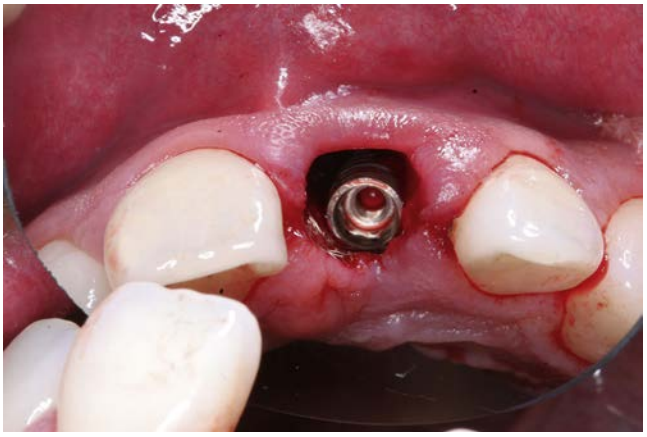
Maxillary anterior implants should be placed in a three-dimensionally correct position in order to achieve maximum esthetic results: bucco-palatal, apico-coronal, and mesiodistal. For the purpose of discussion, it is assumed that a root form, self-tapping bone-level implant is used for immediate maxillary anterior implant placements. A surgical guide based on CBCT is recommended for less experienced clinicians who are contemplating immediate maxillary anterior implants. The guide should be designed to allow the implant abutment screw to emerge through the cingulum of the future implant crown. This will help to ensure that the implant shoulder will not be too close to the buccal plate, leaving the desired larger gap between buccal bone and implant for grafting. Bressan and colleagues,[66] in an experimental study in dogs, found a higher degree of bone formation at buccal plate when the immediate implants were placed more lingually. Evans and coworkers[67] found three times more facial gingival recession when implants were positioned more buccally. Le and associates[68] studied the relationship between crestal labial soft tissue thickness and implant bucco-lingual angulation of maxillary anterior implants. They found a strong correlation between implant angulation and the labial soft tissue thickness, especially when there was less than 2 mm thickness of facial bone. Implants with labial angulation had thinner facial soft tissue thickness compared to implants with cingulum angulation. This correlation disappeared when more than 2 mm of facial bone thickness was found around the implant. Because soft tissue thickness less than 2 mm has been associated with increased marginal bone loss and thinner underlying bone, a connective tissue graft to thicken the soft tissue has been recommended for long-term gingival stability.[69,70]

The extraction should be completed preferably without flap elevation. If the surgical guide is not available, the clinician must control the direction of the osteotomy to minimize deflection of the drill off the palatal wall. A 2.0-mm round burr can be used to create a slot along the coronal third of the palatal socket wall to prevent "slippage" of the drill as described by Hwang and Park.[71] Root-form or tapered implant fixtures have a natural tendency to deflect towards the buccal plate as they are seated apically. Unless side-cutting drills are used, it is often necessary to prep the palatal wall using a Lindeman burr or piezosurgery to prevent the implant from moving facially as it is seated. When the implant is placed following these principles, it is common to visualize exposed facial threads of the coronal two thirds of the implant within the buccal bone gap (Figure 27-10). The horizontal bone resorption following immediate implants has been reported to be about 1.9 mm.[71,72] In healed sockets, implant placement requires 2 mm of facial bone thickness remaining to account for 1.4 mm of biological width.[58] When immediate implants are placed in the maxillary anterior sockets, a distance of at least 2 mm should be present between the buccal plate and the implant shoulder[9,72,73] (Figure 27-11). In an animal study, Pluemsakunthai and Le[73] reported that a 3-mm gap distance led to more bone formation than a 2 mm or 1 mm gap distance. This minimum gap distance of 2 to 3 mm appears to ensure predictable bone regeneration to cover the exposed threads of the implant. Proper apico-coronal positioning of the implant is dictated by the desired final position of the free gingival margin. If the existing free gingival margin is acceptable, the gingival zenith can be used as the reference point,[74] and the implant is seated approximately



• **Figure 27-10** Exposed implant threads visible on facial aspect away from the buccal plate.

• **Figure 27-11** Minimum of 2 to 3 mm of gap should be available for grafting.

3 to 4 mm apical, to allow adequate "running room" for a proper emergence profile. If the implant is seated too apically, it will lead to excessive bone loss as the biological width reestablishes around the micro-gap. If the implant is seated too shallow, there will not be enough prosthetic space to develop a proper emergence profile for the crown. The mesiodistal position of the implant should be at least 1.5 mm away from the PDL of adjacent teeth.[75] Use of a platform-switched restorative design may allow the implant to be as close as 1.0 mm to the adjacent teeth in reported cases.[75]

Peri-implant Grafting: Hard and Soft Tissue Augmentation

Peri-implant grafting (hard and soft tissue) is done primarily to augment the horizontal facial tissue volume for esthetic results. Grafting of the facial bone gap is suggested for long-term maintenance of facial bone volume and soft tissue support. New bone will regenerate spontaneously without the need for grafting. Some studies have shown that grafting the gap will minimize horizontal bone loss,[58] while others found no beneficial effect of grafting the gap.[76] Most clinicians recommend a gap distance of at least 2 mm.[9,72,73] Average horizontal bone resorption measured 4 to 6 months after immediate implant placement has been reported to be as much as 1.9 mm.[72,73] It should be noted that in these studies, the extractions were done after raising full-thickness flaps. It is also believed that the overlying connective tissue becomes thinner following a tooth extraction.[62] Recent studies showed that when immediate implants are placed without raising a flap, a lesser degree of horizontal tissue volume loss is seen,[62,63] supporting the idea that preserving blood supply to the alveolar crest will lead to less tissue volume loss. Tarnow and colleagues[62] reported that flapless extractions with gap grafting with anatomic healing abutments or immediate provisionalization produced less than 0.4 mm of horizontal tissue volume reduction compared to the average of 1.0 mm when the gap was not grafted. To preserve the horizontal and vertical dimension of the extraction socket from this inevitable volume loss, augmentative procedures should be performed with minimal or no flap elevation. Grunder[69] proposed "extra-alveolar" concomitant connective tissue grafting to augment the labial tissue volume at the time of immediate implant placement in the maxillary anterior region. He reported average tissue collapse of 1.06 mm in the horizontal dimension with no connective tissue augmentation and 0.34-mm gain when connective tissue grafting was done (Figures 27-12 through 27-15). A study by Rungcharassaeng and colleagues[70] also supports concomitant labial connective tissue grafting as beneficial to conceal underlying restorative materials. In their study, the average gingival tissue thickness, measured 2 mm apical to the free gingival margin, was only 1.15 mm following a flapless extraction. Because a gingival tissue thickness greater than 2 mm is ideal for esthetics, the authors recommend soft tissue

augmentation with a connective tissue graft in all maxillary anterior cases. Le and co-workers,[68,78,79] however, have reported that the thickness of the labial crestal soft tissue after implant placement can be influenced by multiple variables such as implant position, angulation, and labial bone thickness.

Immediate Provisionalization

Comparable implant survival rates have been reported when implants were placed in healed sites with immediate provisionalization (100%),[11] or when a traditional delayed loading approach was used (97%).[12] Similarly, the immediate provisional restoration has no adverse affect on the survival rate of immediate implants, and the advantages of IIIP have been well documented.[3-6,8-10] They include reduced treatment time, increased case acceptance by the patient, and optimal esthetic results by preserving soft tissue architecture. It is recommended that 35 N-cm of insertion torque is achieved to gain primary stability before immediate provisionalization is considered. The Implant Stability Quotient (ISQ) is a value from 1 to 100 which indicates the level of the implant stability in bone. The number is derived from an instrument which sends magnetic pulses to a sensor that is attached to the implant being tested, and vibrates with certain frequency. Determining the specific frequency an object vibrates is a technique known as resonance frequency analysis (RFA). In general, the higher the frequency the implant vibrates, the higher the ISQ value, inferring higher implant stability. Some clinicians rely on high ISQ values of RFA as a predictor for success with immediate implants. However, a systemic review and meta-analysis of 15 RFA studies with 2,236 immediate-loaded implants by Atieh and colleagues[80] showed poor predictive value and discriminative ability. The osteotomy site is typically "underprepped" in order to increase the insertion torque. Underprepped osteotomy sites, however, make it more difficult to prevent "slippage" of the implant facially during insertion and may necessitate enlarging the osteotomy site to allow a proper angle of insertion.

• **Figure 27-17** Occlusal view of immediate molar provisional with screw access filled.

Provisional crowns can be made from a dental laboratory in advance to maximize the esthetic result. A stock of commercially available prefabricated polymethylmethacrylate (PMMA) shells or plastic denture teeth can also be used. In case of molars with intact crowns, an impression can be taken before the extraction to duplicate the shape of the tooth (Figures 27-16 through 27-18). In the hands of experienced clinicians, an existing restoration such as porcelain-fused metal (PFM) (Figures 27-19 through 27-23) or the patient's own tooth (Figures 27-24 through 27-28) can be used to convert to a screw-retained provisional restorations. The screw-retained method is preferred to avoid potential cement entrapment in the fresh extraction site and frequent loss of retention. Two temporary abutment

options are polyetheretherketone (PEEK) and titanium. For a single-tooth restoration, an engaging abutment is used to prevent rotation of the temporary crowns. For immediate provisional restoration, the authors prefer PEEK abutments and "direct" intraoral pickup technique using flowable

• **Figure 27-21** Porcelain-fused metal (PFM) is being modified extraorally by adding additional acrylics to contour the cervical portion of the provisional crown #7.

• **Figure 27-22** Immediate postoperative view of #7 provisional restoration.

composite or self-curing acrylic as luting agents.[81] Once the temporary abutment and the crown are luted together in the mouth, it is removed and the subgingival portion of the provisional crown is contoured using either composite or acrylic. A flat or concave labial emergence profile will help encourage coronal tissue migration and increase the gingival tissue thickness on the facial aspect of the provisional crown (Figure 27-29). The provisional restoration is relieved to be out of occlusion, and the screw access is filled with either cotton pellets or Teflon tape over the screw head before

• **Figure 27-23** Definitive restoration of #7. Note the presence and level of interimplant papilla between #7 and #8.

• **Figure 27-24** Preoperative view of tooth #24 to be removed due to external resorption of the root.

closing the access with temporary filling materials. When a provisional restoration is not needed, a custom healing abutment can be fabricated to maintain the soft tissue architecture of the extraction socket (Figure 27-30).

Immediate Molar Implants

The application of immediate implant treatment modality has expanded recently to the molars. High survival rates (93.9% to 100%)[13,14] have been reported for immediate molar implant placements, and the marginal bone loss around immediate molar implants has been studied and shown to be comparable to that in implants placed in healed sockets.[15,16] Several different socket configurations exist for maxillary and mandibular molars,[17] each with its own technical challenges for achieving primary stability and proper positioning. Placing a standard-diameter implant into one of the existing root sockets of a multirooted molar has been reported; however, it invariably led to a compromised emergence profile, off-axis loading, and a cantilever effect.[17,82] Larger diameter implants placed in the center of the socket have been recommended for ideal axial loading and

• **Figure 27-25** Natural crown of #24 is used as a veneer and luted to the temporary abutment.

• **Figure 27-26** Immediate postoperative view of #24 provisional restoration.

restorations.[83] A three-dimensionally correct placement is important to minimize ridge-lap or overcontoured restorations. Smaller diameter implants should be placed deeper in order to have adequate "running room" for a proper emergence profile. Ideally, the molar is extracted with a flapless approach by sectioning the crown and removing the roots

• **Figure 27-27** Two weeks postoperative view.

• **Figure 27-28** Definitive restoration of #24.

individually to prevent inadvertent loss of the inter-radicular bone.[17] Skillfully engaging this native mature bone to achieve primary stability is the key to success of immediate molar implants. Some advocate placing the implant before removing the roots to ensure correct mesiodistal placement, as it can be difficult to center the drill in the interfurcal bone without dropping into one of the root sockets.[84] Larger diameter implants may allow greater engagement of the apical and lateral walls of the socket and the bone beyond the socket depth. Proximity to the sinus cavity and inferior alveolar nerve can limit the availability of the apical engaging bone. If 3 to 4 mm of mandibular apical bone is not available for primary stability, the lateral walls of the socket can be engaged otherwise, use of a staged approach must be considered.[85] Implants with diameter greater than 5 mm have been advocated, and implants as large as 10 mm in diameter have been reported.[86] Short implants less than 10 mm in length[87] have been used with high success in the atrophic posterior mandible and maxilla.[88] The use of wide diameter implants in fresh molar extraction sockets has been described.[13-17,89] However, a controlled clinical trial by Atieh and colleagues[89] reported an unusually low success rate of 66.7% for immediate molar implants. These immediate molar implants were immediately loaded within 48 hours with provisional restorations. The fact that majority of the failures occurred within 3 months of definitive restoration suggests the possibility of premature loading. Some

authors suggest the implant platform should be flushed with the furcal bone while others advocate placing the implant 2 to 3 mm below the intact buccal plate.[86] Grafting of the residual gap around the implant may not be necessary for successful osseointegration but is recommended to reduce the ridge remodeling.[14,15,17] A minimum insertion torque of 15 N-cm is recommended for primary stability, with higher insertion torque leading to higher success rates.[90] When excessive maxillary sinus pneumatization limits apical engagement, the sinus floor can be augmented in combination with immediate implant placement. Augmenting the sinus floor using osteotomes via the extraction socket was introduced by Summers[91] as a less invasive technique than a conventional "lateral window" approach. Some controversy exists regarding the minimum residual bone height required to engage the implant for a successful outcome. It is generally accepted that a minimum residual bone height of 4 mm is needed for adequate primary stability.[17,93]

Multiple Immediate Implants and Adjacent Implants in the Esthetic Zone

When multiple teeth are extracted simultaneously, the loss of interdental bone may result in a poor esthetic outcome.[58,94,95] The space between two adjacent implants should be at least 2.8 to 3.0 mm apart to avoid lost of the interimplant alveolar bone height, which can lead to shortened papilla height[58,94] (Figure 27-31). The average interimplant papilla height in the esthetic zone is reported to be 3.5 mm, which is significantly shorter than the normal 5 mm found between 2 healthy natural teeth[95] (Figure 27-32). For this reason, the replacement of adjacent maxillary central and lateral incisors with inadequate mesial-distal space for two implants should consider the use of a pontic to maximize the esthetic outcome.[95] The soft tissue height between an implant and a pontic is reported as high as 5.5 mm,[96] (Figures 27-33 and 27-34). When two central incisors are missing, the central papilla between the two implants may be shortened, but the relative sulcular symmetry can be maintained[97] (Figures 27-35 and 27-36). In 2007, Salama and colleagues[98] reintroduced the root submergence technique[99] for pontic site development adjacent to dental implants (Figures 27-37 through 27-40). Intentionally leaving root remnants to prevent resorption to maintain tissue support was soon applied to immediate implant placement. Case reports of implants placed in direct contact

• **Figure 27-31** Interimplant papilla is absent between #7 and #8.

• **Figure 27-32** #7, #8, #9, #10 are individual implant restorations.

with ankylosed root with more than 5 years of follow-up showed no detrimental effects from the retained roots[100] (Figures 27-41 and 27-42). These experimental studies coupled with case reports on human subjects have led to the concept of the "socket shielding" technique proposed by Hürzeler and co-workers in 2010.[101] In an animal study, a buccal segment of the root was intentionally left intact against the buccal plate, with an implant placed lingual to the root fragment. While preserving the buccal plate from remodeling, this technique showed successful osseointegration of the implant with new cementum formation where the implant came in direct contact with the root fragments. Various modifications of this technique has been advocated to preserve the interproximal and buccal bone after

immediate implant placement. A "proximal socket shield" of intentionally leaving a root remnant in the interproximal areas adjacent to an implant was introduced by Kan and Rungcharassaeng to preserve the interimplant papilla.[102] Similarly, a "root membrane" technique was introduced by Siormpas and colleagues[103] to preserve the facial bone from remodeling. Clinicians are advised to use discretion when considering these unconventional techniques until more long-term studies are available.

Summary

Achieving an esthetically pleasing result with immediate dental implants requires application of the prosthetic and surgical principles discussed in this chapter. Using flapless procedures for extraction of the tooth, hard/soft tissue grafting, proper implant positioning in three dimensions, and immediate provisional restoration provide the best prospect for achieving an optimal esthetic outcome. Immediate provisional restoration delivery provides a convenient service for the patient by eliminating a removable appliance, while maintaining near-normal gingival architecture and avoiding an additional tissue training period.

Bone Grafting Techniques and Materials

TARA L. AGHALOO, JOAN PI-ANFRUNS, SAMANTHA JONES, RAQUEL M. ULMA, PAYAM AFZALI, NORA KAHENASA

Introduction

Bone grafting is an essential component of the surgeon's armamentarium for successful treatment outcomes in implant dentistry. In the United States alone, more than 1 million bone grafting procedures are performed each year, with a 13% annual increase and a market reaching $1 billion a year.[1] Mandibular and maxillary bony defects occur as a result of dental extractions, as residual defects following surgical treatment of pathology, or as congenital alveolar bone defects. Regenerative procedures in the form of bone grafts are often performed to solve these problems. Each defect is unique and requires a tailored treatment plan for reconstruction. Increased understanding of implant success has shown that there is no significant difference in implant survival when bone grafting is performed as compared to implants in native bone.[2,3] The goal of such procedures is to create an optimal site for implant placement and support of soft tissues. Prosthetically driven implant dentistry should focus on form, function, and esthetics. The goal of these reconstructive procedures is to provide a three-dimensional housing that will support and maintain gingival contours in a predictable manner.[4] In recent years, the dental profession has come to understand that implant therapy and placement of endosseous implants must be prosthetically driven, thereby often necessitating alveolar reconstruction to achieve ideal implant placement. Since the first documented bone graft by Van Meekeren in 1668,[5] extensive research has been performed to evaluate a number of bone graft substitutes, but the sheer abundance of biomaterials and techniques currently available can be confusing when making a selection for a particular case. As with any surgical procedure, the clinician must weigh the potential benefits against the risk of complications in order to provide the best treatment possible for the patient.

Bone Biology and Healing

Bone grafting outcomes can be improved by simply understanding the physiology of bone healing and detailed analysis of the properties of materials used. The biology of nonvascularized bone grafting can essentially be described through understanding basic bone healing and regeneration[6-10]:

1. Osteogenesis: The survival of cellular elements within a donor graft allows synthesis of new bone at the recipient site.
2. Osteoinduction: Active recruitment of host mesenchymal stem cells, including growth factors and bone morphogenetic proteins, from the surrounding tissue allows formation of new bone.
3. Osteoconduction: Graft material facilitates invasion of blood vessels and connection of bone cells to the lattice framework.[11]

An ideal bone graft or bone graft substitute should possess these osteogenic, osteoinductive, and osteoconductive characteristics, while maintaining a favorable environment for bone formation without early resorption.

As with normal bone repair, bone grafts heal in three major phases: inflammation, proliferation, and remodeling.[6-10] The inflammation phase begins at the time of injury and continues for up to 5 days. As in all wound healing, inflammation results from blood vessel injury and triggers hemostasis. Platelets assist with hemostasis, and vasoconstriction allows a blood clot to form, beginning the healing process. Inflammatory and phagocytic cells such as neutrophils and macrophages debride the wound site and help decrease bacterial accumulation. The proliferation phase of graft healing results in the production of a disorganized osteoid, or new bone woven by the bone graft cells. In the remodeling phase that follows, the immature bone is resorbed and replaced by organized lamellar bone. The grafted cells initially survive (the first 3 to 5 days) by

diffusion of nutrients from the recipient bed. This process is known as plasmatic inhibition. Adequate graft nutrition is therefore dictated by the quality of the recipient bed. For example, a densely scarred recipient bed would not be an optimal site, as imbibition and vascularization will likely be compromised.

Vital graft cells are needed to form the new osteoid. Angiogenesis is also an important principle for graft healing and integration to occur and is dictated by growth factors secreted by macrophages and platelets in response to the hypoxic graft bed environment. Approximately 3 to 5 days after grafting, budding vessels infiltrate from the surrounding soft tissues and bone edges into the graft. Cancellous bone is revascularized faster than corticocancellous or cortical bone grafts, as the budding vasculature is free to inosculate throughout the large spaces between trabeculae in cancellous bone without having to follow the existing cortical bone haversian system. Early revascularization is key for osteoid apposition, as blood vessels will bring the osteoblasts much-needed oxygen and nutrients and aid in metabolic waste removal. The cortical components serve as an osteoconductive scaffold. The scaffold is resorbed by osteoclasts and remodeled, before osteoid is laid down by osteoblasts. The osteoid and endosteum fuse, and the new bone consolidates.[12]

The remodeling phase starts at about 2 weeks and lasts months to even years, depending on the type of bone graft material used. So long as the bone graft remains immobilized, maintains an adequate blood supply, and remains free of infection, the remodeling stage will complete the healing process. Osteoclasts gradually resorb the immature bone and more organized lamellar bone is laid down. The lamellar bone is mechanically stronger than woven bone. The gradual osteoclastic resorption of immature woven bone with osteoblastic bone formation and maturation to lamellar bone is known as creeping substitution.[13]

Each bone graft type has its own set of material characteristics, including composition, structure, particle size, bone growth method, and resorption time. The surgeon may select a single bone graft material, or a combination of materials, based on individual material properties, advantages, and disadvantages. Bone grafts can be combined or layered to maximize specific properties of each material. Quite often these materials are mixed to combine preferable properties in a particular site.[14,15]

Bone grafts can be categorized according to morphology. Particulate, marrow, or block grafts each have properties that may be better suited to restoring a particular recipient site, and thus choice of material should take form into consideration.[16] Cortical block grafts have structural stability and are valuable for horizontal and vertical defects, yet take comparatively longer to revascularize and have little osteogenic potential compared to marrow and cancellous grafts.[17] Particulate graft structure is lower in density than a block graft and allows for more rapid revascularization of the graft, but also necessitates a scaffold to provide structure. Guided bone regeneration is based on the concept of using a resorbable or nonresorbable barrier membrane to stabilize the blood clot and create a space into which bone cells can grow without interference of the more quickly proliferating soft tissue cells.[18]

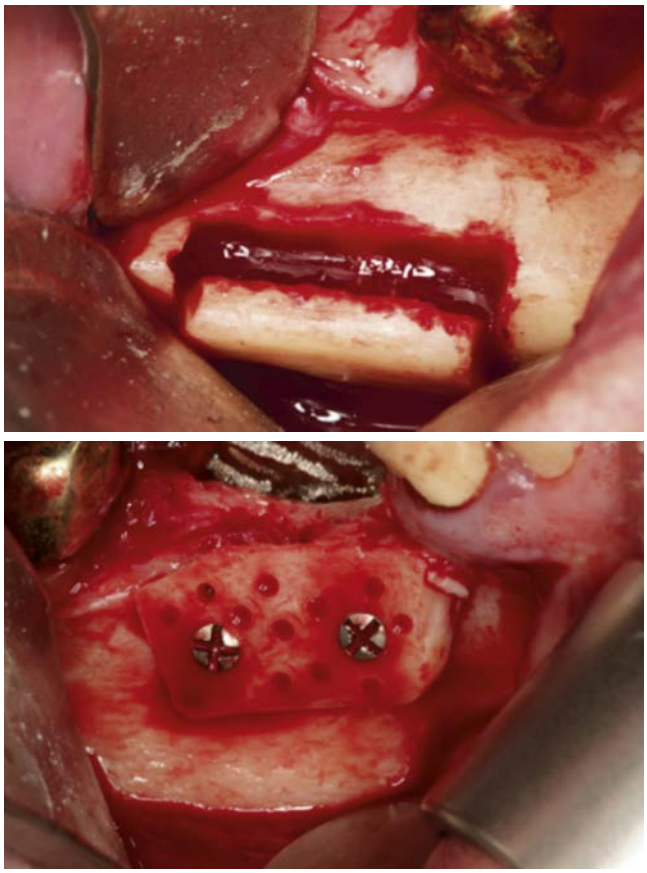
Bone grafts can also be classified according to the source from which they were derived. Autografts are composed of tissue from the same individual, allografts are taken from another individual of the same species, xenografts are from a different species than the recipient, and alloplastic grafts are composed of synthetic material. Current research is focusing on creating the ideal versatile graft. Bone graft substitutes are based on the concept of bone tissue engineering, which focuses on improving their osteogenic, osteoconductive, and osteoinductive potential by incorporating bone progenitor cells and growth factors to stimulate cells into a scaffold made of various natural or synthetic materials or their combination, which mimic the bone microenvironment.[19]

Autogenous Grafts

Autogenous bone is considered the "gold standard" for grafting, as it possesses all the necessary features of an ideal graft material.[20-22] Autogenous bone has the ability to induce undifferentiated stem cell maturation through secretion of growth factors and has the biomechanical stability of a framework, allowing invasion of blood vessels and bone cells. Autogenous grafting can include harvesting of cancellous bone or cortical bone. Cancellous bone heals primarily by osteogenesis and possesses a greater concentration of osteocompetent cells than cortical bone, which has a slower turnover and remodeling rate. Autogenous bone remains the only type of bone graft containing osteocompetent cells that can undergo osteogenesis; they contain growth factors and bone morphogenetic proteins (BMPs) that induce bone regeneration and promote soft tissue healing and angiogenesis.

Once harvested, the autogenous graft should be promptly transplanted into the recipient bed to maximize the number of live cells transferred to the recipient site (Figure 28-1). The graft may be temporarily stored in sterile normal saline (or other sterile normotonic solution) until ready for use, and it is recommended that the time to transplantation be minimized so as to ensure graft vitality. Little is known about the influence of the intraoperative storage of autologous bone or the exact amount of time for graft vitality to diminish. However, it is recommended to avoid intraoperative storage of cancellous bone under dry conditions, and longer storage times (more than 2 hours) should be performed in saline solution.[23] This is of particular importance because the amount of new bone formed is directly dependent on the number of osteoblasts that survive transplantation.

Autografts can be of cancellous, corticocancellous, or cortical origin. Although cancellous, corticocancellous, and cortical bone differ in the concentration of osteoblasts that they house, all three contain growth factors and BMPs within an osteoconductive scaffold. Cancellous bone has



• **Figure 28-1** Block graft harvested from mandibular ramus and fixated into position as a veneer graft for horizontal augmentation.

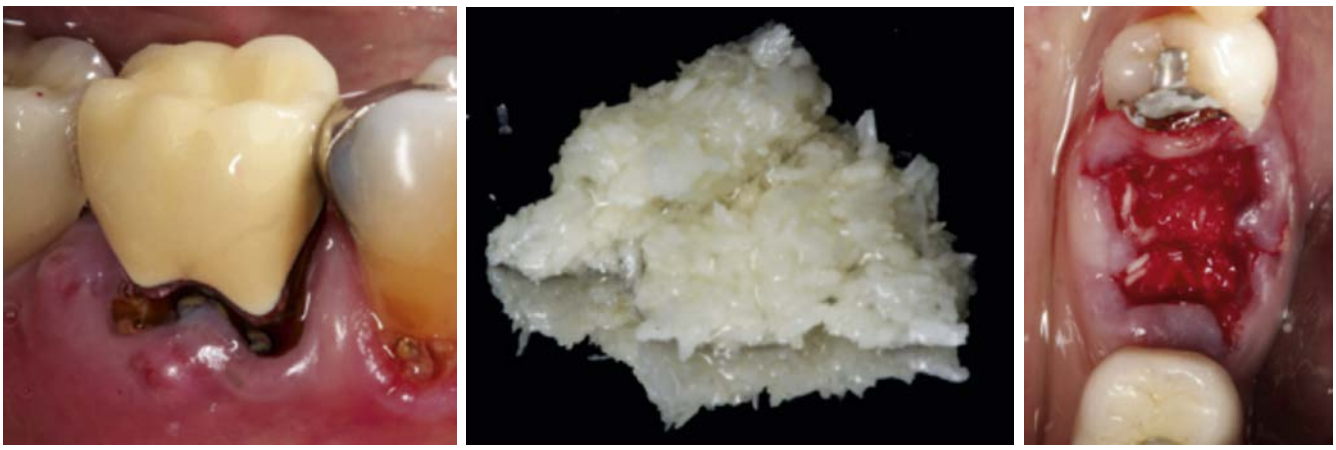
higher concentrations of osteoblasts, which will eventually deposit new bone, as compared to corticocancellous and cortical bone grafts. Cancellous bone grafts (particulate) inherently contain more progenitor cells and osteoblasts and therefore have more osteogenic and osteoinductive properties than cortical bone. The surgeon must consider all the factors discussed here for each type of autogenous bone graft and choose the one most suited to the recipient site based on these properties, along with their ability to maintain the reconstructed space.

There is an inherent morbidity associated with a second surgical site needed for harvesting autogenous bone, which can be a downfall of our "gold standard." There are a number of potential sites for autogenous grafts. Intraoral sites include mandibular ramus, symphysis, and maxillary tuberosity. Extraoral sites include anterior and posterior iliac crest, proximal tibia, and calvarium. These autogenous donor sites, as well as surgical techniques, are discussed in depth in a subsequent chapter. There are numerous studies substantiating the effectiveness of autogenous grafts for applications in implant dentistry. Aghaloo and Moy in 2007 found that for maxillary sinus grafting in a total of 5128 implants the survival was 92% (confidence interval [CI]: 87.2-96.8) for implants placed into autogenous and autogenous/composite grafts, 93.3% (CI: 83/1-92.9) for implants placed into allogeneic/nonautogenous composite grafts, 81% (CI: 67.5-94.5) for implants placed into alloplast and alloplast/xenograft materials, and 95.6% (CI: 91.1-100) for implants placed into xenograft materials alone.[24] A systematic review by Al-Nawas and Schiegnitz in 2014, looking at implant survival in both sinus floor and alveolar ridge augmentation, found that implant survival seems to be independent of the biomaterial used, with no evidence that autogenous bone grafting is superior to bone substitute materials.[25]

Allografts

Allografts are bone grafts from a donor of the same species, derived from living or deceased donor bone. In 1878, William MacEwen performed the first human bone allograft by reconstructing the infected humerus of a 4-year-old with a graft obtained from the tibia of a child with rickets.[26] Interest in methods of preserving and storing bone showed that bone refrigerated for as long as 3 weeks could be successfully transplanted in dogs.[27] As an alternative to autogenous material, allogeneic bone has recently demonstrated similar efficacy to autogenous bone grafts with decreased patient morbidity.[1,28] Harvesting from an intraoral or extraoral site requires a second surgery, increasing the duration as well as invasiveness of the procedure, and in turn the morbidity of the patient. The various allograft options that are available include fresh-frozen bone allograft (FFBA), freeze-dried bone allograft (FDBA), and demineralized freeze-dried bone allograft (DFDBA).[1,28] Implant survival rates in allografts have been more than 95% in numerous published case series and approaching 99% in some, demonstrating the reliability of this alternative means of bone grafting.[5,28,29] The FFBA is considered osteoconductive, promoting bone regeneration from forming a scaffold allowing the ingrowth of cellular and vascular components.[30-32] FFBA microparticulate allografts lag considerably behind their freeze-dried counterparts in inducing bone healing.[33]

In the freeze-drying process, the water is removed from the ice as vapor. Thus the ice disappears without melting and the water vapor is resolidified through cool temperatures. This significant process has been attributed to alterations in protein configuration or the blocking of hydrophilic sites of proteins.[5,29,32,33] Freeze-dried bone allografts should be rehydrated before implantation to preserve their mechanical strength and resiliency. However, in oral surgical procedures, bone preparations become rehydrated by body fluids relatively quickly and bone preparation rehydration is not as important.[29,32,33] This demonstrates the durability of freeze-dried microparticulate allografts for use in oral and maxillofacial surgery. DFDBA forms are processed by acid demineralization in 0.5 to 0.6 M hydrochloric acid; as a result, 40% of the mineral content is removed, leaving the organic matrix intact.[32] Although this process preserves the BMPs present in bone, DFDBA has very weak osteoinductive properties. To determine the osteoinductive properties of a material, it has to be tested in a rat subcutaneous ectopic implant model. If the material tested is osteoinductive, it should be able to form a bony nodule after 2 weeks of



• **Figure 28-2** Tooth #19 planned for extraction. Cortico-cancellous mineralized freeze-dried allograft used for socket augmentation.

implantation in an ectopic site (subcutaneous). Because of the faster rate of bone formation in rats, a material's osteoinductive potential should also be tested in a higher order species, where a higher potency is needed to induce bone formation. If the material tested is able to induce new bone formation in these two models, it is then likely to induce bone formation in humans.[34]

Once the allograft is harvested, it is processed through several methods, including physical debridement to remove soft tissue and reduce cellular load, ultrasonic washing to remove remnant cells and blood, ethanol treatment to denaturalize proteins and deactivate viruses, antibiotic wash to kill bacteria, and sterilization through gamma radiation and ethylene oxide for spore elimination.[35,36] The antigenicity and infectivity of allogeneic materials depend on donor selection and this purification process, which has been reduced because of this more extensive removal of cells.[36] The rigorous protocol for bone processing, which eliminates living cells and consequently the risk of transmission of diseases, and the reduced immunologic reaction to the graft have increased clinical and scientific interest in FFBA.[37-39] The transmission of hepatitis C and human immunodeficiency virus (HIV) after transplantation of allograft material has been documented.[40] The risk of HIV infection through allograft implantation has been estimated to be 1 in 1.6 million, compared with the risk of 1 in 450,000 in blood transfusions.[35]

Bone allografts commonly used in reconstructive oral surgical procedures can be broadly divided into particulate and structural grafts, as the former are used most frequently. Both FDBA and DFDBA are preferably obtained from cortical bone of long bones because of its high levels of inductive proteins and lower antigenic activity compared with cancellous bone.[32] Bone allografts come in various configurations, including but not limited to powder, ground bone, and cancellous and cortical bone chips (Figure 28-2).[32] Particulate grafts are used for filling defects with largely intact walls. The structural grafts are bone plates, sections of mandibles, and cortical and cancellous bone blocks.[41]

Xenografts

The first reported use of demineralized bone dates back to 1889, when Senn used xenogeneic, decalcified bone to repair canine skull defects.[38] Bone xenografts are bone tissues harvested from one species and implanted into a different species. Xenograft bone used in oral and maxillofacial surgery is usually anorganic bovine bone (ABB), but can also be porcine or equine in origin. It has a crystalline structure and a calcium-to-phosphate ratio similar to human bone.[42,43] Xenografts are deproteinized to remove all organic material, alleviating the risk of inducing a host immune response.[44] The remaining inorganic components provide a natural matrix as well as an excellent source of calcium. The structure consists of a wide interconnective pore system with a particle size of 0.25 to 1 mm that can easily be invaded by blood vessels, resulting in osteoblastic migration. ABB is up to 75% porous and has a high specific surface area of almost 100 m^2/g that results in increased angiogenesis and strong osteoconduction properties promoting bone growth.[45,46] ABB lacks osteoinductive and osteogenetic properties, because it is rigorously treated to reduce antigenicity.

The disadvantage of xenografts beyond only having osteoconductive properties is that the resorption rate of bovine cortical bone is slow. In addition, despite being extremely rare, patients may have sensitivity to mad cow disease or bovine spongiform encephalitis as well as religious beliefs against its usage.[47] Cornelini and colleagues evaluated the use of a porous bone mineral matrix xenograft (Bio-Oss) as an adjunct to a biodegradable barrier membrane (Bio-Gide) to support healing following the immediate placement of transmucosal implants into extraction sockets.[48] The soft tissue margin was located 2.6 mm more coronal than the shoulder of the implant in the test group, compared to 1.3 mm in the control group. They concluded that the use of ABB as a membrane support at immediately placed implants may offer advantages in terms of soft tissue support[28] (Figure 28-3).

Lee and co-workers compared the osteoconductive effects of deproteinized bovine bone mineral (DBBM), irradiated

• **Figure 28-3** Anorganic bovine bone (xenograft) and resorbable collagen membrane placed for guided bone regeneration with simultaneous implant placement.

cancellous allograft (ICA), and solvent-dehydrated allograft (SDA) in preserving the extraction socket of 20 patients. DBBM induced more new bone deposition in the periphery of the native bone particles than ICA or SDA, whereas ICA and SDA were more frequently surrounded by fibrous tissue than DBBM. In addition, DBBM retained more residual graft bony particles than ICA or SDA, producing a more rigid bony structure. It is therefore suggested that DBBM may be more favorable for the preservation of extraction sockets than allogeneic graft materials.[42]

In regards to sinus grafting, Aghaloo and Moy demonstrated xenograft superiority with survival of 92% for implants placed into autogenous and autogenous/composite grafts, 93.3% for implants placed into allogeneic/nonautogenous composite grafts, 81% for implants placed into alloplast and alloplast/xenograft materials, and 95.6% for implants placed into xenograft materials alone.[24] In a randomized controlled trial by Merli and colleagues in 2013, no differences apart from chair time were observed when comparing autogenous bone and deproteinized bovine bone matrix grafts with simultaneous implant placement in sinus elevation.[49] Esposito and co-workers researched the efficacy of bone augmentation for implants through a Cochrane systematic review of randomized control trials and found Bio-Oss to be as effective as autogenous bone in regard to sinus lift procedures in extremely atrophic maxillas.[50] All these studies demonstrated excellent success of xenograft in sinus lift procedures.

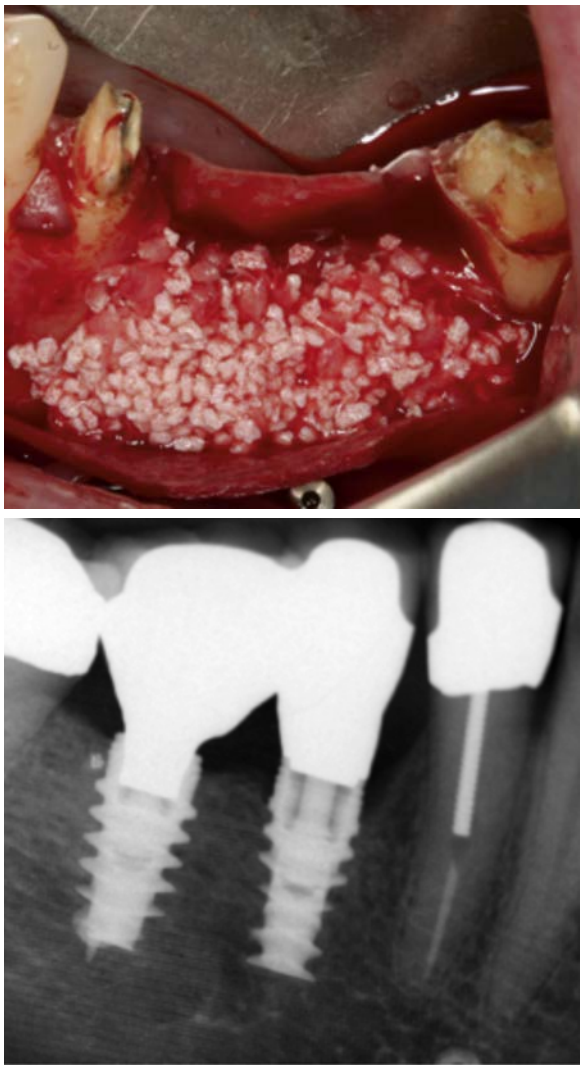
Alloplasts

Alloplastic biomaterials offer advantages in autogenous bone harvest morbidity and no disease transmission to allograft and xenografts. An alloplast with osteogenic potential will be a welcome addition to a surgeon's treatment of localized alveolar ridge defects. Conflicting opinions about the superiority of autogenous bone grafts were found in several articles, which reported that bone substitutes, whether alone or combined with other materials, were as effective as autogenous bone.[51]

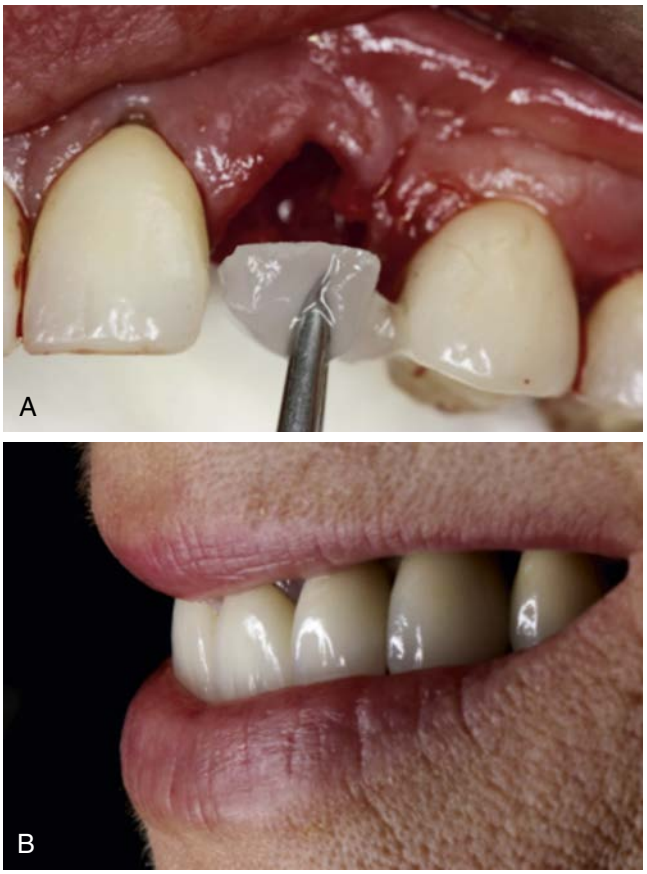
Alloplasts have the benefits of osteoconductivity and no donor site morbidity. However, alloplasts incur the risk of incomplete graft material resorption, a process that may take months to years. Alloplastic bone graft material is in essence a scaffold (Figure 28-4).

Alloplasts are synthetic biocompatible bone graft materials such as calcium phosphate (hydroxyapatite derived), calcium carbonate (coral-derived), or bioactive glass ceramics.[9] Hydroxyapatite is a synthetic bone graft, which is most used now because of its osteoconduction properties and acceptability of bone. Calcium carbonate is being used less because it is completely resorbable in a short time and makes the bone easier to break. Finally used is tricalcium phosphate in combination with hydroxyapatite, thus giving effect of both osteoconduction and resorbability. Biphasic calcium phosphate (BCP), composed of hydroxyapatite (HA) and β-tricalcium phosphate (β-TCP), is a bone graft substitute that resembles the inorganic phase of human bone tissue. The insoluble HA retains its form and structure to maintain space, while the β-TCP will stimulate new bone formation by dissolving into calcium and phosphate ions. Alteration of the HA/β-TCP ratio has been demonstrated to positively influence the substitution rate as well as the bioactivity of these materials.

Preclinical trial provides clinical and histologic evidence to support three formulations of HA/β-TCP as efficacious bone substitutes for regenerating large alveolar ridge defects to receive osseointegrated dental implants.[52] HA presents some disadvantages related to its resorption, because it is hardly absorbed, which hampers remodeling and new bone formation, resulting in poor local stability or permanent stress concentration. Currently, biphasic calcium phosphates, mixtures containing HA/β-TCP (ç-TCP or ë-TCP), are preferably used in clinical practice with varied proportions of HA and TCP because of their considerable difference in the resorption rate—HA reabsorbs very slowly



• **Figure 28-4** Alloplastic materials combined with autogenous bone grafts are used for guided bone regeneration procedures that can eventually support dental implants.



• **Figure 28-5 A,** Rh-BMP2 delivered on an absorbable collagen sponge for socket augmentation after extraction of tooth #11. **B,** Final restoration.

compared with TCP. The difference in the resorption rate influences in the osteoconductive property of these materials. TCPs are more osteoconductive than HA because of their greater biodegradability rate, and clinical and experimental studies have shown that a mixture of HA and TCP promotes intense activity of bone formation with high osteoconductivity.[53,54] However, even though the resorption rate of TCP is faster than that of HA, clinical studies that used only TCP reported the presence of TCP particles long-term postoperatively in maxillary sinus lift and mandible defects.[53-55]

One formulation of BCP (60% HA and 40% β-TCP) is being used more commercially because of its success in alveolar ridge augmentation, maxillary sinus grafting, and the treatment of implant dehiscence and fenestrations.[56] The percentage of new bone formation in human sinus augmentation procedures has ranged from 28% to nearly 38% in less than 8 months.[55,57] So BCP has been shown to be safe, biocompatible, and bioresorbable and can effectively serve as a scaffold for new bone formation. Previous studies have also shown that BCP bone substitute material can be successfully used to reconstruct large alveolar bone defects with excellent clinical and histologic evidence.

Growth Factors

Growth factors are signaling peptides involved in wound healing. Clinically, recombinant growth factors are used to accelerate the healing process.[9] More information on growth factors is detailed in a subsequent chapter. Currently two growth factors are U.S. Food and Drug Administration (FDA) approved for use in bone grafting of intraoral sites: Bone morphogenetic protein (BMP) and platelet-derived growth factor (PDGF).

BMPs are growth factors that bind to pluripotent cells and induce expression of osteoblast markers to stimulate bone formation. BMP-2 is part of a family of osteoinductive proteins that stimulate endochondral and intramembranous bone formation from mesenchymal cells in situ.[58] BMP-2 is an osteoinductive material for bone regeneration in preparation of implants that rivals autogenous bone grafts. For clinical use it is formulated as recombinant human bone morphogenetic protein-2 (rhBMP-2), which is reconstituted with sterile water and placed on an absorbable collagen sponge as the carrier (Figure 28-5, *A*). Postoperative edema is a major anticipated side effect as it is extremely

chemotactic, drawing in inflammatory cells. It is currently FDA-approved for maxillary sinus augmentation and grafting of localized alveolar ridge defects (extraction sites) in adults (see Figure 28-5, *B*). It has been used in large continuity defects, to extend or enlarge a bone graft for alveolar clefts or augment the maxillary sinus.[59,60]

PDGF aids in wound healing by promoting cellular proliferation and angiogenesis.[61] Recombinant PDGF has also been shown to reduce periodontal defects. The biologic profile of PDGF, including its ability to recruit osteoprogenitor cells, makes it particularly suited to address the skeletal defects that are seen with comorbid conditions such as osteoporosis, diabetes, and the effects of smoking.[62] The clinical success and safety that have been demonstrated with use of recombinant human PDGF (rhPDGF) in the repair of periodontal defects have led to FDA approval of rhPDGF for this indication.

Preoperative Evaluation

Bone grafting, soft tissue augmentation, and dental implant placement all require an in-depth evaluation of the patient's medical history to ensure that there are no absolute or relative contraindications to the procedures necessary to provide a successful outcome. Once the patient has been deemed medically stable to proceed with the implant therapy, the clinician must evaluate and use the appropriate biomaterials, including the proper selection of bone augmentation material, technique, and source, in addition to the specific implant type and dimension. Though the surgeon must know how to manage the complications associated with the surgical procedure and materials used, the most important factor for success is to select the most appropriate approach with the highest level of predictability and lowest risk of complication.

The proper placement and successful restoration of the dental implant is directly dependent on the alveolar bone morphology, symmetry, space, and alignment. Stark differences are apparent when an implant is placed and restored without proper attention to the alveolar bone height and soft tissue contours. To ensure graft success, the recipient site must be of good quality, with angiogenic potential, and must remain free of infection. Evaluation with adequate imaging is necessary for planning what type of graft is to be placed. Computed tomography (CT) is used for three-dimensional assessment of bony defect dimensions as well as potential intraoral donor sites. It is vital to quantify the defect as well as assess the quality of the bone from imaging, along with clinical examination.

Factors leading to suboptimal healing can be categorized as systemic or local. Systemic conditions such as advanced age, diabetes, malnutrition, immunosuppression, and tobacco use can adversely affect bone graft healing; thus it is also important to optimize the patient's medical comorbidities and nutritional status. As with wound healing, bone grafts can be compromised by any factor that extends the inflammatory phase of healing, resulting in nonunion of bone grafts, graft loss, fibroplasia, increased tissue scarring, and wound contracture. Local factors that impair graft healing include graft mobility, infection, and poor recipient bed quality. For a bone graft to succeed, it must remain immobile, maintain the reconstructed space, and be free of pressure from an overlying prosthesis. Tension-free and adequate soft tissue closure is crucial in preventing wound dehiscence and graft loss (Figure 28-6). The graft must also be permitted adequate time for healing and bone regeneration prior to implant placement.

Factors Contributing to Suboptimal Bone Graft Healing

Systemic Factors

Aging

Physiology changes with age, and wound healing may decrease with age. Older patients generally have more health problems and take multiple medications, which may interfere with or adversely affect healing. Vascularity is also often compromised, with poor perfusion, friable tissues, and potential for delayed wound healing. These factors are important to consider in the patient's overall treatment plan, especially because a large portion of patients seeking dental implant therapy are of advanced age and more likely to require bone grafting. In order to reduce the risk of poor wound healing associated with advanced age, patients should undergo preoperative optimization of comorbid conditions.[63,64] It is vital for the surgeon to review the patient's medication list, including vitamins, herbal supplements, and alternative medications. It is important to conduct preoperative medication reconciliation, as certain prescription medications, vitamins, and supplements may lead to undesired perioperative events such as increased bleeding and alter the metabolism of other medications. Nutritional status is an extremely important consideration in all wound healing, as it is with consolidation of bone grafts.[64,65]

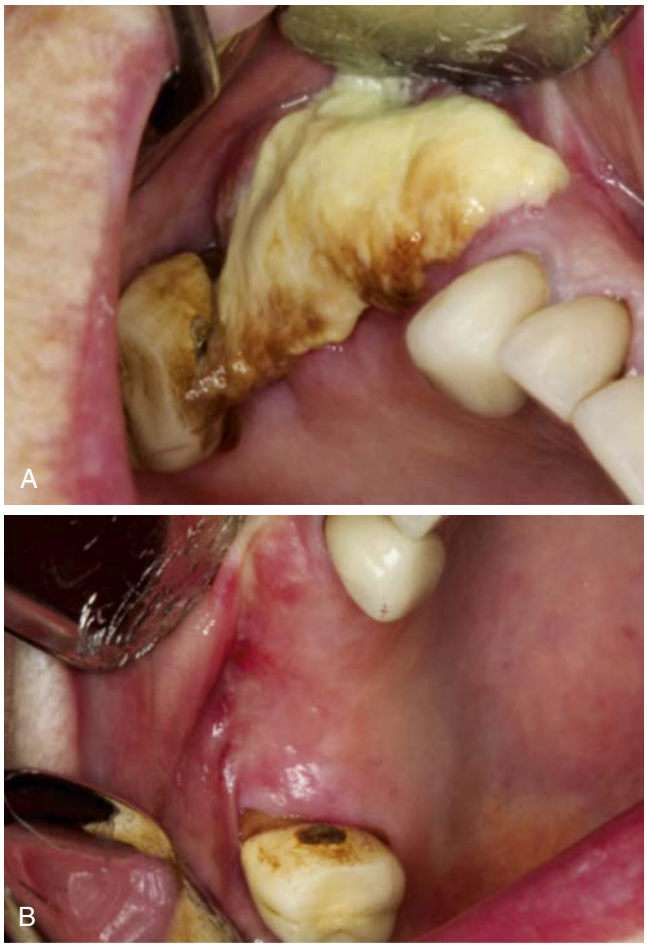
• **Figure 28-6** Wound dehiscence after 6 months of healing. A guided bone regeneration procedure was performed with xenograft and titanium reinforced non-resorbable membrane.

Diabetes

Patients with diabetes, especially those with inadequate glucose control, are at risk for compromised healing and decreased wound vascularity from microvascular disease. Poor glucose control also affects neutrophil and lymphocyte function, chemotaxis, and phagocytosis, causing greater incidence of wound infection. Release of oxygen to tissues is also reduced, as glycosylated hemoglobin has a higher affinity for oxygen than nonglycosylated hemoglobin. Further, uncontrolled blood glucose decreases red blood cell permeability and microvascular blood flow to the wound. The combination of poor cell recruitment and wound ischemia is detrimental to overall wound healing (Figure 28-7, *A*), often requiring longer healing times (see Figure 28-7, *B*).[66] Good serum glucose control is recommended to improve the likelihood of graft healing. Perioperative antibiotic therapy should be considered for diabetic patients undergoing bone grafting procedures and implant placement.

Smoking

Smoking is known to inhibit wound healing and thus is a risk factor for failure in bone grafts. Smoking tobacco causes release of nicotine, which is known to influence normal bone turnover. Nicotine affects bone metabolism by preventing vascular ingrowth and slowing the formation of osteoblasts, as well as diminishing osteoblast function during the proliferative stage and decreasing the number of osteoclasts.[67] Tobacco releases chemicals, including carbon monoxide and nitrosamine, in turn reducing oxygen delivery to peripheral tissues secondary to vasoconstriction by epinephrine and norepinephrine, causing tissue hypoperfusion and hypoxia. It also causes platelet aggregation and neutrophil dysfunction and increases collagen deposition and blood viscosity, negatively affecting wound healing.[10,64,68] Smoking has been associated with bone graft failure, as demonstrated by Lindfors and colleagues.[69] One of the main findings in this study was that smoking influenced the healing of guided bone regeneration procedures. The study evaluated 27 ridge augmentations performed with particulate autogenous bone and titanium-reinforced ePTFE membrane. Success rates of 94.7% in nonsmokers and 62.5% in smokers ($p = .031$)[69] were found. In a study by Moy and co-workers, smoking was found to increase the risk of implant failure (RR= 1.39; $p = .03$) in a cohort of 1140 implants placed.[64] The authors suggested a smoking cessation protocol prior to elective surgery, where patients should be advised to discontinue tobacco use for at least 2 weeks and should refrain from smoking until wound healing is complete.[68]



• **Figure 28-7** After sinus augmentation surgery in a poorly controlled diabetic patient, the soft tissue wound healing was significantly delayed. The combination of poor cell recruitment and wound ischemia is detrimental to overall wound healing **(A)** often requiring longer healing times **(B)**.

Local Factors

Infection

Infection is a major cause of impaired wound healing and bone graft loss.[70] Traditionally, wounds are described as sterile, contaminated, colonized, or infected. This classification depends on the mechanism of injury (surgical vs. traumatic wound) and the wound's location with respect to normal bacterial flora. In the oral cavity, surgical wounds are clean-contaminated, as they are in contact with endogenous oral and respiratory microbial flora. The bacterial burden increases in sites associated with odontogenic infection. In order to reduce the risk of graft loss, all sources of infection must be addressed before bone grafting is undertaken. A more detailed discussion of antibiotic prophylaxis in implant dentistry is found in a subsequent chapter.

Adherence to surgical principles and aseptic techniques is also crucial in the prevention of postsurgical infections and graft contamination.[70] Whenever possible, incisions should be made on intact keratinized tissue. Tissues should be handled gently to avoid crushing and compromising vascular perfusion. The recipient bed should be gently debrided free of granulation tissue and irrigated to dilute bacterial load. Bone graft particles should be kept away from saliva and other contaminants. Antibiotic solution (i.e., intravenous clindamycin, penicillin, or cefazolin) may be added to the bone graft material prior to placement. The incision should be closed primarily in a tension-free manner to avoid dehiscence, contamination of the graft, and graft loss. If needed, periosteum can be scored to allow flap advancement over the graft.

If not properly addressed, bone grafts can become infected. A high microbial burden within a surgical wound increases the host's inflammatory response to the area. Bacteria release endotoxins and metalloproteases that destroy the extracellular matrix of healing tissue and cause cell lysis. Bacterial infection and increased inflammation can result in further tissue damage and graft loss. Bacteria also compromise wound healing by competing with the healing tissue for nutrients and oxygen. Infected wounds should be addressed with adequate debridement, removal of graft particles and foreign bodies, and irrigation. Such measures decrease bacterial load and optimize host defenses. Systemic antibiotics can be administered in conjunction with incision and drainage or debridement. Whenever possible, cultures should be obtained prior to initiating empiric antibiotic therapy. Targeted antibiotic therapy should be instituted based on culture antibiotic sensitivity results. Avoidance of broad-spectrum antibiotics helps reduce the risk of developing antibiotic-resistant organisms.

Graft Mobility and Pressure

There is greater chance of graft failure if the bone graft is mobile. Nonunion results when the graft does not form bone-to-bone contact with the host bed, but instead remains bridged by fibrous tissue. Rigid fixation for onlay grafts can minimize mobility during consolidation similar to principles of repairing fractures and achieving anatomic reduction. Repeated microtrauma to a bone graft can also result in graft loss, therefore it is crucial to explain this to the patient so that any function on the grafted area is limited during consolidation. Continuous or extreme tension will produce mobility at the graft site and favor formation of cartilage or fibrous tissue rather than bone.[10,17] Excessive pressure over the bone graft can lead to bone resorption. This is usually encountered when an interim prosthesis has not been adequately relieved. Careful inspection and adjustment of the temporary prosthesis is essential to prevent resorption.

Vascular Compromise

Periosteal preservation during bone graft has been shown to improve graft survival in the craniofacial region. This attests to the importance of early revascularization in bone graft survival, as it is believed that the periosteum facilitates this process.[71] Graft orientation is also crucial to survival and is maximized when the graft's cancellous surface abuts the freshened edges of the host bone and the periosteal surface is in contact with the soft tissues.[72]

Bone Graft Biology and Histology

MICHAEL D. ROHRER, HARI S. PRASAD

Introduction

The need for bone augmentation and bone growth–enhancing strategies is great in both medicine and dentistry. In the maxillofacial region, the need can be the result of trauma, postsurgical reconstruction, loss of alveolar bone due to periodontal disease, or the need to increase the amount and quality of bone to accept an endosseous implant. For many years the technique accepted as the gold standard was the harvesting of autologous (autogenous) bone and transplanting it to the needed recipient site.[1,2] Although highly desirable biologically, harvesting autologous bone from a patient at the time of maxillofacial bone augmentation presents several problems. The anatomic site that provides the most bone is the iliac crest. Occasionally other long bone areas are used. This results in a second operation and the accompanying morbidity. Autologous bone can be harvested from the jaws, but the yield is often too low to be satisfactory for augmentation in other parts of the jaws.

Concerns about the morbidity of additional surgical procedures to obtain autologous bone or stem cells and the fear of transferring infectious organisms from animal or human products[3] have led to the development of a wide variety of biologic and synthetic materials to accomplish bone augmentation.[4] In this chapter we will discuss the various materials available, emphasizing the histologic findings of placing these materials in the maxillofacial region.

Classification of Bone Substitute/ Augmentation Materials

A graft is any tissue or organ used for implantation or transplantation. An implant is an object or material partially or totally inserted or grafted into the body for prosthetic, therapeutic, diagnostic, or experimental purposes. Although many of the materials used to augment bone could be called implants, we do not use that term because *implant* in dentistry is strictly defined as an alloplastic material implanted into the oral tissues beneath the mucosal or periosteal layer or within the bone to provide support and retention to a partial or complete denture.

The following definitions are needed for an understanding of grafted or implanted materials:

- Autologous (autogenous)—originating within the individual itself.
- Allogeneic (allogenic)—tissues that are from the same species but a different individual (genotype). Types of donors are cadaveric, living related, and living unrelated.
- Alloplastic—an inert or synthetic foreign material.
- Xenogeneic (xenogenic)—tissues that are from a different species.
- Biomaterial—any material, synthetic or natural, that can be used as a system or part of a system that treats, augments, or replaces any tissue, organ, or function of the body.
- Biologic (biological)—medicinal preparations made from living organisms and their products.

Allogeneic and xenogeneic materials could be considered a graft (tissue), but more frequently they are considered as biomaterials. It is often easier, however, to refer to them as allografts or xenografts. Generally xenografts have been treated in some manner to change the character of the bone, for instance with heat so that they are considered a ceramic. A reasonable classification of bone substitute and augmentation materials is the following, which restricts the term "graft" to living tissue.

Bone Grafts, Biomaterials, and Biologics

Grafts

Autologous bone; fresh/frozen
Autologous stem cells
Allogeneic—not used in dentistry
Xenogeneic; fresh/frozen—not used in dentistry
Osteoblast cell constructs (experimental)

Biomaterials

Bone derivatives (processed cadaver bone)
    Allogeneic bone implants (demineralized and mineralized freeze-dried allogenic bone; deproteinized allogenic bone)

Xenogeneic bone implants (deproteinized and heat-treated bovine bone mineral)
Bone substitutes (alloplasts, synthetic bone)
Ceramics
β-Tricalcium phosphate (β-TCP)
Hydroxyapatite (HA)
Ca_2SO_4 (plaster of Paris)
Calcium phosphate cements
Bioactive glass
Coral and marine algae derivatives
Polymers

Biologics

Matrix factors (fibronectin, vitronectin, thrombospondin-1, amelogenins)
Growth factors (PDGF, TGF-β, IGF-1, VEGF)
Differentiation factors (BMP-2, OP-1/BMP-7, GDF-5)
Peptides (thrombin peptide, TP508, P-15)
Small molecules (PGE receptor agonists)
Platelet-rich plasma

Classification of Bone Growth Enhancing Materials Related to the Influence on Bone Growth

Materials used to enhance bone growth are classified as osteogenic, osteoinductive, or osteoconductive.[5,6]

Osteogenic: An osteogenic substance is one that is derived from or composed of any tissue that is concerned in the growth or repair of bone. Therefore, there must be living osteogenic tissue, either viable osteoblasts or stem cells capable of differentiating into osteoblasts, which can only come from autologous bone or autologous stem cells.

Osteoinductive: An osteoinductive substance stimulates osteogenesis. This is primarily restricted to biologics, not biomaterials. Some authors have proposed that residual substances in biomaterials, such as allogeneic or xenogeneic bone, or alloplastic substances are osteoinductive. However, this is very unlikely and difficult to differentiate from osteoconduction.

Osteoconductive: This generally refers to a biocompatible resorbable or nonresorbable material that aids in the spatial growth of bone. Most frequently this is thought of as a scaffold process whereby the bone can be aided in going in a desired direction from one place to another, generally filling a void, by a "stepping stone" effect.

The optimal outcome of any bone enhancement strategy is the formation of vital cancellous bone. Bone physiology will not tolerate dense cortical bone thicker than is normal for a particular area. Clinicians often want the result of bone enhancement to be type I bone, described as "solid oak." This type of bone can only be found in the anterior mandible where the lingual and facial cortical bones are so close that there is no apparent cancellous bone. The optimal outcome is cancellous bone characterized by trabeculae of sufficient girth and a typical interconnected architecture. The quality of the three-dimensional interconnected architecture is described in two-dimensional analysis as "connectivity" of the trabeculae. When histologically analyzing new bone formation, one has to be tolerant of some "free floating" trabeculae, and numerous trabeculae that in two dimensions do not appear to be continuous with other trabeculae. However, the experienced observer can judge how much two-dimensional connectivity translates to a good interconnected architecture of healthy cancellous bone.

Histologic Examples of Different Bone Augmentation Techniques

Autologous Bone

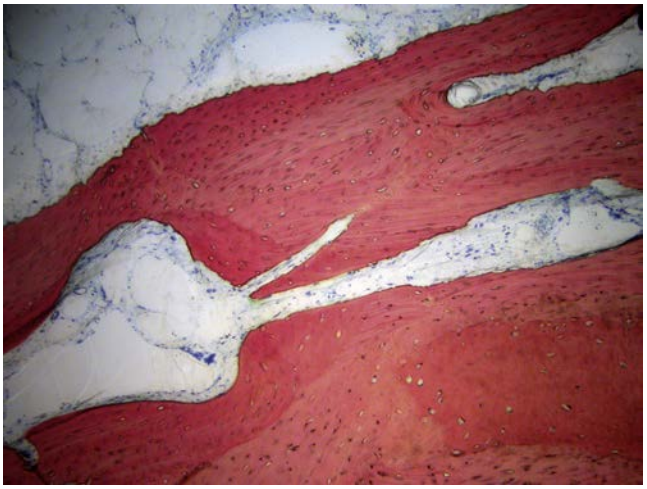
Influence on Bone Growth: Osteogenic

Although considered the "gold standard" of bone augmentation techniques, in histologic samples, autologous bone is difficult to demonstrate. We feel the main reason is that the autologous bone is devitalized at the time of harvest. The possible surviving osteocytes and progenitor cells may contribute almost immediately to new bone formation. The calcified portion of the autologous bone may be quickly incorporated into the new bone and revitalized with neovascularization and rapidly remodeled or rapidly resorbed. Core specimens in areas of autologous bone grafting lack areas of very mature lamellar trabeculae of bone in the resulting new bone formation. The possibility exists that the calcified portion of the devitalized autologous bone is very quickly resorbed by osteoclasts during active and rapid osteogenesis. Figure 29-1 shows an example of a core sample of autologous bone grafting.

Autologous Adult Stem Cells

Influence on Bone Growth: Osteogenic

Autologous stem cells are progenitor cells for bone retrieved by bone marrow aspiration. Complications have been associated with autogenous bone-harvesting procedures. It has been



• **Figure 29-1** Autologous bone graft particles (lighter stain) surrounded by newly formed bone (darker red stain). (Stevenel's blue and Van Gieson's picro fuchsin × 200.)

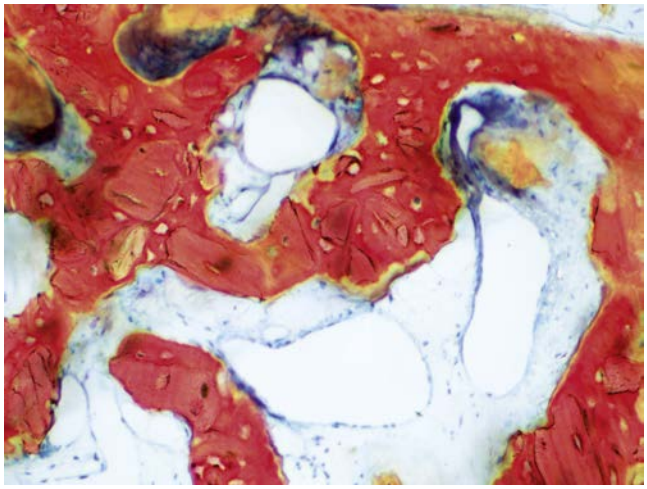
suggested that an alternative approach, grafting with autogenous bone marrow aspirate, may work as well as autologous bone grafting with less comorbidity.[7-11] Bone marrow provides a rich source of adult stem cells as well as growth factors that facilitate osteogenesis. Mixed with a resorbable matrix or scaffold, bone marrow aspirate has the potential to reconstitute various bony defects in the mouth to reconstruct the severely atrophic maxilla and mandible. Figure 29-2 shows examples of core samples of autologous adult stem cell grafting.

Allogeneic Bone

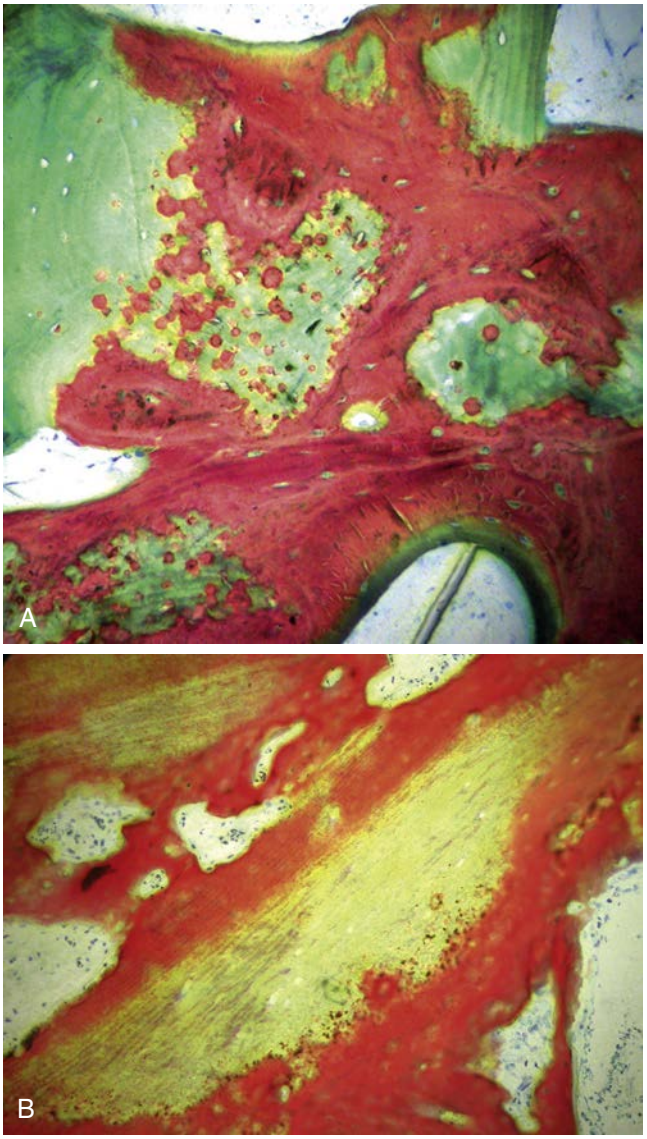
Influence on Bone Growth: Osteoconductive

Demineralized allogeneic bone has been used for a very long time as an osteoconductive material to increase bone formation in areas requiring enhanced new bone formation and was referred to as bone formation by autoinduction.[12] In humans it is very important to have the demineralized allogeneic bone placed in an area of potential bone formation. In our experience the osteoconductive properties of demineralized allogeneic bone are enhanced in areas where vital bone is very close by. Early concepts of the fate of demineralized allogeneic bone included very rapid resorption and replacement by new bone formation. It has been very clear to us for decades that two things can happen to the demineralized allogeneic bone. First, the osteoconductive capabilities of the demineralized allogeneic bone encourage new bone formation around the periphery of the particles of demineralized allogeneic bone. When the particles are close enough together, the new bone bridges among the particles, forming a cancellous bone pattern. This is the desired outcome of any nonresorbable particulate introduced to enhance bone growth. Second, the best result is if the demineralized allogeneic bone can then become recalcified or "reossified." The apparent process is that the demineralized bone matrix in the right location and in the milieu of possible bone formation becomes revascularized. Following revascularization, the demineralized matrix is repopulated by stem cells that take up residence in the empty lacunae and transform into osteocytes. Once the cells are functioning as osteocytes, they control the calcification of the collagen matrix. This recalcification takes place in the collagen matrix of the previously demineralized bone. Polarized images prove that the previously demineralized bone must be totally "reossified" before remodeling can occur. Figure 29-3 shows examples of core samples of demineralized allogeneic bone and new bone formation.

Mineralized allogeneic bone is a relatively recent addition to the armamentarium in the attempt to enhance bone

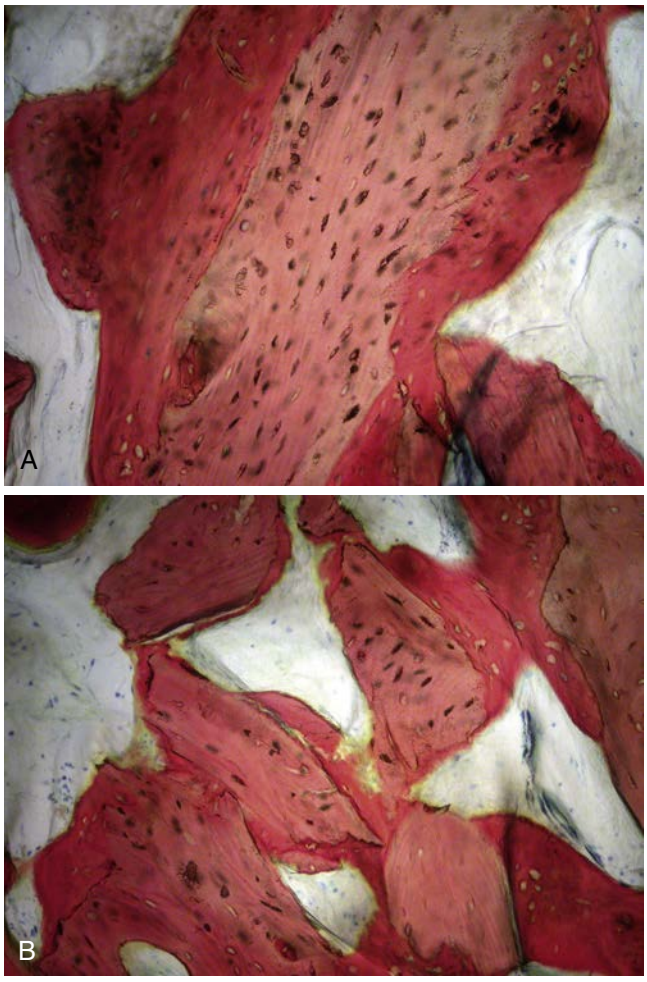


• **Figure 29-2** A combination of mineralized allograft and bone marrow–derived stem cells resulted in this cancellous bone pattern. Small, irregular particles of mineralized allograft are surrounded by new bone formation. Green-staining osteoid is produced by osteoblasts that surrounds the mineralized allograft and transforms into red-staining bone. (Stevenel's blue and Van Gieson's picro fuchsin, 200×.)



• **Figure 29-3** **A,** The demineralized allograft stains green, and the lamellar pattern of the bone and the empty lacunae are evident. Droplet calcification of this matrix occurs with eventual recalcification of the demineralized matrix. Osteocytes repopulate the empty lacunae as the matrix reossifies. (Stevenel's blue and Van Gieson's picro fuchsin, 200×.) **B,** Particles of green-staining demineralized allograft are becoming recalcified. Simultaneously, new bone is forming bridges among the particles, which will result in a pattern of cancellous bone. (Stevenel's blue and Van Gieson's picro fuchsin, 200×.)

growth.[13-16] This bone is deproteinized to remove fat, cells, and antigens and to inactivate pathogens, but no attempt is made to remove the calcium from the collagen matrix of the bone. The product is supplied as both cortical and cancellous particles of various sizes. The reaction in vivo is different than that for demineralized allogeneic bone. There is no recalcification step, and the particles appear to be very osteoconductive and very quickly become part of a new bone matrix. Being rapidly assimilated into the newly formed bone, the mineralized allogeneic bone seems to become revascularized and repopulated with osteocytes very quickly. This results in rapid remodeling. Histologic observation of this material reveals a relatively good amount of new bone formation and minimal recognizable allogeneic bone within a short time, much faster than is seen with demineralized allogeneic bone. Figure 29-4 shows examples of core samples of mineralized allogeneic bone and new bone formation.



• **Figure 29-4** **A,** The light red–staining bone is mineralized allograft surrounded by darker red–staining new bone formation. Irregular outlines of the mineralized allograft being transformed into vital bone can be seen. This transformation to vital bone takes place relatively fast once the mineralized allograft is incorporated into a mass of newly formed vital bone. (Stevenel's blue and Van Gieson's picro fuchsin, 200×.) **B,** Particles of light red–staining mineralized allograft being surrounded by green-staining osteoid formed by osteoblasts. The osteoid becomes immature bone that bridges among the mineralized allograft particles, resulting in a cancellous bone pattern. (Stevenel's blue and Van Gieson's picro fuchsin, 100×.)

Xenogeneic Bone

Influence on Bone Growth: Osteoconductive

Xenogeneic bone is generally bovine derived. There is a great deal of interest recently in equine derived bone. This bone is treated to render it a ceramic. The level of the sintering temperature determines the physical properties of the resulting calcium phosphate material. Low temperature sintering maintains the structural morphology of the bone (Figure 29-5,*A*). High temperature sintering converts the bone entirely into a ceramic, totally losing the natural structure of the bone (see Figure 29-5,*B*). Xenogeneic bone remains in place and is resorbed extremely slowly, if at all. The goal when using xenogeneic bone is to have it act as a scaffold in osteoconduction and become part of the cancellous bone pattern.[17-20] Although the sintered xenogeneic bone does not remodel, the new bone formation associated with it does remodel to accommodate the insertion of a dental implant. Xenogeneic bone is extremely biocompatible, and histologic examination for several decades has not shown adverse effects when the titanium implants are in direct contact with the residual xenogeneic bone. Figure 29-5 shows examples of core samples of xenogeneic bone and new bone formation.

Alloplastic Implants

Influence on Bone Growth: Osteoconductive

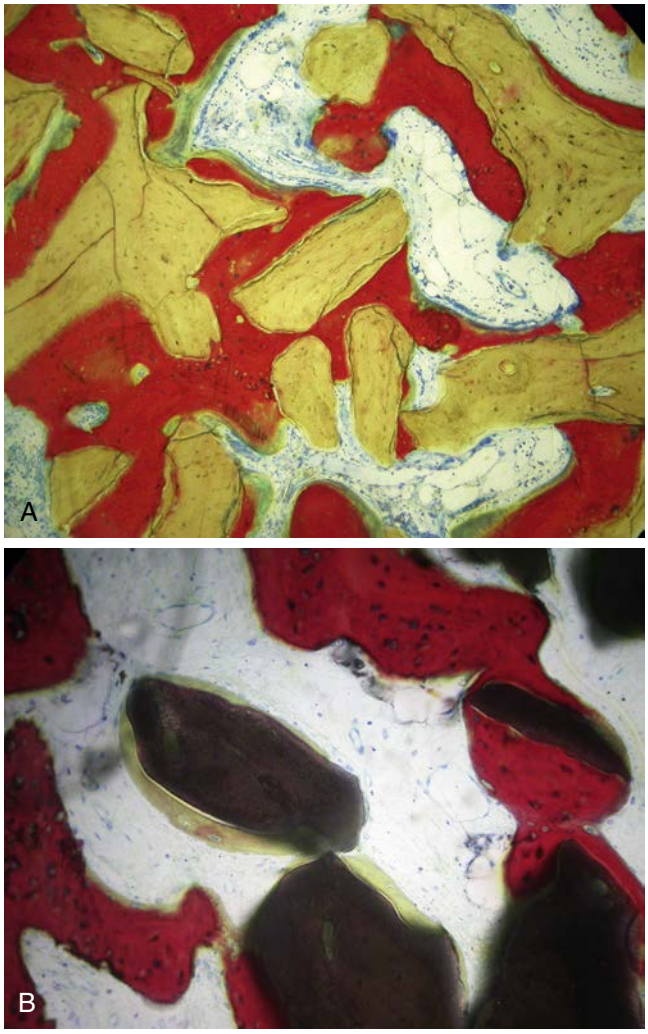
A large group of substances considered bone substitutes, synthetic bone, or alloplastic implants are used in attempts to augment or enhance bone growth. They can generally be grouped into ceramics, polymers, and coral and marine algae derivatives. In the ceramics category, β-tricalcium phosphate (β-TCP),[21] hydroxyapatite,[22] and calcium phosphate cements are calcium phosphate products, perhaps owing their success to the relationship to bone as a calcium phosphate tissue.[23-26] Ca_2SO_4 (plaster of Paris)[27] has been used for years and is quite successful. Bioactive glass seemed to have good potential some years ago but does not seem to be used very frequently at this time.[28,29] Bioactive glass has the advantage of forming a porous, gel-like calcium phosphate, hydroxyapatite-like substance on the surface of the glass when subjected to a physiologic environment. The chemical formula and the size and shape of the bioactive glass particles seem to be very critical in the formation of bone along the surface of the glass. Coral has been used because it is a natural hydroxyapatite substance, often with a geometry and microarchitecture thought to be advantageous for bone growth enhancement. The use of calcified marine algae has also been advocated.[30] Histologic examination shows osteoconductivity but also calcification within the small cell-like structure of the algae. In our experience over the years, polymers have not been very successful as bone augmentation or bone enhancement materials. Histologic specimens have often shown decreased bone formation in the area of polymer

placement. Figure 29-6 shows examples of core samples of alloplastic implants and new bone formation.

Biologics

Influence on Bone Growth: Osteoinductive

Biologics are medicinal preparations made from living organisms and their products. In general, these can be referred to as growth factors. The growth factor that has been receiving the most attention is a group called bone morphogenetic proteins (BMP).[31] The rationale is to mimic the natural osteoinduction through proteins that send signals among cells and enter the cell nucleus where osteoblast differentiation genes are controlled. The goal is to cause bone to be induced to grow. Often clinicians wish to induce bone growth without introducing osteoconductive materials that may or may not resorb and may, in fact, impede the natural or stimulated growth of bone into an area. A host of matrix factors, growth factors, differentiation factors, bone growth peptides, and plasma rich in platelets (in order to get platelet-derived growth factor, PDGF) have been used. In our experience with histologic examination of attempts to use these various biologics, the method of delivery and the concentration of the biologic are critical. Our laboratory has had the most experience with rhBMP-2,[31] P-15 peptide,[32,33] and platelet-rich plasma.[34]



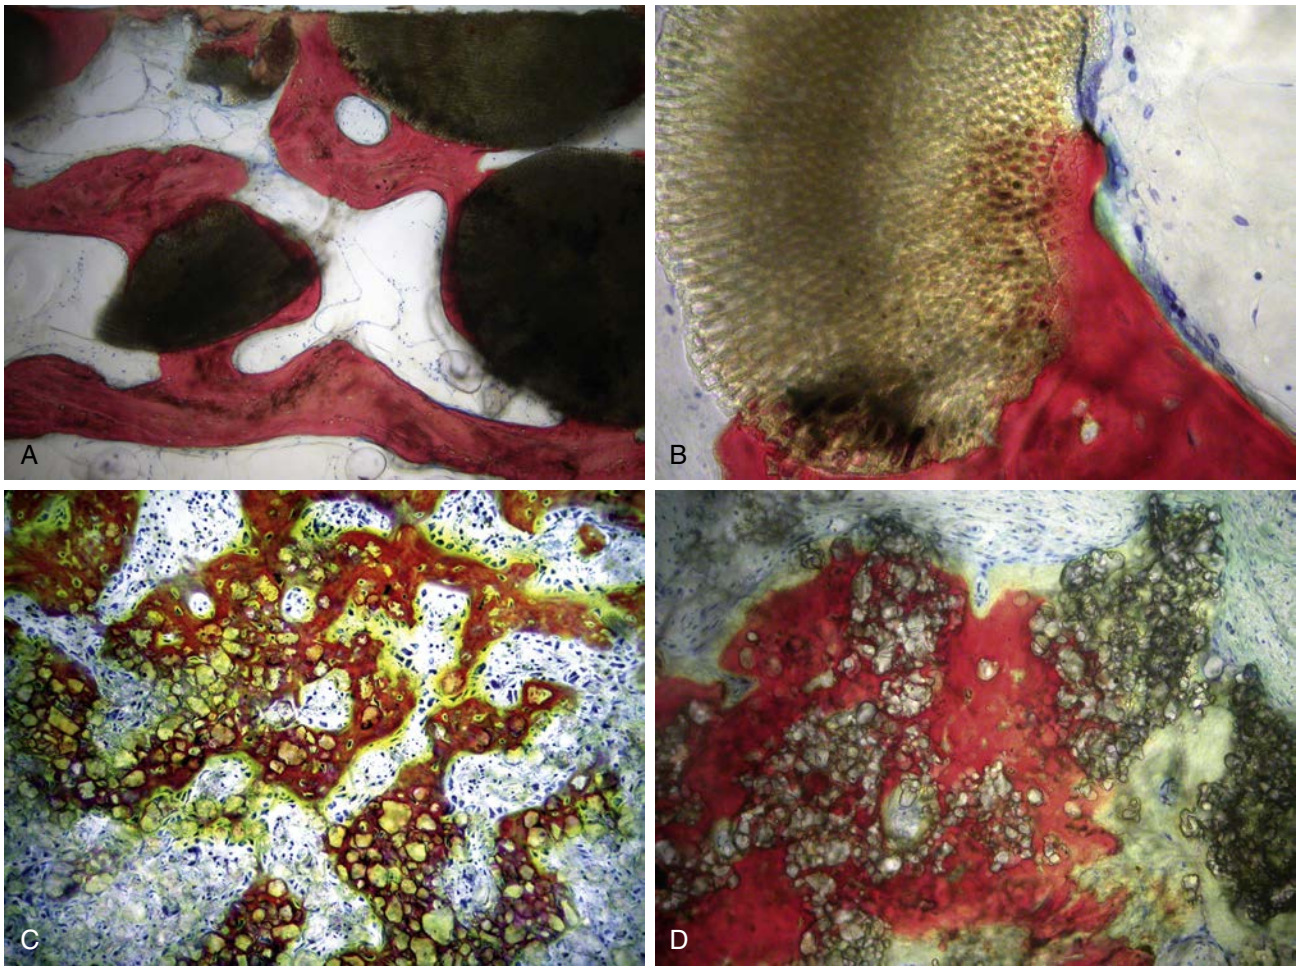
• **Figure 29-5** **A,** Particles of bovine-derived xenograft are surrounded by new bone formation that bridges among the particles, resulting in a dense cancellous bone pattern. A rim of green-staining osteoid lined by osteoblasts can be seen on the surface of the new bone. (Stevenel's blue and Van Gieson's picro fuchsin, 100×.) **B,** Bovine-derived xenograft ceramic being surrounded by green-staining osteoid that calcifies and becomes bone. The osteoblasts seen entrapped in the osteoid are now considered osteocytes and will control the biochemical activities that will result in calcification of the osteoid matrix. A slight red color around the osteocytes in the osteoid surrounding the xenograft particle in the center of the image is an example of this. (Stevenel's blue and Van Gieson's picro fuchsin, 200×.)

Factors Involved with Poor Results

Simply choosing a bone augmentation strategy or a particular material because of intensive literature research, promotions of manufacturers, a lecture from a clinician on the circuit, or suggestions from a colleague will not guarantee success. We are often asked, "There are so many different bone grafting materials—what is the best for me to use?" Many factors regarding the patient and the clinician influence the outcome. We have witnessed greatly disparate results from the same excellent clinicians using the same material. Several new materials showed dismal histomorphometric results when first used clinically and examined histologically. This was often followed by very rapid improvement, which may have been due to technique adaptations or improvements, not changes in the formulation of the materials. Most causes of poor results cannot be discerned histologically. However, a common factor noted histologically is overpacking. This appears to cause lack of bone formation due to an inability of granulation tissue to fill the spaces among the particles of graft or biomaterial. The granulation tissue contains the vascularity, stromal cells, and bone progenitor cells needed to form bone. In these cases the introduced material is truly "osteo-obstructive" rather than "osteoconductive" (Figure 29-7). Another problem noted histologically is the failure to place the graft or biomaterial within the area where bone will form. Osteoconductive materials cannot make bone form in an area such as gingiva and submucosa superficial to the area where bone would normally occur. An exception to this is a technique of forming a protective area by providing a "tent," whereby an increase in the actual height of maxillary or mandibular alveolar bone can be accomplished.[35-37]

Evaluation of Bone Augmentation Procedures

Bone augmentation and enhancement strategies can be evaluated clinically by visualization, measurement, radiography, and ultimate success or failure of dental implants placed in the area of augmentation. However, the best



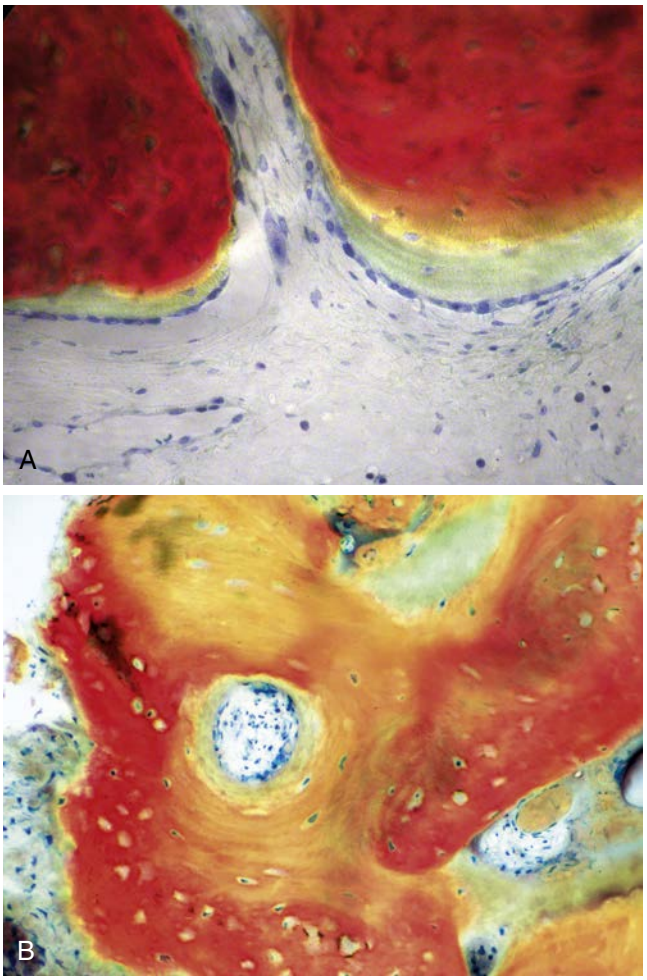
• **Figure 29-6** **A,** New bone formation around particles of mineralized natural marine algae has formed an excellent cancellous bone pattern with trabeculae of good size and connectivity. The bone marrow is delicate and non-inflamed. (Stevenel's blue and Van Gieson's picro fuchsin,100×.) **B,** The new bone formation associated with this particle of mineralized natural marine algae exhibits calcification of the fine, regular cellular pattern of the algae. The dark blue–staining osteoblasts have deposited bright green–staining osteoid. (Stevenel's blue and Van Gieson's picro fuchsin, 200×.) **C,** New bone forms a cancellous network as it forms around particles of calcium sulfate. Plump osteoblasts line the trabeculae. This slightly polarized image emphasizes the osteoid being produced by the osteoblasts that is becoming cancellous bone. (Stevenel's blue and Van Gieson's picro fuchsin, 100×.) **D,** New bone forms around particles of calcium sulfate. Osteoblasts form green-staining osteoid that engulfs the calcium sulfate and matures to calcified bone. The calcium sulfate will totally disappear from the resulting bone formation. (Stevenel's blue and Van Gieson's picro fuchsin, 200×.)

• **Figure 29-7** Core specimen of alloplastic graft showing overpacking resulting in no bone formation. (Stevenel's blue and van Gieson's picro fuchsin, 25x.)

way to evaluate the efficacy and success of osteogenic, osteoinductive, or osteoconductive strategies is to histologically evaluate bone from the area of interest. In order to evaluate all of the possible materials, and especially to differentiate between bone and demineralized allogeneic bones, the bone must be examined histologically without subjecting it to acidic decalcification. Although properly called mineralized specimens, because the standard method of microscopically examining bone for more than 100 years has been decalcification, the common designation is non-decalcified specimens. Additionally, numerous materials either cannot be sectioned even if the bone is decalcified, or, because they are calcium based, will disappear upon decalcification. Several methods have been

adapted from mineralogy research or have been specifically developed in order to produce tissue sections of calcified material capable of being examined with light microscopy. Professor Dr. (mult.) Karl Donath at the University of Hamburg, Germany, invented a system that was further refined with his help by the EXAKT company in Norderstedt, Germany (Donath/EXAKT Technique).[38,39] With this technique, samples may include titanium, ceramics, calcified material, polymers, glass, or almost any traditionally non-sectionable material, and thin sections capable of light microscopic examination can be routinely produced. Staining techniques have been used over the years by bone researchers in order to identify different areas of bone such as osteoid, different maturity levels, and growth patterns. For many years our laboratory has used and has modified Stevenel's blue and Van Gieson's picro fuchsin stains so that they are the most helpful in differentiating osteoid and demineralized bone from mineralized bone, and qualitatively differentiating immature bone from mature bone. The different staining colors and qualities are striking, so that computer image analysis is improved. All of the photomicrographs in this chapter are of bone sections stained in this manner (Figure 29-8). Polarization examination and vital staining is much more successful with non-decalcified sections. Stain introduced into a living organism (vital, or in vivo staining) in both humans and animals can determine the rate and precise location of bone growth. More stains are available for animal studies than are acceptable for humans, and frequently specimens are triple or quadruple labeled (Figure 29-9). Polarization is most useful for determining whether the bone is mature (lamellar) or immature (woven) (Figure 29-10).

