. This improves urine flow and relieves symptoms of BPH. Side effects include dizziness, headache, asthenia/fatigue, orthostatic hypotension, rhinitis, and sexual dysfunction (Chapple, Steers, & Evans, 2020; Cheng et al., 2019).

Another method of treatment involves hormonal manipulation with antiandrogen agents. The 5-alpha-reductase inhibitors, finasteride and dutasteride, are used to prevent the conversion of testosterone to DHT and decrease prostate size. Side effects include decreased libido, ejaculatory dysfunction, erectile dysfunction, gynecomastia (breast enlargement), and flushing. Combination therapy (doxazosin and finasteride) has decreased symptoms and reduced clinical progression of BPH (Chapple et al., 2020; Cheng et al., 2019).

The use of alternative and complementary phytotherapeutic agents and other dietary supplements (*Serenoa repens* [saw palmetto berry] and *Pygeum africanum* [African plum]) are not recommended by the medical community, although they are commonly used (Rowland, McNabney, & Donarski, 2019). They may function by interfering with the conversion of testosterone to DHT. In addition, *S. repens* may directly block the ability of DHT to stimulate prostate cell growth. These agents should not be used with finasteride, dutasteride, or estrogen-containing medications (Rowland et al., 2019).

Surgical Management

Other treatment options include minimally invasive procedures and resection of the prostate gland.

Minimally Invasive Therapy

Several forms of minimally invasive therapy may be used to treat BPH. Transurethral microwave thermotherapy involves the application of heat to prostatic tissue. High-energy devices (CoreTherm, Prostatron, Targis) and low-energy devices (TherMatrx) are available (Cheng et al., 2019). A transurethral probe is inserted into the urethra, and microwaves are directed to the prostate tissue. The targeted tissue becomes necrotic and sloughs. To minimize damage to the urethra and decrease the discomfort from the procedure, some systems have a water-cooling apparatus.

Other minimally invasive treatment options include transurethral needle ablation by radiofrequency energy and insertion of a stent. Transurethral needle ablation uses low-level radiofrequencies delivered by thin needles placed in the prostate gland to produce localized heat that destroys prostate tissue while sparing other tissues. The body then reabsorbs the dead tissue. Prostatic stents are associated with significant complications (e.g., encrustation, infection, chronic pain); therefore, they are used only for patients with urinary retention and in patients who are at poor surgical risks (Cheng et al., 2019).

Surgical Resection

Surgical resection of the prostate gland is another option for patients with moderate to severe lower urinary tract symptoms of BPH and for those with acute urinary retention or other complications. The specific surgical approach (open or endoscopic) and the energy source (electrocautery vs. laser) are based on the surgeon's experience, the size of the prostate gland, the presence of other medical disorders, and the patient's preference. If surgery is to be performed, all clotting defects must be corrected and medications for anticoagulation withheld because bleeding is a potential complication of prostate surgery.

Transurethral resection of the prostate (TURP) remains the benchmark for surgical treatment for BPH. It involves the surgical removal of the inner portion of the prostate through an endoscope inserted through the urethra; no external skin incision is made. It can be performed with ultrasound guidance. The treated tissue either vaporizes or becomes necrotic and sloughs. The procedure is performed in the outpatient setting and usually results in less postoperative bleeding than a traditional surgical prostatectomy.

Other surgical options for BPH include transurethral incision of the prostate (TUIP), transurethral electrovaporization, laser therapy, and open prostatectomy (Chapple et al., 2020; Smith et al., 2019). TUIP is an outpatient procedure used to treat smaller prostates. One or two cuts are made in the prostate and prostate capsule to reduce constriction of the urethra and decrease resistance to flow of urine out of the bladder; no tissue is removed. Open **prostatectomy** involves the surgical removal of the inner portion of the prostate via a suprapubic, retropubic, or perineal (rare) approach for large prostate glands. Prostatectomy may also be performed laparoscopically or by robotic-assisted laparoscopy.

Nursing management of patients undergoing these procedures is described later in this chapter.

Cancer of the Prostate

Prostate cancer is the most common cancer in men other than nonmelanoma skin cancer. It is the second most common cause of cancer death in American men, exceeded only by lung cancer, and is responsible for 10% of cancer-related deaths in men. Among men diagnosed with prostate cancer, 98% survive at least 5 years, 84% survive at least 10 years, and 56% survive 15 years (ACS, 2020).

Prostate cancer is common in the United States and northwestern Europe but is rare in Africa, Central America, South America, China, and other parts of Asia. African American men have a high risk of prostate cancer; furthermore, they are more than twice as likely to die of prostate cancer as men of other racial or ethnic groups. Health care providers need to offer education about prostate cancer and appropriate screening in African American men, who are at higher risk compared to all other ethnic communities (Riviere, Luterstein, Kumar, et al., 2020). Health care providers should also ensure the delivery of culturally sensitive education

programs and counseling about prostate cancer screening not only to the African American patient at risk for prostate cancer, but also to his friends and family (Kelly, Morgan, Connelly, et al., 2019; Owens, Kim, & Tavakoli, 2019).

Other risk factors for prostate cancer include increasing age; the incidence of prostate cancer increases rapidly after the age of 50 years. More than 70% of cases occur in men older than 65 years. A familial predisposition may occur in men who have a father or brother previously diagnosed with prostate cancer, especially if their relatives were diagnosed at a young age. Genes that may be associated with increased risk of prostate cancer include hereditary prostate cancer 1 (*HPC1*) and *BRCA1* and *BRCA2* mutations (Cheng et al., 2019). The risk of prostate cancer is also greater in men whose diet contains excessive amounts of red meat or dairy products that are high in fat (ACS, 2020). Endogenous hormones, such as androgens and estrogens, also may be associated with the development of prostate cancer.

Clinical Manifestations

Cancer of the prostate in its early stages rarely produces symptoms. Usually, symptoms that develop from urinary obstruction occur in advanced disease. Prostate cancer tends to vary in its course. If the cancer is large enough to encroach on the bladder neck, signs and symptoms of urinary obstruction occur (difficulty and frequency of urination, urinary retention, and decreased size and force of the urinary stream). Other symptoms may include blood in the urine or semen and painful ejaculation. Hematuria may occur if the cancer invades the urethra or bladder. Sexual dysfunction is common before the diagnosis is made.

Prostate cancer can spread to lymph nodes and bones. Symptoms of metastases include backache, hip pain, perineal and rectal discomfort, anemia, weight loss, weakness, nausea, oliguria (decreased urine output), and spontaneous pathologic fractures. These symptoms may be the first indications of prostate cancer.

Assessment and Diagnostic Findings

If prostate cancer is detected early, the likelihood of cure is high (Brant, 2019). It can be diagnosed through an abnormal finding with the DRE, serum PSA, and TRUS with biopsy. Detection is more likely with the use of combined diagnostic procedures. Routine repeated DRE (preferably by the same examiner) is important because early cancer may be detected as a nodule within the gland or as an extensive hardening in the posterior lobe. The more advanced lesion is “stony hard” and fixed. DRE also provides useful clinical information about the rectum, anal sphincter, and quality of stool.

The diagnosis of prostate cancer is confirmed by a histologic examination of tissue removed surgically by TURP, open prostatectomy, or ultrasound-guided transrectal needle biopsy. Fine-needle aspiration is a quick, painless method of obtaining prostate cells for cytologic examination and determining the stage of disease.

Most prostate cancers are detected when a man seeks medical attention for symptoms of urinary obstruction or are found by routine DRE and PSA testing. Cancer detected incidentally when TURP is performed for clinically benign disease and lower urinary tract symptoms occurs in about 1 of 10 cases.

Concept Mastery Alert

DRE and PSA testing are important screening procedures because abnormal DRE and elevated levels of PSA may raise suspicion of prostate cancer. However, a diagnosis of cancer requires confirmation with a prostate biopsy.

TRUS helps detect nonpalpable prostate cancers and assists with staging of localized prostate cancer. Needle biopsies of the prostate are commonly guided by TRUS. The biopsies are examined by a pathologist to both determine if cancer is present and to grade the tumor. The most commonly used tumor grading system is the Gleason score. This system assigns a grade of 1 to 5 for the most predominant architectural pattern of the glands of the prostate and a secondary grade of 1 to 5 to the second most predominant pattern. The Gleason score is then reported as, for example, 2 + 4; the combined value can range from 2 to 10. With each increase in Gleason score, there is an increase in tumor aggressiveness. Lower Gleason scores indicate well-differentiated and less aggressive tumor cells; higher Gleason scores indicate undifferentiated cells and more aggressive cancer. A total score of 8 to 10 indicates a high-grade cancer (Smith et al., 2019; Zhou, Salles, Samarska, et al., 2019).

Categorization of low-, intermediate-, and high-risk prostate cancer is determined by the extent of cancer in the prostate gland, whether or not the cancer is localized to the prostate, the aggressiveness of the cells, and the spread to the lymph nodes and beyond. Level of risk, in turn, is used to determine treatment options.

Bone scans, skeletal x-rays, and magnetic resonance imaging (MRI) may be used to identify metastatic bone disease. Pelvic computed tomography (CT) scans may be performed to determine if the cancer has spread to the lymph nodes. The radiolabeled monoclonal antibody capromab pendetide with indium 111 is an antibody that can be used to detect either recurrent prostate cancer at low PSA levels or metastatic disease (NCCN, 2020b).

Medical Management

Treatment is based on the patient's life expectancy, symptoms, risk of recurrence after definitive treatment, size of the tumor, Gleason score, PSA level, likelihood of complications, and patient preference. Therapy is often guided by the use of a nomogram or risk stratification scheme suggested by the NCCN (2020b) clinical practice guidelines. A multidisciplinary team approach is essential for the development of appropriate treatment. Management may be nonsurgical and

involve watchful waiting or be surgical and entail prostatectomy. Nursing care of the patient with cancer of the prostate is summarized in Chart 53-3.

For patients with prostate cancer who choose nonsurgical watchful waiting, this approach involves actively monitoring the course of disease and intervening only if the cancer progresses or if symptoms warrant other intervention. It is an option for patients with life expectancy of less than 5 years and low-risk cancers. Advantages include absence of side effects of more aggressive treatment, improved quality of life, avoidance of unnecessary treatment, and decreased initial costs. Disadvantages include missed chance at cure, risk of metastasis, subsequent need for more aggressive treatment, anxiety about living with untreated cancer, and need for frequent monitoring (NCCN, 2020b).

Therapeutic vaccines kill existing cancer cells and provide long-lasting immunity against further cancer development. Sipuleucel-T is the first therapeutic cancer vaccine approved by the U.S. Food and Drug Administration (FDA) for use in men with metastatic prostate cancer that is no longer responding to hormone therapy. This is an immunotherapy treatment that stimulates the patient's own immune system to identify and target prostate cancer cells, and it has minimal side effects (Caram, Ross, Lin, et al., 2019).

In addition, two other medications, abiraterone acetate and cabazitaxel, are treatment options for patients requiring care for the management of metastatic castration–resistant prostate cancer, which does not respond to sipuleucel-T or the usual treatment options (Nuhn, De Bono, Fizazi, et al., 2019).

Surgical Management

Radical prostatectomy is considered first-line treatment for prostate cancer and is used with patients whose tumor is confined to the prostate (Smith et al., 2019). It is the complete surgical removal of the prostate, seminal vesicles, tips of the vas deferens, and often the surrounding fat, nerves, and blood vessels. Laparoscopic radical prostatectomy and robotic-assisted laparoscopic radical prostatectomy have become the standard surgical approaches for localized cancer of the prostate. Although erectile dysfunction is a common side effect, these laparoscopic radical prostatectomy approaches result in low morbidity and more favorable postoperative outcomes, including improved quality of life and less sexual dysfunction if the nerves are spared. Surgical approaches are discussed in detail later in this chapter.

Radiation Therapy

Two major forms of radiation therapy are used to treat cancer of the prostate: teletherapy (external) and **brachytherapy** (internal). Teletherapy (external-beam radiation therapy [EBRT]) is prescribed by the radiation oncologist for a total dose over a certain time frame—for example, 28 treatments over 5½ weeks (Cheng et al., 2019). It is a treatment option for patients with low-risk prostate cancer; progression-free survival is similar to that of low-risk patients treated with radical prostatectomy. Patients with intermediate- and high-risk cancers receive

higher doses of EBRT. They may also be candidates for both pelvic lymph node irradiation and **androgen deprivation therapy** that entails surgical (orchiectomy) or medical castration (e.g., with luteinizing hormone–releasing hormone agonists) (NCCN, 2020b). Intensity-modulated radiation therapy is one method of delivery of EBRT. Intensity-modulated radiation therapy sets a dose for the target volume and restricts the dose to surrounding tissue. Another approach to delivery of radiation uses a computer-controlled robotic arm to deliver a course of radiotherapy (i.e., stereotactic radiosurgery) to localized prostate cancer. This method, referred to as the CyberKnife, is considered a safe and reliable method of delivering radiation to treat prostate cancer (Pollom, Wang, Gibbs, et al., 2019).

Chart 53-3 PLAN OF NURSING CARE

The Patient with Prostate Cancer

NURSING DIAGNOSIS: Anxiety associated with concern and lack of knowledge about the diagnosis, treatment plan, and prognosis
GOAL: Reduced stress and improved ability to cope

Nursing Interventions	Rationale	Expected Outcomes
1. Obtain health history to determine the following: **a.** Patient's concerns **b.** His level of understanding of his health problem **c.** His past experience with cancer **d.** Whether he knows his diagnosis of malignancy and its prognosis **e.** His support systems and coping methods **2.** Provide education about diagnosis and treatment plan. **a.** Explain in simple terms what diagnostic tests to expect, how long they will take, and what will be experienced during each test. **b.** Review treatment plan and encourage patient to ask questions. **3.** Assess his psychological reaction to his diagnosis/prognosis	**1.** Nurse clarifies information and facilitates patient's understanding and coping. **2.** Helping the patient to understand the diagnostic tests and treatment plan will help decrease his anxiety and promote cooperation. **3.** This information provides clues in determining appropriate measures to facilitate coping. **4.** Institutional and community resources can help the patient and family cope with the illness and treatment on an ongoing basis.	• Appears relaxed • States that anxiety has been reduced or relieved • Demonstrates understanding of illness, diagnostic tests, and treatment when questioned • Verbalizes adequate coping ability • Engages in open communication with others

and how he has coped with past stresses. **4.** Provide information about institutional and community resources for coping with prostate cancer: social services, support services, community agencies.		
NURSING DIAGNOSIS: Urinary retention associated with inability to empty bladder completely **GOAL:** Improved pattern of urinary elimination		
Nursing Interventions	**Rationale**	**Expected Outcomes**
1. Determine patient's usual pattern of urinary function. **2.** Assess for signs and symptoms of urinary retention: amount and frequency of urination, suprapubic distention, complaints of urgency and discomfort. **3.** Initiate measures to treat retention. **a.** Encourage assuming normal position for voiding. **b.** Recommend using Valsalva maneuver preoperatively, if not contraindicated. **c.** Administer prescribed	**1.** Provides a baseline for comparison and goal to work toward. **2.** Voiding 20 to 30 mL frequently and output less than intake suggest retention. **3.** Promotes voiding: **a.** Usual position provides relaxed conditions conducive to voiding. **b.** Valsalva maneuver exerts pressure to force urine out of bladder. **c.** Stimulates bladder contraction. **d.** If unsuccessful,	• Voids at normal intervals • Reports absence of frequency, urgency, or bladder fullness • Displays no palpable suprapubic distention after voiding • Maintains balanced intake and output

medication. **d.** Monitor effects of medication. **4.** Consult with primary provider regarding intermittent or indwelling catheterization; assist with procedure as required. **5.** Monitor catheter function; maintain sterility of closed system; irrigate as required. **6.** Prepare patient for surgery if indicated.	another measure may be required. **4.** Catheterization will relieve urinary retention until the specific cause is determined; it may be an obstruction that can be corrected only surgically. **5.** Adequate functioning of catheter is to be ensured to empty bladder and to prevent infection. **6.** Surgical removal of obstruction may be necessary.	

NURSING DIAGNOSIS: Lack of knowledge associated with the diagnosis of cancer, urinary difficulties, and treatment modalities

GOAL: Understanding of the diagnosis and ability to care for self

Nursing Interventions	Rationale	Expected Outcomes
1. Encourage communication with the patient. **2.** Review the anatomy of the involved area. **3.** Be specific in selecting information that is relevant to the patient's particular treatment plan. **4.** Identify ways to reduce pressure on the operative area after prostatectomy. **a.** Instruct patient to avoid prolonged sitting (in a chair,	**1.** This is designed to establish rapport and trust. **2.** Orientation to one's anatomy is basic to understanding its function. **3.** This is based on the treatment plan because it varies with each patient; individualization is desirable. **4.** This is to prevent bleeding; such precautions are in	• Discusses his concerns and problems freely • Asks questions and shows interest in his disorder • Describes activities that help or hinder recovery • Identifies ways of attaining/maintaining bladder control • Demonstrates satisfactory technique and understanding of catheter care

long automobile rides), standing, walking.

b. Instruct patient to avoid straining, such as during exercises, bowel movement, lifting, and sexual activity.

5. Familiarize patient with ways of attaining/maintaining bladder control.

a. Encourage urination every 2 to 3 hours; discourage voiding when supine.

b. Instruct patient to avoid drinking cola and caffeine beverages; urge a cutoff time in the evening for drinking fluids to minimize frequent voiding during the night.

c. Describe perineal exercises to be performed every hour.

d. Develop a schedule with patient that will fit into his routine.

6. Demonstrate catheter care; encourage his questions; stress the importance of position of urinary receptacle.

order for 6 to 8 weeks postoperatively.

5. These measures will help control frequency and dribbling and aid in preventing retention.

a. By sitting or standing, patient is more likely to empty his bladder.

b. Spacing the kind and amount of liquid intake will help to prevent frequency.

c. Exercises will assist him in starting and stopping the urinary stream.

d. A schedule will assist in developing a workable pattern of normal activities.

6. By requiring a return demonstration of care, collection, and emptying of the device, he will become more independent and also can prevent backflow of urine, which can lead to infection.

- Lists signs and symptoms that must be reported should they occur (e.g., abnormal bleeding, infection)

NURSING DIAGNOSIS: Impaired nutritional intake associated with decreased oral intake because of anorexia, nausea, and vomiting caused by cancer or its treatment

GOAL: Maintain optimal nutritional status

Nursing Interventions	Rationale	Expected Outcomes
1. Assess the amount of food eaten. **2.** Routinely weigh patient. **3.** Elicit patient's explanation of why he is unable to eat more. **4.** Cater to his individual food preferences (e.g., avoiding foods that are too spicy or too cold). **5.** Recognize effect of medication or radiation therapy on appetite. **6.** Inform patient that alterations in taste can occur.	**1.** This assessment will help determine nutrient intake. **2.** Weighing the patient on the same scale under similar conditions can help monitor changes in weight. **3.** His explanation may present easily corrected practices. **4.** He will be more likely to consume larger servings if food is palatable and appealing. **5.** Many chemotherapeutic agents and radiation therapy promote anorexia. **6.** Aging and the disease process can reduce taste sensitivity. In addition, smell and taste can be altered as a result of the body's absorption of by-products of cellular destruction (brought on by	• Responds positively to his favorite foods • Assumes responsibility for his oral hygiene • Reports absence of nausea and vomiting • Notes increase in weight after improved appetite

	malignancy and its treatment).	
7. Educate patient about appropriate oral hygiene interventions. 8. Use measures to control nausea and vomiting. a. Administer prescribed antiemetic agents, around the clock if necessary. b. Provide oral hygiene after vomiting episodes. c. Provide rest periods after meals. 9. Provide frequent small meals and a comfortable and pleasant environment. 10. Assess patient's ability to obtain and prepare foods.	7. Food will be more palatable and appealing following good oral hygiene. 8. Prevention of nausea and vomiting can stimulate appetite. 9. Smaller portions of food are more tolerable for the patient. 10. Disability or lack of social support can hinder the patient's ability to obtain and prepare foods.	

NURSING DIAGNOSIS: Impaired sexual functioning associated with effects of therapy: chemotherapy, hormonal therapy, radiation therapy, surgery
GOAL: Ability to resume/enjoy modified sexual functioning

Nursing Interventions	Rationale	Expected Outcomes
1. Determine from nursing history what effect patient's medical condition is having on his sexual functioning. 2. Inform patient of the effects of prostate surgery,	1. Usually, decreased libido and, later, erectile dysfunction may be experienced. 2. Treatment modalities may alter sexual function, but each	• Describes the reasons for changes in sexual functioning • Discusses with appropriate health care personnel alternative approaches and

orchiectomy (when applicable), chemotherapy, irradiation, and hormonal therapy on sexual function. **3.** Include his partner in developing understanding and in discovering alternative, satisfying close relations with each other.	is evaluated separately regarding its effect on a particular patient. **3.** The bond between a couple may be strengthened with new appreciation and support that had not been evident before the current illness.	methods of sexual expression • Includes partner in discussions related to changes in sexual function

NURSING DIAGNOSIS: Acute pain associated with progression of disease and treatment modalities
GOAL: Relief of pain

Nursing Interventions	Rationale	Expected Outcomes
1. Evaluate nature of patient's pain, its location, and intensity using pain rating scale.	**1.** Determining nature and causes of pain and its intensity help to select proper pain relief modality and provide baseline for later comparison.	• Reports relief of pain • Expects exacerbations, reports their quality and intensity, and obtains relief • Uses pain relief strategies appropriately and effectively • Identifies strategies to avoid complications of analgesic use (e.g., constipation)
2. Avoid activities that aggravate or worsen pain.	**2.** Bumping the bed is an example of an action that can intensify the patient's pain.	
3. Because pain is usually related to bone metastasis, ensure that patient's bed has a bed board or a firm mattress. In addition, protect the patient from falls/injuries.	**3.** This will provide added support and is more comfortable. Protecting the patient from injury protects him from additional pain.	
4. Provide support for affected extremities.	**4.** More support, coupled with reduced movement of the part, helps in pain control.	
5. Prepare patient for radiation therapy if prescribed.	**5.** Radiation therapy may be effective in controlling pain.	
6. Administer analgesic or opioid agents at regularly scheduled intervals as prescribed.	**6.** Analgesic agents alter perception of pain and provide comfort. Regularly scheduled analgesics around the clock rather than PRN (as needed) provide more consistent pain relief.	
7. Initiate bowel program to prevent constipation.	**7.** Opioid analgesic agents and inactivity contribute to constipation.	