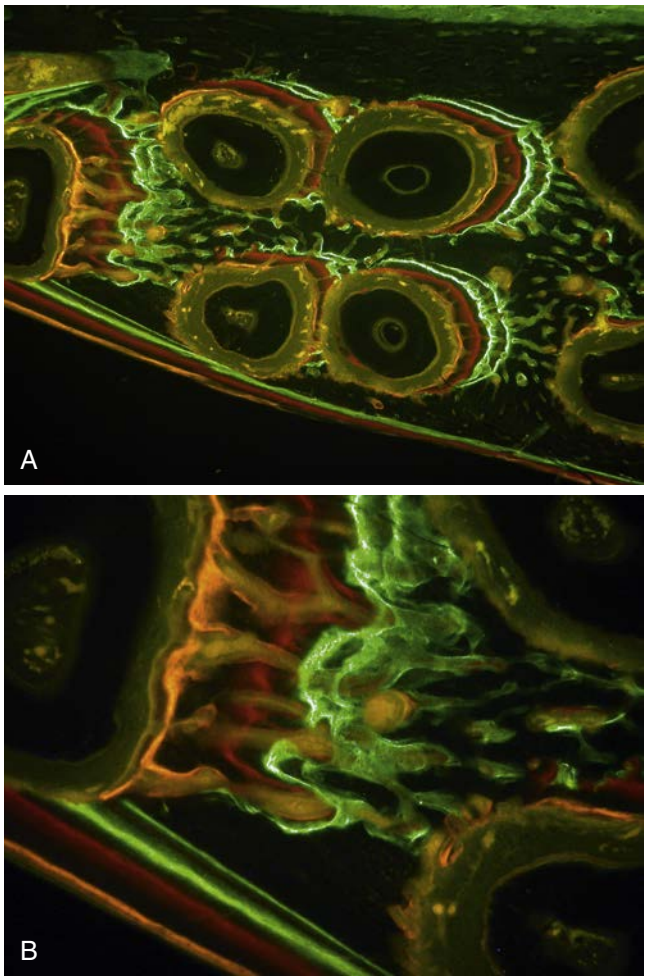
Histomorphometric analysis is the method of quantification of various components in a bone sample. Numerous computer analysis-histomorphometric programs are available, including NIH Image, Bioquant, OsteoMeasure, Quantimet 720, and Morphomet. Outside of research, the major use for histomorphometric analysis is the management of osteoporosis. We prefer the accuracy and ease of use of NIH Image combined with Adobe Photoshop. In a non-decalcified bone sample we can differentiate and measure BIC (bone-implant contact), total bone, vital and nonvital, mineralized and demineralized, bone marrow, osteoid, non-bone grafts, and biomaterials. The histology slides are two-dimensional, so one can only measure area. The more sections examined, the closer one comes to measuring volume, which is the goal and the assumption when bone and biomaterial percentages are reported and compared in the literature. Micro–computed tomography (micro-CT) is beginning to become available, and with the numerous "slices" available, nearly three-dimensional analysis of small specimens is possible. Micro-CT together with histology and histomorphometric analysis will give a very accurate picture of the quantity, identity, and quality of material in augmented bone areas.



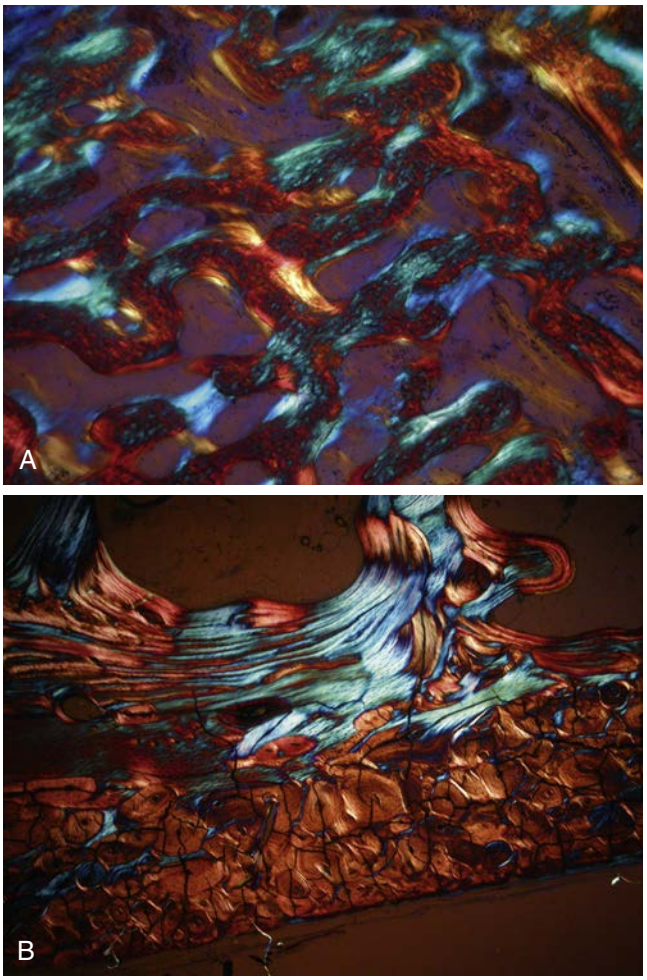
• **Figure 29-8** **A,** The advantage of non-decalcified sections and Stevenel's blue and Van Gieson's picro fuchsin stains is that the osteoid stains a dramatically different color from calcified bone. Calcified bone stains different colors depending on the maturity of the bone. In this image the transition from uncalcified osteoid to calcified bone is seen through color changes from green to red. The dark blue–staining osteoblasts as well as other cells of the delicate bone marrow can be easily identified. The strikingly different colors make computer image analysis easier. (Stevenel's blue and Van Gieson's picro fuchsin, 400×.) **B,** This image of very immature bone shows the advantage of non-decalcified sections and Stevenel's blue and Van Gieson's picro fuchsin stain. The osteoid stains green, the osteoblasts stain dark blue, and the bone stains progressively more red as it matures. Osteocytes are easily seen in the lacunae of the very immature bone. (Stevenel's blue and Van Gieson's picro fuchsin, 200×.)

Advantages and Limitations of Human Bone Core Specimens

The ability to secure and analyze human specimens of bone-augmented areas has clear advantages but numerous limitations in comparison with animal experimental specimens. The most obvious advantage is the ability to study the reaction of human bone to different bone augmentation strategies in the exact areas that bone augmentation and implant placement will take place, in patients who



• **Figure 29-9 A,** This cross section of a rat molar being moved orthodontically shows quadruple labeling with vital stains. The amount of bone formation per unit time can be determined with vital staining. (Fluorescent stains excited by ultraviolet light, 200×.) **B,** The different pattern of cortical versus cancellous bone formation is readily seen in this very high power image of a rat maxilla. (Fluorescent stains excited by ultraviolet light, 400×.)



• **Figure 29-10 A,** This is a very immature network of newly formed cancellous bone. Polarization shows a "woven" or "basketweave" pattern. The different colors are only indicative of the pattern of the light wave direction resulting from the polarization filter. Polarizing filter and (Stevenel's blue and Van Gieson's picro fuchsin, 100×.) **B,** This is an example of polarization of very mature bone exhibiting lamellar bone. Cortical haversian bone consisting of multiple osteons is seen at the bottom and trabecular bone at the top. The different colors are only indicative of the pattern of the light wave direction resulting from the polarization filter. (Polarizing filter and Stevenel's blue and Van Gieson's picro fuchsin, 100×.)

are actually undergoing that treatment. The fortuitous situation of bone needing to be removed (which would ordinarily be discarded) in the creation of a pilot hole for implant placement creates an excellent opportunity for human-based clinical research. An immediate limitation is that the outside diameter of the trephine drill that will obtain the specimen must be equal to or less than the diameter of the implant pilot hole. This size is often less than ideal. The biggest disadvantage is that the area of bone augmentation, often an extraction socket or a sinus lift, is not a critical size defect. Defects of a size that will not heal during the lifetime of the animal may be termed critical size defects. Critical size defects have been established in the calvaria of rats, rabbits, and dogs.[27,40,41] Wikesjö has developed a critical size defect in canines related to testing bone growth related to implants.[42] However, critical size defects have not otherwise been established in mandibles of dogs and monkeys.

Autogenous Bone Grafting for Dental Implants

CRAIG M. MISCH

Introduction

Autogenous bone has long been considered the gold standard of graft materials. It has earned this distinction from both a historical and biologic perspective.[1] Autogenous bone has been used for many years in oral and maxillofacial reconstruction including trauma repair, preprosthetic surgery, and repair of mandibular discontinuity or ablative defects. The use of autogenous bone grafting for dental implants was originally researched by Branemark and colleagues.[2] Early studies focused on the use of iliac bone grafts in the treatment of the edentulous atrophic maxilla and mandible.[3] As implant treatment became more widely used, clinicians realized the need for bone augmentation to place implants in prosthetic-driven positions. Over the years numerous techniques have been used for implant site development. The utility of autogenous bone has been well documented for use in guided bone regeneration, block bone grafting, interpositional grafting, particulate grafting with titanium mesh, and sinus bone augmentation. Alternative donor sites to the ilium have been evaluated, including the calvarium, proximal tibia, and intraoral harvest from the maxillofacial region. Autogenous bone can be used in several forms, including cancellous marrow, particulate graft, or cortical and corticocancellous blocks.

Autogenous bone grafts offer several advantages over bone substitutes. Autogenous bone has superior biologic qualities compared to osteoconductive bone substitutes. Viable bone-forming cells transplanted with the graft, such as osteoblasts and mesenchymal stem cells, can actively form new bone. Bone morphogenetic proteins found in the graft recruit and induce pluripotent cells to become osteoblasts. The healing time of autogenous bone grafts is shorter than that of bone substitutes.[4] This permits earlier implant placement and shorten treatment length. Implants can usually be placed after only 4 months of graft healing. In addition, the newly formed bone is often of superior quality. This is especially noted with cortical or corticocancellous block grafts compared to guided bone regeneration using bone substitutes. Denser bone quality can shorten implant healing times and provide improved implant stability. This can allow one-stage implant healing or the option of immediate implant loading. Patients will accept the use of their own tissue and may object to using cadaver bone or products derived from animal sources. From an economic perspective, autogenous bone lowers overhead costs for the surgeon. The inherent disadvantages of using autogenous bone must also be considered. It does require additional clinical time to procure bone, especially when remote donor sites are used. There can be added morbidity from the bone harvest procedure. There are also limitations on the amount of bone that can be harvested from a particular donor site. Donor sites such as the calvarium and iliac crest usually require the use of a hospital operating room unless the surgeon's office has been designed for these more advanced procedures. General anesthesia or intravenous sedation is often necessary for patient comfort and safety. However, most of these augmentation procedures can be done in an outpatient setting and do not require hospitalization of the patient.

Advancements in biologic engineering will produce alternatives to autogenous bone that may very well exceed existing clinical outcomes and replace traditional indications for its use.[5,6] However, the increased costs of technology can be an obstacle to routine use of new products. Autogenous bone grafting offers a well-proven and predictable method of defect repair and ridge augmentation for dental implant placement.

Bone Biology

Autogenous bone is the only graft material with osteogenic properties that can directly form bone. Bone cells, in higher concentration in the cancellous marrow, that survive transplantation can produce new bone. In addition, bone

morphogenetic proteins (BMPs) and growth factors present within the autograft induce bone formation in the surrounding tissues.[7] BMP is chemotactic for osteocompetent mesenchymal cells. These cells proliferate and are transformed into osteoblasts through osteoinduction. The cortical portion of the autogenous bone graft acts as an osteoconductive scaffold for bone formation.[8] The graft is remodeled and replaced with new bone over time. Free autogenous bone grafts must become revascularized in order to incorporate. The cancellous portion of the graft revascularizes faster than the cortex.[9] The denser cortical bone revascularizes through its existing haversian system.[9] In addition, cancellous bone grafts heal differently than do cortical grafts. Bone is directly deposited along the existing trabeculae of the cancellous graft.[9] Thereafter, the trabeculae are resorbed, leaving only the new formed one. Cortical bone grafts incorporate through creeping substitution.[9] Cutting cones remodel the graft through the existing haversian system of the cortical graft. The graft is slowly resorbed as new bone is formed. This results in an admixture of grafted and new bone that eventually completely turns over (Figure 30-1).

The subject of embryologic origin of autologous bone grafts has received much attention regarding graft incorporation and resorption. Membranous bone grafts, from the mandible or calvarium, reveal less resorption than grafts from endochondral sites, such as the iliac crest.[10-13] More recent studies examining graft loss have challenged the hypothesis of embryologic origin and emphasize the microarchitecture of the bone used for grafting.[8,14] Ozaki and Buchman found that regardless of their embryologic origin, cortical bone grafts reveal less volume loss than cancellous bone grafts. Cancellous grafts require protection, such as titanium mesh or a barrier membrane, to maintain their volume for onlay augmentation. Cortical bone grafts from the mandible exhibit minimal resorption and maintain their dense quality, making them ideal for onlay augmentation prior to implant placement[15] (Figures 30-2 and 30-3).

Following harvest, the bone graft should immediately be stored in sterile saline to maintain cell vitality, and minimal time should elapse between graft procurement and placement.[16] The fewer number of viable cells contained in cortical grafts may be less significant in new bone formation. If block grafts or trephine cores are milled, the size of the particles should be limited. Some burrs or mills pulverize the bone graft into a powder or paste. Whereas bone powder is quickly resorbed, slightly larger particles are more osteoconductive and act as a better scaffold for bone formation.[17-19] The other potential disadvantages of bone particles collected through a suction trap include the negative effects of heat generated in bone preparation, desiccation, and bacterial contamination.[20] Bone scrapers produce ribbon-like shavings that have a favorable three-dimensional morphology for revascularization and graft incorporation[21] (Figure 30-4).

The choice of a particular augmentation technique or graft material will depend on several factors, including the degree of atrophy and the morphology of the osseous defect. Regeneration and repair of an osseous defect primarily originates from the surrounding bony walls. The ingrowth of blood vessels from the surrounding bone provides a path for osteoprogenitor cells and new bone formation. Therefore the morphology of a bone defect should influence the choice of material or technique. Sites with fewer surrounding osseous

walls and greater jaw atrophy are more demanding and require materials and/or techniques that offer greater biologic activity and regenerative capacity. As a general rule, vertical onlay bone augmentation is more biologically and clinically challenging than horizontal bone augmentation. Explanations for this difference include fewer osseous walls, graft stability, soft tissue coverage, space maintenance during healing, and avoidance of graft loading. Most classification systems used to describe maxillary atrophy focus on the pattern of progressive ridge resorption.[22,23] Recently the Cologne Classification for Alveolar Ridge Defects[24] was proposed to address the morphology of the defect as well as augmentation needs. The orientation of the defect is described as horizontal, vertical, or combined. The relationship of the augmentation and defect region is classified as internal (inside the bony contour) or external (outside the bony contour). This distinction is important, as bone defects inside the bony contour are much easier to reconstruct than onlay augmentations required outside the osseous contour. Intrabony defects have a higher regenerative capacity with greater ease in achieving soft tissue coverage (Figures 30-5 through 30-7).

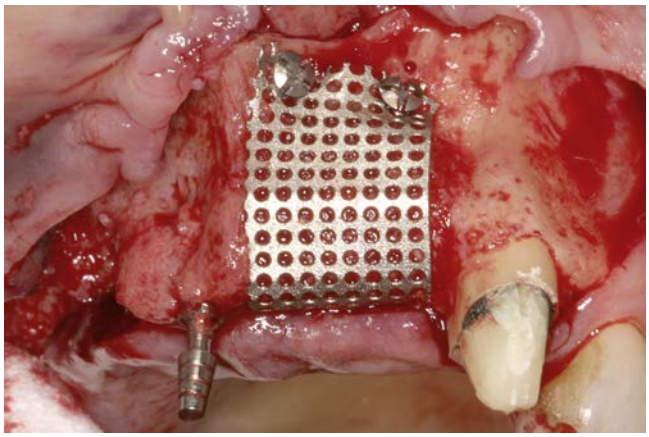
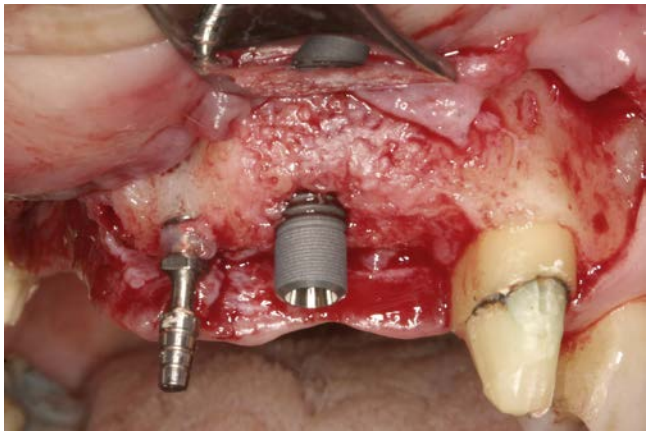
Preoperative Evaluation

A comprehensive evaluation of the site is necessary for planning of bone graft surgery. It is also important to define the prosthetic goals before the reconstruction. The design of the final prosthesis determines the size and number of implants required and their ideal positions. If there is inadequate available bone for implant placement in the desired locations, then bone augmentation is considered. This concept has been termed "prosthetic guided bone augmentation."[25] Mounted study casts and diagnostic wax-ups allow the clinician to better appreciate the ridge morphology in relationship to planned prosthetic outcome (Figure 30-8).

Panoramic and periapical radiographs can be used to evaluate the bone defect, surrounding dentition and regional anatomy. Computed tomography is preferred for three-dimensional viewing of the bone deficiency and surrounding area. It can also be used to assess intraoral donor sites for bone harvest. Many surgeons have cone beam computed tomography (CBCT) machines in their office. CBCT exposes the patient to less radiation and allows an immediate assessment of the patient's condition. The diagnostic wax-up may also be used for the fabrication of a



• **Figure 30-6** Intraosseous defect filled with particulate autograft and covered with a titanium mesh.



• **Figure 30-7** The defect is completely repaired after 6 months of healing.

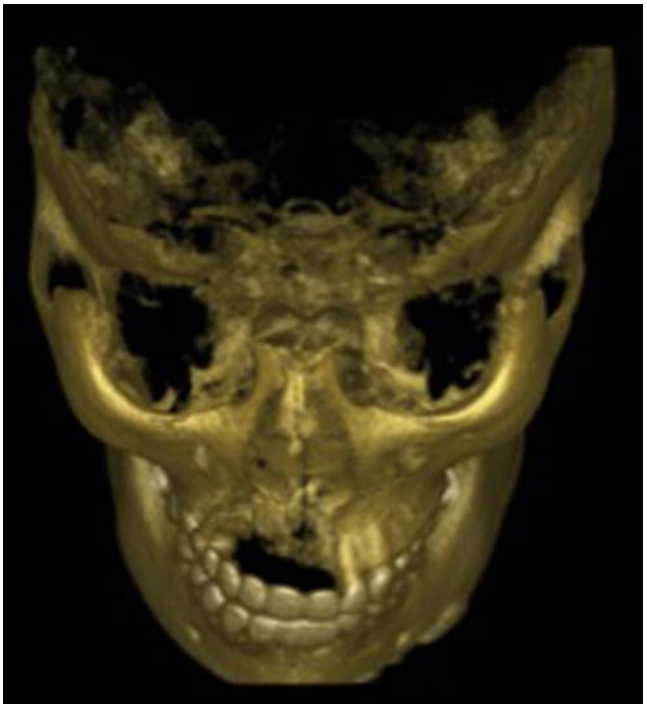
radiographic computed tomography (CT) scan template[26] (Figure 30-9). The template is worn during the scan and reveals the radiopaque outline of the prosthetic tooth position in the tomographic view of the residual ridge (Figure 30-10). This allows a determination of graft size requirements and donor site options.

Implant planning software can be used with the scan to more precisely evaluate the reconstructive needs of the patient.[26,27] Virtual implants are positioned in the preferred sites to determine the amount of augmentation required. A stereolithographic model of the jaw can be generated from the CT scan to further plan the case[25] (Figure 30-11). This model can be used before surgery to cut and shape titanium mesh, plates, or membranes. It may also be sterilized and used intraoperatively to assist in the fitting of block bone grafts or placement of bone plates or titanium mesh. A template of the planned prosthetic tooth position is also helpful for use during graft surgery to confirm graft positioning and fulfillment of the grafting requirements.

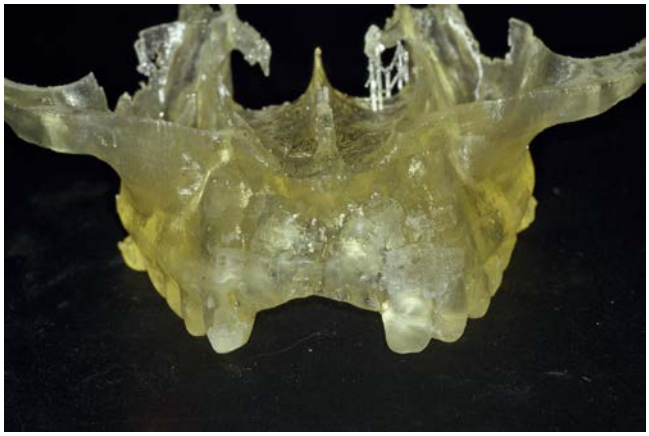
Treatment of the anterior maxilla requires an esthetic zone evaluation.[28] This includes determination of the high lip line and need for lip support. A diagnostic wax-up will help determine tooth length and need for vertical augmentation to develop the correct tooth size. An emphasis must be placed on creating adequate osseous volume for implant placement as well as providing a proper soft tissue profile for the implant restoration. The surgeon and restorative dentist must determine if the missing hard and soft tissue will be surgically reconstructed or replaced with the prosthesis. Even when skilled surgeons obtain a successful repair of the defect, the restoring dentist and patient may find esthetic shortcomings in the final result. Longer prosthetic teeth, missing papilla, and lack of facial contour are not uncommon flaws when reconstructing larger defects. An alternative to surgical repair is to replace the missing hard and soft tissues prosthetically using gingival colored porcelain,

• **Figure 30-8** Diagnostic wax-up of a maxillary defect from trauma. Pink wax is used to assess the missing hard and soft tissue.

• **Figure 30-9** The diagnostic wax-up is converted into a radiographic template with barium teeth.



• **Figure 30-10** Computed tomography scan is taken with the radiographic template to show the planned prosthetic tooth position in relation to the bone defect.



• **Figure 30-11** A stereolithographic model of a maxilla with an anterior bone deficiency.

acrylic, or composite. It is also important to determine if the transition area between the prosthesis and the ridge is above or below the high lip line. It is very difficult to make this transition area between artificial gingiva and the mucosa appear natural. In many cases, if it is not feasible to rebuild the ridge to obtain normal tooth length, it may be better to reduce the ridge height and camouflage the prosthetic transition area under the lip.[29] The need for lip support is evaluated when multiple teeth are missing. This is more significant when a fixed prosthesis, without a flange, is planned. A diagnostic wax-up without a flange can be used to assess the need for lip support.

The soft tissue character of the recipient site should be assessed, including quantity of keratinized tissue, gingival biotype, mucosal thickness, vestibular depth/muscle attachments, and the presence of scar tissue. It is often better to correct soft tissue problems before bone grafting. The lack of keratinized tissue in a region is best treated with autogenous free gingival grafts from the palate (Figures 30-12 through 30-16). Thin mucosa is a risk for flap perforation or erosion of titanium mesh through the tissue. Areas of thin alveolar mucosa can be enhanced with the interpositional placement of connective tissue grafts or allogeneic dermis. A frenum, a high vestibular muscle attachment, and/or a lack of vestibular depth can restrict the ability to advance a flap. Vestibuloplasty or frenectomy techniques can be employed to address these issues. The removal of scar tissue improves blood supply to the area and helps improve the mobility of the soft tissue flap over the bone graft. Soft tissue corrective surgery should be performed at least 8 weeks prior to bone graft

surgery to allow incorporation of any grafts and reestablishment of vascularity to the area. The surgeon should be aware that facial flap advancement over a bone graft moves the mucogingival junction more palatal or lingual. The keratinized gingiva can be repositioned during subsequent surgical procedures, or connective tissue grafting can be performed.

The periodontal health and endodontic status of teeth adjacent to the graft recipient site should be evaluated before grafting. It may be prudent to extract hopeless teeth before grafting, especially if infection is present. The marginal bone height on the teeth bordering the bone defect determines the level that can be achieved with vertical bone augmentation. It may be necessary to extract stable teeth if they have marginal bone loss that limits the augmentation needs. It is usually preferred to extract compromised teeth 8 weeks before the bone graft surgery and allow soft tissue healing over the site.

Patient Preparation

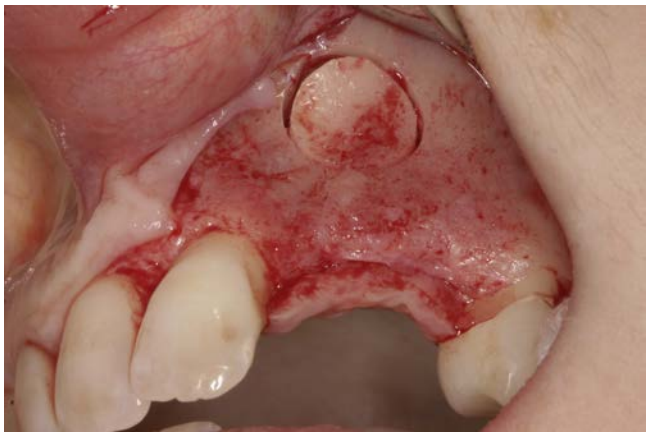
Patients undergoing autogenous bone grafting require antibiotic prophylaxis. The antibiotic of choice for most cases is amoxicillin. For patients allergic to amoxicillin, either a cephalosporin or clindamycin may be considered. A loading dose of antibiotic should be administered prior to surgery and continued for 1 week. The use of short-term glucocorticoids can diminish postoperative facial swelling, local flap edema, and discomfort. Dexamethasone can be administered intravenously before surgery, and then a tapered oral dose is prescribed. The use of a long-acting local anesthetic, such as bupivacaine, is helpful to delay the onset of postoperative pain. Some studies have found bacterial contamination of orally harvested bone grafts, especially when suction traps are used to collect drilled bone debris.[30] Chlorhexidine rinsing before surgery has been shown to significantly reduce this problem. Preoperative antisialogogue agents, such as glycopyrrolate, are also useful to decrease salivary flow that may carry bacteria into the graft site. Aseptic surgical technique should be maintained, as these reconstructive procedures are more involved and may often require more operative time. Most cases involving autogenous bone grafting in the office are performed under intravenous anesthesia. Shorter, less involved graft procedures may be carried out using oral sedation or simply local anesthesia.

Smoking has been associated with a high rate of wound dehiscence and graft failure.[31] Unless the patient will commit to no smoking during the early postoperative course, onlay bone grafting is discouraged. A smoking cessation protocol may be employed, including the use of prescription medications, such as bupropion and the nicotine transdermal patch. The use of electronic cigarettes may be an alternative to regular cigarettes, but the effect of nicotine on wound healing is still detrimental. Patients are instructed to quit 1 week prior to surgery and told not to smoke at least until the incision is healed (2 weeks). The use of a platelet concentrate under the flap closure may be beneficial in this patient population to improve wound healing.

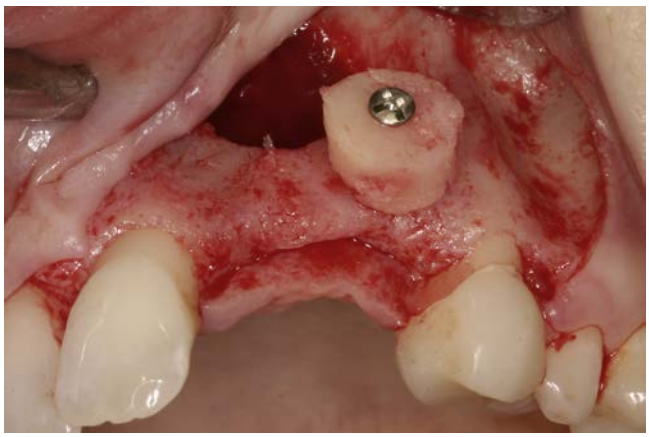
Bone Graft Donor Sites

Local Bone Grafts

Harvesting a bone graft from the same surgical field as the area of augmentation adds minimal morbidity to the procedure. Particulate autogenous bone can be obtained using drills or scraping devices. The particle size influences the behavior of the graft. Bone slurry or smaller particles from drilling are more quickly resorbed.[32] Larger particles from bone scrapings or a bone mill not only provide better scaffolding, they show higher cell viability and stronger osteogenic potential.[33] The particulate bone can be used for guided bone regeneration of implant dehiscent defects.[34] Small block bone grafts or particulate bone may be harvested from the palate or zygomatic buttress.[35] Circular blocks of bone can be harvested with a large trephine burr from the superior aspect of the edentulous ridge or above the surrounding tooth roots (Figures 30-17 and 30-18).



• **Figure 30-17** A large trephine burr is used to harvest a circular block from the edentulous site.



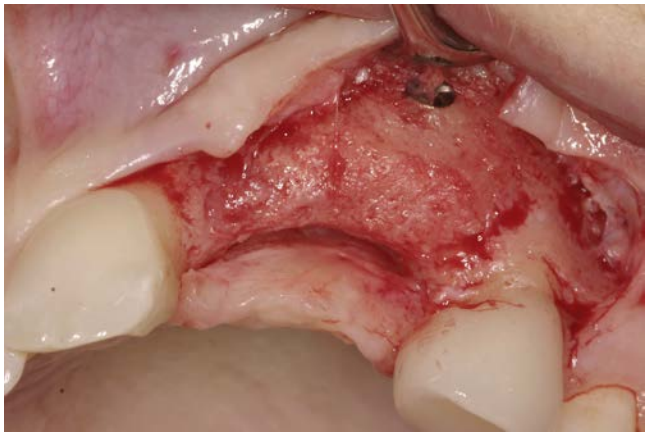
• **Figure 30-18** The circular block bone graft is fixed to the maxilla with a screw.

These larger trephine cores can be morselized or used as a circular block with a fixation screw (Figures 30-19 and 30-20).

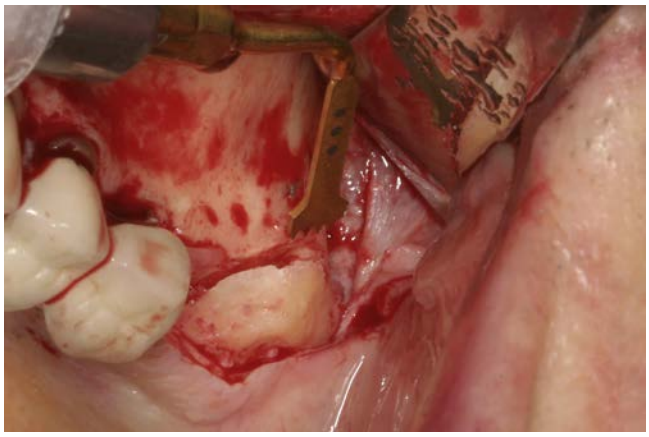
Maxillary Tuberosity

Although the maxillary tuberosity offers a smaller amount of bone than other donor sites, the softer consistency of the graft is often favorable for filling bone defects.[36] The tuberosity graft can be used in block form or easily particulated with a rongeur. The bone in the tuberosity area is porous, and the outer cortical layer is thin. The amount of bone that may be obtained can be deceiving, as the mucosa over the tuberosity is usually much thicker. Computerized tomography of the maxillary sinus region can allow three-dimensional quantification of the area. The anatomical limitations of tuberosity bone harvest include the maxillary sinus, pterygoid plates, molar teeth, and greater palatine canal. To gain access to the area for bone harvest, an incision is made along the ridge crest over the tuberosity. A vertical releasing incision is made along the lateral aspect of the posterior maxilla. Mucoperiosteal reflection exposes the tuberosity, ridge crest, and lateral maxilla. The palatal tissue should also be elevated to reveal the entire width of the tuberosity. The graft may be harvested with a chisel, rongeurs, or a piezoelectric saw (Figures 30-21 through 30-24). The chisel edge should be kept slightly superficial to the maxilla to shave off pieces of tuberosity bone and avoid entering the sinus. Inadvertent sinus communication is usually not a problem, as the flap is easily closed and the tissue is thick.[37] The tuberosity is in the same surgical field when performing sinus grafting, so it should be routinely considered for bone harvest.[38] The sinus is grafted in layers with particulated tuberosity placed along the sinus floor.

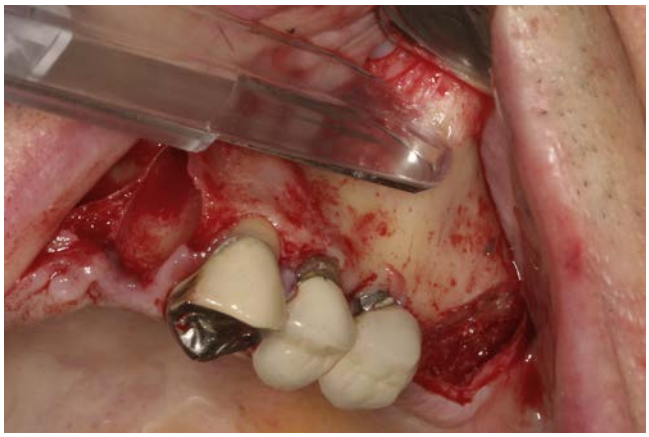
• **Figure 30-19** Particulate autograft and bovine hydroxylapatite are used around the block graft to complete the reconstruction of the defect.



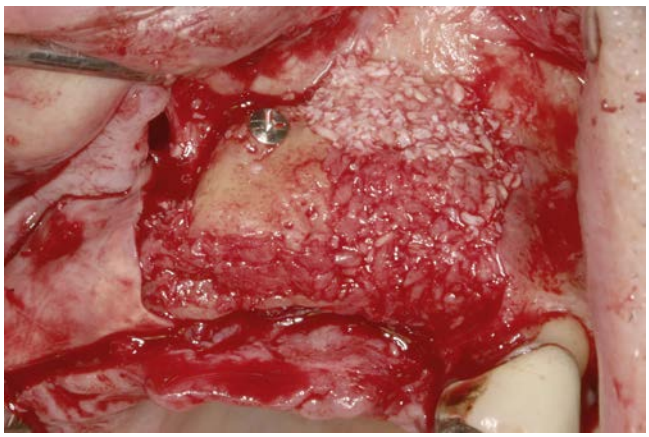
• **Figure 30-20** Incorporation of the bone graft after 4 months of healing.



• **Figure 30-21** A piezoelectric saw is used to harvest a block bone graft from the maxillary tuberosity.



• **Figure 30-22** A bone scraping device is used to harvest particulate bone from the zygomatic buttress area.



• **Figure 30-23** The tuberosity block bone graft is fixated to the maxilla with a screw, and particulate bone is packed around the graft.

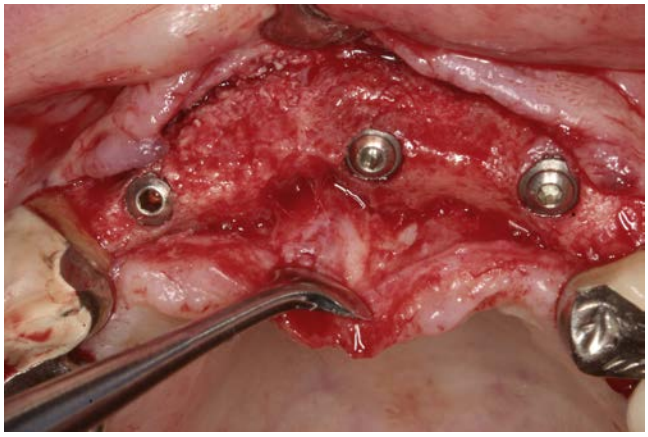
A thin piece of cortical bone can be obtained from the posterior lateral maxilla with a chisel to cover the window following grafting of the sinus floor (Figures 30-25 through 30-27).

Mandibular Symphysis

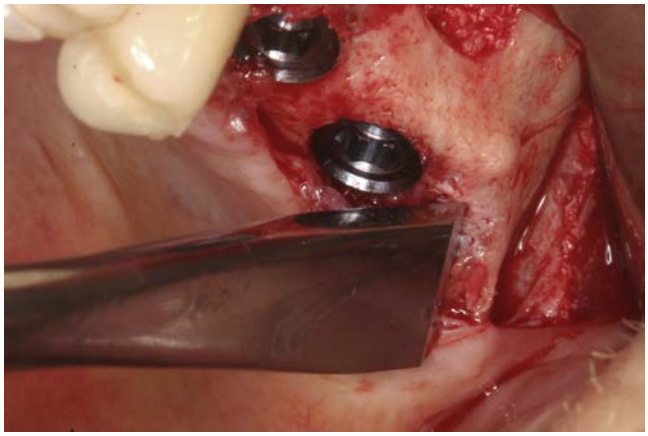
The symphysis of the mandible has been used extensively for sinus and onlay bone grafting.[15,39-44] Techniques to harvest block or particulate bone grafts from the anterior mandible have been reported. The symphysis donor site offers the greatest volume of intraoral bone. The average interforaminal distance is approximately 5.0 cm, and the depth of the anterior mandible usually exceeds 1.0 cm.[45] A panoramic radiograph or CT scan is used to evaluate the available bone in this donor site. A lateral cephalometric radiograph can be useful to determine the anteroposterior dimension of the anterior mandible. Periapical radiographs give a more accurate measurement of the length of the tooth roots.

The ease of surgical access is one of the main advantages of the symphysis region. Exposure of the symphysis may be obtained through a sulcular or vestibular incision. The vestibular incision is made in the mucosa between the cuspid teeth approximately 1 cm from the mucogingival junction. Limiting the distal extent of the incision will reduce the risk of mental nerve injury. A vestibular approach allows easy access but produces more soft tissue bleeding and possible intraoral scar formation. The sulcular approach should not be used when mucogingival defects are present and may result in gingival recession if the biotype is thin. The sulcular incision should extend to the premolar regions bilaterally. A mucoperiosteal flap is reflected to expose the mental foramina and the anterior aspect of the inferior border of the mandible. Additional local anesthesia is often needed at the base of the mandible to block cervical innervation.

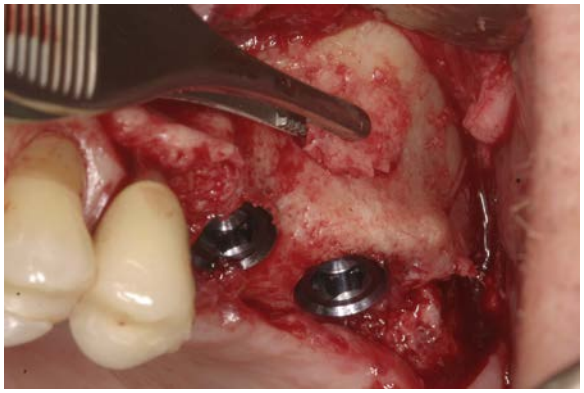
After the symphysis region is exposed, the osteotomies for graft harvest are planned. The bone volume needed to reconstruct the recipient site determines the dimensions of the graft. Osteotomies should be kept at least 5 mm from the root apices and the mental foramina.[15,46,47] In most cases the inferior and lingual cortices of the mandible are left intact. The facial cortex is thick, and the underlying cancellous bone is usually dense. The osteotomies may be made with a carbide fissure burr (No. 557, No. 701) in a surgical handpiece, sagittal saw, or piezoelectric saw (Figures 30-28 through 30-30). Following the osteotomies through the outer cortex and into the cancellous bone, the graft is removed with a chisel. A unibeveled chisel is tapped along the osteotomies, with the exception of the inferior border, to fracture the



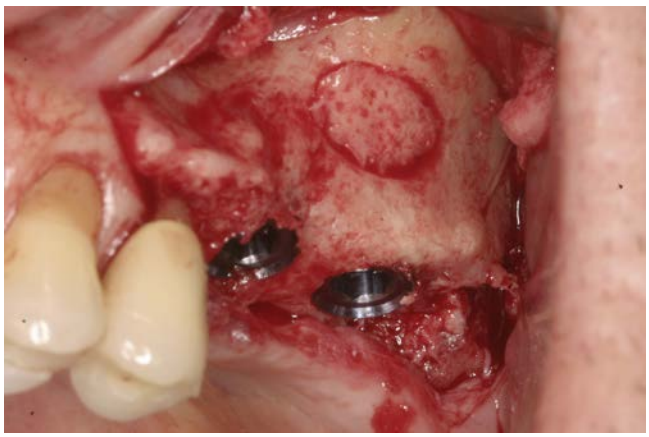
• **Figure 30-24** Dental implants are placed following 4 months of graft healing.



• **Figure 30-25** A chisel is used to harvest a thin piece of cortical bone graft from the posterior maxilla.



• **Figure 30-26** The thin cortical bone graft is used to cover the sinus window.



• **Figure 30-27** The thin piece of cortical bone acts as a biologic barrier over the sinus bone graft.

block from its base. The block bone graft may also be harvested in segments by sectioning the rectangular piece in the midline. Two bone blocks are often easier to harvest, as the second block can be fractured from its lingual base with the chisel. After the block is removed, some additional cancellous bone may be procured with a curette, chisel, rongeur, or trephine, but the volume is usually meager.[45] Following the removal of the block graft, hemostatic materials, such as collagen or gelatin, may be placed over the cancellous bone. When larger bone grafts are harvested, the donor site should be filled with a bone substitute, such as bovine hydroxylapatite, to maintain facial contour.[15] Smaller or particulate bone grafts may be procured using trephine burrs, bone collection traps, or bone scraping instruments[21,48,49] (Figures 30-31 and 30-32). Closure of the donor site is typically performed after the graft is inserted into the recipient site. This minimizes the time between graft harvest and placement. The mucosa superior to the vestibular incision is reflected to reduce tension on the flaps from edema and lip movement. The vestibular incision is closed in layers using resorbable sutures. The deeper layers may be sutured with 4-0 polyglactin, and the superficial mucosa can be closed primarily with 4-0 chromic gut. Postoperative pressure dressings are used over the chin to reduce edema, hematoma formation, and incision line opening.

The use of the mandibular symphysis has diminished, as it is associated with a higher incidence of postoperative complications than other maxillofacial donor sites.[42,50,51] Altered sensation of the lower anterior teeth is a relatively common postoperative symptom when bone blocks are

• **Figure 30-28** An oscillating saw blade is used to perform the osteotomies in the symphysis.

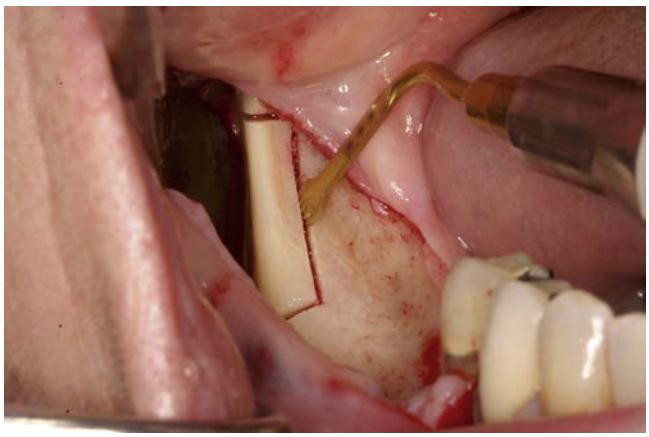
removed.[15,42,50,51] The contents within the incisive canal of the symphysis that innervate the teeth are disrupted during bone harvest. Patients describe dullness in sensation of the incisors, which usually resolves within 6 months. The need for endodontic treatment of anterior teeth is rare. Neurosensory disturbances in the chin region also may be encountered, even when a sulcular incision is used.[50,51] The incidence of temporary mental nerve paresthesia for symphysis graft patients is usually low but has been found to be as high as 43%.[50] Permanent neurosensory deficits have been reported. Meteorotropism of the chin has also been found.[50] Although the vast majority of these nerve injuries recover, they are disconcerting to patients. It is prudent to discuss the possibility of temporary altered sensation of the teeth and chin prior to surgery. Although no postoperative alteration in soft tissue chin contour has been reported, patients are often concerned with the possible esthetic consequences of bone removal from this area.[50] Radiographic evidence of incomplete bony regeneration has been reported in elderly patients.[52] Filling the donor site with a bone substitute, such as bovine bone, can help alleviate patient concerns.[15] Ptosis of the chin has not occurred and can be prevented by avoiding complete degloving of the mandible.[53]

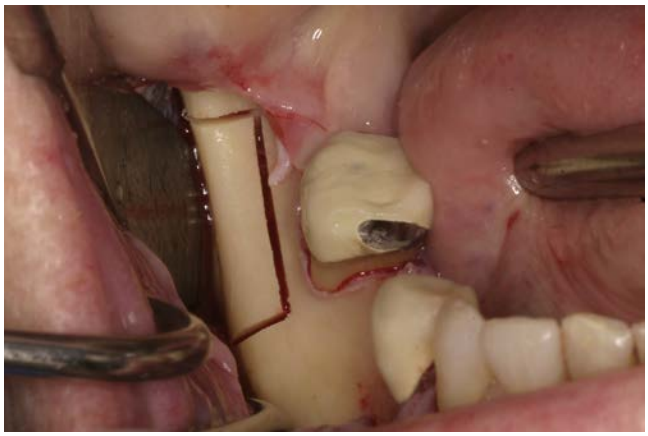
Mandibular Ramus

The posterior mandible is an excellent donor site for bone harvest, and this region offers several advantages over the symphysis.[42,54-56] A CT scan or panoramic radiograph is used to evaluate the bony anatomy, including the ramus, external oblique ridge, and mandibular canal. The incision design for access to this region differs for block and particulate bone harvest. When taking a block graft, the incision is made similar to one used in third molar removal. A sulcular incision is made along the posterior teeth. The incision is continued posteriorly and lateral at a 45-degree angle from the distobuccal aspect of the second molar, or the base of the retromolar pad if no molar is present. The incision extends superiorly along the ascending ramus. Following the incision, a mucoperiosteal flap is reflected to expose the lateral ramus and body of the mandible. The masseter muscle is reflected laterally with a large retractor to form a large open pocket. Additional local anesthesia is often required in this area to block cervical innervation. The limits of harvesting bone from the ramus area are dictated by clinical access in addition to the coronoid process, molar teeth, and mandibular canal. The average anteroposterior dimension of the mandibular ramus is 30.0 mm, and the lingula is typical in the posterior third.[57]

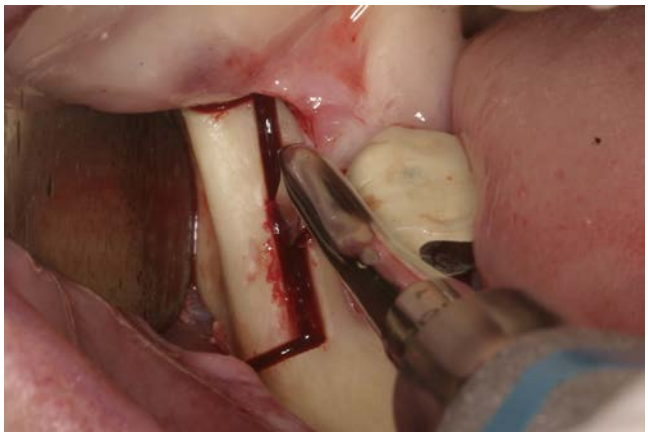
Four osteotomies are made to harvest a block bone graft—external oblique, superior ramus, anterior body, and inferior.[55] The bone volume needed to reconstruct the site determines the length of the osteotomies. The cortical cuts are made with a carbide fissure burr (No. 557, No. 701) in a straight handpiece under sterile saline irrigation. A piezoelectric saw may also be used, as the cuts are thinner (Figure 30-33). The external oblique cut is made along the anterior border of the ramus approximately 4.0 to 6.0 mm medial to the external oblique ridge. This osteotomy can extend as high as the base of the coronoid process and anteriorly up to the first molar area. This can produce a graft that may approach 40.0 mm in length. The superior ramus cut is made through the lateral cortex of the ramus and perpendicular to the external oblique cut. It may extend as far posteriorly on the ramus as the opposing lingula on the medial side of the ramus. However, the length of this cut is typically about 10.0 mm. The anterior body cut may often extend over the path of the mandibular canal. Although the bucco-lingual position of the mandibular canal is variable, the distance from the canal to the medial aspect of the buccal cortex (medullary bone thickness) was found to be greatest at the distal half of the first molar (mean 4.05 mm).[58] Therefore, the anterior body cut should be made in this area and not in the third molar region, where the canal is closer to the buccal surface. This anterior body cut is progressively deepened until bleeding from the underlying cancellous bone is visible. The inferior osteotomy is only a partial thickness cut made with a round carbide burr (No. 8). It connects the inferior aspects of the superior ramus and anterior body cuts. This osteotomy on the lateral aspect of the ramus parallels the external oblique cut and creates the base of the rectangular bone block. It extends only partially through the cortex and creates a line of fracture. The block graft is then removed with a chisel wedged within the external oblique osteotomy. Care should be taken to parallel the chisel with the lateral surface of the mandible and limit the depth of penetration. An alternative technique is to insert an extraction elevator and pry the graft free (Figures 30-34 and 30-35). This donor site is not augmented with bone substitutes, as the inferior alveolar nerve may be exposed and irritated by the graft particles. The incision is closed primarily with resorbable sutures such as 4-0 chromic gut. A rectangular piece of bone approximately 4.0 mm in thickness may be harvested from the ramus (Figure 30-36). This morphology is well suited for veneer grafting to gain additional ridge width, or the block may be particulated in a bone mill.



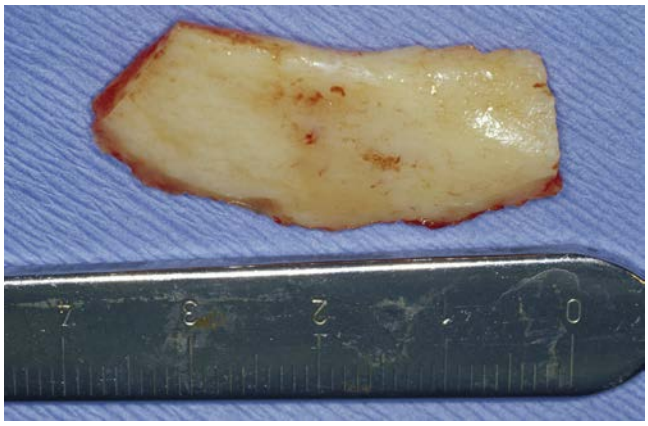
• **Figure 30-33** The osteotomies for ramus graft harvest are performed with a piezoelectric saw.



• **Figure 30-34** A piezoelectric saw creates thin bone cuts, allowing bone harvest lateral to the molar.

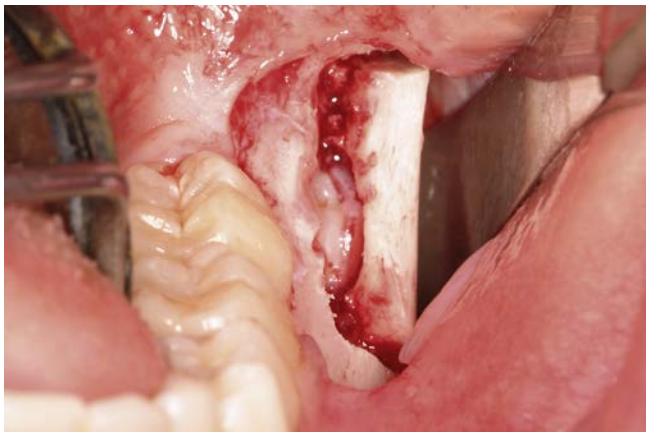


• **Figure 30-35** The cortical block bone graft is pried from the donor site with an extraction elevator.



• **Figure 30-36** A cortical bone graft, 40.0 mm × 10.0 mm, harvested from the mandibular ramus.

The mandibular ramus is also convenient donor site for bone harvest in conjunction with third molar removal.[59] This is often planned for the repair of alveolar deficiencies from congenitally absent teeth in young adults. If the third molar is partially erupted, the tooth is removed prior to bone harvest. If the molar is bony impacted, then the block graft is harvested and the tooth can be removed laterally

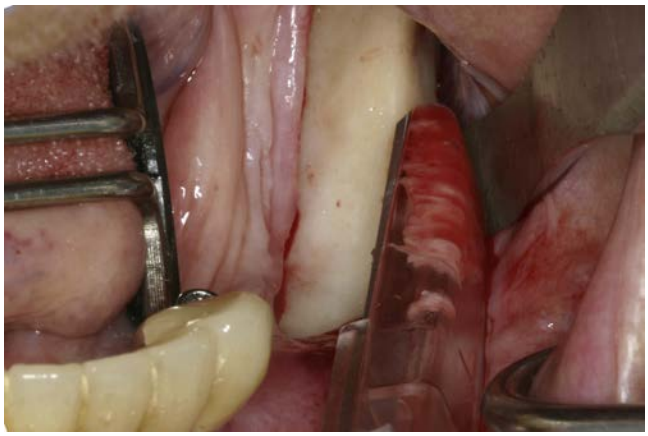


• **Figure 30-37** Harvesting a ramus bone graft in conjunction with third molar removal in a younger patient.

through the donor site (Figure 30-37). The cortical block graft can be used to reconstruct the ridge deficiency.

The posterior mandible is the preferred area for harvesting large amounts of particulate bone with a scraper device.[21] The initial incision for this approach is made in the buccal vestibule, similar to one used in a sagittal split osteotomy. It is made just lateral to the external oblique ridge and extends the length of the molar regions. This incision design requires minimal time to reflect and gain access to the mandible and is equally as easy to close. A larger area of mandibular exposure allows longer strokes with the scraper blade and expedites graft harvest (Figure 30-38). The dense cortical bone should be repeatedly lubricated with sterile saline during the scraping. Routinely, 4.0 mL of particulate autograft may be harvested from the ramus and body of the mandible (Figure 30-39). There is minimal morbidity in harvesting bone from the cortical surface with a scraper blade.

Compared with the symphysis region, the ramus donor site is associated with a much lower incidence of complications.[42,56] Patients have shown less concern with bone removal from the ramus area. The masseter muscle provides soft tissue bulk, and augmentation of this donor site has been unnecessary. Although damage to the inferior alveolar nerve is possible, the incidence of this complication is very low.[60] It is important to plan osteotomies in the posterior mandible around the position of the mandibular canal. The use of a piezoelectric saw has been postulated to decrease the risk of nerve injury, as the ultrasonic blade does not cut soft tissue.[61] In contrast to the common complaint of altered sensation of the incisors with chin bone harvest, no ramus graft patients have noted numbness of their molar teeth.[42,56] Although the posterior incision along the external oblique ridge could possibly damage the buccal nerve, reports of sensory loss in the buccal mucosa are rare and will most likely go unnoticed.[62] Ramus graft patients appear to have fewer difficulties with managing postoperative edema and pain compared with chin graft surgery.[42,56] Patients may experience trismus following surgery and should be placed on postoperative glucocorticoids and nonsteroidal



• **Figure 30-38** A bone scraping device is used to harvest particulate bone from the posterior mandible.

• **Figure 30-39** The bone scrapings from the mandible are collected and stored in sterile saline.

anti-inflammatory medications to help reduce dysfunction. The mandibular ramus has significantly less morbidity than the symphysis and has become the preferred donor site of many clinicians.[21,42,51,56]

Tibia

The proximal tibial metaphysis provides an excellent source of cancellous bone for grafting.[63-65] This donor site offers up to 40 mL of cancellous bone with low reported morbidity.[63,64] The surgery may be performed in an office environment under intravenous sedation. The most common approach to the donor site is laterally at Gerdy's tubercle, a bony protuberance located 1.5 cm below the articulating surface of the tibia[63] (Figure 30-40). However, a medial approach to the tibia has also been proposed.[66] The leg is elevated with a rolled towel or firm pillow and the knee is slightly bent. The leg is shaved, and the skin is prepped with an antimicrobial solution (povidone-iodine or chlorhexidine). Sterile drapes are positioned to isolate the surgical field, and the surgical team should follow strict aseptic technique including sterile gowns and gloves. A sterile surgical marking pen is used to plan the incision and local anesthetic

• **Figure 30-40** The incision planned on the lateral aspect of the proximal tibia over Gerdy's tubercle.

with a vasoconstrictor is infiltrated along the site. The local anesthetic needle is then directed to the bone for additional infiltration over the area. A 2.0- to 3.0-cm oblique incision is made through the skin on the anterolateral aspect of the leg directly over Gerdy's tubercle.[64] No major nerves or arteries are located in this site. Therefore, placement of a tourniquet is usually unnecessary and bleeding is controlled with electrocautery. After incising through the subcutaneous and fascial layers of the iliotibial tract, the periosteum is visualized. An oblique incision is made over the bone with short inferior releasing incisions. The periosteum is reflected to expose the cortex of the tibia. Rake retractors are helpful in reflecting the dense tissue flaps. The 1.5-cm opening through the cortical bone is made with a carbide fissure burr (No. 702). Alternatively a large trephine burr (10.0 mm) may be used (Figure 30-41). The surgeon should direct the burr medially and inferiorly to avoid the knee joint. The cortex is fairly thin, so the block piece of cortical bone may be pried from the donor site and placed aside for reconstruction of the ridge defect (Figure 30-42). The cancellous bone is harvested using orthopedic bone curettes or a No. 2-4 Molt curette. Studies have found that the amount of cancellous bone that may be obtained is the same as an anterior iliac harvest[67] (Figure 30-43). If needed, hemostatic agents, such as microfibrillar collagen or gelatin, may be placed into the bony void. The wound is closed in layers with resorbable sutures such as 3-0 polyglactin. The skin is closed with sutures (5-0 nylon) or staples. Antibiotic ointment is applied, and the knee is wrapped with an elastic pressure dressing. Patients are encouraged to keep the leg elevated and apply ice. They may begin ambulation on the donor leg following the surgery, but should avoid full weight bearing

for a few days. Although normal activities can be resumed thereafter, the patient should avoid strenuous exercise for 4 to 6 weeks.

Postoperative pain from tibia bone harvest is well managed with moderate narcotic analgesics. Ecchymosis of the leg distal to the donor site is quite common. There has been a low incidence of significant complications with this procedure.[63-65,68] Complications may include hematoma formation, wound dehiscence, infection, and fracture. Although quite rare, most cases of tibia fracture are due to a bony access too low on the leg.[69]

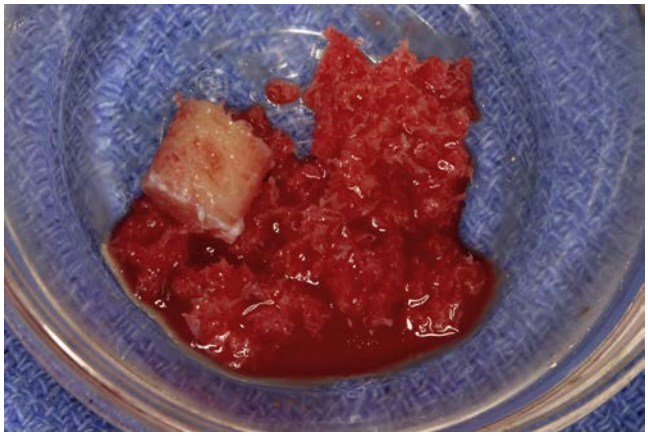
• **Figure 30-42** The cortical bone plug is removed to gain access to the cancellous bone.



• **Figure 30-43** The cortical bone plug and cancellous bone harvested from the proximal tibia.

Ilium

The grafting of larger areas of bone deficiency often requires bone harvest from the ilium. As the tibia offers a convenient site for harvesting cancellous bone, the ilium is most often reserved for cases requiring corticocancellous block grafting. Currently the atrophic edentulous mandible is less often grafted using iliac bone. Even with more severe mandibular atrophy, short implants may be used for prosthetic support.[70] However, iliac bone grafts are still useful for treatment of the severely atrophic edentulous maxilla. A LeFort I osteotomy with interpositional iliac bone has been well documented for the reconstruction of the atrophic maxilla. The maxilla is downfractured and moved inferior and anteriorly. Corticocancellous blocks are placed between the midface and maxilla, and plates are used to secure the advancement. Earlier reports on this technique detailed simultaneous placement of machine surface implants.[71,72] Delayed implant placement after graft healing and the use of moderately rough implant surfaces may increase implant survival.[73-75] LeFort I interpositional grafting addresses both bone volume and interarch relationship problems that are common in the long-term edentulous patient, but pose significant challenges such as hospitalization, long operating time, and general anesthesia. Another method to reconstruct the atrophic edentulous maxilla is to combine block onlay bone grafting anteriorly and sinus bone grafting posteriorly. The grafted maxilla is allowed to heal for delayed implant insertion 4 to 6 months later. This allows prosthetic-driven implant placement for overdenture support or a fixed prosthesis. Large bone defects in the partially edentulous patient, resulting from trauma, pathology, or infection, can be well managed with corticocancellous blocks.[28] Although the use of recombinant human bone morphogenetic protein-2 (rhBMP-2) with allograft has been proposed as an alternative to autograft for maxillary reconstruction, this method is an off-label application of the product and lacks long-term data on implant survival.[76] In addition, the quality of the bone regenerated by rhBMP-2 is often less dense compared to autogenous cortical/corticocancellous block grafts.[77,78]

In most cases adequate bone may be harvested using an anterior approach to the hip. A posterior approach to the ilium is less often required and is usually reserved for major reconstructive surgeries requiring large amounts of cancellous bone. In addition, the need to rotate the patient after posterior bone harvest is an inherent disadvantage. Although posterior bone harvest is reported to result in less postoperative pain, the postoperative use of an anesthetic pain pump can minimize the problem with anterior harvest.[79-82]

There are varying shapes of blocks that may be harvested from the hip. A reciprocating saw and chisels are used to

perform the osteotomies for bone harvest. Square or rectangular corticocancellous blocks used for width augmentation are harvested from the medial cortex or lateral cortex.[83] The crestal osteotomy should begin at least 1.0 cm from the anterior iliac spine. Otherwise the remaining anterior segment of bone may be weakened and fracture.[83] The iliac crest is cut along its length for unicortical bone harvest, leaving the opposing cortex intact (Figures 30-44 and 30-45). When thicker pieces of bone are needed for vertical bone augmentation, a bicortical bone graft may be harvested from the entire width of the crest. The gluteal muscle attachments are reflected from the lateral cortex along the crest of the ilium. This graft geometry is typically used for reconstructing the severely atrophic premaxilla (Figure 30-46). Following the harvest of the corticocancellous block(s), significant amounts of additional cancellous bone may be harvested with bone curettes. The edges of the iliac cortex should be smoothed with a rasp or file before closure. Following the removal of the bone graft, hemostatic materials, such as a sheet of microfibrillar collagen or gelatin, can be placed over the cancellous bone. A pain pump with long-acting local anesthetic catheter is placed into the wound following closure of the periosteal layer (Figure 30-47). The muscle layers and subcutaneous tissues are closed with polyglactin mattress and interrupted sutures. The skin may be closed with nylon interrupted sutures or surgical staples. The pain pump is removed a few days after surgery when the local anesthetic has been pumped out. The patient is instructed to avoid full leg weight bearing on the side of graft harvest for 1 week. Crutches or a walker may be used for ambulatory assistance. Using the left hip for harvest allows patients to return to driving their car earlier. The patient should avoid exercise and heavy lifting for 6 weeks following surgery.[84]

The iliac crest provides the greatest source of bone for jaw reconstruction but also has the greatest morbidity of any donor site. Postoperative pain from the hip is usually the most common complaint.[83] Although acute postoperative pain can be significant, the use of a local anesthesia infusion device can provide exceptional pain control that exceeds the duration of pharmacologic activity.[82,85] The infusion device delivers controlled amounts of local anesthetic to the area for improved postoperative pain management. Preemptive use of analgesics is also beneficial for patient comfort. Chronic pain of the donor site has been reported.[86] Temporary gait disturbances may require ambulatory assistance for a week or longer. There is a low incidence of hematoma

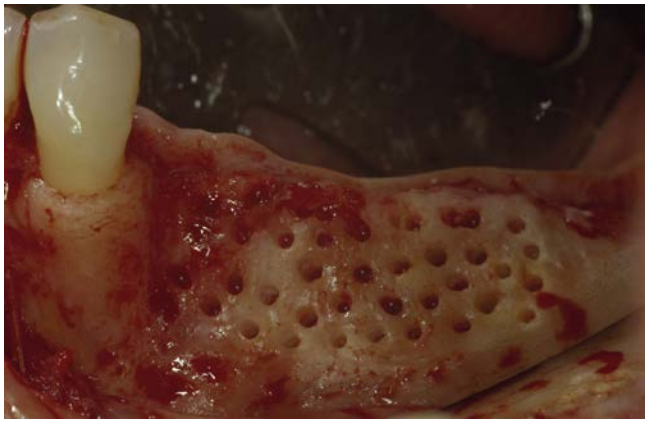
formation. Cutaneous paresthesia of the thigh area has been reported with an anterior approach to the iliac crest, but this is usually temporary.[86,87] Although it is usually covered by underwear, some patients may object to the appearance of a scar. Anterior iliac spine fractures are rare.[86] Assessment studies on patients who had iliac bone grafting of the maxilla found low morbidity and high patient acceptance, supporting its use.[83,84,88,89]

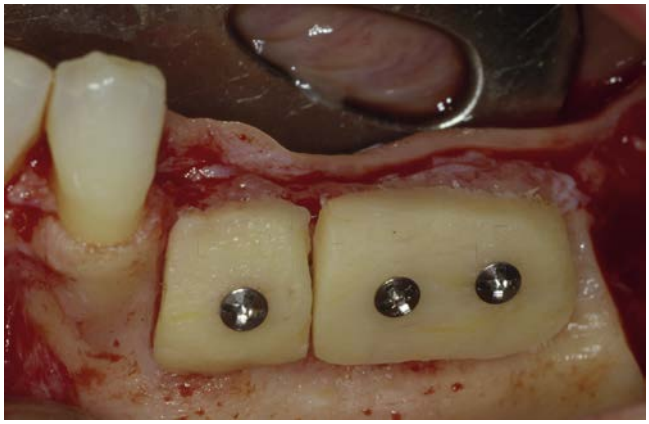
Graft Recipient Site

The bone defect is usually exposed and prepared prior to bone graft harvest. This allows a better determination of the need for bone repair and minimizes the length of time from bone harvest to graft placement. The flap design is an important consideration in bone augmentation and should be well planned prior to surgery. Incisions to expose the recipient site are typically made along the ridge crest through attached gingiva. As blood vessels do not cross over the ridge crest (facial-palatal/lingual), a crestal incision maintains vascular supply to the flap.[90] Divergent releasing incisions remote to the defect facilitate closure and also help maintain blood supply to the flap. Making vertical releasing incisions one tooth lateral to the graft site is prudent. For larger grafts in the anterior edentulous maxilla or mandible, a vestibular incision through the mucosa may be considered, especially if vertical augmentation is planned. The mucoperiosteal reflection is made over a broad area well beyond the defect margins. This provides a larger flap for advancement over the augmented site. Several perforations of the cortical surface of the bone may be performed with a small round burr to release local growth factors and expedite revascularization of the graft[91] (Figures 30-48 and 30-49).

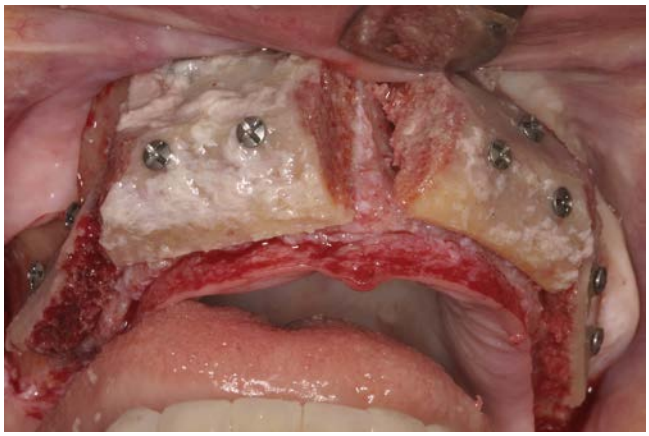
The addition of supplemental autologous growth factors, such as platelet-rich plasma, has been reported to enhance and accelerate the incorporation of autologous cancellous bone grafts.[92] In addition, platelet-rich plasma may be useful as a matrix for soft tissue repair, for adhesion of bone graft particles, and for improving hemostasis. Adding a prepared concentrate of the patient's platelets to the grafted site may also enhance and accelerate soft tissue wound healing. The various cytokines and mediators found in the alpha granules of the platelets promote angiogenesis and collagen synthesis.[93] This may diminish the risk of wound dehiscence and bone graft exposure to the oral cavity (Figures 30-50 through 30-52). The platelet concentrate is placed over the graft and under the flap margins prior to closure.



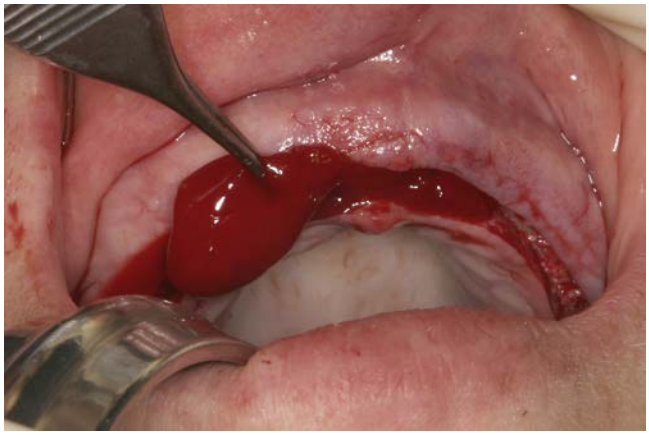
• **Figure 30-48** Perforation of the cortical bone in the recipient site to facilitate incorporation of the bone graft.



• **Figure 30-49** Cortical bone grafts are fixated onto the lateral aspect of the posterior mandible.



• **Figure 30-50** Corticocancellous block bone grafts from the iliac crest are used to reconstruct the atrophic maxilla.



• **Figure 30-51** Platelet concentrate is placed over the bone graft and under the flaps during closure of the incision.

Complete flap coverage and tension free closure is essential to the successful incorporation of the bone graft. Incision of the periosteum along the base of the facial flap allows advancement of the flap over the grafted site. After the periosteal releasing incision is made the flap is gently stretched to assess closure without tension. If resistance to the adaptation of the wound margins is noted then further flap release can be obtained with blunt dissection through the periosteal release and beyond the vestibular depth. Blunt scissors or a hemostat can be advanced through a plane parallel to the facial bone. This will avoid compromising the blood supply to the flap. Procedures to enhance graft coverage will usually result in a loss of vestibular depth. This is rarely a problem with implant supported restorations as the prosthesis does not require a soft tissue seal for retention. Patient may complain of some reduced lip mobility. The advancement of the facial flap over the graft may often reposition the keratinized gingiva more palatal or lingual. In some cases soft tissue grafting may be necessary but the keratinized tissue can usually be moved facially during second stage uncovery of the implants. Although it is important that the flap margins are well approximated, the sutures should not be pulled too tightly or ischemia will occur. The flaps should be closed over the bone graft with suture materials that maintain their tensile strength until the wound has completely healed. Polyglactin and polytetrafluoroethylene (PTFE) suture is preferred over materials such as chromic gut or silk. Horizontal mattress sutures evert the flap margins and coapt the connective tissue surfaces. Multiple interrupted sutures are used to close the vertical releasing incisions.

Postoperative Care

It is imperative that the graft not be traumatized during healing. A fixed provisional prosthesis, such as a temporary bridge or bonded prosthesis, is preferred if possible. A removable vacuum formed or Essix retainer is another excellent option for cosmetic tooth replacement, as it is supported by the teeth and does not place any pressure on the graft site. The use of any soft tissue borne removable prosthesis is discouraged for the first few weeks until the incision has healed. If the removable prosthesis is only replacing posterior teeth, then patients should avoid using it during the entire healing period. Removable prostheses should be adjusted to minimize any contact with the grafted site. The facial flange is completely removed, and the ridge area over the graft is relieved. The prosthesis may be relined with tissue conditioner, and denture adhesive is often necessary for added retention. The patient is instructed to use the removable prosthesis for cosmetic appearance and minimize function. Unfavorable concentration of forces from the opposing dentition should be avoided, and a broad distribution of occlusal contacts is preferred.[94] Patients wearing removable prostheses over larger bone grafts should maintain a softer diet for at least 2 months after surgery. After this time period, the onlay graft has formed a union to the host bone and relies less on the fixation screws for immobility. Small-diameter temporary or transitional mini-implants have been used successfully to support fixed interim prostheses for patients less tolerant of complete or partial removable dentures.[95] The transitional implants should be placed in native bone and not within the graft.

• **Figure 30-52** A postoperative view of the incision line after 1 week of healing.

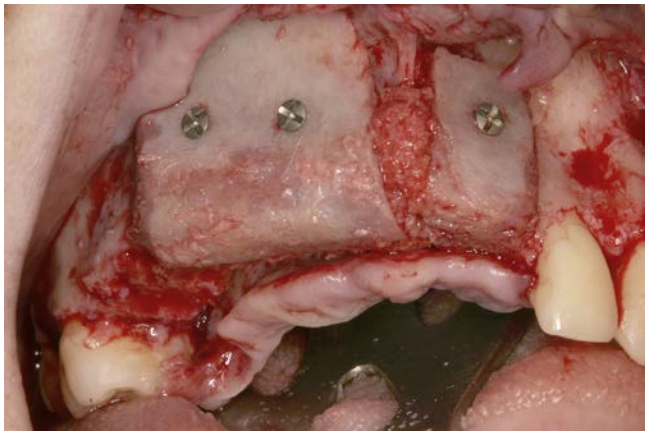
Postoperatively the patient should continue antibiotic therapy for at least 1 week. The continued short-term use of glucocorticoids can diminish swelling and edema of the soft tissues. Narcotic analgesics are prescribed for use after surgery. Thereafter the patient may transition into the use of nonsteroidal anti-inflammatory medications for pain control. Chlorhexidine rinsing is used for oral hygiene until the sutures are removed. Smoking has been associated with a high rate of wound dehiscence and graft failure.[96] Patients are instructed to quit 1 week prior to surgery and told not to smoke at least until the incision is completely closed.

Block Bone Grafts

Autogenous block bone grafting is a well-proven and predictable method to augment the maxilla and mandible for dental implant placement. Block bone grafts may be preferred to other techniques (ridge splitting, distraction osteogenesis, interpositional grafts), as they can better three-dimensionally reconstruct the lost anatomic ridge contour. Smaller cortical blocks can be harvested from intraoral donor sites (symphysis, ramus). Corticocancellous blocks from the iliac crest have proven to be very effective in managing larger bone defects and greater atrophy[28] (Figures 30-53 through 30-56).

The osseous recipient bed is prepared to improve the fit and contact of the bone block to the ridge. Perforation of the cortex with a small round burr releases growth factors, expedites revascularization of the graft, and improves graft-to-host union.[91] The bone graft should have intimate contact with the underlying host bone. The clinician should preferably decorticate the host bone to mortise the cortical bone block to the ridge rather than significantly adjusting the graft.[91] Block bone grafts should be oriented with the cancellous side against the host bone. Corticocancellous

block grafts from the iliac crest require less adjustment, as the softer cancellous bone will mold to the ridge. Block grafts do not tolerate micromovement and will fail to incorporate unless rigidly fixated. The graft is mortised into position and fixated to the ridge with screws. Fixation screws typically range from 1.0 to 2.0 mm in diameter. A screw length that maximizes retention within the host bone should be selected. A lag screw technique is used for fixation of cortical onlay bone grafts. The screw engages and threads the host bone but fits passively through the cortical bone graft to compress and rigidly fixate the block. Although one screw may be considered for small block grafts, two or more screws should be used for larger grafts. The fixation screws may also have a positive effect on graft retention, as they tent the periosteum during remodeling. The periphery of the block graft and small discrepancies between the graft and host bone may be filled with a variety of graft materials. If available, autogenous cancellous bone is preferred. An alternative is to locally harvest cortical shavings using a bone scraping device. Particulate mineralized bone allograft may also be considered for grafting the borders of the block.

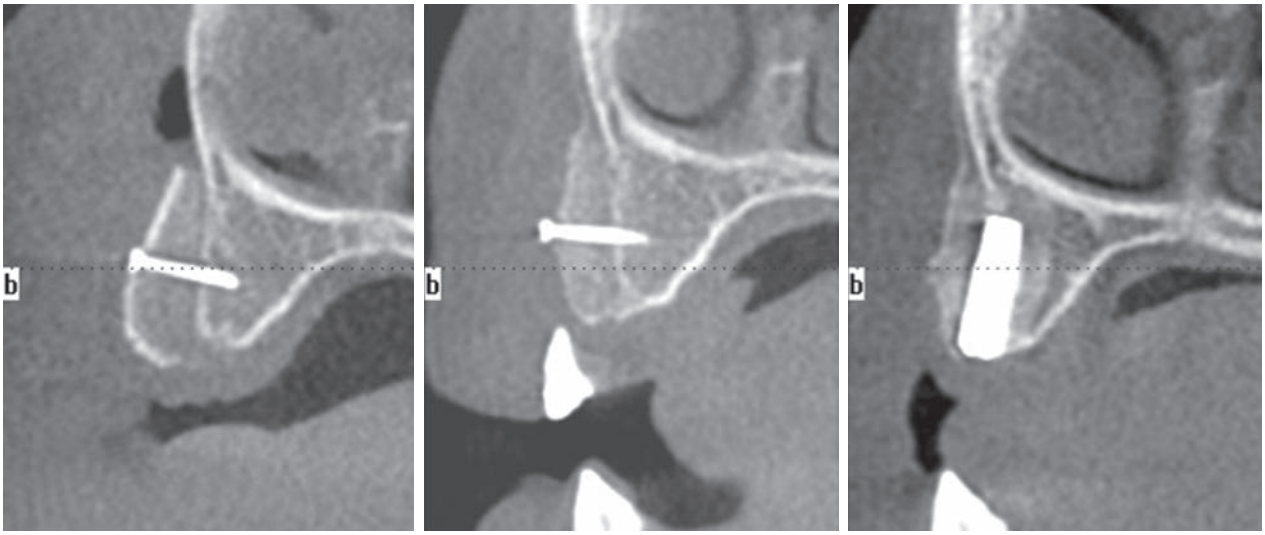


• **Figure 30-53** Corticocancellous block bone grafts from the iliac crest are used to reconstruct the maxillary bone defect (patient from Figures 30-8, 30-9, and 30-10).

The routine need for barrier membrane coverage over block bone grafts has been a debated topic. Although some studies have found that membranes have a positive influence on graft healing, others dispute their significance.[97,98] Cortical bone grafts exhibit minimal resorption and do not typically require membrane protection.[14,15,99,100] Cancellous bone and particulated bone grafts are more susceptible to volume loss and would benefit from membrane use. The use of a barrier membrane may improve the incorporation of the peripheral particulate graft around a block (Figures 30-57 through 30-59). Bovine hydroxylapatite has also been found to reduce graft loss when placed over and around autograft blocks.[101] Collagen membranes are preferred over PTFE as they are associated with fewer complications such as exposure and infection.[102]

Guided Bone Regeneration

Guided bone regeneration (GBR) uses the principle of selective cell repopulation to repair bone defects. A barrier membrane is used to occlude soft tissue cells and allow slower growing bone cells to repopulate the defect and regenerate bone.[103] The barrier membrane is shaped to extend beyond the bone defect margins and cover the area during healing. The original studies on GBR used an expanded PTFE membrane.[103] This nonresorbable membrane allows the barrier to remain intact during the entire healing period but also requires removal thereafter. To prevent migration and exposure, a PTFE membrane needs to be sutured or fixated into place with sutures, tacks, or screws. Development of resorbable membranes simplified the technique, as removal is unnecessary and there is less need for fixation. Collagen membranes have several unique and favorable properties, including improved hemostasis, chemotaxis for fibroblasts, and ease of manipulation.[104] Many resorbable membranes



• **Figure 30-54** Computed tomography scan images of the corticocancellous block after placement, after 4 months of healing, and after implant insertion.

are made from bovine or porcine type I collagen. Bovine pericardium and allogeneic dermis also have suitable properties for use as barrier membranes for GBR.[105,106] Crosslinking of the collagen fibers is a laboratory modification that acts to prolong the resorption time of the membrane, increasing barrier function.[104] Crosslinked collagen membranes may last 2 to 6 months or longer. However, as GBR is a volume-dependent process, a resorbable membrane must remain intact long enough for bone cells to repopulate the area. Larger bone defects or vertical augmentation treated by GBR may necessitate use of a nonresorbable membrane. In most cases a particulate bone graft material is placed under the membrane to act as an osteoconductive scaffold for bone replacement. Several types of bone graft materials have been used for this purpose, including autogenous bone, allografts, xenografts, and alloplastic bone substitutes. Particulate autograft may be obtained from the local surgical area or posterior mandible using a scraping device or drills.[21] Block autogenous bone may also be harvested from the posterior mandible area and particulated with a bone mill. Tenting screws, titanium plates, or even a dental implant can also be used to assist in space maintenance under the membrane.[107,108] The inclusion of titanium reinforcement within a PTFE membrane prevents collapse and allows the clinician to shape the desired contour.[109,110] The healing period of membrane-protected defects typically ranges from 6 to 9 months. Larger vertical defect require longer healing periods, whereas smaller dehiscent-type defects may require less time.

Horizontal Bone Augmentation Using GBR

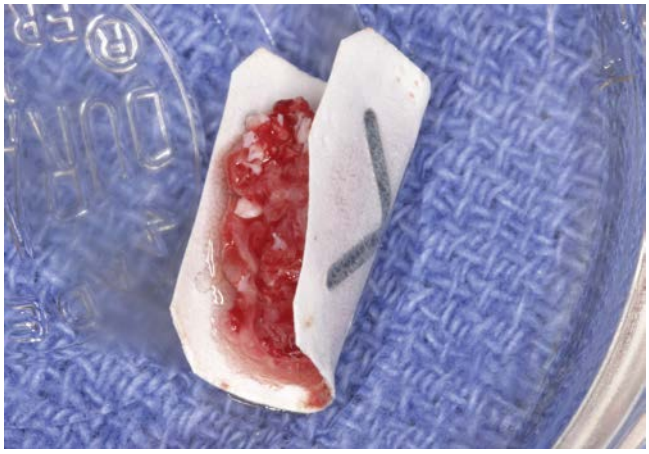
Guided bone augmentation is often used to repair dehiscent defects around dental implants. In the anterior maxilla, resorption of the facial plate following extraction often results in a ridge width deficiency. The greatest area of bone volume loss is at the facial ridge crest. Therefore it is not uncommon to need bone augmentation around the neck of the implant. Guided bone regeneration has proven to be a very reliable method to repair localized bone defects with simultaneous implant placement.[111] In most cases a bone substitute and a resorbable collagen membrane will suffice. If local bone can be harvested, this may be used to cover exposed threads. When facial ridge contour is also deficient, it can be restored with a slower resorbing graft material under the membrane, such as bovine hydroxylapatite.[112] The grafted implant can be covered by the flap and submerged for protected healing.

In the case of more extensive bony width defects, precluding implant placement, a delayed implant protocol following lateral ridge augmentation is indicated. The amount of horizontal bone augmentation with using GBR has been reported to range from 2.0 to 4.5 mm.[113] The osseous bed may be prepared by perforation of the cortex with a small burr. The intramarrow penetration can facilitate angiogenesis and allow osteogenic cells to migrate into the grafted area.[114] Modest gains in ridge width may be obtained using bone substitutes, such as mineralized bone allograft, and a resorbable collagen membrane. Slightly greater horizontal gains have been found using a mixture of particulate autograft and bovine hydroxylapatite with a collagen membrane.[115]

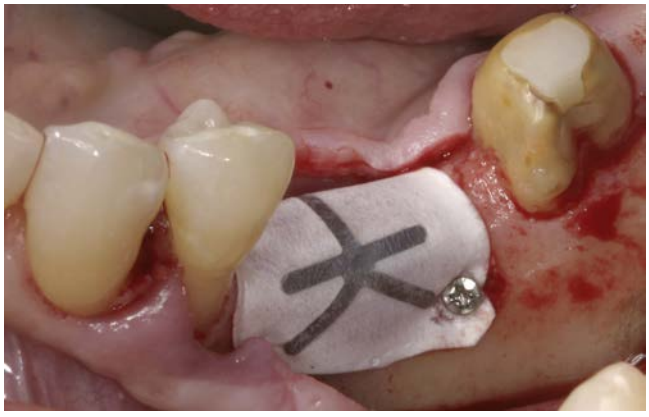
Vertical Bone Augmentation Using GBR

Although simultaneous vertical bone augmentation and implant placement has been reported, a two-stage procedure is usually indicated.[116,117] As vertical bone augmentation is more biologically challenging, the GBR technique may require modification. The majority of studies evaluating GBR for vertical bone augmentation used particulate autograft with a titanium-reinforced PTFE membrane[117,118] (Figures 30-60 and 30-61). Often a secondary donor site is needed for harvesting larger amounts of particulate bone. The use of a bone scraping device within the mandibular ramus and body has been shown to be a useful technique with low morbidity.[21] The titanium-reinforced PTFE membrane should be stabilized with tacks or screws. It is helpful to fixate the membrane on the palatal or lingual bone before adding the bone graft and then rotating it over the augmented site. Flap advancement procedures are then performed to obtain tension-free primary closure.

The most frequent postoperative complication of GBR is membrane exposure.[117] Surgical methods to passively advance the flaps during closure over the membrane must be employed. Exposure of expanded PTFE membranes has been shown to significantly reduce bone regeneration.[116]



• **Figure 30-60** A titanium-reinforced polytetrafluoroethylene (PTFE) membrane is filled with particulate autogenous bone and bovine hydroxylapatite.



• **Figure 30-61** The vertical defect in the posterior mandible treated with a titanium-reinforced polytetrafluoroethylene (PTFE) membrane filled with particulate autogenous bone and bovine hydroxylapatite.

Exposure rates as high as 31% resulting in infection and GBR failure have been reported.[119] A membrane made of high-density polytetrafluoroethylene (d-PTFE) was developed for use in socket grafting.[120] Dense PTFE membranes have also been found to be as effective as the expanded version when used for ridge augmentation.[121] However, primary closure and avoidance of membrane exposure are advised with this application. Exposure of collagen membranes to the oral cavity increases the rate of degradation and loss of barrier function.[122]

Sinus Bone Grafting

It is often unnecessary to consider a secondary donor site for bone harvest when performing sinus augmentation. Over the years numerous bone substitutes have been successfully used for sinus grafting. The 1996 Sinus Graft Consensus evaluated retrospective data on various graft materials and concluded that they all seemed to perform well.[123] However, the data analysis did not factor the amount of residual bone below the sinus. Bone substitutes have been suggested for the posterior maxilla with less resorption or modest

sinus pneumatization. The highly pneumatized sinus with minimal bone along the floor can be biologically challenging to graft with bone substitutes alone. There has been concern for resorption and volume loss when using cancellous marrow for sinus floor grafting. Mixing the cancellous bone with a slow-resorbing graft material, such as bovine hydroxylapatite, can diminish volume changes with healing. In the management of the pneumatized sinus, rhBMP-2 has been compared with autogenous bone with favorable results.[5]

There are many possible advantages in using autologous bone in sinus grafts, especially when minimal bone remains below the sinus floor.[124-126] Several studies have found an increase in bone formation when autologous bone is used alone or added to other grafting materials in sinus grafts.[124,127-129] Froum and colleagues[127] found a significant increase in vital bone formation when as little as 20% autologous bone was added to bovine-derived grafts. As previously discussed, local bone can be easily harvested from the tuberosity or collected from a bone scraper passed over the lateral maxilla and zygomatic buttress. The use of a barrier membrane over the sinus window has also been advocated to increase vital bone formation when bone substitutes are used.[130] Instead of using a commercially available membrane, a thin piece of cortical bone obtained from the tuberosity area can be used as an autologous barrier to cover the window. A membrane may not even be necessary when a significant portion of the graft is autologous bone.

Compared to bone substitutes, the healing time requirements of autologous bone grafts are shorter, especially in larger pneumatized sinuses. The healing period for sinuses grafted with autologous bone can be as short as 4 months compared to the 8 to 10 months often recommended for bone substitutes.[127] The addition of autologous bone to composite bone grafts can also shorten healing times.[56,127] This offers a significant advantage, as patients often object to extended treatment lengths. Not only do autologous bone grafts heal faster than bone substitutes, the quality of the regenerated bone is often better. Histological studies have shown greater bone formation and higher bone-implant contact when autologous bone grafts are used compared with allografts in sinus grafting.[129] This improved bone formation at an earlier time can allow for shorter implant healing periods compared to the use of bone substitutes. The use of growth factors, such as rhPDGF, may offer an alternative to using autograft to accelerate graft healing.[131]

It may also be beneficial to use autologous bone for sinus grafting when additional simultaneous onlay augmentation is desired. The posterior maxilla resorbs medially following tooth loss, and this pattern of bone loss often results in an unfavorable ridge relationship with the opposing lower dentition. It is not unusual to require sinus bone grafting to increase the vertical bone dimension as well as onlay bone grafting to augment the ridge width and/or correct bone deficiencies in the posterior maxilla. Autologous bone may be harvested for sinus bone grafting and simultaneous residual ridge reconstruction using autologous block grafts. The healing period of the onlay block and sinus bone grafts will be similar, allowing for earlier implant placement. This approach may be preferred to a staged reconstruction where sinus grafting is performed first using bone substitutes and autologous block bone grafts are placed at a later date.

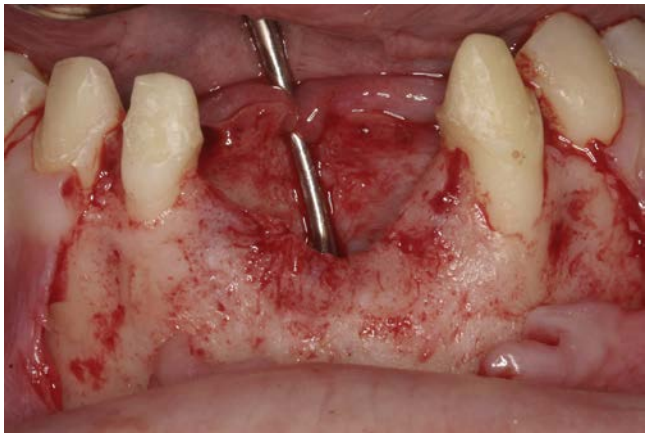
Titanium Mesh Grafts

The use of titanium mesh for bone augmentation should not be confused with guided bone regeneration techniques. Guided bone regeneration uses a cellular occlusive barrier membrane to impede soft tissue penetration and allow the slower growing bone cells to repopulate the osseous defect.[103] Titanium mesh acts as a protective matrix to maintain space and facilitate bone fill but is not cellular occlusive. The mesh lattice is porous and allows passage of nutrients, cells, and vascular ingrowth. One study on mesh pore size suggests that macroporous openings may be preferable to a micropore mesh.[132]

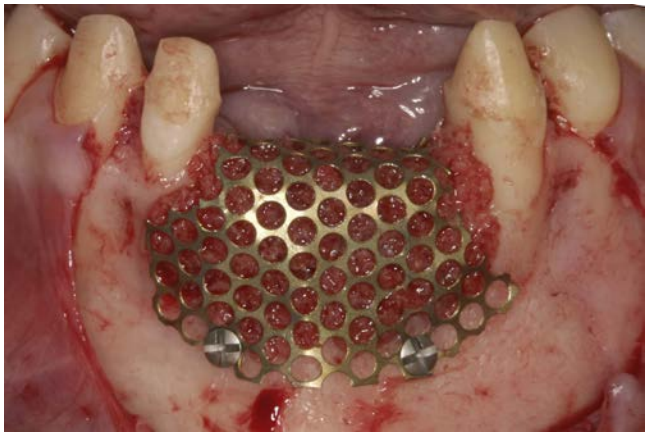
Traditionally, the titanium mesh technique used cancellous autogenous bone graft from the iliac crest[133,134] (Figures 30-62 through 30-64). This approach has been shown to produce significant vertical bone augmentation gains exceeding 1.0 cm.[135,136] However, a secondary donor site, such as the iliac crest or tibia, is required with the associated morbidity of graft harvest. As an alternative, particulate intraoral autograft may be combined with bone substitutes using titanium mesh, but the reported volume gains are modest.[137,138] Use of rhBMP-2 has been actively studied as an alternative to harvesting autogenous bone.[28,76,78] Marx and colleagues[76] compared cancellous autograft with a composite graft of rhBMP-2/ACS with mineralized bone allograft and platelet-rich plasma and found similar outcomes for vertical ridge augmentation using titanium mesh.

The titanium mesh may be cut and formed before surgery. The traditional preparation of the mesh involved making a maxillary impression and pouring a stone cast. A mock buildup of the reconstructed ridge was made on cast and the mesh was cut and shaped over it. The formed mesh would then be cleaned and sterilized. With the advent of CBCT technology, a stereolithographic model can replace the stone cast, allowing the surgeon to have an exact replica of the bony anatomy. If this is prepared before surgery, the clinician should use gloved hands when handling the mesh to avoid surface contamination. Titanium mesh is easy to cut, shape, and adapt to the residual ridge. It takes little time for an experienced surgeon to accomplish this task at the time of surgery. Clinical trials have been performed on custom titanium shells made before surgery.[139] Resorbable scaffolds are also under development.

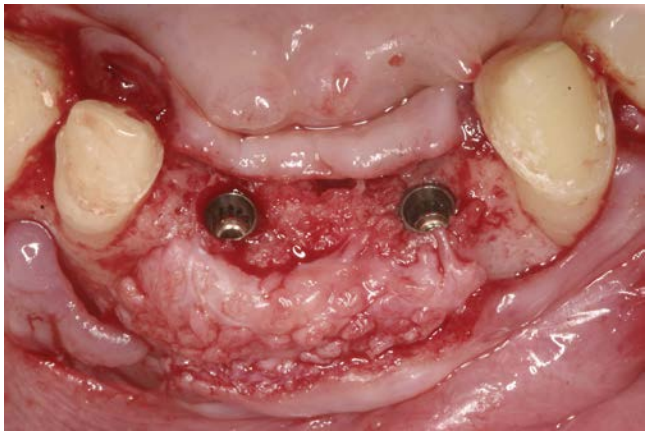
The mesh should extend well onto the palatal bone and be cut to avoid any contact with adjacent teeth. The edges of the cut mesh should be smoothed and well adapted to the bone. The mesh thickness should be adequate to resist flexing and micromovement during healing but thin enough to easily mold. A 0.2-mm thickness mesh appears to fulfill these requirements. The bone graft is packed into the formed mesh and molded onto the site. Platelet-rich plasma



• **Figure 30-62** A vertical bone defect in the anterior mandible.



• **Figure 30-63** The defect is reconstructed with cancellous autograft and covered by a titanium mesh.



• **Figure 30-64** The bone graft is well incorporated after 6 months of healing.

helps with containment of the particulate graft. Monocortical fixation screws (4.0 mm) can be used to secure the mesh. Self-drilling screws can be used in the maxilla, eliminating the need for site preparation. The screws are placed along the outer edge of the mesh and should avoid the surrounding tooth roots. Often the placement of screws into the facial cortex is adequate for mesh stabilization. However, the use of a palatal screw is encouraged for added fixation.

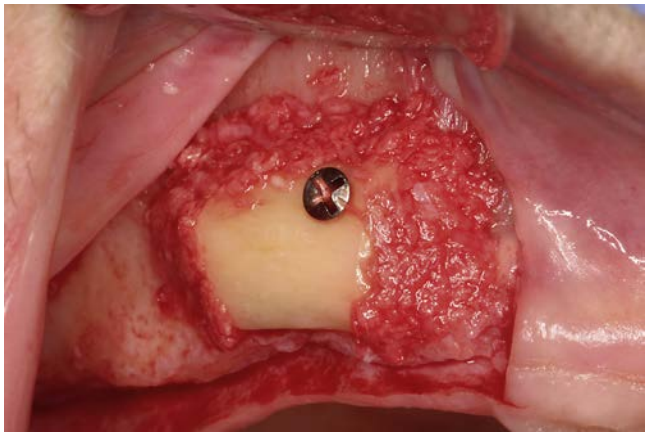
Exposure of the titanium mesh is the most common complication with this technique.[135] As previously discussed, the need for tension-free primary closure is of paramount importance. The use of platelet-rich plasma or a collagen membrane over the mesh has been shown to reduce exposures.[140,141] Early mesh exposure, within the first 2 weeks, is of greater concern as the graft is more prone to infection and failure.[76] Late mesh exposure may well be tolerated and does not seem to have a significant negative influence on underlying bone formation.[135] During healing, the mesh can erode through the thinner facial mucosa. There should be no pressure on the area from a soft tissue–borne prosthesis. The patient can clean the exposed mesh with chlorhexidine on a cotton ball or sponge. Rarely does the exposed mesh need to be prematurely removed unless the exposure is significant.

The titanium mesh grafted site is re-entered after at least 6 months of healing for implant placement. A mucoperiosteal flap is reflected to completely expose the mesh. The fixation screws are removed, and the edge of the mesh can be grasped with a hemostat to facilitate its removal. The mesh may be cut and pried off the bone. A fibrous layer or "pseudo-periosteum" is typically found under the mesh covering the newly formed bone.[134]

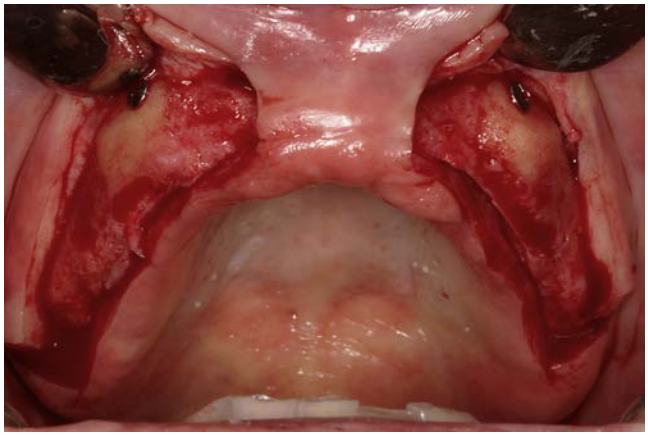
This tissue can be incised along the ridge crest and reflected, leaving it intact. The quality of the bone regenerated by this technique is often less dense (type 3).

Graft Resorption

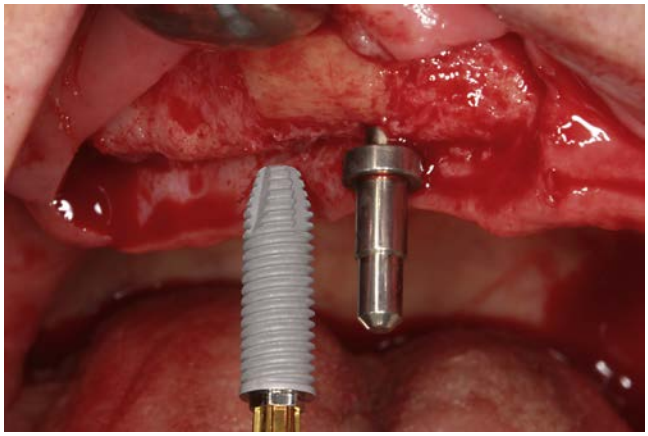
Bone graft remodeling is a necessary biologic aspect of autograft healing and incorporation to the osseous recipient site. There are several factors that may affect the amount of graft resorption during healing. Bone grafts inserted between osteotomized segments (interpositional grafts) resorb less than onlay grafts placed outside the bone contour.[142] Vertical bone grafts are more technically demanding and subject to greater volume changes than horizontal augmentations.[117] The osseous microarchitecture of the graft will also influence graft healing. Denser cortical grafts, from the calvarium or mandible, tend to resorb less than those containing a greater cancellous component, such as the iliac crest.[143-145] The volume loss of cortical bone grafts used for onlay augmentation has been measured as less than 25%.[100,145] Corticocancellous bone grafts from the ilium are associated with greater resorption (up to 50%) due to the thinner outer cortex and more porous cancellous component.[146,147] Although some studies have reported significant graft resorption, they still conclude that onlay bone grafting is a predictable technique for implant placement.[145,146,148,149] When using iliac bone, it may be prudent to overbuild the reconstructed ridge in anticipation of volume loss upon healing (Figures 30-65 through 30-71). Reconstruction of the atrophic ridge is usually staged with implant placement after graft healing to allow for remodeling (Figures 30-72 and 30-73). Enough time should elapse for graft incorporation, but



• **Figure 30-65** The thin anterior edentulous maxilla is augmented with a cortical block bone graft from the mandibular ramus.



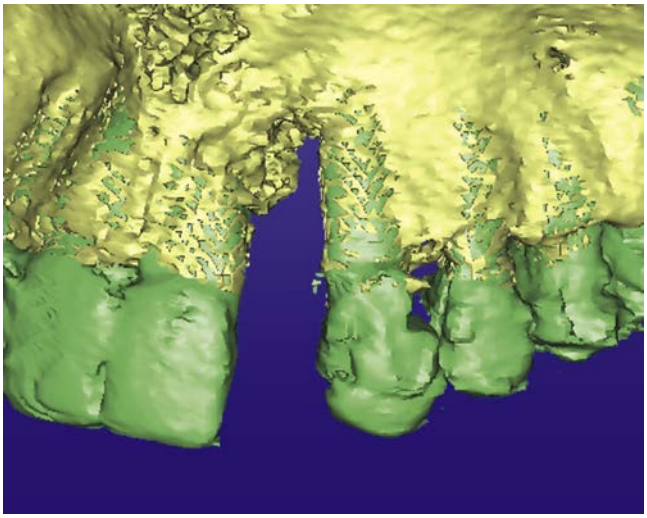
• **Figure 30-66** The cortical bone graft is well incorporated after 4 months of healing.



• **Figure 30-67** Placement of implants into the dense bone graft sites results in favorable primary stability.

• **Figure 30-68** The maxillary implants are restored with an immediate-load fixed provisional prosthesis.

• **Figure 30-69** Defect in the anterior maxilla following implant failure and failed attempts at repair.



• **Figure 30-70** A computed tomography scan of the maxilla reveals the significant vertical defect and loss of alveolar bone around the teeth.

implants should be inserted early enough to stimulate and maintain the regenerated bone.[150] Most studies report that the majority of the resorption occurs within the first year and thereafter is low.[143,146,147,151] Although the degree of iliac bone resorption can be variable and in some cases significant, it does not appear to be detrimental to long-term dental implant survival.[146,147,149,152] Several studies document minimal marginal bone loss after implant placement and loading in grafted sites.[72] This may be a factor of implant surface and/or neck design.[72,153]

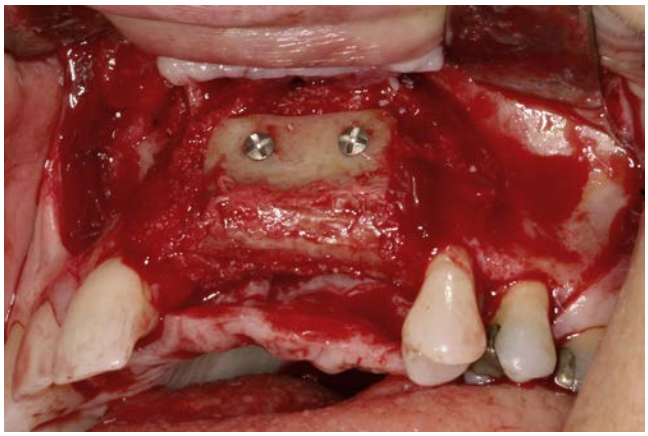
Implant Placement in Grafted Sites

It is well accepted that survival is typically higher when implants are placed into native bone.[154-156] Several studies on autogenous onlay bone grafts report lower implant survival rates. There are several variables that can account for this finding. The most significant factor is the use of machined-surface dental implants. During the developmental and early routine periods of reconstructing severely atrophic jaws, machined surface implants were used with iliac bone grafts.[3] The lower survival of machined surface implants in the maxilla and poorer quality bone is well documented.[157,158] The use of textured surface implants in onlay bone grafts can provide implant survival rates similar to native bone.[159]

Simultaneous placement of dental implants into block autografts also has a much lower survival rate than staged insertion after graft healing.[3,40,160,161] This approach was used initially in an attempt to fixate the bone graft, decrease the number of surgeries, and shorten treatment length. A staged technique is preferred, allowing the bone graft to remodel and incorporate before implant insertion. This approach has been shown to result in higher bone-to-implant contact and higher implant survival.[159] It also allows the surgeon to place implants in more ideal prosthetic positions. Enough time should elapse for graft incorporation, but implants should be inserted early enough to stimulate and maintain the regenerated bone.[146] Autogenous block grafts should heal for approximately 4 months before implant placement.[15,162] Particulate cancellous bone grafts with barrier membranes or titanium mesh used for ridge augmentation often require longer healing periods of at least 6 months. A CT scan is taken to evaluate the augmented site and plan the implant surgery.

The placement of implants into healed bone grafts is similar to their use in sites that have not been grafted. However, with horizontal augmentation, the implant site is often at the junction between the block and host bone. The surgeon should be careful not to displace the block from the ridge during the implant osteotomy and placement. Fixation screws are usually removed before implant insertion. Elevation of large flaps simply for screw removal is discouraged as this disrupts the vascular supply to the healed graft. A small mucosal incision over the screw head allows for easy retrieval. If a fixation screw is not in the path of implant insertion, it may be left intact, especially if it will provide added stability to the graft. Upon healing, the quality of block mandibular bone grafts is often dense regardless of the original quality of the recipient bone. An appropriate drilling sequence for dense bone and even tapping may be necessary for implant insertion in cortical bone grafts.

The healing period of implants placed into incorporated bone grafts is similar to that for native bone. Microtextured implant surfaces have decreased implant healing periods to as little as 6 weeks.[163] Immediate implant loading in grafted bone may even be considered if primary implant stability is adequate[163] (Figures 30-74 through 30-77). Additional graft resorption following implant placement and delayed loading has not been noted radiographically.[72,164-166]



• **Figure 30-74** A corticocancellous block bone graft from the iliac crest is used to reconstruct the defect.

Guided Tissue Regeneration in Implant Dentistry

BACH LE, BRADY NIELSEN

Introduction

The concept of guided tissue regeneration (GTR) began many years ago in the field of neural regeneration. In the early 1940s it was observed that regeneration of a severed nerve was impaired by ingrowth of fibrous tissue and scarring.[1] However, when the principle of compartmentalization was applied, using allogeneic aorta as a protective conduit over the cut ends of the nerve, regeneration of the nerve was seen.

In 1957 the same principle was applied by Murray to bone regeneration in dog studies. He found that bone defects created in the ilium and protected with a plastic cage would later fill with new bone. The bone fill could even be enhanced beyond the original anatomy of the ilium if the protective cage created a compartment with an expanded volume.[2]

Hurley and colleagues were among the first to use guided bone regeneration (GBR) in humans in 1959. Their use of GBR for experimental spinal fusion involved the placement of a cellulose acetate filter over a grafted site to exclude the overlying, fully differentiated tissues from the bony defect.[3] Their work provided the foundation for GBR techniques still used in implant dentistry today. Over the next 20 years, the principle of compartmentalization to allow regeneration of a select tissue type was advanced until its widespread use in the field of dentistry occurred with the growth of dental implants during the 1980s.

During the developmental phase, many contributed valuable research and data on the topic of guided tissue regeneration by compartmentalization. Linghorne performed dog studies to demonstrate the regeneration of 15-mm long bony continuity defects created in the fibulae by application of a polyethylene tube across the defect.[4] Melcher placed cellulose acetate barriers over surgically created bone defects in rats to allow bony regeneration. He theorized that the importance of the membrane was to protect the hematoma from invasion by nonosteogenic soft tissues and to prevent distortion of the hematoma by pressure from the overlying tissue.[5] This reasoning still applies today.

In the field of dentistry, and specifically oral surgery, Philip Boyne was among the first to develop GTR in the 1960s. Boyne and Bassett tested microporous cellulose acetate laboratory filters in the healing of cortical defects in long bones and used cellulose acetate barriers for regeneration of mandibular defects.[6,7] Successful use of another barrier material, Teflon mantle leaf, was described by Kahnberg for the regeneration of mandibular defects in rabbits.[8]

Prior to the work by Hurley et al. on the concept of GBR, Linghorne and O'Connell in 1950 demonstrated the potential for regeneration of specific periodontal structures.[9] They observed that bone defects created adjacent to teeth and grafted with autogenous bone chips would only heal with regeneration of bone, cementum, and periodontal ligament when new connective tissue attachment formed coronal to the bony defect, thus serving as a barrier for unwanted gingival tissue ingrowth. Because membranes were not used in their studies, the more aggressive gingival epithelium would invade the bony defect in those cases where the connective tissue attachment did not form above the level of the bone defect. Their findings gave rise to the epithelial exclusion theory and served as a foundation for later studies in regenerative periodontics that would also contribute to our understanding of guided tissue regeneration.

In 1976 Melcher described the role of progenitor cells in periodontal regenerative treatment.[10] In the 1980s Karring and Nyman applied barrier membranes to periodontal regeneration research and discovered that the first cells to populate a wound area would determine the type of tissue to ultimately occupy that space.[11,12] Further studies supported the use of barrier membranes to isolate a defect area and allow regeneration of a specific tissue type.[13,14] The implications of guided tissue regeneration for alveolar bone regeneration began to be apparent, and the use of barrier membranes specifically for the regeneration of bone was further demonstrated.[15,16]

	Low Risk	Moderate Risk	High Risk
Type of Defect	Horizontal defect	Vertical defect (1-3 mm)	Vertical defect (>5 mm)
Edentulous Span	Single tooth	Two teeth defect	Multiple teeth
Number of walls	3 Wall defect	2 wall defect	1 wall defect (knife-edge)

• **Figure 31-1** Defect configuration.

The use of GTR in implant dentistry today, more specifically guided bone regeneration, is recognized as an effective method of alveolar ridge augmentation and a means for managing localized defects associated with dental implant placement.[17,18] Guided bone regeneration is now an important part of implant dentistry due to its ability to restore form, function, and esthetics through more ideal implant placement.[19]

Defect Configuration

An important prognostic factor for GBR success is defect configuration (Figure 31-1). Width of the edentulous span, the number of intact bony walls, and the horizontal and vertical component of the defect are critical factors affecting the success of GBR procedures. A single tooth site defect can be predictably augmented with GBR (Figure 31-2, *A*), whereas wider defects involving multiple missing teeth (see Figures 31-2, *B* and *C*) are much more difficult due to poor graft stability over a wide span.[20] Particulate grafts tend to migrate in larger defects due to greater flap reflection.

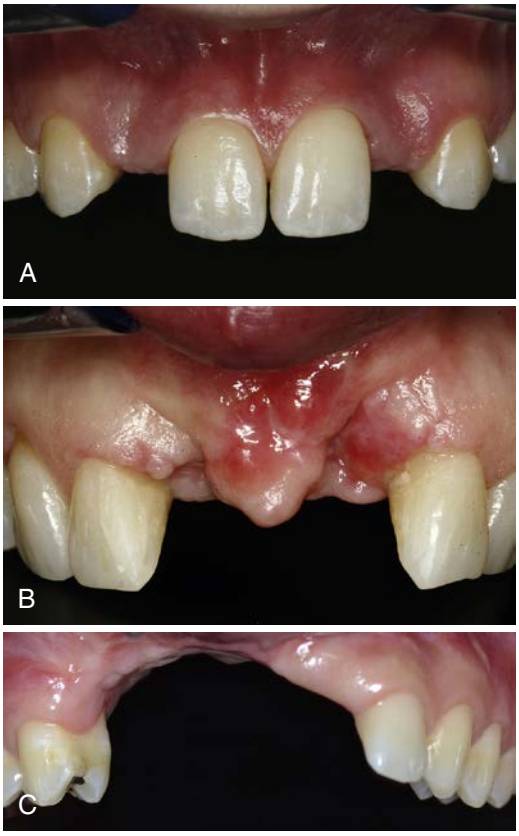
Another important variable in evaluating a defect is the number of bony walls. Defects with three or four intact walls (Figure 31-3, *A*), have better graft containment and osteogenic potential than two- or three-wall defects (see Figure 31-3, *B*). Socket preservation in intact socket defects is more predictable than that performed in sites where the buccal plate has been lost. For lateral augmentation, the shape and contour of the defect site are also important factors. A concave defect (Figure 31-4, *A*), is more predictably treated than a flat wall defect (see Figure 31-4, *B*), because its shape helps support and contain the graft.

Ridge defects with severe vertical components (see Figure 31-2, *C*), are more challenging to correct with GBR due to poor osteogenic potential, space maintenance, and graft stability. Titanium mesh, titanium re-enforced membrane, and tenting screws have been described to improve graft stability and space maintenance.[21,22] Defects with only horizontal components are more predictably treated due to better graft stability and more osteogenic surface area to support the graft.

Principles of GBR

Patient Selection

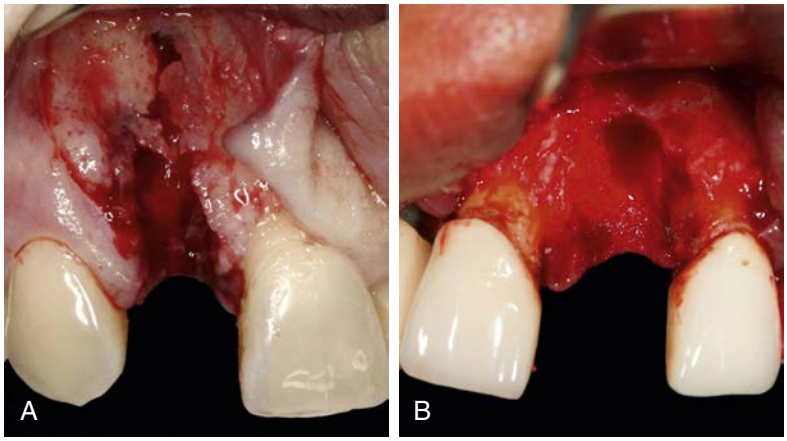
GBR is a viable treatment option for correction of the majority of localized alveolar ridge defects. Patients must understand that achieving the ideal esthetic result may require a lengthy course of treatment that could involve multiple procedures. In addition, patient factors such as uncontrolled diabetes, immunocompromised state, smoking, poor oral hygiene, history of radiation or bisphosphonate use, and heavy alcohol consumption may negatively affect treatment outcome.



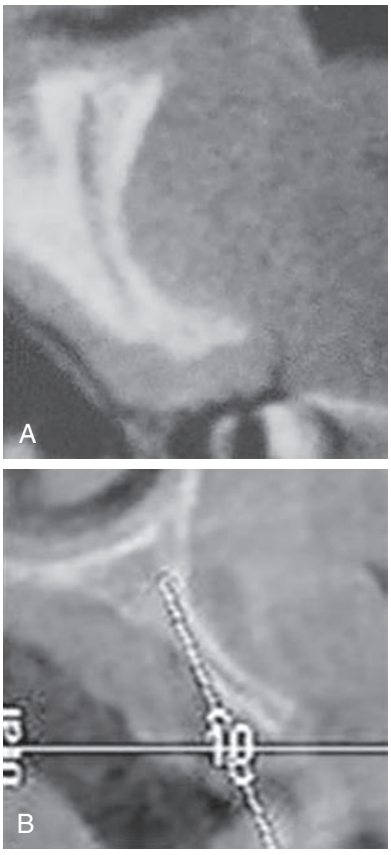
• **Figure 31-2** **A,** Single tooth defect sites are ideal for treatment with GBR. **B,** Multiple tooth defect is also treated predictably with GBR. **C,** Large, multiple tooth defect with significant alveolar deficiency. (**A** and **B** from Le B, Nielsen B: Esthetic implant site development, *Oral Maxillofac Surg Clin North Am* 27(2):283-311, 2015. **C** courtesy of Brady Nielsen, DDS, Los Angeles, CA.)

Incision Design

Various incision designs can be utilized for GBR, each with advantages and disadvantages. A wide flap access allows greater visibility, but may cause unwanted graft migration due to greater dissection. A narrow flap runs the risk of necrosis and dehiscence, and incisions made within the confines of the bony defect will limit the extent of augmentation. An important prerequisite of incision design is a broad-based flap to improve vascularity and prevent flap necrosis or dehiscence. A vertical incision facilitates release of the soft tissue to accommodate augmentation of larger defects.



• **Figure 31-3** **A,** Narrow single wall defect with nearly 4 walls intact. **B,** Wide single wall defect with only three walls intact. (From Le B, Nielsen B: Esthetic implant site development. *Oral Maxillofac Surg Clin North Am* 27(2):283-311, 2015.)



• **Figure 31-4** **A,** Concave defect shape supports and maintains the graft. **B,** Flat defect shape allows for graft migration. (From Le B, Nielsen B: Esthetic implant site development. *Oral Maxillofac Surg Clin North Am* 27(2):283-311, 2015.)

In situations where GBR is performed with extraction, it is also important to limit the amount of disruption to the existing soft tissue architecture. This requires careful planning to allow for adequate tissue release with as little disturbance to the existing normal anatomy as possible. Incisions must be placed outside defect margins on stable bone, and should never be made within the defect site.

In edentulous sites, the flap apex is generally created using a crestal incision. This incision can be extended into the sulcus of adjacent teeth as a sulcular incision for augmentation of small horizontal defects (1-2 mm). A vertical releasing incision typically is not necessary for small horizontal defects. If significant augmentation is required, a vertical releasing incision is used. The releasing incision is placed distal to the defect over the adjacent tooth. It allows for effective periosteal release and greater expansion of the soft tissue matrix. The vertical incision should begin as a curvilinear extension from the crestal incision, and may be done sparing the papilla (Figure 31-5, *A*). The incision extends distal to follow the mucogingival junction to the midline of the adjacent tooth. The vertical release is then made apically to the depth of the vestibule. This "open-book incision" is an effective technique to maximize release for augmentation while still preserving esthetics (see Figure 31-5, *B*).[23] This minimal access design also facilitates graft confinement and decreases graft migration common with wider dissection. In addition, the single site-specific vertical release design allows for sliding rotation of the distal arm of the flap coronally in cases where slight vertical augmentation is required to correct soft tissue defects (Figure 31-6). Bilateral vertical releasing incisions can be used for additional release, especially for significant vertical defects or when augmenting near the mental foramen.

Exposure should be carried to the depth of the vestibule and be sufficient to visualize healthy bony margins around the entirety of the defect. Keep in mind the desired area of augmentation to avoid placing incisions within the defect area. Unnecessary or excessive flap reflection should also be avoided because this will result in apical and lateral graft migration away from the crest of the ridge (Figure 31-7). Predictability of augmentation using particulate grafts is largely dependent on the ability to stabilize and maintain the soft tissue matrix. Maintenance of this space and graft containment becomes more difficult in wide edentulous spans or with excessive flap elevation. Another measure to mitigate apical graft migration is to ensure adequate basal

• **Figure 31-7 A,** Alveolar contours can affect graft migration, especially when there is excessive flap reflection. **B,** Post-operative CT scan demonstrating inadequate crestal bone volume due to undesirable apical migration of particulate bone graft. (Courtesy Bach Le, DDS, MD, Los Angeles, CA.)

graft volume to support the crestal portion of the grafted site. The analogy of building a sandcastle applies with the use of particulate grafts for ridge augmentation. When building a sandcastle, a wide base is needed first to support the sand at the highest portion.

Defect Site Preparation

Following elevation of the mucoperiosteal flap, any remaining soft tissue remnants must be removed to create an osteogenic bed for augmentation. The need for perforation of the recipient site in GBR is controversial. The blood supply to the graft and access to osteoprogenitor cells are thought to be made more available by perforation of the recipient site bone. This has been shown to improve graft success using autogenous bone block, but its benefits in GBR are debatable.[24,25] The senior author of this chapter does not routinely perforate the recipient bone bed and has not seen a difference in the outcome of the graft procedure.

Membrane Placement and Space Maintenance

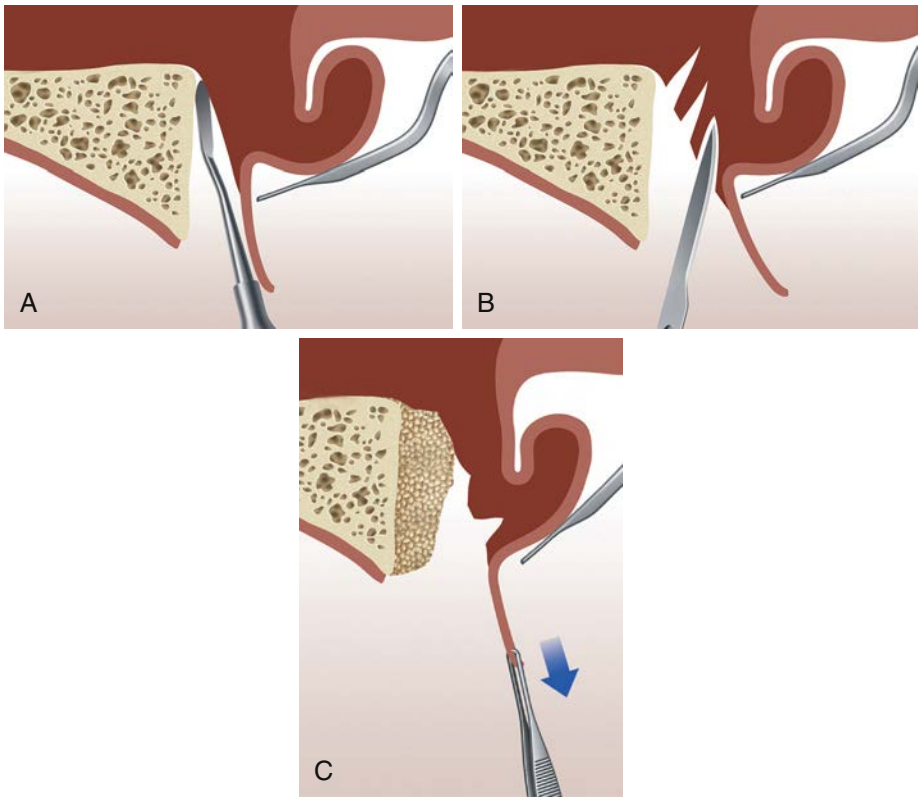
Membranes should be prepared according to the manufacturer's guidelines. Some resorbable membranes are designed to have one side exposed to the compartment being augmented and the other side toward the overlying flap. Membranes should also be trimmed to properly fit the site. The membrane should extend slightly beyond the defect margins to allow the borders of the membrane to lie on stable bone.[26] This allows containment of the graft and isolation of the bony defect from the overlying soft tissue.

Stabilization of the augmented volume is the most important factor for GBR success. The compartmentalized space must be maintained to allow for bone regeneration and maturation. This is commonly done with the use of autogenous bone graft or bone substitute. The stability of the graft and membrane must be sufficient to prevent micromotion which prolongs the inflammatory phase and results in fibrous tissue formation or infection. Some resorbable membranes are soft and pliable, allowing intimate adaptation to the space-maintaining graft. These generally do not require additional methods for stabilization.[27] Rigid resorbable and non-resorbable membranes, such as PTFE or titanium reenforced membranes, often require the use of microscrews, tacks, or sutures for stabilization. An adequate amount of healthy tension on the overlying mucoperiosteal flap can also help prevent migration of the graft or movement of the membrane. The closure should not produce excessive tension capable of causing flap necrosis or dehiscence, but some amount of tension is desirable to stabilize and maintain the membrane and graft in the ideal position. This requires significant experience on the part of the clinician.

Soft Tissue Closure

In general, primary closure is advised for most GBR procedures. However, in some circumstances this may be difficult to achieve or undesirable. Certain membranes have been shown to provide predictable results even when exposed, and these membranes and clinical situations will be further discussed in the next section. Several techniques exist for releasing the flap to allow adequate advancement and primary closure. When a crestal incision with sulcular extension does not provide adequate release for closure, consider adding vertical releasing incisions from either end of the sulcular incision. Vertical releasing incisions should be carried high into the vestibule to allow for significant release. Additional flap release is achieved with deep horizontal cuts made at the base of the periosteal flap to both reduce the possibility of flap perforation and allow for maximum release (Figure 31-8).

Meticulous closure using interrupted sutures is recommended to achieve esthetic tissue approximation and provide a seal from the oral cavity. Interrupted sutures (3-0 gut) are placed first for approximation of the crestal incision,



• **Figure 31-8** **A,** Flap reflection to the base of the defect. **B,** Deep, horizontal periosteal releasing incisions made at the base of the flap. **C,** Flap advancement for primary closure over the augmented site is facilitated by the periosteal releasing incisions. (Courtesy Bach Le, DDS, MD, Los Angeles, CA.)

followed by closure of the vertical arm using a smaller suture (5-0 gut). Some authors prefer a monofilament suture to protect against bacterial wicking.[28]

Primary closure may be undesired in some clinical situations. These include extraction defects where primary closure may cause excessive distortion of the natural gingival architecture. Certain membranes can also be used without primary closure, such as the dense polytetrafluoroethylene (PTFE) membranes and cross-linked resorbable collagen membranes. The various types of membranes available are discussed in more detail in the next section. Due to the varying properties of membranes, some can be used when primary closure is not attainable or undesired. This allows healing by secondary intention, which can maximize the amount of keratinized tissue.[29] This is most beneficial in socket preservation or augmentation. The membrane over the crest is intentionally exposed to heal by secondary intention and gain additional keratinized tissue migrating from the periphery of the defect (Figure 31-9).

Membrane Selection

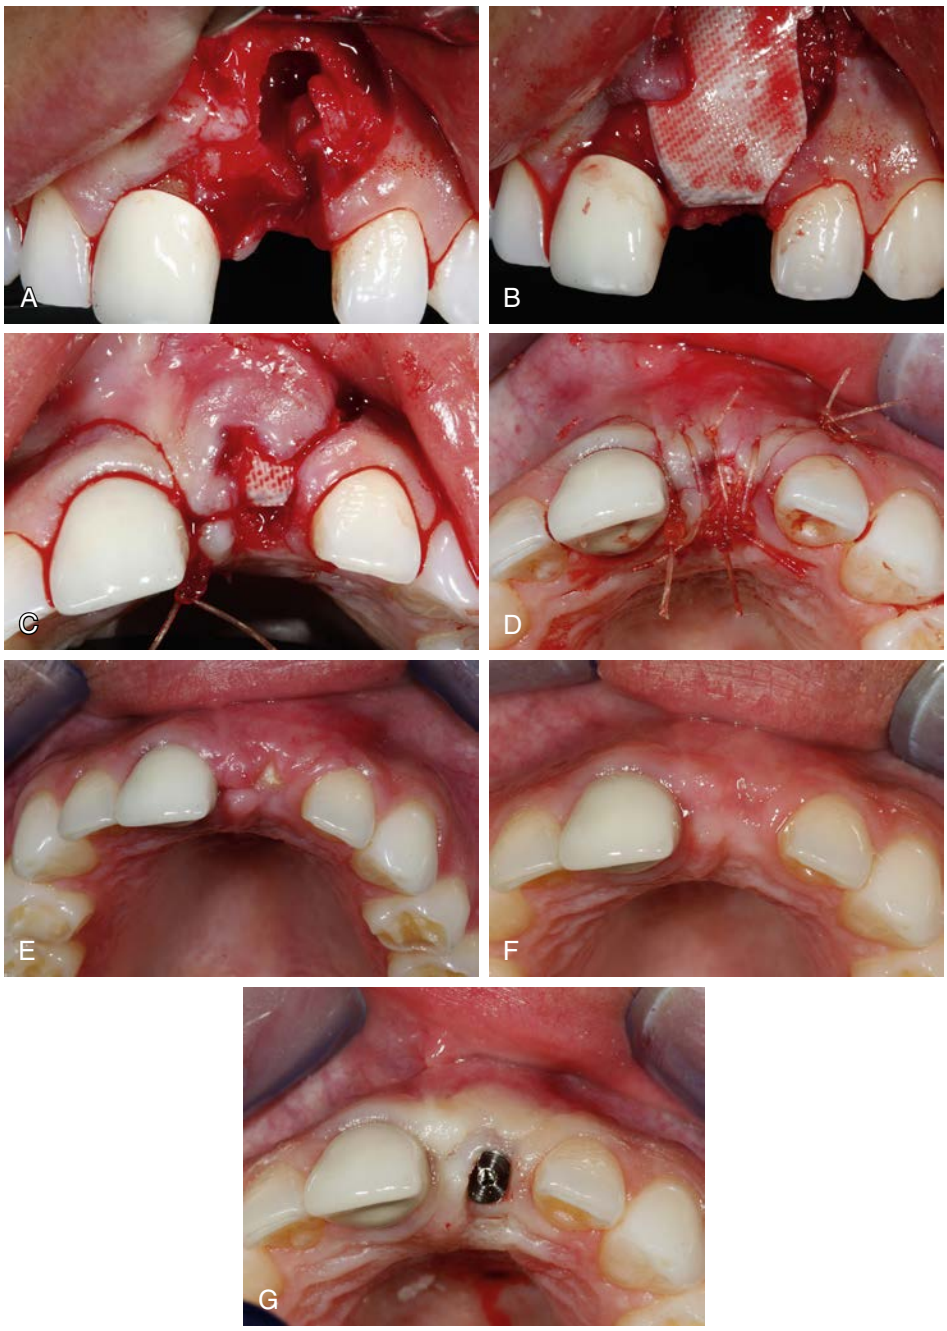
The use of a barrier membrane to isolate the bony defect site from the surrounding epithelial cells is critical for regeneration of the defect with bone. Epithelial cells migrate 15 times faster than bone cells and would quickly fill the defect without the use of a barrier membrane.[30] The membrane not only functions to isolate the defect site for bony regeneration, but also helps to maintain the graft and blood clot in the desired location.

Functional requirements exist for membranes to be successful. The first of these requirements is stability. The smallest amount of motion at the regenerate site can prolong the inflammatory response, leading to fibrous tissue invasion and inhibited bone formation.[31] The membrane must provide sufficient stability to prevent micromotion of the grafted site.

The second requirement of membranes is the ability to facilitate space maintenance. This property depends largely on membrane rigidity and is an important factor for success. A common challenge encountered with GBR is soft tissue collapse into the space created for bony regeneration. This is especially true for larger defects. The use of bone graft substitute, tenting screws, and titanium reinforced membrane or mesh have been described to facilitate space maintenance.

A third requirement for GBR membranes is biocompatibility. The membrane should have minimal inflammatory response, no caustic breakdown products, and no harmful changes to local pH or the local environment. Biocompatibility varies among the several types of membranes commercially available, and their effects should be considered when deciding on a membrane.

The final requirement for barrier membranes is ease of use. The membrane should be easily manipulated to allow proper adaptation while still maintaining all of its other strengths, such as stability and biocompatibility. There are a number of membranes available on the market today that satisfy these requirements.



• **Figure 31-9** **A,** Facial wall defect following extraction of tooth #9. **B,** Treatment of the facial wall defect with GTR. **C,** Soft tissue closure at the extraction site intentionally leaves the membrane partially exposed. **D,** Partial membrane exposure allows healing by secondary intention to maximize keratinized tissue. **E,** Healing by secondary intention maximizes the amount of keratinized tissue. **F,** Healthy keratinized tissue after healing by secondary intention. **G,** Flapless implant placement is possible due to the thick zone of keratinized tissue. Non-resorbable Membranes

Non-resorbable membranes were the first membranes used for guided bone regeneration. They were originally shown to be successful even without bone graft material.[32] A variety of non-resorbable membrane materials have been shown to be effective, including titanium foil, micro titanium mesh, Teflon mantle leaf, cellulose acetate, polytetrafluoroethylene, silicone sheet, and even rubber dam material.[26] A distinct advantage of non-resorbable membranes is their increased mechanical rigidity compared to their resorbable counterparts. This is important in large three-dimensional defects where space maintenance is critical for a successful outcome.

Among those available today, the most common are the expanded polytetrafluoroethylene (e-PTFE) and dense polytetrafluoroethylene (d-PTFE) membranes. Both are chemically identical, made of a synthetic

polymer that does not cause an immunologic reaction and is resistant to breakdown by the host tissue.[33] They differ in their preparation, which affects density and pore size. The e-PTFE is a sintered material with a large pore size, and the d-PTFE is a nonsintered material with a much smaller pore size. The d-PTFE membranes have a pore size less than 0.2 μm, compared to a pore size of 8 to 30 μm found in the e-PTFE membranes. Although the porosity of both the e-PTFE and d-PTFE membranes is capable of excluding epithelial cells, the improved microporosity of the d-PTFE membranes also prevents penetration by bacteria.[34]

Preventing membrane contamination by bacterial infiltration with premature exposure is critical to success. Machtei reported a six-fold decrease in bone formation at sites where a microporous membrane was exposed compared to sites where the membrane was not exposed.[35] One disadvantage of non-resorbable barrier membranes when compared to resorbable membranes is their tendency for premature exposure in the oral cavity (see Figure 31-9). A systematic review on the clinical outcomes of GBR to correct peri-implant defects by Chiapasco et al. reported a 20% exposure rate with nonresorbable membranes, compared to only 5% with resorbable collagen membranes.[36] However, the d-PTFE membranes have the distinct advantage of being able to withstand infection when exposed to the oral cavity due to their improved pore size.[37] Some denser collagen membranes also have this advantage and respond favorably even when exposed.[37,38] This characteristic offers a distinct advantage for the d-PTFE and resorbable collagen membranes when primary closure is not possible or when membrane exposure in the postoperative period is likely. The e-PTFE membranes, on the other hand, are at risk of bacterial colonization and infection with early exposure of the membrane. Premature removal of the membrane may then be required, resulting in impaired bone regeneration.[36,39-46]

Resorbable Membranes

Resorbable membranes are comprised of two main subgroups: natural membranes and synthetic membranes. Natural membranes are made of collagen which can be derived from human, bovine, and porcine sources. The raw collagen material is processed and purified to remove noncollagenous protein before forming the final product. Membranes can be cross-linked to provide biologic stability and slow the resorption rate of the membranes. Cross-linking can provide some protection in premature exposure by preventing early breakdown. Chemical cross-linking is done with a variety of methods including glycosylation and exposure to formaldehyde and glutaraldehyde, among other chemical agents. Nonchemical methods include ultraviolet radiation and dehydrothermal cross-linking.

Natural collagen membranes are widely used in GBR procedures and are well documented in human studies.[16,43,46] These membranes perform the function of a membrane barrier and may act to thicken the soft tissue at the surgical site.[47] Collagen membranes quickly integrate with host tissues to form new vascularization and are biodegradable without a foreign body reaction.[48-50] A distinct advantage of the high density collagen membranes is the ability to allow healing by secondary intention. When exposed, the dense collagen membranes allow epithelialization over the membrane, unlike non-resorbable e-PTFE membranes that tend to become infected.[38,46,51] Friedman et al. reported that in cases of collagen membrane exposure by gingival dehiscence, the exposure always resolved in the following weeks without affecting the healing process.[38]

Another factor to consider is the degradation time of the resorbable membrane. Collagen membrane degradation times vary significantly depending on chemical and enzymatic modifications made to the membrane.[49] Increased cross-linking is believed to prolong degradation time. However, it has also been reported to cause increased foreign body reactions, mucosal dehiscence, impaired soft tissue healing, infections, and decreased tissue integration.[50] Studies have shown that cross-linked membranes have at least the same or superior results compared to unmodified natural collagen membranes.[43,44] While the data may be inconsistent, the idea of a longer lasting resorbable membrane is favorable.

Synthetic membranes comprise the other group of resorbable membranes. These membranes are made of aliphatic polyesters including polylactic acid, polyglycolic acid, trimethylcarbonate, and other co-polymers.[33] Breakdown of these products occurs through hydrolysis, metabolically eliminating the polymers as CO_2 and water. The end products of degradation are nontoxic, but some concern exists over the possible adverse effects their breakdown could have on bone formation. Studies have shown significantly higher levels of the enzymes catalase and superoxide dismutase with synthetic membranes, which can negatively affect wound healing.[52] Another effect of these synthetic membranes is the change in local pH that occurs during degradation, causing a significant drop in local pH.[53] Other disadvantages include possible foreign body reaction and reduced defect fill compared to non-resorbable membranes.[54-58]

Newer forms of synthetic resorbable membranes include the form-stable polylactic acid/polyglycolic acid copolymer (PLGA) membranes modified with *N*-methyl-2-pyrrolidone as a plasticizer and the in situ polymerized polyethylene glycol membrane. Of the two co-polymers, polyglycolic acid is the weaker component, being more hydrophilic, more flexible, and demonstrating a faster degradation rate.[26] Polylactic acid, on the other hand, is the stronger co-polymer. It is more hydrophobic, brittle, and has a longer degradation rate. Varying the ratio of the two co-polymers does allow for some manipulation of the membrane properties. Due to the rigidity of these agents, they are generally prepared in a mesh-type design to improve flexibility. Another option is the addition of a plasticizing

agent or an additional polymer. Studies of the PLGA membranes have shown some limitations including membrane fracture in large defects when they are not supported by a graft material. Other disadvantages include reduced bone fill and more soft tissue complications when compared to non-resorbable membranes.[59,60] The in situ polymerized polyethylene glycol membrane does show promise due to the fact that it undergoes degradation by hydrolysis with no acidic byproducts capable of causing a foreign body reaction.[61,62] Early studies have shown it to be as effective in defect repair as non-resorbable barriers and other resorbable barriers such as natural collagen and polylactic acid membranes.[63-65]

In a prospective split-mouth study comparing the outcomes of horizontal augmentation using resorbable collagen membranes versus non-resorbable e-PTFE membranes with xenograft, a slight advantage was observed for resorbable membranes over the non-resorbable membranes, but was not statistically significant.[46] The advantage was likely due to the fact that the resorbable collagen membranes in the study experienced less dehiscence than the non-resorbable e-PTFE membranes. In the treatment of dehiscence and fenestration defects, a systematic review showed a slight advantage of resorbable collagen membranes over non-resorbable membranes. Use of the resorbable membranes resulted in a greater percentage of defect fill and lower rate of mucosal dehiscence when compared to the non-resorbable membranes. Although the trend did favor the resorbable membranes, the results again were not shown to be statistically significant.[66] The choice of membrane should be made after assessing the individual needs of the clinical situation and weighing the advantages and disadvantages of the various membranes.

Space Maintenance

Space maintenance can be facilitated by the use of bone grafts, bone substitutes, and auxiliary support mechanisms.

Bone Grafts and Substitutes

The most common method for achieving space maintenance in GBR is the placement of a bone graft or bone substitute under the membrane to support, maintain, and fill the defect area. Four categories of bone graft are available for use in GBR: autograft, allograft, xenograft, and alloplasts. Grafts are also available in multiple forms including block, particulate, putty, and injectable varieties.

All bone graft or bone substitutes used in GBR must have certain properties. They must be biocompatible, biodegradable, osteoconductive, provide mechanical support, and allow replacement bone formation by the host.[67-69] The rate of bone graft substitution by host bone is variable depending on the resorption characteristics of a given graft material.

The gold standard for bone graft has always been autogenous bone due to its innate osteogenic, osteoinductive, and osteoconductive properties. The disadvantages of autogenous bone graft are apparent, including donor site morbidity, limited graft availability, and less predictable graft resorption.[70-72] Autogenous bone graft is available in either a block or particulate form. Particulate autograft is resorbed more readily compared to bone blocks. Autogenous bone is obtained from a variety of intraoral and extraoral donor sites, including the mandibular ramus or symphysis, calvarium, proximal tibia, and iliac crest. Due to the limited volume of autograft available, it can be combined with bone substitute to increase the volume available for augmentation of larger defects.

Ridge augmentation has historically been performed using block grafts alone without a barrier membrane. The effectiveness of barrier membranes in decreasing block graft resorption and improving incorporation of the graft has been subject to debate.[73] Comparative studies evaluating outcomes of ridge augmentation using autogenous bone blocks with and without membrane coverage have shown mixed results.[74,75]

When long-term maintenance of the augmented volume is desired, a material with a slower substitution rate is advocated.[76,77] Among those with the slowest substitution rates are xenografts. Xenograft of bovine origin has been extensively studied and documented in dentistry.[66] In one study, deproteinized bovine-derived bone mineral particles were found unchanged in sites that underwent sinus floor augmentation after 11 years.[78] There is ongoing debate regarding the ability of deproteinized bovine-derived bone mineral to be resorbed. Other types of xenograft include bone substitutes of porcine, equine, coral, or algae origin, but their use is not as well documented as bovine-derived sources.[33] Xenografts can also be used as a composite graft by mixing with autograft or allograft.

Allografts comprise another category of bone substitute, including fresh-frozen bone, freeze-dried bone, and demineralized freeze-dried bone.[33] The turnover time for allograft is shorter than that of xenografts. Allografts have been shown to be effective for ridge augmentation in multiple clinical studies.[79-82] They are effectively used in both implant site development and treatment of periimplant defects as the only graft material or as a composite graft mixed with autogenous bone, xenograft, or alloplasts.

The last category of graft materials is alloplastic bone substitutes, including calcium phosphate, calcium sulfate, and bioactive glass and polymers.[33] Each of the alloplastic bone substitutes demonstrates different structures and resorption properties. A variety of calcium phosphate products exist and they are among the most studied of the alloplastic bone substitutes.[83,84] Hydroxyapatite is the least soluble of the naturally occurring calcium phosphates. On the other hand, tricalcium phosphate undergoes such rapid resorption that the amount of bone replacement is reduced compared to the original augmented volume.[77,85] This has led to the development of biphasic grafting compounds made

of hydroxyapatite and tricalcium phosphate to combine the space maintaining properties of hydroxyapatite with the substitution ability of tricalcium phosphates.[76] When compared to deproteinized bovine-derived xenograft, the biphasic alloplasts have been found to produce similar bone formation for sinus augmentation and the treatment of vertical defects, and even improved preservation of extraction sockets.[86-89] Alloplastic bone substitutes are best used as biphasic compounds or in combination with allografts and autografts.

Particulate xenograft, allograft, and autograft have been well documented for the treatment of peri-implant dehiscence and fenestration defects.[36,66] When used with either a resorbable collagen membrane or an e-PTFE membrane, studies have shown that autogenous bone grafts do not provide a superior result compared to bone substitute.[36,66]

Soft Tissue Matrix Expansion Technique

Three-dimensional ridge augmentation of the severely resorbed alveolar ridge was once fraught with difficulty and unpredictability, but is now done with the use of space maintaining mechanisms. In addition to the stability provided by rigid membranes and bone graft materials, the use of tenting screws, dental implants, and titanium mesh have been described to facilitate space maintenance in the treatment of large three-dimensional defects. Marx et al. described a tent-pole technique to predictably reconstruct the severely resorbed mandibular ridge from an extraoral incision.[90] Dental implants were used to tent the soft tissue matrix along with autogenous bone graft to gain adequate bone height for dental prosthesis rehabilitation. A problem encountered by many surgeons in using this technique is inaccurate placement of the dental implants through a transcutaneous approach. Use of a prefabricated, computer-generated surgical template when using this technique facilitates more accurate positioning of the dental implants (Figure 31-10).

Screw Tent-pole Technique

Tenting screws with mineralized allograft can also be used for bone augmentation to correct localized alveolar defects. Using particulate allograft and screws, horizontal and vertical height gain can be achieved to allow successful implant placement (Figures 31-11). This technique requires a membrane for optimal results and is technique sensitive. Vertical defects with large spans (two missing teeth or more) have a higher risk of wound dehiscence. Correction of these defects in a two-surgery grafting protocol of smaller increments per graft may reduce the risk of graft dehiscence. Vertical, single tooth defects may be corrected in a one-staged surgery protocol. Usually failure results from inadequate release of the flap leading to bone graft exposure and resorption. The resulting wound dehiscence can lead to more pronounced bone graft resorption. Proper flap design and manipulation is critical to prevent wound dehiscence when using these techniques.

Titanium Mesh

The use of titanium mesh with or without barrier membrane can provide effective space maintenance and graft stability for ridge augmentation. The ability to custom contour the size and shape of the mesh makes it an effective option for large three-dimensional defects. The use of titanium mesh in GBR is prone to dehiscence, premature exposure, and requires a secondary procedure for removal. Louis et al. reported on the use of titanium mesh for reconstruction of the severely atrophic maxilla or mandible using iliac crest bone graft with a 97% overall graft success rate.[91] The exposure rate of the titanium mesh was reported to be high (52%), and the obstacles to using iliac crest bone are obvious. In addition to the higher resorption rate of iliac crest grafts, other disadvantages include the high cost of hospitalization, risk of general anesthesia, and morbidity of the procedure.

Applications for Guided Bone Regeneration

Implant Site Development

Most post-extraction losses of alveolar ridge dimensions occur in the horizontal (width) rather than the vertical (height) plane.[92] Even when there is adequate bone to place implants, irregular ridge anatomy that is not corrected can result in an unnatural appearance of the final restoration (Figure 31-12). In a study by Sesma et al., 12.2% of dental implants placed for single tooth defects required some type of bone augmentation.[4] This number likely underestimates the true need for bone augmentation to allow for ideal implant placement and esthetics. The study also looked at only single tooth defects, and the need for bone augmentation is generally much greater for multiple tooth defects. Bone augmentation prior to or simultaneously with implant placement may allow for better implant position. Additionally, the augmented bone will correct ridge contour defects for a more natural looking restoration and increase facial bone support for long-term peri-implant soft tissue stability.

GBR with particulate bone graft alone has been shown to be effective for treatment of mild to moderate size horizontal defects.[51,93] Concave horizontal defects are easier to correct with GBR than flat one-walled defects. The use of tenting screws or other space maintenance mechanisms to prevent soft tissue collapse should be considered when augmenting large horizontal defects with unfavorable defect configuration (Figure 31-13).

Block and Degen described a minimally invasive tunneling technique using mineralized particulate allograft to horizontally augment partially edentulous defects for successful implant placement.[94] However, a disadvantage of the tunneling technique is that it can be difficult

to position and maintain the graft in a coronal position to augment the peri-implant soft tissue. Additional bone grafting is usually necessary at the time of implant placement to address this issue. Maintaining the graft in the crestal area is important for long-term peri-implant soft tissue stability.

Implant Placement With Simultaneous GBR: "Esthetic Contour Graft"

Two types of bony defects are commonly encountered when implants are placed at sites with reduced bony volume: dehiscence defects and fenestration defects. These defects can occur through either the buccal or lingual wall, but generally occur on the buccal. Buccal or facial defects are of greater concern due to their potential esthetic compromise.

When there is adequate basal bone and the lateral ridge deficiency is mild (<4 mm), implants can be placed simultaneously with the augmentation procedure. Traditional GBR procedures are performed as a staged approach with a second surgical intervention to place the implant. If simultaneous bone grafting is performed, it is usually followed by submerged implant site healing beneath the repositioned soft tissue flap. Submerge healing requires an additional surgical intervention for uncovering and can lead to shrinkage of an already thin keratinize mucosa. Le et al. described a bone grafting procedure, the "esthetic contour graft," done simultaneously with implant placement and nonsubmerged healing by adding a healing abutment to improve peri-implant tissue contour (see Figure 31-11).[95] This approach offers several advantages. The single-stage protocol minimizes compression and migration of particulate graft material, and allows the bony and soft tissue architecture to develop around the healing abutment during site healing. A healing abutment will provide some horizontal tenting of the peri-implant soft tissues and result in less apical migration of the graft material. This improves the prognosis for retaining the greatest width and height of the remaining crestal bone. Grafting at the time of implant placement also takes advantage of the regional acceleratory phenomenon that is induced by the trauma of implant placement, helping to accelerate healing.[96]

The esthetic contour graft can be done with two different conservative surgical incisions. In cases with small ridge defects (<2 mm), a sulcular flap without vertical releasing incisions can be used. In cases with more extensive defects, an open-book flap design is preferred to enhance visualization and access to the graft site. The latter consists of a crestal incision made slightly lingual to the ridge midline to ensure that there is an adequate amount of keratinized tissue present in the flap (Figure 31-14, *A* and *B*). This is followed by a distal, curvilinear, vertical incision that follows the gingival margin of the distal tooth. A wide subperiosteal reflection is made to expose two to three times the treatment area, and the papilla is then reflected on the mesial side of the edentulous site.

During implant placement, the implant's restorative platform is positioned at the desired level and a healing cap is attached to the implant (see Figure 31-14, *B*). The peri-implant soft tissue is released and advanced by scoring the periosteum so that tension-free closure is achieved around the neck of the implant. This is done because moderate graft resorption will occur if there is not an adequate tissue seal around the implant neck or if tension-free closure is not achieved.

To induce bleeding in the graft site, periosteum release is performed as the last step just prior to graft placement. Human mineralized bone allograft is packed into the defect and overcontoured by approximately 20% to 30% to compensate for anticipated apical migration and resorption of the material (see Figure 31-14, *C*). Prior to surgery, the allograft is hydrated according to the manufacturer's directions and mixed with the patient's blood, which serves as a coagulant. After grafting, the allograft is covered with a resorbable membrane (e.g., Ossix Plus, OraPharma Inc., Warminster, PA), and a wide healing abutment is attached to the implant. A variation of Palacci's papilla regeneration technique helps to release the tissue tension around the healing abutment and augment the interdental height of the soft tissue papilla.[98] The soft tissues are approximated and sutured around the healing abutment (see Figure 31-14, *D*). This creates a tenting effect over the allograft and, together with the healing abutment, helps to hold the particulate material in place. The result is an esthetic, natural looking final restoration (see Figure 31-14, *E*).

Le et al. assessed the outcome of single-stage, nonsubmerged implant placement with simultaneous augmentation of vertical buccal bone dehiscence defects using a mineralized particulate allograft (Puros Cancellous; Zimmer Dental) covered with a collagen membrane (Ossix Plus; OraPharma Inc.).[97] The vertical buccal defects were classified as small (less than 3 mm in height), medium (3-5 mm in height), or large (greater than 5 mm in height). The initial defects were recorded by measuring the amount of implant rough surface exposure after implant placement. To assess site healing, sectional CBCT scans were obtained at 36 months post-grafting. Evaluation of the sites showed 100% bone regeneration of small vertical dehiscence defects and 79.3% for medium-sized defects. Large-sized defects showed only partial improvement. The likelihood of wound dehiscence, graft exposure and resorption, and subsequent implant thread exposure is increased when larger defects are treated simultaneously. A two-stage approach with the bone augmentation procedure followed by implant placement is recommended for large (>5 mm) defects.

In another published study, Jensen et al. analyzed the long-term stability of bone contour augmentation used in the esthetic zone with early implant placement (6 to 8 weeks of healing after tooth extraction).[99] Outcomes were assessed using biopsies harvested after various time intervals. Implant placement was performed with simultaneous contour augmentation using a combination of autogenous bone (placed in direct contact with the exposed implant surface) and deproteinized bovine bone mineral (DBBM) covered with a double layer of collagen barrier membrane. Biopsies collected after 14 to 80 months of healing were subjected to histologic and histomorphometric analysis. These biopsies consisted of 32.0 ± 9.6% retained DBBM particles and 40.6 ± 14.6% bone; 70.3 ± 14.5% of the

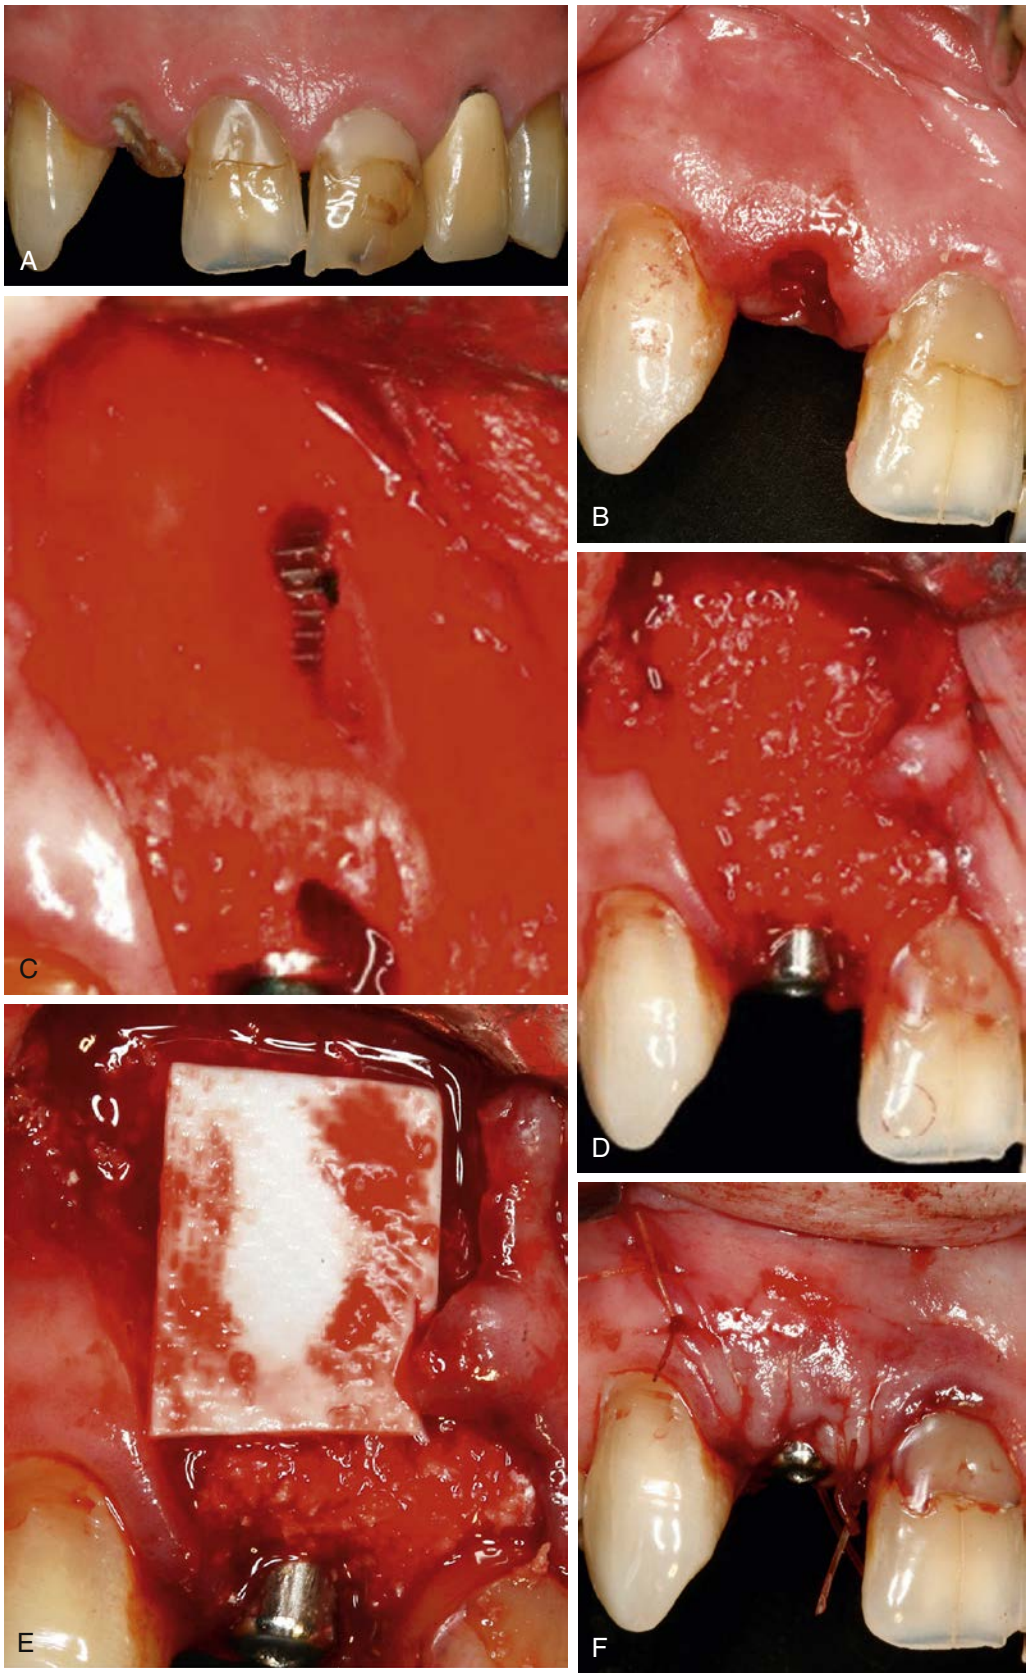
DBBM particle surfaces were covered with bone. The investigators concluded that their study confirmed previous findings that osseointegrated DBBM particles do not undergo significant resorption and substitution over time, and that this low substitution rate is likely the reason for the long-term clinical and radiographic stability of contour augmentations using this procedure.

Fenestration type defects occur when a perforation through a bony wall occurs, leaving a window-like defect where the marginal bone is still intact. This often occurs at sites where the crestal width is adequate for implant placement but a significant bony undercut exists facially. Fenestration defects can be missed without adequate flap reflection to visualize the facial alveolus. The risk of a fenestration defect can be minimized with the use of shorter implants with a tapered body design. Fenestration defects are easily corrected with GBR (Figure 31-15).

Vertical Defects

Severe vertical alveolar ridge defects are usually three-dimensional and present a difficult challenge to the implant surgeon. Patients with vertical defects usually have concomitant horizontal defects and these defects must be fully reconstructed in all dimensions to create an esthetic and functional result. This often requires a staged protocol where the horizontal defect is addressed first with GBR before the vertical defect is treated. Wide span vertical defects in the esthetic zone usually require multiple surgical interventions in conjunction with GBR (i.e., distraction osteogenesis and interpositional



• **Figure 31-15** **A,** Decayed, retained root requiring extraction and immediate implant placement. **B,** Surgical site following atraumatic extraction of the root. **C,** Immediate implant placement resulting in a fenestration type defect. **D,** Open-book flap design to allow treatment of the fenestration defect with GBR using particulate allograft. **E,** Esthetic contour graft (GBR) with a barrier membrane to isolate the augmented site. **F,** Nonsubmerged healing of the dental implant. (Courtesy Bach Le, DDS, MD, Los Angeles, CA.)

osteotomies) to achieve an ideal result. Furthermore, many vertical defects also have loss of bone attachment on the teeth adjacent to the defect. In many instances, it is more beneficial to extract these teeth so that a healthy bone attachment level can be established adjacent to the defect prior to grafting. If multiple grafting procedures are planned for a severe defect, a consideration should be given to the timing of extraction to minimize the width of the edentulous span and maximize the outcome of any initial GBR procedure. Vestibuloplasty with free gingival graft after implant placement is often necessary to increase keratinized tissue attachment and improve esthetic outcomes (Case Study 31-9).

Socket Augmentation

Augmentation of extraction socket with labial wall defects is an additional application for GBR. Following tooth loss, a predictable resorptive pattern occurs with the more apical two-thirds of the extraction socket filling with bone and the more coronal one-third healing by soft tissue ingrowth.[100,101] Socket preservation results in complete bone fill of an extraction socket by 5 to 6 months.[102,103] Considerable postextraction remodeling occurs in the bucco-lingual dimension of up to 60% resorption of the alveolar ridge width.[58,104] This is seen even with immediate implant placement, although the magnitude is reduced.[105] Studies evaluating postextraction ridge remodeling occurring with and without GBR have shown a clear advantage for grafting. Use of either a resorbable or non-resorbable membrane for GBR at extraction site defects results in a statistically significant improvement in ridge dimensions compared to the untreated control sites.[106,107] Extraction sockets not treated with GBR can expect significant ridge width reduction following tooth loss of up to 4.5 mm.[108] When a barrier membrane is used without bone graft, ridge width decreases by only 1.3 to 1.8 mm. When bone graft is used in addition to the barrier membrane, similar improvements in ridge width preservation are observed and even vertical gains are possible. Another observed benefit of socket augmentation is improvement in soft tissue parameters (increase in soft tissue thickness and keratinize mucosa) through the use of healing by secondary intention. The senior author routinely utilize GBR in conjunction with the "open book" flap to address extraction defects where there is a lack of keratinize mucosa (Case Study 31-7).

Management of Labial Mucosal Recession

The efficacy of GBR surgical protocols in repairing localized hard tissue defects and dehiscence and fenestration defects around implants is well described in the dental literature .[109] However, the use of GBR for the management of labial soft tissue recession is a new application recently described by Le et al.[47-47b] The use of a pericardium membrane in combination with a particulate mineralized allograft and tenting screw resulted in approximately 1.0 mm of mean gain in soft tissue thickness, keratinized tissue width, and gingival height around implants with labial mucosal recession. Although the goal of the GBR procedure was to treat bone defects in this clinical case series, improvements were coincidentally observed not only in the soft tissue dehiscence, but also in the keratinized tissue width and soft tissue thickness. The authors hypothesize scoring of the periosteum and foreign-body reaction from placement of a biomaterial and resorbable membrane may result in scar tissue formation that augments the soft tissue profile. The authors also note the successful use of GBR in their group of patients could be attributable, in part, to the exclusion of patients with signs of infection and implants in poor position. The technique involves the removal of the crown on the implant, with strategic placement of a tenting screw on the labial bone adjacent to the implant. No surface treatment is used to decontaminate the exposed implant surface because implants with infection are excluded. A mineralized cancellous allograft is placed and covered with a resorbable membrane using the esthetic contour grafting protocol described here (non-sumerged healing; Figure 31-16).

Postoperative Considerations

Careful postoperative management of the surgical site is important for success. Patient controlled factors such as diet and hygiene should be managed through careful patient education. A soft diet and oral rinses with chlorhexidine gluconate or a saline solution are appropriate for at least the first week following surgery while the sutures remain. Ideally sutures are maintained for at least 10 days following surgery, at which time they should be promptly removed. Antibiotic therapy may also be prescribed prophylactically for up to 7 days postoperatively.

In the esthetic zone, a temporary restoration is generally required for patient satisfaction during the healing phase. Avoid the temptation to use any immediate temporary appliance that is tissue borne and would apply pressure to the grafted site in the early postoperative period. Even when the intention is to mold the soft tissue, it is better done later. The goal of the augmentation is to gain as much tissue height and width as possible, and this can be compromised by early loading of the tissue. Soft tissue contouring with temporary restorations can always be performed at a later date. Early loading of the tissues may risk tissue loss that could prove detrimental to the cosmetic result.

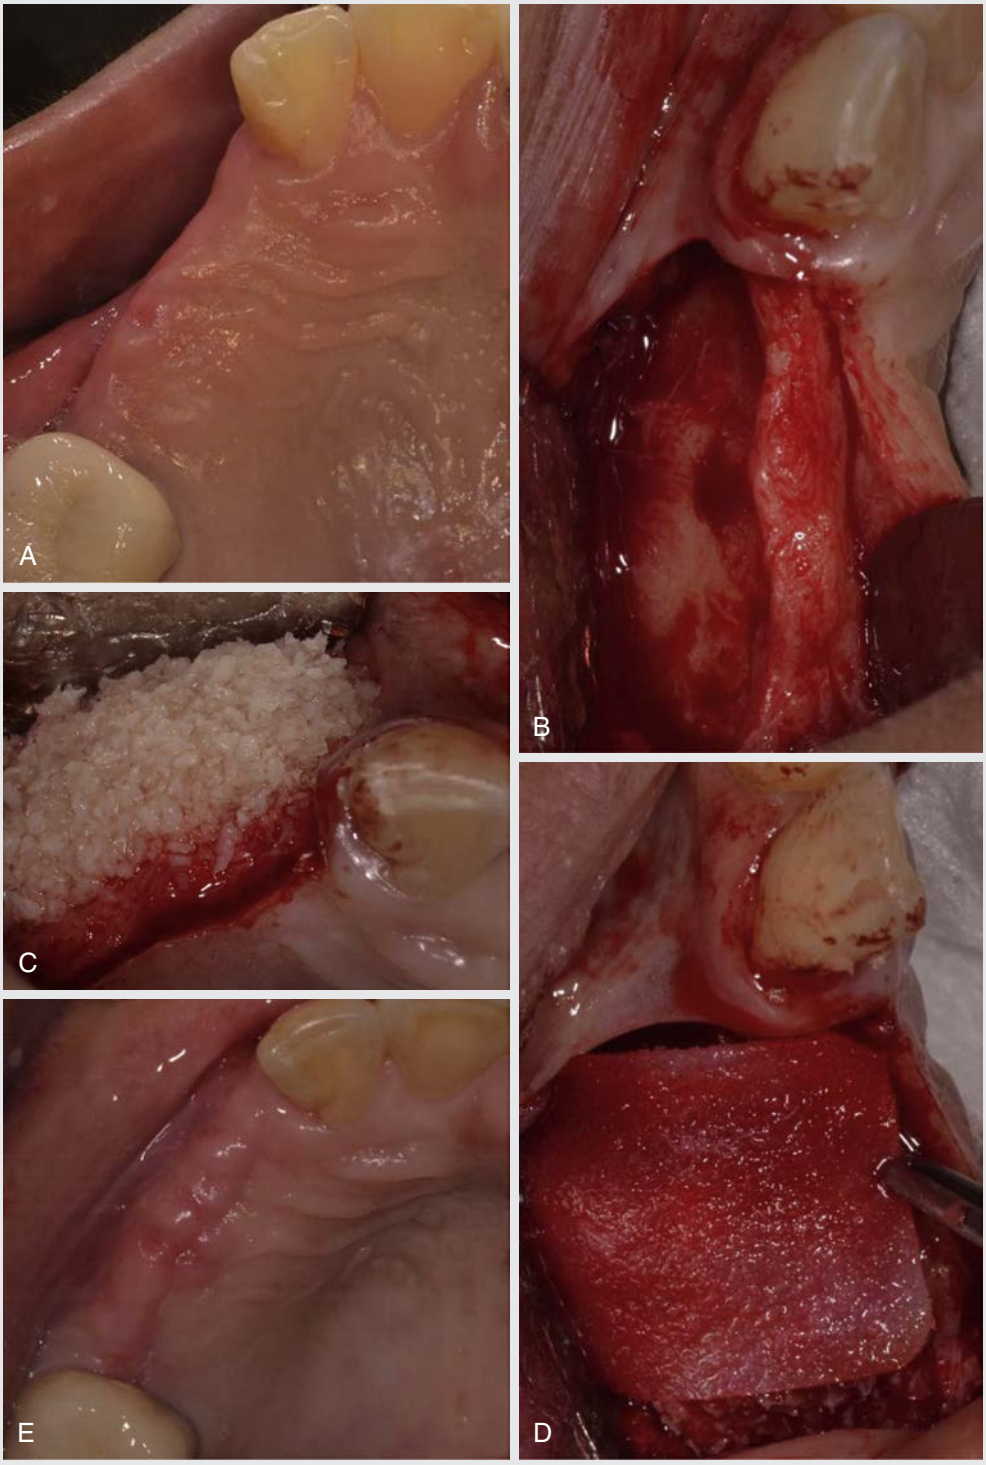
If a temporary restoration is to be used during the healing period, a tooth-borne temporary restoration is preferred to a removable tissue-supported appliance. Tooth-borne temporary restorations help prevent a reduction in graft volume or dehiscence that can be caused by early pressure on the tissues. If dehiscence of the incision and exposure of the membrane does occur during the healing period, it is best managed by topical application of chlorhexidine gluconate to clean the site. Oral rinses with normal saline or chlorhexidine gluconate are also appropriate. Exposed membranes can be removed after 3 weeks of healing with little risk of disrupting the GBR outcome.

(From Le B, Borzabadi-Farahani A, Nielsen B: Management of the ailing implant: An innovative technique for the treatment of labial gingival recession around dental implants. *Dental Implant Abstract/How I Do It Session,* AAOMS 96th Annual Meeting, 2014; Honolulu, HI.)

CASE STUDY 31-1

Implant Site Development With GBR

A 42-year-old female presented with missing teeth #4, #5, and #6. Clinical exam revealed an obvious collapse of the alveolus requiring augmentation prior to implant placement (Figure 31-17, *A*). The treatment plan involved a staged approach with second stage implant placement at #4 and #6 for an implant supported bridge after initial treatment with GBR alone. An open-book flap design was utilized to spare the distal papilla of tooth #7. Following flap reflection, the bony ridge defect was obvious (see Figure 31-17, *B*). The defect was occupied with particulate allograft bone substitute (see Figure 31-17, *C*), and then compartmentalized using a resorbable collagen membrane barrier (see Figure 31-17, *D*). After healing, the augmented site was ready for implant placement (see Figure 31-17, *E*).



• **Figure 31-17** **A,** Clinically evident collapse of alveolar width. **B,** Obvious bony defect following flap reflection. **C,** Placement of particulate allograft to occupy the augmented volume. **D,** Resorbable collagen barrier membrane used for compartmentalization of the defect. **E,** Restored alveolar width following healing. (Courtesy Brady Nielsen, DDS, Los Angeles, CA.)

CASE STUDY 31-2

Implant Site Development With GBR

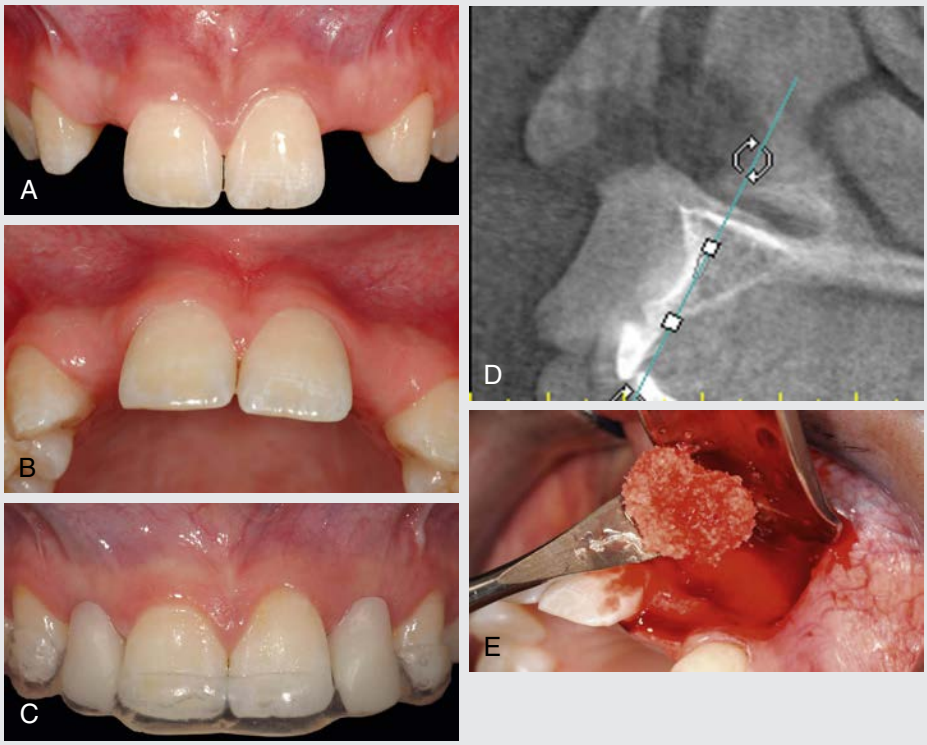
A 21-year-old female presented with missing teeth #9 and #10. The teeth had been lost 1 year prior and collapse of the alveolar width was evident on clinical exam (Figure 31-18, *A*). The patient was treatment planned for implant placement at #9 with a cantilevered pontic restoration at #10. The patient would first require augmentation of the deficient alveolus. Using the open-book flap design, the mesial papilla on #11 was spared with a distal vertical releasing incision. The incision was carried anteriorly in a sulcular fashion at #8. Upon flap reflection the labial ridge defect was visible (see Figure 31-18, *B*). The site was treated with GBR utilizing particulate allograft bone substitute with an overlying resorbable collagen membrane for compartmentalization of the defect (see Figure 31-18, *C*). Closure was achieved in a taut fashion using a combination of vicryl sutures at the alveolar crest and chromic gut sutures along the vertical release without excessive tension on the flap (see Figure 31-18, *D*). After 5 months of healing, the site was ready for implant placement. The alveolar width was noticeably improved (see Figure 31-18, *E* and *F*). Three months following implant placement the patient was transitioned to a screw-retained temporary appliance. After 6 months of soft tissue contouring with the temporary restoration, an acceptable esthetic result was obtained (see Figure 31-18, *G*).

• **Figure 31-18** **A,** Ridge width deficiency following tooth loss. **B,** Alveolar bone width deficiency. **C,** Particulate allograft bone and a resorbable collagen barrier membrane used to augment the site. **D,** Soft tissue closure of the augmented site. **E,** Significant clinical improvement in ridge width. **F,** Following healing, the bony dimensions are ideal for implant placement. **G,** After tissue sculpting with a temporary, screw-retained restoration, an esthetic result is obtained. (Courtesy Brady Nielsen, DDS, Los Angeles, CA.)

CASE STUDY 31-3

Implant Site Development With GBR

An 18-year-old male presented with congenitally missing lateral incisors (Figure 31-19, *A*). Clinical exam revealed a collapsed alveolar width at both sites #7 and #10 (see Figure 31-19, *B*). An Essix splint was fabricated for use as a temporary appliance. The splint was also used to determine ideal tooth shape and form, and to determine where additional tissue augmentation was needed (see Figure 31-19, *C*). 3D imaging was obtained with the radio-opaque Essix splint in place to evaluate the ideal tooth position in relation to the existing alveolus (see Figure 31-19, *D*). An open-book flap design was utilized at both sites to place particulate allograft bone substitute in the defect (see Figure 31-19, *E*). Following placement of the resorbable collagen barrier membrane, the flap was closed in a tension-free manner (see Figure 31-19, *F*). 3D imaging immediately following the procedure shows the augmented bone volume (see Figure 31-19, *G*). Clinical exam after 6 months of healing displays the improved alveolar width (see Figure 31-19, *H*). The improved alveolar dimensions allowed for ideal implant placement at both sites with cingulum access holes in the final restoration (see Figure 31-19, *I* and *J*). The natural alveolar contours allowed for an esthetic final restoration (see Figure 31-19, *K*).



• **Figure 31-19** **A,** Missing lateral incisors with ridge width defect. **B,** Missing lateral incisors with ridge width defect. **C,** Essix splint used as a temporary restoration and to determine where additional augmentation is necessary. **D,** CBCT using the radio-opaque Essix splint to evaluate bone for implant placement. **E,** Placement of particulate bone allograft to occupy the defect volume.

CASE STUDY 31-4

Implant Placement With Simultaneous GBR

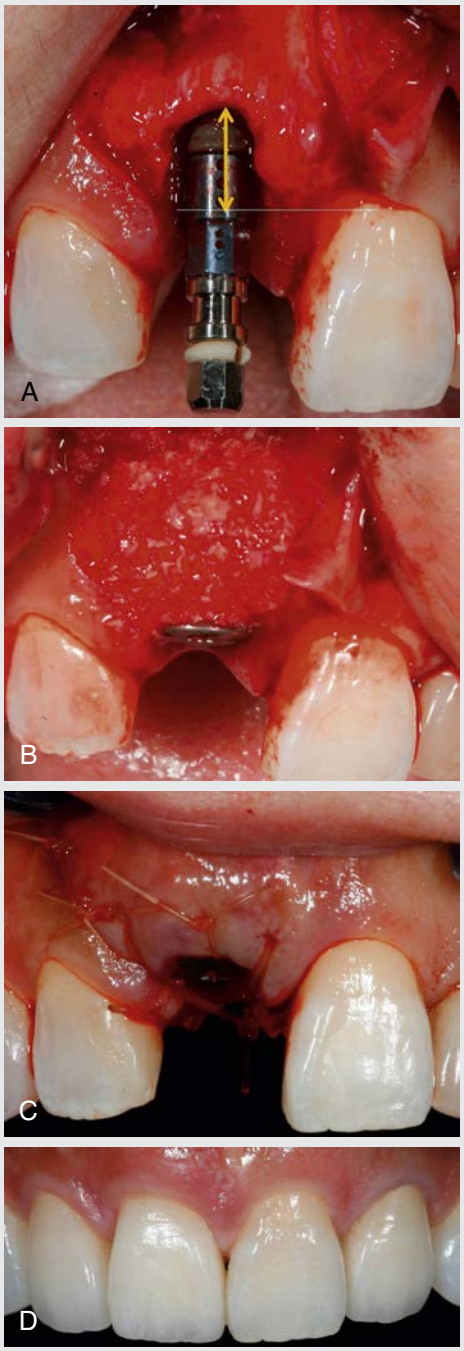
A 32-year-old male presented missing tooth #30 with obvious collapse of the alveolar width (see Figure 31-14, *A*). Open-book flap design was used to expose the edentulous site and allowed for implant placement. Due to ridge resorption, implant placement resulted in a small bony dehiscence defect on the buccal (see Figure 31-14, *B*). The implant achieved primary stability and a healing abutment was attached.

Treatment of the dehiscence defect was performed using particulate allograft bone substitute and placement of a resorbable collagen barrier membrane (see Figure 31-14, *C*). Closure was obtained around the healing abutment (see Figure 31-14, *D*). Following a healing stage, the implant was restored and provided a natural appearing, esthetic outcome (see Figure 31-14, *E*).

CASE STUDY 31-5

Immediate Implant Placement With Simultaneous GBR

A 26-year-old male presented with a fractured tooth #8 requiring extraction. An open-book flap design was used sparing the mesial papilla of tooth #7 and placing a distal vertical releasing incision. Anterior extension was performed with a sulcular incision at tooth #9. Following an atraumatic extraction and implant placement, a defect of the labial plate was observed (Figure 31-20, *A*). Due to the small nature of the defect and primary implant stability, a healing abutment was attached and the defect was treated with GBR (see Figure 31-20, *B*). Tension-free soft tissue closure was achieved around the healing abutment (see Figure 31-20, *C*). The implant was later definitively restored and provided a very natural appearing, esthetic outcome (see Figure 31-20, *D*).



• **Figure 31-20** **A,** Dehiscence defect during immediate implant placement following tooth extraction. **B,** Simultaneous treatment of the defect using GBR. **C,** Soft tissue closure around the healing abutment. **D,** Final restoration with natural appearing alveolar contours. CASE STUDY 31-6

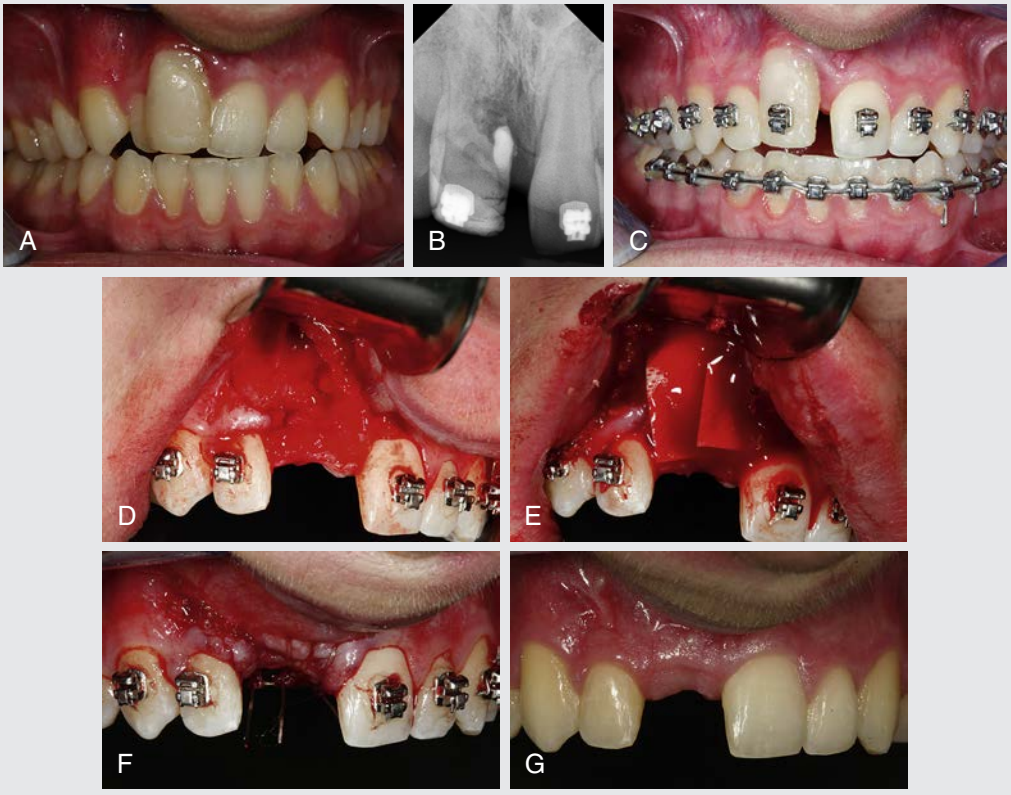
Socket Augmentation With GBR

A 19-year-old male presents with ankylosed tooth #8. Severe gingival margin discrepancy is noted between teeth # 8 and # 9. There is also a lack of labial keratinized mucosa on tooth # 8. The treatment plan involved orthodontic treatment to correct cross-bite and improve arch space. Forced orthodontic eruption was also attempted but failed to bring down tooth #8. Extraction of tooth # 8 with socket augmentation using GBR was performed with an "open book" flap design with intentional exposure to allow for healing by secondary intention.

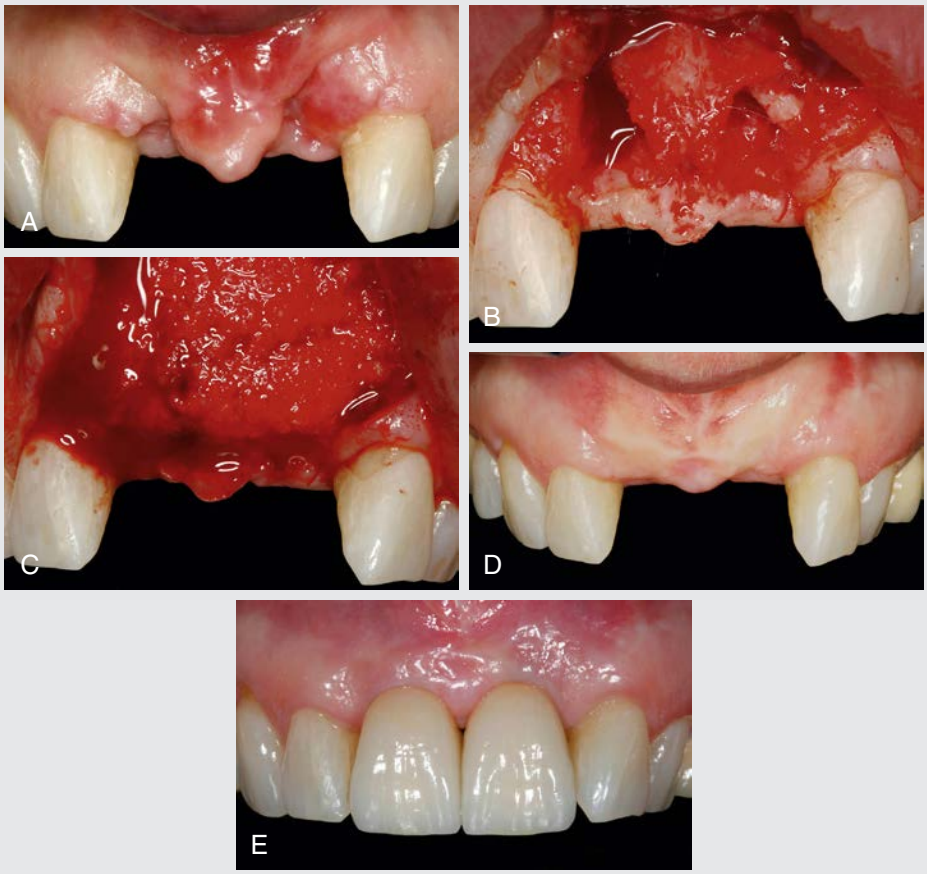


• **Figure 31-21** **A,** Ankylosed tooth # 8 with severe gingival margin discrepancy with contralateral central incisor and a lack of labial keratinized mucosa. **B,** Radiograph showing ankylosed tooth # 8. **C,** Clinical situation after orthodontic treatment with unsuccessful forced orthodontic eruption of tooth #8. **D,** Extraction of tooth #8 with "open book" flap design. **E,** Particulate allograft is placed into defect and covered with a resorbable collagen membrane. **F,** Coronal advancement flap with intentional slight exposure of collagen membrane at alveolar crest to allow for healing by secondary intention. **G,** Healing 1 year after treatment showing favorable gingival marginal level with increase in keratinized tissue. (Courtesy Bach Le, DDS, MD Los Angeles, CA.)