NURSING DIAGNOSIS: Impaired mobility associated with limitations in

independent, purposeful movement of the body or one or more extremities
GOAL: Improved physical mobility

Nursing Interventions	Rationale	Expected Outcomes
1. Assess for factors causing limited mobility (e.g., pain, hypercalcemia, limited exercise tolerance). **2.** Provide pain relief by administering prescribed medications. **3.** Encourage the use of assistive devices: cane, walker. **4.** Involve significant others in helping patient with range-of-motion exercises, positioning, and walking. **5.** Provide positive reinforcement for achievement of small gains. **6.** Assess nutritional status.	**1.** This information offers clues to the cause; if possible, cause is treated. **2.** Analgesic/opioid agents allow the patient to increase his activity more comfortably. **3.** Support may offer the security needed to become mobile. **4.** Assistance from partner or others encourages patient to repeat activities and achieve goals. **5.** Encouragement stimulates improvement of performance. **6.** See Nursing Diagnosis: Impaired nutritional intake	• Achieves improved physical mobility • Relates that short-term goals are encouraging him because they are attainable

COLLABORATIVE PROBLEMS: Hemorrhage, infection, bladder neck obstruction
GOAL: Absence of complications

Nursing Interventions	Rationale	Expected Outcomes
1. Alert the patient to changes that may occur (after discharge) and that need to be reported: **a.** Continued bloody urine;	**1.** Certain changes signal beginning complications, which call for nursing and medical interventions. **a.** Hematuria with or without blood clot	• Experiences no bleeding or passage of blood clots • Reports no infection or pain around the catheter

passing blood clots **b.** Pain; burning around the catheter **c.** Frequency of urination **d.** Diminished urinary output **e.** Increasing loss of bladder control	formation may occur postoperatively. **b.** Indwelling urinary catheters may be a source of pain or infection. **c.** Urinary frequency may be caused by urinary tract infections or by bladder neck obstruction, resulting in incomplete voiding. **d.** Bladder neck obstruction decreases the amount of urine that is voided. **e.** Urinary incontinence may be a result of urinary retention.	• Experiences normal frequency or urination • Reports normal urinary output • Maintains bladder control

Brachytherapy involves the implantation of interstitial radioactive seeds under anesthesia. It has become a commonly used monotherapy treatment option for early, clinically organ-confined prostate cancer. The surgeon uses ultrasound guidance to place 80 to 100 seeds (depending on the prostate volume), and the patient returns home after the procedure. Exposure of others to radiation is minimal, but the patient should avoid close contact with pregnant women and infants for up to 2 months. Radiation safety guidelines include straining urine for seeds and using a condom during penile-vaginal intercourse for 2 weeks after implantation to catch any seeds that pass through the urethra. This approach can be completed in 1 day, with little lost time from normal activities. Brachytherapy may be combined with EBRT with or without neoadjuvant androgen deprivation therapy for patients considered at intermediate risk. High-risk patients are considered poor candidates for permanent brachytherapy (Brant, 2019).

Although cure rates with radiation are comparable to those of radical prostatectomy, radiation therapy possesses its own unique set of side effects, which differ depending on the method of radiation administration. Patients receiving EBRT or brachytherapy may experience inflammation of the rectum, bowel, and bladder (proctitis, enteritis, and cystitis) because of the proximity of these structures to the prostate and the radiation doses. Inflammation and mucosal loss at the bladder neck, prostate, and urethra can cause acute urinary dysfunction. Both irritative and obstructive urinary symptoms can cause pain with urination and ejaculation until the irritation subsides. Rectal urgency, diarrhea, and tenesmus may occur as a result of radiation of the anterior rectal wall. Late side

effects include rectal proctitis, bleeding, and rectal fistula; painless hematuria; chronic interstitial cystitis; urethral stricture erectile dysfunction; and, rarely, secondary cancers of the rectum and bladder (Brant, 2019).

Hormonal Strategies

The number of survivors of prostate cancer in the United States is estimated at 2 million; approximately one third of these men currently receive androgen deprivation therapy (Jeong, Cowan, Broering, et al., 2019). Androgen deprivation therapy is commonly used to suppress androgenic stimuli to the prostate by decreasing the level of circulating plasma testosterone or interrupting the conversion to or binding of DHT. As a result, the prostatic epithelium atrophies (decreases in size). This effect is accomplished either by surgical castration through bilateral **orchiectomy** (removal of one or both testes), which has traditionally been the mainstay of hormonal treatment, or by medical castration with the administration of medications, such as luteinizing hormone–releasing hormone (LHRH) agonists. Bilateral orchiectomy decreases plasma testosterone levels significantly because approximately 93% of circulating testosterone is of testicular origin (7% is from the adrenal glands). Thus, the testicular stimulus required for continued prostatic growth is removed, resulting in prostatic atrophy.

However, orchiectomy often results in significant morbidity. Although the procedure does not cause the side effects associated with other hormonal therapies (described later), it is associated with considerable emotional impact. Because patients who have prostate cancer are living longer with the disease, health care providers are focusing on effective therapeutic modalities that promote an acceptable quality of life. Patients may be given the option for testicular prostheses to be placed during surgery.

LHRH agonists include leuprolide and goserelin. Additional hormonal manipulation with antiandrogens may be prescribed for patients who do not show adequate serum testosterone suppression (less than 50 ng/mL) with medical or surgical castration. Antiandrogen receptor antagonists include flutamide, bicalutamide, and nilutamide. LHRH agonists suppress testicular androgen, whereas antiandrogen receptor antagonists cause adrenal androgen suppression. When LHRH agonists are initiated, a testosterone flare may occur, causing pain in bony metastatic disease. Antiandrogens given for the first 7 days may reduce this uncomfortable symptom. The most common uses of LHRH agonists are in the adjuvant and neoadjuvant setting in combination with radiation therapy, after radical prostatectomy, and in the treatment of recurrence indicated by an elevation in the PSA but without clinical or x-ray evidence. Medical and surgical castration causes hot flushing because these treatment modalities increase hypothalamic activity, which stimulates the thermoregulatory centers of the body (Kunath, Goebell, Wullich, et al., 2020; Shore, Guerrero, Sanahuja, et al., 2019).

The management of hormone-refractory prostate cancer remains somewhat controversial. Another category of medication used as a second-line hormonal intervention is the adrenal ablating drugs. Ketoconazole is used to inhibit

cytochrome P450 enzymes, which are required for the synthesis of androgens and other steroids. High-dose ketoconazole lowers testosterone by decreasing both testicular and endocrine production of androgen. Administration of this medication requires steroid supplementation to prevent adrenal insufficiency.

Hypogonadism is responsible for the adverse effects of androgen deprivation therapy, which include vasomotor flushing, loss of libido, decreased bone density (resulting in osteoporosis and fractures), anemia, fatigue, increased fat mass, lipid alterations, decreased muscle mass, gynecomastia (increased breast tissue), and mastodynia (breast/nipple tenderness). Hypogonadism is associated with an increased risk of diabetes, resulting from insulin resistance, metabolic syndrome, and cardiovascular disease (Cheng et al., 2019).

Chemotherapy

Recent studies have shown clear benefits in terms of survival with chemotherapy treatment that includes a docetaxel-based regimen for non–androgen-dependent prostate cancer (NCCN, 2020b). Other studies are under way to determine the importance of the vascular endothelial growth factor system. Tumor angiogenesis is essential for tumor growth, including growth of prostate carcinomas and other high-grade cancers. Therefore, antiangiogenic treatment in combination with conventional therapies may play a future role in treatment. Gene-based therapy in prostate cancer is an emerging and promising adjuvant to conventional treatment strategies.

Possible complications related to chemotherapy are specific to the type of chemotherapy given (see Chapter 12, Chart 12-4).

Other Therapies

Cryosurgery of the prostate is used to ablate prostate cancer in patients who cannot tolerate surgery and in those with recurrent prostate cancer. Transperineal probes are inserted into the prostate under ultrasound guidance to freeze the tissue directly.

Keeping the urethral passage patent may require repeated TURPs. If this is impractical, catheter drainage is instituted by way of the suprapubic or transurethral route. For men with advanced prostate cancer, palliative measures are indicated. Although cure is unlikely with advanced prostate cancer, many men survive for long periods, free of debilitating symptoms.

Bone lesions that result from metastasis of prostate cancer can be very painful and result in pathologic fractures. Opioid and nonopioid medications are used to control bone pain. EBRT can be delivered to skeletal lesions to relieve pain. Radiopharmaceuticals, such as strontium or samarium, can be injected IV to treat multiple sites of bone metastasis. Antiandrogen therapies are used in an effort to reduce the circulating androgens. If antiandrogen therapies are not effective, medications such as prednisone have been effective in reducing pain and improving quality of life (Dong, Zieren, Xue, et al., 2019; Sargon, Lamb, & Patel, 2019). Bisphosphonate therapy with pamidronate can be given to reduce the risk

of pathologic fracture. In advanced prostate cancer, blood transfusions are given to maintain adequate hemoglobin levels when bone marrow is replaced by tumor.

More than one third of men with a diagnosis of prostate cancer elect to use some form of complementary and integrative health. Because research on many forms of complementary, alternative, and integrative health is lacking, patients often rely on anecdotal information to make decisions about which modalities to use. Nurses and other health care professionals play a vital role in assisting patients to locate and evaluate available information about these practices to ensure that harmful forms are avoided (Brant, 2019). The National Center for Complementary and Integrative Health (NCCIH) website can assist nurses in providing patients with evidence-based information (see the Resources section at the end of the chapter).

The Patient Undergoing Prostate Surgery

Prostate surgery may be indicated for the patient with BPH or prostate cancer. The objectives before prostate surgery are to assess the patient's general health status and to establish optimal kidney function. Prostate surgery should be performed before acute urinary retention develops and damages the upper urinary tract and collecting system or, in the case of prostate cancer, before cancer progresses.

Surgical Procedures

Several approaches can be used to remove the hypertrophied portion of the prostate gland: TURP, suprapubic prostatectomy, perineal prostatectomy, retropubic prostatectomy, TUIP, and laparoscopic radical prostatectomy and robotic-assisted laparoscopic radical prostatectomy (see Table 53-4). With these approaches, all cancerous or hyperplastic tissue is removed, leaving behind only the capsule of the prostate.

Transurethral Resection of the Prostate

TURP, which is the most common procedure used, can be carried out through endoscopy. The prostate gland is removed in small chips with an electrical cutting loop (see Fig. 53-4A). This procedure decreases the risk of transurethral resection syndrome (hyponatremia, hypervolemia). Transurethral resection syndrome is a potential but rare complication of TURP that occurs in approximately 2% of men who undergo the procedure (Hahn, 2019) (see Chart 53-4).

Urethral strictures are more frequent than with nontransurethral procedures, and repeated procedures may be necessary because the residual prostatic tissue grows back. TURP rarely causes erectile dysfunction but may trigger retrograde ejaculation, because removal of prostatic tissue at the bladder neck can cause the seminal fluid to flow backward into the bladder rather than forward through the urethra during ejaculation.

Suprapubic Prostatectomy

A suprapubic prostatectomy is an open surgical procedure (see Fig. 53-4B). Disadvantages include blood loss, the need for an abdominal incision, and the risks associated with any major abdominal surgical procedure.

Perineal Prostatectomy

A perineal prostatectomy (see Fig. 53-4C) is practical when other approaches are not possible and is useful for an open biopsy. However, incontinence, sexual dysfunction, and rectal injury are more likely to occur with this approach.

Retropubic Prostatectomy

Retropubic prostatectomy is used more commonly than the suprapubic approach (see Fig. 53-4D). This procedure is suitable for large glands located high in the pelvis. Although blood loss can be better controlled and the surgical site is easier to visualize, infections can readily start in the retropubic space.

Transurethral Incision of the Prostate

TUIP is indicated when the prostate gland is small (30 g or less), and it is an effective treatment for many cases of BPH (see Fig. 53-4E). TUIP can be performed as an outpatient procedure and has a lower complication rate than other more invasive prostate procedures.

Laparoscopic Radical Prostatectomy

A laparoscopic radical prostatectomy has fewer risks compared with open radical prostatectomy (Smith et al., 2019).

Robotic-Assisted Laparoscopic Radical Prostatectomy

Robotic-assisted laparoscopic radical prostatectomy is a minimally invasive approach that uses a computer console and a robot to move instruments, replicating the movements of the surgeon's hands (Peard, Goodwin, Hensley, et al., 2019; Smith et al., 2019).

Pelvic Lymph Node Dissection

Pelvic lymph node dissection (PLND) is not always performed. It may be used in some patients to provide information for staging the tumor and to remove an area of microscopic metastasis. The planned treatment may influence the surgeon's decision to perform PLND and the extent (limited vs. extended) of the dissection. Dissection of nodes anterior and lateral to the external iliac vessels is associated with an increased risk of lymphedema (NCCN, 2020a).

Complications

Postoperative complications depend on the type of prostatectomy performed and may include hemorrhage, clot formation, catheter obstruction, and sexual dysfunction. All prostatectomies carry a risk of erectile dysfunction because of potential damage to the pudendal nerves. In most instances, sexual activity may be resumed in 6 to 8 weeks, which is the time required for the prostatic fossa to heal. The anatomic changes in the posterior urethra can lead to retrograde ejaculation. During ejaculation, the seminal fluid goes into the bladder and is excreted with the urine. A vasectomy may be performed during surgery to prevent infection from spreading from the prostatic urethra through the vas and into the epididymis.

After total prostatectomy (usually for cancer), the risk of erectile dysfunction is high. If this is unacceptable to the patient, options are available to produce erections sufficient for sexual activity: prosthetic penile implants, negative-pressure (vacuum) devices, and pharmacologic interventions (see earlier discussion and Table 53-2).

TABLE 53-4 Surgical Approaches for Treatment of Prostate Disorders

The surgical approach of choice depends on the size of the gland, the severity of the obstruction, the age of the patient, the condition of the patient, and the presence of associated diseases.

Surgical Approach	Advantages	Disadvantages	Nursing Implications
Transurethral Resection of the Prostate (TURP) Removal of prostatic tissue by optical instrument introduced through urethra; used for glands of varying size. Ideal for patients who are at poor surgical risks (see Fig. 53-4A).	Avoids abdominal incision Safer for surgical-risk patient Shorter length of hospital stay and recovery periods Lower morbidity rate Causes less pain Can be used as a palliative approach with history of radiation therapy	Recurrent obstruction, urethral trauma, and stricture may develop Delayed bleeding may occur	Monitor for hemorrhage. Observe for symptoms of urethral stricture (dysuria, straining, weak urinary stream).
Open Surgical Removal			
Suprapubic approach Removal of prostatic tissue through abdominal incision; can be used for gland of any size (see Fig. 53-4B).	Technically simple Offers wide area of exploration Permits exploration for cancerous lymph nodes Allows more complete removal of obstructing gland Permits treatment of associated bladder lesions	Requires surgical approach through the bladder Control of hemorrhage is difficult Urine may leak around the suprapubic tube Recovery may be prolonged and uncomfortable	Monitor for indications of hemorrhage and shock. Provide meticulous aseptic care to the area around suprapubic tube.
Perineal approach Removal of gland through an incision in the perineum; preferred approach for patients with obesity (see Fig. 53-4C).	Offers direct anatomic approach Permits gravity drainage Particularly effective for radical cancer therapy Allows hemostasis under direct vision Low mortality rate Low incidence of shock Ideal for patients with large	Higher postoperative incidence of erectile dysfunction and urinary incontinence Possible damage to rectum and external sphincter Restricted operative field Greater potential for contamination	Avoid using rectal tubes or thermometers and enemas after perineal surgery. Use drainage pads to absorb excess urinary drainage. Provide foam rubber ring for patient

	prostate who are very old, frail, and at poor surgical risks	and infection of incision	comfort in sitting. Anticipate urinary leakage around the wound for several days after the catheter is removed.
Retropubic approach Low abdominal incision; bladder is not entered (see Fig. 53-4D).	Avoids incision into the bladder Permits surgeon to see and control bleeding Shorter recovery period Less bladder sphincter damage Suitable for removal of large glands	Cannot treat associated bladder disease Increased incidence of hemorrhage from prostatic venous plexus; osteitis pubis	Monitor for hemorrhage. Anticipate posturinary leakage for several days after removing the catheter.
Transurethral Incision of the Prostate (TUIP) Urethral approach; 1–2 cuts are made in the prostate and prostate capsule to reduce pressure on the urethra and to reduce urethral constriction (see Fig. 53-4E).	Results comparable to TURP Low incidence of erectile dysfunction and retrograde ejaculation No bladder neck contracture	Recurrent obstruction and urethral trauma Delayed bleeding	Monitor for hemorrhage.
Laparoscopic Radical Prostatectomy In this approach, 4–6 small (1 cm [0.5 inch]) incisions are made in the abdomen; laparoscopic instruments inserted through the incisions are used to dissect the prostate.	Minimally invasive technique Improved patient satisfaction and quality of life Shorter length of hospital stay Short convalescence More rapid return to normal activity Short indwelling catheter duration Decreased blood loss to 400 mL Reduced infection risk Less scarring Better visualization of surgical field	Lack of tactile sensation available with open prostatectomy Inability to palpably assess for induration and palpable nodules Inability to delineate the proximity of involvement of the neurovascular bundles due to lack of palpation	Observe for symptoms of urethral stricture (dysuria), straining, and weak urinary stream. Monitor for hemorrhage and shock. Provide meticulous aseptic care to area around suprapubic tube. Monitor for changes in

	than other approaches	Long surgical time (4–5 h)	bowel function. Avoid using rectal tubes or thermometers and enemas after perineal surgery. Use drainage pads to absorb excess urinary drainage. Provide foam rubber ring for patient comfort in sitting. Anticipate urinary leakage around the wound for several days after the catheter is removed.
Robotic-Assisted Laparoscopic Radical Prostatectomy Involves using computer console and da Vinci (see Chapter 14, Fig. 14-1). In this approach, 6 small (1 cm [0.5 inch]) incisions are made in the abdomen; laparoscopic instruments inserted through the incisions are used to dissect the prostate.	Minimally invasive technique Improved patient satisfaction and quality of life Shorter length of hospital stay Short convalescence More rapid return to normal activity Short indwelling catheter duration Decreased blood loss to 150 mL Improved magnification of operative field, using a three-dimensional view (includes, magnification, high resolution,	Lack of tactile sensation available with open prostatectomy Inability to palpably assess for induration and palpable nodules Inability to delineate the proximity of involvement of the neurovascular bundles due to lack of palpation	Observe for symptoms of urethral stricture (dysuria), straining, and weak urinary stream. Monitor for hemorrhage and shock. Provide meticulous aseptic care to the area around suprapubic tube. Monitor for changes in bowel function.

	and depth perception) Less postoperative pain Reduced risk of infection Less scarring Laparoscopic instruments have 6 degrees of movement with joints, allowing extensive range of motion and precision Nerve sparing with less incontinence and sexual dysfunction	Avoid using rectal tubes or thermometers and enemas after perineal surgery. Use drainage pads to absorb excess urinary drainage. Provide foam rubber ring for patient comfort in sitting. Anticipate urinary leakage around the wound for several days after the catheter is removed.