CASE STUDY 31-7

Vertical Augmentation With GBR

A 41-year-old male presented following traumatic loss of teeth #8 and #9 (Figure 31-22, *A*). A significant alveolar hard and soft tissue deformity was present. An open-book flap design was used to expose the alveolus (see Figure 31-22, *B*). Significant vertical defects were present. The site was treated with GBR using particulate allograft bone substitute for space maintenance (see Figure 31-22, *C*). A resorbable collagen membrane was applied to isolate the defect site for GBR. Following 6 months of healing, clinical exam revealed a significantly improved alveolar architecture (see Figure 31-22, *D*). Following implant placement, a natural appearing esthetic outcome was eventually achieved with the final restorations (see Figure 31-22, *E*).

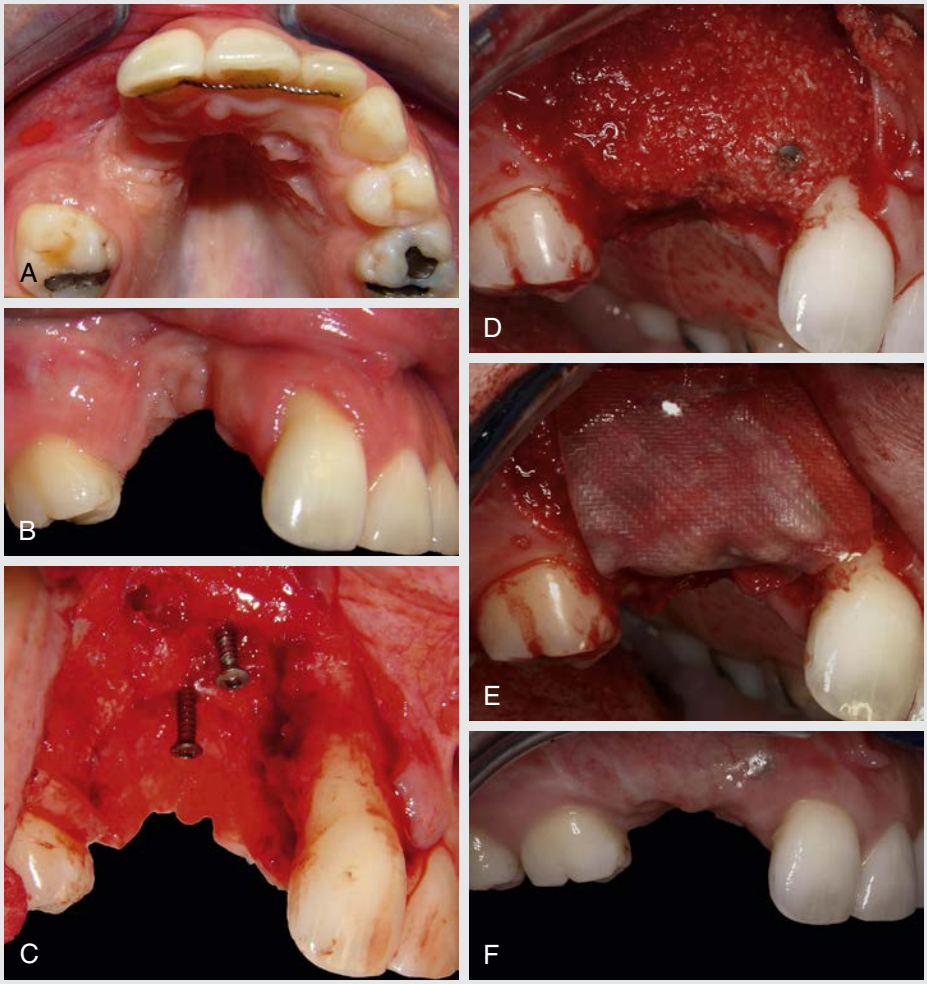


• **Figure 31-22** **A,** Significant alveolar defect following traumatic tooth loss. **B,** Open-book flap design used to expose the deficient alveolus. **C,** Placement of particulate allograft to occupy the augmented volume. **D,** After 6 months of healing the reconstructed alveolus is ready for implant placement. **E,** Esthetic final result due to the restored alveolar dimensions. (From Le B, Nielsen B: Esthetic implant site development. *Oral Maxillofac Surg Clin North Am* 27(2):283-311, 2015.)

CASE REPORT 31-8

Vertical and Horizontal Augmentation With GBR

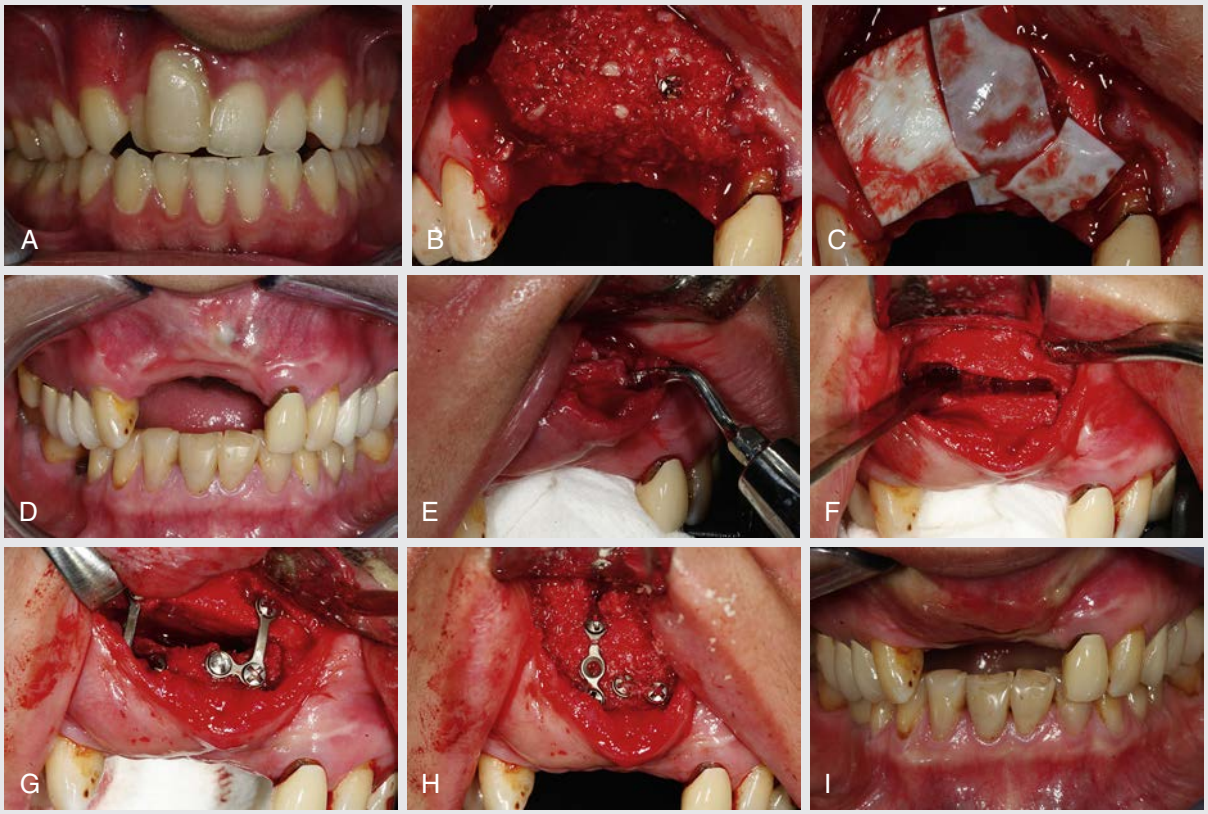
A 36-year-old female presented following the loss of teeth #5, #6, and #7 due to pathology. A significant horizontal and vertical defect is clinically evident (Figure 31-23, *A* and *B*). The site was treated with GBR utilizing tenting screws as an additional support mechanism (see Figure 31-23, *C*). Particulate allograft bone substitute was packed into the defect site for space maintenance (see Figure 31-23, *D*). A resorbable membrane was then applied to compartmentalize the defect site (see Figure 31-23, *E*). Six months following treatment with GBR a significant improvement in alveolar dimensions was seen, making implant placement possible (see Figure 31-23, *F*).



• **Figure 31-23** **A,** Significant vertical and horizontal defect. **B,** Significant vertical and horizontal defect. **C,** Tenting screws placed to support the augmented volume. **D,** Space maintenance achieved with tenting screws and particulate allograft. **E,** Resorbable barrier membrane used to compartmentalize the defect. **F,** After healing, the restored alveolar dimensions allow for implant placement. (From Le B, Nielsen B: Esthetic implant site development. *Oral Maxillofac Surg Clin North Am* 27(2):283-311, 2015.)

CASE STUDY 31-9

Severe Vertical Defect in the Anterior Maxilla Treated With Staged Surgical Approaches



• **Figure 31-24** **A,** A severe, multiple-teeth span vertical defect will require a staged reconstruction. **B,** Initial staged GBR using the screw tent-pole technique to develop adequate horizontal width. **C,** The defect site filled with particulate allograft is isolated using a resorbable collagen barrier membrane. **D,** After 4 months of healing following the initial GBR, ridge width is improved but ridge height is still deficient. **E,** Second-stage surgery performed as an osteotomy and down-graft to restore ridge height. **F,** Down-grafting of the segment with an osteotomy. **G,** Segment stabilized with plates. **H,** Mineralized particulate allograft placed between osteotomy defect and covered with a collagen membrane. **I,** Healing after 4 months.

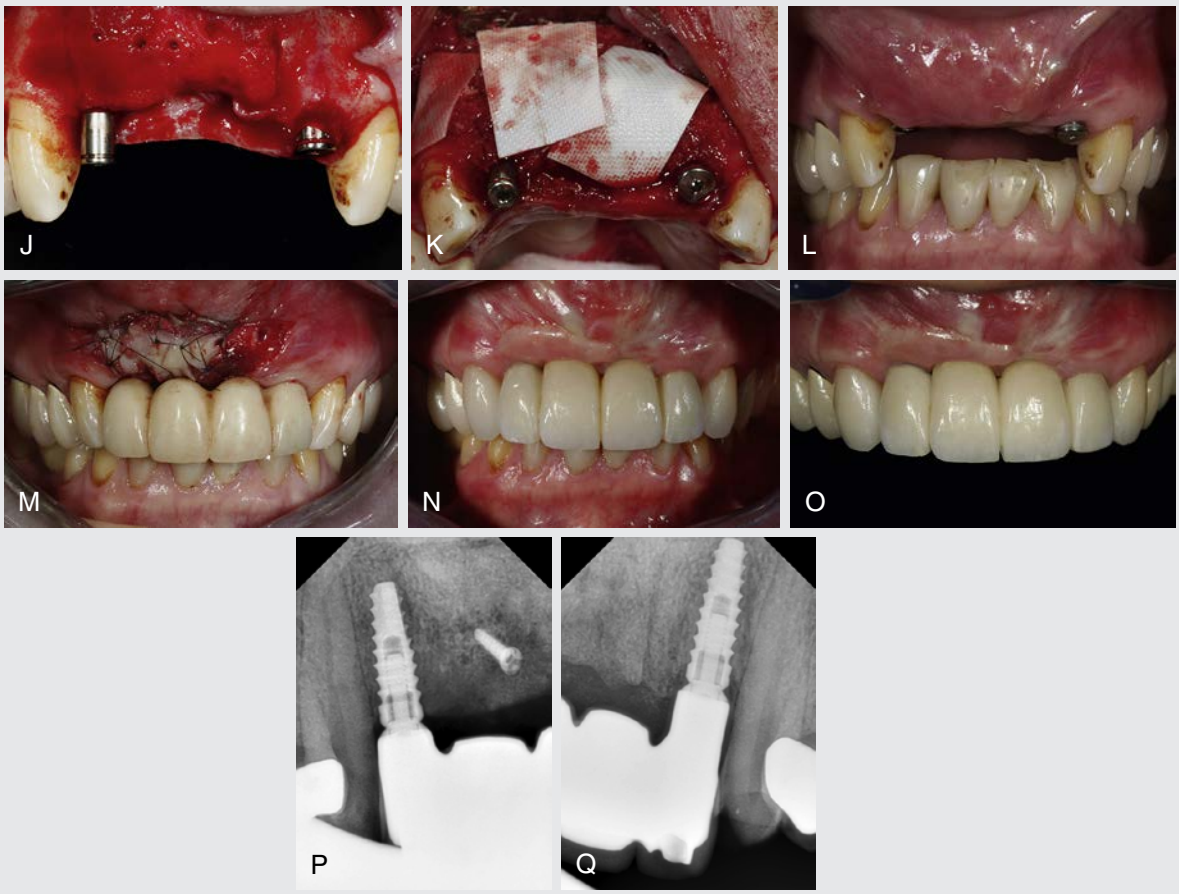
Severe Vertical Defect in the Anterior Maxilla Treated With Staged Surgical Approaches



• **Figure 31-24, cont'd J-K,** Implants placed at site # 7 and # 10 with "esthetic contour grafting" protocol (non-submerged grafting). **L,** Healing after 2 months showing a lack of attached tissue and vestibular depth. **M,** Vestibuloplasty with free gingival graft from palate to increase the zone of attached tissue. **N,** Final restorations delivered at 1 year. **O,** 3 years follow-up. **P-Q,** Radiograph at 3 years follow-up. (From Le B, Nielsen B: Esthetic implant site development. *Oral Maxillofac Surg Clin North Am* 27(2):283-311, 2015.).

Summary

Since its origin in the early 1940s, guided tissue regeneration has evolved to become a predictable regenerative option and a critical technique in the field of implant dentistry. Compartmentalization to allow regeneration of a select tissue type is its guiding principle. A variety of techniques and materials exist, each with its advantages and disadvantages. The many applications for GBR in implant dentistry make possible the esthetic, natural appearing outcomes in implant dentistry.

Contemporary Sinus-Lift Subantral Surgery and Graft

BACH LE, FELIX KYLE YIP

Introduction

The atrophic, edentulous posterior maxilla is a frequent problem encountered in the modern dental implant era. Decreased vertical bone height as a result of tooth loss, aging, and pneumatization of the sinus result in alveolar bone height as low as 1 to 2 mm, precluding the successful placement of dental implants.[1,2] In order to address this limitation, several approaches have been described to increase the height of the alveolar ridge by augmentation of the maxillary sinus: lateral window, vertical or transcrestal, or Le Fort I approaches.[1-5] Most thin sinus floors can be augmented using the lateral or transcrestal approach.

Biologic and Anatomic Considerations

Morphology

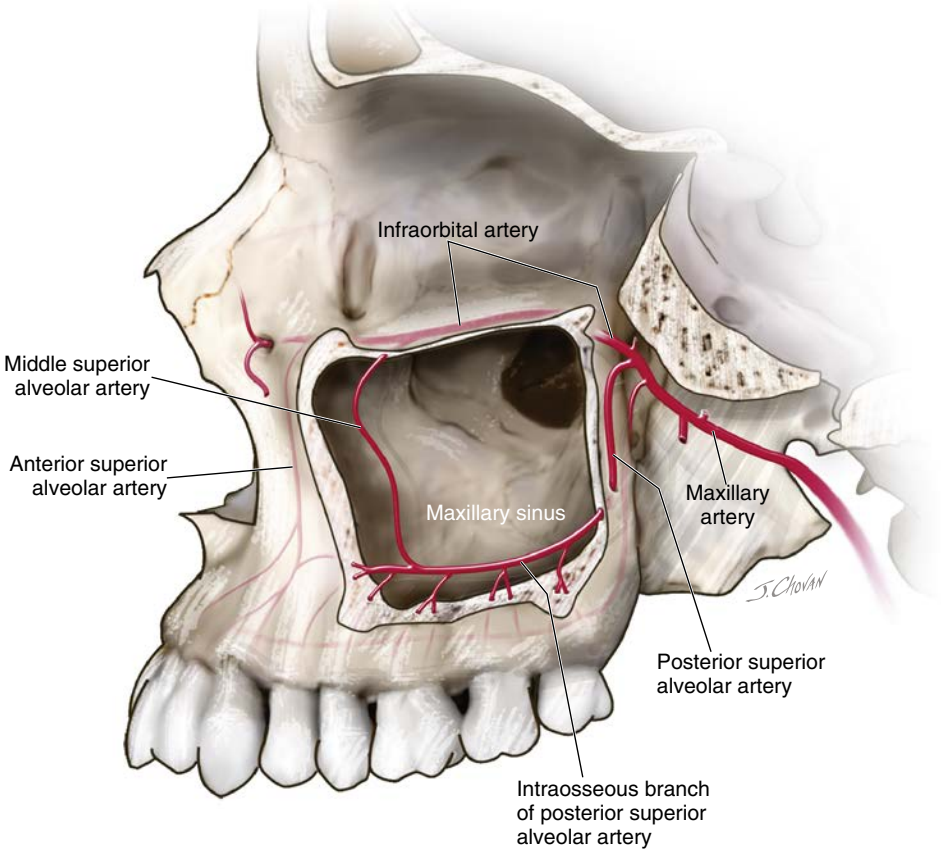
The paired maxillary sinus, the antrum of Highmore, is the largest of the paranasal sinuses. It is located just lateral to the nasal cavity, inferior to the orbit, and extends into the zygomatic process[6] (Figure 32-1). The cavity is lined with pseudostratified columnar ciliated epithelium, as is the remainder of the respiratory tract, and is known as the Schneiderian membrane, named after a German anatomist of the 17th century.[7] It has an average thickness of 0.8 mm.[8] The sinus undergoes pneumatization throughout childhood and reaches a level parallel to the nasal floor by age 12 to 13.[9,10] Complete eruption of the maxillary molars marks the end of vertical growth of the sinus. Pneumatization is then complete by age 20 and is on average 5 mm inferior to the nasal floor.[10,11] The sinus typically extends from the canine fossa to the tuberosity. The average dimensions of the adult sinus are 2.5 to 3.5 cm wide, 3.6 to 4.5 cm tall, and 3.8 to 4.5 cm deep, with an estimated volume of approximately 12 to 15 cubic centimeters[6,12,13] and the shape of a quadrilateral pyramid.[8] A more acute angle formed by the lateral and medial sinus walls, often seen in the premolar region, can influence the risk of perforation during elevation of the Schneiderian membrane.[8,14,15] Cho and colleagues found a 28.6% to 37.5% perforation rate with angles of 60 degrees or less, and a 0% perforation rate with angles greater than 61 degrees.[14] The sinus drains into the middle meatus of the nasal cavity via the maxillary sinus ostium, which is located on the posterior-superior aspect of the medial wall and is approximately 2.4 mm in diameter.[16]

Pneumatization of the Sinus

Although the volume of the adult sinus remains stable after age 20,[9,10,17] multiple factors can cause further pneumatization. The primary cause is tooth loss, with the most vertical bone loss occurring after extraction of second molars.[11] This appears to occur within the first 4 to 6 months after extraction.[11] This inferior movement of antral bone is exacerbated by bone loss at the alveolar crest after tooth extraction, resulting in a combined reduction in vertical height that may be as low as 1 to 3 mm.

Septa

The presence of septa can increase the risk of membrane perforation.[8,15] Septa in the maxillary sinus were first described by Underwood in 1910 and are often referred to as Underwood septa.[18] They may occur as congenital, complete (primary) septa or acquired, incomplete (secondary) septa in the case of tooth and bone loss.[18,19] In a prospective series of 100 cases, Zijderveld found a prevalence of septa in 48%.[15] Other studies using prior computed tomographic (CT) and anatomic specimens have demonstrated a wide range of prevalence from 16% to 58%.[8,20-25] Septa are found more commonly in the premolar region and are more prevalent in atrophic edentulous maxilla.[15,21,22] Their orientation may vary in the sagittal (Figure 32-2, *A*) or medial-lateral direction (see Figure 32-2, *B*), as well as varying in height, and may affect the surgical approach.[23] Medial-lateral



• **Figure 32-1** The maxillary sinus has an estimated volume of 12-15 cm^3. It is supplied by the maxillary artery via branches of the infraorbital artery and posterior superior alveolar artery. (From Kademani D, Tiwana PS: *Atlas of oral and maxillofacial surgery,* St Louis, 2016, Saunders.)

septa or multiple septa are often best approached from a lateral approach, using multiple windows (see Figure 32-2, *C*), whereas sagittally oriented septa may be managed from a crestal or lateral approach (see Figure 32-2, *D*).[23] A CT scan should be considered in the preoperative evaluation as Krennmair reported a 21% rate of false diagnosis of septa using panoramic imaging compared to CT scan.[21]

Thickness of the Schneiderian Membrane

Normal membrane thickness averages 0.8 mm. Wen reported membrane perforations were correlated with both overly thin (<0.5 mm) and overly thick (>3 mm) membranes.[26] Yilmaz, in a study of 50 patients, found a strong correlation between thick gingival phenotype and thicker Schneiderian membrane, and a moderate correlation between residual ridge height and membrane thickness.[27]

Pseudocysts

In a retrospective study of 109 patients undergoing maxillary sinus augmentation, 8 (7.3%) were found to have a pseudocyst (Figure 32-3).[28] The authors concluded that a pseudocyst of the maxillary sinus is not a contraindication for sinus augmentation. It is reported that most cysts spontaneously regressed or showed no significant change in size over the long term.[29] In the absence of associated complications, "wait and see" may be appropriate management of pseudocysts. The low frequency of sinus membrane perforation and postsurgery sinusitis associated with pseudocysts make the operation safe. In large lesions and in patients with an unclear diagnosis, further evaluation is needed before sinus augmentation.[28]

Vascular Supply

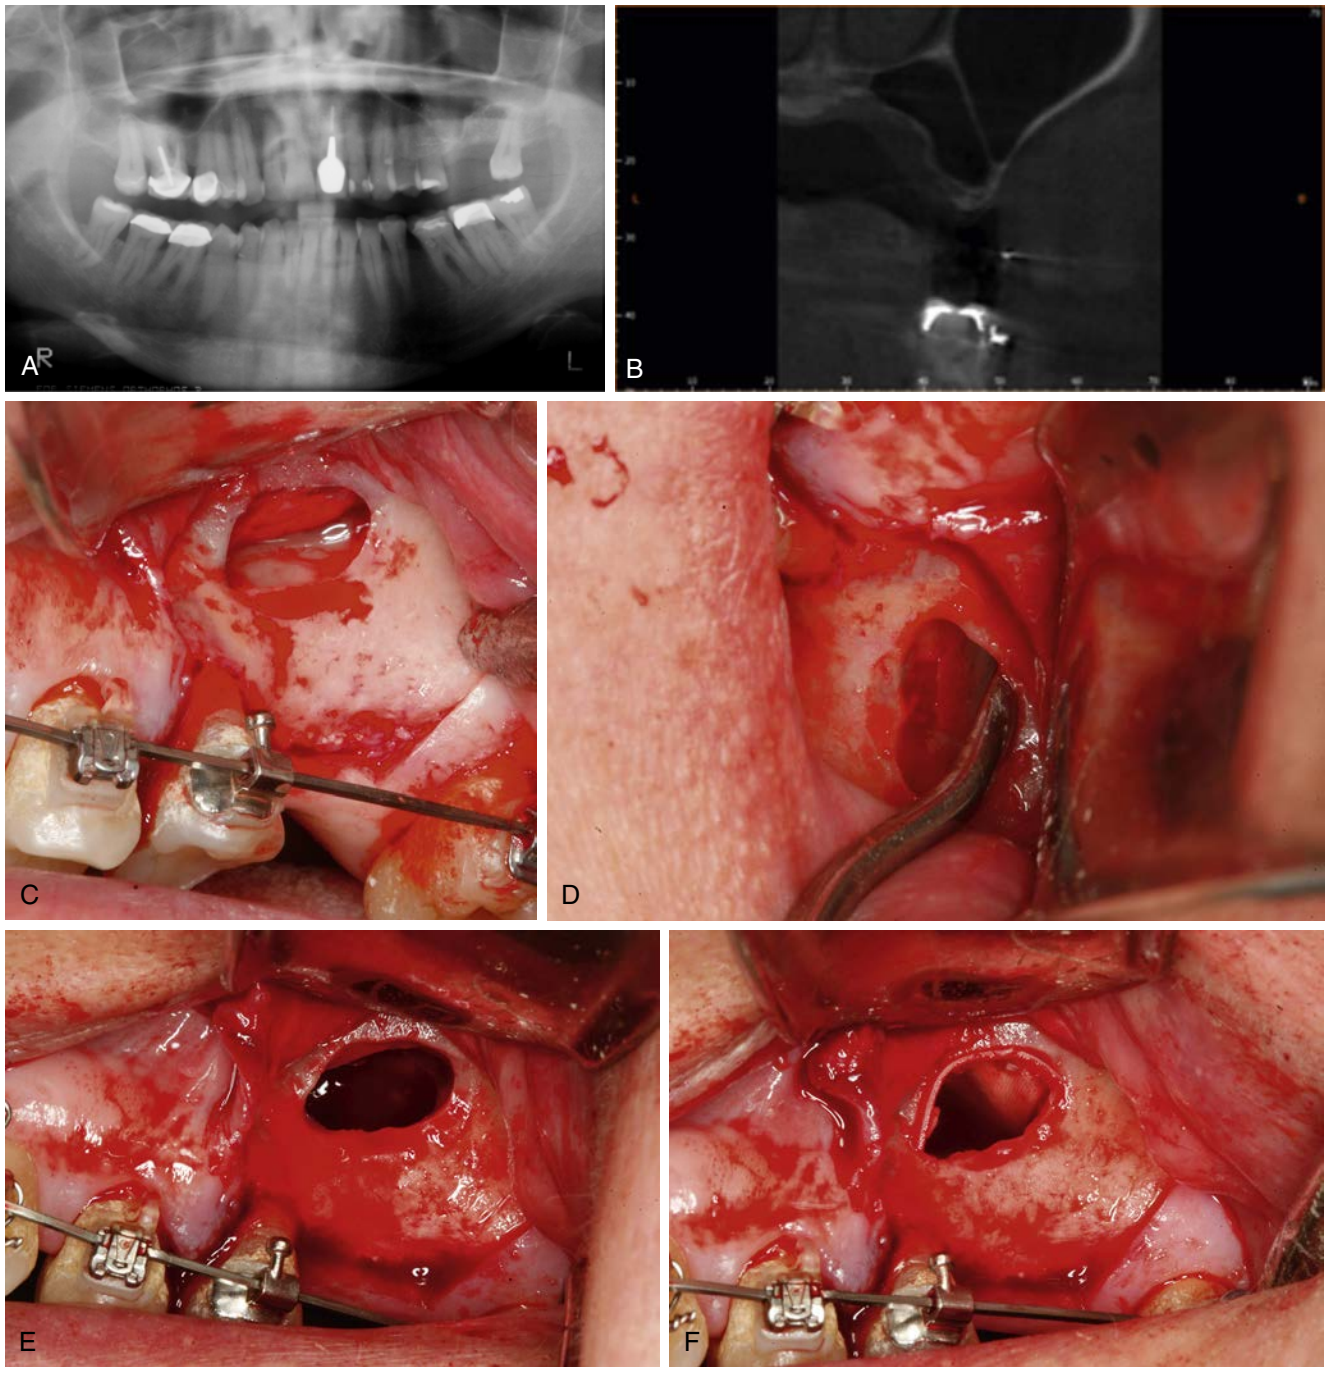
Blood Supply

The blood supply to the lateral aspects of the maxillary sinus comes from the maxillary artery via the posterior superior alveolar (PSA) artery and infraorbital (IO) artery (see Figure 32-1). The greater palatine artery supplies the remainder of the sinus. The PSA artery also supplies the mucoperiosteal layer on the lateral portions of the maxillary sinus wall.[30] Elian and colleagues reported that PSA and IO arteries may anastomose to form an intraosseous branch detectable by CT scan at least 50% of the time, with approximately 80% greater than 15 mm from the alveolar ridge.[31] Preoperative CT scan may aid in avoiding potential hemorrhage (Figure 32-4).

Pretreatment Considerations

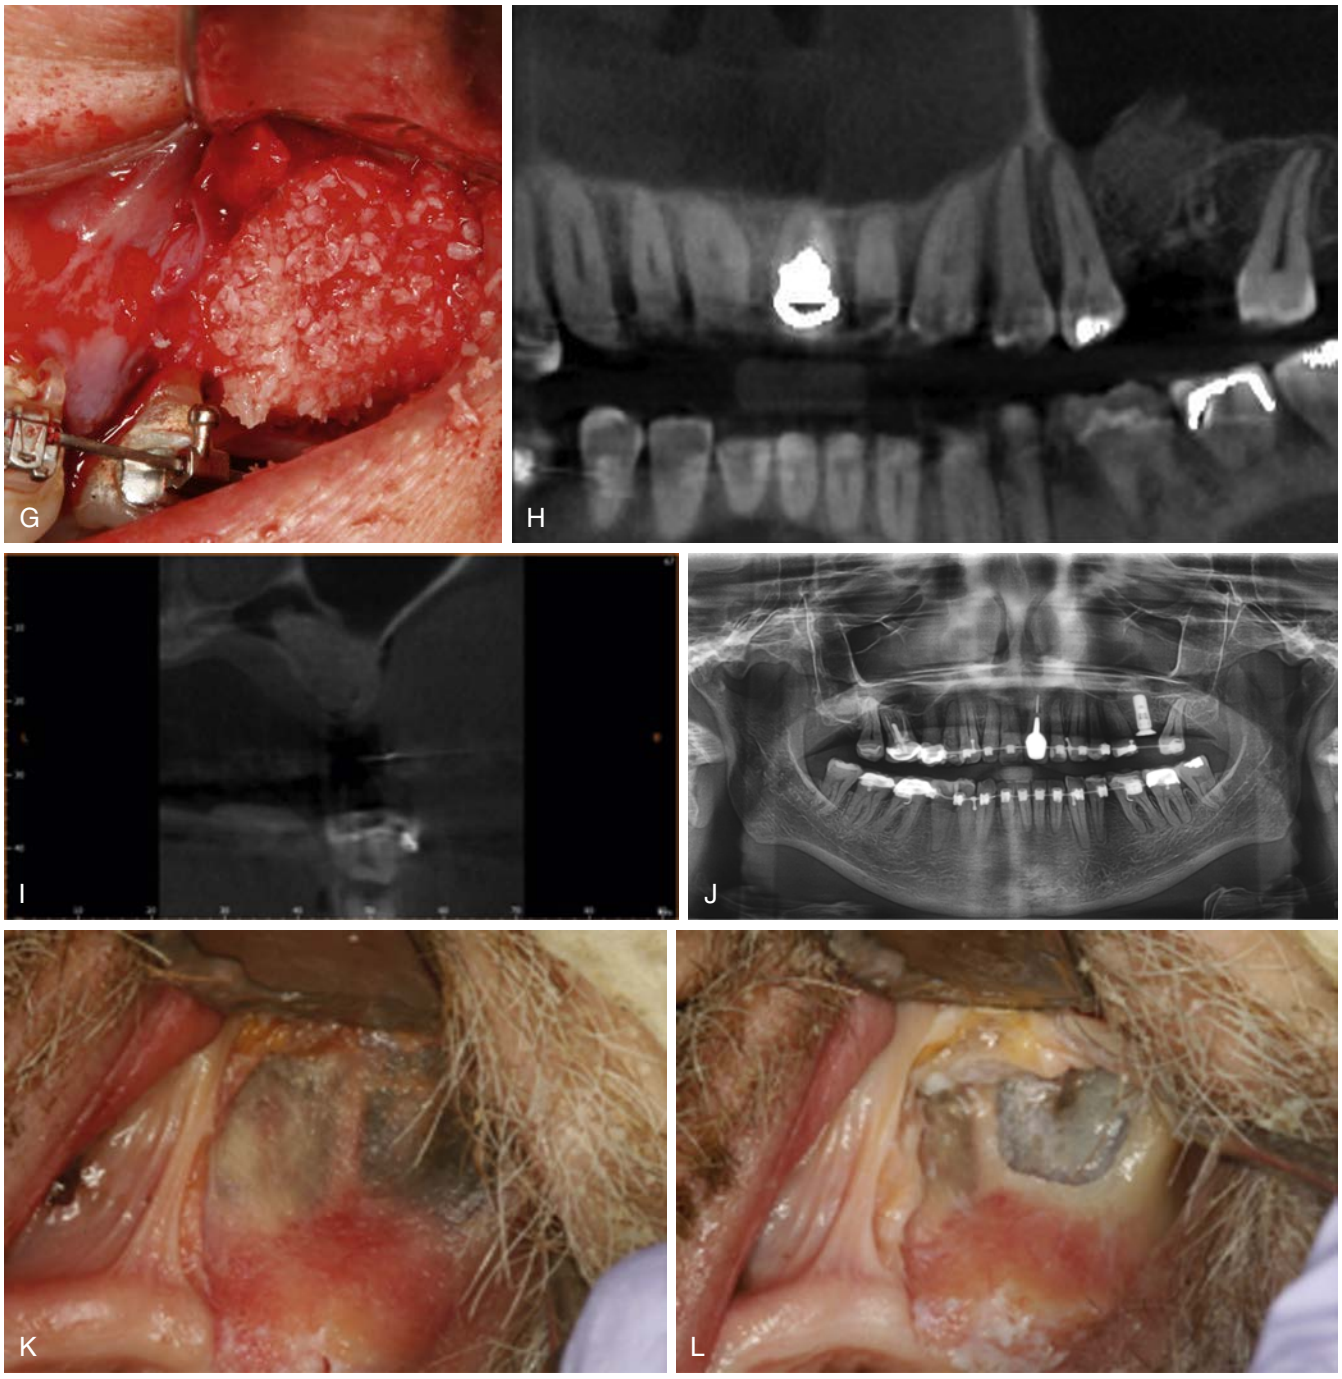
Graft Materials

Debate remains as to which graft material is best for sinus augmentation. The 1996 Sinus Consensus concluded bone



• **Figure 32-2** Septa can be found in a sagittal **(A-J)** or medial-lateral **(K-L)** orientation. Sagittally oriented septa can be managed through a crestal or lateral approach. **C**-**G**, Illustrate a lateral osteotomy approach to gain access to the sagittal septum and creating a second ostetotomy in the septum for augmentation of the medial compartment or the sinus. Medial-lateral septa are best approached via a lateral approach with multiple windows (**K** and **L**).

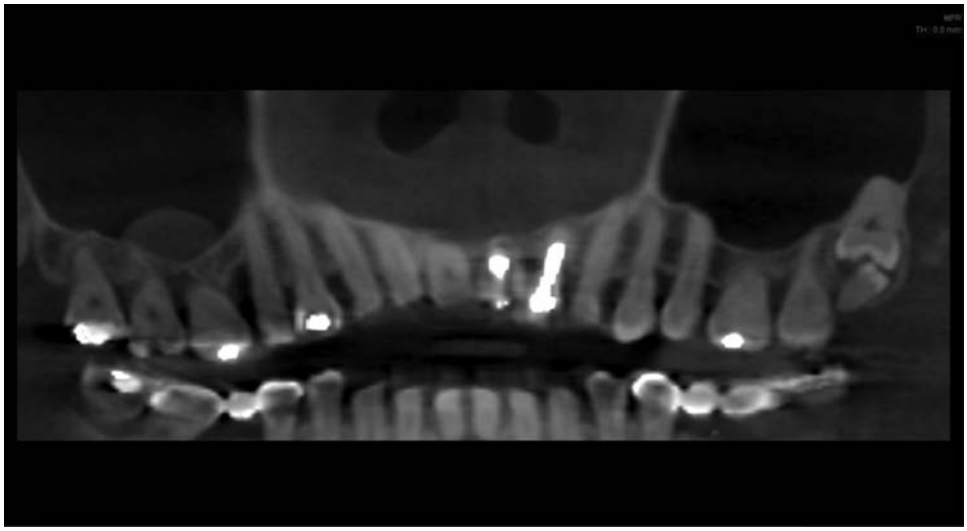
Continued



• **Figure 32-2, cont'd**

formation through the lateral window approach was predictable with various graft materials, but no consensus was reached on which material was best.[1] The original description for sinus augmentation recommended the use of autogenous bone for its inherent osteoinductive and osteogenic properties. Various bone substitutes such as bovine xenograft,[32,33] human allograft,[34] synthetic alloplasts,[35] and recombinant human bone morphogenic protein type 2 (rhBMP-2)[36] have since been shown to be equally effective for sinus augmentation. Platelet-derived products such as platelet-rich plasma and platelet-rich fibrin have shown inconclusive data.[34,37-39] Comparison studies and systematic reviews have not demonstrated any advantages for any of the listed materials.[40-44] Long-term studies have shown approximately 20% loss of bone height over the first 2 years regardless of autogenous or composite grafts,[32,45] although a recent systematic review by Shanbhag and co-workers suggests that greater reduction may be seen with autogenous bone (45%) than bone substitutes or composite grafts (20%).[46]

De novo bone formation using autogenous blood clot alone[47-50] or a hemostatic sponge,[47,51] without the presence of graft material, has also been demonstrated in prospective studies. This highlights the concept that inducing new bone in the sinus may not depend solely on bone type, but



• **Figure 32-3** Pseudocysts can be detected on radiographic imaging.

rather space maintenance within an osteogenic environment surrounded by native bony walls and the Schneiderian membrane. Srouji and colleagues demonstrated new bone formation with sinus membrane cell transplants, indicating the innate osteogenic potential within the Schneiderian sinus membrane and its possible contribution to bone regeneration in sinus augmentation procedures.[52]

Barrier Membranes

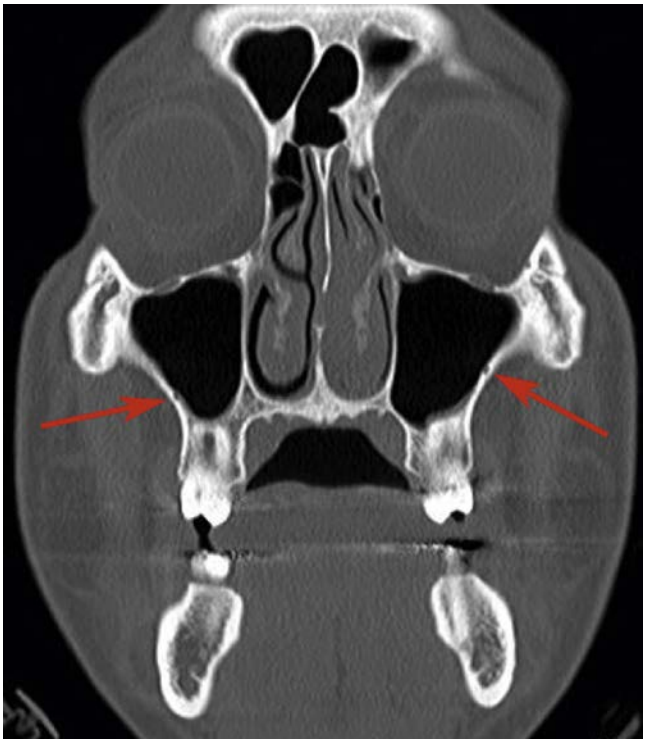
The use of a barrier membrane to cover the lateral window is suggested to prevent soft tissue ingrowth and improve the quality of bone formation within the sinus cavity. Considerable controversy exists regarding the use of a membrane as it relates to implant survival. Some researchers found no differences in implant survival rates between membrane-covered and uncovered groups.[53,54] Garcia-Denche and colleagues, in a split-mouth study, reported that membrane coverage did not improve implant survival at 1 year, nor did it allow for histologically superior bone growth.[53] Others reported higher implant survival rates when antrostomy defects are covered with a membrane.[55-58] Duttenhoefer, in a systematic review and meta-analysis of 122 publications and 16,268 endosseous implants in grafted sinuses, reported that the application of membranes was the only significant variable to reduce the hazard ratio and improve long-term implant survival when compared to other variables (i.e., surgical approach, graft materials, implant types, implant surfaces, native bone height, and implant staging).[59]

Preoperative Evaluation

Medical Evaluation

Sinusitis

Acute sinusitis should be treated before the augmentation procedure.[16] Chronic sinusitis is considered a relative contraindication. The presence of sinus disease has been shown to range from 40% to 66% based on CT diagnosis



• **Figure 32-4** Preoperative computed tomography demonstrating the anastomosis *(red arrows)* between the infraorbital and posterior superior alveolar arteries in the lateral sinus wall.

of symptomatic patients, and even as high as 25% in asymptomatic patients.[60-62] Timmenga followed 45 patients for 1 to 5 years after sinus augmentation and implant placement and found postoperative sinusitis in 2 of 5 patients predisposed to sinusitis preoperatively, but none in the other 40 patients without disease.[63] In the healthy sinuses, Timmenga found, through endoscopy and biopsy, minimal histologic changes and no clinical consequences at 9 months.[64] Augmentation of a thickened sinus membrane in the setting of chronic sinusitis may cause obstruction of the osteomeatal complex and worsen sinusitis.[63,65] The presence of

septal deviation, allergies, and asthma may increase the risk of sinusitis.[66]

Smoking

The effect of smoking on dental implant treatment remains controversial. Smoking has been shown to decrease the success of dental implants, with an increased complication rate of up to 46% and decreased 5-year survival rate from 97.1% to 87.8% in one study.[67] Lambert and colleagues noticed a trend of greater failures in smokers between the time after uncovering and before insertion of the prosthesis.[68] Esposito et al. and De Bruyn and Collaert reported that smokers had a higher implant failure rate in the maxilla.[69,70] Higher implant failure rates have also been reported in smokers after rehabilitation of severely resorbed maxillae with and without bone grafts.[71,72] The maxillary bone is more sensitive to tobacco exposure, with heavy smokers exhibiting more marginal bone loss (MBL) than mild smokers.[71] A systematic review by Chambrone revealed a statistically significant increase in the risk of implant loss placed in augmented sinuses of smokers compared to nonsmokers.[73] Limited evidence has not demonstrated a clear detriment of smoking on the success of the sinus augmentation procedure itself.[67,74] Smoking has also been correlated with an increased risk of sinus membrane perforation.[75] Patients must therefore be counseled that smoking, although not an absolute contraindication, may adversely affect the reliability of sinus grafting and implant survival.

Radiographic Evaluation

Cone-beam CT (CBCT) has emerged as the definitive tool for accurate three-dimensional evaluation of the maxillary sinus for preoperative implant treatment planning.[76] Panoramic imaging has limitations and may result in distortions that preclude accurate measurement, underestimate the actual need for sinus augmentation,[76] and fail to reveal sinus anomalies or pathology.[62,77-79] Transcrestal approaches require accuracy to at least 1 mm for proper osteotomy preparation and sinus membrane elevation. CBCT will identify the bone thickness of the lateral antrostomy site, the presence of sinus pathology such as polyps, cysts, sinusitis, and the presence of abnormalities such as septa.[25,77-79] Preoperative identification of the position of the anastomosis between the PSA and IO arteries may reduce the risk of intraoperative bleeding.

Techniques

Lateral Approach

The lateral approach to the sinus via a lateral window osteotomy was first described separately by Caldwell and Luc in the late 19th century for treatment of sinus abscesses (Figure 32-5).[80,81] Using this approach, Tatum in 1975 developed a technique to increase alveolar bone height by placing a graft material under the sinus membrane before implant placement.[82] Boyne and James first published the technique in 1980.[83,84] Sinus augmentation has since been studied thoroughly and has produced excellent results with long-term graft stability and implant survival.[1,2,6,82,85-88]

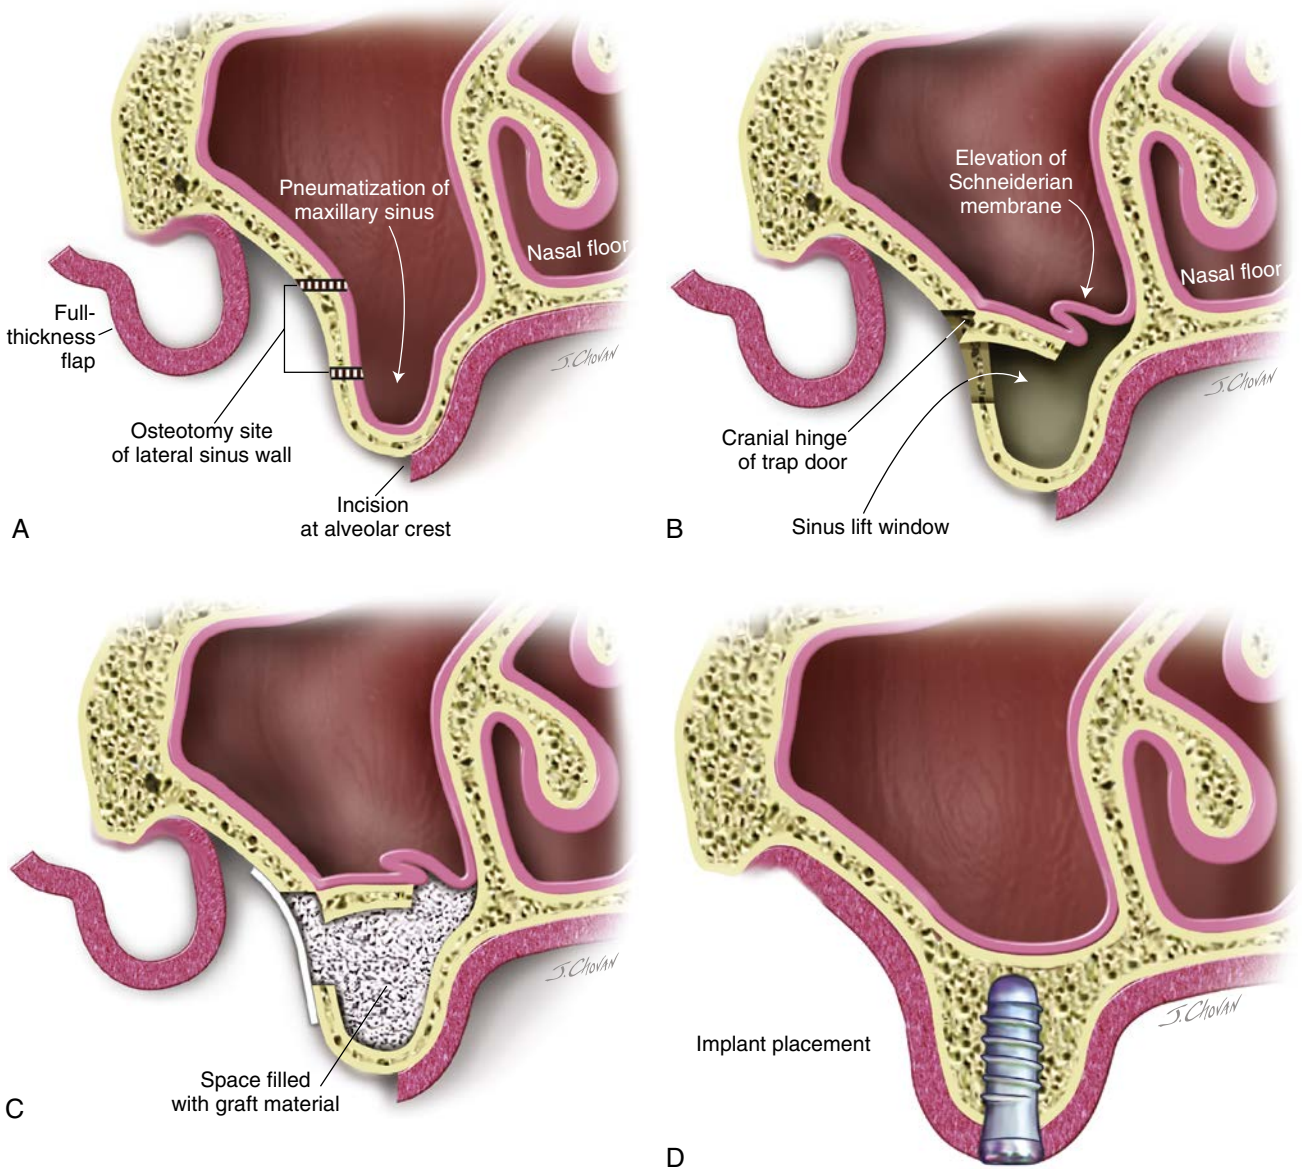
Peleg and colleagues studied 2132 implants placed into the grafted sinus of 731 patients in a longitudinal study over 9 years and demonstrated cumulative survival of 97.9%, with survival rates of 95.0% in residual bone height of 1 to 2 mm and 98.4% in both 3 to 4 mm and more than 5 mm residual bone height groups.[89] Similarly, a systematic review by Del Fabbro reports an overall survival rate of implants over three years in grafted sinuses using lateral techniques to be 93.7%.[90] The conclusions of evidence-based reviews indicate that the use of bone substitutes,[46] rough-surface implants,[90] results in the best outcomes when considering implant survival. The use of piezoelectric surgery, rather than rotary diamond burrs, for lateral window preparation and membrane separation has decreased the occurrence of intraoperative complications of bleeding and membrane perforation.[54,74-76,91] Compared to indirect techniques, the lateral approach allows direct visualization of the sinus cavity for sinus membrane elevation and placement of biomaterial. This approach is recommended for ridges with residual height less than 4 mm.[59,90,92]

In appropriate cases with adequate bone height for primary implant stability, simultaneous sinus augmentation and implant placement can be accomplished.[93,94]

Protocol

A full-thickness flap is elevated to the depth of the vestibule using a crestal incision with a single anterior vertical release (Figure 32-6, *A*). An osteotomy of appropriate size is made using piezoelectric surgery instrumentation or rotary burrs (#6 or 8 round burr) (see Figure 32-6, *B*). A larger osteotomy may facilitate membrane exposure and elevation, but will decrease the osteogenic potential of the grafted site by removing supporting native bone. Avila-Ortiz and colleagues studied the effect of osteotomy dimensions on vital bone formation and reported that larger osteotomy dimensions were positively correlated with lesser vital bone formation.[95] The inferior border of the osteotomy should be 1 to 2 mm superior to the level of the sinus floor and can be estimated from preoperative radiographs (Figure 32-7). The superior osteotomy is made parallel to the inferior osteotomy and similar in length (see Figure 32-6, *C*).

If rotary burrs are used, care is taken to remove bone incrementally until only membrane or a thin layer of bone remains. A hand instrument such as a small curette can then be used to remove the remaining layer of bone and expose the Schneiderian membrane. Once the window is osteotomized circumferentially, elevation of the membrane begins at the superior aspect with a curved dissection elevator (see Figure 32-6, *D*). The sharp edge of the elevator is directed toward bone, with the back, curved surface of the instrument supporting the membrane. The bony window can be left attached to the membrane if it is firmly attached. The senior author prefers to make a small osteotomy without a bony window to increase the osteogenic potential of the grafted environment and to decrease the risk of



• **Figure 32-5** The lateral approach involves elevation of a full-thickness buccal flap and osteotomy through the lateral wall **(A),** infracture and elevation of the sinus membrane **(B),** placement of graft material **(C),** and simultaneous or delayed implant placement **(D).** (From Kademani D, Tiwana PS: *Atlas of oral and maxillofacial surgery*, St Louis, 2016, Saunders.)

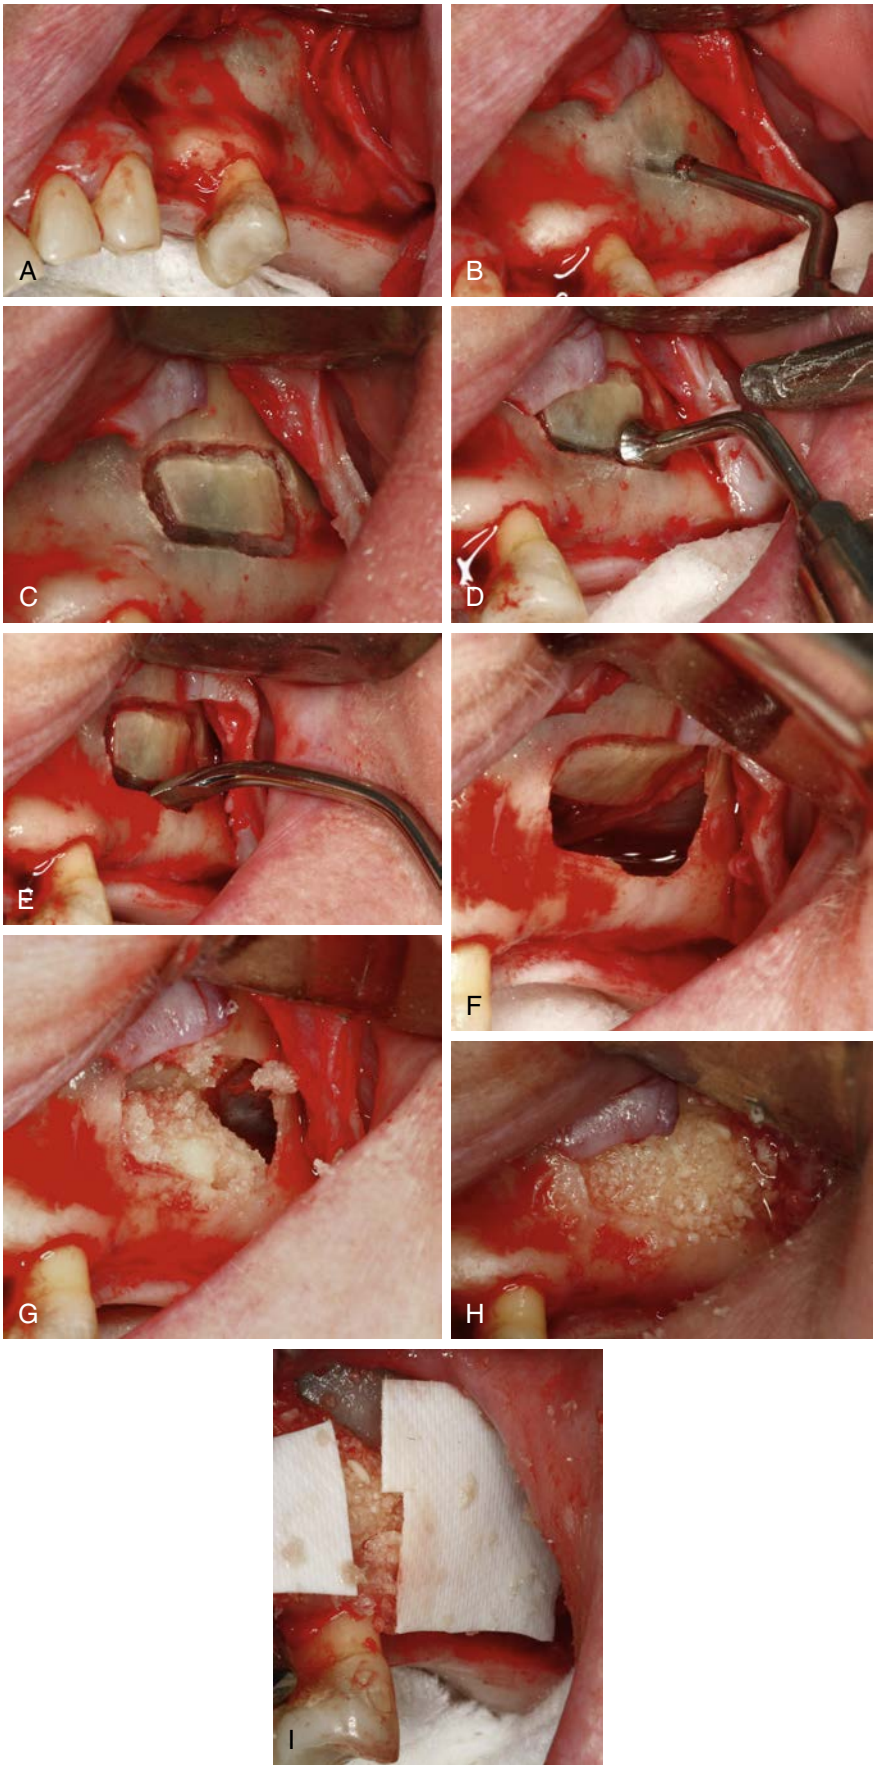
bone sequestrum that can occur after loss of blood supply to the bony window. Membrane elevation is initially carried circumferentially around the osteotomy and slowly elevated from the sinus floor and carried out medially to the medial wall of the sinus (see Figure 32-6, *E*). As a result, the bony window is elevated superiorly in a "trap-door" fashion and lies horizontally above the graft site (see Figure 32-6, *F*).

If septa are present in a medial-lateral direction, two separate windows adjacent to the septation can be used, essentially creating two separate window osteotomies (see Figure 32-2, *A* and *B*).

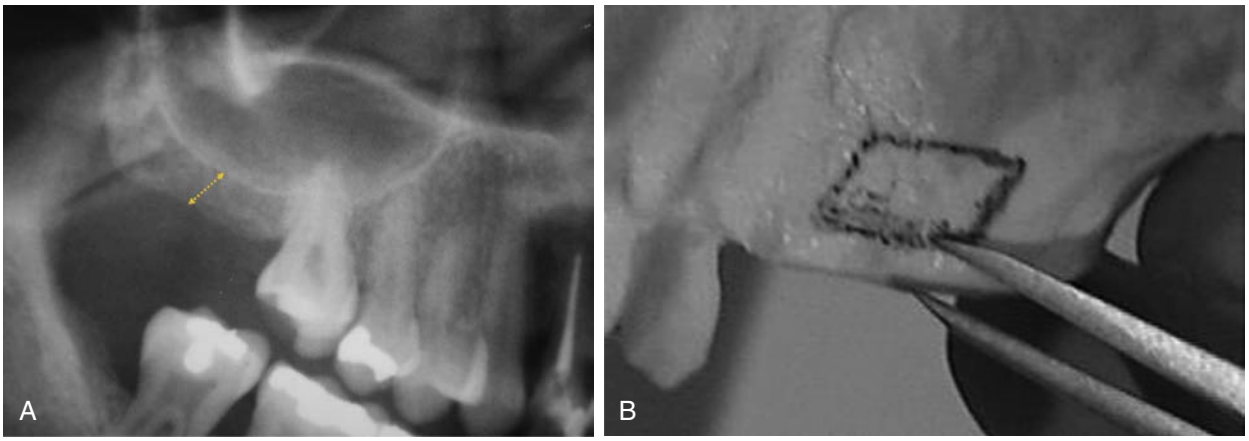
Graft material is placed against the anterior and medial sinus walls first (see Figure 32-6, *G*) and subsequently filled laterally (see Figure 32-6, *H*) to avoid inadequate graft fill (Figure 32-8). If simultaneous implant placement is planned, graft material is placed before implant insertion to allow better access to the medial aspect of the sinus cavity (Figure 32-9). Care is taken not to overfill the sinus with graft material to reduce the risk of membrane necrosis and postoperative sinusitis. Doud Galli and colleagues reported that of 14 patients who developed sinusitis after sinus augmentation, more than half received more than the recommended volume (2-5 mL) of bone graft material.[65] A slow-resorbing collagen membrane is then placed over the lateral window to avoid fibrous ingrowth (see Figure 32-6, *I*). The mucoperiosteal flap is then closed with resorbing interrupted sutures.

Managing Perforations

Perforation of the Schneiderian membrane is the most common complication of sinus augmentation surgery.[96]

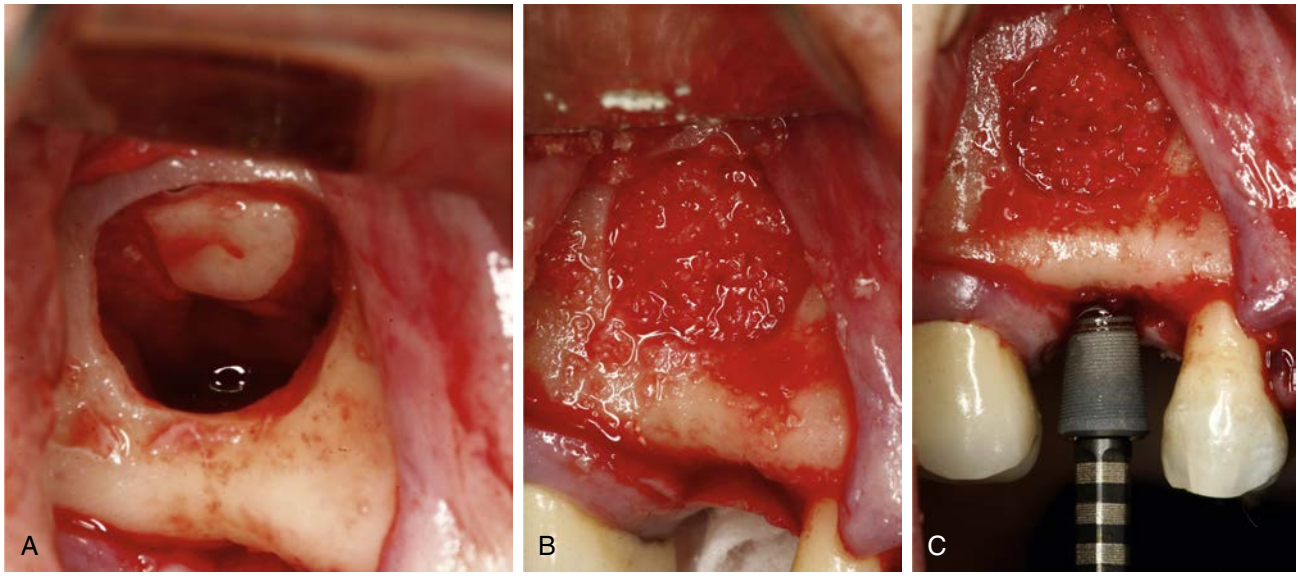


• **Figure 32-6** A full-thickness flap with an anterior release is elevated to the depth of the vestibule **(A).** An osteotomy is outlined with a piezoelectric instrument or rotary burr, staying 1-2 mm superior to the sinus floor **(B, C).** A curved osteotome or specialized blunt elevator infractures the window **(D)** and begins elevating the Schneiderian membrane from the sinus floor **(E).** Once the membrane and window are sufficiently elevated **(F),** graft material is placed against the anterior and medial walls **(G),** and filled laterally **(H).** A bioresorbable membrane covers the graft material **(I).**

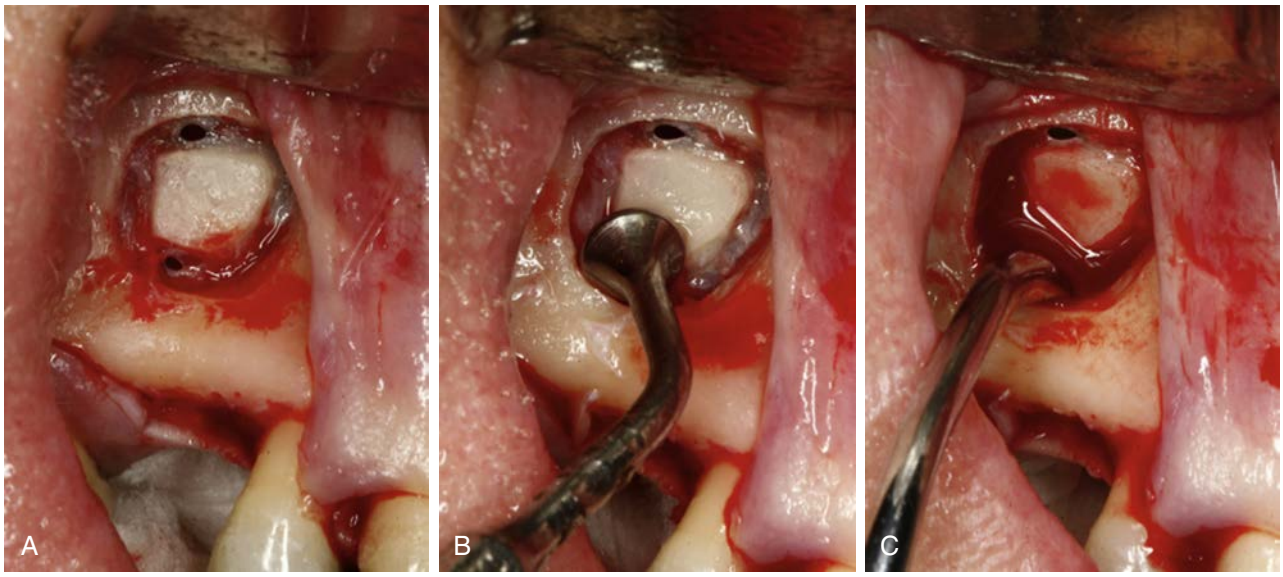


• **Figure 32-7** Preoperative imaging demonstrates the height of the sinus floor **(A)** and guides the osteotomy in situ **(B).**

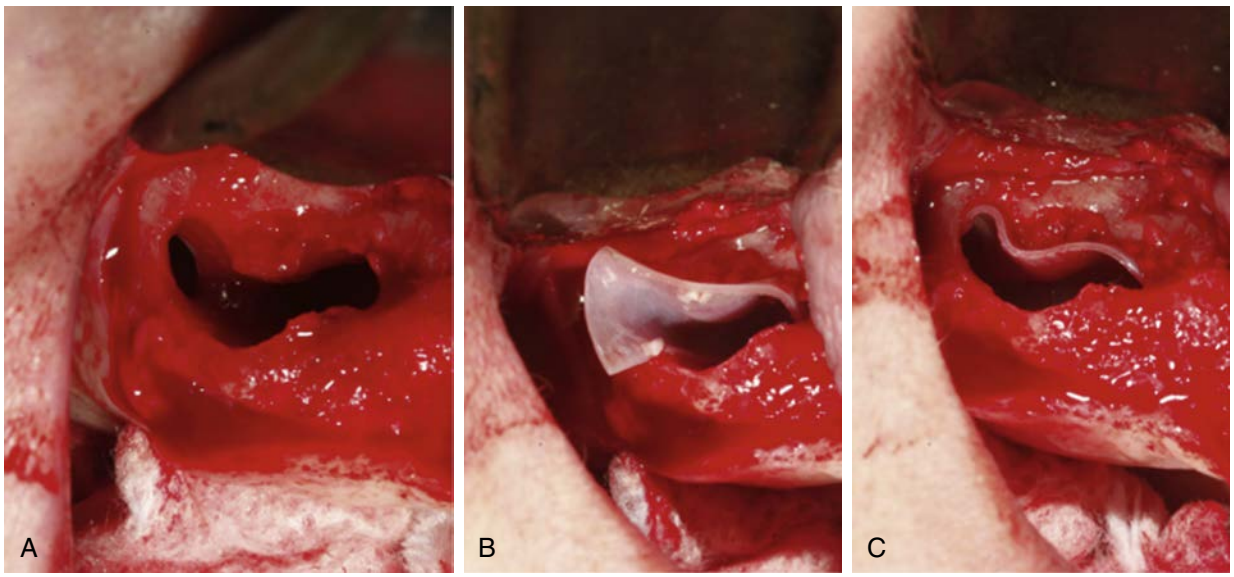
• **Figure 32-8** Preoperative **(A)** and postoperative **(B)** cone-beam computed tomography demonstrating incomplete sinus fill of the anterior graft site.



• **Figure 32-9** Simultaneous implant placement can be placed with sufficient native ridge height **(A).** Graft material is placed first **(B),** followed by implant osteotomy and placement **(C).**



• **Figure 32-10** Small perforations (<5 mm) can be seen at the superior and inferior aspects of the lateral window **(A).** The window and membrane are carefully elevated **(B),** and the procedure can continue without propagating or repairing the perforations **(C).**

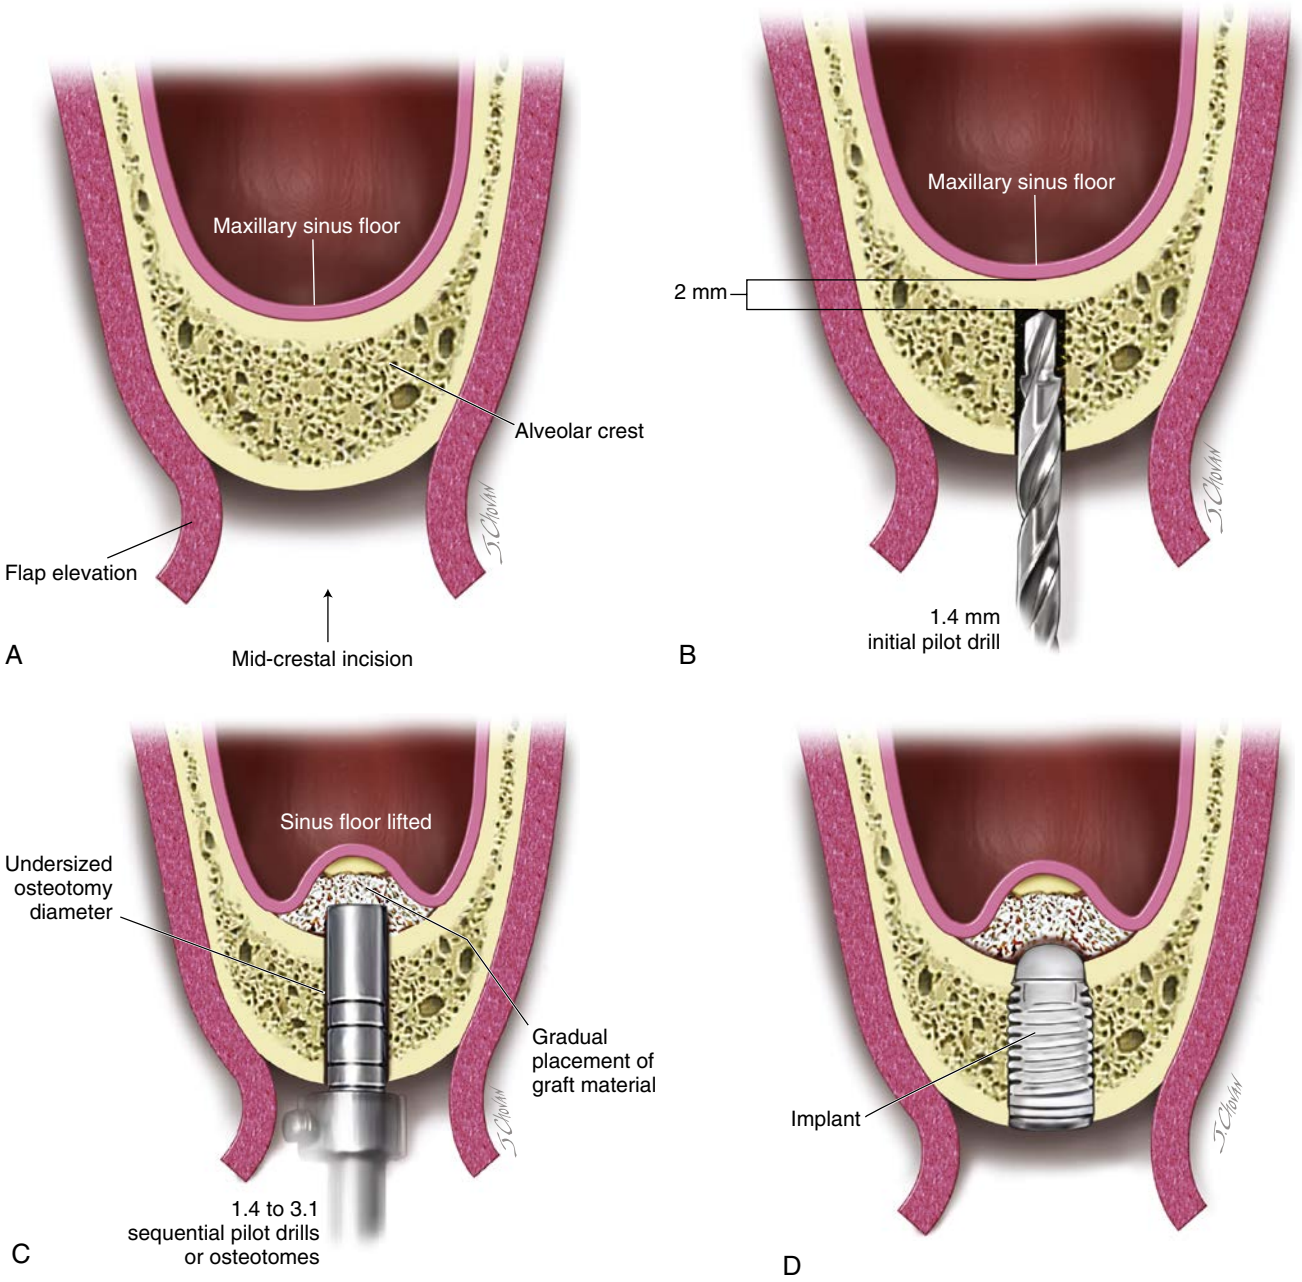


• **Figure 32-11** Larger perforations (>5 mm) in unfavorable locations **(A)** can be managed by occlusion with a bioresorbable membrane **(B),** allowing containment of the graft material **(C).**

Implant survival rate is reported as inversely proportional to the size of the perforation, with tears of less than 5 mm and 5 to 10 mm correlated with implant survival of 97% and 92%, respectively.[97] When tears were larger than 10 mm, implant survival dropped to 74%. Ardekian and colleagues demonstrated similar results with no significant difference between control groups and membrane perforations less than 10 mm.[75] Small tears less than 5 mm at the superior aspect of the window may not need repair, as the elevated membrane will fold together and will not impede graft containment (Figure 32-10). Small tears less than 5 mm toward the crestal aspect of the window can be directly repaired with resorbable sutures or occluded with a resorbable collagen membrane. Larger tears (5-10 mm) located in unfavorable areas can be occluded passively with a collagen membrane (Figure 32-11). Postoperative antibiotics are recommended, as Nolan and co-workers have reported a significantly higher rate of secondary infection requiring antibiotics in the presence of membrane perforation.[98]

Indirect (Transcrestal) Approach

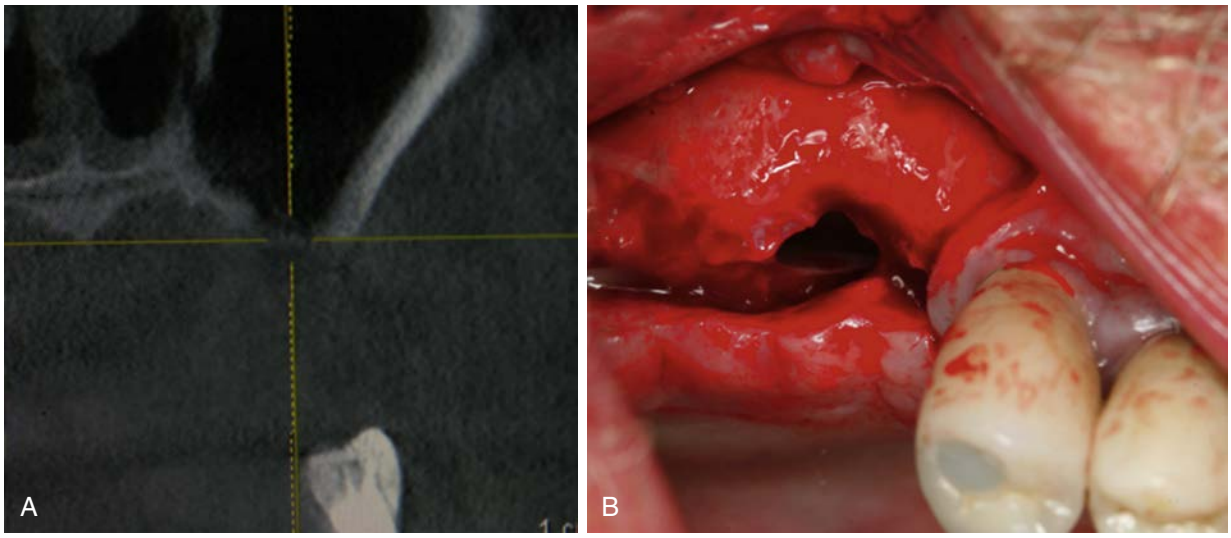
The indirect, transcrestal approach through the alveolar ridge or extraction socket was first introduced by Summers in 1994,[4,5] consisting of an osteotomy through the alveolus and elevation of the sinus floor using specialized osteotomes (Figure 32-12).



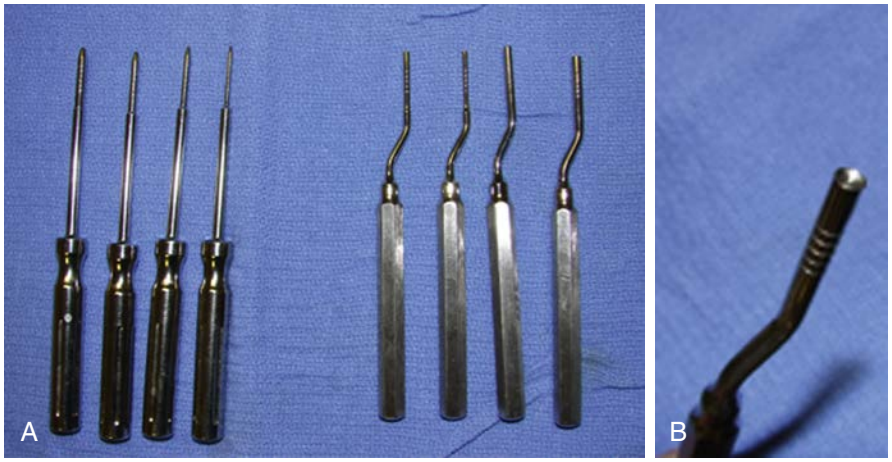
• **Figure 32-12** Indirect, crestal sinus-lift requires minimal flap elevation to approach the alveolar crest **(A).** A pilot drill is stopped 1-2 mm short of the sinus floor **(B).** The osteotomy is expanded with sequential drills or osteotomes and the sinus floor is subsequently infractured. A small amount of graft material may be used to buffer the impact **(C).** Simultaneous implant placement is achieved with sufficient native bone height **(D).** (From Kademani D, Tiwana PS: *Atlas of oral and maxillofacial surgery*, St Louis, 2016, Saunders.)

This technique has been modified over time to include drilling and use of ultrasonic cutting. Several systematic reviews have shown similar long-term implant survival rates between indirect sinus augmentation procedures and lateral window sinus augmentation, although these findings have been largely limited to cases with at least 5 mm of native bone.[59,90,99,100]

The transcrestal approach has gained popularity, as it provides a less invasive access to the maxillary sinus. The approach is carried out through the alveolus or a fresh extraction site by preparing the osteotomy just below the level of the sinus floor, then using piezoelectric instrumentation or osteotomes to elevate the sinus floor and membrane. A recent meta-analysis reviewing outcomes of osteotome sinus floor elevation showed bone height gain of 2.07 to 4.62 mm in ridges with residual bone height of 4.1 to 8.8 mm.[101] Simultaneous implant placement with indirect techniques is predictable when adequate residual bone height exists (>5 mm) for primary implant stability.[49,92,99,100,102] Several modifications to this technique, with the use of piezotomes, lasers, hydraulic balloons, and hydrodynamic pressure, have



• **Figure 32-13** Fistula is seen on cone-beam computed tomography **(A)** and through alveolar crest **(B).**



• **Figure 32-14** Specialized osteotomes for expansion of the osteotomy in soft bone **(A).** Concave osteotome for infracture of the sinus floor **(B).**

been reported to minimize membrane perforation.[103-108] Although indirect transcrestal sinus augmentation can be successfully performed in limited residual bone height, higher rates of complications such as sinus fistula formation, unpredictable bone fill, and implant failure may be associated with it (Figures 32-13).

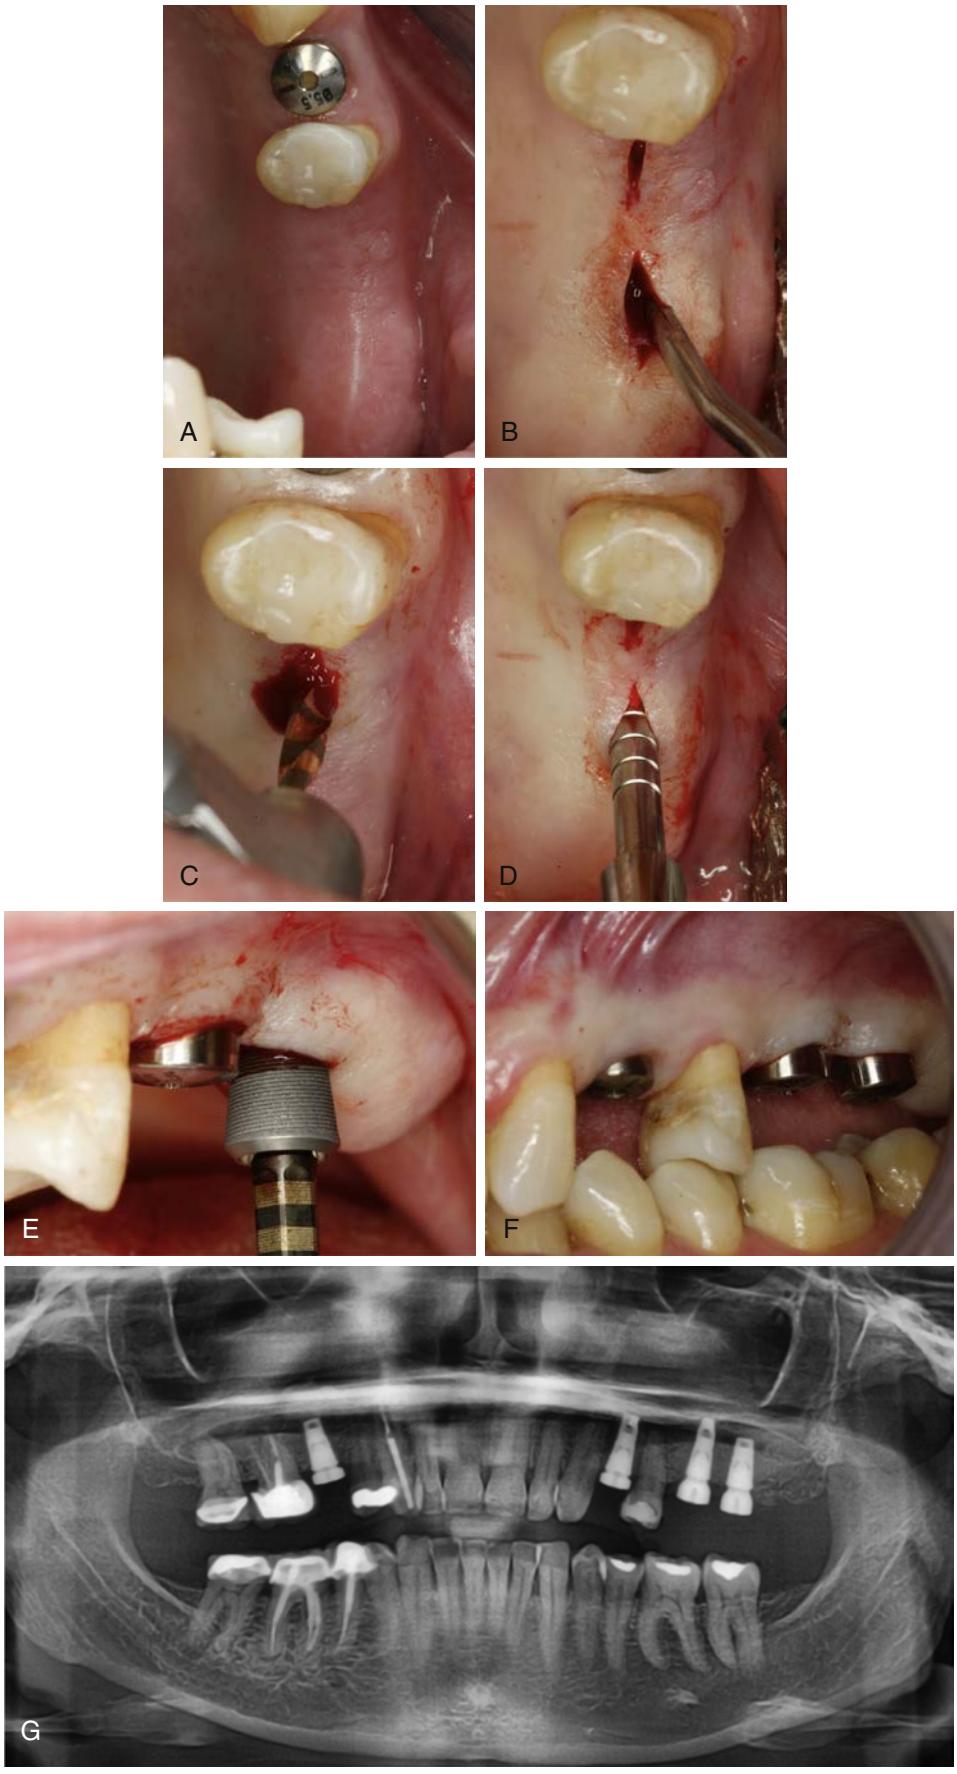
Protocol

Minimal flap elevation or a flapless protocol can be used with the indirect technique (see Figure 32-15). The residual bone height is measured from the CBCT, and the implant site is then enlarged sequentially under copious irrigation to a length 1 mm short of the sinus floor. Drills manufactured specifically for sinus elevation, with mechanical height stops, can be used for this purpose. Tactile feedback with the 2-mm pilot drill may reveal the underlying quality of bone at the osteotomy site. In soft bone, osteotomy preparation is prepared using sequentially expanding osteotomes with gentle malleting after the pilot drill (Figure 32-14, *A* and Figure 32-15). Expansion of the osteotomy by either method stops at the diameter one step before the final diameter. A concave-tipped osteotome is gently tapped to infracture the sinus floor (see Figure 32-14, *B*). A small amount of graft material can be placed in the osteotomy to buffer the impact of the infracture. Alternatively, dental lasers or piezotomes can be used to access the remaining sinus floor before the placement of any graft material. A single-staged implant is then placed (see Figure 32-15, *E*).

Complications

Perforations

Membrane perforation during the transcrestal approach to sinus lift can be difficult to detect and avoid.[109] Studies report perforations occur with a frequency of 3.8 to 6.28% with indirect techniques.[92,100,110] The introduction of biomaterial through an unrecognized perforation can



• **Figure 32-15** Indirect, crestal approach can be performed with minimal flap elevation **(A, B).** A pilot drill is carried 1-2 mm short of the sinus floor **(C),** and an osteotome infractures the sinus floor and elevates the membrane **(D).** Implants are placed with sufficient native bone **(E, F, G).**

result in potential sinusitis and should be avoided. De novo bone formation has also been demonstrated to be reliable in the absence of graft material, with only tenting of the membrane by simultaneous implant placement.[49,100,111,112] Nedir and colleagues, in a 10-year prospective study, followed 23 implants placed without graft material simultaneously with indirect sinus lifts, and found a mean gain of 3.0 mm.[112] Membrane elevation beyond 4 mm from the sinus floor increases the risk of membrane perforation. In cases with undetected membrane perforation, implants penetrating the maxillary sinus have shown minimal adverse effects.[113]

Paroxysmal Positional Vertigo

Surgical trauma induced by the percussive forces on the maxilla during osteotome sinus floor elevation procedure can lead to paroxysmal positional vertigo (PPV). The forces exerted by the mallet and osteotome can cause detachment of otoliths from the utricular macula while the patient's head position is hyper-extended. Di Girolamo and colleagues examined 146 patients undergoing maxillary surgery and found that four showed signs of PPV 1 or 2 days after the surgical procedure, which was treated with the Epley repositioning maneuver.[114] The use of piezosurgical instrumentation instead of osteotome may decrease the risk of PPV.

Postoperative

During the week following surgery, patients should be counseled to expect ecchymosis, swelling, minor nosebleeds, and mild to moderate discomfort. Perioperative antibiotics and decongestants are recommended based on clinical experience but are not supported by direct evidence.[115] In the case of larger membrane perforation, higher incidence of postoperative sinusitis, infection, and graft failure has been reported[98] and should be followed closely and lower the threshold for postoperative antibiotics.

Complications

Symptoms that present or persist beyond 2 weeks may be indicative of a postoperative complication such as sinusitis or infection. These findings warrant investigation clinically and with CBCT. A course of antibiotics with sinus coverage should be the first-line treatment, along with decongestants. More severe clinical findings such as purulence or drainage from the graft site or loss of containment of the graft may warrant surgical removal of the graft, irrigation and debridement, and antibiotics.

Osteoperiosteal Flaps and Distraction Osteogenesis

OLE T. JENSEN, KATSUHIRO HORIUCHI

Alveolar Osteotomy Space Maintenance Using Osteoperiosteal Flaps

Ole T. Jensen

Introduction

Alveolar bone mass deficiency can be corrected by multiple techniques, which frequently use onlay bone grafting or guided bone regeneration. These two techniques have been the mainstay of oral and maxillofacial surgery reconstruction for dental implants over the past 2 decades.[1,2]

A newer approach that has the advantage of less disturbance to osteogenic periosteum, improved continuity of crestal gingivoalveolar form, and greater resistance of the augmentation to resorption remodeling is the use of the osteoperiosteal flap.

The osteoperiosteal flap or "bone flap," commonly used in segmental orthognathic surgery, is a bone fragment moved in space without detachment of the investing periosteum. The best example of this concept in reconstructive alveolar surgery as it relates to implant osseointegration is the interpositional bone graft or "sandwich graft." Other uses of the bone flap in dentoalveolar augmentation are the alveolar split graft (book flap), edentulous alveolar repositioning osteotomy, and various alveolar distraction osteogenesis procedures that add width or height to an alveolar segment.[3-7]

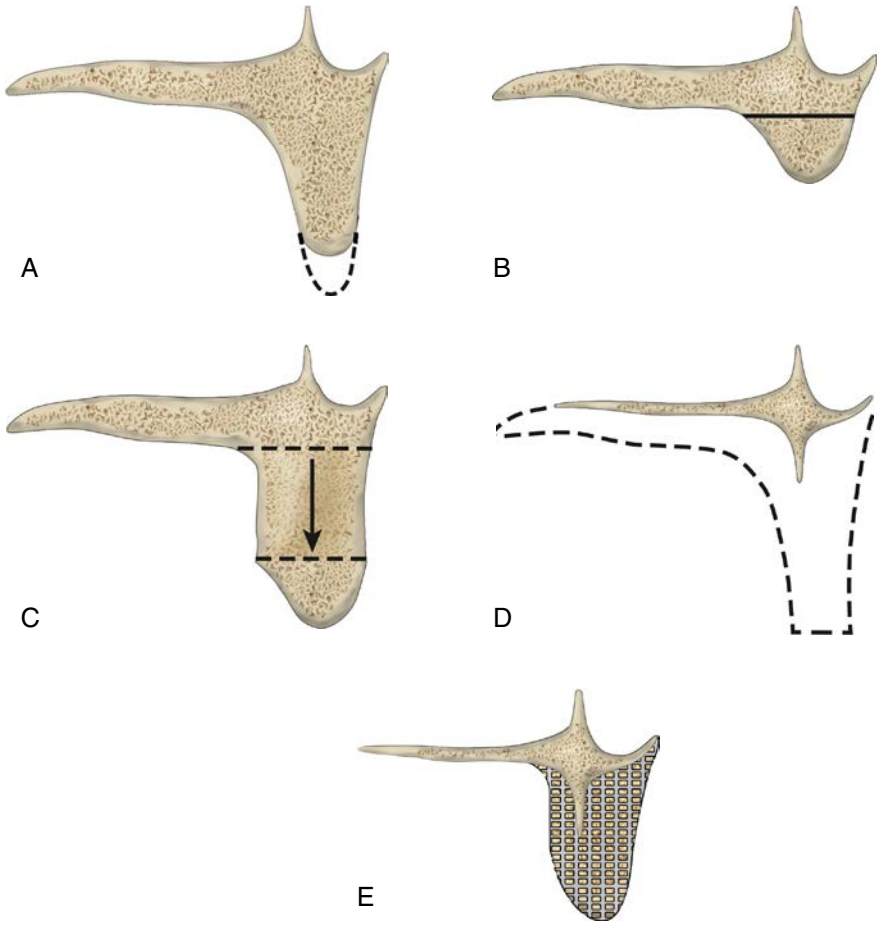
Space Maintenance

A key principle in developmental biology is replacement of a space-maintaining preliminary structure in the process of generation *os novum* of the sustaining tissue. An example of this is Meckel's cartilage of the in utero mandible. Meckel's cartilage serves as a scaffold for bone replacement in several ways, including establishment of the primordial nerve and blood supply, acting as a strut for conversion to ossified tissue, and, not least of all, the establishment of three-dimensional space for the growing mandible. In sum, the cartilage serves as a template from which ossification from adjacent connective tissue elements form bone by bone morphogenetic protein (BMP) induction.

In surgical repair, conceptualization of a space-making procedure is derivative of developmental biology in that the surgical wound created must prepare space for regenerative capacity to operate. In this sense, de novo bone formation, as with the use of BMP-2/acellular collagen sponge, must have a closed environment, a space, in which to operate. Another example is the space-maintaining function of graft materials such as autograft or allograft, which provide a place for adjacent connective tissue elements, such as unreflected periosteum, to populate the wound with induced bone-forming elements. When surgical design and wound care are circumspect, the defined space can fill with bone regenerated in any number of combinations of formation methods, including de novo, inductive/conductive-appositional, or replacement by creeping substitution.

Space Maintenance Strategy

A defect can be treated in a number of technical ways and there is clinical controversy as what to do in many settings. A decision to treat a defect could be based on what method might best create adequate space for the reconstructive effort. Adequate space could be based on creating adequate bone for orthoalveolar form with optimal gingival esthetic profile or alternatively adequate bone stock to fix implants for prosthetic restoration. Three basic methods are used today including, guided bone regeneration (GBR) for small defects, osteotomies for larger defects, and titanium mesh with either BMP-2 or iliac graft for larger defects. Block



• **Figure 33-1** As bone is lost in the anterior maxilla shown in cross section above near the midline, modest alveolar defects are treated with guided bone regeneration **(A),** whereas more severe vertical defects can be treated with an osteotomy **(B)** that is then interpositionally grafted to gain vertical height **(C).** If bone loss is severe **(D)** then a mesh graft with BMP or iliac particulate is suggested **(E).**

bone grafting is also used but will not be discussed as an optimal alternative here.

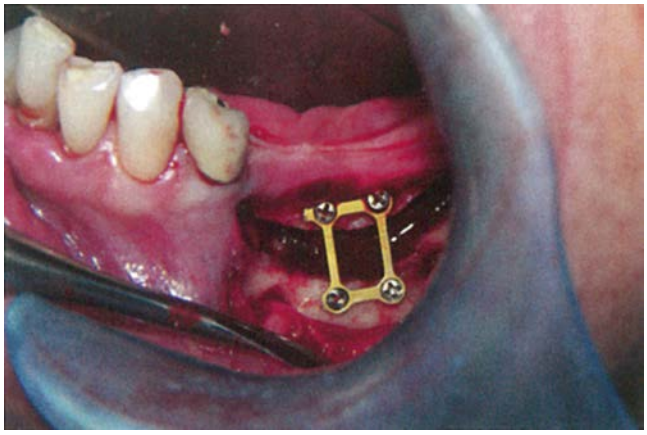
When to use these three methods, GBR, osteotomy, or mesh, is based on the complexity of the osseous defect. Defects of a few millimeters vertical/horizontal, perhaps as much as 4 or 5 mm, can be treated with guided bone regeneration using a barrier membrane. Vertical defects greater than 4 or 5 mm, perhaps up to 10 mm can be treated by interpositional grafting using the sandwich osteotomy bone graft. (Alveolar distraction is used for vertical defects 10 mm or greater.) And titanium mesh with BMP-2/acellular collagen sponge (ACS)/allograft or iliac particulate are reserved for gross defects with both height and width deficiency—often over 10 mm vertical.

Figure 33-1 shows schematic treatment for three magnitudes of defect and possible management for the anterior maxilla. The surgical method of choice must take into account the simplicity of the proposed operative procedure as well as the medical necessity—that is, what will best heal in a given situation.

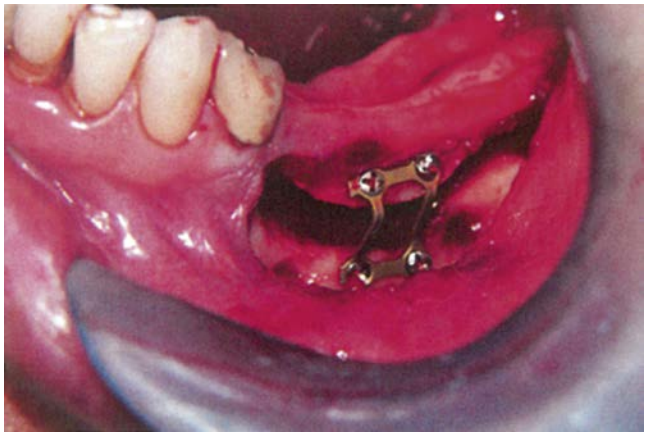
Osteoperiosteal flaps have great utility and advantage when bone is adequate for creating an osteotomy and the existing alveolar crest is not too thin or unstable from previous trauma. However, osteoperiosteal flaps have the disadvantage of being unidirectional in their augmentation strategy, meaning that either width or height can be increased but not both. Also, because of the indirect interpositional grafting technique, there is often a requirement for additional crestal bone grafting, which is commonly done at the time of implant placement to define final alveolar form.

Interpositional Bone Graft

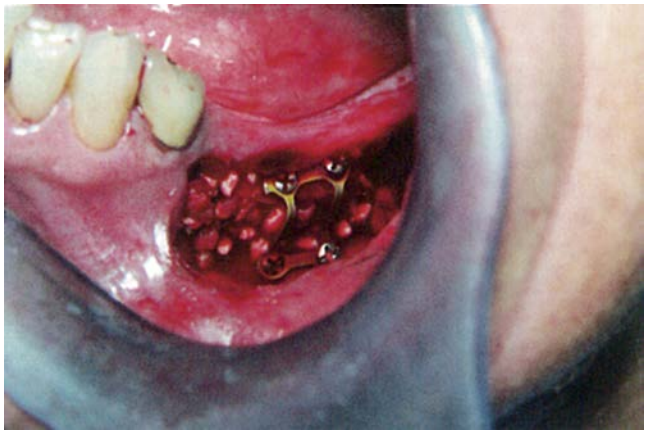
The interpositional bone graft can be done anywhere in the mouth but is most indicated in the anterior esthetic zone and the posterior mandible. A depth-of-vestibule, horizontal incision is made to bone with complete reflection away from the alveolar crest and minimal reflection crestally. Vital structures, such as nerve, tooth roots, and the respiratory space, are identified to be avoided. The osteotomy design in the posterior mandible is shaped as a "smile line," tapering anterior and posterior with at least 5 mm of height in the middle of the segment suggested, noting that small bone volumes are less well vascularized and at greater risk for vascular embarrassment and late-term resorption. A through-and-through osteotomy is done from buccal plate to lingual plate, and an osteotome is used to gently free the segment. This is done taking care not to disturb the lingual pedicle.



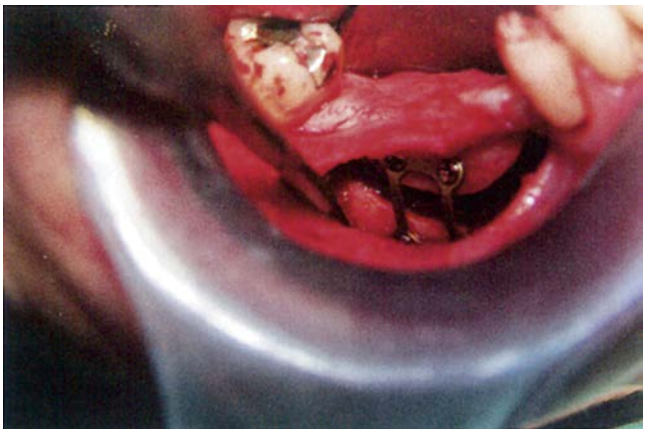
• **Figure 33-2** Alveolar elevation to the alveolar plane made with a "smile"-shaped osteotomy before graft insertion.



• **Figure 33-3** Particulate graft is inserted after bending the plate to orient the ridge into proper alignment.



• **Figure 33-4** Particulate graft and PDGF-bb placed.



• **Figure 33-5** Right side "smile" osteotomy elevated 6 mm to the alveolar plane.

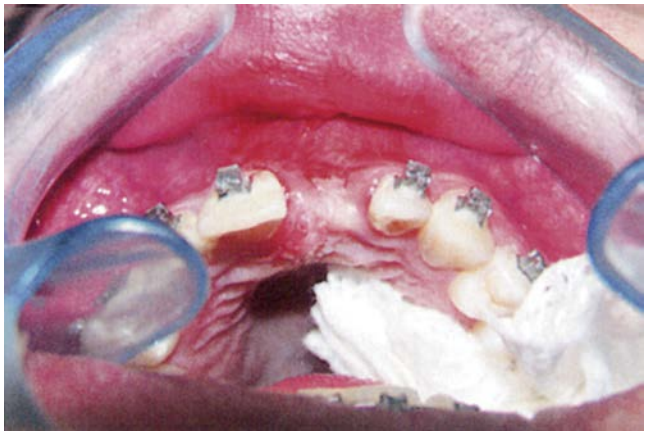
• **Figure 33-6** Wound closure (left side) of the vestibular incision is done in layers with resorbable suture.

The segment can be elevated up to 10 mm vertically (see Figure 33-1; Figures 33-2 through 33-6). A bone plate and interpositional graft material are placed, usually autograft, although bone morphogenetic protein (BMP-2), platelet-derived growth factor (PDGF-bb), and/or alloplast with PDGF-bb have been used successfully. Four months following bone healing, the plate is removed, and dental implants are placed. Often the alveolar ridge will need to be grafted laterally at the time of implant placement in these settings, but vertical augmentation should be adequate.[5]

The major advantage of an interpositional graft is an endosteal, marrow-accessed graft site—a highly vascular area conducive to graft incorporation. Very few seams, scar encleftations, bone graft exposure, bone graft resorption, or infections occur with this approach. Other advantages for using the interpositional graft technique are undisturbed alveolar crestal bone, improved gingival esthetic form in anterior locations, and a stable post-grafting architecture. One precaution in case selection is to avoid dense cortical bone, which may not be well vascularized and can lead to wound dehiscence and graft compromise.

Alveolar Split Graft (Book Flap)

The common alveolar finding from a late-healed extraction socket is a loss of alveolar width as a result of resorption of the buccal plate. The alveolus can be widened using a crestal incision that does not reflect beyond the crest buccally and lingually, but serves to identify the set point for osteotome or piezoknife osteotomy. Vertical cuts of the buccal plate are made blindly without flap reflection 1 or 2 mm from adjacent tooth roots and then connected sagittally to a depth of



• **Figure 33-7** A moderately difficult single-tooth site, commonly the result of loss of the buccal plate.

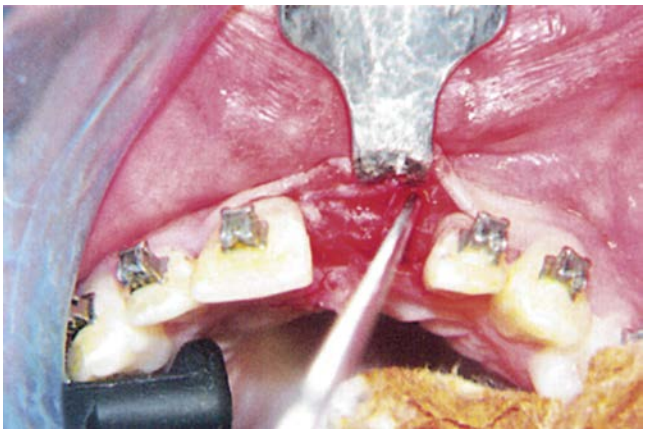
• **Figure 33-8** Exposure of the site is done using a crestal incision made about 2 to 3 mm toward the palatal side.

about 10 mm. Then the buccal plate is split sagittally; the buccally directed out-fracture is done without detachment of the mucoperiosteum from the mobilized osseous segment (Figures 33-7 through 33-10).[6]

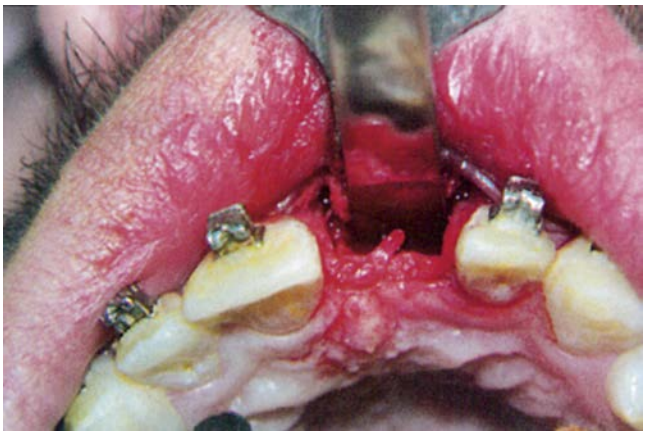
The intraosseous defect created is then grafted. Delayed implant placement is usually preferred in these settings. Primary closure is sometimes obtainable if the initial crestal incision is placed a few millimeters palatally. If the wound is left open, exposing the graft, collagen can be placed, such as that used for socket grafting to protect the graft. A good alveolar split gap is about 4 mm.

This technique requires about a 4-mm wide alveolar minimum, but if a piezoknife is used, a narrower width can be more easily managed. In practice, however, the use of titanium mesh is excellent for narrow ridges, so that a technical decision has to be made as to when a ridge is too narrow to split. A 4-mm width is a very conservative threshold to consider.

The alveolar split bone flap easily augments the majority of healed maxillary dental extraction sites. It can be used in the mandible, though hard bone is less flexible to greenstick fracture, and therefore flap detachment is a greater risk. For this reason, the split technique is used guardedly in the mandible.



• **Figure 33-9** An alveolar split to widen the ridge is first limited by vertical cuts made about 2 mm from the adjacent tooth. This protects the subpapillary bone from fracturing off during the crest-splitting procedure.



• **Figure 33-10** The alveolus is split crestally by inserting a straight osteotome about 10 mm, stopping at about vestibular depth. The wedged osteotome is then brought forward, spreading apart the alveolus until it greenstick out-fractures at the vestibular level. This is done without detachment of the mucoperiosteum. Bone graft is then placed in the gap and left to heal for 4 months before implant installation.

Alveolar Repositioning Osteotomies

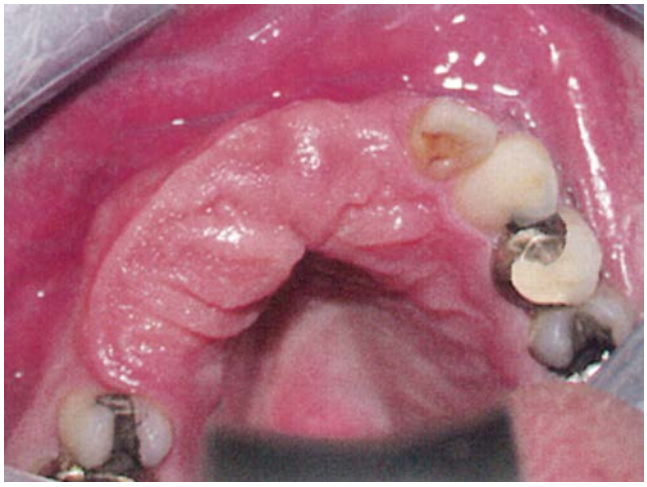
Sometimes the alveolus has enough bone mass, but the alveolar crest is in an off-axis position, such as in an anterior or lateral (alveolar) cross bite. An alveolar segment can be freed and repositioned and fixed without grafting, as shown in Figures 33-11 through 33-14. And, of course, an entire jaw can be changed in position to optimize alveolar relation.

Implant Repositioning Osteotomy

Integrated dental implants that cannot be easily removed without leaving a substantial osseous defect can be moved with a segmental osteotomy. This is usually done to improve esthetic emergence of the implant (Figures 33-15 through 33-17).

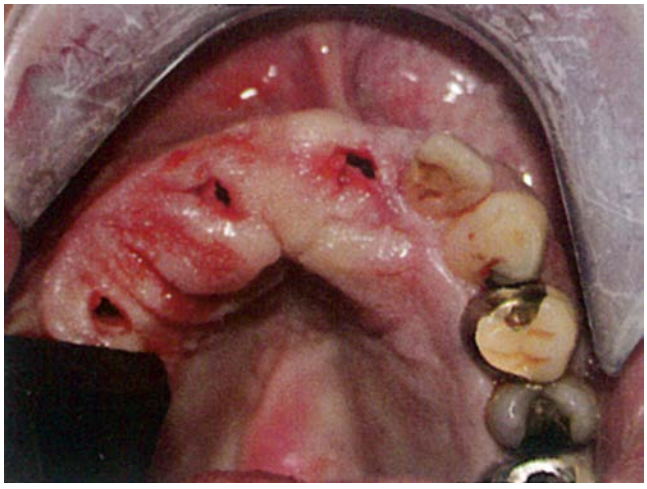
Alveolar Width Distraction Osteogenesis

One area in which alveolar width can be achieved by distraction is the posterior mandible, a sometimes difficult area to

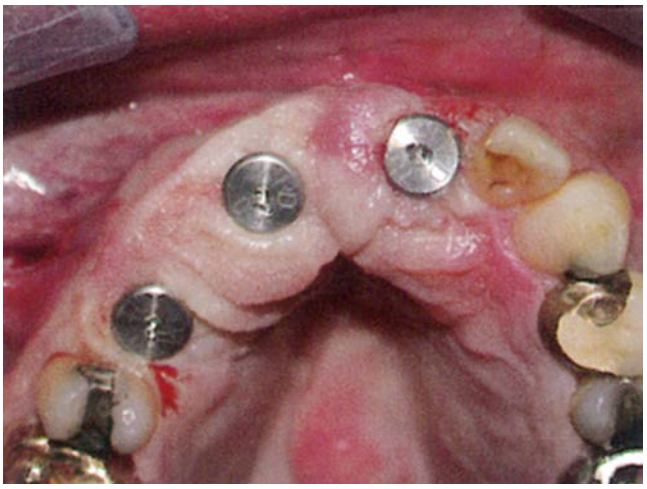


• **Figure 33-11** An anterior alveolar cross bite is present despite adequate alveolar width for implants.

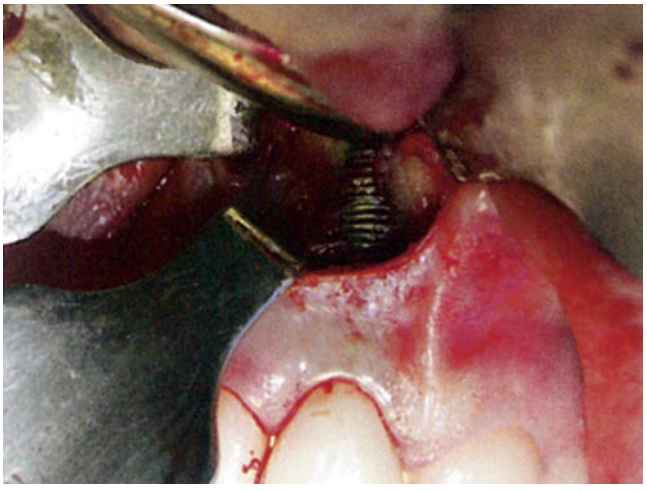
• **Figure 33-12** Following segmental osteotomy to move the alveolus forward 4 mm, the guide stent shows the improved alveolar projection.



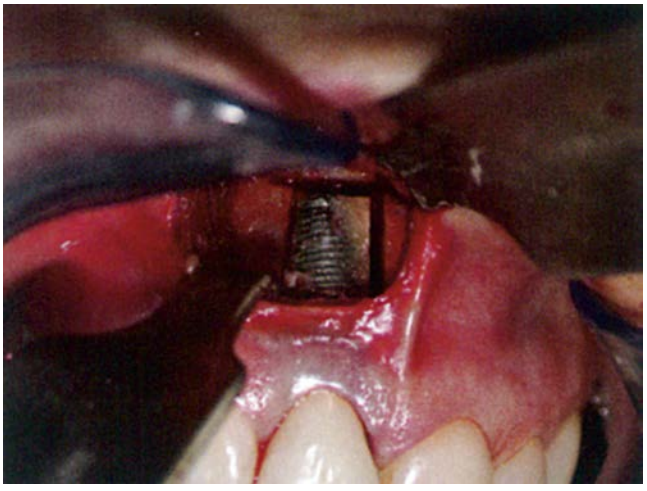
• **Figure 33-13** Transgingival implant placement is done using the guide stent.



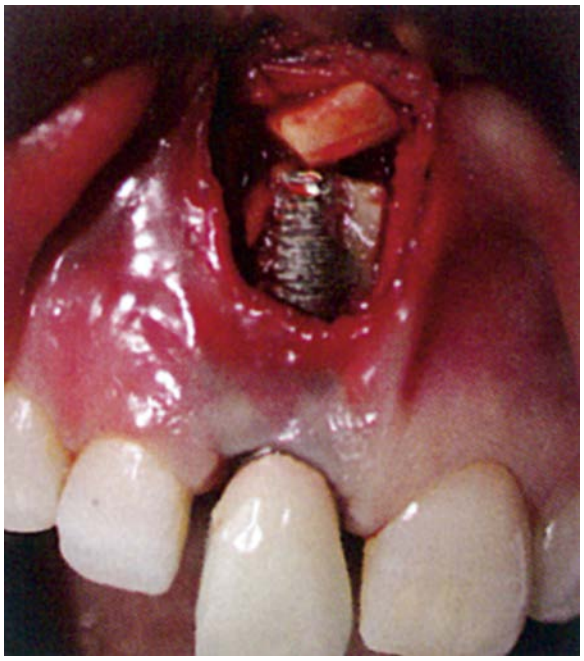
• **Figure 33-14** Implants are placed 3 mm below tissue level.



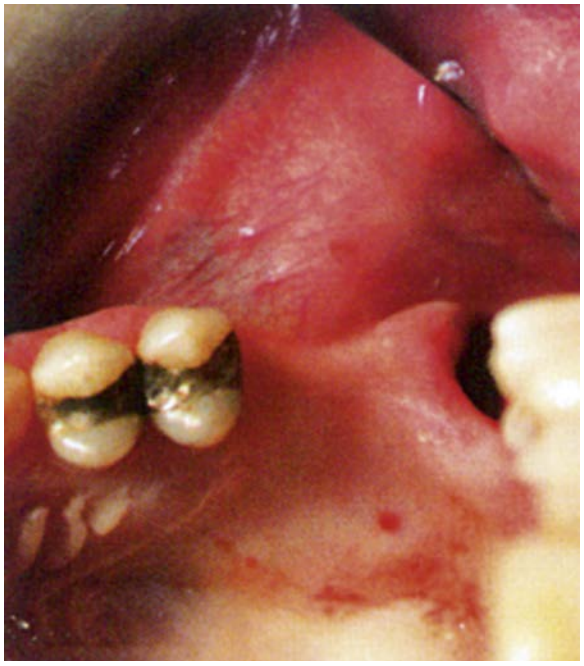
• **Figure 33-15** A poorly aligned dental implant can be moved bodily using a single-tooth osteotomy from a vestibular incision.



• **Figure 33-16** An implant transposition osteotomy is a risky one because tooth roots are likely nearby and it is difficult to keep enough bone on the implant to maintain osseointegration following mobilization of the implant segment.

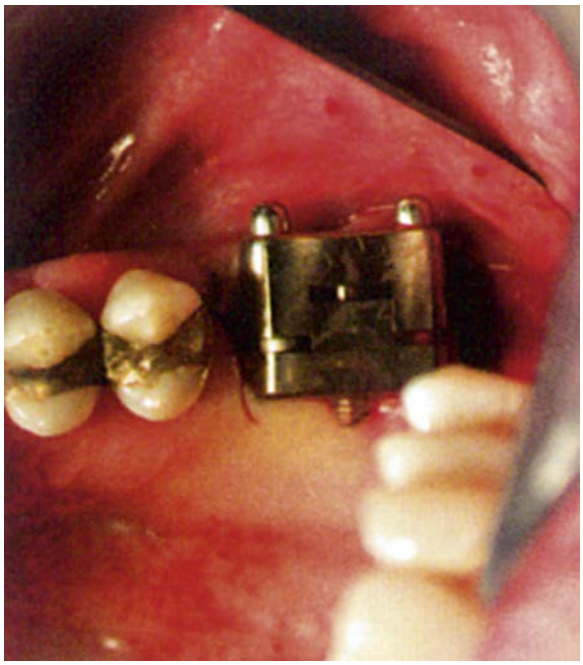


• **Figure 33-17** Once the implant cervical margin is placed at a more optimal position, typically a 4-mm coronal movement, grafting and stabilization of the implant can be done. The crown of the tooth is trimmed back to the occlusal plane to be remade at a later date. A healing time of 4 to 6 months is advisable before finalization in a setting like this for what is primarily done to improve the esthetic profile.

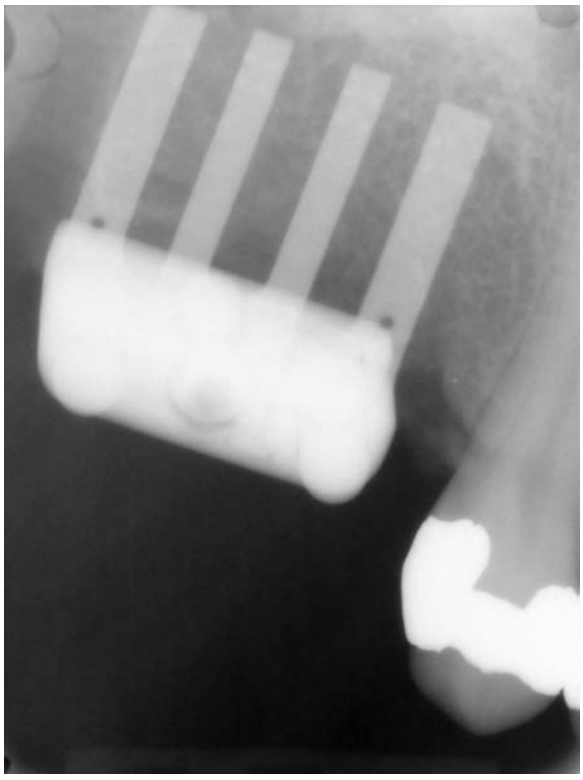


• **Figure 33-18** A narrow maxillary posterior alveolus can be widened by a split made through a crestal incision without periosteal reflection.

bone graft. It can be split through the crest in a relatively brief operation in which no bone graft is required. The wound can be left to heal for a week, and then at that point a bone spreader is tapped into place and activated. If the blood supply to the segment appears good, the device can be placed at the time of the initial surgery and activated 1 week later. Adequate width is

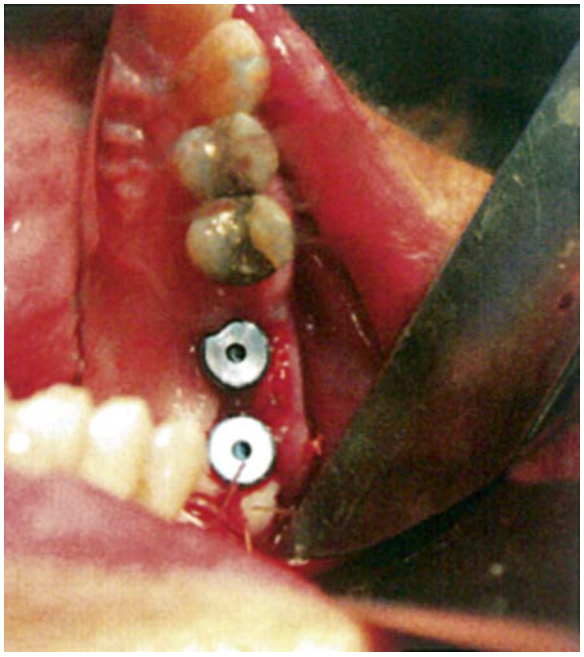


• **Figure 33-19** Following alveolar splitting, a bone spreader is placed.

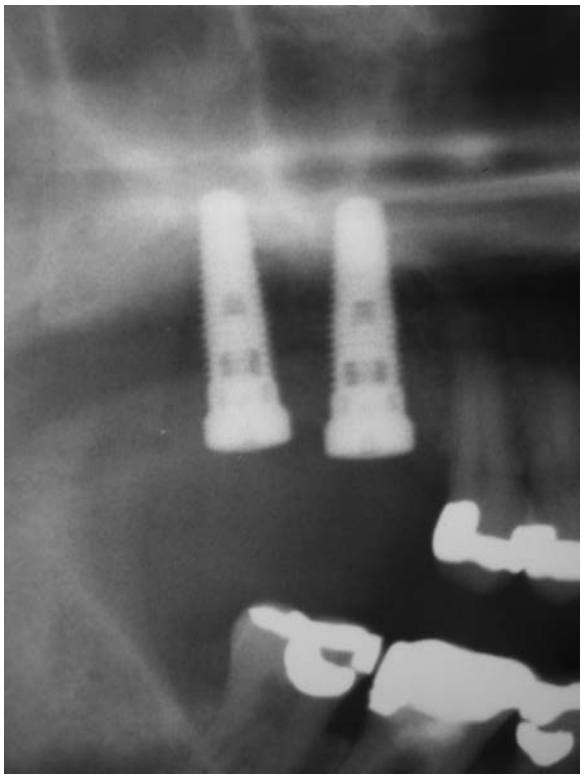


• **Figure 33-20** Immediate postoperative x-ray with a Laster crest distractor in place.

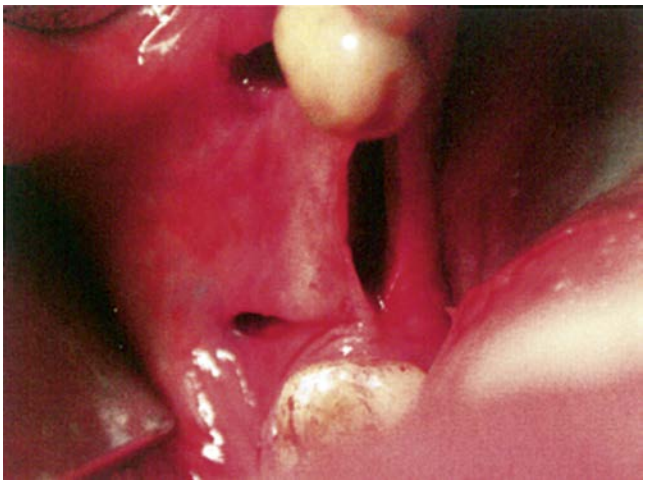
achieved in 7 to 10 days using an activation rate of 0.4 mm per day. Then the site is left to heal for a month, and implants are placed through the distraction zone, engaging into apical bone. Treatment time and morbidity are less for this approach when compared with onlay or veneer bone grafting. The procedure can be done in either the maxilla or the mandible, as shown in Figures 33-18 through 33-27.[7]



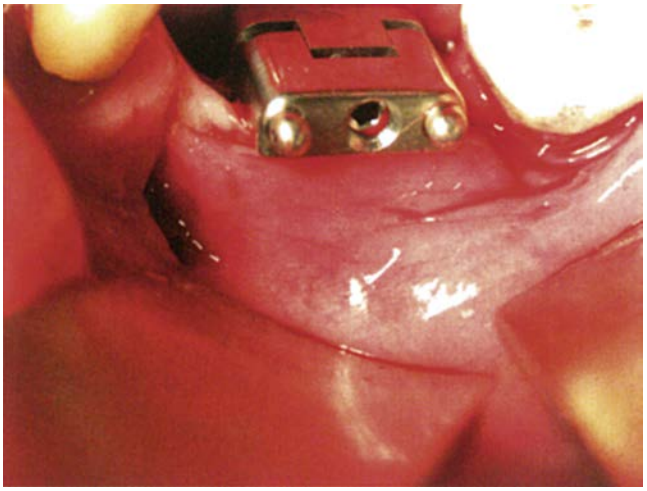
• **Figure 33-21** The distractor is removed 6 to 8 weeks later and implants are placed.



• **Figure 33-22** X-ray finding at the time of placement of two implants.



• **Figure 33-23** The alveolar width distraction flap should be carefully reflected. In the mandible, vertical cuts are made, but not reflected or connected to the crestal soft tissue wound. Bone cuts are made through these sites with very minimal reflection.



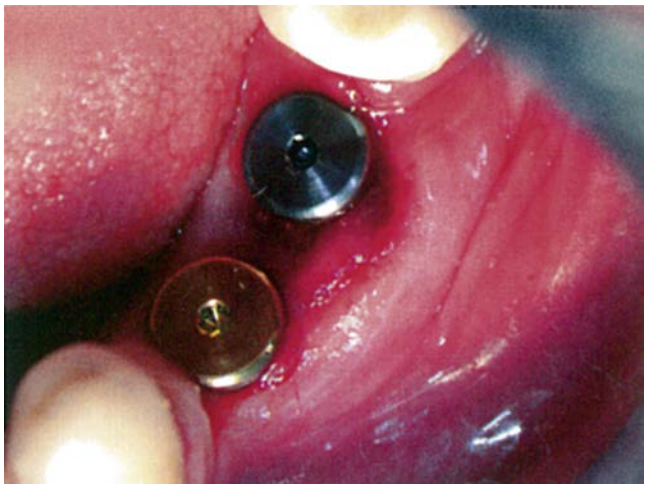
• **Figure 33-24** The distractor is placed.

Alveolar Vertical Distraction Osteogenesis

Alveolar vertical distraction osteogenesis is now well founded as a technique, but is still not broadly used because most vertical defects are less than 10 mm and can be more easily managed with the sandwich osteotomy or titanium mesh BMP-2/ACS. Also, vertical distraction almost always requires supplemental bone grafting before or after distraction. Vertical distraction osteogenesis is technically difficult, and therefore this factor must be a consideration for selecting this treatment alternative.

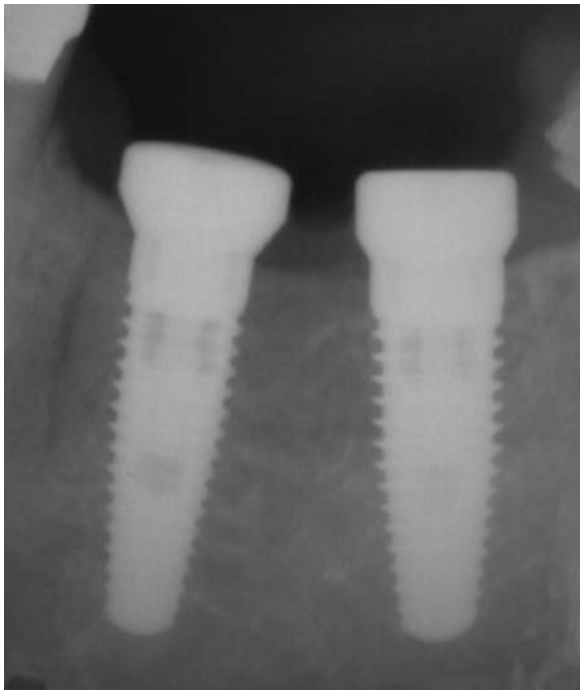
The most common indication for vertical distraction osteogenesis is in the anterior maxilla, where for esthetic reasons, the alveolus needs to be brought down and usually forward.

Figures 33-28 through 33-33 show an anterior maxillary defect treated with a bone flap translated by distraction. After the segment is cut and fixated with the distractor, the segment is moved down and forward at a rate of 0.8 mm per day until the segment engages the provisional or prosthetic guide. After a 4-month consolidation period, the implants follow with eventual prosthetic rehabilitation.[8,9]



• **Figure 33-25** Implants are placed 2 months later.

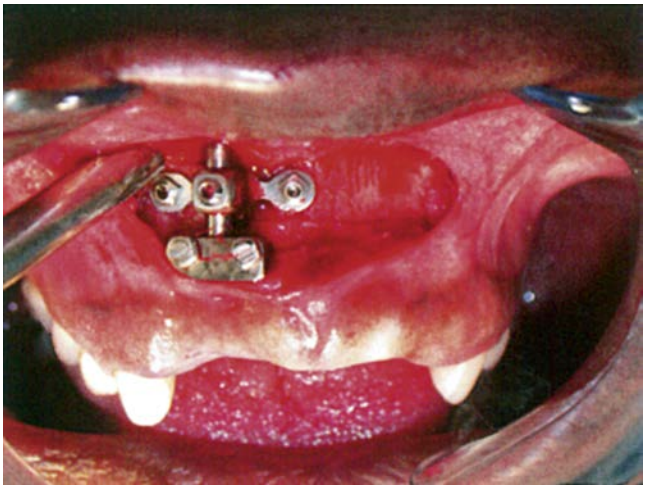
• **Figure 33-28** A maxillary defect as a result of traumatic loss of #7, 8, 9, and 10 in a patient with apertognathia and a high smile line. X-ray findings show about 5 to 6 mm of vertical bone loss.



• **Figure 33-26** X-ray finding 4 months later.

• **Figure 33-29** Preoperative views.

• **Figure 33-27** Final restoration shows an increase in alveolar width.



• **Figure 33-30** Placement of a vestibular bone distractor (Mommaerts-Laster) following osteotomy mobilization of the anterior segment.

• **Figure 33-31** The wound is closed primarily with a small access hole for distraction.

• **Figure 33-32** Following distraction and a 4-month healing time period, the distractor is removed, and implants are placed transgingivally.

Summary

In summary, the use of an osteoperiosteal flap is a space-maintaining strategy that allows the surgeon to handle most moderately atrophic dentoalveolar defects with a relatively simple surgical technique that requires no major bone grafting. It also allows for bone healing that is more stable, less likely to resorb, and more likely to consolidate or integrate into the graft site. The use of interpositional bone access engages the marrow vascular space—a place where graft material is less likely to sequester, become infected, or resorb away. The use of bone flap distraction also generates osteogenic bone of high quality, conducive to implant osseointegration.

• **Figure 33-33** Implants 4 months later before final single-tooth restorations.

Bone flap procedures in general present a more certain way of accomplishing greater alveolar width and height augmentation, with less complication than many other commonly used space-maintaining procedures.

Three-Dimensional Alveolar Distraction for Implant Placement

Katsuhiro Horiuchi

Introduction

The goal of prosthetically-driven implant therapy is to provide restorations with ideal functional and esthetic results. Tooth loss resulting from trauma, periodontal disease, tumor resection, or congenital absence leads to loss of height and width of alveolar bone and mucosa. Therefore, to achieve an esthetic and functional restoration using dental implants, the atrophic alveolus may need to be augmented. Recently, a variety of bone grafting procedures,[10-13] including guided bone regeneration (GBR)[14-17] and tissue engineering,[18,19] have gained popularity for alveolar ridge augmentation. GBR alone however, does not always induce predictable bone formation, especially for vertical ridge augmentation of more than 10 mm.[20] Though a variety of allogeneic bone and biomaterials has been developed, they are not always useful for extensive alveolar ridge augmentation.[21] Autogenous bone is still generally considered the best material for all types of osseous reconstruction, including alveolar ridge augmentation. However, it has some disadvantages, such as the need for a second surgical intervention, donor site morbidity, unpredictable bone resorption, and difficulty in managing soft tissue coverage and post-grafting soft tissue management.[21,22]

The first description of distraction osteogenesis was by Codivilla in 1905, when, after femoral osteotomy, he subjected the fragments to a strong tension using nails fixed in the bone.[23] With the design of new distraction devices and defined distraction rates by Russian orthopedist Gabriel

Abramowich Ilizarov in the early 1950s,[24,25] the concept has been widely applied to the lengthening and reconstruction of extremities. Distraction osteogenesis has some advantages compared to autogenous bone grafting: no additional surgery involving a harvesting procedure, no limit to lengthening, and simultaneous lengthening of the surrounding soft tissues, such as skin, muscle, blood vessels, and nerves. However, the disadvantages include a long treatment period, the need for a suitable distractor, patient inconvenience during distraction and consolidation, and risk of infection.[26,27]

In the field of oral and maxillofacial surgery, McCarthy and co-workers[28] first reported lengthening the human mandible by gradual distraction in hemifacial microsomia patients in 1992. Since this report, distraction osteogenesis has been used to lengthen or repair continuity defects in the mandible,[29,30] maxilla,[31-33] and cranial complex.[34,35]

In 1996, Block and colleagues demonstrated clinical, radiographic, and histologic vertical bone augmentation using alveolar distraction in dogs.[36] In the same year, Chin and Toth[37] described alveolar distraction and implant placement for a human in the reconstruction of an alveolar ridge defect following traumatic loss of teeth. Most reports on alveolar distraction have been related to vertical distraction in both mandible and maxilla. There have been few reports on horizontal or oblique alveolar distraction. In relatively small defects, veneer bone grafting or GBR can be used for alveolar ridge augmentation. In significant defects, however, bone augmentation is commonly done with iliac bone graft. In addition to complications and morbidity associated with the iliac bone graft, there is also the challenge of adequate soft tissue coverage, bone resorption, and inadequate vestibule depth.

All bone augmentation techniques are compromised when there is inadequate soft tissue present or when there is significant scar tissue. This is particularly problematic in the anterior maxilla and mandible when vertical hard and soft tissue defects exist after trauma or treatment of a pathologic condition. Tightly bound tissue in this area can make primary closure difficult.

Alveolar distraction osteogenesis techniques take advantage of the development of bone that results when an osteomized segment of bone is slowly moved, allowing new bone formation within the gap. The technique has the disadvantage of increased cost associated with the distraction device and esthetic compromise during the distraction phase. However, it is a predictable way to gain large vertical increases in hard and soft tissue, especially in difficult areas such as the anterior maxilla and mandible, including areas where there is significant scar tissue. Moreover, many patients with a severely resorbed alveolus require augmentation in not only vertical, but also horizontal and sometimes oblique direction. There have been few reports on alveolar distraction in such a direction. The authors have experienced three-dimensional alveolar distraction using ready-made or/and customized distraction devices for dental implant placement with good esthetic and functional results.

This section reports on alveolar distraction and a variety of three-dimensional aeolar distraction techniques, including anteroinferior (oblique) using a palatal distraction device,[38] fan-shape, and mesiodistal.

• BOX 33-1 Clinical Phases of Alveolar Distraction

Osteotomy:	Vestibular incision
Latency:	7-10 days
Distraction:	Distraction rate: 0.15-0.5 mm/day Distraction rhythm: once or twice/day
Consolidation:	2-3 months

Distraction Protocol

Alveolar distraction is one of the procedures using distraction osteogenesis and includes the concept of transport distraction osteogenesis.[39,40] There have been few long-term clinical reports with good esthetic and functional outcomes. Therefore, this is a subject for future analysis.

Since Chin and Toth[37] reported on alveolar distraction in 1996, a variety of the distraction devices have been developed and different distraction protocols have been established. However, the original clinical phases of distraction still remain the same: osteotomy, latency, distraction, and consolidation (Box 33-1).

Alveolar distraction involves cutting an osteotomy in the alveolar ridge to obtain the transport bone. After an initial latency period of 7 to 10 days that leads to soft tissue healing, the distractor is gradually activated to separate the transport bone at 0.15 to 0.5 mm per day. The gradual tension placed on the distracting bony interface produces continuous bone formation resulting from endochondral ossification.[41] In addition, the adjacent tissue including mucosa and attached gingiva expands and adapts to this gradual tension. Because the adaptation and tissue genesis involve a variety of tissue types in addition to bone, this concept should also include the term "distraction histogenesis."[42] The distracted segment and newly generated bone are allowed to heal for 2 to 3 months during the consolidation phase. The distractor is then removed.

Incision

For successful bone formation in distraction osteogenesis, Ilizarov emphasized that it required preservation of blood supply in the osteotomized area of the cortical bone.[24] However, Kojimoto and colleagues reported that preservation of the periosteum is more essential than preservation of blood supply in the osteotomized area of the cortical bone.[43] As alveolar distraction requires full-thickness osteotomy of the alveolus, not only the lateral cortex but also cancellous bone and inner cortex, it is critical not to damage the periosteum. Therefore, a vestibular rather than crestal incision is recommended to minimize reflection and damage of the periosteum. Moreover, careful and conservative dissection will maintain the vascularity of the transport segment,

decreasing excessive bone resorption and avoiding damage to adjacent structures, especially periosteum.

Osteotomy

The transport bone in alveolar distraction must be well-vascularized, similar to a pedicle vascularized bone graft.[39] When there is an inadequate volume of transport bone, moderate reflection of the periosteum has been shown to induce resorption of the transport segment in animal studies,[44,45] clinical reports,[46,47] and the author's experience. Therefore, the author recommends securing a transport segment more than 8 mm in height and more than 30 mm in length. A vestibular incision is recommended to minimize reflection of the periosteum, and the osteotomy must be performed carefully to minimize detachment of the palatal or lingual periosteum. A larger transport segment will avoid a higher rate of resorption. To prevent the transport bone from being caught up on the osteotomized edge during the distraction period, palatally (lingually) and apically convergent osteotomies must be performed. This is also very useful to decrease the lingual tipping of the distraction vector.

The osteotomy has been conventionally done with rotary burrs, bone saws, and osteotomes. González-García and colleagues reported that piezoelectric-assisted osteotomy for alveolar distraction significantly decreased surgical difficulty and the incidence of intraoperative complications, compared with conventional osteotomy.[48] A piezoelectric-assisted osteotomy may allow a deeper cut, decreasing the amount of chiseling required.

Latency Period

The latency period is defined as the time from the surgery seating the distraction device to the beginning of distraction. Saulacic and co-workers[49] reported that the most common latency period was 7 days to allow for healing of the mucoperiosteum and reduce the risk of wound dehiscence. In contrast, extended latency periods over 15 days were applied to ensure complete revascularization of the transport segment in cases where the mucoperiosteal pedicle is small or endangered.[49] The discrepancy in the effect of a latency period on bone healing might be related to the variation in the distraction parameters such as distraction rate, the amount of lengthening, and the post-distraction period that were used in the various studies.[49] A latency period may be essential for long bone lengthening (limb extension) but less crucial in the craniofacial region, where better vascularization may permit reduction or even elimination of a latency period.[50]

Distraction Period

The distraction period is the time between initial activation and the end of activation of the distractor device. The distraction period depends on the amount of distraction and distraction rate. The amount of distraction is generally based on the amount of tissue necessary to place the implant ideally. Some investigators recommend 20% to 30% of overcorrection (overdistraction), considering the amount of alveolar distraction relapse and bone resorption.[38,51,52]

Distraction Rate

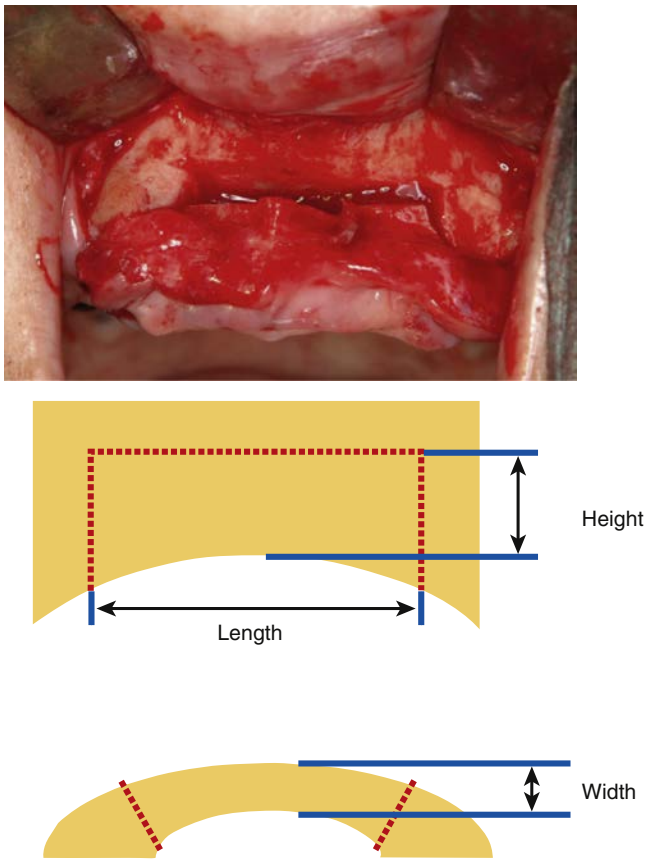
The distraction rate is the daily amount of the transport bone to be distracted. Most investigators report a distraction rate of 1 mm per day in alveolar distraction osteogenesis of the maxilla and mandible as well as the extremity. Saulacic and colleagues reported in a systematic review that the mean distraction rate was 0.71 ± 0.27 mm per day.[53] They also noted a lower distraction rate of 0.4 to 0.5 mm in cases where distractor implants and horizontal distraction were used. According to Amir and colleagues, a distraction rate of 0.5 mm per day results in faster osteogenesis than a distraction rate of 1 mm in elderly patients.[54] Therefore, the rate of alveolar distraction was reported to be 0.3 to 1.0 mm, but there is still no established theory. Although manufacturers of alveolar distraction devices recommend a distraction rate of 1 mm, the author experienced a higher incidence of soft tissue dehiscence, poor bone formation, or non-union at this rate. With a distraction rate less than 0.5 mm, even in larger bone defects, such problems have not occurred. Gradual distraction results in less tension of the soft tissue than fast distraction at a rate of 1 mm, and seldom induces resorption of the transport bone. Therefore, the author recommends a gradual distraction rate of less than 0.5 mm per day, despite an increase in the distraction duration. In clinical situations with small transport bone, a distraction rate of 0.15 to 0.3 mm per day is likely to be more acceptable. Saulacic and co-workers also reported that the type of device used and an augmentation rate of more than 0.5 mm/24 h were significantly related to insufficient bone formation and evidence of complications.[55] Conversely, a slower distraction rate than usual may result in premature bone union during the distraction phase, which may require re-osteotomy. This author has experienced premature bony union requiring re-osteotomy in two cases where the defect included more than six teeth.

Distraction Rhythm

Distraction rhythm is the frequency of distraction activations per day. Saulacic and colleagues reviewed 209 distractions in 197 patients, where the rhythm of distraction was 1 (62%), 2 (35%) or 4 times daily (3%).[53] A more frequent distraction rhythm was correlated with a smoother alveolar distraction. The author recommends that the distraction rhythm should be twice per day when the patient or family can manipulate the distraction device. When this is impossible, the patient visits every day or every other day. However, there was no significant difference between the two when managed carefully.

Consolidation Period

A retention or consolidation period allows for maturation and corticalization of the regenerated bone. Amir and colleagues reported that bridging 10 mm of alveolar distraction gap with regenerated bone required at least 10 weeks.[54] It has been suggested that the poorly mineralized bone tissue found after 10 weeks of consolidation will start an adaptive



• **Figure 33-34** Prerequisites of alveolar distraction. Transport bone: well-vascularized with periosteal blood supply. Bone height >8 mm; bone length >30 mm (more than four teeth missing); bone width >6 mm.

response that would increase the bone matrix mineralization with placement of dental implants.[55] A systematic review of 209 cases in 20 articles found that the mean consolidation period was 12.22 ± 5.58 weeks.[53] Although some reports[56,57] recommend early implant placement, in the author's experience, early placement after only a 3 month consolidation period often results in increased crestal bone resorption of 1 to 2 mm. Therefore, the author recommends a consolidation period of at least 4 months to retain the transport bone until bone formation and resorption have stabilized. In addition, overdistraction of 2 to 3 mm should be done in anticipation of bone resorption or relapse.

In addition to the duration of the retention period, the prognosis of alveolar distraction depends on the stability of the transport bone. It is necessary to fix the transport bone rigidly with screws when the distraction device is removed earlier to seat the provisional restoration. Instability of the transport bone during the consolidation period will result in failure of alveolar distraction due to poor bone formation in the bone gap, resulting in non-union or pseudoarthrosis.

Indications for Alveolar Distraction Osteogenesis

Alveolar distraction has many advantages compared to other ridge augmentation procedures: no bone harvesting, no limitation of bone augmentation, simultaneous elongation of the surrounding soft tissue, and high predictability of tissue augmentation. In contrast, it has some disadvantages: the need for an adequate distraction device, the need for the patient's cooperation, the possibility of bone necrosis, and the inability to place implants simultaneously.

As for prerequisites of alveolar distraction, the transport bone must be well vascularized with periosteal blood supply[39] (Figure 33-34). Considering vascularization of the transport bone, small vertical defects of only one or two teeth tend to have a higher rate of complication when distracted and should usually be treated with conventional bone grafting techniques.[58] Bradley and Thomas reported that indications for alveolar distraction should include a minimum of 6 to 7 mm of bone height above vital anatomic structures and at least a 4-mm vertical defect of edentulous zone including three or more missing teeth.[59]

Jensen and Block proposed a site classification based on mild, moderate, and severe vertical bone loss (classes I to III) with a fourth class (class IV) designating significant loss of bone on adjacent teeth.[60] Class I is a mild, alveolar deficiency with up to 5 mm of vertical loss that ideally can be treated by a sandwich bone graft, although distraction can also be considered. In class II lesions with a defect of 6 to 10 mm, distraction is done more frequently to obtain ideal ridge form. If the residual alveolus is thin at the crest, a follow-up bone graft may be required. Class III lesions with a defect of greater than 10 mm need augmentation with a bone graft to increase the bone stock in order to do a distraction. Occasionally, when there is some bone present, the site is distracted first with follow-up grafting done to obtain an ideal ridge form.

Class IV lesions with significant loss of bone on adjacent teeth are best converted to class II or III sites by removal of the adjacent compromised teeth to make the problem more predictable and easier. A good rule of thumb is to remove any tooth with 50% bone loss or more unless orthodontic forced eruption is prescribed. In animal studies, attempts to improve the attachment level of natural teeth with distraction were unsuccessful.[61] With no evidence existing that the attachment level on teeth can be improved through distraction, it may be necessary to sacrifice a compromised tooth to optimize the amount of vertical bone improvement.[59]

Although the author mostly agrees with Jensen's classification, he has not suggested the prerequisites of the transport bone (or segment) for successful alveolar distraction. The author's opinion is that the transport bone should have a height of more than 8 mm, a length of more than 30 mm (more than four-tooth defect), and a width of more than 6 mm in order to maintain its viability. The author proposes four factors for selection of alveolar ridge augmentation procedures and indications for alveolar distraction. The four factors include the length of the bone defect, the remaining bone height, the remaining bone

width, and the amount of ridge augmentation (vertical and horizontal) (Box 33-2).

Factor 1: Length of the Bone Defect

In a single- to three-tooth defect, alveolar distraction should not be used, considering the viability of the transport bone.

• BOX 33-2 Guidelines for Selection of Alveolar Ridge Augmentation Procedures

Length of the Bone Defect

- Single- to 3-tooth: bone graft or guided bone regeneration (GBR)
- More than 4-tooth: case by case

Remaining Bone Height

- Less than 10 mm: vertical augmentation (onlay graft or vertical GBR) followed by alveolar distraction
- More than 10 mm: alveolar distraction, if needed

Remaining Bone Width

- Less than 6 mm: horizontal augmentation veneer graft or GBR
- More than 6 mm: no augmentation

Amount of Ridge Augmentation (Vertical, Horizontal)

- Vertical augmentation of less 5 mm: onlay graft or GBR
- Vertical augmentation of more than 5 mm: alveolar distraction, if needed
- Horizontal augmentation of less 5 mm: ramus veneer graft or GBR
- Horizontal augmentation of 5-10 mm: chin corticocancellous block bone graft
- Horizontal augmentation of more than 10 mm with the wide ridge of more than 6 mm: horizontal or oblique alveolar distraction

TABLE 33-1 Guidelines for Selection of Alveolar Ridge Augmentation Procedures in More Than Four-Tooth Defects

Remaining Alveolar Ridge Height ≥10 mm		
	Alveolar Ridge Width (ARW)	
VBD	ARW <6mm	ARW ≥6 mm
VBD ≤5 mm	BG	BG or AD
VBD >5 mm	AD→BG	AD

Remaining Alveolar Ridge Height <10 mm		
	Alveolar Ridge Width (ARW)	
VBD	ARW <6mm	ARW ≥6 mm
VBD ≤5 mm	BG	BG
VBD >5 mm	BG→AD	BG→AD

AD, Alveolar distraction; *BG,* bone grafting or guided bone regeneration; *VBD,* vertical bone defect.

This clinical scenario should be treated by bone graft or GBR. In defects with more than a four-tooth span, treatment planning should be determined on a case-by-case basis. Considering the factors mentioned next, the author would like to propose guidelines for selection of alveolar ridge augmentation procedures in more than a four-tooth defect.

Factor 2: Remaining Bone Height

Alveolar distraction requires a residual bone height of more than 10 mm to obtain a transport segment of at least 8 mm with remaining basal bone of at least 2 mm. Therefore, when the alveolar ridge height is less than 10 mm, onlay bone graft or vertical GBR should be first performed to gain the alveolar ridge height of minimum 10 mm prior to alveolar distraction.

Factor 3: Remaining Bone Width

When an implant with 4-mm diameter is placed, a bone width of more than 6 mm is necessary. If bone width is less than 6 mm, veneer bone graft or horizontal GBR is needed before or at the time of implant placement.

Factor 4: Amount of Ridge Augmentation (Vertical, Horizontal)

When the amount of vertical ridge augmentation is more than 5 mm, alveolar distraction is generally thought to be superior to bone graft or GBR.[18,60] Although there have been some reports on horizontal alveolar distraction for the narrow ridge,[62,63] it is generally not accepted because of resorption or loss of the transport bone and unpredictability. The author has sometimes employed horizontal or oblique alveolar distraction in a wide ridge of more than 6 mm to place implants in an ideal position.[38] For horizontal ridge augmentation of a narrow ridge of less than 6 mm, horizontal GBR or intraoral block bone graft is easier and more predictable. A corticocancellous symphyseal block bone graft can be used to augment up to approximately 10 mm of bone horizontally or vertically.

Alveolar distraction can be employed in the esthetic zone (the anterior maxilla and mandible). Vertical ridge augmentation in the posterior maxilla can be achieved by use of sinus augmentation or/and bone graft or GBR. Though alveolar distraction for vertical defects of the posterior mandible has been reported,[62-64] it has a variety of complications, such as fracture or resorption of the transport bone and mental paresthesia.[65-67] Moreover, if the defect also has a horizontal component, a more traditional approach with onlay bone graft or vertical GBR is recommended.[68,69]

Based on the aforementioned factors, guidelines for the selection of ridge augmentation procedures in sites with more than four-tooth defects are summarized in Table 33-1. More than four-tooth defects are classified into two groups according to whether the remaining bone height is greater or less than 10 mm. Defects with residual bone height greater than 10 mm are further

divided into two subgroups: those with a bone width greater than 6 mm and an amount of vertical ridge augmentation more than 5 mm, and those without. Defects with bone width less than 6 mm require veneer bone graft or horizontal GBR prior to or simultaneous with implant placement. In defects where the amount of vertical ridge augmentation is greater than 5 mm, alveolar distraction is the first choice because it is more predictable compared to conventional ridge augmentation. Even if the amount of vertical ridge augmentation is less than 5 mm, the large defect with the remaining bone width greater than 6 mm often requires horizontal or oblique alveolar distraction to place implants in an ideal position. In defects where the remaining bone height is less than 10 mm, conventional vertical ridge augmentation should be first performed, followed by alveolar distraction if needed.

Three-Dimensional Alveolar Distraction

Most severe alveolar ridge defects have both vertical, as well as, horizontal component, requiring three-dimensional ridge augmentation to achieve optimal implantation. In these severe defects, three-dimensional alveolar distraction (vertical, horizontal, oblique, fan-shaped, or mesiodistal) should be considered because conventional ridge augmentation with bone graft or GBR may not be able to resolve the entire defect. This is especially true in defects with massive loss of hard and soft tissue and where significant scar tissue is present.

Vertical Alveolar Distraction

All ready-made distraction devices are only vertical and are of three types; screw-type (LEAD System),[37] plate-type (TRACK PLUS System, KLS Martin, Germany),[44,46,53,56] and implant-type (ACE Distractor).[56,70]

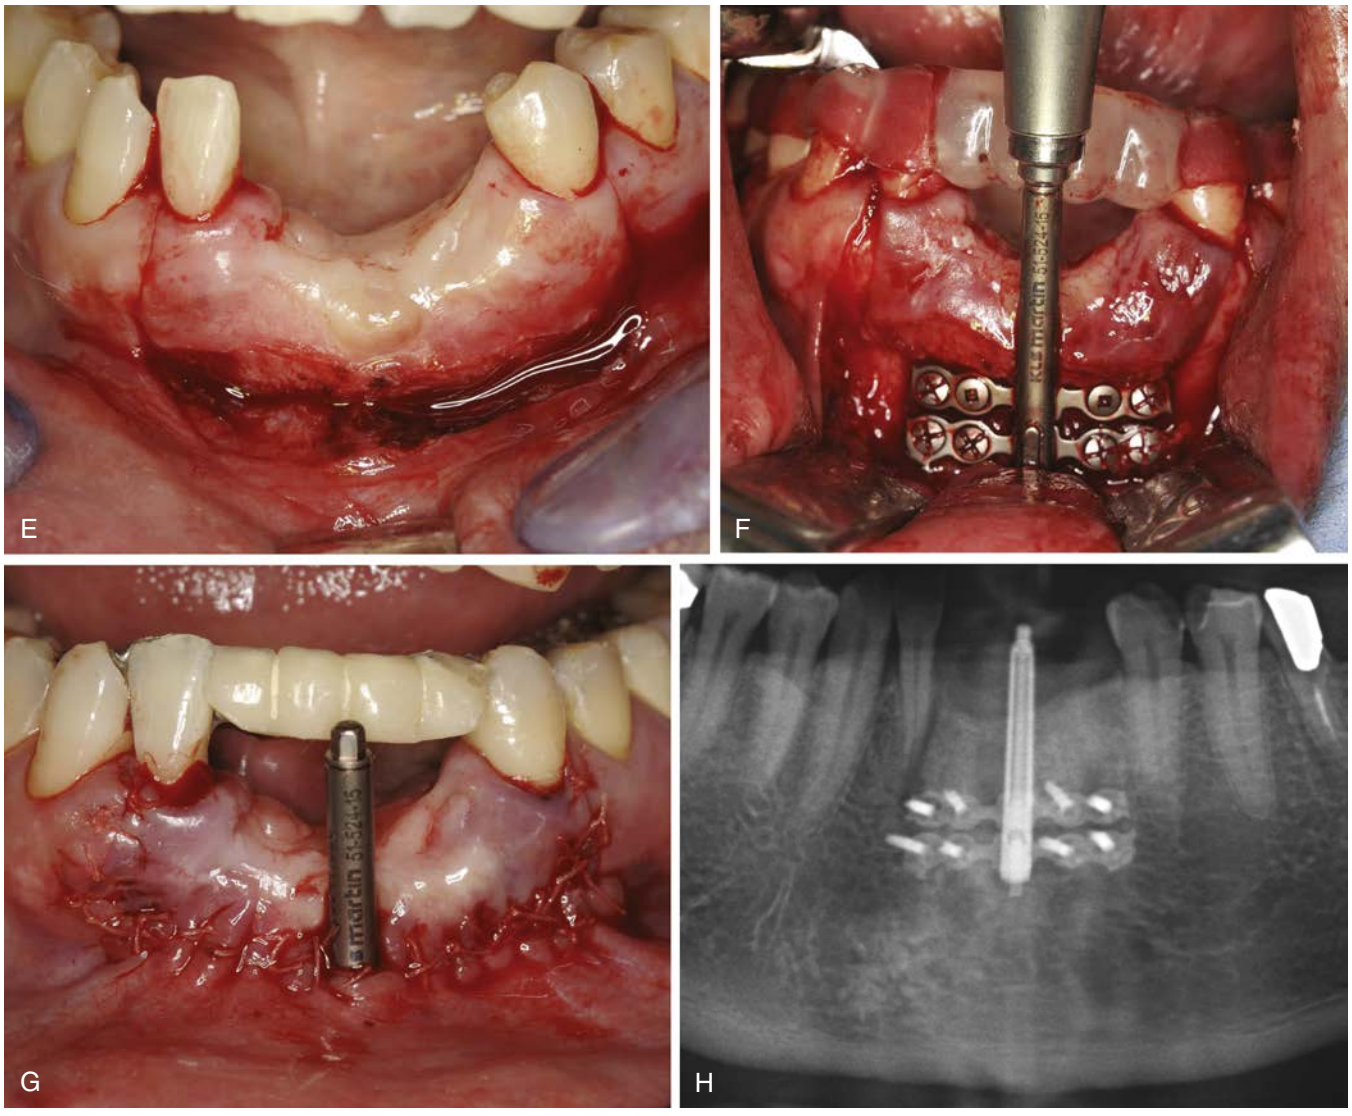
In a bone defect with more than five teeth, it may be difficult for the LEAD System and ACE Distractor to distract the transport bone successfully using only one device. Therefore, in such a case, several devices are required, resulting in a problem of parallelism of devices. Moreover, both distractors need adjunctive fixation for stabilization. When the bone defect span is large, there are few remaining teeth for adjunctive fixation of a screw-type or implant-type device. In these bone defects involving more than five teeth, the rigid plate-type TRACK PLUS System (KLS

• **Figure 33-35** Severe vertical defect of the anterior mandible as a result of a failed implant placed at the left mandibular incisal region. **A,** Unsuccessful guided bone regeneration (GBR) was attempted twice by a referring clinician, resulting in severe attachment loss to both adjacent teeth. **B,** Radiograph showing vertical bone defect and failing implant. **C,** After extraction of both adjacent teeth, the alveolus had vertical bone defect of 8 mm and significant deficiency of the soft tissue. **D,** Soft tissue scarring due to failure of repeated GBR.

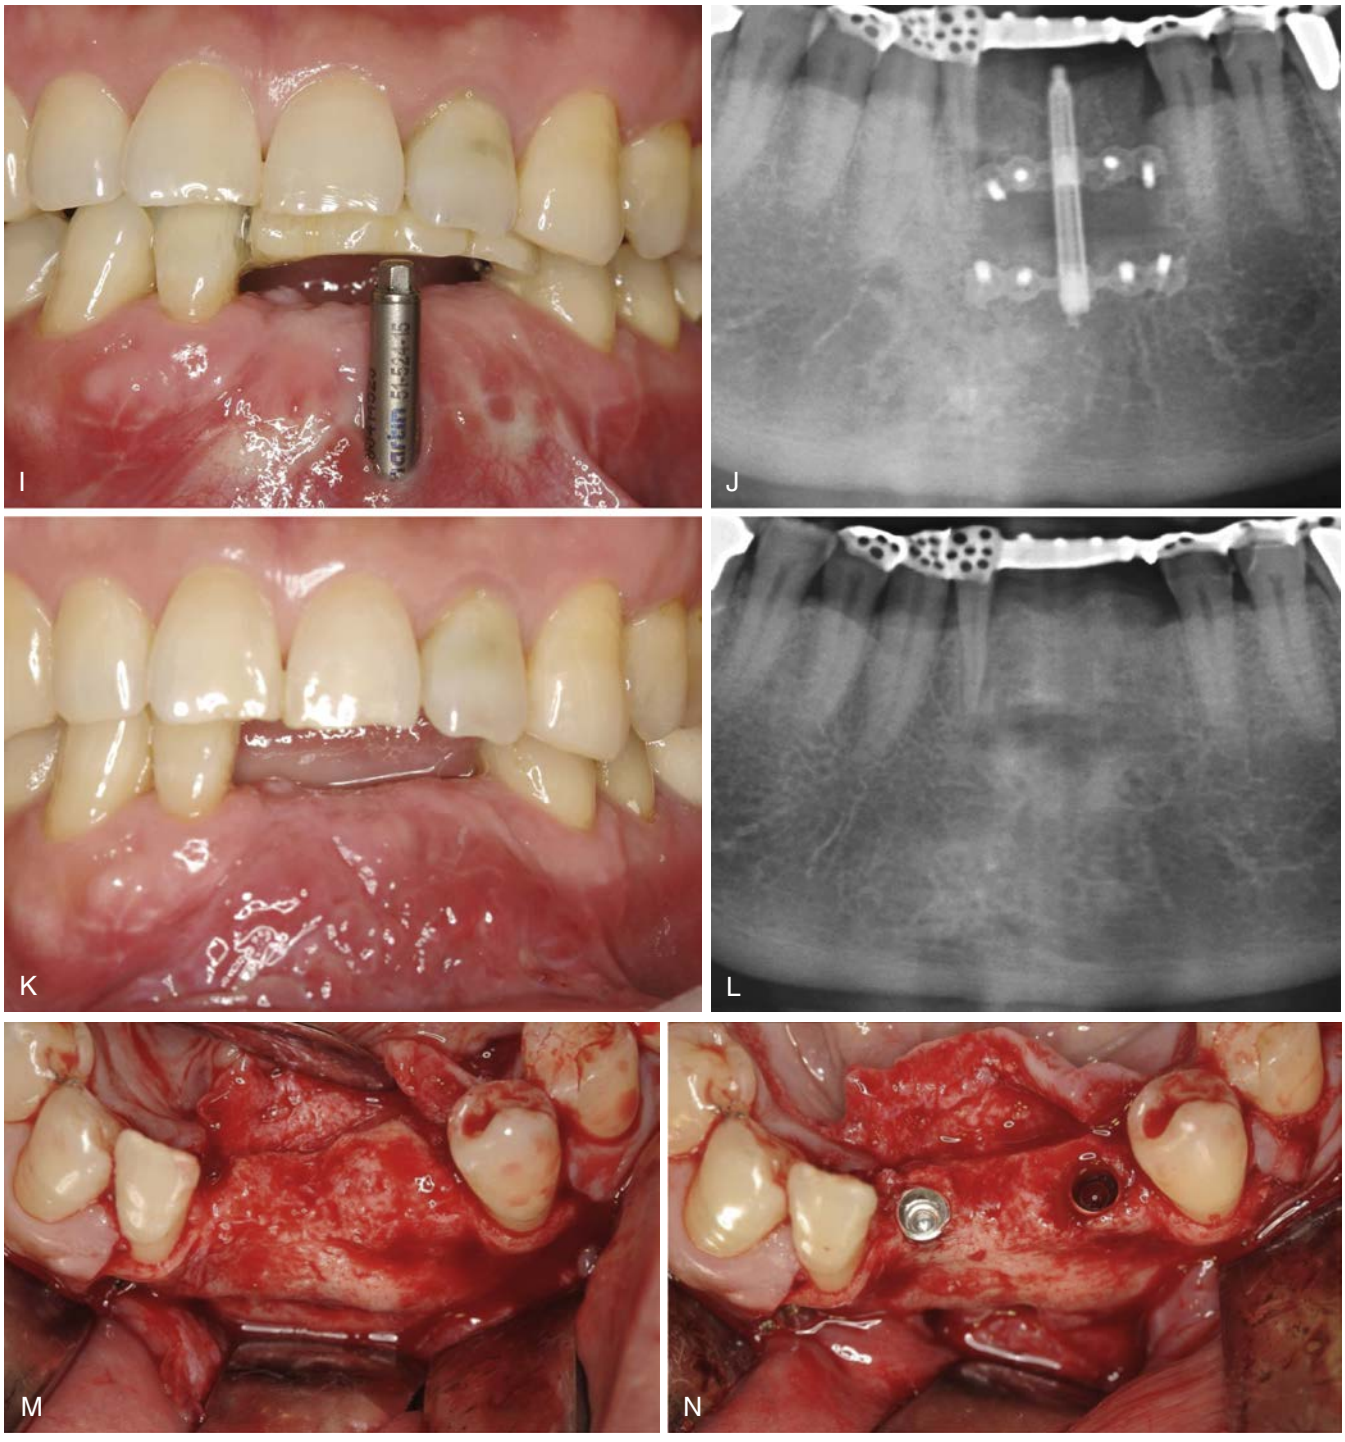
Continued

Martin) without adjunctive fixation is more suitable. The author recommends a plate-type distractor because of better rigid stabilization of the transport bone, compared with screw-type and implant-type devices. Vector control during alveolar distraction to achieve an optimal direction can be challenging because the pull from the oral musculature and the thick palatal tissue can alter the desired vector in a palatal or lingual direction.[71] Some techniques for vector control have included the use of adjuvant devices, elastomeric chain, wire splint, resin splint, and cross-arch elastics.[71,72] In addition, some reports have shown the clinical value of multidirectional alveolar distraction devices to better control the distraction vector.[73,74]

The author overcompensates by directing the unidirectional distractor more toward the facial to overcome the soft tissue pull, in addition to supporting the distractor rod with a provisional restoration. Unexpected distraction direction may be corrected by performing limited "molding" of the newly formed bone within 1 to 2 weeks after completion of the distraction.[71] In cases with a narrow alveolar ridge, adjunctive ridge augmentation with veneer bone graft or horizontal GBR may be needed (Figure 33-35).

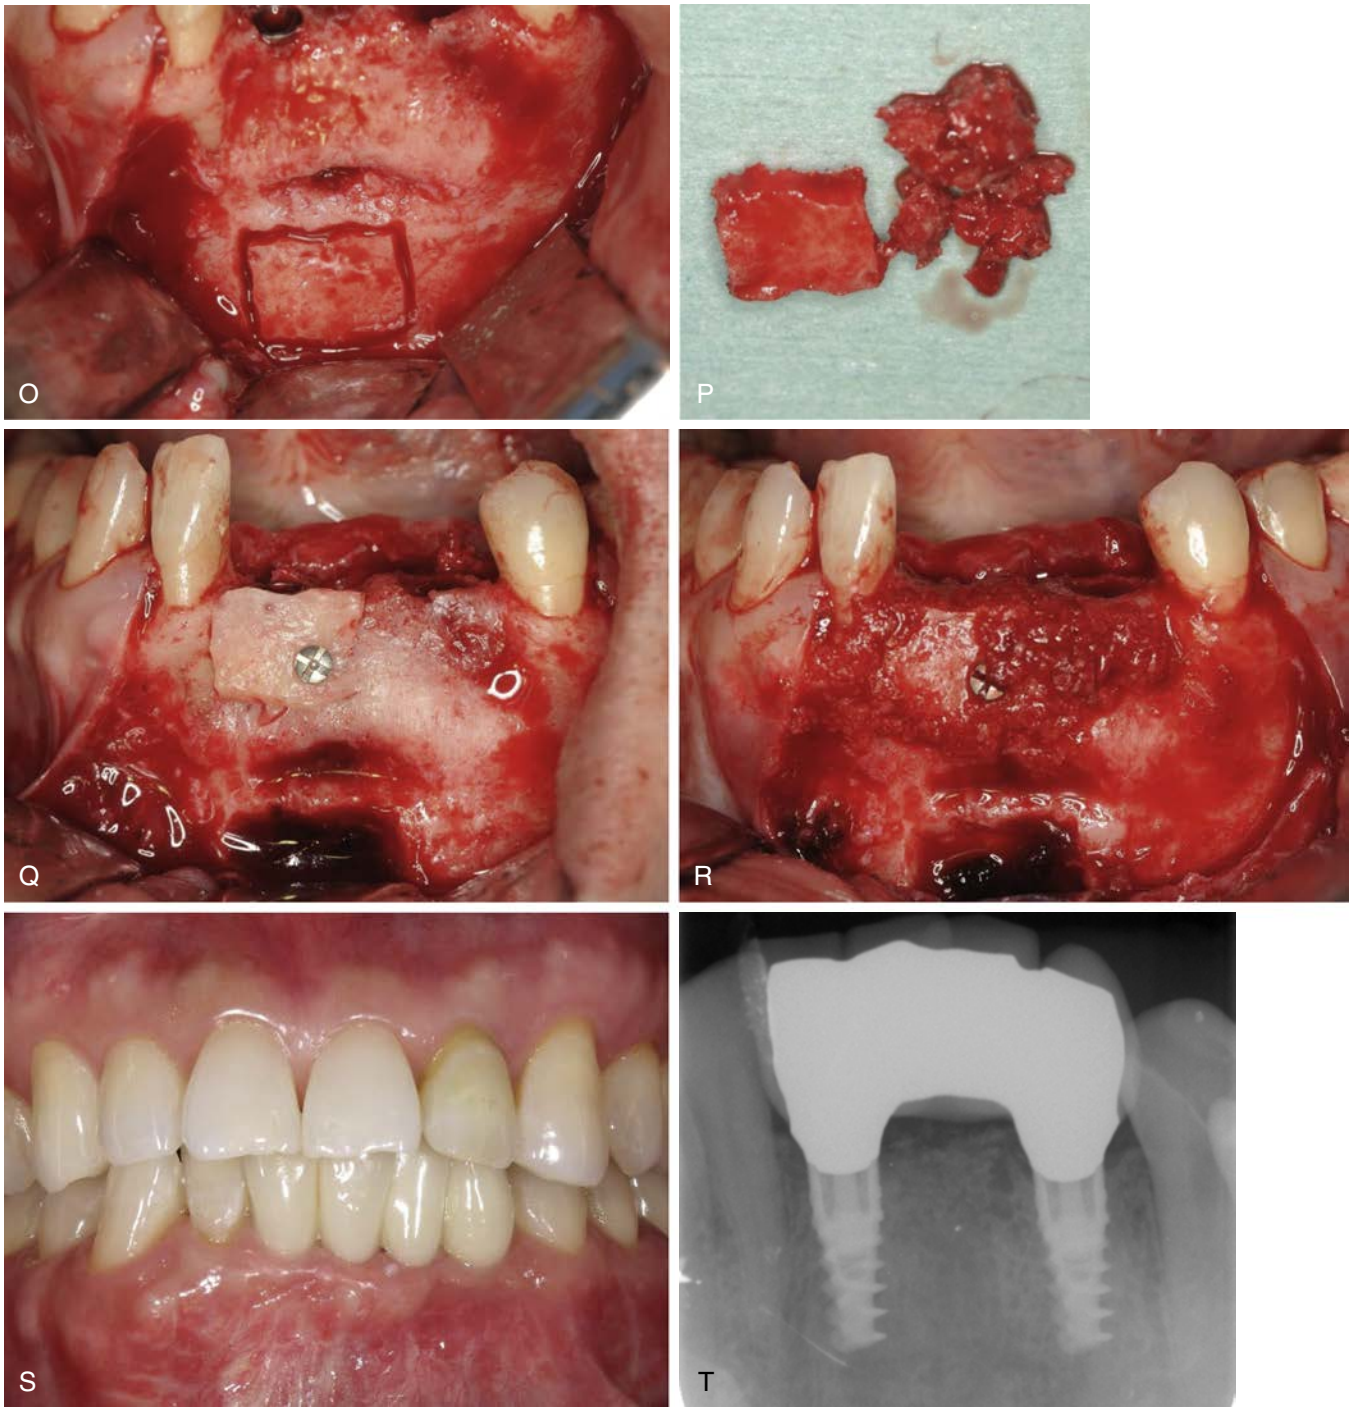


• **Figure 33-35, cont'd** **E,** To preserve the periosteal blood supply of the transport bone, a vestibular incision was made in combination with two vertical incisions to perform vertical osteotomy 1.5 mm mesial to the adjacent tooth. **F,** Horizontal and two vertical osteotomies were performed using a fissure burr and an oscillating bone saw, followed by a fine chisel. The transport segment must have a minimum height of 8 mm and length of 30 mm to reduce the amount of resorption. A plate-type alveolar distractor was placed with the micro-screws inclined in a more labial distraction vector to compensate for the pull from the lingual musculature. **G,** Wound closure. Alveolar distraction started after a latency period of 10 days for soft tissue healing. **H,** Radiograph showing alveolar distractor placement.



• **Figure 33-35**, **cont'd** **I,** Distraction rate was 0.15 mm per day because the defect was relatively small and had significant scarring. **J,** Vertical distraction of 11 mm completed for 11 weeks. Overcorrection of 3 mm of the transport segment was achieved in anticipation of future resorption. **K,** After a consolidation period of 3 months, the alveolar distractor was removed. Gradual distraction achieved lengthening of not only bone but also the surrounding soft tissue, despite the scar tissue. **L,** Most of the distraction gap was filled with radiopacity resulting from endochondral ossification. **M,** The transport bone was distracted 2 mm lingually, resulting from the pull of lingual musculature. **N,** Two implants were placed in an ideal position.

Continued



• **Figure 33-35**, **cont'd** **O,** To ensure adequate labial bone thickness for implant placement, additional horizontal bone augmentation is performed. Osteotomy was performed for harvesting the symphyseal bone. **P,** Cortical block bone and cancellous bone harvested. **Q-R,** Bone block fixated with micro-screw in combination with cancellous bone. **S,** Final restorations. Simultaneous lengthening of the soft tissue made vestibuloplasty unnecessary. **T,** The reconstructed alveolar crest is approximately 2 mm incisal to the junction between the implant and the abutment.

A ready-made plate-type distractor has the limitation of maximum distraction length of 15 mm. In cases with vertical defect of more than 20 mm, repeated vertical alveolar distraction is required (Figure 33-36).

Horizontal Alveolar Distraction

Some investigators have reported on horizontal alveolar distraction using a modified titanium screw with a 2-mm diameter or uniquely designed distractors.[62,63,70,75-78] All of these devices have in common a distraction rod that is fixed in the cortical lingual/palatal bone plate and allows for buccal/labial movement of the transfer segment.[77] Aparicio and Jensen reported that the most ideal area for horizontal distraction was a knife-edge posterior mandible with sufficient bone height and good access to the bone marrow.[75] However, the difficulty of performing an osteotomy in a narrow alveolar ridge, instability of the device, and resorption of the transport bone have greatly limited the use of horizontal alveolar distraction.[53,66,67,78] In most cases with horizontal alveolar deficiency, conventional ridge augmentation procedures with autogenous block bone graft or GBR are more advantageous than distraction osteogenesis.[75]

Oblique Alveolar Distraction

In the esthetic zone, it is important for the atrophic alveolus to be augmented to correct ridge form in three dimensions (vertical, horizontal, and oblique). Advancement of the total maxilla or anterior maxilla by distraction osteogenesis through a horizontal vector has been reported experimentally[79,80] and clinically,[31-33] but there have been few reports on oblique alveolar distraction. The author first reported anteroposterior (oblique) distraction of the atrophic subtotal maxillary alveolus for implant placement. The maxillary alveolus between the second premolars was distracted anteroinferiorly (horizontal 10 mm, vertical 5 mm) with an extraosseous custom-made distractor over the hard palate 0.25 mm twice a day for 25 consecutive days, which allowed placement of implants in a more ideal position. When the

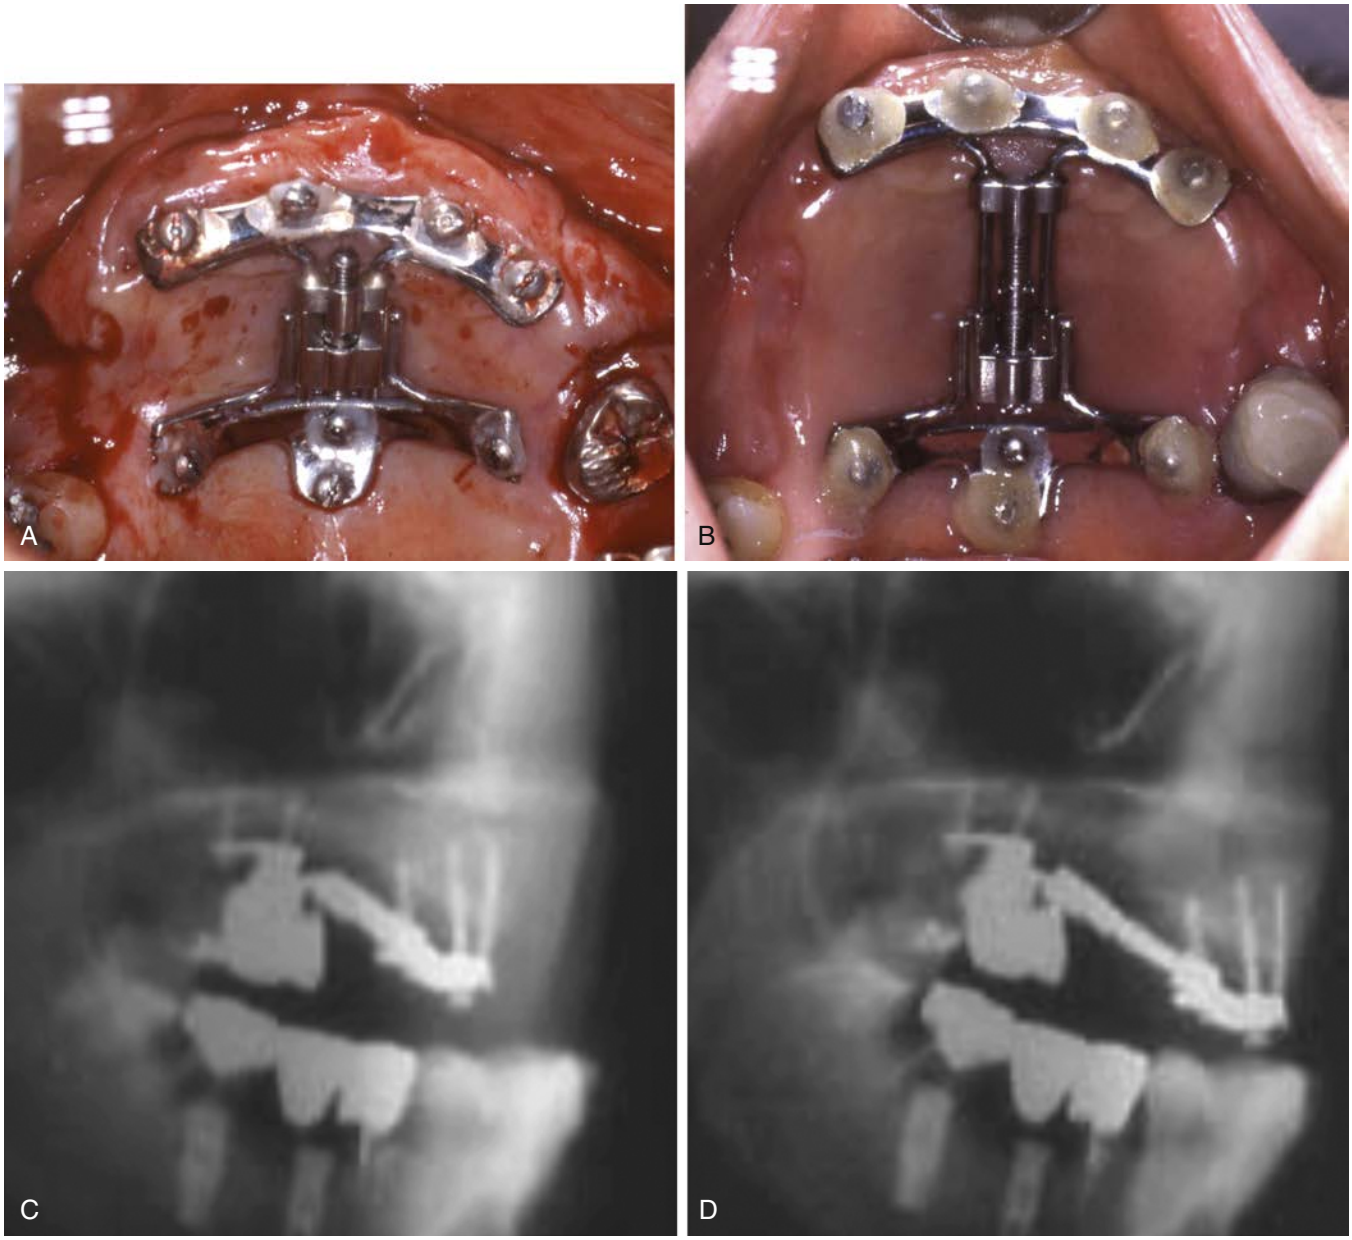
• **Figure 33-36, cont'd** **E-F,** After 15 mm of distraction, a vertical defect of approximately 10 mm still remained. **G-H,** For additional vertical ridge augmentation, the upper plate of the distractor changed the position to the lowest one. **I-J,** After additional 13-mm distraction (total 28-mm distraction), the alveolar crest was in a more ideal position. **K-L,** After a retention period of 4 months, the distractor was removed. Additional minor ridge augmentation was needed at the time of implant placement to achieve a more ideal bony architecture.

ratio of vertical direction in oblique distraction is greater than that of the horizontal one, a plate-type distractor can be employed facially. However, in cases with a greater ratio of horizontal vector, a palatal extramucosal distractor should be used to control the distraction direction more easily, usually parallel to the anterior palatal surface (Figure 33-37). The palatal distractor can be fixed rigidly with titanium micro-screws into the palatal mid-portion and bilateral sides. In addition, the transport bone can be secured to the distractor using 10-mm–long titanium microscrews in combination with adhesive resin cement. Alveolar distraction induces not only bone augmentation but also soft tissue elongation, which can improve the depth of the vestibule, despite the large bone augmentation of 13 mm.

Fan-Shaped Alveolar Distraction

Fan-shaped alveolar distraction describes a protocol where the transport bone is distracted at only one side with the pivot on the other side, similar to opening a fan. This technique can be employed when the alveolus has uneven height, where the defect site has more than a 10-mm discrepancy with the normal side. After osteotomies are performed, a



• **Figure 33-37** Severely atrophic subtotal maxilla resulting from severely advanced periodontitis. **A,** The anterior alveolar ridge was positioned 10 mm palatally and there was 5-mm vertical bone loss between the bilateral second premolar regions. For antero-inferior (oblique) alveolar distraction, a distraction device was seated with titanium mini-screws and adhesive resin cement over the hard palate. **B,** A lateral cephalogram revealed skeletal Class III. **C,** After a 7-day waiting period, the maxillary alveolus was distracted antero-inferiorly 0.25 mm twice a day for 25 consecutive days to an ideal ridge form. **D,** A comparison of pre- and post-distraction lateral cephalograms revealed 10 mm of anterior movement and 5 mm of inferior movement of the subtotal maxillary alveolus, converting from skeletal Class III to a Class I.