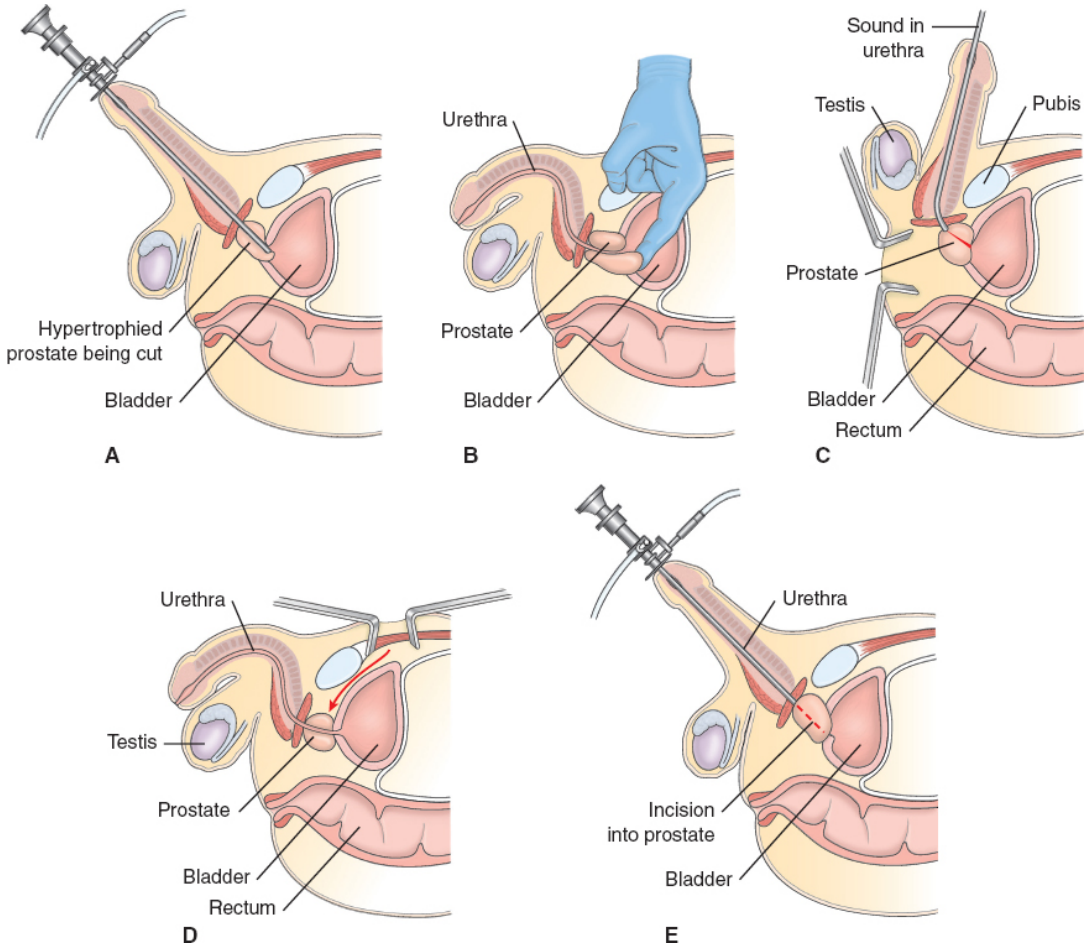

Figure 53-4 • Prostate surgery procedures. **A.** Transurethral resection of the prostate. A loop of wire connected with a cutting current is rotated in the cystoscope to remove shavings of prostate at the bladder orifice. **B.** Suprapubic prostatectomy. With an abdominal approach, the prostate is shelled out of its bed. **C.** Perineal prostatectomy. Two retractors on the left spread the perineal incision to provide a view of the prostate. **D.** Retropubic prostatectomy is performed through a low abdominal incision. Note two abdominal retractors and *arrow* pointing to the prostate gland. **E.** Transurethral incision of the prostate involves one or two incisions into the prostate to reduce pressure on the urethra.

Chart 53-4

Transurethral Resection Syndrome

Transurethral resection syndrome is a rare but potentially serious complication of transurethral resection of the prostate (TURP). Signs and symptoms are caused by neurologic, cardiovascular, and electrolyte imbalances associated with absorption of the solution used to irrigate the surgical site during the surgical procedure. Hyponatremia, hypervolemia, and occasionally hyperammonemia may occur.

Signs and Symptoms

- Collapse
- Headache
- Hypotension
- Lethargy and confusion
- Muscle spasms
- Nausea and vomiting
- Seizures
- Tachycardia

Interventions

- Discontinue irrigation.
- Administer diuretic agents as prescribed.
- Replace bladder irrigation with normal saline.
- Monitor intake and output.
- Monitor the patient's vital signs and level of consciousness.
- Differentiate lethargy and confusion of TURP syndrome from postoperative disorientation and hyponatremia.
- Maintain patient safety during times of confusion.
- Assess lung and heart sounds for indications of pulmonary edema, heart failure, or both as fluid moves back into the intravascular space.

Adapted from Hahn, R. G. (2019). What the intensive care physician should know about the transurethral resection syndrome. In J. L. Vincent (Ed). *Annual update in intensive care and emergency medicine 2019*. New York: Springer.

NURSING PROCESS

Patient Undergoing Prostatectomy

Assessment

The nurse assesses how the underlying disorder (BPH or prostate cancer) has affected the patient's lifestyle. Questions to ask during assessment include the following: Has the patient's activity level or activity tolerance changed? What is his presenting urinary problem (described in the patient's own words)? Has he experienced decreased force of urinary flow, decreased ability to initiate voiding, urgency, frequency, nocturia, dysuria, urinary retention, or hematuria? Does the patient report back pain, flank pain, and lower abdominal or suprapubic discomfort? Possible causes of such discomfort include infection, retention, and renal colic. Has the patient experienced erectile dysfunction or changes in frequency or enjoyment of sexual activity?

The nurse obtains further information about the patient's family history of cancer and heart or kidney disease, including hypertension. Has he lost weight? Does he appear pale? Can he raise himself out of bed and return to bed without assistance? Can he perform usual activities of daily living? A comprehensive functional assessment helps determine how soon the patient will be able to return to normal activities after prostatectomy.

Diagnosis

Preoperative Nursing Diagnoses

Based on the assessment data, major preoperative nursing diagnoses may include the following:

- Anxiety about surgery and its outcome
- Acute pain associated with bladder distention
- Lack of knowledge about factors associated with the disorder and the treatment protocol

Postoperative Nursing Diagnoses

Based on the assessment data, major postoperative nursing diagnoses may include the following:

- Risk for hypovolaemia
- Acute pain associated with the surgical incision, catheter placement, and bladder spasms
- Lack of knowledge about postoperative care

Collaborative Problems/Potential Complications

Potential complications may include the following:

- Hemorrhage and shock
- Infection
- Venous thromboembolism (VTE)
- Catheter obstruction

- Complications with catheter removal
- Urinary incontinence
- Sexual dysfunction

Planning and Goals

The major preoperative goals for the patient may include reduced anxiety and learning about his prostate disorder and the perioperative experience. The major postoperative goals may include maintenance of fluid volume balance, relief of pain and discomfort, ability to perform self-care activities, and absence of complications.

Preoperative Nursing Interventions

Reducing Anxiety

The patient is usually admitted to the hospital or surgical center on the morning of surgery. Because contact with the patient may be limited before surgery, the nurse must establish communication with the patient to assess his understanding of the diagnosis and of the planned surgical procedure. The nature of the surgery and expected postoperative outcomes are clarified. In addition, the nurse familiarizes the patient with the pre- and postoperative routines and initiates measures to reduce anxiety. Because the patient may be sensitive and embarrassed discussing problems related to the genitalia and sexuality, the nurse provides privacy and establishes a trusting and professional relationship. The patient is encouraged to verbalize his feelings and concerns.

Relieving Discomfort

If the patient experiences discomfort before surgery, bed rest may be prescribed, analgesic agents are given, and measures are initiated to relieve anxiety. If he is hospitalized, the nurse monitors his voiding patterns, watches for bladder distention, and assists with catheterization if indicated. An indwelling catheter is inserted if the patient has continuing urinary retention or if close monitoring is needed because of laboratory test results that indicate azotemia. The catheter can help decompress the bladder gradually over several days, especially if the patient is an older adult and hypertensive and has diminished kidney function or urinary retention that has existed for many weeks. For a few days after the bladder begins draining, the blood pressure may fluctuate, and kidney function may decline. If the patient cannot tolerate a urinary catheter, he is prepared for a cystostomy and insertion of a suprapubic catheter.

Providing Education

Before surgery, the nurse reviews with the patient the anatomy of the affected structures and their function in relation to the urinary and reproductive systems, using diagrams and other educational aids as indicated. Web-based prostate cancer education both before and after surgery, along with phone and internet communication, promotes self-care management and support for

patients, their partners, and families (Meyer, 2020; Remacle, 2019). This education can occur during the preadmission testing visit, with the nurse in prescribed settings, or in the urologist's office. The nurse explains what will take place while the patient is prepared for diagnostic tests and then for surgery (depending on the type of prostatectomy planned). The nurse also reinforces information given by the surgeon about the type of incision, which varies with the surgical approach (see Table 53-4), and describes the likely type of urinary drainage system (urethral or suprapubic) and the recovery room procedure. The amount of information given is based on the patient's needs and questions. The nurse explains procedures expected to occur during the immediate perioperative period; answers questions the patient, family, or significant other may have; and provides emotional support. In addition, the patient is given information about postoperative care and pain management.

Preparing the Patient

If the patient is scheduled for a prostatectomy, the preoperative preparation described in Chapter 14 is provided. Antiembolism stockings are applied before surgery and are particularly important to prevent VTE if the patient is placed in a lithotomy position during surgery. An enema is usually given at home on the evening before surgery or on the morning of surgery to prevent postoperative straining, which can induce bleeding.

Postoperative Nursing Interventions

Maintaining Fluid Balance

During the postoperative period, the patient is at risk for deficient fluid volume because of the irrigation of the surgical site during and after surgery. With irrigation of the urinary catheter to prevent its obstruction by blood clots, fluid may be absorbed through the open surgical site and retained, increasing the risk of excessive fluid retention, fluid imbalance, and water intoxication. The urine output and the amount of fluid used for irrigation must be closely monitored to determine whether irrigation fluid is being retained and to ensure an adequate urine output. An intake and output record, including the amount of fluid used for irrigation, must be maintained. The patient is also monitored for electrolyte imbalances (e.g., hyponatremia), increasing blood pressure, confusion, and respiratory distress. These signs and symptoms are documented and reported to the surgeon. The risk of fluid and electrolyte imbalance is greater in older patients with preexisting cardiovascular or respiratory disease.

Relieving Pain

After a prostatectomy, the patient is assisted to sit and dangle his legs over the side of the bed on the day of surgery. The next morning, he is assisted to ambulate. If pain is present, the cause and location are determined, and the severity of pain and discomfort is assessed (Brant, 2019). The pain may be related to the incision or may be the result of excoriation of the skin at the catheter site. It may be in the flank area, indicating a kidney problem, or it

may be caused by bladder spasms. Bladder irritability can initiate bleeding and result in clot formation, leading to urinary retention.

Patients experiencing bladder spasms may report urgency to void, a feeling of pressure or fullness in the bladder, and bleeding from the urethra around the catheter. Medications that relax the smooth muscles can help ease the spasms, which can be intermittent and severe; these medications include flavoxate and oxybutynin. Warm compresses to the pubis or sitz baths may also relieve the spasms.

The nurse monitors the drainage tubing and irrigates the system as prescribed to relieve any obstruction that may cause discomfort. Usually, the catheter is irrigated with 50 mL of irrigating fluid at a time. It is important to make sure that the same amount is recovered in the drainage receptacle. Securing the catheter drainage tubing to the leg or abdomen can help decrease tension on the catheter and prevent bladder irritation. Discomfort may be caused by dressings that are too snug, saturated with drainage, or improperly placed. Analgesic agents are given as prescribed. The nurse notifies the primary provider if the analgesic medications do not relieve the patient's pain and obtains a prescription for new doses or different medications.

After the patient is ambulatory, he is encouraged to walk but not to sit for prolonged periods, because this increases intra-abdominal pressure and the possibility of discomfort and bleeding. Prune juice and stool softeners are provided to ease bowel movements and to prevent excessive straining. An enema, if prescribed, is given with caution to avoid rectal perforation.

Monitoring and Managing Potential Complications

After prostatectomy, the patient is monitored for major complications such as hemorrhage, infection, VTE, catheter problems, and sexual dysfunction.

Hemorrhage. Although patients are advised to discontinue all aspirin, nonsteroidal anti-inflammatory drugs, and platelet inhibitors 10 to 14 days before the surgery to prevent excessive bleeding, bleeding and hemorrhagic shock remain risks. The risk is increased with BPH because a hyperplastic prostate gland is very vascular. Bleeding may occur from the prostatic bed. Bleeding may also result in the formation of clots, which then obstruct urine flow. The drainage normally begins as reddish-pink and then clears to a light pink within 24 hours after surgery. Bright-red bleeding with increased viscosity and numerous clots usually indicates arterial bleeding. Venous blood appears darker and less viscous. Arterial hemorrhage usually requires surgical intervention (e.g., suturing or transurethral coagulation of bleeding vessels), whereas venous bleeding may be controlled by applying prescribed traction to the catheter so that the balloon holding the catheter in place applies pressure to the prostatic fossa. The surgeon applies traction by securely taping the catheter to the patient's thigh if hemorrhage occurs. Less blood loss (150 mL) is expected with robotic-assisted laparoscopic radical prostatectomy, compared to the 500 to 900 mL loss that may occur with open prostatectomy.

Nursing management includes assistance in implementing strategies to stop the bleeding and to prevent or reverse hemorrhagic shock. If blood loss is extensive, fluids and blood component therapy may be given. If hemorrhagic shock occurs, treatments described in Chapter 11 are initiated.

Nursing interventions include closely monitoring vital signs; administering medications, IV fluids, and blood component therapy as prescribed; maintaining an accurate record of intake and output; and carefully monitoring drainage to ensure adequate urine flow and patency of the drainage system. The patient who experiences hemorrhage and his family are often anxious and benefit from explanations and reassurance about the event and the procedures that are performed.

Infection. After perineal prostatectomy, the surgeon usually changes the dressing on the first postoperative day. Further dressing changes may become the responsibility of the nurse in the inpatient setting or the home health nurse upon discharge. Careful aseptic technique is used because the potential for infection is great. Dressings can be held in place by a double-tailed, T-binder bandage or a padded athletic supporter.

Rectal thermometers, rectal tubes, and enemas are avoided because of the risk of injury and bleeding in the prostatic fossa. After the perineal sutures are removed, the perineum is cleansed as indicated. Sitz baths are also used to promote comfort and healing.

UTIs and epididymitis are possible complications after prostatectomy. The patient is assessed for their occurrence; if they occur, the nurse administers antibiotic agents as prescribed. Because the risk of infection continues after discharge from the hospital, the patient and family need to be educated to monitor for signs and symptoms of infection (fever, chills, sweating, myalgia, dysuria, urinary frequency, and urgency). The patient and family are instructed to contact the urologist if these symptoms occur.

Venous Thromboembolism. Patients undergoing prostatectomy are at risk for VTE, including deep vein thrombosis and pulmonary embolism; therefore, the nurse assesses the patient frequently after surgery for manifestations of VTE. Early postoperative ambulation is essential to reduce the risk of VTE. Medical and nursing management of VTE is described in Chapter 26. In addition, if the patient is at high risk for clot formation, additional antithrombotic interventions may be prescribed (Klaassen, Wallis, Lavallée, et al., 2020).

Potential Catheter Problems. After TURP, the catheter must drain well; an obstructed catheter produces distention of the prostatic capsule and resultant hemorrhage. Furosemide may be prescribed to promote urination and initiate postoperative diuresis, thereby helping to keep the catheter patent.

The nurse observes the lower abdomen to ensure that the catheter has not become blocked. A distinct, rounded swelling above the pubis is a manifestation of an overdistended bladder. If the nurse ascertains that the client's bladder is distended, a portable bladder scanner may be used to determine if urine retention is a problem (see Chapter 47).

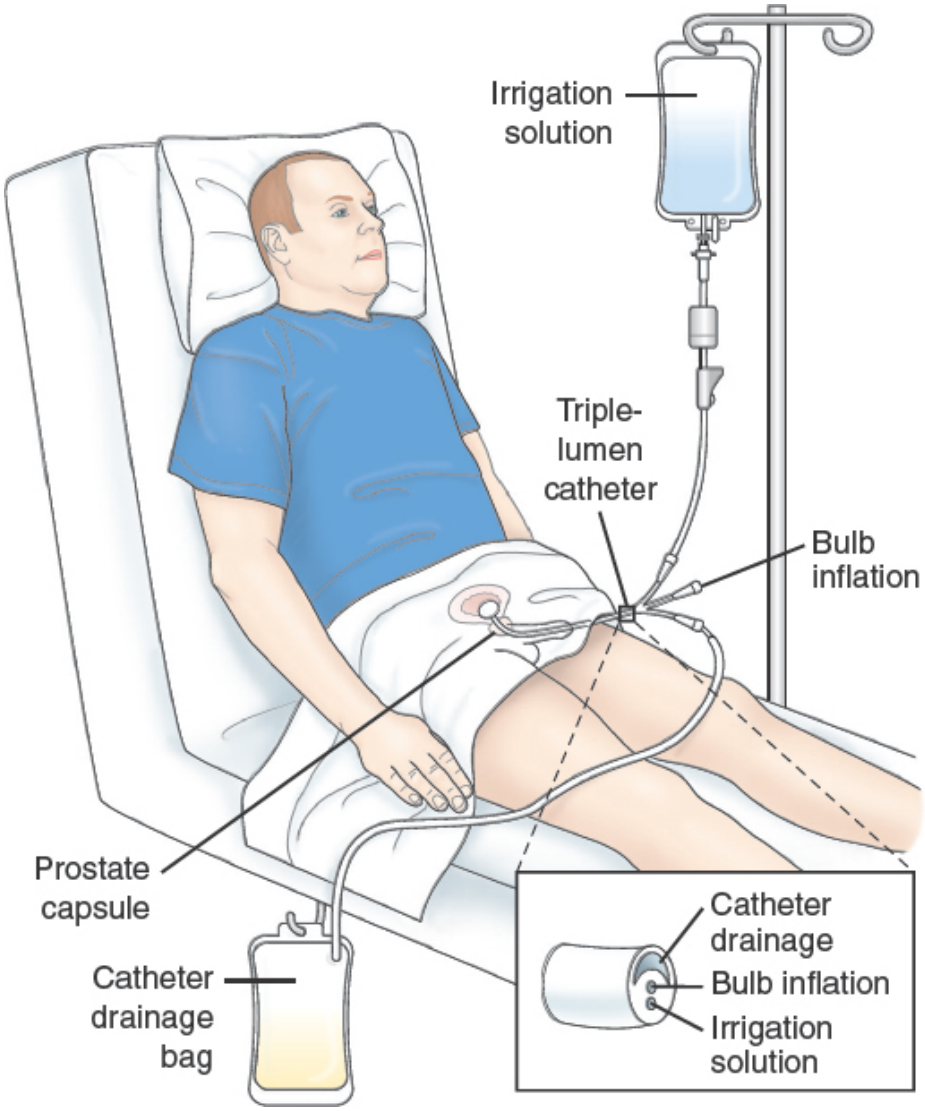

Figure 53-5 • A three-way system for bladder irrigation.

The drainage bag is monitored for bloody urine, and the dressings and surgical incision are examined for bleeding. The color of the urine is carefully noted and documented; a change in color from pink to amber indicates reduced bleeding. Blood pressure, pulse, and respirations are monitored and compared with baseline preoperative vital signs to detect hypotension. The nurse also observes the patient for restlessness, diaphoresis, pallor, any drop in blood pressure, and an increasing pulse rate.

Drainage of the bladder may be accomplished by gravity through a closed sterile drainage system. A three-way drainage system is useful in irrigating the bladder and preventing clot formation (see Fig. 53-5). Continuous irrigation may be used with TURP. Some urologists leave an indwelling catheter attached to a dependent drainage system. Gentle irrigation of the catheter may be prescribed to remove any obstructing clots.

If the patient complains of pain, the tubing is examined. The drainage system is irrigated with irrigating fluid (usually 50 mL), if indicated and

prescribed, to clear any obstruction.

Quality and Safety Nursing Alert

The amount of fluid recovered in the drainage bag must equal the amount of fluid instilled. Overdistention of the bladder should be avoided because it can induce secondary hemorrhage by stretching the coagulated blood vessels in the prostatic capsule.

To prevent traction on the bladder, the drainage tube (not the catheter) is secured to the inner thigh. If a cystostomy catheter is in place, it is secured to the abdomen. The nurse explains the purpose of the catheter to the patient and assures him that the urge to void results from the presence of the catheter and from bladder spasms. Reassurance is given to the patient that medication (anticholinergics) will be given to control his bladder spasms. He is cautioned not to pull on the catheter, because this causes bleeding and subsequent catheter blockage, which leads to urinary retention.

After the catheter is removed (usually when the urine appears clear), urine may leak around the wound for several days in the patient who has undergone perineal, suprapubic, or retropubic surgery. The cystostomy tube may be removed before or after the urethral catheter is removed. Some urinary incontinence may occur after catheter removal, and the patient is informed that this is likely to subside over time.

Urinary Incontinence. Postoperative urinary incontinence is a complication that can be reduced through the use of a surgical technique called puboprostatic ligament-sparing, or through the use of a male sling (Tasso, Beels, Del Favero, et al., 2020). Even without these techniques, current surgical procedures have decreased the incidence of urinary incontinence following surgery. Factors associated with postoperative continence are younger age, preservation of both neurovascular bundles, absence of an anastomotic stricture, eversion of the bladder neck, and a smaller prostate volume. The nurse can encourage the patient who experiences incontinence to take steps to prevent incontinence, improve continence, anticipate leakage, and cope with lack of complete control (Remacle, 2019). Preventing incontinence involves increasing voiding frequency, avoiding positions that encourage the urge to void, and decreasing fluid intake prior to activities. Promoting continence involves pelvic floor exercises (see the Educating Patients About Self-Care section that follows), biofeedback, and electrical stimulation. Anticipating leakage may entail lifestyle modifications such as using absorbent pads and carrying extra clothes to prevent urinary incontinence; this can improve confidence when bathroom access is limited. It also helps to know the location of public bathrooms. Coping long term with complete lack of control may involve collagen injections, artificial sphincter implants, medications, and leg bags (Cheng et al., 2019; Remacle, 2019).