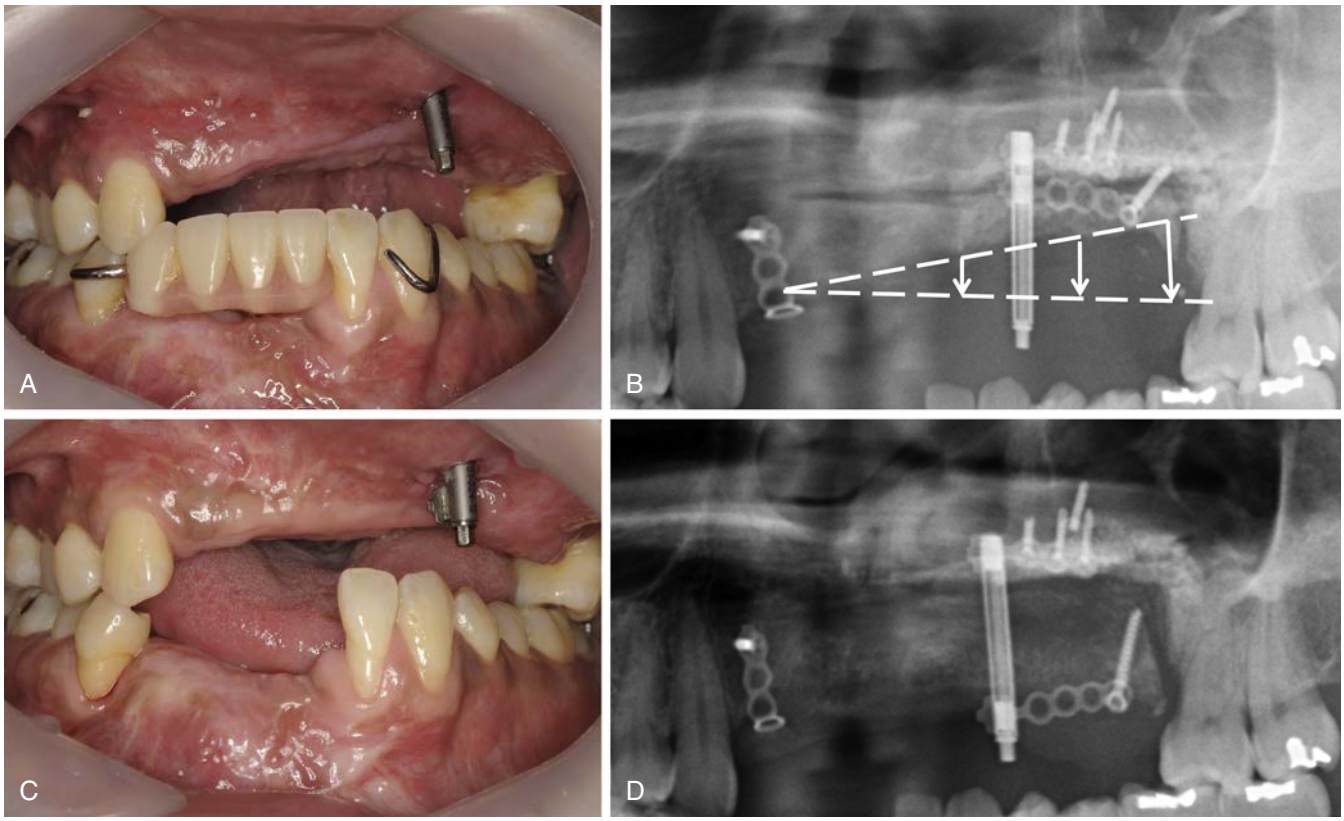
• **Figure 33-37, cont'd** **E,** DentaScans revealed that the anterior alveolar ridge was positioned 10 mm palatally and 5 mm apically. **F,** Post-distraction DentaScans demonstrated that the maxillary alveolus was adequately distracted to allow placement of implants in an ideal position. **G-H,** A comparison of pre- and postdistraction casts showed 13-mm of antero-inferior lengthening. **I-J,** The definitive restoration without artificial gingivae was possible. **K-L,** There was no significant marginal bone resorption around the implants 16 years after placement of the definitive restoration.



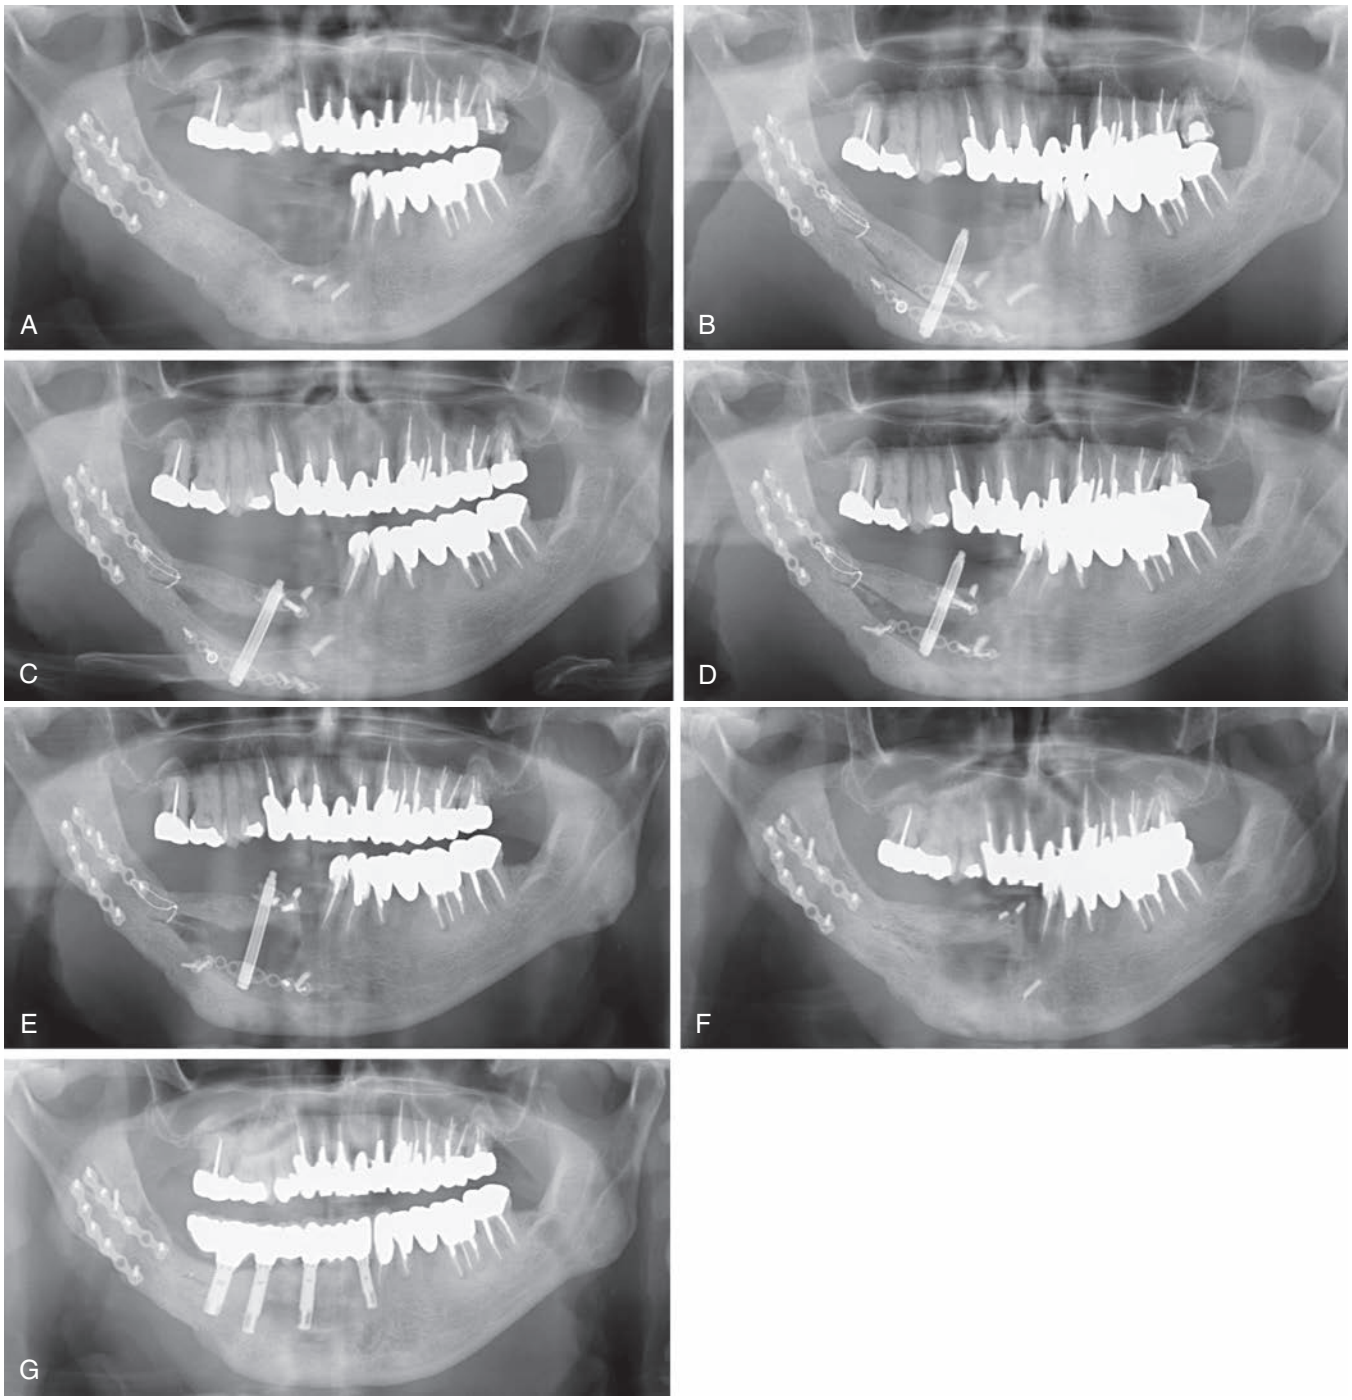
• **Figure 33-38** Uneven vertical bone defect in the maxilla secondary to maxillary alveolar fracture because of a traffic accident. **A-B,** The alveolus has uneven height with a 10-mm vertical defect on the left posterior and optimal height on the anterior maxilla. The transport bone is distracted on only one side with the pivot on the anterior maxilla, analogous to opening a fan. **C-D,** 12-mm fan-shaped distraction resulted in a more optimal and even ridge height.

plate-type distractor is fixed rigidly with the basal bone using titanium micro-screws. The transport bone is secured loosely with the distractor using one titanium bi-cortical micro-screw on the side with vertical bone defect and immobilized with a mini-plate or a wire on the other side with normal ridge height (Figure 33-38). In cases with an uneven ridge height greater than 15 mm, fan-shaped alveolar distraction may be applied repeatedly (Figure 33-39).

Mesiodistal Alveolar Distraction (Horizontal Alveolar Transport Osteogenesis)

Alveolar distraction is categorized as transport distraction osteogenesis and used mainly in vertical ridge augmentation. Mesiodistal alveolar distraction (horizontal alveolar transport osteogenesis) has been reported in cases with cleft palate,[81-85] segmental (or marginal) mandibulectomy, or maxillectomy.[86-88] The closure of wide alveolar clefts and fistulae in patients with clefts and the reconstruction of maxillary dentoalveolar defect in patients with trauma are challenging for both orthodontists and surgeons. This is because of the difficulty of achieving soft tissue closure with the limited local attached gingiva and the greater volume of bone required for the graft. Liou and co-workers first reported interdental distraction osteogenesis (IDO) for lengthening of the dental arch, minimizing the alveolar cleft/fistula, and reconstructing a maxillary dentoalveolar defect by approximating the native alveoli and gingivae.[82] IDO is a modification of bifocal distraction osteogenesis that has been used successfully in long bones[89] and in the correction of mandibular defects.[90] IDO in conjunction with rapid orthodontic tooth movement through the regenerate has many advantages, including minimizing the need for extensive alveolar bone grafting, eliminating tooth extraction in cases of dental crowding, and maintaining velopharyngeal function of those cleft patients who need distraction of the entire maxilla.[82] In addition, transport distraction osteogenesis is useful for the reconstruction of segmental maxillary and mandibular defects in selected patients with poor general health.[87]

Mesiodistal alveolar distraction can be beneficial in patients with large segmental maxillary defects (Figure 33-40). In the case shown in Figure 33-40, the transport bone of the anterior maxilla was distracted 20 mm distally using an intraoral, unidirectional device originally designed for the distraction of the ascending ramus and mandibular body (Zürich Pediatric Ramus Distractor, KLS Martin). The flexible activator improved patient's comfort, which resulted in better compliance. In large defects where the activating plate moves toward the basal one from a large distance, the distractor is activated as much as possible and should be



• **Figure 33-39** Severely atrophic hemi-mandible resulting from segmental resection due to ameloblastoma followed by iliac bone graft. **A,** In the mesial end of the defect, there was a 20-mm vertical bone defect. The distal end of the defect had no bone defect. **B,** For fan-shaped distraction, a plate-type distractor was placed in the mesial portion of the defect and the transport bone was immobilized with a wire in the distal end with normal ridge height. **C,** Even after 12-mm fan-shaped distraction, a vertical bone defect still remained. **D,** For additional 10-mm vertical augmentation, the distractor and the upper plate changed optimal position. **E,** Total of 22-mm fan-shaped distraction made the ridge height ideal. **F,** The distractor was removed after a consolidation period of 4 months. **G,** The bone gap between the mesial portion of the transport bone and the native mandible was filled with autogenous bone graft, and four implants were placed in an ideal position simultaneously.

inactivated (closed) to distract the transport bone for reconstructing the bony defect. Transport distraction osteogenesis is usually followed by a minor bone graft procedure to fill in the residual bone gap between the transport bone and basal bone.

Conclusions

Alveolar distraction, categorized as pedicle vascularized bone graft and transport distraction osteogenesis, is a reliable, predictable option to gain large vertical increases of hard and soft tissue in difficult areas such as the anterior maxilla and mandible. It is also beneficial in cases with compromised or inadequate soft tissue and scar tissue. As for prerequisites for alveolar distraction, the transport bone must be well vascularized with periosteal blood supply. Patient selection is critical for success of alveolar distraction. The author's opinion is that the transport bone should have a height of more than 8 mm, length of more than 30 mm (more than a four-tooth defect), and width of more than 6 mm in order to maintain its viability and minimize resorption. In single- to three-tooth defects, bone graft or GBR is simpler and more predictable than alveolar distraction, considering the viability of the transport bone. When the alveolar ridge height is less than 10 mm, onlay bone graft or vertical GBR should be first performed to gain an alveolar ridge height of at least 10 mm before alveolar distraction. If the ridge width is less than 6 mm, veneer bone graft or horizontal GBR is needed before or after alveolar distraction. If the alveolar crest is very thin but a few millimeters apical from the alveolar crest is adequately thick, the transport bone can be overdistracted and the thin ridge reduced at the time of implant placement, leading to a more ideal ridge. Overdistraction of 2 to 3 mm should be necessary because of resorption and relapse of the transport bone in all patients. A gradual distraction rate of less than 0.5 mm/day results in no dehiscence of the

• **Figure 33-40, cont'd** **K-L,** Minor bone graft from the ramus was performed in the bone gap between the transport bone and basal one. In the left, segmental bone defect was reconstructed with ramus bone graft simultaneously. **M-O,** The fixed definitive restoration was supported by six implants. The patient obtained good functional and acceptable esthetic results, though she refused additional ridge augmentation.

soft tissue, better bone formation, and decreased risk of non-union compared with a distraction rate of 1 mm/day.

As complexity or severity of the bone defects increases, there is an increased need for bone grafting before or after distraction is done. In addition, patients must be informed of the difficulty of treating a defect with exposed root surface in an esthetic manner without dental extraction or orthodontic forced eruption. Three-dimensional alveolar distraction (vertical, horizontal, oblique, fan-shaped, or mesiodistal) can be useful in complex defects where conventional ridge augmentation with bone graft or GBR cannot resolve all of the defect, especially massive bone and soft tissue defects with scar. To succeed in three-dimensional alveolar distraction, the use of an optimal distractor and the control of distraction vector are important factors.

Peri-implant Soft Tissue Augmentation

HOMAYOUN H. ZADEH, DIANE ANTHONY-COSTANDI, NAVID SHARIFZADEH

Peri-implant Soft Tissue Interface

During the initial years after the discovery of osseointegrated dental implants the focus was on the bone-to-implant interface. Bone of sufficient volume and density has been regarded as the most important factor in the success of dental implants. The reason for the emphasis on bone quantity and quality has been to provide initial stability, which is to be supplanted by secondary stability (i.e., osseointegration). Peri-implant soft tissues have predominantly been discussed in the context of esthetics. An important question is whether peri-implant mucosa has any significance beyond esthetic aspect.[1-4] Prior to considering the functional significance of the soft tissue interface around implants, it will be important to review the anatomy of the peri-implant mucosal tissues.

Anatomy of Peri-implant Mucosa

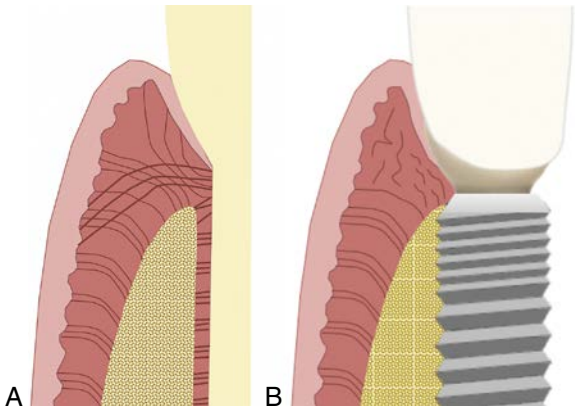
The soft tissue interface around implants has many features in common with that of teeth, including a sulcus, junctional epithelium, and connective tissue attachment.[5] However, subtle differences exist between teeth and implants.[6] The peri-implant connective tissue attachment is in direct contact with the implant surface and consists of two zones (Figure 34-1). The zone immediately adjacent to the implant surface is characterized by an abundance of fibroblasts and an absence of blood vessels. The deeper zone in the connective tissue has more collagen fibers and blood vessels and fewer fibroblasts. This anatomic structure of the peri-implant mucosal interface is distinctly different from the connective tissue attachment around teeth, where connective tissue fibers directly attach into the root cementum.[7-9]

Significance of Peri-implant Mucosa

Animal and clinical studies have addressed the quantitative and qualitative significance of peri-implant mucosa on the stability of peri-implant tissues. The influence of peri-implant mucosal thickness was investigated in a canine study by Berglundh and Lindhe.[10] Three months after bilateral placement of implants in canine mandible, mucosal thickness was maintained on the control side. On the experimental side, mucosa was thinned to 2 mm or less. Results at 6 months postoperatively demonstrated establishment of a transmucosal attachment that was similar on both sides of the mandible, with 2 mm of epithelial attachment and 1.3 mm of connective tissue attachment. On the other hand, peri-implant bone loss was observed on the experimental side, where mucosa was thinned. This study concluded that the dimensions of the biologic width are predetermined, and in cases of thin mucosa, peri-implant bone loss occurs in order to create the space for this biologic width. These results are confirmed in human studies, where increased marginal bone loss is observed in sites with thin mucosa.[11,12]

In addition to the demonstrated significance of quantitative properties of peri-implant mucosa, qualitative differences in peri-implant mucosa have also been shown. The significance of keratinized mucosa has been documented in a canine study.[13,14] In this study, at the time of implant installation the entire zone of peri-implant keratinized mucosa was excised from the flap in the experimental group, while in the control group a zone of keratinized mucosa was present. Increased bone resorption and mucosal recession was observed in experimental sites where the keratinized mucosa was removed. Interestingly, complete removal of peri-implant keratinized mucosa led to bone resorption in sites with thick (2 mm) as well as thin (1 mm) buccal alveolar bone plates. A free gingival graft in sites with deficient keratinized mucosa reduced the magnitude of the peri-implant bone resorption and soft tissue recession.[14]

A number of clinical studies have been conducted to investigate the role of peri-implant keratinized mucosa on the success of implants.[3,6,13,15,16] Most of these studies have demonstrated that in patients with good oral hygiene and regular implant maintenance, less than 2 mm of peri-implant keratinized mucosa is associated with increased plaque accumulation, inflammation, and progression of recession.[3,6] Therefore, it is clear that peri-implant mucosa is



• **Figure 34-1** Soft tissue interface around teeth and implants. The periodontal attachment apparatus includes junctional epithelium that can be attached to enamel, dentin, or both **(A).** There is also supra-alveolar connective tissue attachment which connects gingiva to cementum on roots. The peri-implant mucosal attachment has the same two components of junctional epithelium and connective tissue attachment, though the nature of these attachments is different. In particular, connective tissue attachment includes a zone closest to the implant surface composed of many fibroblasts that are flattened against the surface. This peri-implant zone has no blood vessels and has low collagen content. The collagen fibers near the implant surface are also oriented parallel to implant surface, unlike periodontal fibers, which are perpendicular to tooth surface. **B,** The peri-implant zone deeper in the tissues is more vascular and contains less fibroblasts and more collagen fibers.

important, not only for esthetics, but also for the long-term stability of peri-implant bone and soft tissue attachment.

Peri-implant Soft Tissue Augmentation

An array of techniques have been utilized for soft tissue augmentation around teeth and implants.[17-23] Whereas the efficacy of soft tissue augmentation around teeth has been extensively investigated,[24] scant evidence exists for peri-implant soft tissue augmentation. Systematic reviews of available evidence have demonstrated that autogenous tissue grafting using epithelialized or connective tissue grafts are the best-documented methods to increase the width of keratinized mucosa.[16,25-29] Autogenous grafts improve soft tissue thickness and esthetics compared to nongrafted sites.

Free Autogenous Grafts

Free autogenous grafts are harvested from either the palate or tuberosity. The free graft may have an intact epithelial layer, in which case it is referred to as free gingival graft (FGG). Alternatively, the graft may be harvested without the epithelial layer, referred to as subepithelial connective tissue graft (SCTG), or simply CTG.

FGG is very efficient in increasing the zone of keratinized gingiva and increasing the vestibular depth. A clinical example of FGG application is illustrated in Figure 34-2. This patient had minimal zone of keratinized mucosa, shallow vestibular depth, and was planned to receive an implant-supported overdenture (see Figure 34-2, *A*). Crestal incision was made in such manner to reposition most of the keratinized mucosa toward the lingual aspect of the implant healing abutments. A supraperiosteal sharp dissection was carried out on the facial aspect, extending apically past the mucogingival junction to the vestibular fornix (see Figure 34-2, *B*). A recipient bed lined with periosteum was created that was devoid of any muscle or movable elastic fibers of the frenal attachments. FGG grafts were harvested bilaterally from the palate, near the edentulous alveolar crest in the premolar region (see Figure 34-2, *C* and *D*). The grafts had uniform thickness of approximately 2 mm. The FGGs were secured with 6-0 polypropylene sutures to the underlying periosteal recipient bed through a series of interrupted sutures (see Figure 34-2, *E*), Criss-cross sutures were anchored in the periosteum of the vestibular fornix and slung around the healing abutments to adapt the grafts securely against the recipient bed. Following a 6-week healing period, a dense keratinized band of attached mucosa was created on the facial aspect of the implants. The vestibule was also deepened by this procedure (see Figure 34-2, *F*).

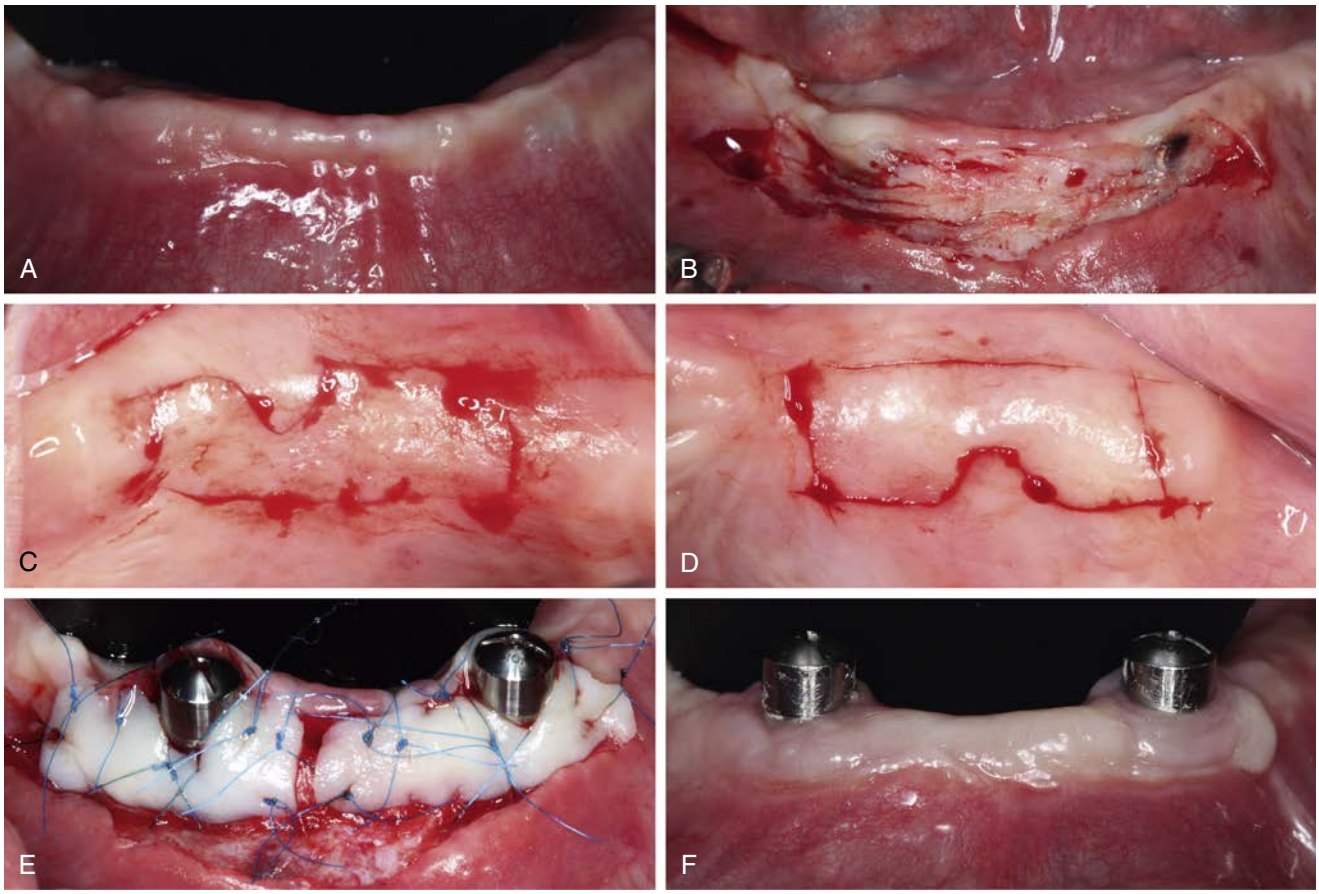
Although epithelialized grafts are very efficient at creating peri-implant keratinized attached mucosa and increasing the vestibular depth, the main drawback is that the grafted area has a distinct color and texture which does not match that of the recipient site. Therefore, in the esthetic zone, application of this procedure may lead to unacceptable esthetics (Figure 34-3).

Another important disadvantage of free autogenous grafts is their significant shrinkage following the augmentation procedure.[30-32]

Pediculated Soft Tissue Grafts

To overcome the problem with shrinkage of free autogenous grafts, pediculated grafts have been applied for ridge defects augmentation.[33-36] It has been speculated that pedicle connective tissue grafts have less volumetric shrinkage because of intact blood supply.[35]

In the maxilla, pedicle graft can be achieved by modifying the incision design during mucoperiosteal flap elevation. The objective of this modified flap design is to reposition the keratinized mucosa and associated connective tissue from the palatal to buccal aspects. This entails initiating the incision palatal to the mucosal crest and repositioning the flap in a buccal direction. The diagrams in Figure 34-4 illustrate the surgical steps involved in repositioning keratinized mucosa from the palatal to buccal aspect of implants. To increase the zone of keratinized mucosa on the buccal aspect, the initial incision is made on the palatal aspect of the alveolar ridge crest (see Figure 34-4, *A*). The blade is directed parallel to the surface mucosa to undermine the palatal tissues. The objective of this sharp partial thickness dissection is to create a palatal flap that is uniformly 2 mm in thickness (see Figure 34-4, *B*). The buccal flap is then apically repositioned to deepen the vestibule and increase the zone of keratinized mucosa on the buccal aspect

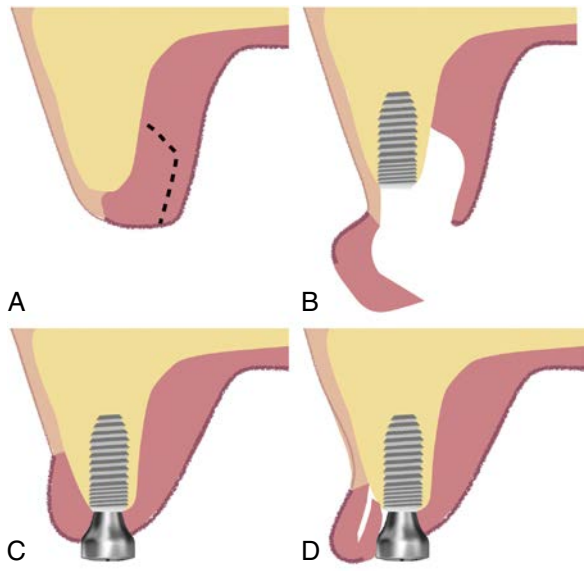


• **Figure 34-2** Free gingival graft for augmentation of keratinized mucosa and vestibular depth. The initial condition following healing of two-stage implant installation showed minimal zone of keratinized mucosa and shallow vestibular depth **(A).** Recipient bed was prepared by sharp dissection to reposition the movable alveolar mucosa in apical direction **(B).** All elastic fibers from frena and muscle attachments were removed to produce a uniform recipient bed lined by periosteum. FGG grafts were harvested bilaterally from the premolar regions of the palate near the edentulous alveolar ridges with uniform thickness of approximately 2 mm **(C, D).** The grafts were secured with 6-0 polypropylene sutures to the underlying periosteal recipient bed **(E).** At three months postoperatively, dense keratinized band of attached mucosa had been created on the facial aspect of the implants **(F).** The vestibule was also deepened by this procedure.

• **Figure 34-3** Unfavorable esthetic result of a free gingival graft in the esthetic zone. The FGG does not match surrounding host tissues in terms of color, texture, and contour.

(see Figure 34-4, *C*). In this arrangement, part of the connective tissue without surface epithelium may be exposed. In some cases, the objective is not to increase the vestibular depth but to increase the buccal mucosal thickness. In such cases, the palatal connective tissue that is contiguous with the buccal flap is folded under the buccal flap margin (see Figure 34-4, *D*). This approach is particularly useful when the palatal connective tissue is thin.

The clinical case shown in Figure 34-5 is a common manifestation, where the edentulous alveolar ridge exhibits lack of keratinized mucosa on the buccal aspect with coronal frenum attachment (see Figure 34-5, *A*). The flap design includes a horizontal incision palatal to the alveolar crest with the blade oriented to undermine the palatal flap (see Figure 34-5, *B*). At the base of the flap, the incision is directed to reach the palatal bone (see Figure 34-5, *C*). The reflected flap shows connective tissue harvested from the palatal region that is contiguous with the buccal flap (see Figure 34-5, *D*). The buccal flap is then apically repositioned (see Figure 34-5, *E*) and approximated in a position to allow an increased zone of buccal keratinized mucosa (see Figure 34-5, *F*). Comparison of initial presentation prior to tooth extraction (see Figure 34-5, *G*) and postoperative condition (see Figure 34-5, *H*) shows an increase in the zone of keratinized mucosa on the facial aspect of



• **Figure 34-4** Strategies for augmentation of keratinized mucosa and ridge defects in the maxilla. In cases with minimal zone of keratinized mucosa, initial incision is made in parallel with the palatal surface contour in an effort to undermine the palatal connective tissue, while leaving a 2-mm overlying mucosal flap. **A,** At an appropriate point, determined by the desired width of postoperative keratinized mucosa, the incision is directed toward the palatal bone. Following reflection of the mucosal flap, the palatal connective tissue harvested will be contiguous with the buccal flap **(B).** The buccal flap is apically repositioned to deepen the vestibule and increase the zone of keratinized mucosa on the buccal aspect **(C).** In cases where the harvested palatal connective tissue is not too thick, or it is desired to maximize restoration of crestal mucosal contour, the buccal flap margin is folded under the flap **(D).**

implant restorations with apical positioning of the frenal attachments.

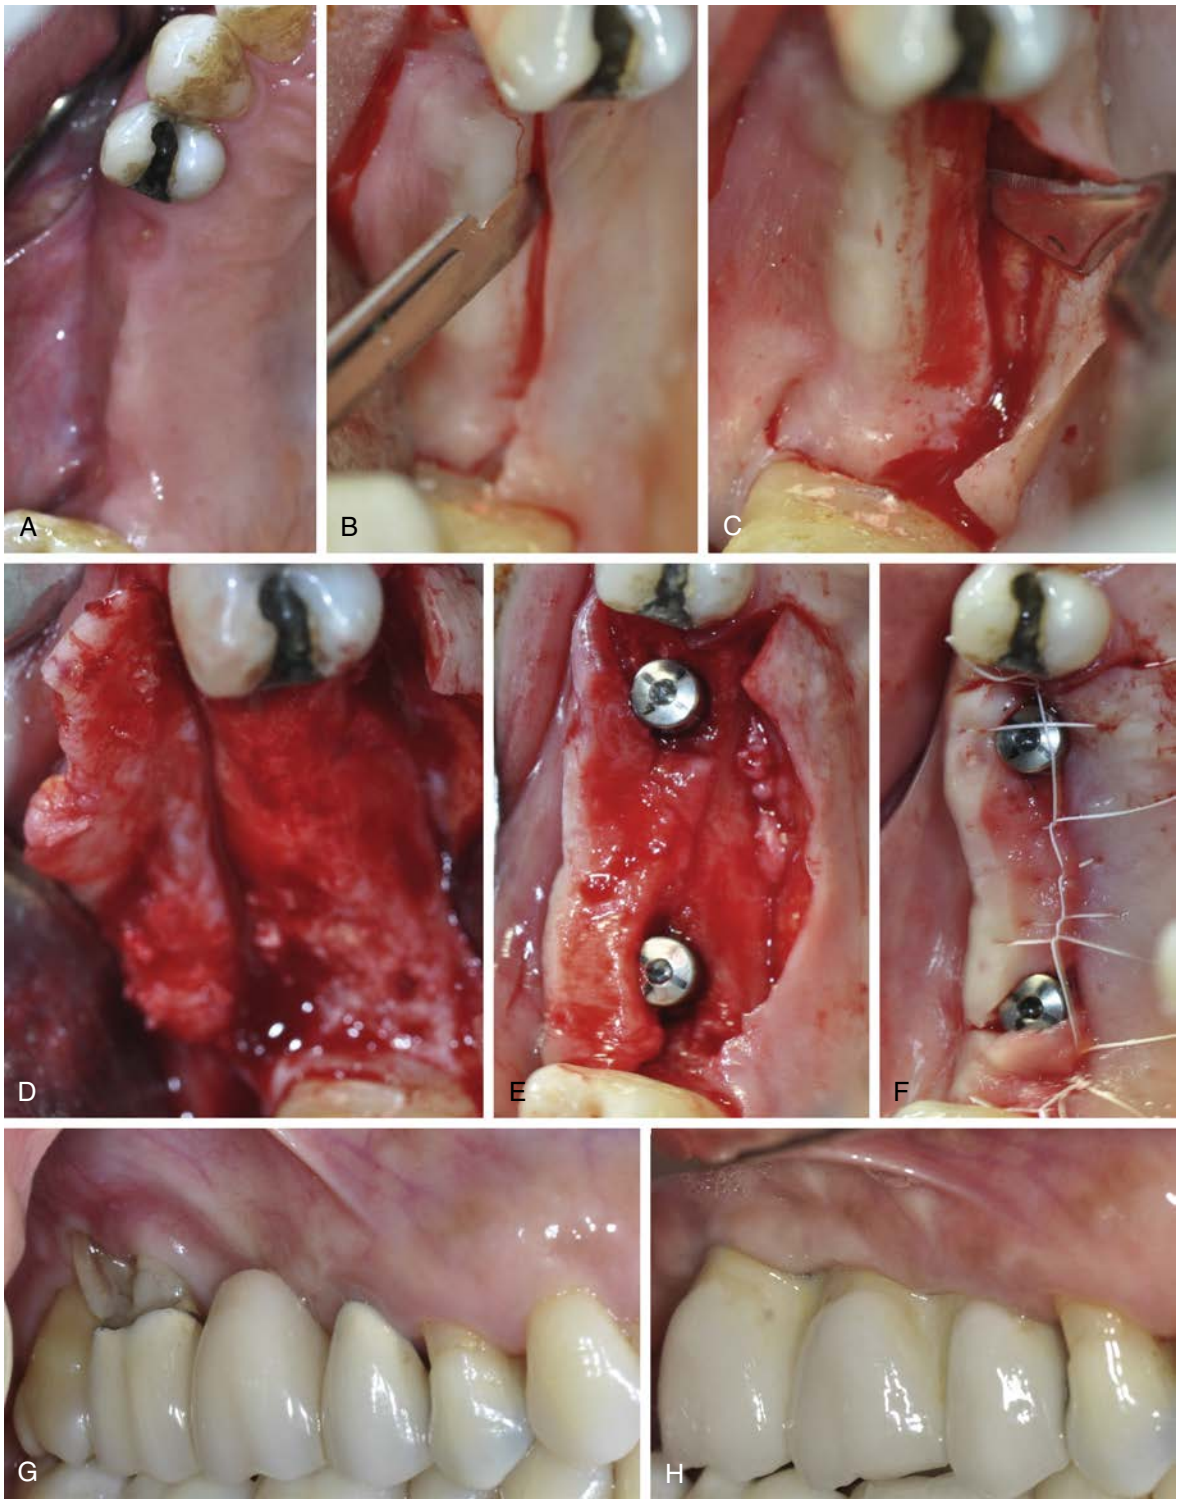
A variation of the pedunculated graft is the vascularized interpositional (VIP) graft. This entails repositioning palatal connective tissue graft with an intact base that can serve both as an anchorage point for rotating the graft from the palatal to buccal, and as the source of vascular support. In recent study, Akcalı et al.[37] utilized three-dimensional volumetric analysis to compare volumetric gain of tissue achieved by free and pediculated connective tissue grafts for ridge defects soft tissue augmentation. They clearly demonstrated that pediculated connective tissue grafts lead to increased volumetric tissue gain.

The clinical case in Figure 34-6 illustrates the clinical scenario of a patient with a high smile with significant alveolar contour deficiency. In this case, ridge preservation was performed in conjunction with tooth extraction, yielding sufficient volume of bone for implant therapy. Soft tissue augmentation was necessary to correct the significant contour deficiency (see Figure 34-6, *A*). In view of the large volume of contour augmentation required, VIP graft was performed. This entailed a crestal incision with mucoperiosteal reflection of the alveolar crest to allow access for implant installation. Just past the alveolar crest, a deep supraperiosteal soft tissue pouch was prepared by sharp dissection extending apically past the mucogingival junction and laterally to the neighboring teeth. On the palatal aspect, horizontal incisions were made approximately 3 mm apical to the gingival margins of maxillary posterior teeth. Partial thickness dissection was carried out, reflecting a mucosal flap with uniform thickness of 1.5 mm (see Figure 34-6, *B*). The connective tissue and underlying periosteum were incised at superior, posterior, and apical borders, leaving the anterior aspect of the graft attached to its vascular bed (see Figure 34-6, *C*). The pediculated graft was rotated facially to augment the crest and facial contour (see Figure 34-6, *D*). Flap margins were approximated to achieve primary closure (see Figure 34-6, *E*). Following healing, the contour deficiency has been corrected (see Figure 34-6, *F*). Final restoration shows acceptable soft tissue contour around implant restorations (see Figure 34-6, *G*). Radiograph taken at one year postoperatively shows the stability of the alveolar bone during the early healing period. The trumpet-shaped transmucosal contour of the CAD/CAM abutments was designed to maximize the peri-implant mucosal thickness.

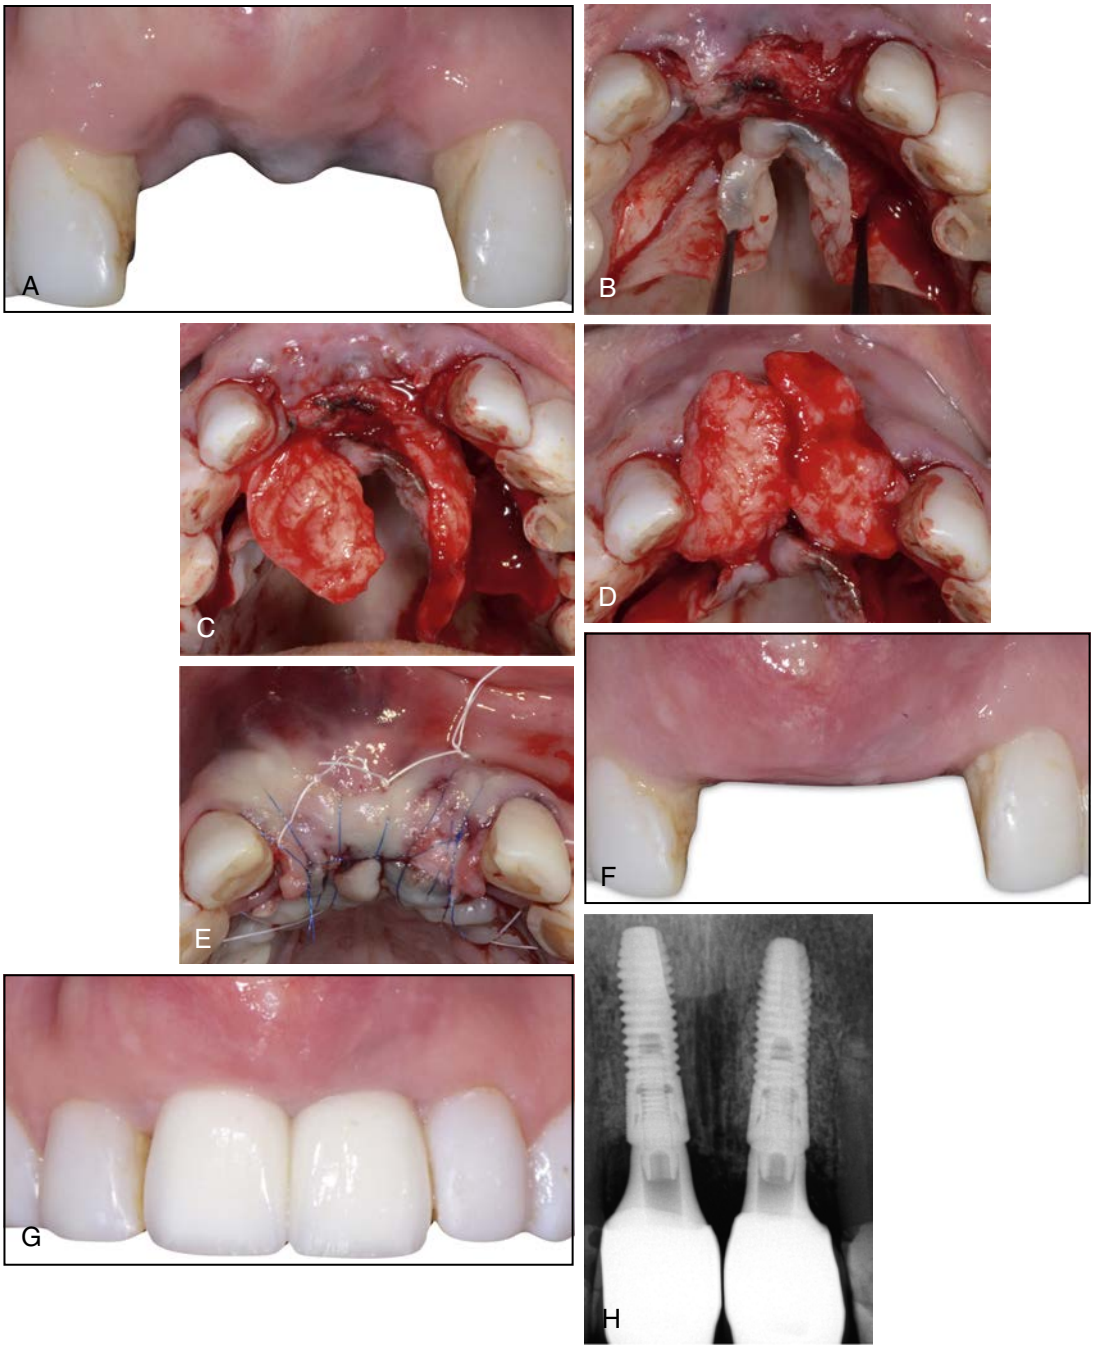
Application of Graft Substitutes For Peri-implant Soft Tissue Augmentation

Autogenous soft tissue grafts harvested from palate or tuberosity with or without epithelium are very effective at increasing the peri-implant zone of attached keratinized mucosa. However, limitations of this procedure include the morbidity associated with autogenous tissue harvesting. In addition, where augmentation is required for large regions of the oral cavity, limited autogenous tissue is available. Moreover, some patients have anatomic limitations such as shallow palatal vault, proximity of greater palatine foramen or the presence of palatal exostoses, which limit the availability of autogenous tissues. Alternatives to autogenous tissue include acellular dermal matrix (ADM) allograft and xenogenic collagen matrix (XCM). Collagen matrix has been demonstrated to lead to less gain in keratinized mucosa, although it has been associated with less morbidity and decreased surgery time.[38] In a randomized controlled clinical trial, the efficacy of CTG and ADM for peri-implant mucosal augmentation have been compared. The result of this study demonstrated increased mucosal thickness, decreased concavity dimensions, and reduction of peri-implant recession.[39]

A representative clinical case illustrating application of ADM is shown in Figure 34-7. The patient presented with a significant mucosal concavity around the second premolar with coronal frenal attachment. (see Figure 34-7, *A*) The first premolar was slated for extraction and immediate implant placement. The incision design included undermining the palatal tissue to have increased connective tissue associated with the buccal flap. Once the implants were placed, an ADM (Perioderm, Dentsply Sirona Implants, Waltham, MA) was positioned on the buccal



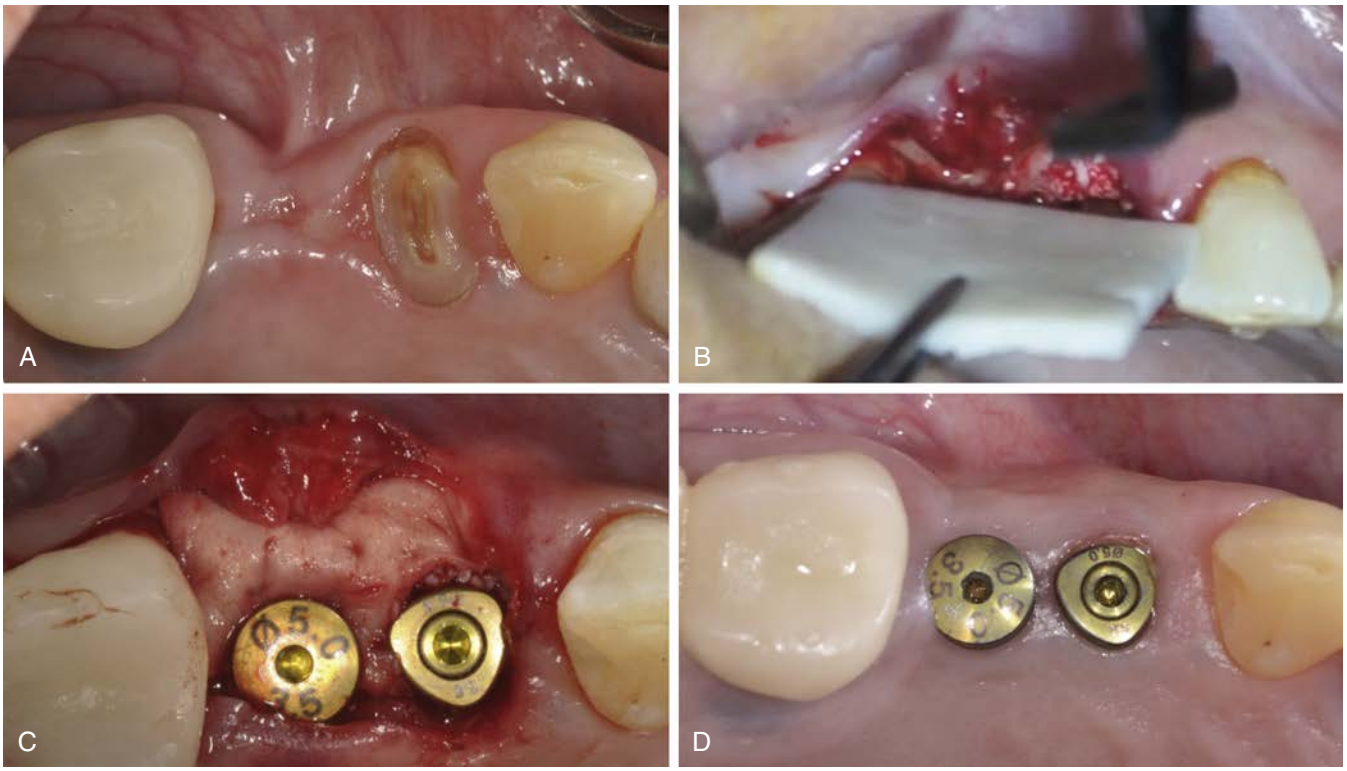
• **Figure 34-5** Augmentation of keratinized mucosa in posterior maxilla by buccal repositioning of palatal connective tissue. A clinical case with minimal zone of attached keratinized mucosa and coronal frenal attachment in posterior maxilla **(A).** The flap design includes horizontal incision palatal to the alveolar crest with the blade oriented to undermine the palatal flap **(B).** At the base of the flap, the incision is directed to reach the palatal bone **(C).** Connective tissue harvested from the palatal region was contiguous with the buccal flap **(D).** The buccal flap is then apically repositioned **(E)** and approximated to achieve primary closure **(F).** Comparison of initial presentation prior to tooth extraction **(G)** and postoperative condition shows increase in zone of keratinized mucosa on the facial aspect of implant restorations with apical positioning of the frenal attachments **(H).**



• **Figure 34-6** Soft tissue augmentation of major alveolar ridge contour defect with VIP graft. Clinical case with significant soft tissue contour deficiency **(A).** Partial thickness dissection was carried out, reflecting a mucosal flap with uniform thickness of 1.5 mm **(B).** The connective tissue and underlying periosteum were incised at superior, posterior, and apical borders, leaving the anterior aspect of the graft attached to its vascular bed **(C).** The pedunculated graft was rotated facially to augment the crest and facial contour **(D).** Flap margins were approximated to achieve primary closure **(E).** Following healing, the contour deficiency has been corrected **(F).** Final restoration shows acceptable soft tissue contour around implant restorations **(G).** Postoperative periapical radiograph illustrates subgingival contours of the implant-supported maxillary central incisor restorations **(H).**

aspect of the implants (see Figure 34-7, *B*) and adapted around the healing abutments (see Figure 34-7, *C*). This augmentation procedure lead to improved buccal soft tissue contour, peri-implant mucosal thickness, deepening of the vestibular depth, and associated frenal attachment (see Figure 34-7, *D*).

Another method to increase the band of keratinized mucosa and vestibular was proposed by Urban.[40] This method utilizes xenogenic collagen matrix and a narrow strip of epithelialized FGG. The concept is to create a recipient bed of periosteum and suture a narrow strip of FGG at the vestibular depth. The space between this FGG and



• **Figure 34-7** Correction of soft tissue ridge contour deficiency and frenal attachment with acellular dermal matrix allograft. Initial clinical presentation showed soft tissue concavity, minimal zone of keratinized mucosa, and coronal frenum attachment **(A).** Mucoperiosteal flaps were reflected on buccal and palatal aspects, dissecting the buccal flap to the vestibular fornix, followed by insertion of an acellular dermal matrix allograft **(B).** An implant was installed immediately into the extract socket of the maxillary right first premolar and another one in the healed site of the second premolar. The horizontal gap between the implant and socket walls was filled with anorganic bovine bone minerals and covered by the acellular dermal matrix allograft **(C).** Six months postoperative outcome shows the correction of the soft tissue depression, increase in mucosal thickness, and loss of the coronal frenum attachment **(D).**

the crestal keratinized mucosa is filled with an XCM, which is also sutured to underlying periosteum. During the healing, cellular infiltration from the crestal keratinized mucosa and apical FGG leads to a wide band of attached keratinized mucosa. This is particularly useful in cases of extensive alveolar ridge augmentation, which typically lead to loss of vestibular depth.

A clinical example is depicted in Figure 34-8, where a patient with severely atrophic anterior maxilla was reconstructed with guided bone regeneration and as a result had significant loss of vestibular depth. Sharp dissection was performed to expose a uniform bed of periosteum without any movable elastic fibers or muscle attachment (see Figure 34-8, *B*). A narrow strip of epithelialized FGG, which was 5 mm in width, was harvested from the posterior maxilla near the alveolar crest during second-phase surgery to expose posterior implants. The FGG strips were sutured to the recipient periosteal bed at the apical border of the vestibule. Keratinized mucosa was present at the alveolar crest. An XCM (Mucograft, Geistlich, Wolhusen, Switzerland) was stabilized on the recipient periosteal bed in between the crestal keratinized mucosa and apical FGG strips (see Figure 34-8, *C*). The site was covered with light-cured periodontal dressing (Barracaid, Dentsply), which was left in place for two weeks (see Figure 34-8, *D*). Healing of the site after 3 weeks showed clearly the increase in the vestibular depth as well as gain of attached keratinized mucosa (see Figure 34-8, *E*).

Vestibular Incision Subperiosteal Tunnel Access

One of the techniques used for soft tissue augmentation around teeth and implants is vestibular incision subperiosteal tunnel access (VISTA).[22,41] The initial access for VISTA begins with a vertical incision in the vestibule remotely from the therapeutic target. The position of the initial incision is dictated by convenience of access and prevention of injury to vital structures such as the mental neurovascular bundle. A typical initial incision in the maxillary anterior area is the midline frenum. For access to the maxillary or mandibular posterior region, the vestibular region anterior of the canines is a suitable location for the initial vestibular incision. Beginning from the initial access incision, a subperiosteal tunnel is created using a series of specially designed elevators (VISTA elevators, Dowell Dental Products, Rancho Cucamonga, CA). The subperiosteal tunnel is extended to the depth of the

• **Figure 34-8** Augmentation of keratinized mucosa and vestibular depth with xenogenic collagen matrix (XCM) in conjunction with FGG strips. Following extensive horizontal and vertical alveolar ridge augmentation, shallow vestibular depth and minimal zone of keratinized mucosa were present **(A).** Partial thickness dissection was performed, leaving a border of keratinized mucosa at the alveolar crest with a uniform bed of periosteum at the recipient site **(B).** Two narrow strips of FGG were harvested from the posterior alveolar crest and sutured to the periosteum at the most apical border of the recipient bed **(C).** The gap between the keratinized tissue at the crest and the FGGs was covered with XCM. The site was covered with light-cured periodontal dressing that was left in place for two weeks **(D).** Healing of the site after three weeks showed abundant zone of attached keratinized mucosa and increase in the vestibular depth **(E).**

vestibule, and any muscle attachments found within the tunnel are released to allow for a tension-free tunnel. If the objective of soft tissue augmentation is also coronal repositioning of the mucosal margins of teeth/implants, a suture is placed in the mucosal margin and is fixated to the coronal tooth/restoration. Wound stability is of paramount importance during the initial stages of the healing.[42] The fixation of the gingival margin during the healing process assists with wound stabilization. The tensile strength at the interface between the tooth/flap following periodontal flap surgery has been demonstrated to progressively increase during the first 2 weeks of healing.[43,44] Therefore, it is recommended to leave the coronally anchored suture in for more than 2 weeks to ensure that the integrity of the attachment between the flap margin and the tooth cannot be easily disrupted. An appropriate soft tissue graft, which will include autogenous connective tissue

graft (CTG), acellular dermal matrix (ADM), or xenogenic collagen matrix (XCM), is inserted inside the tunnel.

VISTA offers a number of advantages, which include maintaining the integrity of mucosa and the periosteum to preserve their vascular supply intact. In the presence of a thin biotype, the full thickness dissection aids in maintaining flap coverage. The tension-free tunnel facilitates coronal advancement of the mucosal margin. To maintain the coronal position of the mucosal margins, a suture is placed and fixated to each tooth or restoration with flowable composite.

The patient depicted in Figure 34-9 presented with implant-supported restoration in the posterior mandible with minimal peri-implant keratinized mucosa, as well as coronal frenal attachments (see Figure 34-9, *A* and *B*). Despite thorough oral hygiene practice, as well as regular periodontal maintenance therapy, persistent mucosal inflammation was present at two years post-implant therapy (see Figure 34-9, *C* and *D*), Therefore, peri-implant mucosal augmentation was achieved using VISTA. Initial vestibular incisions were made anterior to each of the mandibular canines. Subperiosteal tunnels were created to beyond the most posterior implants. Two subepithelial connective tissue grafts were harvested from each side of the palate and placed within each mandibular tunnel. Because the main objective of the surgery was not to cover exposed implant components, the mucosal margins were not coronally repositioned (see Figure 34-9, *E* and *F*). Healing was uneventful and resulted in increased mucosal thickness with widened vestibular depth. However, the attached mucosa did not exhibit surface keratinization. The clinical images demonstrate improved mucosal health that was maintained at 4 years following soft tissue augmentation (see Figure 34-9, *G* and *H*). The clinical phenotype achieved by VISTA typically is characterized by nonkeratinized surface mucosa. This may be attributed to the fact that in VISTA, the connective tissue graft is subperiosteally placed. This leads to the formation of thicker attached tissue, which is devoid of frenal attachments. Therefore, it is usually not necessary to perform an additional frenectomy.

The patient in Figure 34-10 was referred because of concern for improper implant positioning. The implant had been placed too far facially and apically (see Figures 34-10, *A* and *B*). The optimal implant position is 2 mm palatal of the cervical contour of the restoration.[45] When the implant is placed facial of the recommended position, the likelihood of mucosal recession is increased.[46] Restoration of the implant in its current state would have led to an elongated restoration. The adjacent canine also exhibited a 3-mm gingival recession. Because the patient had a high smile line, this led to an unesthetic outcome. VISTA was used for soft tissue augmentation of the implant to add extra mucosal bulk and reposition its facial soft tissue margin to a more coronal level. Additionally, periodontal root coverage was attempted on the adjacent canine. The treatment began with replacement of the healing abutment on the implant with a cover screw (see Figure 34-10, *C*). The cervical root prominence of the canine was reduced by odontoplasty followed by root conditioning with 24% EDTA gel with neutral pH (Prefgel, Straumann, Andover, MA) for 3 minutes. A vestibular incision was made at the midline frenum and a subperiosteal tunnel was created that extended both in an apical direction and past the first premolar tooth (see Figure 34-10, *C*). Connective tissue grafts were harvested from the palate, as well as from the tuberosity (see Figure 34-10, *D*). The tuberosity graft was de-epithelialized ex vivo.

The tuberosity generally consists of dense fibrous connective tissue with fewer glands, less fat, and fewer blood vessels. As a result, the donor site is generally more comfortable postoperatively and bleeds less than the palate. Moreover, the sites augmented with the tuberosity graft exhibit less volumetric shrinkage than palatal CTG. The tuberosity CTG was positioned within the subperiosteal tunnel on the facial aspect of the implant, and the palatal CTG was used for augmentation of the adjacent canine (see Figure 34-10, *E* and *F*). The gingival margin of the canine was coronally repositioned using a 6-0 polypropylene suture, which was bonded to the tooth with flowable composite (see Figure 34-10, *G*). The mucosal margin of the implant was coronally repositioned. An all-resin Maryland bridge was used as the interim restoration with the pontic site relieved to allow room for expansion of the tissue during healing. Healing after 3 months revealed improvement of the keratinized mucosa in the vertical and horizontal dimension, resulting in a more esthetic appearance and lack of space between the implant and restoration (see Figure 34-10, *H*). During the restorative phase, a CAD/CAM zirconia restoration (Atlantis abutment, Dentsply Sirona Implants, Waltham, MA) was created (see Figure 34-10, *I* and *J*). The abutment was angled palatally and designed with as little material on the facial cervical area as possible. Following restoration of the implant, the dimensions of the restoration were symmetric with the contralateral tooth (see Figure 34-10, K and *L*). Complete root coverage was achieved around the canine (see Figure 34-10, *M* and *N*).

Conclusions

Evidence has clearly demonstrated that the quantity and quality of peri-implant mucosal tissues can influence not only the esthetics, but also the long-term stability of peri-implant bone and soft tissues. It is important to perform risk assessment for implants, which includes evaluation of the zone of keratinized mucosa, position of the implant, oral hygiene level, and esthetic requirements. Soft tissue augmentation may be considered for the following conditions:

- In the absence of a minimum of 2 mm of keratinized and/or attached peri-implant mucosa
- For implants positioned too far facially (i.e., beyond the recommended position of 2 mm palatal of the cervical contour of the restoration)
- When the patient is unable to perform adequate oral hygiene because of thin peri-implant mucosa
- In cases of high esthetic demand

A variety of therapeutic techniques and materials are available for soft tissue augmentation. These include application of free autogenous epithelialized or subepithelial connective tissue graft, as well as pedunculated vascularized connective tissue graft. Alternatives to the application of autogenous soft tissue include acellular dermal matrix and xenogenic collagen matrix. The decision for application of different tissues depends on the following factors:

- In the maxilla, where small or moderate volumes of augmentation are required, it is often possible to reposition palatal connective tissue to the facial aspect. Where correction of large contour defects is desired, VIP graft is very effective.
- In areas with low esthetic priority, epithelialized free gingival graft can be very effective in increasing the zone of keratinized mucosa and deepening the vestibule.
- The tuberosity provides effective donor tissue, which can achieve a large volume of soft tissue augmentation that remains stable over time.
- Where autogenous harvesting is not an option due to limited donor site availability, large volume of tissue required, or where decreased morbidity is desired, acellular dermal matrix or xenogenic collagen matrix are viable options.

In terms of methods of soft tissue augmentation, the traditional partial or full thickness flaps have many drawbacks, including compromised blood supply, scar formation, and increased morbidity. For these reasons, VISTA offers some advantages for introduction of graft tissues to sites to be augmented, including a single incision in a remote area from the therapeutic target, providing an effective access for creation of a tension-free tunnel, maintenance of intact mucoperiosteal complex, coronal repositioning, and fixation of sutures to allow for stability of the tissue level during healing.

Zygomatic Implant: A Graftless Approach for Treatment of the Edentulous Maxilla

EDMOND BEDROSSIAN, EDMOND ARMAND BEDROSSIAN JR, PER-INGVAR BRÅNEMARK

The edentulous maxillae has a unique anatomic presentation, which limits the number and the distribution of implants within the alveolar ridge. The maxillary sinuses bilaterally and the position of the nasal floor in the premaxillary region may limit the vertical volume of alveolar bone available for placement of implants in the maxilla for a fixed, implant-supported prosthesis. The palatal and posterior resorption pattern of the edentulous maxillae may also limit the horizontal bony volume necessary to house endosseous implants. Therefore, in review of the literature,[1] the recommended treatment for the edentulous maxilla has been the tissue-supported, overdenture appliance. To establish support for a fixed prosthesis, reconstruction of the maxilla with various bone grafting techniques has been designed to recreate the alveolar volume and topography needed for stabilization of dental implants.[2-5] If the sinuses are pneumatized, sinus grafting[6] or tilted implants[7-9] have also been recommended.

For patients with significant anterior extension of their maxillary sinuses into the bicuspid region, the zygomatic implant is recommended. The zygomatic implant allows for establishing posterior maxillary support by using the limited crestal alveolar bone in the bicuspid region and the os zygomaticum for establishing initial stability of the implant. The use of the zygomatic implant has been reported internationally with a success rate between 94% and 100%.[10-15]

The 94% survival, as reported by Branemark et al., represents three failures out of 52 zygoma fixtures placed in their initial study. The first failure was due to enveloping of muscle tissue around the zygoma fixture. The second involved the inadequate centering of the implant within the zygomatic bone. The third failure occurred in a patient with Paget's disease who had loosely textured and low density bone.[14] Overall, this highly predictable implant allows for establishing posterior maxillary support for reconstruction with a fixed prosthesis without the need for bone grafting.

Historical Perspective

The treatment of the moderately to severely resorbed maxillae presents a challenge for the implant surgical-restorative team. The typically large pneumatized sinuses in this group of patients require extensive bone grafting if conventional implant placement is envisioned. Various procedures have been available for treatment of the resorbed maxillae. Adell,[16] and Breine and Branemark[17] used composite grafts to provide a tooth anchorage system. Le Fort I osteotomy[18] and iliac block graft[19,20] have also been used to reestablish bony volume for placement of implants. To create bone mass in the posterior maxillae, sinus-lift grafting procedures[19-22] have been performed. Survival of implants in sinus-lift procedures was studied in the sinus consensus conference.[6] The conclusion reached was similar to Tolman's report in 1995: The material was so "multivariate and multifactorial that it was difficult to draw definitive conclusions; these must await controlled prospective studies."[23] Grafting of the maxillae with delayed implant placement has been described in the literature.[24] Rasmusson presented success with autogenous grafting to establish favorable topography of the resorbed maxillae for implant placement using inlay, onlay, and/or Le Fort I procedures.[25] A success rate of 80% was reported for grafting with delayed implant placement and 77% for grafting with simultaneous implant placement. The success rate of implants placed in nongrafted bone was only 89% in the group studied. Keller et al., who used inlay grafts in their report on the reconstruction of the compromised maxillae,[24] reported an 87% implant survival rate and a prosthetic survival of 95%. The somewhat limited success with these adjunctive procedures has deterred patients from seeking reconstruction of their resorbed maxillae. An alternative for the treatment of

this group of patients is the zygomatic implant, which was introduced by Professor Brånemark in 1988.

Patient Selection

A systematic preoperative evaluation of the patient is required before the surgical treatment.[45] Both surgical and prosthetic needs must be considered before initiation of the surgical treatment to allow for a predictable outcome. The preoperative evaluation protocol takes into consideration the available alveolar bone in the different zones of the maxilla (Figure 35-1). It also determines whether the final prosthesis is a ceramometal bridge or profile prosthesis.[26] The determination is based on the lack or the presence of composite defect.[12] Evaluation of the esthetics of the final prosthesis is made by recognizing the transition line between the prosthesis and the residual edentulous crestal soft tissues (Figure 35-2). The zygomatic implant is considered in the group of patients who demonstrate bone in zone 1 only. In patients who also have limited horizontal alveolar width in zone 1, veneer grafting[27] before placement of the conventional implants for the anterior support is considered. A separate group of patients with advanced maxillary alveolar atrophy present with complete lack of the alveolus. This group may be candidates for the quad zygoma treatment concept (Figure 35-3).[14] The surgical procedure may be performed in the hospital setting using general anesthesia or in the office under IV sedation and local anesthesia.[12] The surgical candidate should be free of any sinus disease before consideration for this treatment concept.

Radiographic Evaluation

Although computerized and conventional tomography can be used, the Panorex radiograph is critical in the initial evaluation of the patient.[12,13,15] The presence of alveolar bone in the premaxilla (zone 1) and the lack of bone in the bicuspid and the molar regions, zones 2 and 3 respectively, are the indications for considering the zygomatic concept. Axial CT scans can be obtained to further evaluate the maxillary sinus. The width of the residual alveolar bone and the width and height of the zygomatic body can be visualized in frontal reformatted sections of the axial CT scans.

Further evaluation of the zygomatic bone has also been described.[27] Although not absolutely necessary, the reformatted frontal images in 2- to 3-mm cuts afford the less experienced operator more information for planning the

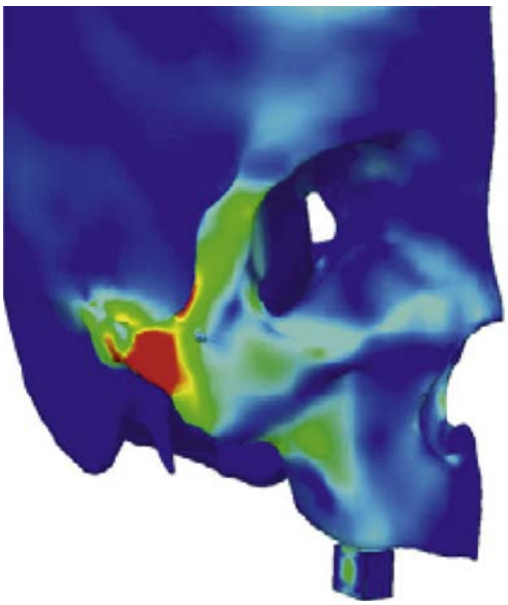
surgery (Figure 35-4). The presence of sinus pathologic conditions including, but not limited to, thickening of the schneiderian membrane and air fluid levels, may be ruled out in both the Panorex and tomographic studies.

Os Zygomaticum: Regional Anatomy

The quantity and the quality of the zygomatic bone have been studied and reported by Nkenke et al.[27] The morphology and the microstructure of the os zygomaticum were assessed by quantitative computer tomography and histomorphometry. Bone mineral density of 30 human zygomatic bone specimens was studied. The trabecular bone mineral density, the trabecular bone volume, and the trabecular bone pattern factor were correlated with each other. The conclusion reached suggested that the trabecular bone of the os zygomaticum was not a favorable site for implant placement. However, Nkenke further suggests that the success seen with the zygomatic implant is due to the engagement of four cortices during the placement of the implant. The lingual cortex of the maxillary alveolus along with the cortical floor of the maxillary sinus provide for bicortical stabilization at the crestal portion of the implant. The superior-lateral portion of the roof of the maxillary sinus is formed by the inferior portion of the zygomatic bone. This portion of the zygoma along with its lateral superior cortical covering form the bicortical stabilization at the apical portion of the zygomatic implant.

To quantify the dimensions of cortical and trabecular bone of the os zygomaticum, morphometric analysis of the zygomatic bone was consistent with the following results: mediolateral dimension of 7.6 mm in males and 8.0 mm in females. The anterior-posterior dimension of the zygoma body was 25.4 mm in males and 24.9 mm in females. The lateral cortical thickness was 1.75 mm in males and 1.71 mm in females. The length of the zygomatic implant within the zygomatic bone was 16.5 mm in males and 14 mm in females. Zygomatic implants placed following ablative surgery have been reported by Weingart et al.[28] The implant survival rate was 65% to 75%. However, with the increased popularity of the zygomatic implant used in the atrophic maxilla, implant survival has increased to 97% to 100%.[10-15]



• **Figure 35-5** Ujigawa model demonstrating the load-bearing zygoma bone.

Primary Load-Bearing Bone Under Function

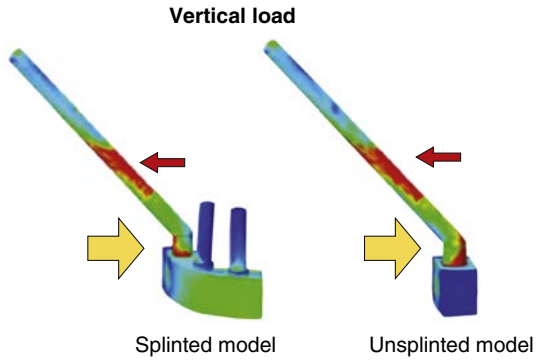
The indication for the placement of the zygoma implant is lack of bone in zones 2 and 3 (bicuspid and the molar region, respectively). For patients where the zygoma implant is considered there is less than 1 mm of residual maxillary alveolar bone remaining in the bicuspid and molar regions. Therefore, after placement of the zygoma implant, minimal bone to implant contact is achieved at the alveolar crest. Knowing that bone to implant contact (BIC) is limited at the maxillary crest, the question becomes: how important is BIC at the maxillary crest in distribution of the occlusal forces? Is there a benefit for having crestal maxillary bone at the implant platform?

Ujigawa and colleagues,[46] in an elegant finite element analysis, described the weight-bearing bones associated with the use of the zygoma implant. In their 2007 Finite Element Analysis paper, they reported that the zygoma bone, and not the maxilla, supports the simulated occlusal loads (Figure 35-5). However, in 2013 and 2015, Freedman et al.[47,48] corrected the observation in the Ujigawa study. The highlighted area over the lateral cortex of the zygoma reported as the load-bearing area in the Ujigawa study was instead the origin of the masseter muscle under activation. Freedman et al. demonstrated in their papers that the maxillary crest plays a role in the distribution of the occlusal loads and the preservation and the anchoring of the implant in the maxillary crest is recommended.

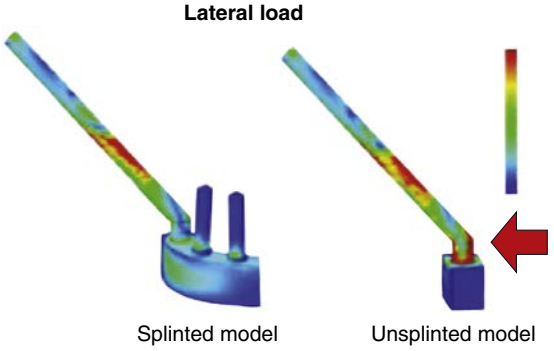
Deformation Under Function

In the Ujigawa study the prosthetic loads were considered using two different models. Each model had two zygoma implants, one in each posterior quadrant as well as two anterior maxillary implants. The difference was that in the first model, the implants were rigidly cross-arch splinted whereas in the second model all implants were lone standing without any cross-arch splinting under function.

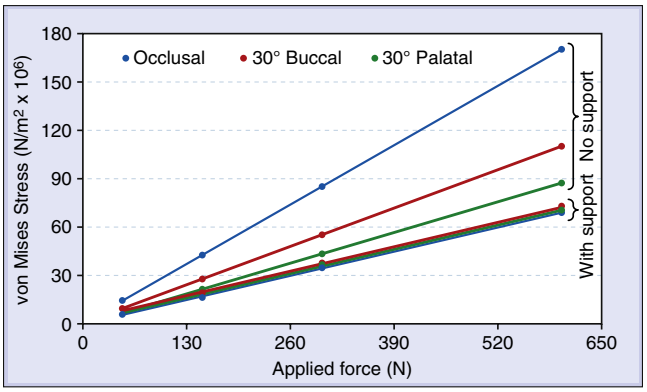
When both models were subjected to simulated occlusal loading (centric occlusion), there were two areas that were identified as load bearing along the implant: the abutment-implant platform interface *(yellow arrow)* and the mid-portion of the implant *(red arrow)* (Figure 35-6). In the unsplinted model, the magnitude of the loads was significantly higher than in the splinted model. Significant increase in the magnitude of the load distribution pattern was seen in lateral excursions with the highest loads seen in the unsplinted zygoma implant model which can lead to stress fractures at the neck of the zygoma implant *(red arrow)* (Figure 35-7).



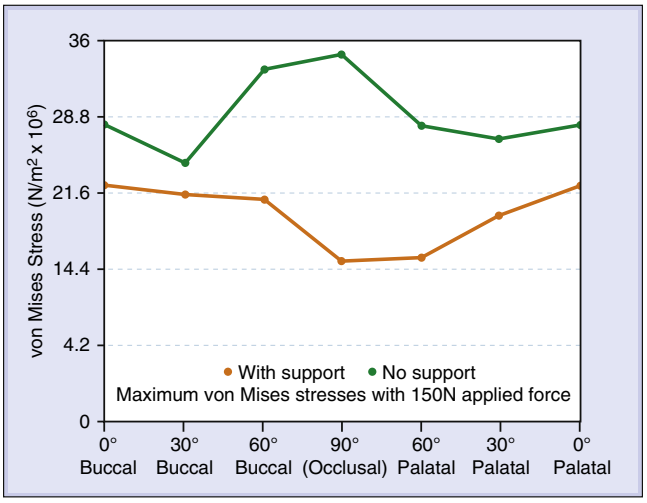
• **Figure 35-6** The *arrows* indicate two areas of stress under occlusal loading.



• **Figure 35-7** The unsplinted model demonstrates concentration of stress at the neck of the implant and the abutment as shown by the *red arrow*.



• **Figure 35-8** Zygoma implants with lack of crestal bony support demonstrate increased stress under load.



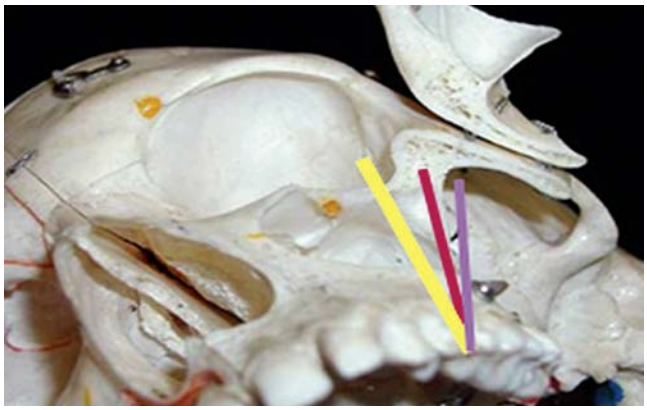
• **Figure 35-9** Maximum von Mises stress (N/m² × 10⁶) for models with and without alveolar support.

Past clinical reports[32] support the observation in this study highlighting the importance of cross-arch splinting zygoma implants with other stable implants within the arch to allow for a more favorable force distribution.

In 2013, the objective of the Freedman et al. study[47] was to investigate the influence of maxillary alveolar bone on the stress distribution of zygomatic implants. Two study models were created. The first model had the zygomatic implants placed in the skull supported by the zygoma and the maxillary alveolar bone with rigid cross-arch stabilization by a fixed bridge. The second model duplicated the first model, however, the area of the maxillary alveolar bone supporting the zygomatic implants was removed. Occlusal and lateral forces were applied to both models and the maximum von Mises stresses were recorded. In the model lacking alveolar support higher maximum stresses were noted. Occlusal stresses were higher than lateral stresses in the model with no alveolar support. The zygoma bone demonstrated low stresses in both models. Therefore, the authors concluded that the maxillary alveolar bone support is beneficial in the distribution of forces for zygomatic implants.

In 2015, Freedman et al.[48] addressed the extra-sinus placement of the zygoma implant. The first model had two zygomatic implants placed in the skull in an extra-sinus position connected by a rigid cross-arch splinted bridge. The second model was the duplication of the first with the area of the maxillary alveolar bone supporting the implants removed, which is an inherent consequence of this type of implant placement. Occlusal and lateral forces were applied with higher maximum stresses noted in the model with no alveolar support (Figure 35-8). Occlusal stresses were higher than lateral stresses in the model with no alveolar support (Figure 35-9). Occlusal stresses were lower than lateral stresses in the model with alveolar support. Low stresses were noted in the zygomatic bone in both models. They concluded that, "Maxillary alveolar bone support is beneficial in the distribution of forces for zygomatic implants placed in an extra-sinus position."

It is important for surgeons to recognize that there is a single trajectory of the zygoma implant as described by the ad modum Brånemark technique. It is also important to recognize that Aparicio[49] has described the relationship of the zygoma implant to the varying anatomy of the lateral maxillary wall; the trajectory of the zygoma implant does not change regardless of the maxillary anatomy being ZAGA 0 or ZAGA 4. The zygoma implant is recommended when there is less than 2 to 3 mm in zones 2 and 3. Under function and in time, the minimal crestal bone may resorb. However, it is prudent to follow the ad modum Brånemark

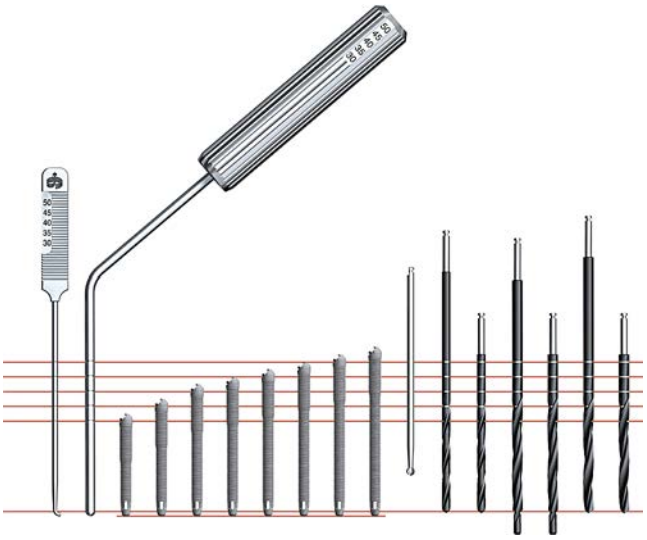


• **Figure 35-10** Axis of zygoma implant. (From Bedrossian E: *Implant treatment planning for the edentulous patient,* St Louis, 2011, Mosby.)

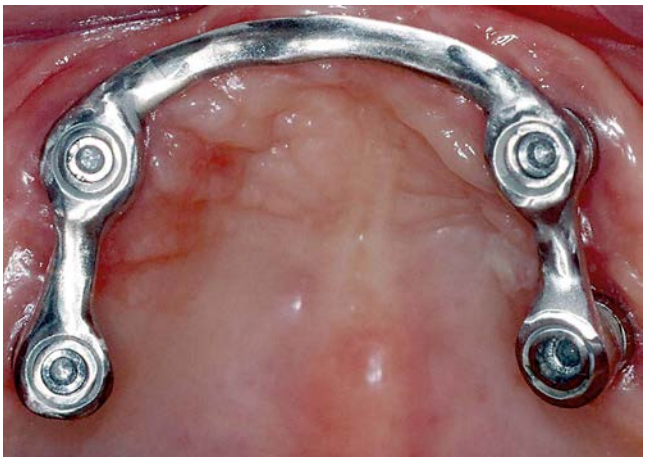
technique to allow initial stabilization of the implant as well as better force distribution as described by Freedman and co-workers.

Preoperative Considerations

The surgical procedure is usually performed in the office setting under IV sedation.[12] All patients are premedicated 1 hour before the surgical procedure. The proper administration of sufficient local anesthesia is critical in the management of these patients under IV sedation. The various infiltrations and nerve blocks include circumvestibular infiltration of the maxilla, greater palatine blocks, and bilateral transcutaneous infiltration of the temporal areas over the zygomatic body. Bilateral inferior alveolar nerve blocks are considered to allow retraction of the lower jaw during the surgery without undue stimulation of the sedated patient. It is recommended that the path of the implant from the premolar area to the base of the zygoma be directly visualized whenever possible.[12,30] Direct visualization of the base of the zygomatic body has also been advocated in clinicians who have used computer-assisted treatment planning and surgical templates for placement of the zygomatic implant.[30] Having a clear view of the path of the instruments needed in establishing the osteotomy and visualizing the path of the implant during its insertion prevent disorientation and potential complications associated with placement of the zygomatic implant. Generally, three potential axes of insertion are possible. The proper axis is a path extending from the bicuspid region through the maxillary sinus, entering the midportion of the zygomatic body. If the entry point in the zygomatic body is more anterior to this line axis, potential for penetration into the orbit exists. However, if the line axis is posterior to this line, the potential for entering the pterygomaxillary space, leading to soft tissue enveloping and the subsequent lack of osseointegration of the implant, along with the potential for unexpected hemorrhage exists (Figure 35-10). The zygomatic implant has a unique design. The diameter of the apical two thirds of the implant is 4.0 mm, yet the alveolar one third widens to a diameter of 5.0 mm. The zygomatic implants are available in lengths ranging from



• **Figure 35-11** Implant and available drill sizes. (From Bedrossian E: *Implant treatment planning for the edentulous patient,* St Louis, 2011, Mosby.)



• **Figure 35-12** Cal bar stabilizing implants at stage II surgery. (From Bedrossian E: *Implant treatment planning for the edentulous patient,* St Louis, 2011, Mosby.)

30 to 52.5 mm. A specialized series of long zygoma drills are used to prepare the osteotomy (Figure 35-11).

Surgical Options

In reconstruction of the edentulous maxilla with the zygomatic implant, the traditional two-stage protocol[10,12,29] or the immediate-load protocol[12,30] may be considered. The two-stage protocol requires the immediate cross-arch splinting of the zygoma implants at the time of the uncovering procedure. This can be accomplished efficiently by using the Cal technique (Figure 35-12) for the fabrication of a passive bar before the uncovering procedure.[32] However, the alternative immediate-load technique cross-arch splints the zygomatic implants with each other by conversion of the patient's existing denture into a fixed provisional bridge. The immediate loading of the zygomatic implants has been reported in the literature with favorable results.[26,30]

Surgical Protocol

The surgical procedure begins by making a crestal incision across the edentulous maxillary arch. Bilateral releasing incisions are made over the maxillary tuberosity, similar to the hockey stick incisions for removal of maxillary wisdom teeth. A vertical window is made on the lateral wall of the maxilla paralleling the junction of the posterior aspect of the lateral maxillary wall and the lateral aspect of the posterior maxillary wall accessing the sinus (Figure 35-13). The schneiderian membrane may be removed or reflected away from the inside of the lateral wall of the maxillary sinus (Figure 35-14). It is critical to be aware of the position of the schneiderian membrane and to ensure that it does not attach to the zygomatic implant during its insertion into the body of the zygoma. Introduction of the soft tissue schneiderian membrane into the body of the zygoma will lead to nonosseointegration of the zygomatic implant.

The osteotomy is initiated by the use of a round bur (Figure 35-15) followed by a 2.9-mm twist drill (Figure 35-16). A 2.9- to 3.5-mm pilot drill stabilizes the 3.5-mm drill, which completes the osteotomy both at the maxillary crest and the body of the zygoma (Figure 35-17). If greater than 3 mm of crestal bone is identified, the alveolar portion of the osteotomy is completed by introduction of the 4.0-mm twist drill. In cases where there is a limited crestal bone width and or height, the 4.0-mm drill is not used. Before implant placement and at all times during preparation of the osteotomy (Figure 35-18), the entire surgical paths of the drills are visualized.[12,30]

The 45 degree angulations of the zygomaticus implant (Figure 35-19) allow for the platform of the implant to be in the same plane as the vertically placed implants in the premaxilla. To facilitate implant placement, the premounted implant carrier allows for easy handling of the implant with the straight zygomatic handpiece (Figure 35-20). To ensure proper orientation of the angulated implant head, the premounted fixture carrier screw head is used as a guide. Once the zygoma implant is placed to the proper depth a "stargrip" screwdriver is inserted into the head of the fixture screw, which secures the implant carrier to the 45 degree zygoma implant platform (Figure 35-21).The shaft of this

screwdriver must be at right angles to the edentulous ridge to ensure proper orientation of the implant platform.

A minimum of two premaxillary implants are required (Figure 35-22).[33] If four implants can be distributed evenly within the premaxilla (zone 1), it may be considered. In the two-stage protocol where both the premaxillary and the zygomatic implants are submerged, single-thread NobelSpeedy Groovy (Nobel Biocare, Goteborg, Sweden) implants have been used. However, in cases where immediate loading is considered, the double-thread NobelSpeedy implants (Nobel Biocare, Goteborg, Sweden) have been used. The zygomatic implant is an external hex implant. The use of the external hex premaxillary implants is recommended to maintain uniformity and ease during the restorative treatment. All immediate premaxillary implants were placed with an initial insertion torque setting of 20 Ncm. Upon "stalling" of the handpiece, the insertion torque setting is increased to 40 Ncm, allowing complete insertion and seating of the implants. The "onion" hand insertion instrument (Figure 35-23) is used in cases where the handpiece stalls at the 40 Ncm setting. The zygomatic implant is hand driven to its final insertion depth, where the implant platform is intimately in contact with the lateral wall of the maxillary alveolus. The criteria for the immediate loading of the premaxillary implants and the zygoma implants include a minimum of 40 Ncm of insertion torque.[26]

The surgical wound is closed using 4-0 Vicryl sutures in cases where the implant surgery was performed in the

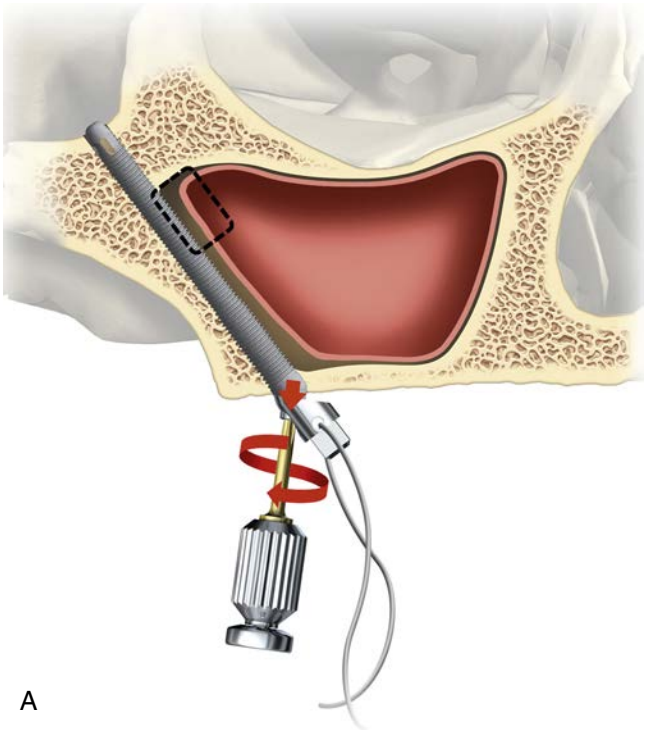
two-stage manner. The denture base over the gingiva covering the platform of the zygomatic implants is relieved to prevent loading and wound breakdown. In patients who received immediate provisional fixed prostheses, 3-0 gut is used to close the soft tissue wound, and their existing full denture is converted to the immediate provisional fixed prostheses by the use of multiunit abutments and titanium temporary cylinders (Figure 35-24).

The Trajectory of the Zygoma Implant

Preparing the trajectory of the osteotomy for placement of the zygomatic implant is a critical step. Orientation of the proper trajectory may take several attempts by the surgeon. Once the trajectory of the osteotomy, hence the implant, is established, the steps needed to complete the osteotomy are readily achieved.

The platform of the zygomatic implant is generally in the second bicuspid or the mesial half of the first maxillary molar. The initial drill enters the maxillary sinus through the crestal osteotomy. Its path is directly visualized through the bony window established through the lateral wall of the maxillary sinus. The goal is for the round drill to create a small indentation in the roof of the maxillary sinus allowing for the purchase of the 2.9 mm twist drill. Once the round drill enters the floor of the sinus, it travels through the maxillary sinus and its apex exits at the front zygomatic notch.



• **Figure 35-21** **A,** Confirming orientation of the zygoma implant platform. **B,** Platform of the zygoma implants in same plane as premaxillary implants. (From Bedrossian E: *Implant treatment planning for the edentulous patient,* St Louis, 2011, Mosby.)

• **Figure 35-23** The onion driver. (From Bedrossian E: *Implant treatment planning for the edentulous patient,* St Louis, 2011, Mosby.)

The shaft of the round drill is immediately parallel to the posterior wall of the maxilla (Figure 35-25).