Sexual Dysfunction. Depending on the type of surgery, the patient may experience sexual dysfunction related to erectile dysfunction, decreased libido, and fatigue. These issues may become a concern to the patient soon after surgery or in the weeks to months of rehabilitation. With nerve-sparing radical prostatectomy, the likelihood of recovering the ability to have erections is better for men who are younger and men in whom both neurovascular bundles are spared. A decrease in libido is usually related to the impact of the surgery on the body. Reassurance that the usual level of libido will return after recuperation from surgery is often helpful to the patient and his partner. The patient should be aware that he may experience fatigue during rehabilitation from surgery. This fatigue may also decrease his libido and alter his enjoyment of usual activities.

Several options to restore erectile function are discussed with the patient by the surgeon or urologist. These options may include medications, surgically placed implants, or negative-pressure devices. PDE-5 inhibitors (see Table 53-3) may be effective for treatment of erectile dysfunction in men after radical prostatectomy, especially if the neurovascular bundles have been preserved. They may also improve erectile function in men with partial or moderate erectile dysfunction after radiation therapy for localized prostate cancer.

Nursing interventions include assessing for sexual dysfunction after surgery. Providing a private and confidential environment to discuss issues of sexuality is important. The emotional challenges of prostate surgery and its consequences need to be carefully explored with the patient and his partner. Providing the opportunity to discuss these issues can be very beneficial to the patient. For patients who have significant difficulty adjusting to sexual dysfunction, a referral to a sex therapist may be indicated.

Promoting Home, Community-Based, and Transitional Care

Educating Patients About Self-Care. The length of the hospital stay for the patient undergoing prostatectomy depends on the surgical approach used and ranges from 1 to 2 days for robotic-assisted laparoscopic prostatectomy to 3 to 5 days for open prostatectomy. The patient and family require education about how to manage the drainage system, how to assess for complications, and how to promote recovery. The nurse provides verbal and written education about the need to maintain the drainage system and to monitor urinary output; about wound care; and about strategies to prevent complications, such as infection, bleeding, and thrombosis. In addition, the patient and family need to know about signs and symptoms that should be reported to the primary provider (e.g., blood in urine, decreased urine output, fever, change in wound drainage, calf tenderness).

As the patient recovers and drainage tubes are removed, he may become discouraged and depressed because he cannot regain bladder control immediately. Furthermore, urinary frequency and burning may occur after the catheter is removed. Educating the patient about the following exercises may help him regain urinary control:

- Tense the perineal muscles by pressing the buttocks together, hold this position, and then relax. This exercise can be performed 10 to 20 times each hour while sitting or standing (Brant, 2019).
- Try to interrupt the urinary stream after starting to void; wait a few seconds and then continue to void.

Perineal exercises should continue until the patient gains full urinary control. The patient is educated to urinate as soon as he feels the first urge to do so. It is important to let the patient know that regaining urinary control is a gradual process; he may continue to "dribble" after being discharged from the hospital, but this should gradually diminish (usually within 1 year). The urine may be cloudy for several weeks after surgery but should clear as the prostate area heals.

While the prostatic fossa heals (6 to 8 weeks), the patient should avoid activities that produce Valsalva effects (straining, heavy lifting) because they may increase venous pressure and produce hematuria. He should avoid long motor trips and strenuous exercise, which increase the tendency to bleed. He should also know that spicy foods, alcohol, and coffee may cause bladder discomfort. The patient should be cautioned to drink enough fluids to avoid dehydration, which increases the tendency for a blood clot to form and obstruct the flow of urine. Signs of complications, such as bleeding, passage of blood clots, a decrease in the urinary stream, urinary retention, or symptoms of UTIs, should be reported to the primary provider (see Chart 53-5). Patients who have undergone robotic-assisted prostatectomy are often able to return to their usual activities in approximately 7 to 10 days (Cheng et al., 2019).

Chart 53-5  **HOME CARE CHECKLIST**

Postprostatectomy Care

At the completion of education, the patient and/or caregiver will be able to:

- Name the procedure that was performed and identify any permanent changes in anatomic structure or function as well as changes in ADLs, IADLs, roles, relationships, and spirituality.
- Locate list of names and telephone numbers of resource personnel involved in care (e.g., health care professionals, home health nurse, urinary catheter/dressing supply vendor).
- Identify the equipment necessary and how to obtain medical supplies to carry out dressing changes, wound care, and other prescribed regimens.
- Describe ongoing postoperative therapeutic regimen, including diet and activities to perform (e.g., increased activity and ambulation, perineal exercises) and to limit or avoid (e.g., lifting weights, driving a car, contact sports).
  - Describe measures to relieve postoperative pain and discomfort (e.g., take analgesics as prescribed; use nonpharmacologic interventions).
  - Demonstrate appropriate care of urinary catheter and collection receptacle.
  - Demonstrate appropriate dressing change/wound care.
  - When appropriate, demonstrate performance of perineal muscle exercises to facilitate bladder control.
- State the name, dose, side effects, frequency, and schedule for all medications.
- Identify signs and symptoms of complications that should be reported to surgeon (e.g., decreased output, blood or clots in urine or urine drainage system, change in wound drainage, fever or symptoms of urinary tract infections, calf tenderness).
- Explain treatment plan and importance of follow-up care to all health care providers.
- State time and date of follow-up appointments, therapy, and testing.
- Identify community resources for peer and caregiver/family support:
  - Identify sources of support (e.g., friends, relatives, faith community).
  - Identify the contact details for support services for people with cancer and their caregivers/families.
- Identify the need for health promotion, disease prevention, and screening activities.

ADL, activities of daily living; IADL, instrumental activities of daily living.

Continuing and Transitional Care. Referral for home, community-based, or transitional care may be indicated if the patient is an older adult or has other health problems, if the patient and family cannot provide care in the home, or if the patient lives alone without available supports. The nurse making a home visit assesses the patient's physical status (cardiovascular and respiratory status, fluid and nutritional status, patency of the urinary drainage system, wound and nutritional status) and provides catheter and wound care, if indicated. The nurse reinforces previous education, assesses the ability of the patient and family to manage required care, and encourages the patient to ambulate and to carry out perineal exercises as prescribed. The patient may need to be reminded that return of bladder control may take time.

The patient is reminded about the importance of routine health screening and other health promotion activities. If the prostatectomy was performed to treat prostate cancer, the patient and family are also instructed about the importance of follow-up and monitoring with the primary provider.

Evaluation

Expected preoperative patient outcomes may include:

1. Demonstrates reduced anxiety
2. States that pain and discomfort are decreased
3. Relates understanding of the surgical procedure and postoperative course and practices perineal muscle exercises and other techniques useful in facilitating bladder control

Expected postoperative patient outcomes may include the following:

1. Reports relief of discomfort
2. Exhibits fluid and electrolyte balance
   a. Irrigation fluid and urinary output are within parameters determined by surgeon
   b. Experiences no signs or symptoms of fluid retention
3. Participates in self-care measures
   a. Increases activity and ambulation daily
   b. Produces urine output within normal ranges and consistent with intake
   c. Performs perineal exercises and interrupts urinary stream to promote bladder control
   d. Avoids straining and lifting heavy objects
4. Is free of complications
   a. Maintains vital signs within normal limits
   b. Exhibits wound healing, without signs of inflammation or hemorrhage
   c. Maintains acceptable level of urinary elimination
   d. Maintains optimal drainage of catheter and other drainage tubes
   e. Reports understanding of changes in sexual function

DISORDERS AFFECTING THE TESTES AND ADJACENT STRUCTURES

Orchitis

Orchitis is an acute inflammation of one or both testes as a complication of systemic infection or as an extension of an associated epididymitis caused by bacterial, viral, spirochetal, or parasitic organisms. Microorganisms may reach the testes through the blood, lymphatic system, or, more commonly, by traveling through the urethra, vas deferens, and epididymis; bacteria usually spread from an associated epididymitis in sexually active men. The majority of cases are caused by viral mumps but other causative organisms include *Neisseria gonorrhoeae, Chlamydia trachomatis, E. coli, Klebsiella, Pseudomonas aeruginosa, Staphylococcus* species, and *Streptococcus* species (Norris, 2019).

Signs and symptoms of orchitis include fever; pain, which may range from mild to severe; tenderness in one or both testicles; bilateral or unilateral testicular swelling; penile discharge; blood in the semen; and leukocytosis.

Treatment of orchitis is based on whether the causative organism is bacterial or viral. Bacterial orchitis is treated with antibiotic agents and supportive comfort measures. If the cause of the orchitis is an STI, the partner should be treated as well. Viral orchitis is treated using supportive treatments of rest, elevation of the scrotum, ice packs to reduce scrotal edema, analgesic agents, and anti-inflammatory medications. Bilateral orchitis can cause sterility in some men. Mumps vaccination is recommended for men who have not had mumps or received inadequate immunization in childhood. Orchitis develops in approximately 30% of males who are post puberty with mumps 4 to 6 days after parotitis starts, and one third of men have irreversible loss of spermatogenesis (Norris, 2019).

Epididymitis

Epididymitis is an infection of the epididymis, which usually spreads from an infected urethra, bladder, or prostate. The incidence is less than 1 in 1000 males per year. Prevalence is greatest in men 19 to 35 years of age. Acute epididymitis occurs bilaterally in 5% to 10% of affected patients (Cheng et al., 2019). Risk factors for epididymitis include recent surgery or a procedure involving the urinary tract, participation in high-risk sexual practices, personal history of an STI, past prostate infections or UTIs, lack of circumcision, history of an enlarged prostate, and the presence of a chronic indwelling urinary catheter.

Pathophysiology

A causative organism can be identified in 80% of patients. In prepubertal males, older men, and gay men, the predominate causal organism is *E. coli*; although in

older men, the condition may also be a result of urinary obstruction. In sexually active men 35 years and younger, the pathogens usually are related to bacteria associated with STIs (e.g., *C. trachomatis, N. gonorrhoeae*). The infection moves in an upward direction, through the urethra and the ejaculatory duct, and then along the vas deferens to the epididymis (Teelin, Babu, & Urban, 2019).

Clinical Manifestations

Epididymitis often slowly develops over 1 to 2 days, beginning with a low-grade fever, chills, and heaviness in the affected testicle. The testicle becomes increasingly tender to pressure and traction. The patient may report unilateral pain, soreness in the inguinal canal along the course of the vas deferens, and pain and swelling in the scrotum and the groin. The epididymis becomes increasingly swollen, with extreme pain in the lower abdomen and pelvis. Occasionally, there may be discharge from the urethra, blood in the semen, pyuria and bacteriuria (pus and bacteria in the urine), and pain during sexual activity and ejaculation. The patient may report urinary frequency, urgency, or dysuria, and testicular pain aggravated by bowel movement.

Assessment and Diagnostic Findings

Laboratory assessment includes urinalysis, complete blood cell count, Gram stain of urethral drainage, urethral culture or deoxyribonucleic acid (DNA) probe, and referral for syphilis and HIV testing in sexually active patients. Acute testicular pain should never be ignored, and it should be distinguished from testicular torsion, which is a surgical emergency.

Medical Management

The selection of an antibiotic depends on the causative organism; if epididymitis is associated with an STI, the patient's partner should also receive antimicrobial therapy. The spermatic cord may be infiltrated with a local anesthetic agent to relieve pain if the patient is seen within the first 24 hours after onset of pain. Supportive interventions also include reduction in physical activity, scrotal support and elevation, ice packs, anti-inflammatory agents, analgesics (including nerve blocks), and sitz baths. Urethral instrumentation (e.g., catheter insertion) is avoided. The patient is observed for scrotal abscess formation as well.

In chronic epididymitis, a 4- to 6-week course of antibiotic therapy for bacterial pathogens is prescribed. An epididymectomy (excision of the epididymis from the testis) may be performed for patients who have recurrent, refractory, and incapacitating episodes of this infection. With long-term epididymitis, the passage of sperm may be obstructed. If the obstruction is bilateral, infertility may result.

Nursing Management

Bed rest is prescribed, and the scrotum is elevated with a scrotal bridge or folded towel to prevent traction on the spermatic cord, to promote venous drainage, and to relieve pain. Antimicrobial agents are given as prescribed until the acute inflammation subsides. Intermittent cold compresses to the scrotum may help ease the pain. Later, local heat or sitz baths may help resolve the inflammation. Analgesic medications are given for pain relief as prescribed.

The nurse instructs the patient to avoid straining, lifting, and sexual stimulation until the infection is under control. He should continue taking analgesic agents and antibiotics as prescribed and using ice packs if necessary, to relieve discomfort. He needs to know that it may take 4 weeks or longer for the inflammation to resolve.

Testicular Torsion

Testicular torsion is a surgical emergency requiring immediate diagnosis to avoid loss of the testicle. Torsion of the testis is rotation of the testis, which twists the blood vessels in the spermatic cord and therefore impedes the arterial and venous supply to the testicle and surrounding structures in the scrotum. The patient presents with sudden pain in the testicle, developing over 1 to 2 hours, with or without a predisposing event. Nausea, lightheadedness, and swelling of the scrotum may develop. On physical examination, testicular tenderness, an elevated testis, a thickened spermatic cord, and a swollen, painful scrotum may be present. If the torsion cannot be reduced manually, surgery to untwist the spermatic cord and anchor both testes in their correct position to prevent recurrence should occur within 6 hours of the onset of symptoms in order to save the testis (Norris, 2019). After 6 hours of impaired blood supply, the risk of loss of the testicle increases.

Testicular Cancer

Although only accounting for about 1% of all cancers in men, testicular cancer is the most common cancer diagnosed in men between 15 and 35 years of age; approximately 9610 new cases and 440 deaths occur in the United States annually (ACS, 2020). It is the second most common malignancy in those 35 to 39 years of age. For unknown reasons, worldwide incidence of testicular tumors has more than doubled in the past 40 years. Because of advances in cancer therapy, testicular cancer is a highly treatable and usually curable form of cancer. The 5-year relative survival rate for all testicular cancers is more than 95% and approaches 99% if the cancer has not spread outside of the testes (ACS, 2020). After treatment, most patients with testicular cancer have a near-normal life expectancy.

Classification of Testicular Tumors

The testicles contain several types of cells, each of which may develop into one or more types of cancer. The type of cancer cell determines the appropriate treatment and affects the prognosis. Testicular cancer is classified as germinal or nongerminal (stromal). Secondary testicular cancers may also occur.

Germinal Tumors

Germinal tumors make up approximately 90% of all cancers of the testis; germinal tumors are further classified as seminomas or nonseminomas. These cancers grow from the germ cells that produce sperm, thus the name *germinal tumors*. Seminomas are slow-growing forms of testicular cancer that are usually found in men in their 30s and 40s (ACS, 2020; NCCN, 2020c). Although seminomas can spread to the lymph nodes, the cancer is usually localized in the testes. Nonseminomas are more common and tend to grow more quickly than seminomas. Nonseminomas are often made up of different cell types and are identified according to the cells in which they start to grow. Nonseminoma testicular cancers include choriocarcinomas (rare), embryonal carcinomas, teratomas, and yolk sac tumors. It is crucial to distinguish between seminomas and nonseminomas because the differences affect prognosis and treatment.

Nongerminal Tumors

Nongerminal tumors account for less than 10% of testicular cancers. These cancers may develop in the supportive and hormone-producing tissues, or stroma, of the testicles. The two main types of stromal tumors are Leydig cell tumors and Sertoli cell tumors. Although these tumors infrequently spread beyond the testicle, a small number metastasize and tend to be resistant to chemotherapy and radiation therapy.

Secondary Testicular Tumors

Secondary testicular tumors are those that have metastasized to the testicle from other organs. Lymphoma is the most common cause of secondary testicular cancer. Cancers may also spread to the testicles from the prostate gland, lung, skin (melanoma), kidney, and other organs. The prognosis with these cancers is usually poor because they typically also spread to other organs. Treatment depends on the specific type of cancer (ACS, 2020).

Risk Factors

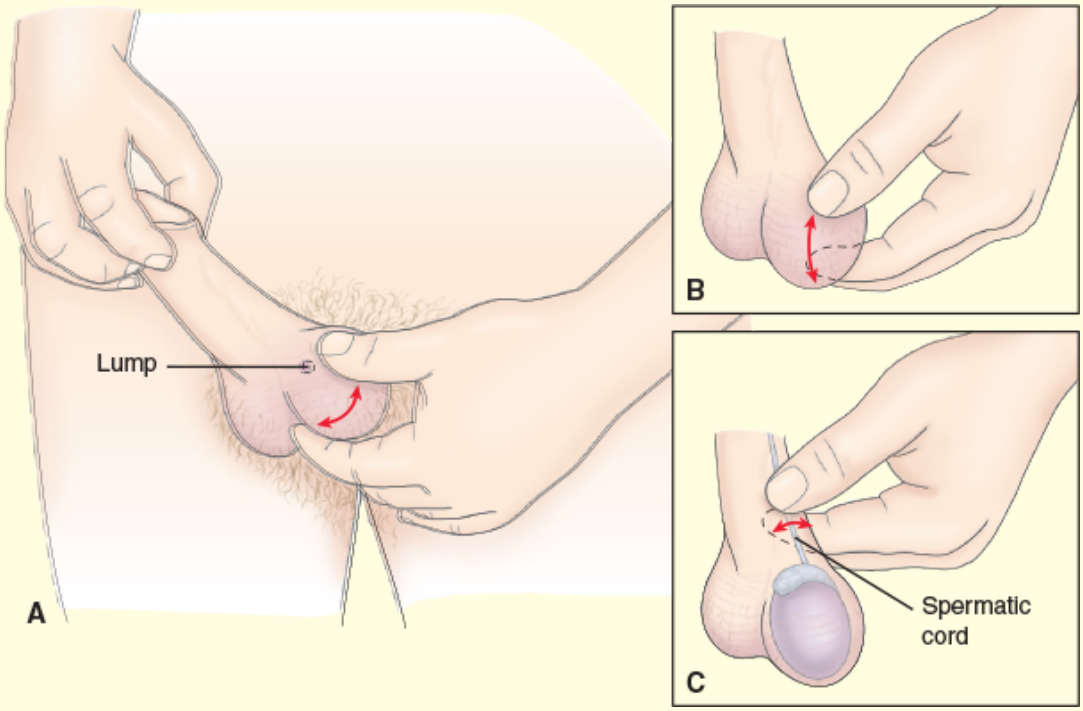
Risk factors for testicular cancer include cryptorchidism (undescended testicles), family history of testicular cancer, and personal history of testicular cancer (ACS, 2020). Other risk factors include race and ethnicity: Caucasian American men have a five times greater risk than African American men and more than two to three times greater risk than Asian, Native American, and Hispanic American men. The risk of developing testicular cancer is higher in HIV-positive men (ACS, 2020). Occupational hazards, including exposure to chemicals encountered

in mining, oil and gas production, and leather processing, have been suggested as possible risk factors. No evidence has linked testicular cancer to prenatal exposure to diethylstilbestrol or to vasectomy (ACS, 2020).

Clinical Manifestations

The symptoms appear gradually, with a mass or lump on the testicle and usually painless enlargement of the testis. The patient may report heaviness in the scrotum, inguinal area, or lower abdomen. Backache (from retroperitoneal node extension), abdominal pain, weight loss, and general weakness may result from metastasis. Enlargement of the testis without pain is a significant diagnostic finding. Some testicular tumors tend to metastasize early, spreading from the testis to the lymph nodes in the retroperitoneum and to the lungs.

Assessment and Diagnostic Findings



Educating young men about testicular cancer and the need for urgent evaluation of any mass or enlargement or unexplained testicular pain is key to early detection (Li, Lu, Wang, et al., 2020). Education about TSE, starting in adolescence, alerts men to the importance of seeking medical attention if a testicle becomes indurated, enlarged, atrophied, nodular, or painful (see Chart 53-6). TSE should be performed monthly. Testicular cancers generally grow rapidly and are easily detected against a typically smooth and homogeneous texture. Annual testicular examination by a clinician can reveal signs and lead to early diagnosis and treatment of testicular cancer. Promoting awareness of this disease is an important health promotion intervention; men should seek medical evaluation for signs or symptoms of testicular cancer without delay (Li et al., 2020; Ustundag, 2019). See the Nursing Research Profile in Chart 53-7. Any suspicious testicular mass warrants prompt evaluation with a thorough history and physical examination, focusing on palpation of the affected testicle.

The tumor markers, alpha-fetoprotein (AFP) and beta-human chorionic gonadotropin (beta-hCG), may be elevated in patients with testicular cancer. Tumor marker levels in the blood are used for diagnosis, staging, and monitoring the response to treatment. Blood chemistry, including lactate dehydrogenase, is also necessary.

Chart 53-6  **PATIENT EDUCATION**

Testicular Self-Examination

Testicular self-examination is to be performed once a month. The test is neither difficult nor time-consuming. A convenient time is usually after a warm bath or shower when the scrotum is more relaxed.

The nurse instructs the patient to:

1. Use both hands to palpate the testis. The normal testicle is smooth and uniform in consistency.
2. Place the index and middle fingers under the testis and the thumb on top; roll the testis gently in a horizontal plane between the thumb and fingers (**A**).
3. Feel for any evidence of a small lump or abnormality.
4. Follow the same procedure and palpate upward along the testis (**B**).
5. Locate and palpate the epididymis (**C**), a cordlike structure on the top and back of the testicle that stores and transports sperm. In addition, locate and palpate the spermatic cord.
6. Repeat the examination for the other testis, epididymis, and spermatic cord. It is normal to find that one testis is larger than the other.
7. If you find any evidence of a small, pea-sized lump or if the testis is swollen (possibly from an infection or tumor), consult your primary provider.

Chart 53-7 NURSING RESEARCH PROFILE

Testicular Self-Examination Knowledge

Ustundag, H. (2019). Assessment of the testicular self-examination knowledge and Health Belief Model of health sciences students. *International Journal of Caring Sciences*, *12*(2), 972–978.

Purpose

Early detection of testicular cancer is possible if men perform monthly testicular self-examinations. However, many men are not aware of the benefits of doing a testicular self-examination. The purpose of this study was to describe young male health sciences students' knowledge of testicular cancer and practice of testicular self-examination, along with their personal health beliefs.

Design

This descriptive survey research study was conducted in a state university in Turkey. There were 372 male students who were given the opportunity to participate, and 262 students (70%) completed the demographic data form and the Turkish version of the Champion Health Belief Model Scale. This scale contains five sub scales: (1) Sensitiveness, an individual's perception of personal risks or sensitivities to a disease or health problem; (2) Caring/Seriousness, an individual's view of the seriousness of the disease outcomes; (3) Benefits, an individual's belief in the benefit of protective behavior to prevent the disease from occurring or decrease the severity of symptoms if it occurs; (4) Perceived barriers to instituting new behaviors and adapting to new situations; and (5) Self-efficacy/Confidence, an individual's belief in the ability to take on the new initiative. Each subscale has its own minimum and maximum scores, and a separate score is determined for each of the five subscales. There is no total calculated score. The statistical analysis was performed using basic descriptive statistics such as frequency, percentage, mean scores, and the nonparametric tests, the Kruskal–Wallis test and Mann–Whitney U test.

Findings

The study participants were 18 to 27 years of age, with approximately 60% of participants in the 18- to 21-year-old age range. Most of the participants (40%, n = 104) were in their second year of education at the university. All the participants indicated that they had knowledge about testicular cancer, with 42% (n = 109) revealing that their knowledge was obtained from the internet or from social media. There were 7% of the sample (n = 18) who acknowledged that they had had a testicular health problem. In their family histories, 93% (n = 244) of the participants stated that there was no history of testicular health problems. There were 225 of the participants (86%) who had no experience doing a self-examination. The most common reason for not performing a testicular self-examination was that 74% (n = 195) did not take the reason for doing the self-examination seriously. The Champion Health Beliefs Model Scale identified that the caring/seriousness subscale had the highest score and that the perceived benefits of performing a testicular self-examination had the lowest score.

Nursing Implications

The study confirmed that young males lack knowledge about testicular cancer and lack experience performing a testicular self-examination. It is important for nurses and other health care providers to address the patient's need for knowledge and practical education on the performance of testicular self-examination. Emphasis must be placed on the fact that testicular self-examination is a significant risk reduction strategy for testicular cancer. The screening for testicular cancer is a topic that not only must be addressed by health care providers, but also included in the curriculum of health science and other educational programs. Frequent discussion and materials about testicular screening must be made available to all males.

A chest x-ray to assess for metastasis in the lungs and a transscrotal testicular ultrasound will be performed. Microscopic analysis of tissue is the only definitive way to determine if cancer is present, but it is usually performed at the time of surgery rather than as a part of the diagnostic workup to reduce the risk of promoting spread of the cancer (ACS, 2020). Inguinal orchiectomy is the standard way to establish the diagnosis of testicular cancer. Other staging tests to determine the extent of the disease in the retroperitoneum, pelvis, and chest include an abdominal/pelvic CT scan and chest CT scan (if the abdominal CT or chest x-ray is abnormal). A brain MRI and bone scan may be obtained if indicated (NCCN, 2020c). Discussion of the option to bank sperm should take place prior to orchiectomy and treatment.

Medical Management

Testicular cancer—one of the most curable solid tumors—is highly responsive to treatment. Early-stage disease is curable more than 95% of the time; thus, prompt diagnosis and treatment are essential. The NCCN practice consensus guidelines for testicular cancer are used to guide diagnostic workup, primary treatment, follow-up, and salvage therapy (treatment given when the cancer does not respond to standard treatment) for both seminomas and nonseminomas (NCCN, 2020c). The goals of management are to eradicate the disease and achieve a cure. Therapy is based on the cell type, the stage of the disease, and risk classification tables (determined as good, intermediate, and poor risk). Primary treatment includes removal of the affected testis by orchiectomy through an inguinal incision with a high ligation of the spermatic cord. The patient is offered the option of implantation of a testicular prosthesis during the orchiectomy. Although most patients experience no impairment of endocrine function after unilateral orchiectomy for testicular cancer, some patients have decreased hormonal levels, suggesting that the unaffected testis is not functioning normally. Retroperitoneal lymph node dissection may be performed after orchiectomy to diagnose and prevent lymphatic spread of the cancer. Alternatives to the more invasive open retroperitoneal lymph node dissection for early-stage germ cell testicular cancer include nerve-sparing and laparoscopic retroperitoneal lymph node dissection, which improve sexual function and promote rapid recovery (Mano, Di Natale, &

Sheinfeld, 2019). Although libido and orgasm are usually unimpaired after a retroperitoneal lymph node dissection, ejaculatory dysfunction with resultant infertility may develop. Two thirds of men who are newly diagnosed with testicular cancer may be considering future fatherhood, and sperm quality is reduced in men with testicular cancer; therefore, sperm banking before treatment may be considered (Mano et al., 2019). Half of patients will not recover fertility as a result of radiation therapy, cytotoxic therapy, unilateral excision of a testis, and retroperitoneal lymph node dissection. Counseling about fertility issues may help the patient make the appropriate choices (Halpern, Brannigan, & Schlegel, 2019).

Radiation therapy is more effective with seminomas than with nonseminomas. Postoperatively, radiation may be used in early-stage seminomas. It is delivered only to the affected side; the other testis is shielded from radiation to preserve fertility. Radiation is also used in patients whose disease does not respond to chemotherapy and in those for whom lymph node surgery is not recommended.

Chemotherapy may be used for seminomas, nonseminomas, and advanced metastatic disease. Cisplatin can be used in combination with other chemotherapeutic agents, such as etoposide, bleomycin, paclitaxel, ifosfamide, and vinblastine, and results in a high percentage of complete remissions. With nonseminomas, aggressive surgical resection of all residual masses following chemotherapy is standard therapy. Good results may also be obtained by combining different types of treatment, including surgery, radiation therapy, and chemotherapy. Even with metastatic testicular cancer, the prognosis is favorable because of advances in treatment. However, for patients who do not respond to high-dose salvage chemotherapy, the cancer is nearly always incurable.

A patient with a history of one testicular tumor has a greater chance of developing subsequent tumors. Late relapse of testicular cancer is currently defined as tumor recurrence more than 2 years after complete remission following primary treatment that included chemotherapy. The most common site of recurrence is the retroperitoneum. Follow-up studies include chest x-rays, excretory urography, radioimmunoassay of beta-hCG and AFP levels, and examination of lymph nodes.

Long-term side effects associated with treatment for testicular cancer include renal insufficiency from kidney damage, hearing problems, gonadal damage, peripheral neuropathy, and, rarely, secondary cancers. Management of a patient with testicular carcinoma is therapy aimed at cure followed by close monitoring to detect and promptly treat any recurrences (NCCN, 2020c). Investigations of new medications, combinations of chemotherapeutic agents, and stem cell transplantation are ongoing.

Nursing Management

Nursing management includes assessment of the patient's physical and psychological status and monitoring of the patient for response to and possible effects of surgery, chemotherapy, and radiation therapy (see Chapter 12). Pre- and

postoperative care is described in Chapters 14 and 16, respectively. In addition, because the patient may have difficulty coping with his condition, issues related to body image and sexuality should be addressed.

Patients may be required to endure a long course of therapy and will need encouragement to maintain a positive attitude. After completing treatment, patients enter a follow-up surveillance period. Nurses educate these cancer survivors about the importance of adhering to follow-up appointments for early detection of cancer recurrence (most often occurring within 2 years posttreatment) and evaluation of late effects of treatment (including secondary cancers). Additional concerns include infertility, cardiotoxicity, neurotoxicity, nephrotoxicity, pulmonary toxicity, and metabolic syndrome; and alterations in quality of life (Brant, 2019). The nurse carefully assesses cultural aspects of care related to testicular cancer and its treatment. The nurse reminds the patient about the importance of performing TSE in the treated or remaining testis. The patient is encouraged to participate in healthy behaviors, including smoking cessation, healthy diet, minimization of alcohol intake, and cancer screening activities. Most experts agree that couples should use birth control for 18 to 24 months after the last cycle of chemotherapy as this is the usual period of time after treatment for sperm to return to normal (Brant, 2019).

Hydrocele

A **hydrocele** is a collection of fluid most commonly located between the visceral and parietal layers of the tunica vaginalis of the testis, although it may also collect within the spermatic cord. This condition is the most common cause of scrotal swelling. At birth, 1 in 10 infants has a hydrocele, which usually resolves without treatment within the first year of life. Acute hydroceles primarily develop in adults older than 40 years; they may occur in association with inflammation (e.g., radiation therapy), infection, epididymitis, local injury, or systemic infectious disease (e.g., mumps). Chronic hydroceles may occur related to the imbalance between fluid secretion and reabsorption in the tunica vaginalis. On physical examination, an easily transilluminated, painless, extratesticular mass is found. Hydrocele can be differentiated from a hernia by transillumination; a hydrocele transmits light, whereas a hernia does not. Ultrasonography is recommended for large hydroceles to differentiate them from testicular tumors (Chapple et al., 2020).

Treatment is usually not required unless the hydrocele is large, bulky, tense, or uncomfortable; compromises testicular circulation; or causes an undesirable appearance. Treatment may involve surgical excision or needle aspiration. Hydrocelectomy (surgical excision) may be performed in an outpatient setting under general or spinal anesthesia with the goal of prevention of recurrence by excising the tunica vaginalis or sclerosing the visceral and parietal layers. Surgical excision involves resection or suturing together the two layers. A drainage tube may be required, and the patient is advised to wear a bulky dressing

over the incisional site for a few days after the procedure. To reduce swelling, ice packs are applied to the scrotal area during the first 24 hours. A scrotal athletic supporter may be worn for a period of time postoperatively for comfort and support. Surgical risks include hematoma in the loose scrotal tissues, infection, or injury to the scrotum.

Needle aspiration is another option used to remove the fluid in the scrotum. Because it is common for fluid to reaccumulate, this treatment may be followed by the injection of a sclerosing agent to prevent this recurrence. This option may be used for men who are at poor surgical risks. Potential risks include infection and scrotal pain.

Varicocele

A **varicocele** is an abnormal dilation of the pampiniform venous plexus and the internal spermatic vein in the scrotum (the network of veins from the testis and the epididymis, which constitute part of the spermatic cord). Varicoceles occur in approximately 15% to 20% of healthy adult men and 40% of men with infertility; the large majority (95%) are in the left testicle because incompetent valves are more common in the left internal spermatic veins (Norris, 2019). Although men may report scrotal pain, tenderness, heaviness in the inguinal area, and infertility, varicoceles are often asymptomatic.

If the varicocele is mild and fertility is not an issue, no treatment is required, and a scrotal support is usually sufficient to relieve symptoms of heaviness. If the condition results in ongoing distressing symptoms or fertility is an issue, the varicocele can be corrected surgically. Postprocedural education and care include an ice pack applied to the scrotum for the first few hours after surgery to relieve edema, dressing removal after 48 hours, nonstrenuous exercise for the first 2 days, scrotal support, pain control, and reporting complications such as infection and hematoma.

Vasectomy

Vasectomy, or male sterilization, involves the surgical interruption of both vas deferens—the tubes that carry the sperm from the testicles and epididymis to the seminal vesicles—to prevent fertilization of an egg after ejaculation. During the outpatient procedure, the surgeon exposes the vas deferens through a small surgical opening or puncture in the scrotum using a sharp, curved hemostat (see Fig. 53-6). The vas is then ligated (cut) or cauterized (burned), with the severed ends occluded by ties or clips to seal the lumens and then placed back into the scrotum. A section of the vas deferens may or may not be removed. The spermatozoa, which are manufactured in the testes, cannot travel up the vas deferens after this surgery (Cheng et al., 2019).

Because seminal fluid is manufactured predominantly in the seminal vesicles and prostate gland, which are unaffected by vasectomy, no noticeable decrease in the amount of ejaculate occurs (volume decreases approximately 3%), even though it contains no spermatozoa. Because the sperm cells have no exit, they are resorbed into the body. A vasectomy usually has no effect on sexual potency, erection, ejaculation, or production of male hormones and provides no protection against STIs.

Couples who were once worried about pregnancy resulting from contraceptive failure often report a decrease in concern and an increase in spontaneous sexual arousal after vasectomy. Concise and factual preoperative explanations may minimize or relieve the patient's concerns related to pain and reduced masculinity. The patient is advised that he will be sterile, but that potency will not be altered after a bilateral vasectomy. On rare occasions, a spontaneous reanastomosis of the vas deferens occurs, making it possible to impregnate a partner.

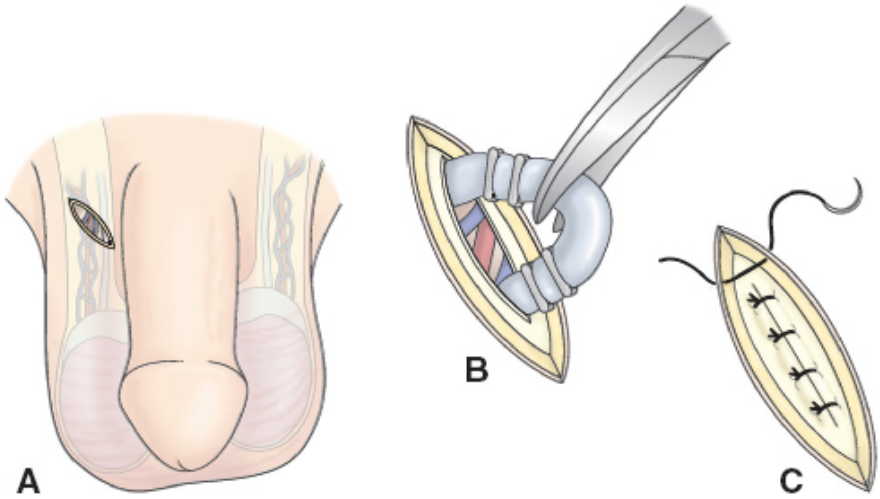

Figure 53-6 • A vasectomy is a resection of the vas deferens to prevent passage of sperm from the testes to the urethra during ejaculation. **A.** An incision or small puncture is made to expose the vas deferens. **B.** The vas deferens is isolated and severed. **C.** The severed ends are occluded with ligatures or clips, or the lumen of each vas is sealed by electrocautery and the incision is sutured closed. (Suturing may not be required if a puncture approach has been used.)

Complications of vasectomy include scrotal ecchymoses and swelling, superficial wound infection, vasitis (inflammation of the vas deferens), epididymitis or epididymo-orchitis, hematomas, chronic pain, and spermatic granuloma. A spermatic granuloma is an inflammatory response to the collection of sperm leaking from the severed end of the proximal vas deferens into the scrotal tissue. A painless small lump is formed, which usually does not require surgical intervention.

Nursing Management

Nursing education focuses on self-management of swelling and discomfort post vasectomy. Applying ice bags intermittently to the scrotum for several hours after surgery can reduce swelling and relieve discomfort. The nurse advises the patient to wear snug cotton underwear or a scrotal support for added comfort and support. Explanation of expected discoloration of the scrotal skin and superficial swelling may alleviate anxiety and concerns. These conditions may be relieved by sitz baths.

Sexual activity may be resumed as desired, usually after 1 week. Fertility remains for a varying time after vasectomy until the spermatozoa stored distally in the seminal vesicles have been evacuated. Sterility is often achieved after 10 to 20 ejaculations following the vasectomy procedure but may take longer. A reliable method of contraception should be used until infertility is confirmed by examination of an ejaculate specimen in the urologist's office at a follow-up appointment, usually 4 to 8 weeks after the vasectomy.

Vasovasostomy (Sterilization Reversal)

Men choosing to undergo vasectomy should not consider the surgical procedure as reversible. However, microsurgical techniques can be used sometimes to reverse a vasectomy and restore patency to the vas deferens in a procedure called vasovasostomy. Many men have sperm in their ejaculate after a reversal, and 50% to 70% can impregnate a partner. The success of the procedure depends on the vasectomy method performed and the amount of time since the vasectomy. The procedure can be very costly, is not covered by insurance, is not permanent with occlusion of the vas recurring 2 or more years after vasovasostomy, and results in sperm counts at lower than prevasectomy levels (Sun & Premal, 2020).

Semen Cryopreservation (Sperm Banking)

Storing fertile semen in a sperm bank before a vasectomy is an option for men who experience a major life change and may want to father a child at a later time. In addition, if a man has just sustained an injury to the spinal cord or is about to undergo a procedure or treatment (e.g., radiation therapy to the pelvis, chemotherapy, orchiectomy) that may affect his fertility, sperm banking may be considered (Halpern, Hill, & Brannigan, 2020). This procedure usually requires several visits to the facility where the sperm is stored under hypothermic conditions. The semen is obtained by masturbation and collected in a sterile container for storage. Insurance carriers rarely cover the cost of semen collection and banking. The costs of semen cryopreservation vary according to facility, method of sperm retrieval, number of specimens, and length of time in storage, making the process cost-prohibitive for some men.

DISORDERS AFFECTING THE PENIS

Phimosis

Phimosis is a condition in which the prepuce (foreskin) cannot be retracted over the glans in uncircumcised males. With the decrease in routine circumcision of newborns, early education should be given to parents about cleansing the foreskin and the need for retraction to cleanse the glans. If the glans is not cleaned, secretions accumulate, causing balanitis (inflammation of the glans penis), which can later lead to adhesions and fibrosis. Phimosis often develops in adults as a result of inflammation, edema, and constriction because of poor hygiene or underlying medical conditions such as diabetes. The thickened secretions, called smegma, can become encrusted with urinary salts and calcify, forming calculi in the prepuce and increasing the risk of penile carcinoma. Treatment for phimosis secondary to inflammation is the application of steroidal cream to the foreskin to soften and correct the narrowness, resulting in decreased constriction. Although phimosis is the most common indication for adult circumcision, it is rarely necessary to surgically correct the condition by loosening or removing the foreskin.

Paraphimosis is a condition in which the foreskin, once retracted over the glans, cannot be returned to its usual position. Chronic inflammation under the foreskin leads to formation of a tight ring of skin when the foreskin is retracted behind the glans, causing venous congestion, edema, and enlargement of the glans, which makes the condition worse. As the condition progresses, arterial occlusion and necrosis of the glans may occur. Paraphimosis usually can be treated by firmly compressing the glans for 5 minutes to reduce the tissue edema and size and then pushing the glans back while simultaneously moving the foreskin forward (manual reduction). The constricting skin ring may require incision under local anesthesia. Circumcision is usually indicated after the inflammation and edema subside (Chapple et al., 2020).

Cancer of the Penis

Penile cancer accounts for less than 1% of cancers among men in the United States. An estimated 1290 new cancer cases and 300 expected deaths occur each year (ACS, 2020). The 5-year survival rates for cancer localized to the penis approaches 80%, but this statistic drops to 52% if the lymph nodes are involved and to 18% if the cancer has spread beyond the inguinal lymph nodes (Chapple et al., 2020). Penile cancer is much more common in some parts of Africa and South America, where it accounts for up to 10% of cancers in men. Because the penis contains different cell types, penile cancer can arise in each type of cell, which determines the prognosis. Types of penile cancer include squamous cell carcinoma (most common; 95% of cases), epidermoid penile cancer, verrucous carcinoma, adenocarcinoma, in situ carcinomas (erythroplasia of Queyrat and Bowen disease), basal cell penile cancer, melanoma, and sarcomas (Cheng et al., 2019). Several risk factors for penile cancer have been identified, including lack

of circumcision, poor genital hygiene, phimosis, HPV, smoking, ultraviolet light treatment of psoriasis on the penis, increasing age (two thirds of cases occur in men older than 65 years), penile metastasis secondary to bladder cancer, lichen sclerosus, and balanitis xerotica obliterans (Chapple et al., 2020). However, the exact cause remains unclear. Because penile cancer is rare, there has been little improvement in diagnostic and staging tests, understanding of risk factors, and development of treatment modalities.

Clinical Manifestations

The penile lesion usually alerts the patient to the presence of penile cancer; however, men may delay seeking treatment for more than a year because of embarrassment, fear, or lack of understanding. Common clinical presentations are a painless lump, ulcer, or wartlike growth on the skin of the penis; a change in skin color such as a red rash, bluish growths, or whitish patches; and malodorous and persistent discharge in late stages.