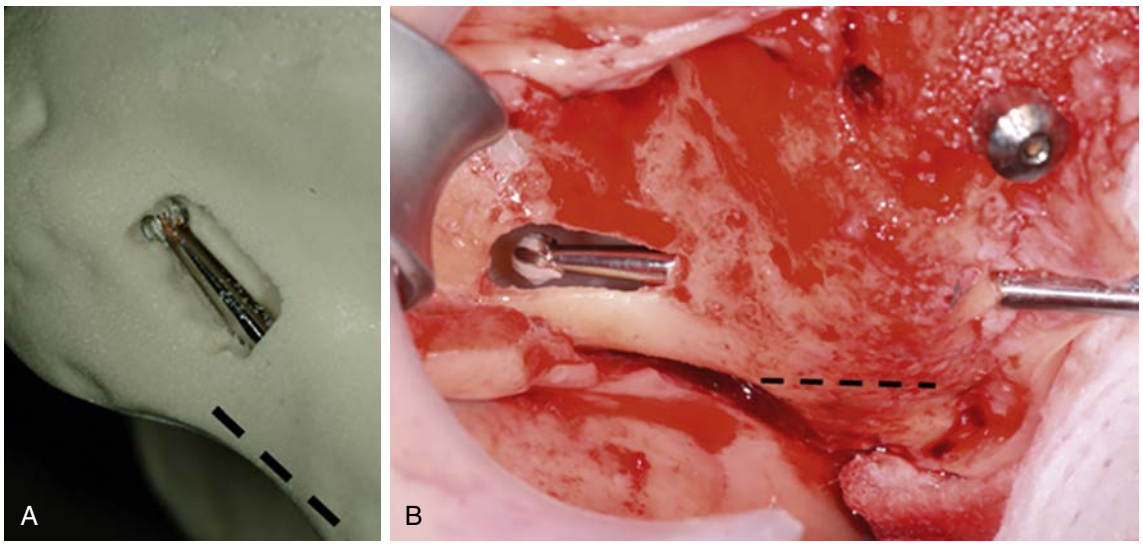
In order to achieve this trajectory—the ad modum Brånemark technique[31,32]—the lateral maxillary wall needs to be studied. After exposing the posterior maxillary alveolar ridge and the lateral wall of the maxilla, the distal portion of the lateral maxillary wall as it turns medially to form the posterior maxillary wall needs to be identified. This is a vertical "corner" of the posterior portion of the maxillary sinus as represented with the black dotted lines in Figure 35-26. By following this trajectory, a "quad-corticalization" of the zygoma implant is achieved. Once the implant has been fully seated, its proper trajectory is confirmed by the distal portion of the zygomatic implant body being immediately adjacent to and in intimate contact with the posterior wall of the lateral maxillary wall (Figure 35-27).

Aparicio in 2011 described the various relationships the midportion of the zygoma implant may have with the lateral maxillary wall.[49] The lateral maxillary wall may be "straight" or "concave." If it is concave, then a portion of the midshaft of the zygoma implant may be "outside" the maxillary sinus. The classification described by Aparicio is ZAGA 0 (straight lateral maxillary wall with the midportion of the zygoma implant inside the sinus) to ZAGA 4, which is the most extreme resorption of the maxillary sinus where the midportion of the implant is "outside the maxillary sinus" due to lack of bone. The authors emphasize that the trajectory of the osteotomy for the placement of the zygoma implant is to be followed as described by Professor Brånemark, regardless of the intra- or extra-sinus relationship of the midportion of the implant (Figure 35-28, *A*). The surgeon must appreciate that the presence of the midportion of the implant directly beneath the vestibular depth may lead to erosion of the mucosa and exposure of the implant shaft (Figure 35-28, *B*). A limited number of case reports have been published for the management of these exposures.[50,51] In extreme cases such as ZAGA 3, ZAGA-4, or in cases of total or partial maxillectomy, the zygoma implant will be immediately below the soft tissues of the vestibule and the occurrence of soft tissue dehiscence cannot be prevented. In all other cases, attempts should be made to place the midportion within the sinus following the Brånemark protocol. The inclusion of the buccal fat pad graft either at time of the initial surgery or as a "preventative" measure against soft tissue dehiscence only adds unnecessary morbidity for the patients. Therefore, it is the recommendation by the authors to continue the ad modum Brånemark technique as described earlier in order to minimize the long-term response of the soft tissues.

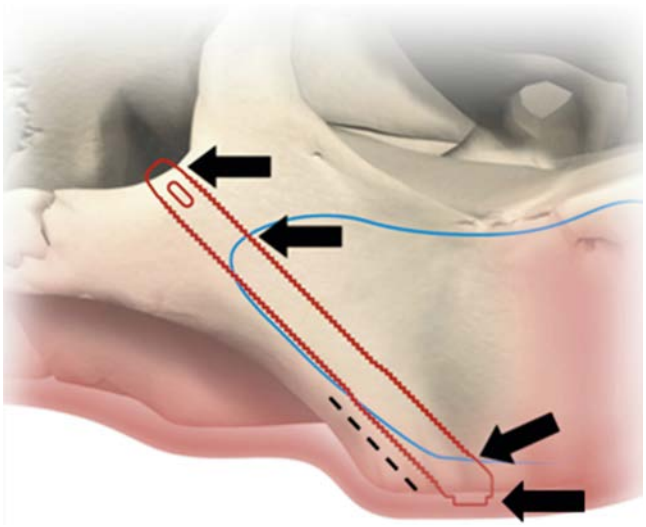
• **Figure 35-24** Temporary titanium cylinders. (From Bedrossian E: *Implant treatment planning for the edentulous patient,* St Louis, 2011, Mosby.)

Prosthetic Conversion Technique

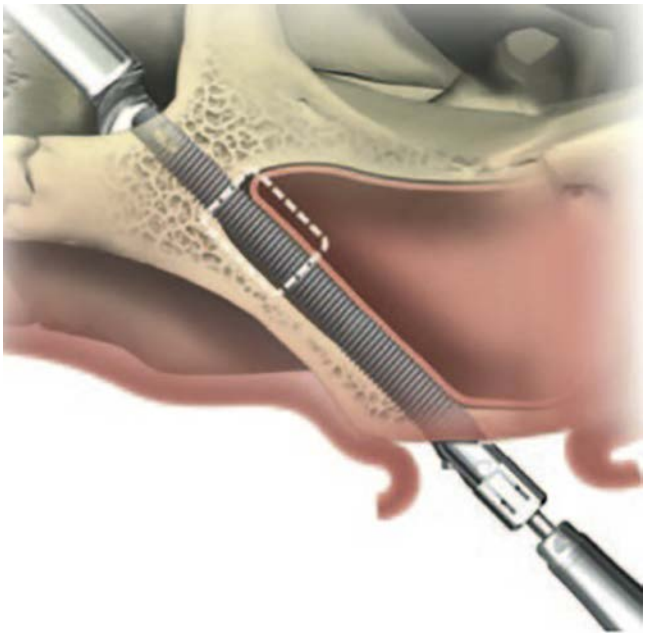
To provide the surgical patient with a fixed provisional prosthesis immediately following the surgical procedure, conversion of the patient's existing full denture or the



• **Figure 35-25** Lateral **(A)** and inferior **(B)** view of the model with holes around the coronal portion of the implants, removing extra support from the alveolar bone.



• **Figure 35-26** The shaft of the round drill parallels the *"black dotted line"* which represents the lateral-posterior corner of the maxillary sinus.

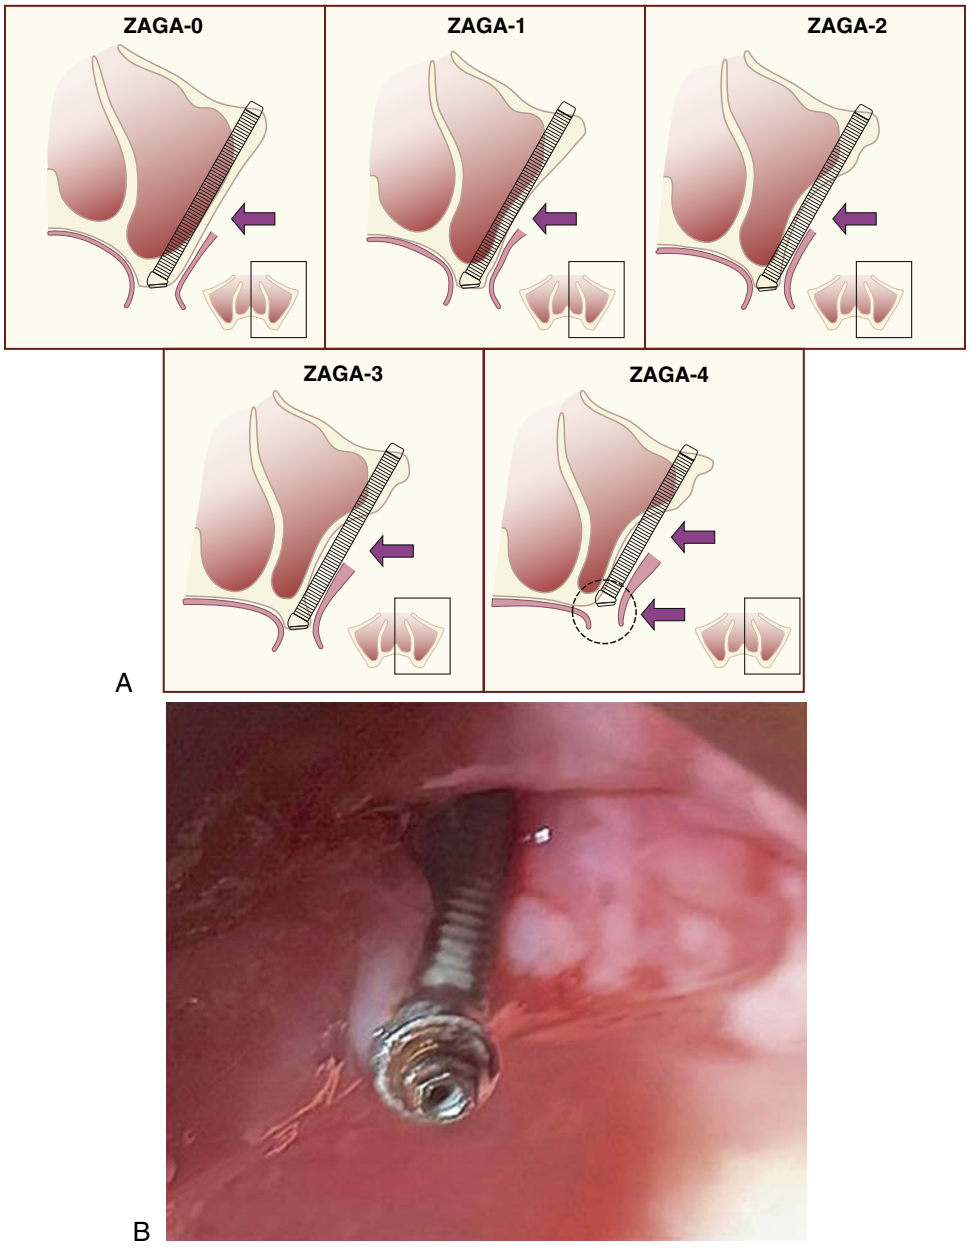


• **Figure 35-27** Ad Modum Brånemark Trajectory of the zygoma implant.

conversion of the newly fabricated immediate denture is undertaken.[26,37] The preoperative denture should be at the proper vertical dimension of occlusion (VDO) and proper tooth position.[34-36] Once the implants have been placed with 40 Ncm insertion torque, healing abutments are connected. The heights of the healing abutments are chosen so that after suturing of the crestal incision, 1 mm of the healing abutment is above the soft tissue line. The patient's denture is adjusted to allow passive seating without interference from the healing abutments and distortion of the soft tissues. Blue mouse bite registration is flowed into the denture as it is seated in the mouth, ensuring proper occlusion with the apposing dentition and proper midline orientation. The positions of the healing abutments are imprinted into the blue mouse as it sets (Figure 35-29). An acrylic bur is used to perforate the denture base, marking and relating the positions of the implants with the denture acrylic. Care must be taken not to make excessive holes or to fracture the denture base. The denture with the prepared holes is once again seated in the mouth in the proper position. Relating the position of the temporary healing abutments to the holes in the denture base allows one to determine whether straight, 17 degree, or 30 degree abutments will be used for the fabrication of the screw-retained provisional profile prosthesis. Once the abutments are chosen and seated onto the implants, reconfirmation of the screw access holes is made by proper seating of the denture in the patient's mouth. The abutments are torqued to 35 Ncm (Figure 35-30). To fabricate this fixed prosthesis, temporary multiunit titanium cylinders are used (Figure 35-31). The temporary titanium cylinders are cold cured to the denture base using quick-setting denture repair acrylic (Figure 35-32). Upon hardening of the acrylic, the denture is removed from the patient's mouth by unscrewing the retaining screws. The voids on the tissue surface of the denture base, around the temporary titanium cylinders, are further reinforced with the quick-setting acrylic, ensuring that no acrylic is introduced into the seating surfaces of the cylinders (Figure 35-33). The palate and the denture flanges are removed. Recontouring of the acrylic on the undersurface of the prosthesis is completed in an attempt to remove all concavities, which may trap food. The patient's occlusion is checked, ensuring group function and uniform loading across the entire prosthesis in centric occlusion.[38,39] To avoid bending moments, as close as possible to 0 degree teeth are used in the fabrication of this provisional prosthesis. A temporary material of choice is used to cover the retaining screw holes (Figure 35-34).

Postoperative Care

Patients are asked to maintain a soft diet. Incising of food is discouraged for the first 3 months. Postoperative medications include oral antibiotics for 1 week and an analgesic of choice, as needed. All patients are asked to use 2% chlorhexidine rinse 20 minutes before sleeping every night. A 1-week follow-up appointment is made to ensure proper occlusion, wound healing, and stability of the prosthesis. If screw loosening is encountered, occlusion is checked, eliminating hyperocclusion on selected areas and interference in lateral excursions. Patients are seen as needed over the next 6 months. Bruxism on occasion will result in the fracture of the provisional prosthesis. The prosthesis may be repaired intraorally or indexed and removed for a laboratory repair at the fracture site. The use of night guards made for the provisional prosthesis and the continual use of a new night guard made after the fabrication of the final definitive prosthesis may aid in management of the excessive forces generated by this group of patients.



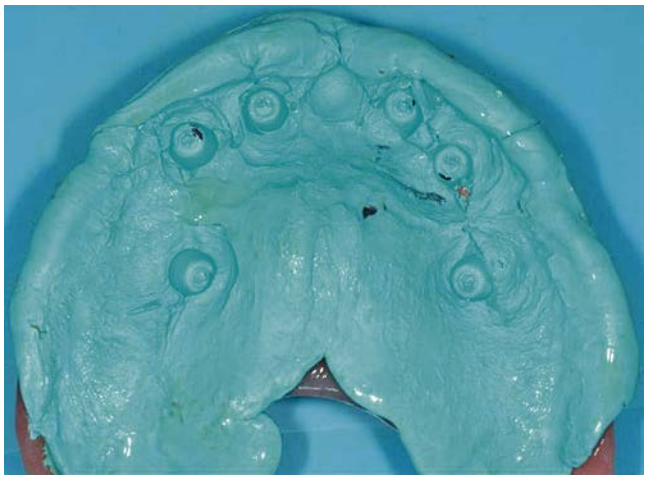
• **Figure 35-28** **A,** ZAGA classification, describing the relationship of the midportion of the implant to the lateral maxillary wall. **B,** The potential for soft tissue breakdown and exposure of the implant is possible in ZAGA 4 cases as well as when following the extra-maxillary technique.

Surgical Complications

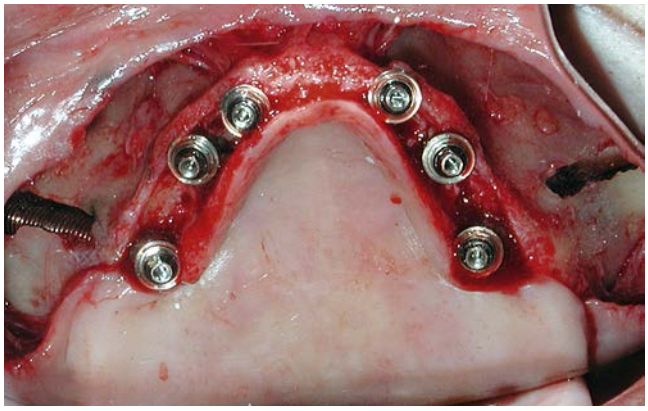
Potential complications include penetration of the orbit and the pterygomaxillary space. Inability to place the zygomatic implant in patients with abnormal anatomy secondary to congenital deformities, trauma, and postcancer resection cases has been reported.[40] Several authors have reported on complications with the zygomatic implant and its management.[15,40,41] Potential complications include soft tissue irritations around the abutment connection with the zygomatic implant,[15,41] which were corrected by minor soft tissue procedures. Delayed acute sinusitis was reported by Aparicio[15] 14, 23, and 27 months after surgical procedures. These infections were resolved following oral antibiotic regimens without further complications. Bjorn Peterson reported on foreign bodies in the nose and the maxillary sinus[55] (Figure 35-35). One-year follow-ups of 14 patients, using an endoscope for rhinoscopy and sinoscopy, determined no signs of infection or inflammation in the mucosa around the fixtures.[29]

Management of Sinus Infections

Delayed sinus infections, 3 to 5 years postoperatively, have been reported by Aparicio et al.[15] The majority of sinus infections are reported as being unilateral (Figure 35-36). The maxillary sinus drains via the osteomeatal complex (Figure 35-37). The opening of the sinus into the nose is



• **Figure 35-29** Imprint of implant positions. (From Bedrossian E: *Implant treatment planning for the edentulous patient,* St Louis, 2011, Mosby.)



• **Figure 35-30** Multiunit abutments seated. (From Bedrossian E: *Implant treatment planning for the edentulous patient,* St Louis, 2011, Mosby.)

simply a bony orifice lined by mucosa. The size of the bony orifice is consistent and free of any congenital malformations measuring 2.4 to 4 mm in diameter.[52] However, the incidence of hyperactive mucosa overlying the bony opening may be congenital.

Triggered by various allergens, the mucosa overlying the ostium may become hyperactive and block the path of drainage from the maxillary sinus.[53] In cases of acute episodes of sinus allergy or infection, simple oral measures such as prescribing Mucinex for thinning the mucosa, Sudafed to decrease the edema within the mucosa and antibiotics, Augmentin, for the first episode and Levaquin for recurring episodes, may be prescribed. However, if the infection does not resolve, functional endoscopic sinus surgery (FESS) is indicated[53,54] (Figure 35-38). The authors have not experienced the incidence of bilateral sinus infections; infections seem to be unilateral, affecting the maxillary sinus and at times the ipsilateral ethmoid sinuses and on very rare occasion the ipsilateral frontal sinus. The "acceptance" of the zygoma implant within the maxillary sinus has been reported favorably in the past.[55] Therefore, the authors agree

with Petruson's report in 2004 that the zygoma implant is not the cause of the sinus infections and does not act like a foreign body. It is strongly recommended that surgeons placing the zygoma implant understand and communicate this information with their otolaryngology colleagues.

Neurosensory disturbance of the zygomaticofacial nerve has been reported as a result of commonly encountering this nerve during the soft tissue reflection over the lateral aspect of the zygomatic body.[42] Failure of one immediate-load zygomatic implant has been experienced by this author. The failed zygomatic implant was noted at initiation of the

fabrication process for the final prosthesis. The zygomatic implant rotated during a reverse torque test. This was corrected by the simultaneous removal of the one failed zygomatic implant and placement of a new zygomatic implant immediately below the existing failed osteotomy site. The new zygoma implant was immediately loaded by connecting

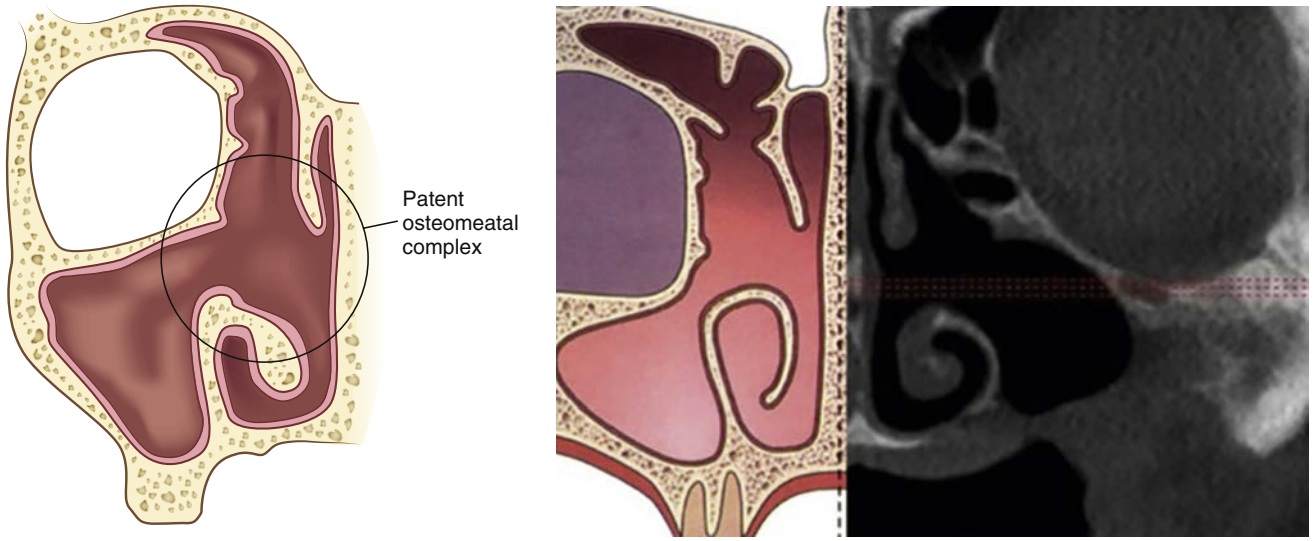
it to the existing provisional prosthesis. After an additional 6-month osseointegration period, all implants were stable, and the final profile prosthesis was completed.

Final Prosthesis Fabrication

After 6 months of osseointegration time, the prosthesis is removed and the stability of the implants is checked. Osseointegration is confirmed by observation of the lack of mobility of the implants and the lack of sensitivity during percussion. Fazad et al.[43] measured implant stability using Osstell (Integration Diagnostics, Savedalen, Sweden). Resonance frequency analysis showed mean ISQ values for the premaxillary implants and zygomatic implants to be 61.6 (range 48 to 71) and 65.9 (range 42 to 100), respectively. Aparicio et al.[15] used the Periotest (Siemens AG, Bensheim, Germany) measurement values, which compared favorably with previously reported measurements of osseointegrated implants. Zwahlen et al.[40] used the reverse torque



• **Figure 35-38** Completed functional endoscopic sinus surgery (FESS) procedure.

technique (10 Ncm) at the second-stage surgery, 6 months after placement of the implants, to determine osseointegration. Upon determination of osseointegration, the patient is ready for either the fabrication of an all-acrylic profile prosthesis[44] or a metal-based and acrylic profile prosthesis using resin teeth.

Summary

The zygomatic implant is a predictable fixture to establish posterior maxillary support for a fixed, implant-supported maxillary prosthesis without the need for bone grafting. In the hands of experienced surgical and prosthetic teams, the zygomatic implant is a viable addition to existing treatment modalities. The implant may be used in either the two-stage protocol or the immediate-load protocol with favorable long-term stability.

Fixed Restoration of the Edentulous Maxilla

MAMALY RESHAD, SAJ JIVRAJ

Introduction

Implant rehabilitation of the edentulous maxilla continues to challenge from a surgical and prosthodontic perspective. However, with proper planning, communication, and execution, these treatments can be highly rewarding and predictable. Difficulties tend to arise from a number of complex situations affecting both the esthetic and functional aspect of the prosthesis.[1] Among the prosthetic designs used to treat the edentulous maxilla are fixed or removable implant-supported restorations. Because the esthetic requirements and preoperative situation of each patient vary, considerable effort must be exercised in accurate diagnosis and planning to ensure that patient needs are met and predictable outcomes are achieved. The purpose of this chapter is to identify key diagnostic factors and compare treatment options and contemporary prosthetic designs for the edentulous maxilla.

With careful consideration given to diagnosis and treatment planning, criteria will be specified to guide the practitioner in deciding what type of prosthesis should be offered to each patient. This objective can be achieved by reviewing various patient cases with regard to changeable design considerations and factors influencing the decision-making process. An overview and introduction of an esthetic classification system and material selection for definitive fixed prosthesis will be presented.

As in all phases of dentistry, diagnosis is critical in obtaining an anticipated outcome. An incomplete or erroneous diagnosis can generate inferior results.

The initial phase in understanding how to restore the edentulous maxilla is to recognize the resorption patterns in this arch. The maxilla does not resorb evenly, nor do all edentulous patients go through the same morphogenic changes.[2] So, one must analyze each patient critically and tailor the restoration to the individual arch. The end result must be clearly visualized from the outset of treatment and communicated with all treatment providers involved.

When evaluating the resorption of the maxilla after tooth loss, the following issues in particular must be considered, as they will affect treatment planning:

1. Subsequent to the loss of all anterior maxillary teeth, horizontal bone resorption is almost twice as pronounced as vertical resorption (Figure 36-1).[2]
2. 65% of all maxilla arches examined were ovoid (Figure 36-2), 25% were triangular, and 10% were irregular.[3]
3. An unquantified number of edentulous patients display their entire maxillary ridge with a high smile (Figure 36-3).

Diagnosis

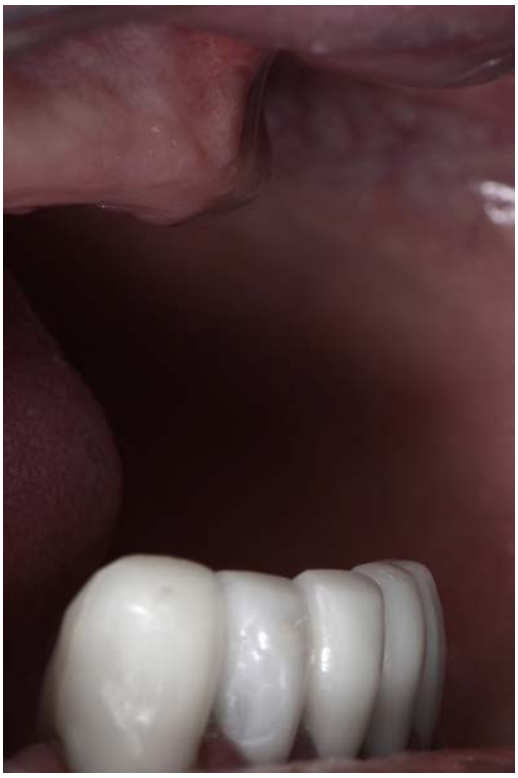
The decision-making constraints when rehabilitating patients require the clinician to decide whether a fixed or a removable prosthesis would be more fitting. Several designs can be used to restore patients.

With overdenture-type designs, one can obtain support from both the implants and the mucosa; in the presence of an adequate number of dental implants, the restoration can be entirely implant supported. Zitzmann and Marinello[4] described, in detail, parameters that need to be evaluated. A fixed restoration should not be guaranteed to a patient until all diagnostic criteria are evaluated. These criteria must include quality and quantity of bone available to support implants, lip line, lip support, and esthetic needs. Implants should not be placed until a definitive treatment plan has been established, as implant positions may vary depending on type of prostheses to be delivered (Figure 36-4).

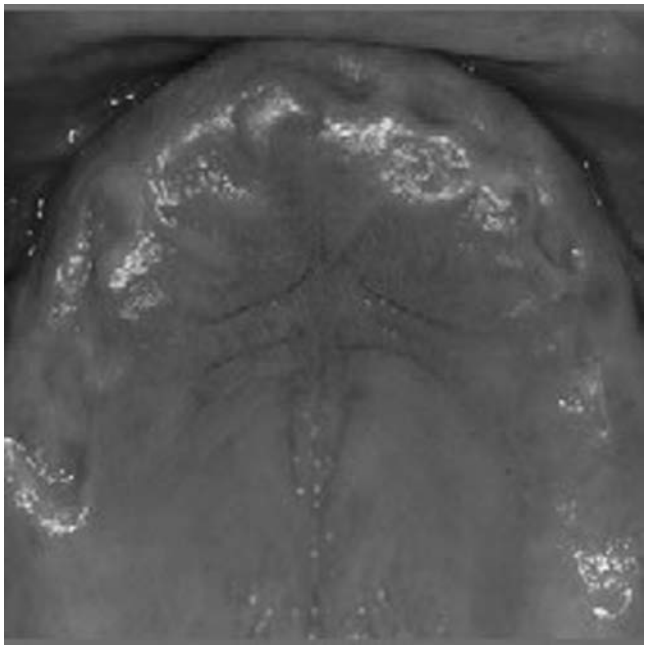
This section discusses key diagnostic elements that will help in planning the restoration of an edentulous maxilla.

Facial and Lip Support

Facial and lip support analysis must be performed before any surgical act. Often it is very difficult to create adequate lip support, proper emergence, and healthy pontic ridge relationships, if the implants have already been placed (see Figure 36-3). Lip support must be evaluated and established



• **Figure 36-1** Intraoral sagittal view of a patient with no maxillary teeth. Bone loss is more pronounced in the horizontal than the vertical dimensions.



• **Figure 36-2** Occlusal intraoral view of a patient with an oval maxillary arch form.

with flangeless try-ins before implant placement (Figures 36-5 through 36-7). Surgical guides must be fabricated after this evaluation to place implants at the correct depth and angulation for ideal emergence. The surgical or bone reduction guide should be almost identical to the planned

• **Figure 36-3** Shows patient smiling and displaying the maxillary alveolar ridge and failed implant prosthesis.

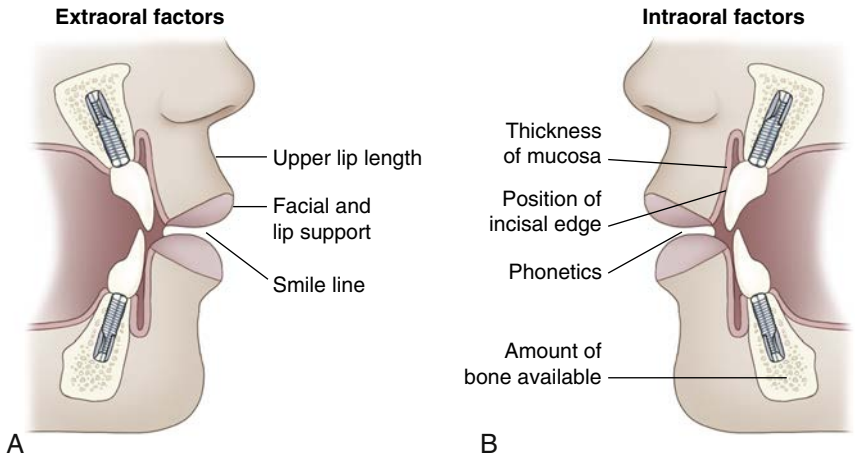
definitive restoration. Figure 36-8 shows how the emergence of the prosthesis can be adversely affected by inadequate apical bone reduction. Functional and biologic complications may ensue with such a steep emergence angle. Figure 36-9 demonstrates how with suitable planning, a restoration with a flat angle of emergence can be fabricated. Appropriate emergence must objectively be evaluated from the sagittal view with a bone reduction guide and prior to implant placement. Empirically, it has been suggested that if the angle of emergence from the ridge crest exceeds 45 degrees from the vertical, functional complications will be more likely.

Lip support can be classified into four groups:

1. Natural teeth present
   a. Natural teeth and ridge provide adequate lip support (Figure 36-10)
   b. Natural teeth and ridge do not provide adequate lip support (concave profile)
2. Natural teeth missing
   a. Existing ridge provides adequate lip support
   b. Existing ridge does not provide adequate lip support (see Figure 36-5)

Patients who are about to receive an implant-supported maxillary prosthesis may present as dentate or edentulous. This classification system provides a road map for proper diagnosis and planning.

The dentate patients in group 1b are likely to present a challenge. After extractions, the lack of lip support will worsen. The clinician must identify this group at the diagnostic phase. A prudent clinician must also pay attention to the facial profile. A concave facial profile is the most challenging situation to manage clinically. A pronounced chin and a "turned-up" nose exacerbate the appearance of the lack of lip support. The patient in Figure 36-5 has a mildly concave facial profile as well as a pronounced chin that exacerbates his lack of lip support. If the patient's nose were turned upward, the lack of lip support would worsen still. Image manipulation (Figure 36-11) explains this concept.[5] By identifying patients with a concave profile before implant placement, the clinician is likely to be more

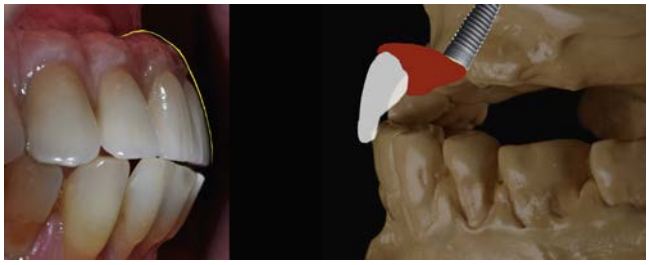


• **Figure 36-4** **A,** Extraoral parameters that should be evaluated for a fixed maxillary restoration. **B,** Intraoral parameters that should be evaluated for a fixed maxillary restoration.

• **Figure 36-5** Sagittal facial view of patient not wearing a maxillary denture and with a lack of lip support.

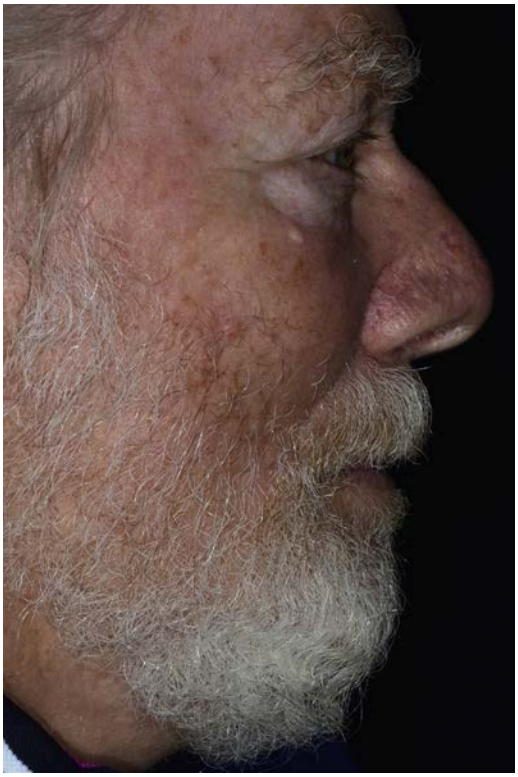
• **Figure 36-6** Sagittal facial view of patient wearing a flangeless maxillary wax tooth try-in with adequate lip support.

• **Figure 36-7** Intra-oral view of the patient in Figures 36-5 and 36-6 wearing a flangeless maxillary wax tooth try-in.



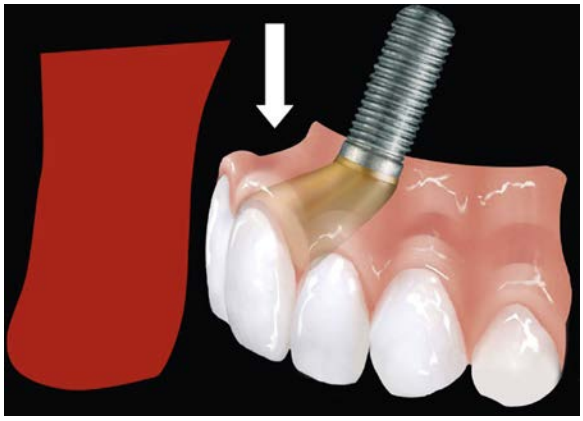
• **Figure 36-8** Sagittal view analysis and illustration show nonideal emergence of the prosthesis at the ridge crest. This area can accumulate food, impede lip mobility, and create patient discomfort. Dental implants were placed too shallowly.

• **Figure 36-9** Sagittal view analysis and illustration show ideal emergence of the prosthesis at the ridge crest. This device is cleansable and tolerated well by the patient. Dental implants were placed at the correct depth for this situation.



• **Figure 36-10** Natural teeth and ridge provide adequate lip support.

• **Figure 36-11** Manipulation of the patient photo in Figure 36-5. Turning the nose upward causes the lack of lip support to be more pronounced.



• **Figure 36-12** Diagram to illustrate discrepancy between ideal tooth position and implant placed into an existing ridge. Poor emergence can cause various functional and esthetic problems.

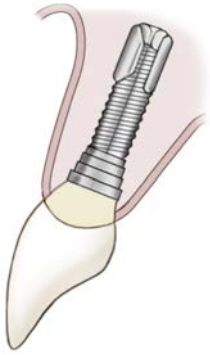
successful in identifying potential esthetic problems. Flat and convex profiles are simpler to manage.

When patients present with missing teeth, the clinician must identify and photograph patients in group 2b. These patients must go through an additional diagnostic phase to establish whether a fixed restoration without a flange can be delivered. The most reliable method to establish whether adequate lip support can be achieved is to perform a flangeless try-in (see Figure 36-7). It has been suggested that adequate lip support equates to a nasolabial angle of between 85 and 110 degrees. The patient in Figure 36-6 has a nasolabial angle of 90 degrees. This figure is within an acceptable range for adequate lip support.

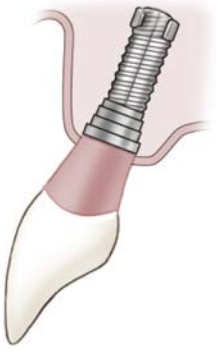
Lip support is derived from the alveolar ridge shape and cervical crown contours of the anterior teeth.[6] Resorption of the edentulous maxilla advances cranially and medially, and this often results in a retruded position of the anterior maxilla.[3]

When evaluating a diagnostic setup with the anterior teeth in correct relation to the lip, the position of the anterior teeth is frequently anterior to the alveolar ridge. Depending on the severity of the resorption, there can be a discrepancy between the ideal location of the teeth and the ridge. This in turn leads to a discrepancy of the anticipated position of the implants in relation to the teeth (Figure 36-12). This divergence must be taken into consideration to achieve a prosthesis that satisfies the parameters of adequate speech,

• **Figure 36-13** Cross section of a tooth indicating bone levels.

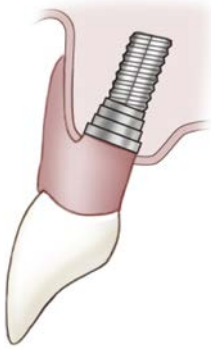


• **Figure 36-14** With minimal resorption, conventional implant-supported fixed partial dentures can be provided.



• **Figure 36-15** With moderate resorption, pink porcelain may be required to disguise tooth length if the patient desires a fixed restoration.

lip support, sufficient tongue space, and patient acceptance. When judged to be large, the discrepancy can be managed only with the flange of a removable prosthesis (Figures 36-13 through 36-16). The patient must be made aware of this from the outset; it must be conveyed that unless extensive grafting procedures are carried out, it is unlikely that a fixed restoration can be provided. When moderate resorption of the anterior maxilla occurs, it may be possible to reestablish lip support while maintaining adequate contours and emergence of the prosthesis. This is achieved by performing a resective procedure in the anterior maxilla. The limiting factor here is the nasal floor and whether enough bone volume will remain to house implants in this area. Consideration must be given to the angle of emergence of the prosthesis



• **Figure 36-16** With excessive resorption, a flange of a removal restoration is required to satisfy parameters of lip and facial support.

• **Figure 36-17** Patient with a high and wide smile with thin lips. These groups of patients are at risk of developing a horizontal line across the upper lip after a maxillary reconstruction.

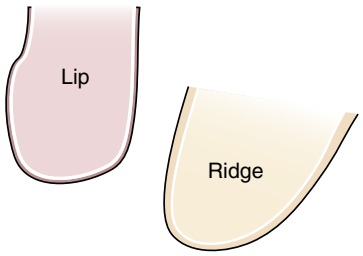
and a hygienic soft tissue contact at the ridge crest for the future prosthesis. An empirical rule exists that the prosthetic angle of emergence form the ridge must not exceed 45 degrees. Otherwise, lip movement may be impeded and food impaction apical to the prosthesis may occur.

There are some additional risk factors that must be accounted for at the diagnostic phase. Following a maxillary implant-supported reconstruction, it has been reported that patients with thin lips, high smile lines, and a wide smile are at risk of an upper lip with a horizontal line across it as the end result (Figure 36-17).[7] This line appears on the lip just superficial to the fixture head. These patients must be warned before the start of treatment and advised that dermal fillers will be required for routine maintenance.

Smile Line and Lip Length

The mobility of the upper lip during function must be evaluated. Tjan and colleagues[8] described the average smile as having the position of the upper lip such that 75% to 100% of the maxillary incisors and interproximal gingiva are exposed. In a high smile-line situation, additional gingiva was visible, and with a low smile line, less than 75% of the maxillary anterior teeth were displayed. Patients should be asked to smile

• **Figure 36-18** Patient with a low smile line, smiling without upper denture in situ.

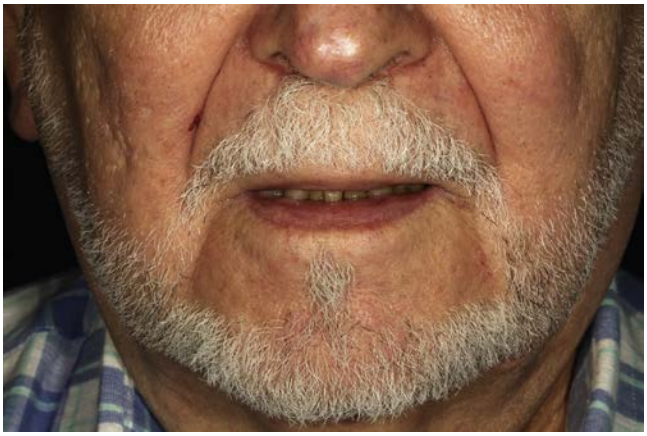


• **Figure 36-19** Sagittal diagrammatic illustration of patient with a very high smile line. If undiagnosed prior to implant placement, this may have disastrous esthetic consequences.

• **Figure 36-20** Improper esthetic diagnosis and evaluation has led to an unacceptable outcome. The horizontal transitional line or the junction between the pink ceramics and ridge crest is visible.

without the denture in situ (see Figure 36-3; Figure 36-18). If the alveolar ridge is visible when the patient smiles without a denture, the esthetics can be very challenging, as the junction between the restoration and the gingival complex will be visible (see Figure 36-3; Figures 36-19 and 36-20). Lip support should also be evaluated, as it influences the position of the maxillary anterior teeth. In a patient with a short upper lip, the maxillary anterior teeth will be exposed in repose, whereas in patients with a long upper lip, the anterior teeth will usually be covered. A long upper lip is more favorable than short for the treating restorative dentist (Figures 36-21 and 36-22).

• **Figure 36-21** Short upper lip. Lips in repose and displaying 3 mm of central incisors.



• **Figure 36-22** Long upper lip.

Evaluation of the smile line and level of tooth and gingival display is arguably the most important factor from a patient's viewpoint. In order to be consistent and be able to satisfy patients' esthetic needs, one must incorporate certain observations into the treatment planning process. The situation that will potentially cause esthetic challenges during treatment, typically related to the patient with excess gingival display. The cause of excess display must be identified.[9] With proper diagnosis, the correct treatment will be implemented.

The causes of excess gingival display are as follows:

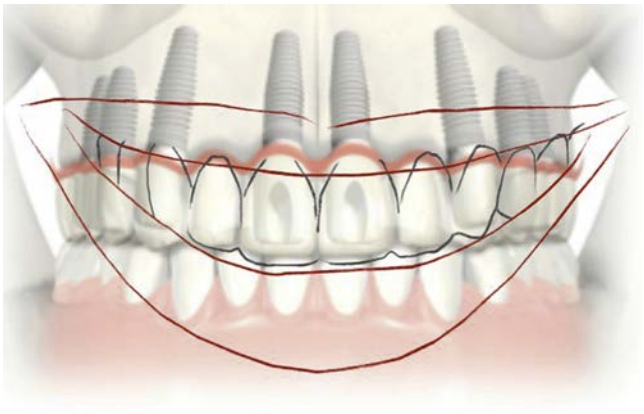
1. Short and hyperactive upper lip
2. Altered passive eruption
3. Dentoalveolar extrusion
4. Vertical maxillary excess
5. Multiple etiologic factors

The next step in the esthetic diagnosis is to decide which of the following structures will be replaced:

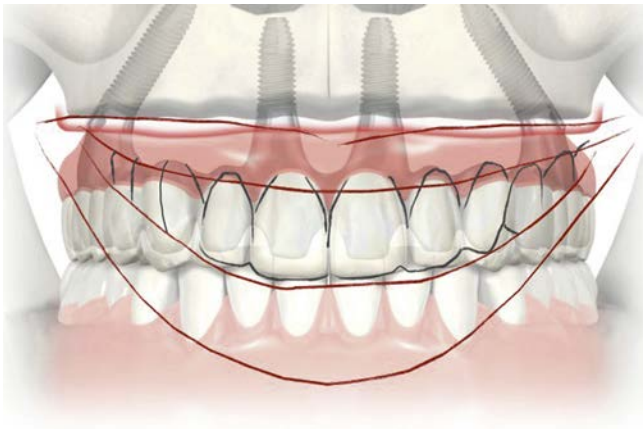
1. Tooth only (Figure 36-23)
2. Tooth and gingival tissues (Figure 36-24)

This can objectively be evaluated with a flangeless tooth try-in.

After this step, the clinician needs to determine whether an augmentative or resective procedure is required. Esthetics



• **Figure 36-23** Teeth only to be replaced.



• **Figure 36-24** Teeth and gingival tissues to be replaced.

will be of paramount importance in this part of the planning. The objective is to avoid the following:

1. A visible horizontal transitional line between pink prosthesis and patient's own ridge crest (see Figure 36-20)
2. Long (more than 12 mm) maxillary incisors that are completely visible

A restorative classification will help in visualizing the future prosthesis. This classification is made during an extreme smile and frontal view.

Class 1a: Tooth replacement only. The whole tooth and ridge is visible (Figure 36-25).

Class 1b: Tooth replacement only. The tooth is only partially visible (Figure 36-26).

Class 2a: Tooth and gingival replacement. The horizontal transitional line is visible (see Figure 36-20).

Class 2b: Tooth and gingival replacement. The horizontal transitional line is not visible (Figure 36-27).

Class 3: Tooth and gingival replacement with severe lack of lip support. (See Figures 36-1, 36-5, 36-6, 36-7, and 36-16.)

The clinician must identify Class 1a and Class 2a at the diagnostic phase. Class 1a will create an esthetic challenge if central incisor teeth are either longer than 12 mm, or if, in attempting to avoid unnaturally long incisor teeth, the

• **Figure 36-25** Class 1a: Fixed maxillary implant reconstruction. Incisors and maxillary anterior alveolar ridge are visible.

• **Figure 36-26** **A,** Class 1b: Smile view. Tooth replacement only. The tooth is only partially visible. **B,** Class 1b: Intraoral anterior view.

clinician attempts to reduce tooth length by adding pink ceramics. This will simply make matters worse by converting a class 1 situation into a class 2a situation (see Figure 36-20). If at the tooth try-in stage, it appears that the patient will have very long incisors, vertical and horizontal hard and soft tissue grafting must be employed to increase ridge height and shorten the length of the definitive incisor teeth. For a patient with a class 1b situation, the length

• **Figure 36-27 A,** Class 2b: Tooth and gingival replacement. The horizontal transitional line is not visible. **B,** Class 2b: Intraoral anterior view.

of the central incisor teeth becomes irrelevant, as it will be hidden by the upper lip during all movements. However, a small group of patients may desire ideal gingival contours and tooth length even if the lip eliminates visibility of the cervical aspect of these teeth.

Similarly, for a patient who presents with a class 2a situation where the horizontal transitional line may be visible after completion of the maxillary reconstruction (see Figure 36-20), it is essential to move the horizontal transitional line in an apical direction by a minimum of 5 mm at the highest smile. Moving the horizontal transitional line apically is usually achieved by osseous reduction in an apical direction. Apical movement of the horizontal transitional line must only be performed after correct diagnosis of the cause of excess gingival display. Certain etiologic factors in excess gingival display will require treatment other than osseous reduction. Table 36-1 demonstrates the appropriate mode of treatment in order to minimize gingival display.

Some patients with edentulous maxillae may require augmentative and others require preservative or resective procedures. A prudent clinician should be familiar with the classification presented in order to achieve predictable esthetic outcomes.

Extraoral Examination

Incisal Edge Position

Evaluation of the incisal edge position should follow examination of the residual ridge. It is paramount that this position be determined before implant placement. The clinician

TABLE 36-1 Appropriate Mode of Treatment to Minimize Gingival Display

Etiologic Factors: Excess Gingival Display	Treatment for Class1b	Treatment for Class 2b
Short upper lip	Graft or resect anterior maxilla to establish central incisor length of 11 mm at appropriate incisal edge position.	**Mild cases:** After tooth extraction, apical reduction of maxillary ridge height to desired levels. **Severe cases:** a. Maxillary impaction. b. Overdenture with flange when lack of lip support is preexisting.
Hyperactive upper lip	Reduce upper lip mobility: Botulinum toxin, or surgical intervention.	Reduce upper lip mobility: Botulinum toxin, or surgical intervention.
Dentoalveolar extrusion	After tooth extraction, apical reduction of maxillary ridge height to desired levels.	After tooth extraction, apical reduction of maxillary ridge height to desired levels.
Vertical maxillary excess	Maintain or resect anterior maxilla to establish central incisor length of 11 mm at appropriate incisal edge position.	Maxillary impaction for severe cases. Apical ridge reduction for mild to moderate cases.
Multiple etiologic factors	Address most dominant causes only.	Address most dominant causes only.

must visualize the tooth in three dimensions. Esthetics and the level of desired tooth display determine the incisor vertical position.[8] Tooth display should be measured while the lips are in repose (at rest; see Figure 36-21). A minimum display of 0.5 mm is desirable.[10] Otherwise the patient may appear edentulous at rest, leading to dissatisfaction. The horizontal position is determined predominantly by speech. If the maxillary anterior teeth are placed more palatally and restrict tongue space, patients may sound as if they are whistling when attempting to pronounce the letter "S." When the maxillary incisor teeth are placed too facially, the tip of the tongue may not be able reach to the palatal aspect of the maxillary incisor teeth, and the "S" sound will be pronounced like a "Sh." The "S" sound is the dominant factor in determining the horizontal position of the maxillary incisor.[11,12]

The secondary factor for horizontal positioning of the maxillary anterior teeth is lip support. The relationship between lip support and horizontal positioning of the upper incisor teeth has already been discussed. The angulation of the upper incisor teeth is determined by the ability to pronounce the "F" sound. The "F" sound is pronounced when the upper incisors create a seal by grabbing the vermilion border of the lower lip. The cervical border of the incisor is placed on average 10.5 mm apical to the incisal edge position.[13,14] By paying attention to maxillary incisor positioning, the clinician can ensure patient satisfaction in terms of speech and esthetics. The remainder of the tooth setup in the maxilla must follow basic denture prosthodontic principles.[13,14] Attention must be afforded to esthetic principles for tooth arrangement, the occlusal planes, and buccal corridors.[15] To determine if a fixed or removable restoration would be appropriate, a wax try-in is prepared without a flange. For a fixed restoration, the clinical crown should ideally end up at the soft tissue level of the alveolar ridge. In this situation, minimal resorption has occurred, inter-arch space is favorable, and an optimal tooth-lip relationship is present (see Figures 36-13 and 36-26). When a large vertical distance exists between the cervical aspect of the tooth and the alveolar ridge but the tooth-lip relationship is favorable, pink ceramic may be used to disguise the tooth length, and a fixed restoration is still possible (see Figures 36-15 and 36-27). When there is both a vertical and horizontal discrepancy between the ideal position of the tooth and the alveolar ridge, and the tooth-lip relationship is not optimal, this may be an indication for use of a removable prosthesis. The flange will provide adequate lip support, and the teeth can be positioned appropriately to satisfy the parameters of esthetics (see Figure 36-16; Figure 36-28).

Treatment Planning

The long-term success of implant rehabilitation of the edentulous maxilla is dependent on consideration of all the factors previously discussed. Treatment planning must address these diagnostic findings. It must also tackle the patient's singular grievances and meet the patient's expectations. The patient needs to have a reasonable awareness of how the definitive restorations will appear. Esthetics is a major cause of failure; going through a lengthy, expensive treatment only to achieve a result that is esthetically inferior to a complete denture can be hugely disappointing. Patient communication at the outset is of utmost importance. To avoid any surprises, a great deal of time must be devoted to educating the patient on the relative advantages and disadvantages of projected treatment. Informed consent becomes important. The patient must fully understand and acknowledge the limitations of the planned treatment, including the possibility of implant failure. The patient must understand that treatment plan modifications may be obligatory and the fact that placement of additional implants may be indicated. Informed consent must include the surgical risks of treatment and also the treatment's possible shortcomings in adequately addressing the patient's chief complaint and expectations.

In treatment planning, the following factors must be considered:

1. Esthetics and patient desires
2. Type of support
3. Amount of resorption and inter-arch space
4. Number of implants
5. Implant distribution
6. Economics

1. Esthetics and Patient Desires

Meeting patient expectations is paramount when planning treatment. As discussed earlier, patients prefer to discard their removable appliance in favor of a fixed alternative. The clinician must know early in treatment if this is possible. Promising a patient a fixed reconstruction when diagnostic deliberations determine otherwise may result in a dissatisfied patient. Patients are also pleased with the esthetic appearance of a complete denture. In particular the appearance of the soft tissues is uniform and interdental papillae between denture teeth are reproduced well with pink acrylic resin (Figure 36-29). When a patient then transitions to a fixed reconstruction, interdental papillae between implants are often absent. An artistic dental technician can create an illusion of interdental papilla by altering the position of the contact point between adjacent teeth and using interproximal stain (Figure 36-30).

2. Type of Support

Fundamentally, with the edentulous maxilla there are two categories of prosthesis, fixed and removable. Fixed prostheses include ceramic-based restorations supported by implants and, depending on the severity of the bone resorption, some pink porcelain may be required to simulate gingival contours. The removable category includes implant-supported overdentures and implant-retained and tissue-supported overdentures. A removable prosthesis can be retained by various methods, including, bar and clip, magnet, ball attachments, or the use of precision-milled or spark-eroded components.

• **Figure 36-28** **A,** Sagittal intraoral view of patient with severe maxillary resorption and implant-supported bar. **B,** Lack of lip support without maxillary prosthesis. Profile view. **C,** Prosthesis with flange provides lip support. Profile view.

• **Figure 36-29** Complete dentures can appear very realistic.

• **Figure 36-30** Pink interproximal ceramic staining to simulate dental papilla.

The diagnostic factors previously discussed will allow the clinician to decide which type of prosthesis will be more suitable.

3. Amount of Resorption and Inter-arch Space

This parameter dictates the type of prosthesis to be fabricated. The clinician must evaluate whether the patient exhibits minimal, moderate, or advanced resorption. Each type of prosthesis has a unique dimensional tolerance, as previously discussed. Patients who exhibit minimal or moderate resorption are candidates for a fixed restoration, providing parameters of facial and lip support are satisfied. Patients with advanced resorption can be satisfied esthetically by fabrication of a removable prosthesis with a flange; this replaces necessary support that has been lost as a result of resorption. If patients in this category request a fixed restoration, they will need to understand that extensive grafting or resective procedures may be required and that even after that, the esthetic outcomes may not meet their expectations.

4. Number of Implants

Many authors have discussed treatment concepts for restoration of the edentulous maxilla with a fixed prosthesis. Recommendations have been made with respect to anticipated prosthesis designs and implants. Placement of four to eight implants has been proposed for a fixed implant prosthesis with cantilever pontics.[16,17] Recommendations have also been made with regard to removable restorations on implants—four to six implants have been recommended for both implant-supported and implant- and tissue-supported restorations.[17,18] Deciding on the number of implants to place is not directed by a formula and is dependent on multiple factors. The number of implants to place in each patient is determined by:

a. Quality of bone
b. Anticipated force to be placed on the restoration
c. Relationship between the shape of the residual ridge and the dental arch form

a. Quality of Bone

Frequently type 3 and 4 bone is encountered in the maxilla. On occasion the quality of the bone is such that conventional drills cannot be used to place the implant, and underpreparation of the osteotomy sites is required. The success of implants in the maxilla is less certain than in the edentulous mandible.

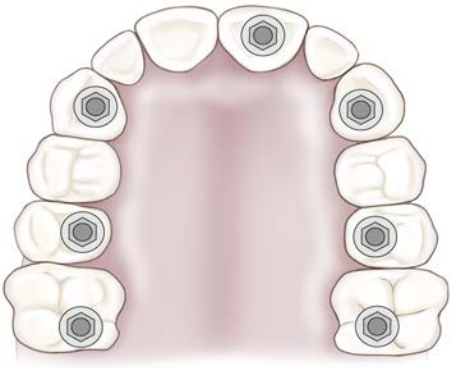
When the quality of bone is not optimal, often the surgeon and restorative dentist consider placing additional implants. These implants are placed to allow the restorative dentist to continue with the anticipated prosthesis should one or two implants fail. Overengineering in the maxilla can be advantageous, but consideration should also be given to the costs that may be encountered should all the implants integrate. Frequently the restorative dentist will have to purchase additional abutments, and the costs of these will need to be passed on to the patient. When the patient has had posterior teeth missing for a considerable length of time, the maxillary sinuses pneumatize, and often there is insufficient bone for implant placement in these areas. If the patient refuses to undergo additional augmentation procedures, the concept of the shortened dental arch can be used and fewer implants placed. The restoration of the maxilla with only four implants is an acceptable contemporary approach. The concept of a shortened dental arch may be used with this protocol.

b. Anticipated Force to be Placed on the Restoration

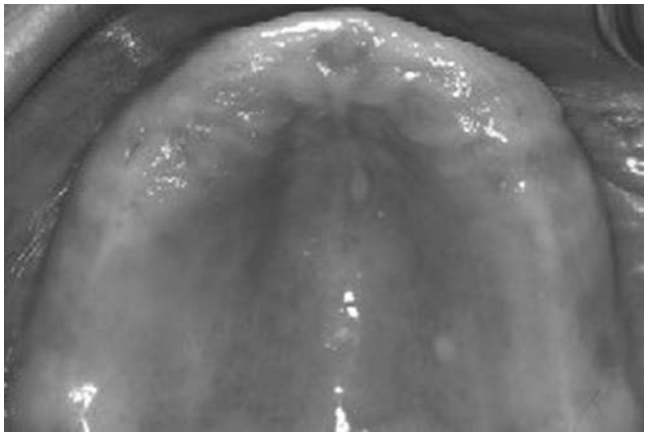
Part of the extraoral examination should also involve analysis of the patient's build and facial musculature. The masseter muscles should be observed for any hypertrophy that may be present. Bruxers often present with a pronounced antegonial notch, and this can be indicative of the likely force to be placed on the restorations. In these types of patients it is wise to overengineer and place additional implants for added support and distribution of force.

The opposing occlusion also has to be evaluated. Patients are likely to exert less force if a complete denture opposes the implant restorations, as compared to the force that can be exerted when the patient has natural dentition opposing them.

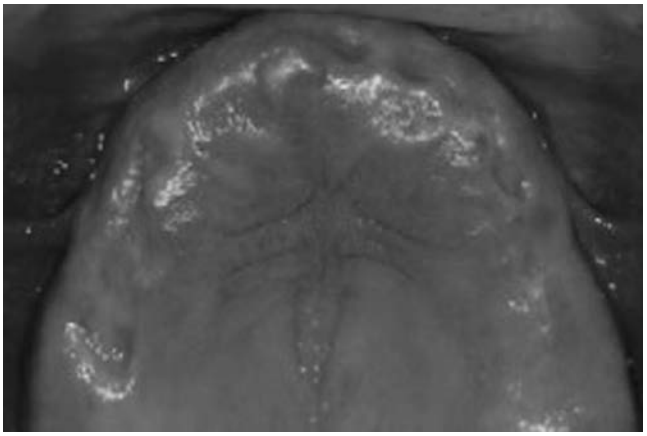
• **Figure 36-31** Square arch form.



• **Figure 36-33** Ovoid arch form.



• **Figure 36-32** Square ridge form.



• **Figure 36-34** Ovoid ridge form.

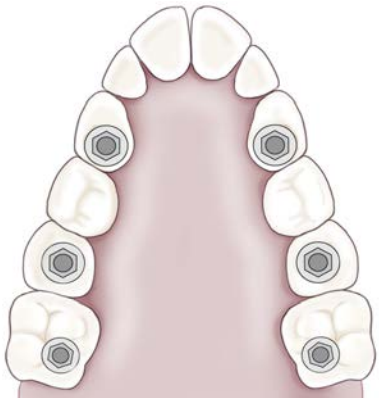
The greater the probable force on the implant restorations, the more implants should be allowed for.

c. Relationship between Shape of Residual Ridge and the Dental Arch Form

Three typical arch forms are prevalent: square, ovoid, and tapering. The edentulous maxillary residual ridge may also have three arch forms.

Esthetic requirements may require a dental arch form different from the residual ridge form. The dental arch form is determined by the final teeth position in the premaxilla and not from the residual ridge form. The final tooth position may need to be cantilevered to the facial in the final prostheses. In a dental square arch, lateral and central incisors are not cantilevered facially, compared with the canine position (Figure 36-31). Mandibular excursions and occlusal forces may be reduced on the canine implants. As a result, implants in the canine position may suffice, especially if they are splinted to posterior implants. The four pontics between the canines create reduced forces because forces are lowest in the incisor region and the square arch form has less cantilevered occlusal forces to the incisors (see Figure 36-31; Figure 36-32).[19]

In a dental ovoid arch (65% of edentulous patients), there should be three implants in the pre-maxilla, not two as in the square arch form (Figures 36-33 and 36-34).



• **Figure 36-35** Tapering arch form.

Sometimes this may require bone augmentation. For an ovoid retraction of mandibular anterior teeth, dental arch form planning for implants in the canine positions and at least one additional implant, preferably in the central incisor region, is imperative. The additional implant in the incisor region resists the additional forces created by this arch form, and biomechanically the prosthesis design will be more stable, as there will be less stress on the abutment screws. The restoration of a tapering arch form places the greatest stresses on the anterior implants, especially when the pontics replace the incisors (Figures 36-35 and 36-36).

• **Figure 36-36** Tapering ridge form.

• **Figure 36-37** Lingual view showing proximal implant placement.

The anterior teeth are cantilevered facially from the incisor position with increased forces in maximum intercuspation and in excursions. In this case four implants need to be placed in the premaxilla to replace the six anterior teeth. The worst-case scenario is a patient with a tapered dental arch form to be restored on a square residual ridge form. Four implants are then required to compensate for the anterior tooth position. In this case bone grafting may be required.[19]

5. Implant Distribution

Implant distribution and placement are critical in order to obtain the optimum emergence profile for the definitive restorations, as well as enabling the patient to maintain adequate hygiene. For a patient who presents with minimal resorption and is treatment planned for ceramic-based restorations on implants, precise placement of implants is imperative and should be facilitated by the use of a surgical guide based on the diagnostic wax-up (see Figure 36-26, *B*). Implants placed in interproximal positions can cause problems from both an esthetic and hygiene perspective. For those patients who display moderate resorption but still qualify for a fixed restoration with the use of pink porcelain, implant placement is not critical, but implant distribution is. Implants placed in interproximal tooth positions will not affect the esthetics, as this will be disguised by the use of pink porcelain

• **Figure 36-38** Lateral intraoral view of patient in Figure 36-37. Proximal implant position has no bearing on esthetics.

(Figures 36-37 and 36-38). Implant distribution is critical because implants will need to be placed so the load can be shared equitably. Splinting the implants is also advantageous, as this improves the biomechanics of the prosthesis design.

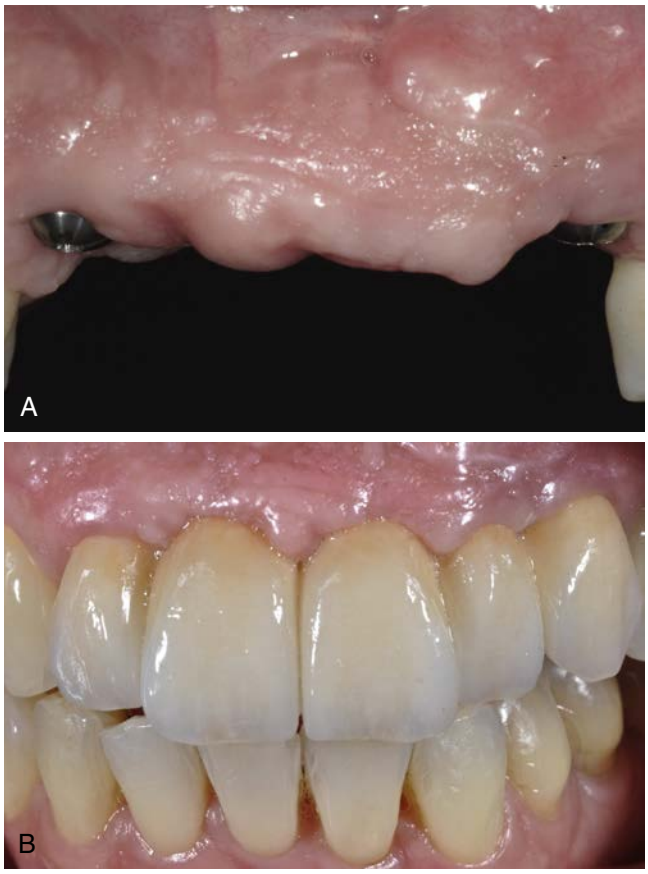
6. Cost

Restoration of the edentulous maxilla is costly, whichever method is used to restore the patient. Fixed reconstructions require more laboratory support and implant parts and hence are much more expensive. However, cost needs to be well thought out not only during fabrication of the prosthesis but also during maintenance. Overdentures seem to have more postinsertion maintenance than their fixed counterparts.[20] If this is consistent, it could be questioned whether choosing an overdenture could be justified on an economic basis when there is sufficient bone to support implants for a fixed prosthesis. The patient must be made aware that maintenance costs for removable prostheses on implants will be higher than those for a fixed prosthesis.

Empirical rules cannot encompass all clinical situations. There will always be "gray areas" when planning treatment of the edentulous maxilla. By combining common sense, the evidence base, and clinical experience, one can find solutions for treating even the most complex situations. It is highly recommended that the patient test all parameters of the proposed final prosthesis in the provisional phase. The provisional restoration serves as a blueprint for the definitive restoration. With the advent of CAD-CAM technology, it is now possible to copy and mill the provisional or acrylic resin prototype restorations very accurately.[21] This will allow form, function, phonetics, and esthetics to be replicated with relative ease and accuracy. This chapter introduces some empirical rules to help make appropriate restorative clinical decisions.

The following factors must be considered when planning a definitive restoration:

1. Amount of tooth and gingival display (see classification)
2. Esthetic demands



• **Figure 36-39** **A,** Maxillary anterior ridge requiring tooth replacement only. **B,** Same patient with definitive ceramic (teeth only) prosthesis.

3. Screw access trajectory
4. Restorative space (acrylic resin vs. ceramics)
5. Opposing occlusion (denture, teeth, implants)
6. Occlusal forces (high or low)

As discussed, patients in Classes 1a and 2a will present with the greatest risk as far as esthetics is concerned. One must decide before implant placement whether an augmentative or resective procedure will need to be employed for optimal results. Class 1a situations require meticulous soft tissue management both surgically and prosthetically in order to create and simulate papillae (Figure 36-39). In the anterior esthetic chapter, clinical situations to demonstrate maintaining and preserving the anterior ridge are discussed. Results are more predictable when Class 2a situations are treated with resective procedures. Resection will convert a Class 2a to a 2b situation, which is more manageable. A controlled and reliable protocol to achieve an appropriate angle of emergence, convex pontic ridge relationship, and acceptable esthetics is demonstrated (Figure 36-40). Stabilizing the surgical guide on posterior teeth that will eventually be removed controls osseous reduction. The bone reduction guide (see Figure 36-40, *D*) is very similar in terms of emergence and form to the definitive restoration (see Figure 36-40, *F*) and serves as a good objective tool for communication between surgeon and restorative dentist.

Material Selection

Acrylic Resin and Titanium

Framework designs for a full-arch, one-piece, implant-supported acrylic resin and titanium–based restoration have changed significantly since the transition from gold frameworks to titanium. Different manufacturers have different designs available, and despite technological advances, a framework with similar characteristics to gold frameworks is not available. This is due to limitations in scanning and milling, but technology is advancing at a rapid rate. Even with the titanium frameworks that are available today, a few key parameters become important; we cannot ignore what we have learnt from gold frameworks.

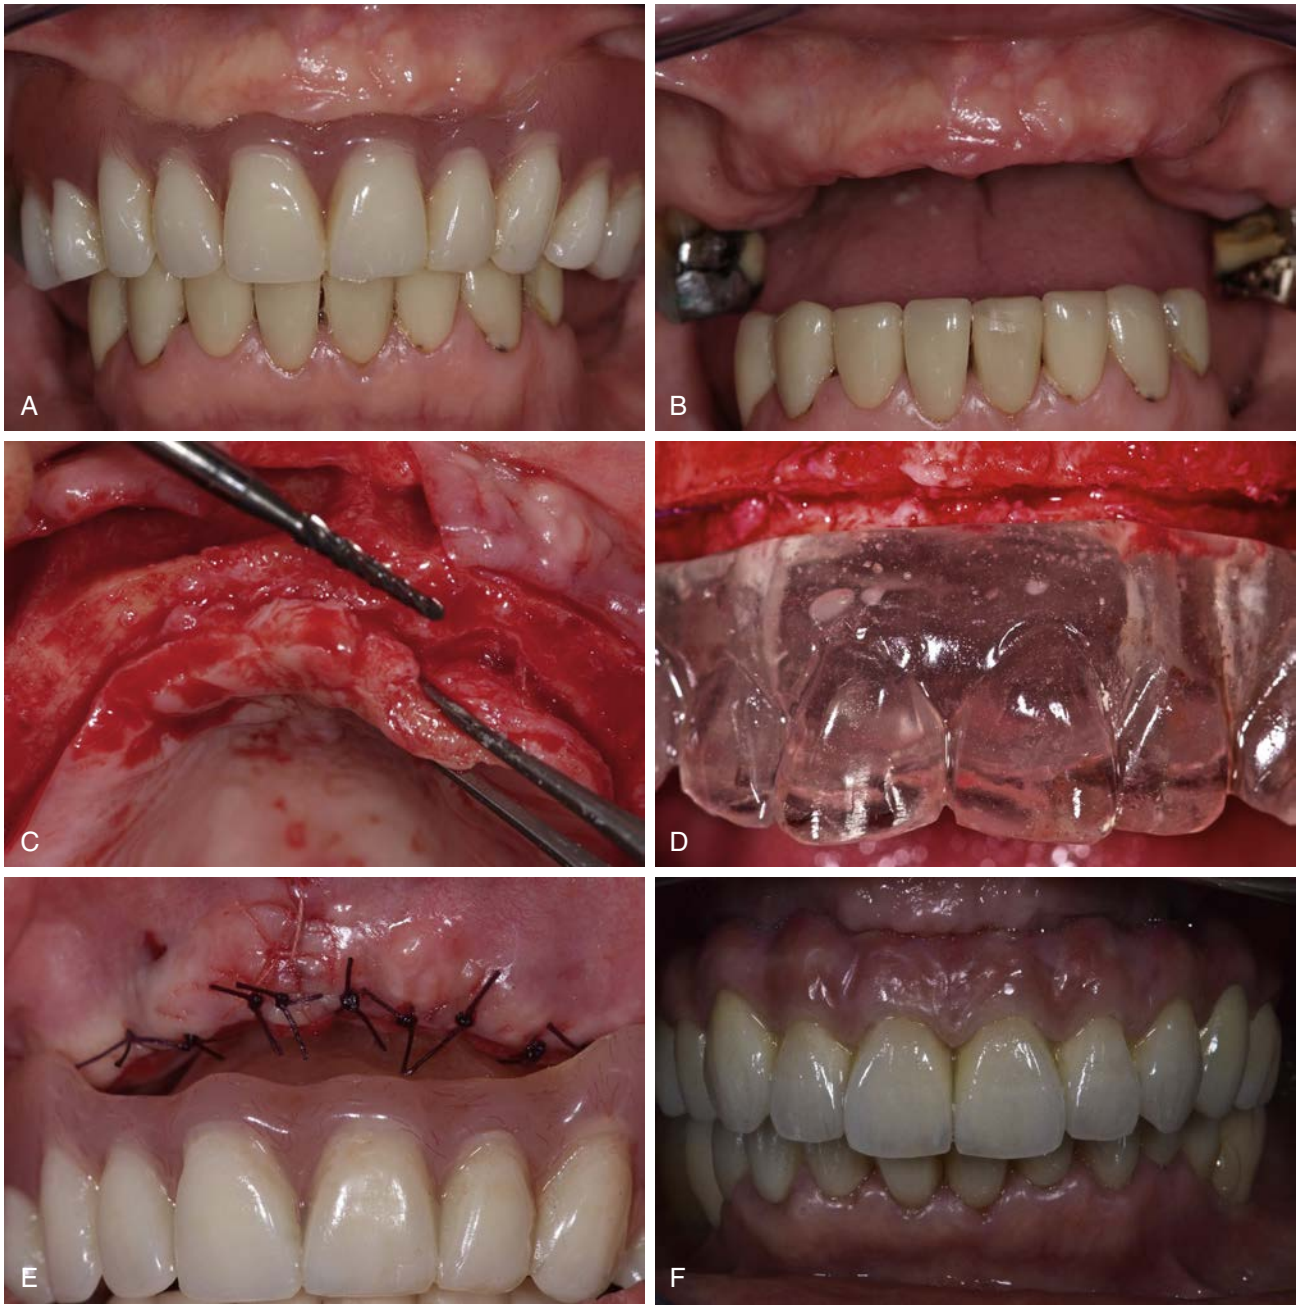
Two types of frameworks to support acrylic resin teeth exist. The minimalist framework where acrylic is wrapped around the tissue surface is made from acrylic resin, and it is more cost effective. It can be relined, but little is known about its longevity in terms of biomechanics. Anecdotally, numerous colleagues have experienced fractures of this type of framework. Failures may be due to excessive cantilever or inadequate bar shape (Figure 36-41).

The second type of framework may include I- or L-shaped bar designs to maximize rigidity. Adequate space and retention for acrylic resin maximizes thickness in the cantilever area. The evidence base is also lacking with this design. Although these frameworks have served many patients well, particularly in the edentulous mandible, success in the mandible does not automatically translate to success in the maxilla. The authors have anecdotal evidence of repeated fractured teeth, acrylic resin delamination, and denture teeth wearing in the anterior maxilla (Figure 36-42). The problem is exacerbated in patients who present with signs of bruxism. Wear of posterior teeth will eventually overload anterior teeth and result in fractures.[22] In order to avoid premature damage to maxillary anterior denture teeth, it is wise to extend the metal framework onto the occlusal surfaces. The fabrication of prototypes with selective and controlled cut-back procedures will allow accurate copy milling and incorporating metal posterior occlusal surfaces into the framework.

In summary, this type of framework is still considered a "workhorse" in prosthodontics. They are cost effective and can be used in a variety of situations.

Ideally at least 15 mm of restorative space is required for bulk of material (Figure 36-43). Compromise in restorative space will inevitably result in fracture of teeth or delimitation of acrylic resin.

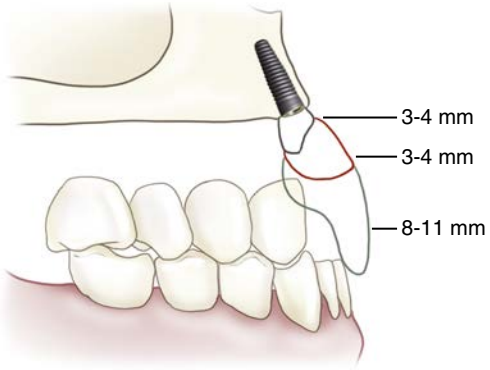
These designs can be used in high- and low-force situations. In high-force situations, the teeth will wear much more quickly and will need to be replaced. Although it is possible to make attractive restorations with denture teeth, the pink acrylic does lose its sheen over time and can accumulate stain. It would be preferable for the opposing arch to have less rigid and hard occlusal surfaces to reduce impact on the maxillary restoration.



• **Figure 36-40** **A,** Preoperative situation of a patient requiring an implant-supported maxillary prosthesis. The existing upper denture has poor contours and concave undersurface. **B,** Upper molars will stabilize the bone reduction guide. **C,** Controlled osseous reduction. **D,** Bone reduction guide stabilized on molar teeth bilaterally and an objective tool for communication. **E,** The restoration in **A** in situ, showing adequate bone reduction. **F,** Definitive prosthesis in situ with adequate shape and emergence form.

• **Figure 36-41** An acrylic resin wraparound prosthesis.

• **Figure 36-42** Patient complaining of repeated fractures of maxillary anterior teeth with a wraparound prosthesis.



• **Figure 36-43** Ideally 17 mm of restorative space is required for a metal and acrylic resin restoration.

In the appropriate situations, this prosthesis remains an acceptable and cost-effective restoration for the edentulous maxilla with moderate to severe resorption.

Milled Cobalt Chromium Frameworks

Cobalt chromium frameworks have had a major resurgence in recent years.[23] All of the traditional problems with fit, bonding, and corrosion related to cast designs have been eliminated with the inception of milled framework designs.[24-26] CAD-CAM designs allow better control of ceramic thickness, passive frameworks, predictable ceramic bonding, and less bending than high Nobel frameworks, especially in cantilevers. Cobalt chrome frameworks are particularly advantageous when less than 15 mm of restorative space is available and a posterior cantilever is present. The restoration can withstand occlusal forces even at minimal thickness. The main attraction, however, seems to be the cost as compared to gold-based frameworks. The only disadvantages are laboratory based, as an industrial milling machine is required, with a skilled dental technician.

In summary, this framework design would be useful where there is limited restorative space of less than 15 mm, posterior cantilevers are present, ceramics are planned, and cost is a moderate factor.

Zirconia Frameworks

Zirconia frameworks currently have huge popularity as a restorative material for maxillary implant-supported prostheses. The primary advantage of zirconia is the whitish color of the framework, which allows the fabrication of a restoration that can predominantly be of monolithic design. Additionally, the white color of zirconia makes it beneficial in esthetic areas of the oral cavity and is suitable material for anterior restorations.

Zirconia technology has had a noteworthy impact in the restoration of the edentulous maxilla because of its biocompatibility, esthetics, and strength.[27-29] Zirconia has a high flexural strength, which makes it suitable as a framework in maxillary reconstructions. These properties have resulted in the increase use of zirconia in the fabrication of maxillary frameworks. The scientific literature lacks data regarding complete mouth zirconia frameworks supported by implants. Clinical reports have evaluated restorations with a zirconia structure supported by implants and have provided some insight; however, a significant amount of data is lacking in relation to this material and its application.

There are many clinical reports with one or two patients treated who have been followed up for 4 years or more. However, from an evidence-based perspective, the literature is lacking wide-ranging data to support monolithic full arch frameworks at this time. This statement should not be considered a deterrent, but caution must be exercised during case selection.

It is possible to achieve strength and maximum esthetics by minimal layering of zirconia frameworks. However, a few clinical studies are showing that unsupported veneered ceramic has a higher risk of chipping (Figure 36-44).[30,31] So, in order to get the best out of the material, it would be wise to design the frameworks such that occlusal contact areas are in monolithic zirconia, minimal layering on the buccal surface, with anatomically shaped design to support the ceramic (Figure 36-45).

Cantilevers (see Figure 36-50) in implant dentistry are valuable for sites where anatomic structures such as the maxillary sinuses exclude the ideal placement of dental implants. Cantilevers are being used more often

• **Figure 36-44** Chipping of layered zirconia crown.

• **Figure 36-45** Minimal and controlled cut-back of zirconia to avoid fractures.

for graftless procedures. They may, however, negatively affect the biomechanics of implant restorations[32] and may result in mechanical and/or biologic problems. Presently, evidence is limited concerning breakage of cantilevered zirconia implant frameworks. This evidence is mainly limited to anecdotal and expert clinical reports. Well-designed, clinically relevant laboratory studies are needed to establish the mechanical properties of zirconia cantilever frameworks.

As cantilevers are unavoidable, one must air on the side of caution in order to reduce the chance of failure, fractures, and overloading.[32] The following are recommended:

1. Maximize connector dimensions, buccal-lingually and occlusal-gingivally.
2. Minimize cantilever length.
3. If cantilevers are unavoidable, ensure very light occlusal contacts in these areas.
4. In situations where low to moderate alveolar resorption has occurred, posterior restorative space is often limited and, in the presence of a cantilever, may result in failure (Figure 36-46).
5. Thicken the chimney around the most distal implant, and thicken the buccal and lingual walls around the chimney of the implant.
6. Well-polished monolithic zirconia is kind to the opposing dentition.[33] One must ensure that any grinding and polishing is performed during the prototype phase. This will also help with preserving the strength of the material and avoiding accelerated ageing failures in the presence of saliva.[34]

• **Figure 36-46** Posterior cantilevers and limited crown height place restorations at risk of fracture.

A potential problem of zirconia is the inherent accelerated ageing or low-temperature degradation problem that is exacerbated in the presence of water or saliva.[34] This leads to a decrease in physical properties by spontaneous phase transformation of the zirconia crystals from the tetragonal phase to the weaker monoclinic phase and may place zirconia-based restorations at risk of impromptu catastrophic failure. Current literature reports a relatively small number of framework fractures, which do not appear to have occurred spontaneously. In both in vitro and in vivo studies, it has been demonstrated that the exclusive mode of failure in all ceramic fixed partial denture frameworks was the fractures of the connectors where tensile forces are the greatest.[35] To prevent such failures, the connectors of all-ceramic fixed partial dentures (FPDs) must have sufficient height and width to withstand these forces. The suggested minimum dimensions for all-ceramic FPDs are greater than those for metal-ceramic FPDs. A minimal connector area of 7 to 16 mm^2 has been recommended for zirconia frameworks.

In contemporary treatment planning, one of the aims is to provide the patient with a retrievable restoration. Retrievability is achieved through screw retention. This allows simple detachment of the appliance and the chance to service the restoration or treat any implant-related problems. With proper implant placement, this can be achieved in most situations when treating the edentulous maxilla. However, despite clinicians' best intentions, anatomic limitations may not allow screw-retained implant placement in the anterior maxilla, even after correction with angled abutments. In these situations a "hybrid" between a monolithic design and individual cemented restoration may solve a challenging problem created by anterior implant trajectory (Figure 36-47).

There have been numerous anecdotal reports of the patient hearing a clicking sound when both maxillary and mandibular prostheses are made with implant-supported monolithic zirconia restorations. Currently, the consequence of forces being transmitted to the supporting implants is unknown. Last, there are very few data to show the longevity of the full arch zirconia maxillary and

• **Figure 36-47** A "hybrid design" for a zirconia framework. The anterior restorations are cemented because of unfavorable implant angulations.

• **Figure 36-48** Pilot study tested load to failure of cantilevers. Titanium zirconia frameworks fractured under much higher loads than monolithic zirconia frameworks.

mandibular situations, with continuous function against one another. In situations where the clicking noise might bother the patient and excess forces in a very rigid system are a concern, the authors recommend using a softer occlusal material (acrylic resin teeth) in the mandibular arch instead. The use of softer acrylic resin teeth can overcome the potential problems discussed earlier. This is achieved by using the preferential wear of acrylic resin teeth in the mandibular arch as a clinical advantage. The patient must be warned of a higher level of maintenance and need for resurfacing the mandibular prosthesis in due course.

In summary, zirconia frameworks may ideally be used where esthetics is a concern, posterior cantilevers are not present, and implant trajectory is ideal. These frameworks may be considered when posterior cantilevers are present, in the presence of adequate posterior restorative space (>15 mm).

Zirconia Titanium Frameworks

Although monolithic zirconia frameworks can be useful in many situations, they do have their limitations:

1. Lack of evidence for restoration survival in a posterior cantilever situation
2. Limited posterior vertical restorative space, weakening connector strength (see Figure 36-46)
3. Excessively facial anterior implant trajectory
4. Maintaining true screw retained situations and retrievability
5. The ability to segment restorations

The zirconia titanium framework design attempts to address all of the issues listed. This design consists of two frameworks. The primary titanium framework is attached to the implants and is screw retained. It eliminates the trajectory problem with implants. The secondary framework is made of monolithic zirconia with minimal facial layering. Pilot studies performed by the authors clearly demonstrate a mechanical advantage where posterior cantilevers are present and in situations with short connector height (Figure 36-48).

In summary the titanium zirconia framework may be used where anterior implant trajectory is unfavorable and posterior cantilevers exist, with less than 15 mm posterior restorative space.

Case Presentation

An overview of a patient treatment will help consolidate some of the concepts presented in this chapter. This patient presented complaining of repeated fractures of her existing implant restorations in both maxilla and mandibular arches (see Figure 36-42). On examination it was determined that the anterior teeth were under heavy occlusal loads, in both centric relation and protrusive movements. This patient reported nocturnal bruxism. Although adequate restorative space was present, the existing restorations were cantilevered posteriorly bilaterally. Restorative space decreased mildly posteriorly, approaching 15 mm in the molar region. One anterior implant presented with an unfavorable trajectory even after correction with an angled abutment.

The patient presented with a severe lack of lip support without her existing prosthesis. These restorations provided adequate lip support and hence served as a flangeless try-in. Existing failing implant prostheses can serve as excellent diagnostic tools, similar to dentures that are in need of replacement. Based on the patient's esthetic and functional demands, a wax try-in was fabricated and examined in vivo. After patient approval, these wax-based trial prostheses were copy milled with implant-supported acrylic resin prototypes. Occlusion was refined at this stage, and all parameters relating to form, function, phonetics, and esthetics were evaluated (Figure 36-49). With the aid of CAD-CAM technology, the prototypes were scanned and primary and secondary bars fabricated. The primary bar was cantilevered (Figure 36-50) and supported and was screwed to the secondary zirconia framework (Figure 36-51). As the patient demonstrated a history of bruxism, a primarily monolithic zirconia framework with minimal facial layering was designed (see Figure 36-45). The primary titanium bar could correct any misaligned implant

• **Figure 36-49** Acrylic resin prototype try-in.

• **Figure 36-50** Primary screw-retained titanium bar.

• **Figure 36-51** Lingual view of partially inserted secondary zirconia restoration on titanium primary bar.

trajectories. The prosthesis was completely screw retained and fully retrievable.

This patient situation demonstrates how with the application of basic diagnostic principles, the clinician can resolve a clinical problem. A satisfactory outcome with adequate form, function, and esthetics was achieved (Figures 36-52 through 36-55). Particular attention was afforded to creating a mechanically sound restoration to reduce maintenance problems.

Summary

This chapter has explored diagnostic concepts as they relate to full maxillary implant-supported reconstructions. The application of these concepts at the presurgical phase of treatment increases the likelihood of esthetic and biologic and biomechanical success. Patient situations to demonstrate appropriate execution have been presented.

Acknowledgments

The authors would like to thank Domenico Cascione for assistance in the laboratory work.

Mandibular Immediate Implant Loading with the Complete Arch Provisional Prostheses

TONY DAHER, VAHIK PAUL MESERKHANI, BACH LE

Introduction

Earlier types of implants, such as blade implants, subperiosteal implants, and vitreous carbon implants, were subjected to immediate loading and exhibited an implant-fibrous tissue interface. Their higher incidences of failure formed the basis for concerns about immediately subjecting titanium root form implants to loading. The original Brånemark protocol placed special emphasis on the critical period of unloaded bone healing where the implant must be covered with soft tissue.

The 3- to 6-month healing phase needed for successful osseointegration of submerged implants is described in recent literature as empirical. Many implant studies, including systematic reviews, have shown that dental implants with immediate or early loading approaches demonstrated similar success rates to the original two-stage protocol or one-stage surgical protocol.[1,2]

Many definitions of immediate loading are given by different investigation centers according to the prosthetic protocol. The interval between placing the implants and the prosthetic fabrication has varied between 0 and 20 days. Because this procedure involves the placement of a provisional restoration, the term "immediate provisionalization" was proposed.

Immediate loading was developed because of the desire to reduce treatment time and provide patients with a stable, esthetic replacement of one tooth, multiple teeth, or all the teeth in an arch either the same day or within a very short time.

Treatments with immediate or early implant loading may be advantageous for many edentulous patients in several aspects. Edentulous patients struggle with inadequate prosthesis retention, and/or poor denture stability, and/or inadequate chewing ability.[3] For patients who have never worn a removable prosthesis, there can be significant psychological and functional difficulties throughout the submerged healing time when they have to wear an interim removable prosthesis. The surgical wound covering the implants will need several days of healing without an overlying removable prosthesis. The removable interim prosthesis will require multiple adjustments and soft reline procedures during the subsequent months to minimize loading of the soft tissues and underlying implants. This periodic relining requires additional appointments and creates inconvenience and additional expense for the patient.

Therefore, modifications to the original two-stage protocol were developed. The implant and prosthesis are placed the same day, providing the patient with an esthetic and stable replacement for the missing teeth in one appointment. The number of surgical procedures and total treatment time is reduced.

Immediate implant loading (IIL) or early implant loading (EIL) protocols provide many benefits to edentulous patients compared with the conventional delayed protocol. These include both functional and psychological advantages from the retention rendered by immediately connecting the provisional prostheses (Figure 37-1).

Literature Review

There is strong evidence that IIL or EIL protocols are predictable in the anterior mandible, irrespective of implant type, surface topography, and prosthesis design (success rates 90% to 100%).[3] Limited evidence is available for the edentulous maxilla (success rates 80% to 100%), underscoring the need for further research.[4]

Indications for immediate load on the edentulous mandible include systemic, psychological, morphologic, and functional factors.[5] Loading forces, anatomy of the area, surgical protocol, and level of oral hygiene will dictate the patient's candidacy.[6-8]

• **Figure 37-1** Before and after rehabilitation with complete dentures. Self-esteem is improved with a pleasing smile.

Immediate-load protocols are contraindicated in patients with delayed wound healing, such as those with hyperparathyroidism, diabetes, heavy smoking habits, current chemotherapeutic therapy, or history of radiation to head or neck.[9,10] Heavy bruxers or clenchers are also best excluded from immediate-load protocols.[11] Primary implant stability (torque >30 Ncm), implant length >10 mm, and surgical skill have been described as important criteria for success.[9,12-14]

IIL protocols offer many advantages over delayed protocols. These include reduced treatment time, increased patient comfort, improved prosthesis stability, and increased masticatory function during the implant healing phase. No additional appointments are necessary for soft reline procedures.[15]

IIL has been advocated to preserve bone and stimulate bone remodeling, enhance gingival contours,[16-18] improve esthetics,[19-21] and decrease the psychological impact of wearing a fixed prosthesis.[22] Immediate full-arch fixed provisional restoration after implant placement allows for improved function, stability, and distribution of load. The provisional restoration offers numerous additional advantages:

- It protects the sutured mucosa.
- It can be modified and serves as a prototype for the final prosthesis.
- It can be used as a verification jig.
- It preserves the original vertical dimension of occlusion.
- It aids in obtaining and transferring the inter-occlusal record.
- It assists long-term patient maintenance.
- It reduces treatment visits.

The advantages of its use clearly outweigh the disadvantages.[23,24]

For completely edentulous patients, IIL must follow strict protocols. The immediate-load concept is based on three important clinical findings:[25]

1. <150 µm of micromotion may constitute a threshold value for implants to osseointegrate properly.
2. Passive connection of all the implants together with the prosthesis will reduce the micromotion and facilitate the healing process.
3. All inserted implants must be stable in the bone with insertional torque values of at least 30 Ncm.

In addition, an optimum occlusal scheme of a balanced or group function is a must in these conditions. Patients should be put on a soft diet for the first few weeks.

Excellent long-term follow-up results have been reported when rigid prostheses are connected to the implants immediately after implant placement. Despite several advantages of immediate loading, there is no agreement on the technique

by which immediate loading can be achieved. The success of immediate loading relies on a number of variables: implant texture and shape, surgical protocol, operators' skills, and prosthetic restoration.