Assessment and Diagnostic Findings

Penile cancer involves the glans most frequently (48%), followed by lesions of the foreskin (21%), the coronal sulcus (6%), the penile shaft (less than 2%), the urethra, and regional or distant lymph nodes (Chapple et al., 2020). A thorough physical examination is necessary, including assessment and palpation of the penis and the inguinal lymph nodes. The size, location, borders, consistency, fixation, and character and time of onset of the penile lesions should be noted. Incisional or excisional biopsy is performed to determine the cell types of the penile cancer. Further staging tests using ultrasonography, MRI, or CT scan may be obtained to determine the extent of local lesions, if metastatic disease is present, and treatment options.

Prevention

The best way to reduce the risk of penile cancer is to avoid known risk factors whenever possible (ACS, 2020). Avoidance of sexual practices that are likely to result in HPV infection may reduce the risk of penile cancer. Gardasil, a vaccine that protects against infection with HPV, the cause of 90% of genital warts, is recommended for males 9 through 26 years old (ACS, 2020). Although men who are uncircumcised have a greater incidence of penile cancer than men who are circumcised, the more important factor in preventing penile cancer is good genital hygiene. Circumcision is not recommended as a prevention strategy (ACS, 2020).

Medical Management

Treatment varies depending on the type and stage of penile cancer, location of the lesion, overall physical health, and personal preferences about treatments and side

effects. Treatment emphasis is on minimizing the cancer's invasiveness and preserving organ function (Goonewardene, Pietrzak, & Albala, 2019). The goal of treatment in invasive penile cancer is complete excision with adequate margins. Surgery is the most common treatment method used in all forms of the disease. Depending on the stage and invasiveness of the cancer, therapeutic options may include simple excision, electrodesiccation and curettage, cryosurgery, Mohs surgery (microscopically controlled surgery), yttrium aluminum garnet (YAG) laser surgery, wide local excision, circumcision, and penectomy (surgical removal of part of the penis or the entire penis). Organ-sparing surgical approaches are preferable. Partial penectomy is preferred to total penectomy because patients can then participate in sexual activity, stand for urination, and maintain cosmesis. Modern reconstructive surgical techniques are providing more options for patients. The shaft of the penis can still respond to sexual arousal with an erection and has the sensory capacity for orgasm and ejaculation. Total penectomy is indicated if the tumor is not amenable to conservative treatment. After a total penectomy, the patient may still experience orgasm with stimulation of the perineum and scrotal area.

Topical chemotherapy with 5-fluorouracil cream or biologic therapy may also be effective. Radiation therapy is used to treat small squamous cell carcinomas of the penis and for palliation in advanced tumors or cases of lymph node metastasis.

Penile cancer spreads primarily to the inguinal lymph nodes; thus, appropriate lymph node management plays a significant role in survival. Because enlarged inguinal lymph nodes are caused by inflammation in 50% of cases, patients who present with enlarged lymph nodes should undergo treatment of the primary lesion followed by a 4- to 6-week course of oral broad-spectrum antibiotic agents. Persistent enlarged lymph nodes after antibiotic therapy should be considered to be metastatic disease and treated with either a sentinel lymph node biopsy (to determine presence of cancer) or with pelvic and bilateral inguinal lymph node dissection. If extensive pelvic lymph node involvement is present, the patient should receive adjuvant or neoadjuvant chemotherapy and postoperative radiation therapy (Goonewardene et al., 2019).

Priapism

Priapism, a relatively uncommon disorder, is defined as a persistent penile erection that may or may not be related to sexual stimulation. The penis becomes large, hard, and painful. Priapism results from either neural or vascular causes, including sickle cell disease, leukemic cell infiltration, polycythemia, spinal cord tumors or injury, and tumor invasion of the penis or its vessels. It may also occur with use of vasoactive agents that affect the central nervous system, antihypertensive agents, antipsychotic and antidepressant medications, substances injected into the penis to treat erectile dysfunction, alcohol, and cocaine. There

are three forms of priapism: ischemic (venoocclusive; low flow), nonischemic (high flow), and stuttering (intermittent).

The ischemic form, which is described as nonsexual, persistent erection with little or no cavernous blood flow, must be treated promptly to prevent permanent damage to the penis. The goal of therapy is to improve venous drainage of the corpora cavernosa to prevent ischemia, fibrosis, and erectile dysfunction. The initial treatment is directed at relieving the erection, preventing penile damage, and simultaneously treating the underlying disease. Recommended treatment is aspiration of the corpora cavernosa (with or without irrigation) or injection of sympathomimetic agents (e.g., phenylephrine). Repeated injections may be needed to resolve priapism. Surgical shunts are used to reestablish penile circulation if repeated injections of the sympathomimetic are ineffective (Goonewardene et al., 2019).

Nonischemic priapism and stuttering are generally not considered emergencies and often resolve without treatment. Conservative treatment (e.g., application of ice and site-specific compression to the injury) may be used. If repeated episodes occur, surgical shunting is considered. Patients with the intermittent form of priapism may be instructed in intracavernosal self-injection of phenylephrine.

Peyronie Disease

Peyronie disease is an acquired, benign condition that involves the buildup of fibrous plaques in the sheath of the corpus cavernosum. These plaques are not visible when the penis is relaxed. However, when the penis is erect, curvature occurs that can be painful and can make penile-vaginal intercourse difficult or impossible. Peyronie disease typically begins between 45 and 65 years of age. Medical management in the first year of active disease includes systemic, topical, intralesional, or extracorporeal techniques, with 50% of men experiencing spontaneous resolution. Surgical removal of mature plaques is used to treat severe disease. Patients should be fully informed of available treatment options and their likely outcomes (Martins, Kulkarni, & Kohler, 2020).

Urethral Stricture

Urethral stricture is a condition in which a section of the urethra is narrowed. It can occur congenitally or from a scar along the urethra. Traumatic injury to the urethra (e.g., from instrumentation or infections) can result in strictures that restrict urine flow and decrease the urinary stream, leading to spraying or double stream, postvoiding dribbling, and dilation of the proximal urethra and prostatic ducts. Prostatitis is a common complication. Treatment involves dilation of the urethra or, in severe cases, urethrotomy (surgical removal of the stricture). Antimicrobial agents are necessary for resolution of UTIs, followed by long-term prophylactic therapy until the stricture is corrected. Treatment should not be

considered successful until at least 1 year has passed, because strictures may recur anytime during that period (Spilotros, Venn, Anderson, et al., 2019).

Circumcision

Circumcision is the surgical excision of the prepuce (foreskin) of the glans penis. Approximately 80% of men are circumcised in the United States, and circumcision is one of the oldest surgical procedures performed worldwide (CDC, 2019). There is controversy about the guidelines to determine the validity of male circumcision as a prevention of disease transmission (Osinibi, Smith, & Henderson, 2020). In adults, circumcision may be indicated as part of treatment for phimosis, paraphimosis, and recurrent infections of the glans and foreskin. It also may be performed at the patient's request.

The primary method of circumcision in adults is surgical excision. Postoperatively, a petrolatum gauze dressing is applied and changed as indicated. The patient is observed for bleeding. Because considerable pain may occur after circumcision, analgesic agents are given as needed.

CRITICAL THINKING EXERCISES

1 pq Address the priorities and the approach you would use to care for and to educate a 46-year-old male patient and his wife from the Middle East about self-care management priorities after undergoing surgery for prostate cancer. How will your priorities and approach to care and patient education integrate cultural considerations into essential information required for effective self-care management for discharge?

2 ebp A 78-year-old male patient who has a history of myocardial infarction with quadruple bypass surgery, hypertension, and type II diabetes is diagnosed with cancer of the penis. What evidence-based information would you provide to the patient and his spouse to assist in preventing postoperative complications during the recovery period? Identify the evidence for and the criteria used to evaluate the strength of the evidence for the nursing care identified.

3 ipc Your patient is a 28-year-old man diagnosed with testicular cancer. You are providing education for the patient and his spouse about the treatment and management of his pre- and postoperative care. The patient asks you about infertility and requests information on sperm banking. Which members of the interdisciplinary health team would you consult to provide this patient with the requested information on sperm banking?

54 Assessment and Management of Patients Who Are LGBTQ

LEARNING OUTCOMES

On completion of this chapter, the learner will be able to:

1. Describe the importance of providing inclusive healthcare environments for people who are lesbian, gay, bisexual, transgender, and queer.
2. Use inclusive terminology when communicating and conducting an assessment with a person who is lesbian, gay, bisexual, transgender, and queer.
3. Explain and demonstrate the proper techniques to perform a health history and physical assessment and discriminate between normal and abnormal findings identified in the patient who is lesbian, gay, bisexual, transgender, and queer.
4. Describe the various medical procedures and hormone treatments available for the person who is undergoing gender reassignment.
5. Compare and contrast surgical procedures available to people seeking gender reassignment in terms of indications and preoperative and postoperative complications.
6. Use the nursing process as a framework for care of the patient who undergoes gender reassignment surgery.

NURSING CONCEPTS

Assessment
Communication
Development/Human Development
Family
Identity
Professionalism/Professional Behaviors
Sexuality

GLOSSARY

bisexual: people who are romantically, emotionally, or sexually attracted to both male and female genders

cisgender: people who identify with the gender that matches the sex assigned to them at birth

gay: people who are romantically, emotionally, or sexually attracted to the same gender, such as men attracted to men

gender: set of socially constructed norms and behaviors that are taught to women and men

gender dysphoria: distress a person feels due to a mismatch between their gender identity and sex assigned at birth

gender identity: the internal self-conception of one's gender

intersex: a term used for a person who is born with biological traits that do not fit into those that traditionally characterize either male or female

lesbian: a term that gay women, or those women who are romantically, emotionally, or sexually attracted to other women, may prefer to use

LGBTQ: acronym that stands for lesbian, gay, bisexual, transgender, and queer

queer: people who are romantically, emotionally, or sexually attracted to numerous genders (male, female, transgender, intersex, etc.) or people who identify as nonheterosexual but do not want to use labels, such as gay, lesbian, or bisexual

questioning: a person who is unsure or is still exploring their sexual orientation or is concerned about applying a social label to themselves

sex: refers to the physical or biological characteristics that distinguish women and men, such as chromosomes, genitals, and hormones

sexual orientation: umbrella term that refers to romantic, emotional, or sexual attraction to persons of the opposite gender, the same gender, or to both or more than one gender

third-person pronouns: a way of referencing a person other than the self that may or may not use gender-specific labels (e.g., he/him, she/her, they/them)

transgender: umbrella term used to describe the full range of people whose gender identity does not match with the sex assigned to them at birth

transgender man: refers to a person who was assigned a female sex at birth but identifies with a male or masculine gender

transgender woman: refers to a person who was assigned a male sex at birth but identifies with a female or feminine gender

transition: process of aligning a person's gender expression with their self-identified gender identity, which can include social, medical, surgical, and legal changes

People who are **LGBTQ** (lesbian, gay, bisexual, transgender, and queer) have unique health care needs. They also experience particular health risks and disparities based on sexuality and gender identity. Increasingly, nursing and medical professionals are recognizing these risks and disparities; furthermore, these professionals are acknowledging the importance of providing culturally appropriate care to people who identify as LGBTQ. Nurses will encounter people who are LGBTQ and their families in every practice setting. As they would for other diverse populations, nurses should be prepared to provide quality and culturally appropriate care. This chapter focuses on the terminology around sexuality and gender identity, culturally appropriate assessment and communication, and assessment and management of patients who identify as LGBTQ, and, in particular, the unique health care needs of those patients seeking gender reassignment. The management of patients seeking gender reassignment using both nonsurgical and surgical treatments is discussed.

Sexuality and Gender Identity

Understanding the meaning and significance of the concepts and terminology for sexuality and gender identity is important to caring for patients who are LGBTQ.

Sexuality

Human sexuality is the way people experience and express themselves sexually. This involves biological, physical, emotional, or social feelings. Sexual orientation, which is a component of sexuality, is different than gender (see discussion below). **Sexual orientation** is an umbrella term that refers to romantic, emotional, or sexual attraction to persons of the opposite gender, the same gender, or to more than one gender. There are many terms that people use to describe their sexual orientation; however, the most commonly used terms are *heterosexual* or *straight*, *gay* or *lesbian*, *bisexual*, and *queer*.

People who are attracted to a different gender, such as women who are attracted to men, typically identify as heterosexual or straight. People who are attracted to the same gender, such as men attracted to men, often identify as **gay**. Gay women may prefer the term **lesbian**. People who are attracted to both male and female genders usually identify as **bisexual**.

Although the term *queer* was historically used as a word of insult, many people now choose to use it to identify their sexual orientation. People who are **queer** typically experience attractions to numerous genders (male, female, transgender, intersex, etc.). A person who does not want to use labels, such as

gay, lesbian, or bisexual, may also use the term queer to identify as a nonheterosexual.

People who are exploring or are unsure of their sexual orientation may refer to themselves as **questioning**. Questioning one's own sexuality can be difficult and confusing and can take years to understand. This term can also apply to people who are concerned about applying a social label (e.g., gay, lesbian, bisexual, queer) to themselves and may prefer to use this term.

Gender Identity

To fully understand the term *gender identity*, the concepts of *sex* and *gender* must be discussed first. **Sex** in the context of gender identity refers to the physical or biological characteristics that distinguish women and men, such as chromosomes, genitals, and hormones (Eliason & Chinn, 2018). For example, women have XX chromosomes, a uterus and ovaries, and the primary sex hormone is estrogen; whereas, men have XY chromosomes, a penis and testicles, and the primary sex hormone is testosterone. In most societies, people are assigned either the male or female sex at birth. However, some persons do not clearly have these defined binary sets of sex chromosomes or may not have clearly distinguishable genitalia. **Intersex** is a term used for a person who is born with biological traits that do not fit into those that traditionally characterize either male or female.

Gender is a set of socially constructed characteristics of women and men (World Health Organization, 2019). Although a person is either assigned as male or female at birth based on sex characteristics, they are taught norms and behaviors that are appropriate for their gender. Gender is usually the first thing we notice about a person based on cues, such as voice, communication style, hairstyle, clothing, and mannerisms. Gender norms, behaviors, and cues vary from society to society and can be changed.

Gender identity refers to how a person feels about themselves or their self-concept as female or male, feminine or masculine, or as something on the continuum between the two extremes (Eliason & Chinn, 2018). **Cisgender** is a term that often refers to people who identify with the gender that matches the sex assigned to them at birth (e.g., a person with a female sex that identifies as a woman). **Transgender** is an umbrella term used to describe the full range of people whose gender identity does not match with the sex assigned to them at birth. Although there is a diversity of terms that transgender people may use to identify their gender (e.g., trans, gender nonconforming, agender, and genderqueer), this chapter will use two main terms: transgender woman and transgender man. **Transgender woman**, or male to female, refers to a person who was assigned a male sex at birth but identifies with a female or feminine gender. **Transgender man**, or female to male, refers to a person who was assigned a female sex at birth but identifies with a male or masculine gender.

It is important to remember that gender identity and sexual orientation are two different self-concepts. Sexual orientation refers to a person's attraction, and gender identity refers to how a person feels about their gender. For example, a transgender man who is attracted only to men has a male gender identity and a gay sexual orientation. Health care professionals should never assume a person's sexual orientation or gender identity based on physical characteristics, mannerisms, communication style, voice, clothing, or hairstyle.

Statistics on LGBTQ Populations

There are many challenges to estimating the LGBTQ population in the United States. The biggest challenge is the lack of federal-level data. Historically, the U.S. government has not collected sexual orientation and gender identity data on surveys such as the census count. Consequently, researchers have had to use statistical modeling to estimate LGBTQ population sizes.

The Williams Institute (2018), a prominent LGBTQ public policy organization, estimates that approximately 4.5% of the U.S. population is LGBTQ. That percentage translates into nearly 15 million people. Although that number encompasses sexual orientation and gender identity, at least 1 million people in the United States identify as transgender (Meerwijk & Sevelius, 2017). Of the 15 million people who are LGBTQ, 58% identify as female and 42% as male; it is important to note that these survey data did not include nonbinary or gender-fluid gender identity options. The distribution of race and age among the LGBTQ population is shown in Figures 54-1 and 54-2, respectively (The Williams Institute, 2019).

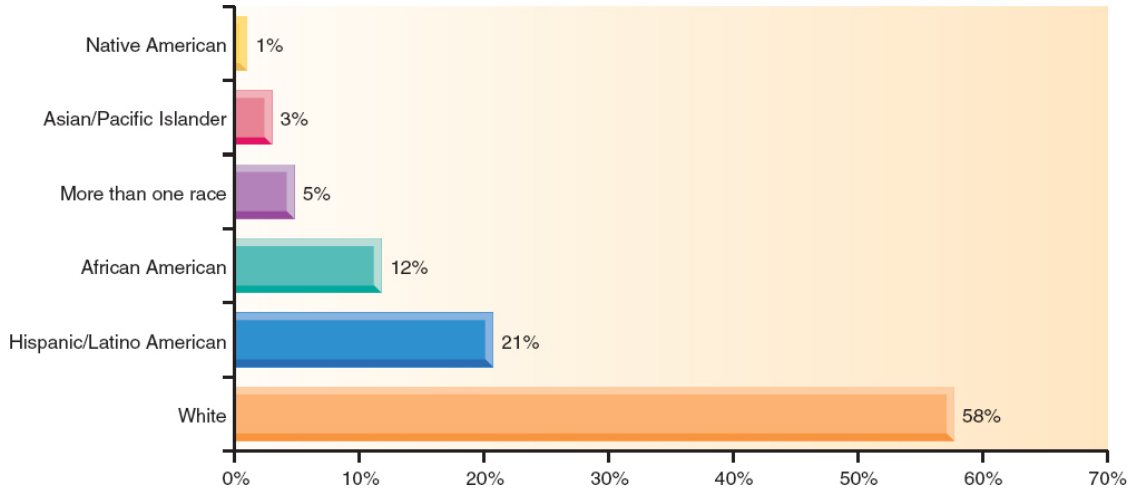

Figure 54-1 • Distribution of race among people in the United States who are LGBTQ. Adapted from The Williams Institute. (2019). LGBT demographic data interactive. Retrieved on 2/17/2020 at: williamsinstitute.law.ucla.edu/visualization/lgbt-stats/?topic=LGBT

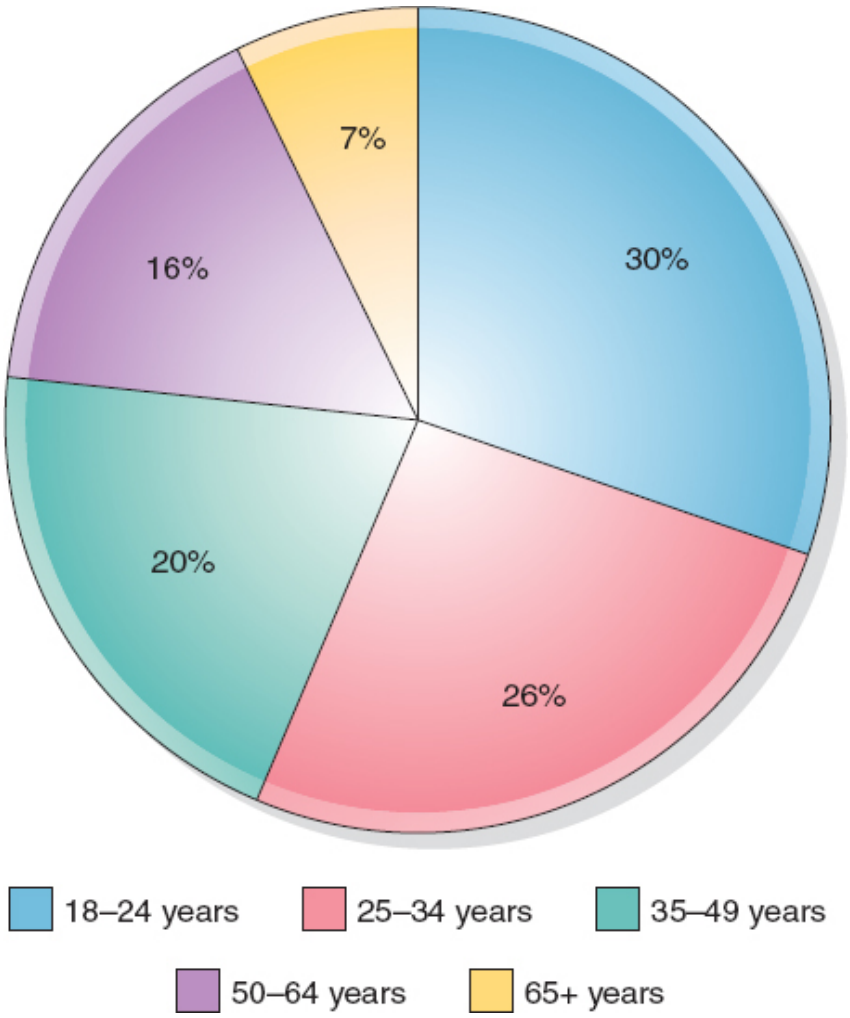

Figure 54-2 • Distribution of age among people in the United States who are LGBTQ. Adapted from The Williams Institute. (2019). LGBT demographic data interactive. Retrieved on 2/17/2020 at: williamsinstitute.law.ucla.edu/visualization/lgbt-stats/?topic=LGBT

Like parents who are heterosexual, parents who are LGBTQ are married, unmarried and cohabiting, separated or divorced, and single. There are intact families and blended families, and children who live between households. There are at least 1.1 million people who are LGBTQ in a legal same-sex marriage, over 1.2 million people who are LGBTQ who are in an unmarried same-sex relationship, and upwards of 3.7 million children under the age of 18 with at least one parent who is LGBTQ (Family Equality Council, 2017). Given the numerous limitations to accurately counting the number of families headed by people who are LGBTQ, these numbers are likely much higher. Also, it is important to note that on June 26, 2015, the U.S. Supreme Court ruled in *Obergefell v. Hodges* (576 U.S.) that the Constitution guarantees same-sex couples the right to marry and have their marriages recognized by the states. In the United States, there are over 1000 statutory provisions

classified in the U.S. Code that provide benefits, rights, and privileges to legally married couples. This ruling was important to protecting couples who are LGBTQ and their children, especially in the health care setting. For example, marriage allows people to make medical, legal, and financial decisions on behalf of an incapacitated spouse even when the spouse does not designate a durable power of attorney. Without legal marriage, people can be barred from visiting their partner in the hospital. Without marriage, people could not easily cover the health care needs of their entire family with health insurance.

Health Risks

The root cause of health risks or disparities among people who are LGBTQ is stigma (i.e., negative and unfair beliefs). For reasons beyond the scope of this chapter, people learn to stigmatize some human differences such as skin color and sexual orientation, whereas other differences are not stigmatized, such as eye color or left-handedness (Eliason & Chinn, 2018). People who are LGBTQ have historically been viewed as different or deviant, which is known as stigmatization. The stigma of people who are LGBTQ has led to many social effects, such as lack of recognition of relationships and family, the right to adopt, hate crimes and violence, discrimination in employment and education, and discrimination in housing (Eliason & Chinn, 2018). A person who is LGBTQ does not experience health risks simply because they identify as gay, lesbian, bisexual, or transgender; the stigma associated with their LGBTQ identity is what puts them at risk for certain health disparities.

As compared to people who are heterosexual and cisgender, people who are LGBTQ are at greater risk for certain physical and mental health issues. In terms of mental health disorders, people who are LGBTQ have a higher rate of depression and anxiety (Bostwick, Hughes, Steffen, et al., 2019; Ross, Salway, Tarasoff, et al., 2018; Witcomb, Bouman, Claes, et al., 2018) and experience more suicidality (Lyons, Walters, Jack, et al., 2019; McNeil, Ellis, & Eccles, 2017). Nearly 50% of people who are transgender have reported suicide attempts. Moreover, people who are LGBTQ tend to experience more victimization, such as physical or verbal harassment, which is associated with higher rates of depression and suicidality (Burks, Cramer, Henderson, et al., 2018).

Women who are lesbian, bisexual, or queer tend to be at greater risk for obesity and cardiovascular disease as compared to heterosexual women (Simoni, Smith, Oost, et al., 2017). Obesity in women who are lesbian, bisexual, or queer is linked to dysregulated eating, such as emotional- or binge-eating. The causes of dysregulated eating are complex and include biological, psychological, and social factors. In women who are lesbian,

bisexual, or queer, stigma is one of the root causes of obesity. Stigmatizing experiences, such as discrimination or victimization, leads to emotional distress, which in turn is associated with dysregulated eating as a coping strategy (Mason, Smith, & Lavender, 2019) (see Chapter 42 for further discussion on obesity).

Men who are gay or bisexual and transgender women have higher rates of infection with the human immune deficiency virus (HIV) as compared to the general population. Men who are gay or bisexual is the population most affected by HIV in the United States (Centers for Disease Control and Prevention [CDC], 2019a). People who are transgender receive an HIV diagnosis at three times the rate of the national average (CDC, 2019b). Among these populations, rates of HIV are even higher among certain subgroups, especially people who are African American and young adult (see Chapter 32 for further discussion on HIV).

Assessment

Nurses should strive to create a welcoming, inclusive, and therapeutic relationship with every patient. To better achieve this type of relationship with people who are LGBTQ, nurses should use inclusive terms and language. This will increase the likelihood of eliciting accurate information from anyone whose experience is different from cultural norms (Eliason & Chinn, 2018). Using inclusive language conveys to the person who is LGBTQ that the interviewer is open to hearing about their sexuality, gender identity, and relationships. If a nurse does not yet know a patient's sexual orientation and gender identity, they should always use neutral language to ensure the patient is comfortable during the assessment (see the Resources section at the end of the chapter for educational materials that promote developing welcoming and inclusive patient–provider relationships).

TABLE 54-1 Sample Questions and Statements Using Gender-Neutral Language

Question/Statement	Question/Statement with Neutral Language
Good morning, sir.	Good morning.
How may I help you, ma'am?	How may I help you?
She is scheduled for an x-ray.	They are scheduled for an x-ray.
Do you have a husband?	Are you in a relationship?
What are the names of your mom and dad?	What are the names of your parents or guardians?

In the United States, people tend to communicate using a binary gender system (female or male) and based on the assumption that people are heterosexual. This type of communication practice can be harmful to people who are LGBTQ, especially in the health care setting. Nurses should strive to use language terms that avoid assumptions about a patient's gender identity and sexual orientation. For example, nurses should avoid using singular **third-person pronouns** (a way of referencing a person other than the self that may use gender-specific labels) and salutations that use gender-specific labels (e.g., sir/miss/madam, Mr./Mrs./Ms.) until confirming the patient's preferences. They should also avoid using terms that assume sexual orientation of the patient and their family (e.g., wife/husband, boyfriend/girlfriend, mother/father). Table 54-1 provides specific examples of neutral questions and statements.

Nurses should routinely assess each patient's sexual orientation and gender identity (SO/GI), including preferred pronouns. In fact, national and federal recommendations for routine collection of SO/GI in health care settings have spanned nearly 20 years (Maragh-Bass, Torain, Adler, et al., 2017). Assessing for SO/GI in the health care setting facilitates the provision of enhanced, holistic, person-centered care. For example, people who are LGBTQ may have unique health risks that need attention or may have a diverse family structure. People who are LGBTQ typically want to disclose their SO/GI to health care professionals. However, most health care professionals do not ask about SO/GI and instead make assumptions about a patient's gender identity and presume every patient is heterosexual. These assumptions put the burden on the patient to disclose ("come out" about their SO/GI), putting them in a vulnerable position (Eliason & Chinn, 2018). Thus, nurses should be skilled at properly assessing for SO/GI and preferred pronouns (Chart 54-1).

Assessing for family structure and other important relationships should be routine for every patient. People who are LGBTQ may have diverse or nontraditional family structures and may include people who are not biologically related. Nurses should assess for family and family of choice. Family of choice is a commonly used term among people who are LGBTQ. Some people who are LGBTQ have been rejected by their family of origin and thus create their own family network of people who support and care for them (Eliason & Chinn, 2018). Moreover, some people who are LGBTQ fear discrimination and exclusion of not only themselves but also their family. This is especially true of people who live in states that sanction narrow definitions of legal relationships (Eliason & Chinn, 2018).

Chart 54-1  **ASSESSMENT**

Personal Information

The nurse introduces these assessment questions by stating:

- "I am going to ask you a few questions about your sexual orientation and gender identity so we can provide personalized and affirmative care to you. These are questions I ask every patient. If you do not feel comfortable answering these questions, we can skip them."

The nurse assesses for gender identity using a two-step question:

- "What sex was listed on your birth certificate?"
- "What is your current gender identity?" or "How do you describe your gender identity?"

Assessing for pronouns:

- "What pronouns do you prefer we use?"
- If the patient is unsure of what this means, you can ask, "Do you use the pronouns he/him, she/her, or something else?"

Assessing sexual orientation:

- "What is your sexual orientation?" or "How do you describe your sexual orientation?"

Assessing for preferred name:

- "What name do you preferred to be called?" or "What is the name that you would like us to use?"

Adapted from Centers for Disease Control and Prevention (CDC). (2020). Collecting sexual orientation and gender identity information. Retrieved on 4/20/2020 at: www.cdc.gov/hiv/clinicians/transforming-health/health-care-providers/collecting-sexual-orientation.html; The Fenway Institute. (2017). Guidelines and tips for collecting patient data on sexual orientation and gender identity. Retrieved on 4/21/2020 at: www.lgbthealtheducation.org/wp-content/uploads/2018/03/Ready-Set-Go-publication-Updated-April-2018.pdf

Nurses should use neutral terms and be sensitive when interviewing all people about their family structure. Since some people who are LGBTQ have nontraditional family structures and families of choice, it is best to start the interview with an open-ended question, such as "Tell me about your family and social support system." As the nurse asks follow-up questions, neutral terms should be used when inquiring about partners/significant others and parents/guardians (examples are listed in Table 54-1). Also, the nurse should not assume a person who is LGBTQ does not have children. Many people who are LGBTQ have children through adoption, surrogacy, and previous relationships. If the patient has children, the nurse should avoid making assumptions about the family structure. Finally, the nurse should mirror the language and terms used by the patient and their family. For example, if a

male-identifying patient refers to his significant other as "husband," the nurse should not choose to use a different term, such as "partner."

In terms of health assessment, people who are LGBTQ typically do not require specific assessments or diagnostic tests. They should receive nursing and medical person-centered care like any other patient. Depending on the health care setting, the nurse may want to focus parts of their assessment on those health risks mentioned earlier in the chapter. Time could be spent asking the person who is LGBTQ about anxiety, depression, suicidality, and discrimination and victimization. Since gay and bisexual men and transgender women have higher rates of HIV, sexual activity, safe sex practices, and HIV status should be assessed. People who identify as transgender should be asked about hormone treatment and surgical procedures only if it is relevant to the care being provided.

Gerontologic Considerations

In understanding older adults who are LGBTQ, it is important to recognize their social, historical, and cultural experiences. The lived experience of older adults who are LGBTQ is vastly different than younger people who are LGBTQ. Older adults who are LGBTQ lived their younger years in stigmatizing and dangerous environments (Ducheny, Hardacker, Claybren, et al., 2019). They frequently experienced discrimination and abuse in multiple areas, including physical, mental, and verbal abuse (Witten & Eyler, 2016). For many decades, it was dangerous for people who were LGBTQ to "come out" (disclose their sexual orientation or gender identity) and extremely difficult to find affirming health care services. Before the 1960s, people who identified as transgender were often committed to psychiatric institutions or forced to live in seclusion. From 1960 through 1990, people who identified as transgender could access rigid and isolating treatment and were made to adhere to narrow requirements (Ducheny et al., 2019). Until 1973, homosexuality was a diagnosed psychiatric mental illness. Moreover, older people who are LGBTQ faced significant discrimination that was sanctioned by state and federal governments. This history has profoundly affected the way in which older adults who are LGBTQ view and access all facets of health care, including clinics, hospitals, and assisted living/nursing homes (Witten & Eyler, 2016). To care for and promote the health of older adults who are LGBTQ, nurses should be mindful and understanding of this background. Moreover, this amplifies the importance of nurses needing to always provide a safe and welcoming space for all patients that promotes human dignity. Older adults who have hidden their sexual orientation or gender identity for many years due to fears of discrimination will be more likely to disclose this information if the nurse uses language and questions that signals to the patient that they are accepting and safe.

Assessment and Management of Patients Seeking Gender Reassignment

People who are transgender may experience **gender dysphoria**, which is the distress caused by the dissonance between the person's gender identity and that person's sex assigned at birth. To assist people with this distress and find a gender role that is comfortable for them, treatment is available and may include medical and surgical interventions. Treatment is individualized, meaning that interventions that effectively alleviate gender dysphoria in one patient may not work for a different patient.

Health care teams who provide psychological, medical, and surgical treatments to people who are transgender often follow the Standards of Care published by the World Professional Association for Transgender Health (WPATH, 2012). Even though the latest version of the Standards of Care was released in 2012, at the time of this book print, it is still the leading resource for the care of people who are transgender. Other important resources include the Guidelines for the Primary and Gender-Affirming Care of Transgender and Gender Nonbinary People from the University of California, San Francisco (Deutsch, 2016) and the Principles of Transgender Medicine and Surgery (Ettner, Monstrey, & Coleman, 2016) (see References and Resources sections at the end of the chapter).

Providing treatment to people who are seeking gender reassignment almost always starts with confirming a diagnosis of gender dysphoria. Many health insurance companies require a gender dysphoria or related diagnosis before covering the costs of gender reassignment treatments. Gender dysphoria is a diagnosis in the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-5). Chart 54-2 lists the criteria used to diagnose a person with gender dysphoria. In short, to be diagnosed with gender dysphoria, a person must exhibit specific thoughts and feelings about the incongruence of their gender identity and their secondary sex characteristics for a period of at least 6 months (American Psychiatric Association, 2013). An experienced mental health care professional, such as a psychiatric mental health nurse practitioner, clinical social worker, psychologist, or psychiatrist, can assess, diagnose, and provide psychological treatment for gender dysphoria. Before a health care provider prescribes medical or surgical treatments (e.g., hormones, gender reassignment surgery), they usually require that the person has consulted with a mental health care provider and received a diagnosis of gender dysphoria.

Chart 54-2

DSM-5[a] Diagnostic Criteria for Gender Dysphoria in Adolescents and Adults

A. A marked incongruence between one's experienced/expressed gender and assigned gender, of at least 6 months duration, as manifested by at least two of the following:

1. Marked incongruence between one's experienced/expressed gender and primary and/or secondary sex characteristics (or in young adolescents, the anticipated secondary sex characteristics).
2. A strong desire to be rid of one's primary and/or secondary sex characteristics because of a marked incongruence with one's experienced/expressed gender (or in young adolescents, a desire to prevent the development of the anticipated secondary sex characteristics).
3. A strong desire for the primary and/or secondary sex characteristics of the other gender.
4. A strong desire to be of the other gender (or some alternative gender different from one's assigned gender).
5. A strong desire to be treated as the other gender (or some alternative gender different from one's assigned gender).
6. A strong conviction that one has the typical feelings and reactions of the other gender (or some alternative gender different from one's assigned gender).

B. The condition is associated with clinically significant distress or impairment in social, occupational, or other important areas of functioning.

[a]DSM-5, *Diagnostic and Statistical Manual of Mental Disorders* (5th edition).

Reprinted with permission from American Psychiatric Association. (2013). *Diagnostic and statistical manual of mental disorders* (5th ed.). Arlington, VA: Author.

When a person wants to address the distress or other negative emotions associated with having a gender that does not align with their sex assigned at birth (gender dysphoria), they will usually work with an interdisciplinary health care team. This team typically includes a mental health care professional, a health care provider experienced in endocrinology, and a surgeon. The mental health care professional will provide psychological support to the person during their gender identity journey; the endocrinology health care provider will prescribe hormones and monitor outcomes; the surgeon will handle gender reassignment surgeries. Depending on the treatment settings, nurses are involved in various capacities along the treatment continuum.

Medical Management

Hormone Therapy

In addition to alleviating gender dysphoria, the goal of hormone gender-affirming therapy is the acquisition of the secondary sex characteristics of the other gender, to the fullest extent possible (Gooren, 2016). To achieve the secondary sex characteristics of the opposite gender, sex steroids/hormones are needed. There is no known difference in sensitivity to the action of sex hormones on the basis of genetics or gonadal/sex status (Gooren, 2016), meaning that a person can develop secondary sex characteristics of the opposite gender by taking sex hormones. However, certain effects of sex hormones cannot be reversed. For example, in people who are transgender women (male to female), the previous effects of androgens on the skeleton (average greater height; size and shape of hands, feet, and jaw; and pelvic structure) cannot be reversed by hormones (Gooren, 2016) (Table 54-2).

For patients who are transgender women, estrogen is prescribed to produce the desired physical changes. The prescribed dose of estrogen is individualized and depends on many different factors, such as the patient's goals, risk/benefit ratio, presence of other medical conditions, presence or absence of gonads, and social and economic issues (WPATH, 2012). Estrogen treatment should produce changes in body hair, breast development, skin, body fat composition, muscle mass, testes, and prostate. In addition to estrogen, androgen-reducing medications to reduce testosterone levels are also often prescribed, which diminish masculine characteristics and minimize the dosage of estrogen needed to suppress testosterone. Common androgen-reducing medications include spironolactone, cyproterone acetate, GnRH agonists (e.g., goserelin, buserelin, triptorelin), and 5-alpha reductase inhibitors (e.g., finasteride, dutasteride) (WPATH, 2012). Progestogen does not add to the feminization process and is typically not recommended due to the higher incidence of breast cancer and cardiovascular disease (Gooren, 2016). See Table 54-3 for commonly prescribed medications.

In people who are transgender men (female to male), testosterone is prescribed to produce the desired physical changes. Like estrogen, the prescribed dose of testosterone is individualized and depends on many different factors. Testosterone treatment should produce changes in scalp hair, skin oiliness, facial and body hair, voice, body fat composition, muscle mass, menses, clitoris, and vagina (see Tables 54-2 and 54-3).

TABLE 54-2 Physical Effects of Hormone Treatment for Gender Reassignment

Feminizing Hormones (Male to Female)	Masculinizing Hormones (Female to Male)
Reduction in growth and thinning of body hair	Growth of facial and body hair; scalp hair loss
Breast formation	Decrease in glandular activity of breasts
Softening of skin and decreased oiliness	Skin oiliness and acne
Increase in body fat and decrease in muscle mass	Decrease in subcutaneous fat, increase in abdominal fat, and increase in muscle mass
Testicular and prostate volume atrophy	Clitoral enlargement and vaginal atrophy
Decreased sperm production	Cessation of menses
Male sexual dysfunction	Deepening of voice

Adapted from World Professional Association for Transgender Health (WPATH). (2012). Standards of care for the health of transsexual, transgender, and gender-nonconforming people (version 7). Retrieved on 2/17/2020 at: www.wpath.org/publications/soc

As with any medical treatment, hormones carry risks to the person. The likelihood of a serious adverse event is dependent on numerous factors, such as dose, route of administration (e.g., oral vs. transdermal vs. intramuscular), and the patient's characteristics (e.g., age, comorbidities, health behaviors). People who take estrogen are at increased risk of venous thromboembolism (VTE), gallstones, elevated liver enzymes, weight gain, and hypertriglyceridemia. People who take testosterone are at increased risk for polycythemia, weight gain, acne, androgenic alopecia (male-patterned balding), and sleep apnea. In addition, both estrogen and testosterone can increase the risk of the person developing type 2 diabetes when they have additional risk factors, such as older age (WPATH, 2012).

TABLE 54-3 Medications Prescribed to Facilitate Gender Transition

Feminizing Hormone Medications for Male to Female		
Medication	Adverse Effects[a]	Nursing Considerations
Androgen-Reducing Medications (Antiandrogen)		
Spironolactone (off-label use) Mechanism of action: diuretic that also directly inhibits testosterone secretion and androgen binding to the androgen receptor	Electrolyte imbalances, especially hyperkalemia Decreased blood pressure	This medication is a diuretic and patients must be advised of frequent urination and need to increase water intake. Caution in patients with adrenal insufficiency, diabetes, hyperkalemia, and chronic kidney disease.
Cyproterone acetate Mechanism of action: antiandrogenic and progestogenic/antigonadotropic properties, resulting in blocked binding of the active metabolite of testosterone and decreased production of testicular testosterone	Thromboembolism Hyperlipidemia Hepatotoxicity Glucose intolerance Mood changes	Assess for signs and symptoms of thromboembolism. Monitor mood changes (anxiety, depression, insomnia), especially during the first 4–6 wks. Monitor liver function tests prior to and during therapy for symptoms of hepatotoxicity.
Dutasteride Finasteride Mechanism of action: inhibits the enzyme 5-alpha reductase, which is responsible for converting testosterone to its potent metabolite	Prostatic hyperplasia	Assess for urinary hesitancy, feeling of incomplete bladder emptying, interruption of urinary stream, and dysuria.
Estrogen		
Ethinyl estradiol Mechanism of action: semisynthetic estrogen that binds to estrogen receptors, increasing estrogen levels and decreasing testosterone levels	Thromboembolism Edema Hypertension Pancreatitis	Assess for signs and symptoms of thromboembolism. Assess blood pressure before

		and during therapy. Monitor hepatic function during therapy.
Masculinizing Hormone Medication for Female to Male		
Medication	**Adverse Effects**	**Nursing Considerations**
Androgen		
Testosterone undecanoate Mechanism of action: synthetic testosterone that binds to androgen receptors throughout body	Glucose intolerance Hypertension	Assess blood pressure before and during therapy. Monitor for hypoglycemia, especially in people taking diabetes medications.

[a]Erectile dysfunction and gynecomastia are side effects of these medications. However, people who are male-to-female transgender are expecting these side effects.

Hair Removal

Hormone treatment does not typically fully eliminate unwanted hair, and thus people who are transgender may seek additional gender-affirming medical procedures. Transgender women typically seek hair removal on the face, neck, and in the genital area as preoperative preparation for vaginoplasty. Transgender men typically seek hair removal on the forearm and thigh when needing graft sites for phalloplasty. Like hormone treatment, hair removal is associated with both decreased dysphoria and increased well-being among people who are transgender (Bradford, 2019). Although numerous treatments exist to help manage unwanted hair, there are two primary medical procedures used for long-term treatment: laser hair removal and electrolysis (Reeves, Deutsch, & Stark, 2016).

Laser hair removal is the leading therapy option for long-term results and works on the principle of selective photothermolysis, whereby photons destroy the hair follicle while sparing the surrounding tissue (Thomas & Houreld, 2019). The main risks of this procedure are overheating resulting in redness, blisters, and burns. Treatments should be avoided when photosensitizing medications are being used, such as acne medications (e.g., isotretinoin, minocycline, doxycycline), antibiotics (e.g., tetracyclines, sulfonamides, quinolones), and spironolactone. Nurses should review a patient's medication list and identify those that are photosensitive. Electrolysis involves the use of

an electric current that destroys the root of individual hair follicles. This treatment is more time consuming and more painful than laser hair removal. The main risks of electrolysis are redness and pigment changes. To help manage the pain during laser hair removal and electrolysis, topical anesthetics (lidocaine-containing products) and acetaminophen are used (Reeves et al., 2016).

Acne Treatment

In transgender men, testosterone is the mainstay of masculinizing hormonal therapy. Although the exact mechanism in the pathogenesis of acne is not yet fully understood, testosterone increases the production of sebum (oily secretion) in sebaceous glands, leading to acne. Facial acne in transgender men who use testosterone peaks within the first 4 months of treatment; over 80% of testosterone-treated transgender men experience facial acne in the first year (Motosko, Zakhem, Pomeranz, et al., 2018). General guidelines for acne treatment can be followed for transgender men (Thiboutot, Dréno, Abanmi, et al., 2018); however, there are some specific considerations and risks. First, combining testosterone with some acne medications, especially minocycline, may lead to hepatotoxicity; thus, frequent monitoring of liver function tests is warranted. Second, some acne medications are teratogenic, such as minocycline, doxycycline, and isotretinoin. For transgender men who are still at risk of pregnancy (intact uterus and ovaries), careful sexual history and counseling should be performed before the initiation of any acne treatment. Third, some acne medications, especially isotretinoin, may delay wound healing and lead to keloid formation after surgery; thus, a discussion about surgical plans is needed before starting acne treatment (Motosko et al., 2018).

Fertility and Reproductive Health

Many people who are transgender will want to have biological children, but because hormone treatment limits fertility, patients should be educated about their options before starting hormone treatment or undergoing surgery to remove or alter their reproductive organs. Although the long-term effects of gender-affirming hormone therapy using testosterone or estrogen on fertility are not known, limited research suggests that testosterone and estrogen can affect the reproductive abilities of ovaries and testes, respectively (Cheng, Pastuszak, Myers, et al., 2019). There are cases of transgender women and men stopping hormone treatment and still having fertile oocytes or sperm; however, there are many cases to the contrary and thus patients who are transgender should be fully informed of the possible implications that hormones have on fertility and preservation options.

In the postpuberty age group, transgender men should be educated about oocyte cryopreservation, embryo cryopreservation, and uterus preservation.

Transgender women should be educated about sperm cryopreservation. In the prepuberty age group, trials are ongoing to determine the effectiveness of ovarian tissue cryopreservation and testicular tissue cryopreservation in transgender men and transgender women, respectively (Cheng et al., 2019).

Gerontologic Considerations

The synthesis and secretion of many endogenous hormones change and the expression of cell receptors in tissues changes in numbers and signaling capacity as the human body ages (Houlberg, 2019). Although there is very little research on the effect of exogenous cross-sex hormones in older adults who are transgender, there are important considerations given the endocrine changes in aging bodies. The major consideration for nurses is the effects of sex steroids on the metabolism of medication. With aging, the metabolism and excretion of many drugs decrease (Ruscin & Linnebar, 2018). Sex hormones also influence the absorption, metabolism, pharmacodynamics, and adverse effects of medications (Gooren & T'Sjoen, 2018). Nurses may need to take additional precautions to monitor for adverse effects and toxicity of certain medications when working with people who are transgender and taking exogenous sex hormones. The other two considerations are cardiovascular disease and bone health. In transgender women, estrogen increases the risk of cardiovascular morbidity and mortality. Additional preventive screening is warranted in these patients and lowering the dose of estrogen in transgender women over the age of 55 should be considered. Lastly, cross-sex hormone treatment can decrease bone health in both transgender women and men (Gooren & T'Sjoen, 2018). Findings from a pilot study suggest that despite having an increased risk for osteoporosis, transgender individuals' knowledge of their risks for osteoporosis can be poor (Sedlak, Roller, van Dulmen, et al., 2017) (see the Nursing Research Profile in Chart 54-3). To help reduce the risk of reduced bone mineral density, nurses should educate about osteoporosis risks and promote physical exercise and intake of vitamin D and calcium to people who are transgender and taking sex hormones (see Chapter 36 for further discussion of osteoporosis). Given these considerations, the risks of hormone treatment can be managed and rarely pose an absolute contraindication (Houlberg, 2019).

Chart 54-3 NURSING RESEARCH PROFILE

Osteoporosis Prevention Among Transgender Persons

Sedlak, C. A., Roller, C. G., van Dulmen, M., et al. (2017). Transgender individuals and osteoporosis prevention. *Orthopaedic Nursing*, *36*(4), 259–268.

Purpose

Many people who are transgender take sex hormones in order to achieve desirable characteristics of the gender that they feel is consonant with their personal identity. An adverse effect of these medications is that bone mineral density can become prematurely depleted, leading to early osteoporosis. The purpose of this mixed methods pilot study was to identify osteoporosis knowledge, beliefs, and prevention behaviors among transgender adults.

Design

Participants were recruited by advertising flyers at LGBTQ community centers and by advertising via LGBTQ support groups on the Internet. In order to be included in the study, participants had to be at least 30 years of age, the age when bone mineral density is considered maximal. Eligible participants could identify with male or female gender, and had to be able to read and speak English. Thirty-one participants were recruited and consented to complete a survey, which included a series of scales such as the *Osteoporosis Knowledge Test,* the *Osteoporosis Health Belief Scale,* the *Osteoporosis Self-Efficacy Scale,* the *Dietary Calcium Rapid Assessment Tool,* and the *Yale Physical Activity Survey.* Fifteen of these participants were randomly selected to participate in online qualitative interviews that focused on their views of bone health and osteoporosis.

Findings

The majority of participants (90.3%) took sex hormones. Most participants had poor knowledge of their osteoporosis risks, with 81% receiving failing scores on the *Osteoporosis Knowledge Test.* Participants selected to partake in the interviews confirmed that their knowledge of osteoporosis and their knowledge of their osteoporosis risks were poor. Several expressed frustration that health care providers had not disclosed these risks to them previously. The mean daily dietary calcium intake for the sample was less than recommended standards as was the minutes of average daily exercise. Most participants were not taking vitamin D supplements. Of those participants who were taking vitamin D supplements, more than half were taking less than recommended dosages.

Nursing Implications

Sex hormones are commonly taken by persons who are transgender; yet, findings from this study suggest that few people who are transgender and take sex hormones have knowledge of their associated higher risk for osteoporosis. Nurses should educate people who are transgender regarding the risk for osteoporosis that is associated with sex hormones. In addition,

nurses should encourage persons who are transgender and taking sex hormones to engage in strategies that can mitigate the effects of sex hormones on their bone mineral density, including increasing their dietary calcium and physical activities, and taking appropriate dosages of vitamin D supplements.

Surgical Management

People who are transgender have many different gender reassignment surgeries available to them as they **transition** from their sex assigned at birth to their gender identity (Table 54-4). Just like hormone treatment, gender reassignment surgeries help reduce gender dysphoria and improve quality of life. The WPATH (2012) recommends that people who are seeking gender reassignment surgeries meet certain criteria. They recommend that the person seeking surgery have (a) persistent, well-documented gender dysphoria; (b) capacity to make a fully informed decision and to give consent for treatment; (c) age of majority in a given country; and (d) any significant medical or mental health concerns be well controlled. For certain surgeries, including hysterectomy, phalloplasty, and vaginoplasty, WPATH (2012) also recommends that the person has had 12 continuous months of hormone therapy and has had 12 continuous months of living in a gender role that is congruent with their gender identity. This is based on clinical consensus, not empirical evidence, that living 12 months in a gender role that is congruent with their gender identity gives them ample opportunity to experience and socially adjust before undergoing irreversible surgery (Colebunders, Verhaeghe, Bonte, et al., 2016).

Male-to-Female Gender Reassignment Surgeries

There are numerous different gender reassignment surgeries for transgender women (see Table 54-4). Over the years, researchers have identified common differences between male and female faces. Typically, the female face is oval and heart-shaped with smooth lines, pointed chin, less pronounced mandibular angles, less nasal prominence, and less angular nasal tip (Colebunders, Verhaeghe, et al., 2016). For people who desire a more feminine face, surgeries are available to modify most structures in the face. Chondrolaryngoplasty, reducing the prominent thyroid cartilage, commonly referred to as the Adam's apple, and feminizing the voice are commonly desired changes in people who are male-to-female transgender; both surgeries can be performed during the same procedure. Feminizing the voice involves shortening the vocal cord length or increasing the vocal cord tension (Colebunders, Verhaeghe, et al., 2016).

TABLE 54-4 Select Gender Reassignment Surgeries

Male to Female	Female to Male
Facial feminization • Angle of mandible • Cheeks • Chin • Forehead • Nose • Upper lip	Facial masculinization • Angle of mandible • Cheekbones • Chin • Forehead
Hair transplantation	Subcutaneous mastectomy
Chondrolaryngoplasty (tracheal shave)	Hysterectomy and salpingo-oophorectomy
Voice feminization	Phalloplasty
Breast augmentation	
Orchiectomy	
Vaginoplasty	

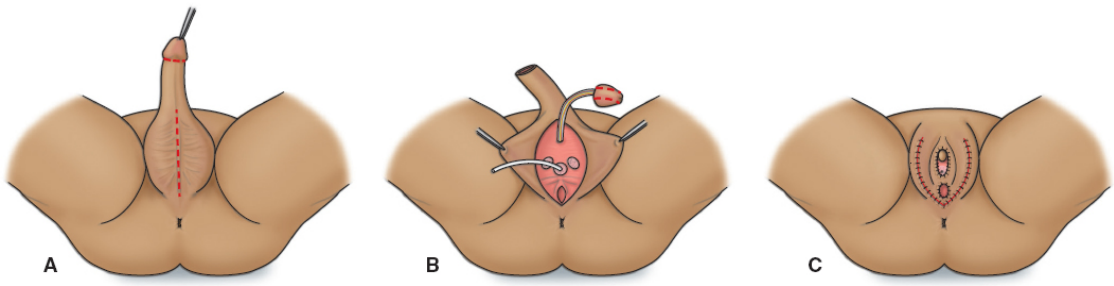

Figure 54-3 • Vaginoplasty in transgender woman (male to female). **A.** Surgically created penile skin flap and dorsal scrotal flap. **B.** Resection of penile and scrotal tissue. **C.** End surgical result is clitoroplasty.

For most transgender women, breast augmentation greatly increases subjective feelings of femininity. Surgeons typically recommend the person take estrogen for at least 12 months prior to the surgery to maximize breast growth and obtain better aesthetic results. Mammogenesis in transgender women receiving estrogen follows a pattern like the Tanner stages of breast development (see Breast Assessment in Chapter 52 for discussion of Tanner stages). Although there are some sexual differences in chest wall and mammary anatomy, the implantation of breast prostheses is not very different from breast augmentation in a female natal patient. The incision is typically made axillary, inframammary, or periareolar. The implant is created behind the glandular tissue or behind the pectoralis muscle (Colebunders, Verhaeghe, et al., 2016).

Some transgender women choose to have genital reassignment surgery. The goal of genital reassignment surgery in transgender women is to create a perineogenital complex as feminine in appearance and function as possible and free of poorly healed areas, scars, and neuromas. To achieve this goal, two procedures are required, including an orchiectomy (removal of the testicles) and vaginoplasty. The major steps of a vaginoplasty (Fig. 54-3) include amputation of the penis, creation of the neovaginal cavity and the lining, reconstruction of a urethral meatus, and construction of the labia and clitoris (Colebunders, Verhaeghe, et al., 2016). Lining the neovaginal cavity requires either a skin flap or skin graft. The penile–scrotal skin flap, or penile inversion vaginoplasty, is the technique of choice and involves inverting the penile and scrotal skin (Ferrando, 2018). If the skin graft technique is used by the surgeon, skin tissue can be harvested from numerous different areas on the body, such as the penile or scrotal area, abdomen, intestines, or buccal mucosa.

The goals of postoperative care of the patient undergoing male-to-female genital reassignment surgery are to prevent complications and infection and to ensure patency of the neovaginal cavity. After surgery, the patient typically remains in bed for five days with a vaginal dilator in place while receiving subcutaneous low-molecular-weight heparin (LMWH) (e.g., enoxaparin; see Chapter 26 for further discussion on anticoagulation medications). After the fifth day, the dilator is periodically removed and daily cleansing of the neovaginal cavity begins. The patient will typically remain in the hospital for 8 days. After discharge, the patient is educated on how to dilate and cleanse their vaginal cavity for 3 to 6 months. Once fully healed, the patient can begin having penetrative vaginal intercourse and stop using the vaginal dilator. If the patient does not engage in regular intercourse, they will need to continue using the vaginal dilator (Colebunders, Verhaeghe, et al., 2016).

Female-to-Male Gender Reassignment Surgeries

There are also numerous different gender reassignment surgeries for transgender men (see Table 54-4). Male-sexed faces tend to have larger facial skeletons, be squarer with sharper angles and stronger jaws. Although facial masculinization procedures are far less common than facial feminization, surgeries are available to modify the forehead, angle of the mandible, chin, and cheekbones. Although the vocal cords can be surgically modified to reduce tension resulting in a more masculine voice, most people who are transgender male achieve their desired voice through testosterone treatment and behavioral therapies (Irwig, 2017; Schneider & Courey, 2016).

Testosterone treatment has little effect on reducing breast size, thus transgender men who desire a flat chest require a subcutaneous mastectomy (Fig. 54-4). From an anatomical standpoint, subcutaneous mastectomy in transgender males is nearly identical to mastectomies for breast disease. The main difference is the removal of breast tissue and excess skin and reduction

and repositioning of the nipple and areola to create an aesthetically pleasing male chest (Colebunders, D'Arpa, Weijers, et al., 2016). The complication rate of subcutaneous mastectomy is very low and carries similar risk to mastectomies for breast disease (Cuccolo, Kang, Boskey, et al., 2019) (see Chapter 52 for further discussion on mastectomy).

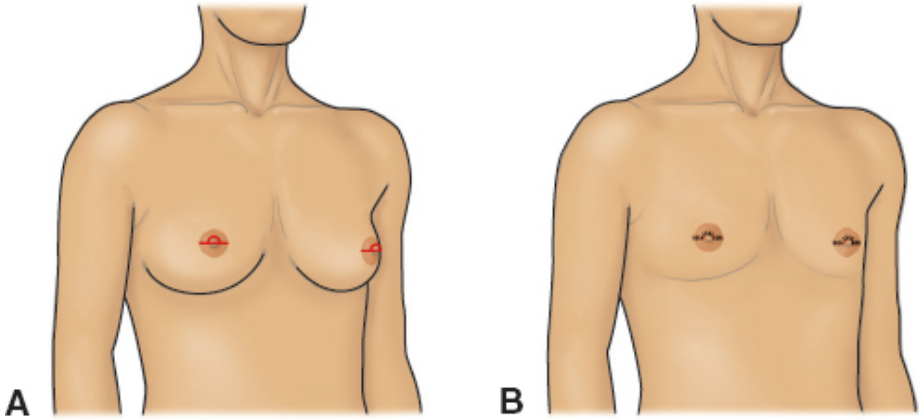

Figure 54-4 • Subcutaneous mastectomy in transgender man (female to male). **A.** Breast tissue with transareolar incision. **B.** Appearance postmastectomy.

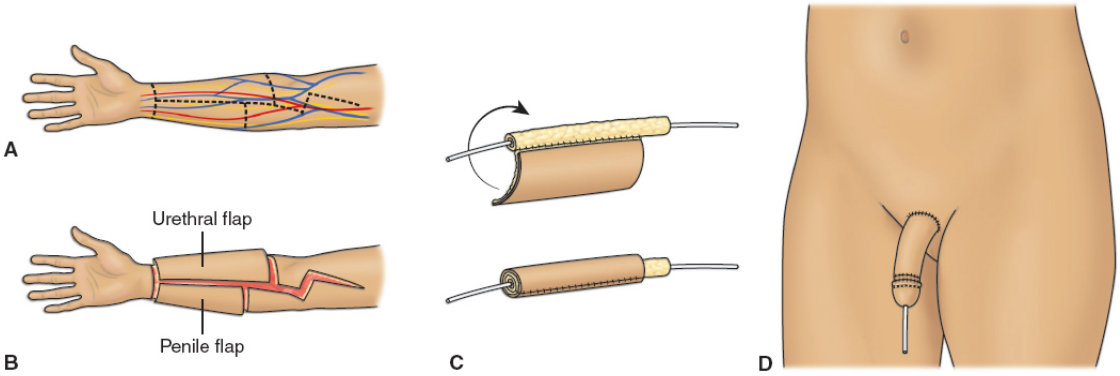

Figure 54-5 • Phalloplasty in transgender man (female to male). **A.** Selection of radial flap on forearm. **B.** The urethral (longer) and penile parts are dissected. **C.** Creation of a urethral tube within a penile tube. **D.** Postoperative results of phalloplasty.

Some transgender men choose to have phalloplasty, which is the construction of a penis. The goals of phalloplasty include (Colebunders, D'Arpa, et al., 2016):

- having an aesthetic appearing penis,
  - achieving tactile and erogenous sensation,
  - having the ability to urinate while standing, and
  - having the ability to have an erection and engage in penetrative intercourse.

Phalloplasty is a complicated surgery that involves numerous subprocedures. Although the selection of subprocedures will depend on the patient's goals, they typically include phallic shaft creation, penile urethroplasty, urethral lengthening, perineoplasty (reconstructing the perineum), scrotoplasty, vaginectomy, hysterectomy and oophorectomy, glansplasty (constructing the head of penis), testicular implants, and erectile device implant (Heston, Esmonde, Dugi, et al., 2019). To help retain erogenous sensation and the ability to achieve orgasm, surgeons try to maintain clitoral nerves. Patients can also elect to have clitoral transposition where the clitoris is placed in a superficial location just below the surface of the neophallus.

Constructing the penis requires a flap of skin to be excised from either the radial forearm or anterolateral thigh. The forearm skin flap is considered as the standard in penis construction (Fig. 54-5), but some patients may choose the thigh to avoid having a wide circumferential scar on the forearm. Due to the size of the skin flap excised from the forearm or thigh, postoperative monitoring and care is imperative to prevent infection and complications. After surgery, the patient typically remains in bed for 1 week with a suprapubic urinary diversion and transurethral catheter. The patient may be prescribed an LMWH agent, such as enoxaparin, during this time frame. However, pelvic or groin hematomas sometimes develop postphalloplasty, which must then be managed by either drains or surgical drainage, and thus the individual risks versus the benefits of prescribing an LMWH agent are carefully considered (Crane, 2016). After the 1-week mark, the transurethral catheter is removed, and the suprapubic catheter is clamped so the patient can begin voiding. The patient will typically remain hospitalized for 2 to 3 weeks after a phalloplasty for close monitoring. To increase the aesthetic aspect of the phalloplasty, the patient may choose to tattoo the glans (head) of the penis after it has healed. Tattooing the glans allows for more natural coloring (Colebunders, D'Arpa, et al., 2016).

There are numerous challenges to achieving the last two goals of phalloplasty; namely, to urinate while standing and to achieve an erection. There have been many reported complications in patients who had urethral lengthening through construction of a neourethra, especially postoperative urethra fistulas and strictures/stenoses. Further, the long-term effects of urethral lengthening on bladder function is unknown. Lifelong follow-up with a urologist is usually required. Achieving rigidity (erection) after a phalloplasty remains a real challenge. There are numerous surgical approaches to creating rigidity, each with unique limitations and complications. One of the more common approaches is implanting an erectile device. Although infections can be a problem with penile implants, the latest erectile devices show promise in being durable and allowing the person to achieve an erection and sexual pleasure (Colebunders, D'Arpa, et al., 2016) (for further discussion of penile implants, see Chapter 53, Table 53-2).

An alternative technique to phalloplasty is metoidioplasty, which uses the clitoris to construct a microphallus. In metoidioplasty, the clitoris is detached from the pubic bone, allowing it to extend out further. This approach usually requires at least 12 months of testosterone treatment, which results in a hormonally hypertrophied clitoris. Metoidioplasty is the only procedure that enables creation of male genitalia with completely preserved protective and erogenous sensitivity. This means that the sexual sensation of the clitoris is preserved and intact, which differs from a phalloplasty that often requires reconstruction or transposition of the clitoris. The scrotum is usually created from labia majora flaps allowing for testicular implants. Compared to phalloplasty, metoidioplasty has a shorter hospital stay and minimal donor site complications. However, metoidioplasty does not allow the person to void while standing nor engage in penetrative sex (Djinovic, 2018).

NURSING PROCESS

The Patient Undergoing Gender Reassignment Surgery

Assessment

Preoperatively, the nurse should first gather details about the patient's gender identity, preferred name, preferred pronouns, and surgery. A person who is undergoing gender reassignment surgery will likely feel vulnerable and emotional. Gender reassignment surgery is a monumental moment for a person who is transgender. The nurse needs to ensure the patient and their family feel welcomed and safe. Using gender-neutral language (see Table 54-1) and properly assessing for gender identity and pronouns (see Chart 54-1) is imperative to creating a welcoming environment.