Excessive occlusal load often leads to excessive movement during the healing process and may cause fibrous encapsulation of the implant. To control load on the dental implants and to reduce micromotion at the bone-to-implant interface, various prosthetic and surgical approaches have been described.[26]

Surgical and Prosthetic Principles and Protocol in Relation to Immediate Implant Loading

Biological Principles for IIL Success

Osteogenesis is success relies on primary stability and achieving abundant interfacial bone formation to offset bone resorption resulting from implant placement. Surgical and prosthetic strategies must be directed to enhance osteogenesis, decreasing occlusal load and micromotion.[27]

Bone Quality Basis for IIL Success

The bone quality and density in edentulous ridges has a primary influence on treatment planning, implant design, surgical approach, healing time, and initial bone loading during prosthetic reconstruction.[28-30] Bone quality and density are defined by four types: Q for quality, Q1 to Q4, according to Lekholm and Zarb in 1985; where Q1 indicates homogenous compact bone, Q2 indicates thick layer of cortical bone surrounding dense trabecular bone, Q3 indicates thin layer of cortical bone surrounded by dense trabecular bone of favorable strength, Q4 indicates thin layer of cortical bone surrounding a core of low-density trabecular bone.[28] D for density, D1 to D4 according to Misch in 1988; where D1 indicates dense cortical bone, D2 indicates dense to thick porous cortical bone on the crest and coarse trabecular bone underneath, D3 indicates a thinner porous cortical crest and fine trabecular bone within, and D4 indicates almost no crestal cortical bone.[29,30] Anterior mandible is in general Q2 or D2, however, resorbed mandible is Q1 or D1.

The bone quality and density can be determined and grossly estimated by radiographic evaluation, but is better evaluated during surgery. The presence and thickness of cortical bone and the density of trabecular bone are easily determined during the osteotomy preparation. It is usually not difficult to achieve the primary implant stability needed for the immediate loading protocol.[29]

The amount of trauma generated during the osteotomy preparation is influenced by the bone quality of the surgical site. This creates a cascade of reactions at the bone-implant interface that affect the quality of the load-bearing surface.[30]

Surgical Principles for IIL Success

Three requirements are necessary for initial rigid fixation: (1) minimal trauma preparation, (2) close approximation between titanium and bone, and (3) absence of movement at the interface during healing.[31] Bone is susceptible to heat, so it is important to limit thermal and mechanical trauma to the surrounding tissues caused by rotary drills.[32] Several factors have been described to influence heat generation during osteotomy preparation: sequencing of drill sizes to the final drill for the preselected osteotomy, drill speed and time, and the use of irrigation. Without irrigation, drill temperatures can reach 100° C within seconds.[29] Copious irrigation is needed, especially in dense bone. The use of new sharp drills in an organized manner, starting with a pilot drill of 2-mm diameter, is always recommended. Additional factors such as internally versus externally cooled drills are less important.[29] The choice of a coolant is also important. Distilled water should not be used, as rapid cell death may occur. Intravenous dextrose or saline solutions are preferable.[29]

The use of three-dimensional planning software before the surgical appointment has many advantages compared to two-dimensional studies:[33] (1) more refined and precise implant placement to avoid critical anatomical structures, (2) better understanding of the quality and quantity of bone, and (3) precision that helps with the implant position, especially when more implants are necessary for adequate support of the fixed prosthesis.

Limitations to digital diagnostics include the added presurgical treatment time and added treatment cost; radiation dosages that may be greater than for two-dimensional studies; the difficulty of implant placement in the posterior region due to longer instrumentation; and the difficulty of cooling during the osteotomy preparation. Despite the limitations of the digital procedures, their advantages outweigh them.[33]

Prosthetic Principles for IIL Success

Restoration using the immediate loading protocol demands the application of six factors for prosthetic success:

1. Optimum esthetic and functional design of the presurgical prosthesis. It is advisable for patients to use the presurgical denture and to allow time for any adjustment to be made. There should not be any compromises at the level of esthetics and occlusal scheme. All basic principles of removable prosthodontics must be applied during denture fabrication.
2. Reduction of occlusal load by connecting all the implants together to achieve a passive fit and by using a soft food diet.[29]
3. Promotion of peri-implant health and controlling peri-implant inflammation. Using an antibiotic therapy before and after implant placement may be beneficial as well as instituting an oral hygiene regimen.[29]
4. Development of an optimum gingival contour with a well contoured provisional prosthesis.[29]
5. Minimizing the length of the cantilever extension to the width of a molar.
6. Customizing an oral hygiene protocol for the specific clinical situation and emphasizing its importance to the patient.[34]

Guided Surgery Principles for IIL Success

Collaboration between the restorative dentist and the implant surgeon is an important aspect of patient care to achieve an accurate diagnosis, thorough treatment planning, and a predictable outcome.[35] The final result is

addressing the needs and concerns of the patient. Incorporating the prosthetic details of the presurgical denture in the cone-beam computed tomography (CBCT) radiographs clearly defines the best location of the implants and renders the final prosthetic treatment predictable. The anticipated treatment outcomes will strengthen the relations between the restorative dentist, the surgeon, and the lab technician and enhance the patient's confidence in oral implantology. Using a preplanned surgical guide has many advantages[35]:

1. It reduces the amount of time required for the surgery.
2. It reduces the time of bone exposure, and consequently postsurgical comfort is improved.
3. It reduces interoperator variability during surgery, thus enhancing security for greater planning accuracy and better implant location.
4. It standardizes the osteotomies according to the final prosthetic outcome, optimizing accuracy in the fabrication and placement of the final prosthesis.
5. It benefits the patient by improved efficiency in treatment planning and simplified treatment.
6. It reduces the need for expensive components to correct angulation problem and reestablish adequate emergence for adequate gingival contour.
7. In maxillary situations, it improves the esthetic outcome to meet the patient's wishes.
8. It helps to determine if adequate interarch space is available for the interim fixed implant prosthesis by measuring the distance between the top of the bone and the intaglio surface of the denture.[35]

Cassetta and colleagues[36] performed an in vivo study of 116 patients to evaluate the accuracy of a computer-designed (SLA) surgical guide by comparing the three-dimensional positions of planned and placed implants. Preoperative and postoperative computed tomographic (CT) images were compared. They found deviations between the postoperative position and the preoperative plan at the coronal and apical portions of the implant, as well as in the angulation of the implant. Although the reported deviation values were extremely high, they do not appear to have resulted in important clinical complications. It suggested the necessity of always keeping a safety zone of at least 2 mm to avoid critical anatomical structures.[36]

Implant Angulation Principles for IIL Success

A minimum of four implants must be placed in the mandibular arch, as parallel as possible to each other for prosthetic and practical reasons, and must be spread as far apart as possible.[37] In case of lack of bone height in the posterior quadrants, it has become very popular to angulate the distal implants to increase the prosthetic arch and consequently decrease the cantilever arm length. The benefits of the tilted implants are: (1) avoidance of the mental foramina, (2) permitting longer implants in less bone, (3) eliminating the need for bone grafting, (4) allowing engagement of dense and mature bone, and (5) improved force distribution.[37]

Kim and colleagues[38] examined the photoelastic effect of the inclination of the two distal implants according to the "all-on-four" concept on the stress distribution within the supporting structure. The authors concluded that within the limitations of the photoelastic stress analysis, the use of tilted implants reduced the maximum stress in the distal crestal bone of the distal implant by approximately 17% relative to the axial implants.[38]

Mandibular Complete Denture Conversion to a Provisional Implant-Supported, Screw-Retained Fixed Prosthesis for Immediate Loading

The technique of immediate loading of endosseous root-form implants has been described mostly for the mandible in completely edentulous patients, with placement of a provisional fixed implant-supported prosthesis on the same day of implant surgery.[22,23,39-46]

The concept of converting removable complete dentures to provisional fixed restorations was described by Balshi in 1985.[46] Since then, many similar techniques with some variations have been described.[23,39-46]

Case Study

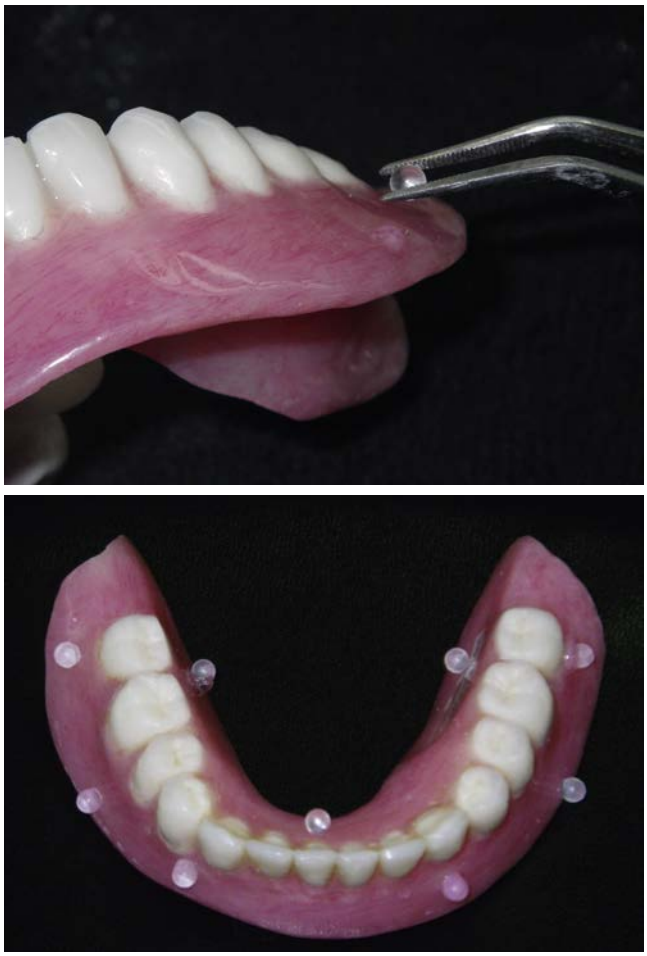
A 72-year-old white woman expressed dissatisfaction with the function and the esthetics of previously fabricated mandibular removable complete dentures (Figure 37-2). After various treatment options were discussed, it was decided to make a set of presurgical complete dentures; to place six root-form implants, four in the anterior segment of the mandible and one in each posterior segment; and to transform the mandibular presurgical complete denture into an implant-supported, screw-retained provisional fixed prosthesis and then fabricate the final fixed complete denture.

The presurgical set of maxillary and mandibular complete dentures was fabricated according to standard procedures for removable prosthodontics[47,48] (Figure 37-3). These complete dentures were to be worn for a period of time to rule out any problem from esthetic and functional perspectives (see Figure 37-3).

A copy cast of the maxillary denture was articulated with an ear-face-bow onto a semi-adjustable articulator programmed with appropriate condylar inclination specific to the patient. The mandibular complete denture was duplicated twice with a Lang duplicator and made of clear autopolymerizing acrylic resin. One duplicate was used as a custom impression tray using a three-visit-in-one technique.[49] The second duplicate was sent with the master cast to fabricate the CAD-CAM frame for the final mandibular fixed complete denture. The mandibular complete denture was prepared for CBCT radiographs as follows: Six to nine plastic radiopaque balls were glued to the cameo surfaces of the denture. (Figure 37-4). A bite registration polyvinyl siloxane (PVS) material was used between the two dentures to secure centric occlusion during radiographic procedures (Figure 37-5). Two CBCT radiographs were made: one with the patient wearing the mandibular denture, and another one just a scan of the denture itself (Figure 37-6). The two scans were uploaded to the Simplant software.

• **Figure 37-2** Esthetic and functional problems with the existing complete dentures. Patient's chief complaints are: "My dentures are very loose, uncomfortable, and ugly. And I cannot eat with them."

• **Figure 37-3** The presurgical set of maxillary and mandibular complete dentures were fabricated according to standard procedures of removable complete prosthodontics. Adequate pleasing esthetics and comfortable removable dentures.



• **Figure 37-4** Six to nine plastic radiopaque balls are glued to the cameo surfaces of the mandibular denture. Care must be taken not to place them all on the same horizontal plane.

• **Figure 37-5** A bite index with radiolucent polyvinyl siloxane is necessary to ensure that the prosthesis remains well-positioned in centric occlusion and the jaws stabilized at the time of radiographic scanning.

A virtual treatment plan was done in which the six implants were virtually placed (Figure 37-7,). Then a surgical guide was designed (Figure 37-8, *A*) and emailed to Materialize for fabrication with a prescription (a) containing the type, diameter, and length of the implants and three fixation screws, and (b) asking the occlusal surfaces of the teeth to be kept as uninvolved as possible with the surgical sites.

With the guidance of a surgical guide that had been fabricated based on the mandibular presurgical complete denture,

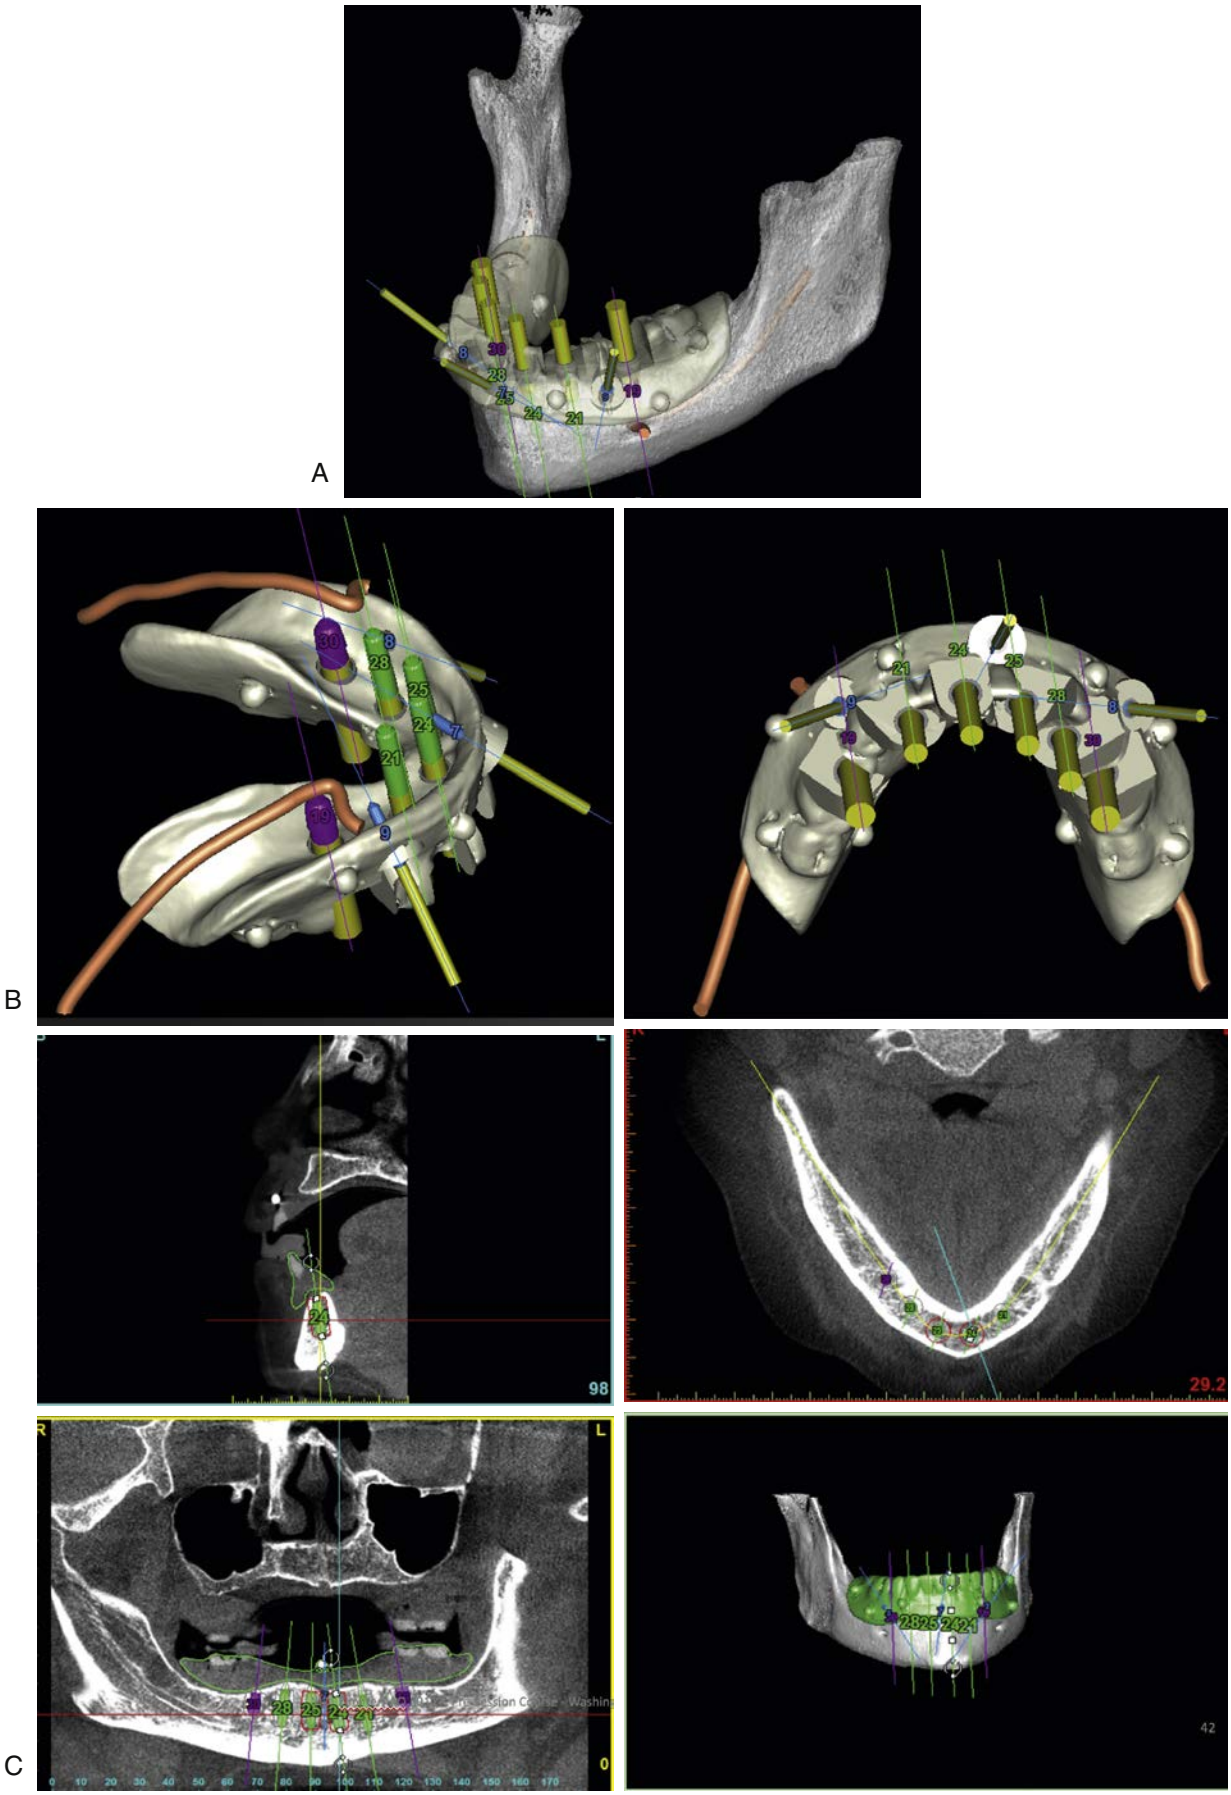
• **Figure 37-6** Cone-beam computed tomography dual scan. **A,** The patient is scanned with the denture in. **B,** A second separate scan is done for the denture.

and secured with three fixations screws, six root-form implants were placed parallel to each other, following a detailed prescription compatible with the implant system used, with no flap required in this patient situation (see Figure 37-8, *B-D*). If all six implants were stable with at least 30 Ncm of torque, we would proceed to convert the mandibular complete denture to an interim implant-supported screw-retained fixed complete denture. Titanium or PEEK plastic polymer temporary abutments are needed for the procedure.

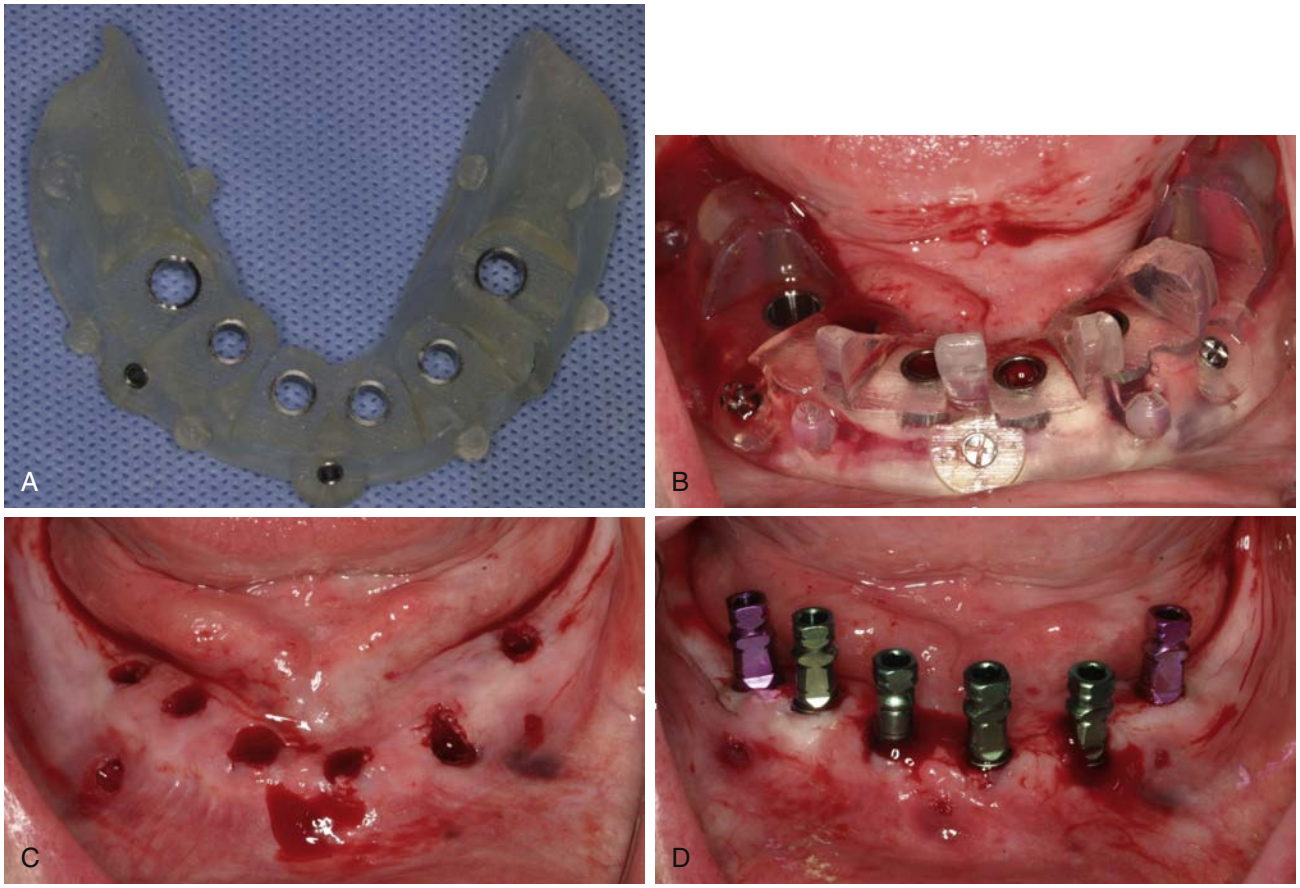
The conversion could be done with any of the following three techniques: intraorally, in the laboratory, or digitally planned and placed.

Intraoral Conversion Technique

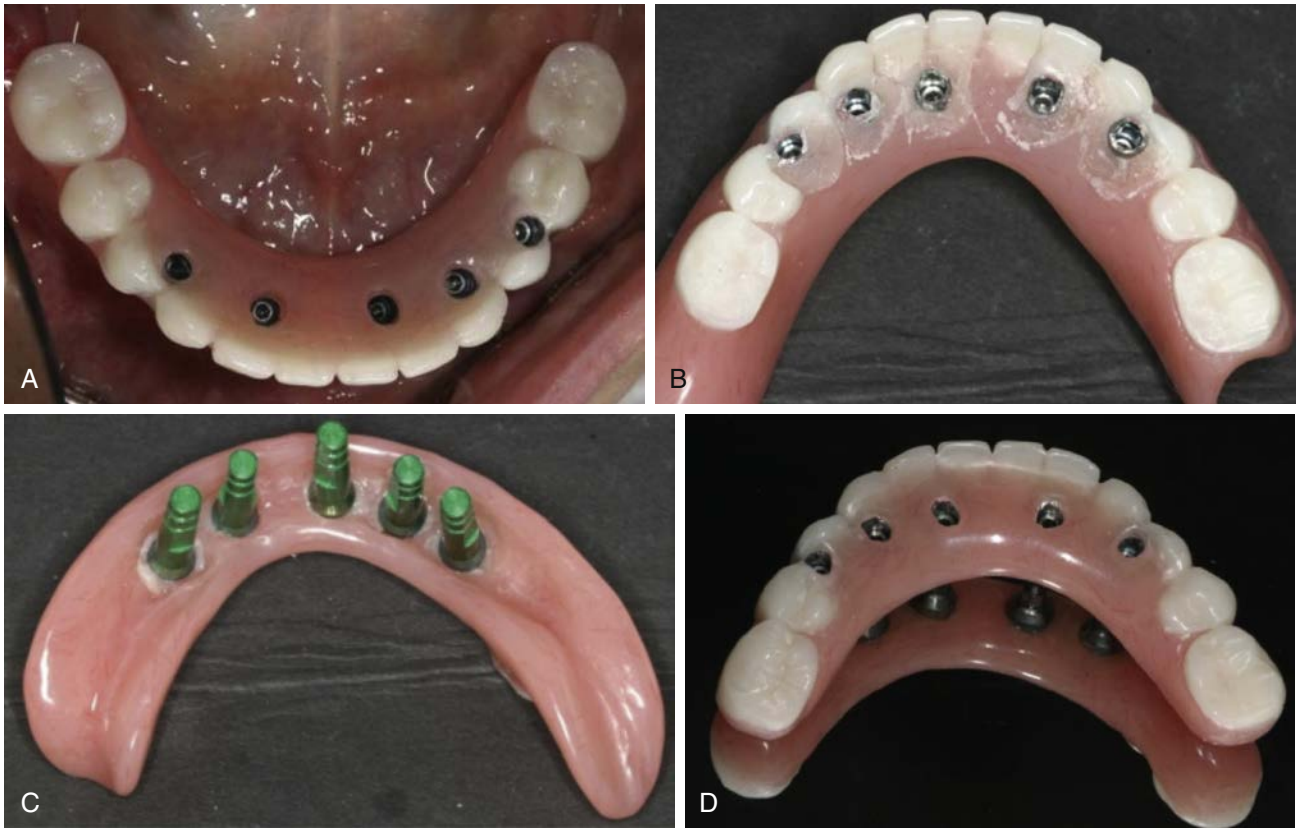
Once the implants are placed, short healing abutments are placed over them (Figure 37-9).



• **Figure 37-7** **A,** Virtual planning of the six implants. **B,** Intaglio and **(C)** cameo views of the surgical guide planning process.



• **Figure 37-8** **A,** Surgical guide. **B**, Surgical guide secured in patient's mouth. **C,** Final flapless osteotomy sites. **D,** Six Zimmer Tapered Screw-Vent implants (Zimmer Dental, Carlsbad, CA) parallel to each other, with their mounts in the surgical sites.



• **Figure 37-9** **A,** Mandibular denture with the implant respective openings in the patient mouth. **B,** The temporary abutments are luted to the denture, and **(C)** implant lab analogues are placed onto the temporary abutments, then sent to the lab to be boxed for making a master stone cast. **D,** Then the flanges are removed. The intaglio surface is rounded. The conversion denture is finessed and polished, then screwed in patient's mouth.

A light to medium viscosity of PVS impression material is placed on the intaglio surface of the mandibular denture, then seated over the healing abutments, making the mandibular denture contact the maxillary denture in centric occlusion. After the setting of the PVS, the mandibular denture it is removed and the contacts of the healing abutments with the intaglio surface are marked with a permanent marker. Using a pear-shaped acrylic carbide burr, openings are made through the marked areas. The denture is then placed and centric occlusion is verified. Temporary abutments are placed over the implants using either a short or long screw, after removing the healing abutments. If the long screw interferes with the opposing occlusion, a short one is used. A space of at least 2 mm should exist around the temporary abutments and the denture acrylic base.

A small increment of autopolymerizing acrylic resin is placed and bead-brushed around an anterior temporary abutment and the adjacent denture acrylic. Then the patient is asked to close in centric occlusion until polymerization of the acrylic resin is complete. Now the denture is secured in place, and all other abutments are luted to the denture using either pink or tooth-colored acrylic resin where the access hole is at an occlusal surface (see Figure 37-9).

When the acrylic resin is completely set, the screws of the temporary abutments are removed, and the mandibular complete denture is removed from the patient's mouth . Healing abutments are placed back over the implants, and implant analogues are placed at the intaglio area of the denture to make a cast (see Figure 37-9).

Autopolymerizing acrylic resin is bead-brushed and then poured around the provisional copings and along the intaglio area of the denture. The acrylic resin is allowed to polymerize in a pressure pot with hot water under 25 psi to increase the strength and reduce the porosity of the acrylic material.[50]

After polymerization, excess acrylic resin material and the denture flanges are removed. A reduced distal cantilever is developed by limiting its length to the width of a molar. A mandibular master cast is fabricated with type IV dental stone. Pink-colored condensation silicone is used to simulate soft tissue.[51]

The mandibular denture is mounted on a semi-adjustable articulator against the mounted maxillary cast. This step is important in the fabrication of the final fixed complete denture. The denture thus is converted into an implant-supported, screw-retained fixed prosthesis. The acrylic resin material of the intaglio surface is shaped into a convex surface 2 mm above the gum area to allow access for oral hygiene (see Figure 37-14, *E* and *F*).[39]

Extraoral Conversion Technique

After the placement of the implants, the clear acrylic mandibular denture duplicate can be prepared to be used as a custom tray (Figure 37-10). Or, the surgical guide can be prepared for use as a custom tray for the fabrication of the master cast as follows: All the metal cylinders of the surgical guide are removed by heating it, leaving wider openings for the final impression (Figure 37-11, *A*)

The impression copings are placed over the implants and connected together and to the guide as follow: A small increment of fast setting auto polymerizing acrylic resin or BIS-GMA type of resin, is to be placed and bead-brushed around an anterior impression coping on the adjacent denture acrylic. Then the patient is asked to close in centric occlusion till the complete polymerization of the acrylic resin. Now the guide-custom tray is secured in place, all other impression copings will be luted to the denture using the same acrylic resin. (see Figures 37-10 and 37-11). The patient is then asked to close in centric. This will verify that the guide tray is in the right position and is maintaining the centric and occlusal vertical dimension positions after connecting all impression copings together and to the guide custom tray.

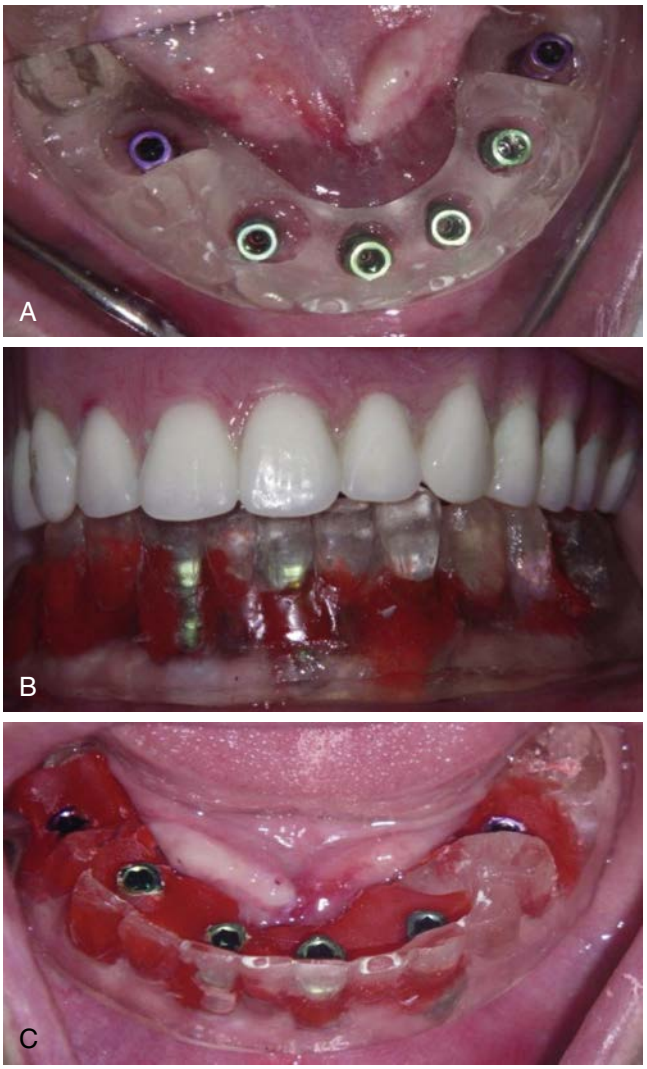
In some situations, where there are not enough occlusal surfaces to maintain the mandibular centric position, bite-registration PVS material can be placed in the mouth over the intact occlusal surfaces of the surgical guide (see Figure 37-11, *D*). The patient is dismissed after placing appropriate healing abutments over the implants. The patient is briefed about the reason why he or she will leave without the interim screw retained fixed complete denture, and will return the next day to receive the interim prosthesis.

A mandibular master cast is fabricated with type IV dental stone after boxing the impression with irreversible hydrocolloid impression material (Figure 37-12). Pink-colored condensation silicone is used to simulate the soft tissue.[51]

The mandibular cast is mounted on a semi-adjustable articulator against the already mounted maxillary cast. The guide tray is removed from the cast. The patient's mandibular denture is fitted onto the master cast. Then temporary abutments are placed one by one and the patient's denture is fitted over them. The opposing cast is closed over to verify that the maxillary and mandibular opposing teeth are in centric occlusion (Figure 37-13). The mandibular denture is finished as in the intraoral technique. The advantage of this technique is that it is done in the lab, minimizing chairside time (Figure 37-14). It is convenient and less stressful to the patient and doctor, and the prosthesis contours and occlusion can be refined easily with clinically and laboratory predictable results (Figure 37-15).

Digitally Planned and Converted Technique

The presurgical dentures are fabricated previously using a CAD-CAM generated milled denture system (Figure 37-16). The surgical guide can be milled from a clear acrylic puck block using the same digital file as for the presurgical denture, or by duplicating the worn presurgical denture. Six to nine fiduciary radiopaque markers are luted at different vertical levels to the cameo surfaces of the duplicate denture. The conversion denture is done as follows. A new digitally fabricated and milled mandibular denture is made using the stored digital information collected from the CBCT images of the radiographic template and of the patient's mandible. The virtual implant positions are then used and superimposed over the digital denture information to fabricate a digital mandibular conversion denture with



• **Figure 37-10** **A,** The duplicate of the presurgical denture with implant openings before the connection procedure in the patient's mouth. **B-C,** Implants are connected at the existing occlusal vertical dimension in a centric occlusion position.

channels milled corresponding to the implant positions.[52] These channels should have adequate openings to clear the temporary abutments corresponding to the implant system used. Temporary abutments are then placed over immediately placed implants, and autopolymerizing acrylic resin is flowed to connect them together and to the mandibular denture following the technique described previously. The finishing steps of the converted denture are done as previously described.

The mandibular provisional implant-supported, screw-retained prosthesis is placed in the patient's mouth immediately after implant surgery (see Figure 37-14). The fit of the mandibular prosthesis can be evaluated through the alternate pressure technique,[53,54] and the occlusion is refined if needed. Light viscosity PVS is placed and trimmed back to 3 mm, and provisional cement is placed into the occlusal access openings. Postoperative medications and instructions are given orally and in a written format with an emphasis on a custom oral hygiene instructions and on using a soft diet for the initial healing phase.

In the case described earlier, healing after implant surgery was uneventful. The patient was followed at 1 week, 2 weeks, and monthly until the third month with no surgical or prosthetic complications. Once the implants were osseointegrated, the final prosthesis was started (see Figure 37-16).

The provisional fixed prosthesis allowed the patient and the treating dentist to evaluate appearance, function, and oral hygiene before the fabrication of the definitive fixed-detachable restoration (Figure 37-17). The technique described can also be used with the conventional two-stage approach at second-stage surgery. It can certainly be applied to partially edentulous patients by transforming the provisional removable partial denture into an implant-supported, screw-retained provisional fixed partial denture.

Fabrication of the Definitive Screw-Retained Fixed Complete Denture

The previously fabricated articulated master mandibular cast and the duplicate of the presurgical denture are sent to a CAD-CAM center for the fabrication of CAD-CAM milled frame. Then denture teeth are set in wax and tried in for verification. After the dentist's and patient's approval, the trial fixed complete denture is flasked, lab remounted, finished, polished, and placed in the patient's mouth (Figure 37-18). Care instructions are delivered orally and in a written format.

• **Figure 37-11 A,** The surgical guide can be transformed to a custom tray by heating the metal cylinders and removing them from the acrylic resin. **B-C,** The guide used as an impression tray, in patient's mouth during the connection of all temporary abutments together and to the acrylic portion of the tray, preserving the centric position and occlusal vertical dimension. **D,** A bite registration polyvinyl siloxane material placed over the occlusal surfaces to capture the centric occlusion at the correct occlusal vertical dimension. **E,** Implant lab analogues are placed onto the temporary abutments and a master cast is made.

• **Figure 37-12** **A-B,** Cameo and intaglio views of the indexed denture duplicate. **C-D,** Duplicate is boxed with irreversible hydrocolloid impression material, and a stone material is poured over. **E,** The indexed guide over the final cast that is ready to be articulated to the opposing cast. **F,** Wax is flowed at the intaglio surface to fill in any voids before the boxing and stone cast fabrication.

• **Figure 37-13** The conversion of the presurgical denture starts. Temporary abutments are placed one at a time after making openings with pear-shaped carbide burrs. Mandibular presurgical denture is fitted over the final cast. Care must be taken not to lose the centric position by closing the articulator and making the mandibular occlusal surfaces contact the opposing respective surfaces.

• **Figure 37-14 A,** Pink and tooth-colored autopolymerizing acrylic resin is placed to fill the voids between the temporary abutments and the denture. **B,** Long screws or wooden sticks are used to prevent the resin from clogging the openings of the temporary abutments. While the added autopolymerizing acrylic resin is setting, the articulator is closed in centric occlusion. **C**-**D,** Denture flanges are removed and the intaglio surfaces are made convex for proper oral hygiene. **E**-**F,** The finished and polished mandibular interim screw-retained fixed complete denture. Note the space between the denture intaglio surface and the soft tissue to facilitate oral hygiene practices.

• **Figure 37-15** **A,** The prosthesis is in the mouth in centric occlusion. **B-C,** Views of the interim fixed screw-retained prosthesis in working and balancing articulation. **D,** Patient's pleasing smile.

• **Figure 37-16** Presurgical CAD-CAM fabricated dentures are done using the AvaDent technique. **A,** Maxillary and mandibular final impressions, a maxillo-mandibular relations record, and a prescription sheet are sent to AvaDent center for the fabrication of digital dentures. **B,** Digital setup of the denture teeth. **C,** Milled mandibular denture base with the corresponding tooth sockets ready for the gluing of artificial teeth.

Contemporary Restorative Options for the Single Implant

BALDWIN W. MARCHACK

Introduction

In the more than three decades since osseointegrated dental implants were first introduced, the use of implant-supported restorations for oral rehabilitation has become a predictably successful treatment, one embraced by patients and dentists worldwide. During that time, recognition has grown that the best functional and esthetic results can be achieved when the surgeon, restorative dentist, and dental laboratory technician work together to plan and achieve the optimal outcome for each individual patient. This chapter provides an overview of the information oral surgeons need in order to collaborate with their restorative dentists on the design and fabrication of successful implant-supported solutions for single posterior sites and single anterior sites in both the maxilla and mandible.

• **Figure 38-1** Screw-retained implant restoration.

Restorative Options

The Single Posterior Implant

When restoring the single posterior implant, the restorative dentist may choose between a screw-retained restoration (Figures 38-1 and 38-2) or a cement-retained restoration (Figures 38-3 and 38-4).

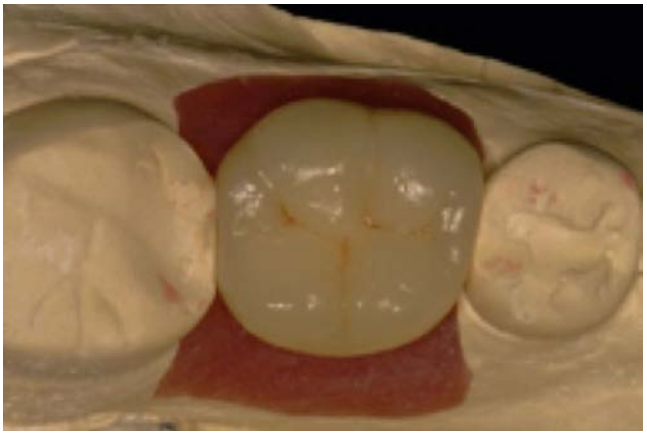
Cement-Retained Single Posterior Implant Restorations

Cement-retained single posterior restorations may be cemented on either a custom (patient-specific) abutment (Figures 38-5 and 38-6) or a stock (prefabricated) abutment (see Figure 38-4; Figure 38-7). Two varieties of stock (prefabricated) abutments are typically available.

- One has a flat, circular margin (Figure 38-8) with accompanying impression copings (Figure 38-9), abutment replicas (see Figure 38-7), and healing caps (Figure 38-10). Implant companies offer these abutments

• **Figure 38-2** Screw-retained implant restoration attached to implant replica on working model.

• **Figure 38-3** Cement-retained implant crown.



• **Figure 38-6** Cement-retained implant crown placed on custom abutment.

• **Figure 38-10** Healing cap placed on stock abutment (Snappy, Nobel Biocare, Yorba Linda, CA).

• **Figure 38-11** Snappy abutment (Nobel Biocare, Yorba Linda, CA).

• **Figure 38-12** Cementable abutment (Straumann, Andover, MA).

• **Figure 38-13** Direct abutment (Dentsply, York, PA).

• **Figure 38-14** Cement-retained implant crown, cemented to stock abutment (Snappy, Nobel Biocare, Yorba Linda, CA).

• **Figure 38-15** Esthetic abutment (Nobel Biocare, Yorba Linda, CA).

under various names, such as the Snappy Abutment (Figure 38-11) from Nobel Biocare (Yorba Linda, CA); the Cementable Abutment (Figure 38-12) from Straumann (Andover, MA); and the Direct Abutment (Figure 38-13) from Dentsply (York, PA). The margins of all such abutments cannot be altered, and, if any attempt is made to modify them, the accompanying components will be rendered useless. Figure 38-8 is an example of such a non-modifiable stock abutment. Figure 38-14 shows it after the cementation of a porcelain-fused-to-zirconia implant crown.

- The second type of stock or prefabricated abutment can be modified. The margins of such abutments are not flat but have a somewhat scalloped design and are intended to be altered to accommodate the existing gingival contours at the site. Again, implant companies have different names for these types of abutments, such as Nobel Biocare's Esthetic abutment (Figure 38-15), Straumann's

• **Figure 38-16** Anatomic abutment (Straumann, Andover, MA).

• **Figure 38-17** TiDesign abutment (Dentsply, York, PA).

• **Figure 38-18** Stock abutment with margins altered (TiDesign, Dentsply, York, PA).

• **Figure 38-19** Cement-retained implant crown, cemented to stock abutment (TiDesign, Dentsply, York, PA).

• **Figure 38-20** Custom zirconia abutment attached to implant.

• **Figure 38-21** Cement-retained implant crown, cemented to custom abutment.

Anatomic abutment (Figure 38-16), and Dentsply's TiDesign abutment (Figure 38-17). Figure 38-18 is an example of such a modifiable stock abutment. Figure 38-19 shows it after the cementation of a porcelain-fused-to-zirconia implant crown.

Custom abutments may be cast with gold alloy or milled from zirconia or titanium to fit the space constraints and soft-tissue conditions at the restorative site. They are patient-specific and site-specific. Examples of the proprietary systems for manufacturing such custom abutments include Procera (Nobel Biocare), Cares (Straumann), and Atlantis (Astra Dentsply). Figure 38-20 shows a custom zirconia abutment before the cementation of a porcelain-fused-to-zirconia crown. Figure 38-21 shows the crown after cementation.

Screw-Retained Single Posterior Restorations

Early implant-supported restorations that were screw-retained were typically non-segmented restorations made from cast gold and veneered with porcelain. As CAD/CAM technology developed for dental applications, the milling of screw-retained restorations from titanium and zirconia became possible. Essentially, variations on this approach made the abutment and crown a single entity milled from zirconia, with the restoration designed to have the full anatomic contours of the tooth or milled

• **Figure 38-22** Screw-retained, one-piece, milled zirconia implant restoration.

• **Figure 38-23** Screw-retained, milled zirconia implant restoration, with titanium base.

• **Figure 38-24** Titanium stock (prefabricated) abutment attached to implant replica on working model.

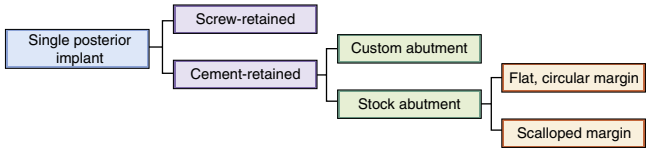
• **Figure 38-25** Milled monolithic zirconia implant crown with pre-milled screw channel, being cemented on stock abutment.

to almost the full contours and then veneered with feldspathic porcelain to complete the anatomic tooth contours (Figure 38-22).

However, one-piece zirconia abutments for internal connection implants exhibit significantly lower fracture resistance, specifically fracturing at the apical portion of the abutment.[1] Because of the relative tensional weakness of zirconia, the use of zirconia restorations with a titanium base is preferable, especially if the design permits the entire assembly to be connected by means of abutment screws (Figure 38-23).

The use of the original manufacturer's components is always recommended.[2] However, a screw-retained anatomically contoured monolithic zirconia restoration with a titanium implant interface may be desired, even though only cement-retained components are available from the manufacturer.[3,4] In such situations, transforming the cement-retained components into a retrievable restoration that more closely resembles the classical screw-retained restoration can be easily achieved by using a modified protocol. This involves obtaining a titanium abutment intended for cement retention (Figure 38-24), designing a cement-retained patient-specific zirconia crown that also incorporates a screw-access channel that will align with that of the abutment screw channel, and then cementing the milled and sintered zirconia crown to the abutment extraorally (Figure 38-25).

After removing any excess cement extraorally (Figure 38-26), the abutment/crown assembly can be seated and secured to the implant with the abutment screw delivered through the access channel milled into the crown (Figure 38-27); the access channel can then be sealed with composite resin (Figure 38-28). The accompanying diagram summarizes the options for the single posterior implant restoration.



• **Figure 38-26** Milled monolithic zirconia implant crown, extraorally cemented to stock abutment. This screw-retained unit is actually a retrievable cement-retained implant restoration.

• **Figure 38-27** Retrievable cement-retained implant restoration fastened to implant.

• **Figure 38-28** Restoration torqued to place, screw head protected, and screw channel sealed with composite resin.

• **Figure 38-29** Facial view of a single anterior, milled zirconia, screw-retained implant restoration.

• **Figure 38-30** Lingual view of a single anterior, milled zirconia, screw-retained implant restoration.

• **Figure 38-31** Milled zirconia custom abutment for a single anterior implant.

The Single Anterior Implant

When restoring the single anterior implant, the restorative dentist may again choose between a screw-retained restoration (Figures 38-29 and 38-30) and a cement-retained restoration (Figures 38-31 and 38-32).

• **Figure 38-32** Cement-retained implant crown placed on custom abutment.

• **Figure 38-33** Stock abutment on a single anterior implant (Esthetic, Nobel Biocare, Yorba Linda, CA).

Cement-Retained Single Anterior Implant Restorations

Cement-retained single anterior restorations may be cemented on a stock (prefabricated) abutment (Figures 38-33 and 38-34) or a custom (patient-specific) abutment (Figures 38-35 and 38-36). Because anterior single implants are often esthetically demanding and the tissue is usually scalloped with well-defined papillae, stock abutments with flat circular margins are often inappropriate. In the esthetic zone, only stock abutments with scalloped adjustable margins (see Figures 38-15 through 38-17) should be used.

• **Figure 38-34** Porcelain fused to zirconia, cement-retained implant crown cemented to stock abutment (Esthetic, Nobel Biocare, Yorba Linda, CA).

• **Figure 38-35** Milled zirconia custom abutment fastened to single anterior implant.

As with the single posterior implant, custom abutments for the single anterior implant may be cast with gold alloy or milled from zirconia or titanium to fit the space constraints and soft-tissue conditions at the restorative site. However, because metal abutments may cause a blue or gray discoloration of the soft tissue, zirconia abutments are preferred in the anterior esthetic zone. Figure 38-35 shows an anterior

• **Figure 38-36** Porcelain fused to zirconia, cement-retained implant crown, cemented to custom abutment.

• **Figure 38-37** Facial view of a single anterior, milled zirconia, screw-retained implant restoration.

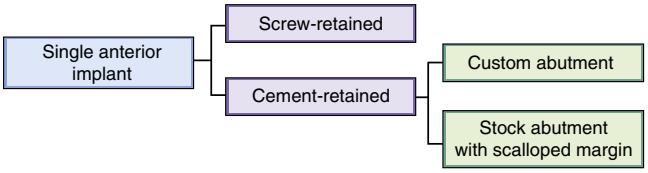
custom abutment milled from zirconia, and Figure 38-36 shows it after cementation of the definitive all-ceramic crown.

Screw-Retained Single Anterior Implant Restorations

As with the posterior restorations, screw-retained single anterior implant restorations may be made from cast gold veneered with porcelain or milled from zirconia. If milled from zirconia, the restoration may be milled as a single entity entirely out of zirconia or milled to almost the full contours and then veneered with feldspathic porcelain to complete the anatomic tooth contours. Figure 38-37 shows a milled zirconia restoration, with minimal porcelain veneering on the facial surface only, torqued into place and with the screw access sealed with composite (Figure 38-38).

• **Figure 38-38** Lingual view of a single anterior, milled zirconia, screw-retained implant restoration, with screw access sealed with composite resin.

The accompanying diagram summarizes the options for the single anterior implant restoration.



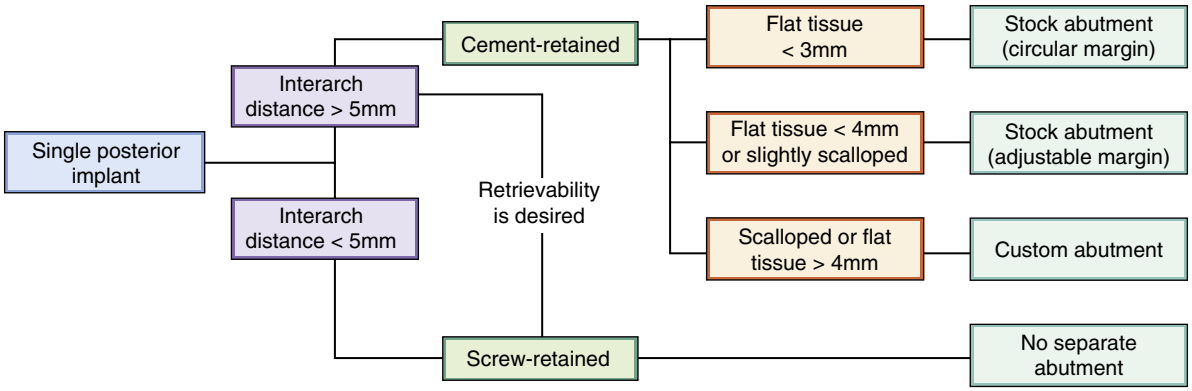
Screw Retention versus Cement Retention

Given the various restorative options, restorative dentists will often seek advice from oral surgeons regarding the best choice for any given patient. Throughout the course of modern dental implant history, opinions have shifted about whether cement or screw retention is best. In the earliest days, when prostheses frequently had to be removed to remove failing implants, screw retention was regarded as clearly superior.[5] However, implant survival rates climbed quickly as understanding of the biomechanics of dental implants grew, better products appeared on the market, and techniques evolved for placing and restoring them. With success rates predictably reaching 90% and above, concerns about occlusion and esthetics moved to the forefront, and cement retention gained proponents.[6] They cited not only the improved esthetic results achievable with cemented prostheses but also their relative simplicity, fewer problems with screw loosening, passivity of fit, better control of occlusion, and economy. More recently, however, new concerns about cement retention have arisen.[7]

As a means of securing prostheses to implants, both cementation and screw retention have limitations and advantages. Some of the most important considerations are discussed in the following sections.

Retrievability

Proponents of cementation argue that, when used properly, cement can be used to retain implant-supported prostheses and still allow for their removal if necessary.[6] Nonetheless,



• **Figure 38-39** The Posterior Abutment Decision Tree.

screws are designed to be removed and present the simplest and most straightforward option for easy retrievability.

Implant Positioning Requirements

In order for screw-retained restorations to be esthetic, the screw-access hole must not be visible. Until quite recently, poorly placed anterior implants have eliminated any possibility of using screw retention. Careful placement of the implant, preferably with the aid of three-dimensional imaging technology and the use of a surgical guide, has been essential. Although a few manufacturers have recently introduced angled components that enable the screw-emergence position of even poorly positioned implants to be hidden from view,[8] such components are not yet available for all implants.

Effects on the Peri-implant Soft Tissue

The most significant concern that has arisen with regard to cement retention relates to its effect on the peri-implant soft tissue. More than 15 years ago, reports of complications resulting from cement extrusion into the subgingival peri-implant tissues began to appear.[9,10] Wilson in 2009 reported that excess dental cement was associated with signs of peri-implant disease in 81% of the implants included in a prospective clinical study, with the presence of the disease going undetected in many patients for years after cementation of the prosthesis.[7] Although in that study signs of the disease were absent in 74% of the test implants after removal of the excess cement, the detection and removal of residual cement can be problematic even when the height of the implant crown cement finish line is controlled. Weber and co-workers found that over the course of their multicenter, 3-year prospective study, the use of cement-retained crowns appeared to increase plaque and bleeding index scores, whereas the use of screw-retained crowns lowered those scores.[11] Any excess cement left on the implant or the surrounding soft tissues appears to significantly increase the risk of peri-implant disease.[12] Micro-organisms retained within the cement are believed to play a major role in the etiology of both mucositis and peri-implantitis.[13] The cement may also be a mechanical irritant.[7]

Decision Making

Given the gravity of the risk to implant survival posed by peri-implant disease, one may conclude that most implant-supported prostheses should be screw-retained. However, certain conditions may preclude that option. Situations that may require cement retention include the following:

- When the implant is positioned so that any screw-access channel is visible on the facial surface of the restoration (and no components are available to correct for that).
- When the incisal or occlusal surface is likely to be compromised either esthetically or in terms of structural stability because of the presence of the restorative material necessary to seal the screw access.

Single Posterior Implants

Limitations on the interocclusal space at any given implant site may also significantly affect the choice between screw or cement retention. This is because, among the many factors influencing the amount of retention that can be achieved by luting a restoration to an implant, the height of the abutment is one of the most significant. (Other factors include the width, taper, and surface treatment of the abutment and the type of luting agent used.[14]) When Abbo and colleagues compared the retention strength of four titanium abutments with different heights and tapers, they found that the least retentive abutment was 4 mm high with an 8-degree taper, while the most retentive was 8 mm high with an 8-degree taper.[15] They found that increasing the height of a 4.3-mm titanium abutment by 1 mm significantly increased the dislodgment resistance of zirconia copings.

Recognizing that one of the most frequent questions the novice restorative dentist will ask the surgeon is "What kind of abutment should I use?" and with all the preceding considerations in mind, the author has developed the following decision trees (Figure 38-39).

For single posterior implants, the first consideration must be the dimensions of the interarch distance. As discussed earlier, cemented crowns can be easily dislodged when the abutment height is less than 4 mm. In addition, cemented crown margins should not be more than 1 mm

• **Figure 38-40** Single posterior implant with limited interarch space.

• **Figure 38-41** Screw-retained implant restoration indicated for limited interarch space.

• **Figure 38-42** Single posterior implant with flat peri-implant tissue contour (Nobel Replace, Nobel Biocare, Yorba Linda, CA).

below the gingival margin; otherwise, excess cement may not be easily removed. With this in mind, if the **distance** between the peri-implant tissue and the opposing dentition is **less than 5 mm**, the space will not be sufficient to accommodate a 4-mm high abutment and a crown. Instead, the implant should be restored with a non-segmented screw-retained restoration such as the one illustrated in Figures 38-23, 38-40, and 38-41. However, the screw-access hole must emerge near the center of the occlusal table.

• **Figure 38-43** Stock abutment fastened to single posterior implant (Snappy, Nobel Biocare, Yorba Linda, CA).

• **Figure 38-44** Milled zirconia cement-retained implant crown.

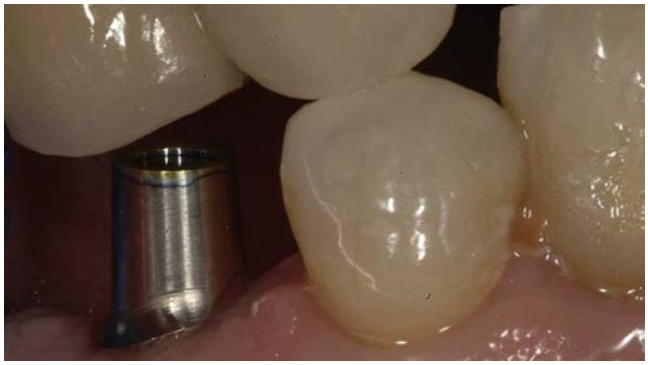
If the screw-access hole emerges on the facial or lingual surface or on a working cusp, then cement retention is the only option. If, however, the position of the screw-access hole allows for screw retention, recent research findings suggest that this option is more likely to promote long-term tissue health.

If the **distance** between the implant platform and the opposing dentition is **greater than 5 mm**, attention should shift to whether the patient has a bruxing habit or whether retrievability is desired. If so, a screw-retained abutment is still recommended.

If the **distance** between the implant platform and the opposing dentition is **greater than 5 mm and retrievability is not an issue**, either cement or screw retention are acceptable options. At this point, if the referring restorative dentist prefers a cemented restoration, the tissue biotype and shape must be considered. If the tissue is flat and not too deep, and the cement margin can be accessed easily, a simple stock abutment with a flat circular margin such as the Snappy, Cementable, or Direct Abutment (see Figures 38-11 through 38-13) can be used. Figure 38-42 is an example of a patient with flat tissue that is not too deep. In this patient, a Snappy Abutment (Figure 38-43) was used, and a simple cementable crown (Figure 38-44) was

• **Figure 38-45** Healing cap attached to stock abutment (Snappy, Nobel Biocare, Yorba Linda, CA).

• **Figure 38-46** Milled zirconia cement-retained implant crown, cemented to stock abutment (Snappy, Nobel Biocare, Yorba Linda, CA).



• **Figure 38-47** Stock abutment used with uneven and asymmetric peri-implant tissue contour (Esthetic, Nobel Biocare, Yorba Linda, CA).

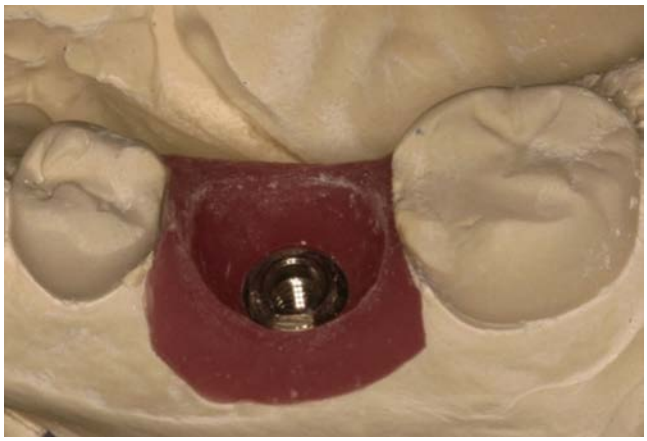
• **Figure 38-48** Stock abutment after modification of margins (Esthetic, Nobel Biocare, Yorba Linda, CA).

• **Figure 38-49** Milled zirconia cement-retained implant crown, cemented to stock abutment (Esthetic, Nobel Biocare, Yorba Linda, CA).

fabricated. In a situation such as this, the surgeon would typically supply the dentist with the impression coping for an abutment-level impression and an abutment replica and send the patient back with a prefabricated healing cap (Figure 38-45). Upon cementation, margins are easily accessible for the removal of any excess cement (Figure 38-46).

To confirm, if the tissue contours are flat, the biotype is thick, and the implant is not too deep, a stock abutment can be used for the restoration. The restorative margins will be accessible, enabling cleaning and ensuring the long-term viability of the restoration. Depending on the implant used, a simple abutment such as the Snappy Abutment (Nobel Biocare), Cementable Abutment (Straumann), or Direct Abutment (Dentsply) (see Figures 38-11 through 38-13) would be indicated. Typically, all are easy to restore.

However, if the tissue is not flat, this type of simple stock abutment should not be used. Instead, selecting an abutment that has a margin that can be modified to follow the tissue contour is recommended (Figures 38-47 and 38-48), offering a simple cemented solution (Figure 38-49). If the tissue is a little deeper or only minimally scalloped, a different kind of stock abutment can be chosen. Commercially available abutments of this type include the Esthetic Abutment (Nobel Biocare), Anatomic Abutment (Straumann), and TiDesign Abutment (Dentsply) (see Figures 38-15 through 38-17). Whereas simple stock abutments cannot be altered at all without jeopardizing the fit of the components, the margins of these abutments can be modified.



• **Figure 38-50** Laboratory model of single posterior implant with deep peri-implant tissues.

• **Figure 38-51** Custom abutment allows crown margins to be located just below tissue level.

• **Figure 38-52** Cement-retained implant crown, cemented to custom abutment.

Finally, if the tissue is very scalloped or very deep (Figure 38-50), a custom abutment will be necessary (see Figures 38-5 and 38-6) to obtain margins that are high enough to provide adequate access for cement removal when the crown is cemented (Figures 38-51 and 38-52). If the site conditions dictate the use of a custom abutment, a final consideration is whether that abutment should be custom milled or cast from precious metal alloys.

In summary, successful single posterior implant-supported cemented restorations must have adequate access to cement margins, adequate interarch clearance, and adequate abutment height to provide long-term retention.

Single Anterior Implants

In the anterior, other concerns come into play, namely esthetic considerations. The following questions should be asked:

- Is the tissue very scalloped or only minimally so?
- How well-defined are the papillae?
- Does the tissue require surgical augmentation? That is, is there sufficient hard and soft tissue to allow an esthetic result?
- Can the soft tissue be managed prosthetically?

Whereas responsibility for ensuring the presence of adequate hard tissue and augmentation of the soft tissue may be delegated to the surgical team member, the restorative dentist can also contribute to soft-tissue sculpting by using screw-retained provisional restorations.

Once the soft tissue esthetics have been established, the following anterior abutment decision tree can be used to guide the restorative decision-making process (Figure 38-53).

The first question to consider is where the screw-access hole would be positioned if the restoration were visualized at full contour. If the position were on the lingual surface (see Figures 38-29 and 38-30), the restoration could be screw-retained (see Figures 38-37 and 38-38), offering the benefits of retrievability. Screw retention also appears to be more beneficial to soft-tissue health and avoids the risk of residual cement leading to peri-implant disease.

If the screw-access hole emerges on the facial or the incisal aspect, the only choice is cement retention, with the exception of unique components that would allow the repositioning of the screw channel. These systems and components are discussed in more detail in the following section. Of course, if the screw-access hole exits on the lingual surface, the restoration can also be cement-retained if the restorative dentist prefers.

The relevant question then becomes, what are the soft-tissue contours? As with single posterior restorations, if the contours are flat or minimally scalloped, a stock abutment, other than the ones with flat circular margins can be used (see Figures 38-15 through 38-17). An example of this type of abutment was previously discussed (see Figures 38-33 and 38-34).

Most commonly, however, the anterior tissue will be deep and/or scalloped. The use of a custom abutment then becomes imperative. Besides providing the necessary marginal access for cleaning, the use of custom abutments to support single anterior prostheses can significantly shape the soft tissue (see Figures 38-35 and 38-36).

Discussion

Abutment Material Choices

Implant abutments are fabricated from one of three main materials: gold, titanium, or zirconia. Whereas gold was once the standard for custom abutments, today it appears to have significant disadvantages compared with either titanium or zirconia.

For one thing, gold has been demonstrated to be less biocompatible. When Welander and colleagues placed implants in dog mandibles and restored them 1 month later with abutments made of titanium, zirconia, or gold/platinum alloy, they found that the soft-tissue dimensions around the titanium and zirconia abutments remained stable.[16] In contrast, around the gold alloy abutments, an apical shift of the barrier epithelium and the marginal bone occurred between 2 and 5 months of healing. Furthermore, the connective-tissue zone lateral to the gold alloy abutments contained lower amounts of collagen and fibroblasts and larger fractions of leukocytes than the corresponding connective tissue zone of the titanium and zirconia abutments.[16]

Gold abutments must be cast, an analog process that is susceptible to distortion.[17] In contrast, custom titanium and zirconia copings that are fabricated using computer-aided design and computer-aided manufacturing (CAD/CAM) technology in conjunction with computer-numerically controlled (CNC) milling machines depend less on manual laboratory procedures than do conventional casting protocols. This allows for better control of the precision of fit. When Ortorp and co-workers used a coordinate-measuring machine to compare the precision of fit of 20 milled titanium frameworks with five conventional cast ones, they found a statistically better fit and higher precision of fabrication in the CNC frameworks.[18]

Kimura and associates found evidence of hemidesmosomal attachment to both mirror-surfaced commercially pure titanium and yttria-stabilized tetragonal zirconia polycrystals (Y-TZP). Although after 1 hour they documented less attachment of the TZP than the titanium in terms of mRNA expression and protein expression of laminin γ2 and integrin β4 ($p < 0.05$), the epithelial attachment at 48 hours was similar.[19]

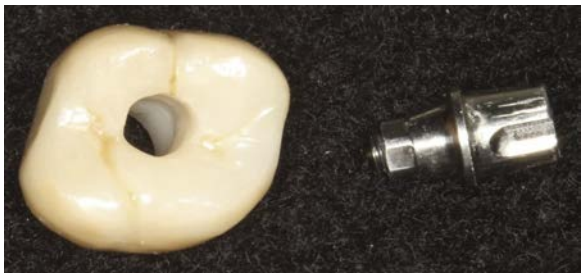
When Rimondini and co-workers assessed microbial colonization of Y-TZP and pure titanium, they found that in vivo Y-TZP accumulated fewer bacteria than titanium in terms of the total number of bacteria and the presence of potential pathogens such as rods.[20] A systematic review by Nakamura and colleagues of published data on zirconia abutments found them to be both biologically and mechanically reliable in the anterior region and potentially less conducive to early plaque retention compared with titanium.[21]

The final question to be considered when choosing between titanium and zirconia abutments is the effect on esthetics. When Jung and associates considered the effect of all-ceramic crowns and ceramic abutments versus porcelain-fused-to-metal crowns on titanium or gold abutments on marginal peri-implant soft-tissue color, they found that if the soft tissue were thicker than 2 mm, the abutment material choice made no difference in the definitive result. However, they concluded that the marginal tissue on all-ceramic restorations matched the tissue color of adjacent natural teeth significantly better than PFM crowns on titanium or gold abutments.[22]

Compatible Components

This chapter has attempted to describe all the available options for screw-retained and cement-retained restorations for single posterior implants and single anterior implants. Although some techniques or materials may have been omitted, the author has attempted to thoroughly describe the reasons for selecting one method over another or one material over another.

Sometimes, the restorative dentist may need to be creative in finding solutions that are available from one manufacturer but not from another. For example, a situation might arise in which an anatomic-contour, monolithic zirconia restoration is desirable for strength with a titanium implant interface that is screw-retained using the implant manufacturer's components. One reason for using the same manufacturer's components is demonstrated in the study by Kim and colleagues.[2] The authors attempted to measure the removal torque after the cyclic loading of the abutment screws from similar implants when the abutments and screws used were made by four different manufacturers. Whereas the removal torque was successfully measured when the abutments and screws from the implant manufacturer were used, broken screws, broken abutments, and



• **Figure 38-54** Stock abutment for conical connection implant with milled zirconia implant crown.

• **Figure 38-55** Milled zirconia implant crown being cemented extraorally to stock abutment.

even broken implants were reported for components from other sources. In fact, the study could not be completed as designed. Thus different material hardnesses and different fit tolerances may pose some risk when components other than those produced by the same implant manufacturer are used.

Retrievable Cement-Retained Restorations

Another issue is the use of zirconia for the apical portion of abutments manufactured for internal connection implants. Foong and co-workers[1] discovered that when abutments were made entirely of milled zirconia for internal connection implants, in one study, all of the apical portions of the zirconia abutments fractured under loading. This led the authors to conclude that the apical portion of abutments for internal connection implants should not be made of

• **Figure 38-56** Retrievable cement-retained implant restoration with all excess cement removed.

• **Figure 38-57** Retrievable cement-retained implant restoration fastened to conical connection implant.

zirconia, but rather of titanium, in order to be compatible with titanium implants. In such patients, the retrievable cement-retained restoration concept (Figures 38-54 through 38-57) as suggested by Chee and colleagues[3] and Rajan and associates[4] should be considered.

Implants with internal connections have become the preferred choice for single missing teeth instead of external connection implants, and Yamanishi and co-workers have shown that internal conical connection implants have a more stable joint.[23] Titanium and zirconia are now also recognized to be the best abutment materials in terms of the interface with the transitional epithelium.[19-21] Also, sometimes zirconia is better for esthetic reasons.[22] In such patients, creativity may be necessary to achieve an end result with an abutment that has a titanium internal connection component manufactured by the same manufacturer as the implant (Figures 38-58 and 38-59), with zirconia as it traverses through the transitional epithelium to avoid discoloration of the soft tissue (Figure 38-60), and with an all-ceramic crown for maximum esthetics (Figures 38-61 and 38-62).

Off-Axis Screw Channels

When the surgeon is forced to facially incline an anterior implant because of bone anatomy, the screw channel will

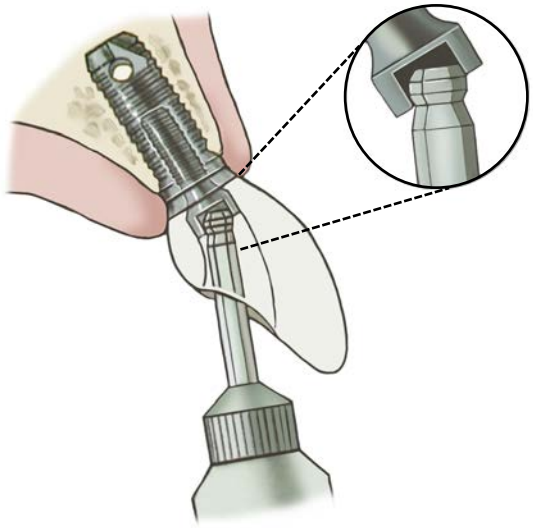
• **Figure 38-59** Stock abutment allows internal apical portion to be titanium.

• **Figure 38-60** Milled zirconia sleeve cemented to the stock abutment converts it to a custom abutment allowing zirconia to contact the transitional tissue.

• **Figure 38-61** Crowns for both the natural tooth and the implant are milled from lithium disilicate for strength and esthetics.

• **Figure 38-62** Custom abutment is fastened, and lithium disilicate crowns are luted with resin cement for strength and esthetics.



• **Figure 38-63** Enlarged screw access hole allows use of a ball-hex driver as described by Parel and Sullivan in 1987.

emerge on the facial or incisal surface of the definitive restoration, making it impossible to fabricate a screw-retained restoration. Since the 1980s, a solution has been sought to this problem. In 1987, Parel and Sullivan described a solution whereby the screw-access opening was enlarged (Figure 38-63) and a ball hexagon screwdriver was used to engage a hexagon-headed screw for an angulation correction of as much as 30 degrees.[24] However, the fit of such a screwdriver to the manufacturer's hexagon-headed screw was not perfect, and the concept was not popular.

It was not until 2004 that a company in Spain (Talladium International Implantology, Lleida, Spain) developed the so-called Dynamic Abutment (Figure 38-64), which

• **Figure 38-64** Dynamic Abutment (Talladium International Implantology, Lleida, Spain). The burn-out chimney can be rotated up to 28 degrees.

• **Figure 38-65** Angulated Screw Channel allows correction up to 25 degrees (Nobel Biocare, Yorba Linda, CA).

allowed an angulation correction of as much as 28 degrees. This abutment is available for several well-known implant systems such as Astra Tech, BioHorizons, Biomet 3i, Nobel Biocare, Straumann, and Zimmer.[8] Although not all components are available in the United States, the Angulated Screw Channel for conical connection implants by Nobel Biocare can correct the angulation of the screw channel by up to 25 degrees. This is accomplished by using specially provided screws and matching screwdrivers (Figure 38-65).

Avoiding Excess Cement Retention

If cementation is unavoidable or preferable, steps that can minimize the risk of complications include the following:

- Using custom abutments that enable careful control of the cement margin.
- Using a displacement cord to prevent extrusion of the cement apically on the abutment surface.
- Using the putty die technique described by Caudry and colleagues[25] or the Blue Mousse die as described by Wadwhani and Piñeyro[26] to prevent material extrusion into the peri-implant tissues.
- Using radiopaque cements.
- Making a post-cementation radiograph.

Conclusion

In conclusion, no right or wrong way exists to restore the single implant. Several variables must be considered in every patient. Although there are many advantages to selecting a screw-retained solution, such as retrievability, avoidance of cement, healthier tissues, and security in minimal interarch spaces, such a solution is technically more difficult to execute. Implant position and angulation must be ideal, and the presence of a screw-access hole covered with a restorative material may not be esthetically ideal. Cement-retained solutions are technically easier to execute, have better esthetics, and are more flexible when implant positions or angulations are less than ideal. However, careful cementation techniques must be used, and the tradeoff of lack of retrievability must be accepted.

Implant Overdentures

TONY DAHER, CHARLES J. GOODACRE, STEVEN J. SADOWSKY

Introduction

The concept of implant-supported/retained overdentures has been used for many years. Osseointegrated implants have been used successfully to support/retain these overdentures in the maxilla and mandible and considerable information has emerged regarding comparisons with other prostheses, such as their impact on function, quality of life, success/failure/complications, design guidelines, and clinical procedures. Implant overdentures have typically been complete arch prostheses (Figure 39-1), but partial overdentures have also been used, whereby natural teeth function in conjunction with implants (Figure 39-2).

From a biomechanical standpoint, overdenture prostheses can be either tissue supported and implant retained (Figure 39-3) or implant supported and implant retained (see Figure 39-1).

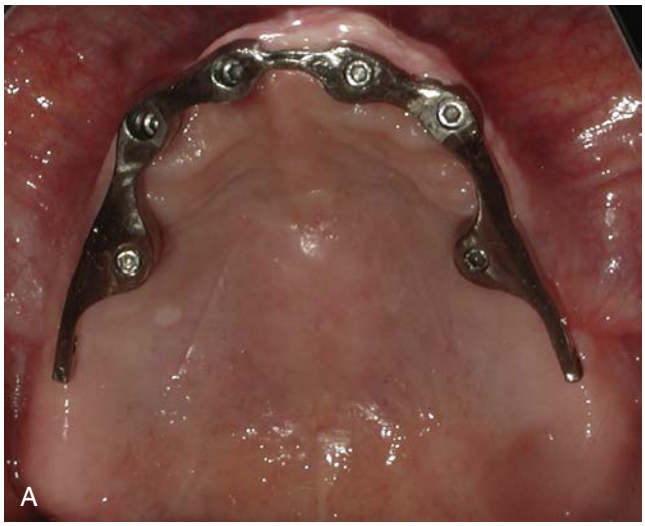
General Guidelines in Treatment Planning

Natural Tooth Overdentures and Implant Overdentures Compared

For decades, roots of natural teeth have been used to preserve bone and to support/retain removable prostheses. Dentures supported by natural teeth have been studied, and many types of complications occur such as periodontal problems that lead to root extraction, recurrent caries, repairs, denture adjustment, relines, and even remakes.[1] When overdentures are supported by implants rather than by roots of natural teeth, there is a higher tendency for success.[2] Long-term survival and success of oral implants retaining overdentures on both arches have been documented in a prospective study.[3]

Conventional Complete Dentures and Implant Overdentures Compared

There have been publications comparing implant overdentures with conventional complete dentures. Patient satisfaction improved when prosthesis retention and stability increased[4] and therefore satisfaction increased when mandibular implant overdentures were used instead of conventional complete dentures.[5] In fact, patients were more satisfied after 10 years with mandibular implant overdentures as compared to complete dentures even if vestibuloplasty was performed prior to fabricating the new



• **Figure 39-1** Six-implant prosthesis; Implant supported and retained by six implants. **A,** CAD-CAM bar with snap pin attachment. **B,** Intaglio view of a metal-reinforced overdenture prosthesis.

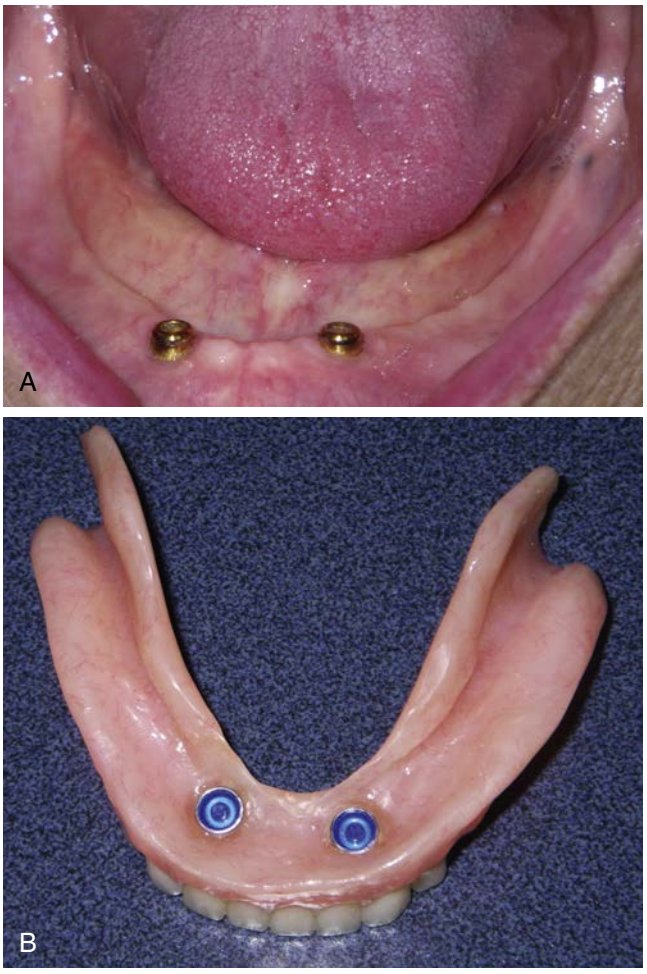
mandibular complete dentures.[6] Implant overdentures generally offer the advantages of improved comfort, support, retention, and stability.

When conventional complete dentures are worn for many years, substantial bone resorption occurs beneath the dentures (Figures 39-4 and 39-5), and this bone loss is about fourfold the amount of bone change that occurs adjacent to dental implants that are used with overdentures.[7]

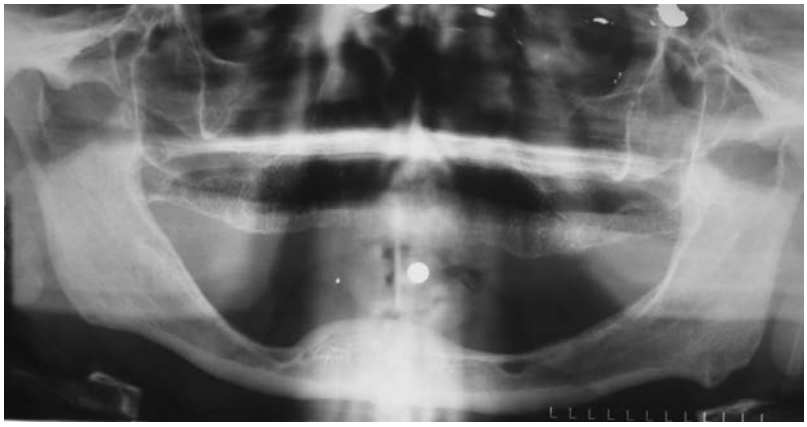


• **Figure 39-3** A two-implant prosthesis. **A,** Intraoral view of two locator abutments over implants. **B,** Implant-retained and tissue-supported overdenture; note the two blue least retentive Locator clips in their metal housings.

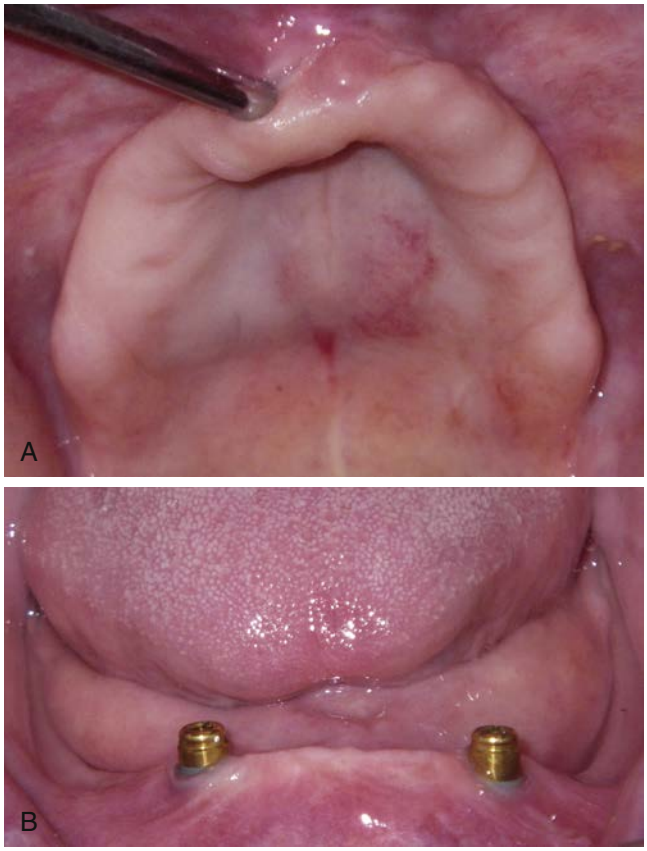
Implant-Fixed Complete Dentures and Implant Overdentures Compared

Although fixed complete dentures provide unparalleled prosthesis stability, clinicians have identified several potential advantages of implant overdentures compared to implant-fixed complete dentures[8]:

1. It may be possible to use a smaller number of implants and thereby decrease the cost.
2. It may be possible to provide better support of the facial soft tissues and improved phonetics for completely edentulous patients.
3. Patients have enhanced access for oral hygiene and better access for inspection of the surgical site.
4. There may be a better result when unfavorable jaw relationships are present (Figure 39-6).
5. When there is an opposing complete denture, it may be more stable; particularly when there is a resorbed residual ridge.
6. It is easier to make modifications to the prosthesis base.



• **Figure 39-4** Excessive bone resorption under a mandibular denture. Note the two mental foramen above the ridge.



• **Figure 39-5** **A,** Continuous resorption observed in the edentulous maxilla with **(B)** a mandibular bar overdenture supported by two interforaminal implants.

When the same patients comparatively wore both implant overdentures and implant-fixed complete dentures, they indicated the fixed complete dentures permitted them to more effectively chew harder foods. However, the general satisfaction of the patients was comparable.[9]

Patient attitudes and expectations should be evaluated when guiding patients in their choice of a prosthesis. Some patients consider stability to be their primary prosthesis requirement, and they would therefore prefer a fixed complete denture. Other patients identify ease of cleaning as the most important factor guiding their choice of prosthesis design, and they preferred an overdenture.[10]

The most frequently cited disadvantage of implant overdentures has been their incidence of complications, which is higher than other implant prostheses. In comparing the maintenance and repair required with implant-fixed complete dentures and implant overdentures, it was determined that implant overdentures accounted for 78% of the total number of repairs and 80% of the prostheses that required repairs. The number of repeat repairs was also substantially greater with overdentures than with fixed complete dentures.[11-13]

Clinicians have calculated the average time spent maintaining mandibular implant overdentures. An average of 72 to 98 minutes of professional time was required per patient during the first year after placement for prosthodontic maintenance (adjusting retentive mechanisms, replacing dislodged or fractured retentive mechanisms, repairing fractured dentures, relining prostheses, and remaking prostheses).[14]

The prosthodontic time required of a clinician (almost 5 hours) and number of appointments to provide mandibular implant overdenture treatment has been compared with the time required to provide conventional mandibular complete denture treatment and it was determined to be comparable (implant overdenture was attached to two implants using individual ball abutments).[15] However, the two-implant overdenture requires more initial expense and aftercare over a 10-year period than conventional denture treatment.[16]

Consensus and Controversy Associated with Mandibular Implant Overdentures

Burns published a literature review of implant overdenture treatment in the edentulous mandible and identified areas of "general consensus" and areas of "controversy."[17] The following areas of general consensus were identified[17]:

1. Complete edentulousness is a substantial health issue and will continue to be a significant issue in the future.
2. Conventional complete dentures create more problems in the mandible than they do in the maxilla.

3. Retention and stability have a substantial negative effect on the treatment outcomes of conventional mandibular complete dentures.
4. Mandibular anterior dental implants are highly successful and may slow the bone resorption process.
5. Mandibular overdentures that use dental implants have many benefits and increased patient satisfaction compared to conventional complete dentures.
6. The response of peri-implant mucosa and bone has been favorable.
7. Complications are a concern, and particularly during the first year of usage.
8. There is a need for routine recall and follow-up care because of the potential for complications to occur.

The following areas of controversy were identified[17]:

1. When the remaining natural teeth require complex treatment, their extraction and replacement with an implant overdenture "may be the best option" but there is a need for decision guidelines.
2. The number of implants required for an appropriate mandibular implant overdenture "remains open to debate."
3. The need for rigid connection of implants placed in the anterior mandible "has not been definitively determined."
4. There is a need for "additional understanding" regarding the effect of a mandibular implant overdenture on the anterior maxilla (the combination syndrome).
5. The "necessity" of placing implants into attached peri-implant mucosa versus unattached alveolar mucosa "is unresolved."
6. A "paradigm shift" may be occurring in dentistry whereby the mandibular implant overdenture becomes the "future standard of care for the edentulous mandible."

• **Figure 39-6** Unfavorable jaw relation implies the placement of the bar under the prosthetic teeth. (Courtesy of Dr. J. Kan.)

Success, Failure, and Complications Data

Conventional implant overdentures are associated with more complications than any other type of implant prosthesis. However, the complications do not negate the benefits these prostheses provide for patients. Implant overdentures have been more successful in the mandible than in the maxilla.[7,18,19] Maxillary overdentures have a much higher number of mechanical problems than mandibular overdentures.

Goodacre et al[20] showed that the most common implant complications for implant overdentures (those with a greater than 15% incidence) were loosening of the overdenture retentive mechanism (33%) (Figure 39-7),

• **Figure 39-7** Loosening of the overdenture retentive Hader bar clip mechanism.

implant loss in irradiated maxillae (25%), resin veneer loss, implant loss with maxillary overdentures (21%), overdentures needing to be relined (19%), implant loss in type IV bone (16%), and overdenture clip/attachment fracture (16%) (Figure 39-8). It was not possible to calculate an overall complications incidence for implant prostheses because there were not multiple clinical studies that simultaneously evaluated all or most of the categories of complications. Although the implant data had to be obtained from different studies, they do indicate a trend toward a greater incidence of complications with implant prostheses than single crowns, fixed partial dentures, all-ceramic crowns, resin-bonded prostheses, and posts and cores.[20]

A systematic review[21] of the incidence of biologic and technical complications reported in prospective longitudinal studies with at least 5 years of follow-up included 15 studies of implant overdentures. A meta-analysis of the studies determined that implant loss prior to functional loading occurs in about 2.5% of the implants, a rate comparable to that found with implant-fixed partial dentures and implant-fixed complete dentures. After functional loading, 5.6% to 5.9% of the implants are lost, creating a total loss of over 8% during a 5-year period. The authors indicated that the higher implant loss after functional loading was mainly related to the higher loss occurring in the maxillary arch. A systematic review showed that there are no detrimental effects on marginal bone levels using early or immediate loading protocols. Significantly more biologic and mechanical problems were found with overdentures compared to fixed implant prostheses.[21] However, patients with chronic problems with their maxillary denture preferred the maxillary long-bar overdenture to the fixed-implant denture 2 to 1 in a crossover study,[22] because of ease of speaking and cleaning (Figure 39-9).

• **Figure 39-8** Multiple overdenture cracks noticed on the cameo **(A)** and on the intaglio **(B)** surfaces, due to lack of adequate intra-arch space that resulted in thinning of the acrylic resin bases.

Design Principles

Number of Implants for Mandibular Implant Overdentures

A consensus conference was held on May 24-25, 2002 at McGill University in Montreal, Quebec, Canada that included 21 recognized authorities in the field of implant dentistry.[23] They published the following concluding statements: "The evidence currently available suggests that the restoration of the edentulous mandible with a conventional denture is no longer the most appropriate first-choice prosthodontic treatment. There is now overwhelming evidence that a two-implant overdenture should become the first choice of treatment for the edentulous mandible." However, patient selection and patient mediated factors such as available time and money for the treatment may dictate a different optimal first choice such as a fixed implant complete denture.[24] The study by Brennan et al[25] on patient satisfaction and oral health–related quality of life (OHQOL) outcomes of implant overdentures and fixed complete dentures found that among all patients who had similar numbers of implants placed, those who received an implant overdenture were less satisfied and had lower OHQOL than the patients who had a fixed prosthesis. Because patient and dentist preferences influenced the type of prosthesis provided, it is likely that subjective, patient-related factors are major determinants of satisfaction and treatment outcomes.

The number of implants used with mandibular overdentures has included one midline implant,[26] two individual implants or implants connected with a bar, and three or more implants connected by a bar (Figure 39-10). In the mandible, clinicians have successfully used one implant and have also successfully used multiple implants. The use of four implants and a bar was compared with two implants and a bar. Batenberg et al[27] evaluated plaque, calculus, bleeding scores, probing depths, gingival recession, and implant percussion, and made standardized radiographs. No differences were noted in the clinical or radiographic parameters, and the authors suggest that two implants may be sufficient in the mandible.[27] However, they did theorize that four implants might be beneficial for patients with

• **Figure 39-9** This patient with chronic problems with a maxillary denture preferred the maxillary long-bar overdenture to the fixed implant denture because of ease of speaking and cleaning. **A,** Intaglio and **(B)** cameo views of the maxillary and mandibular implant supported overdentures. **C,** Computer aided design of the mandibular bar according to the prosthetic teeth. **D,** Intra-oral view of the maxillary and mandibular CAD-CAM Hader bars fabricated by Cagenix, Memphis, TN. **E,** Final smile with the overdentures in place.

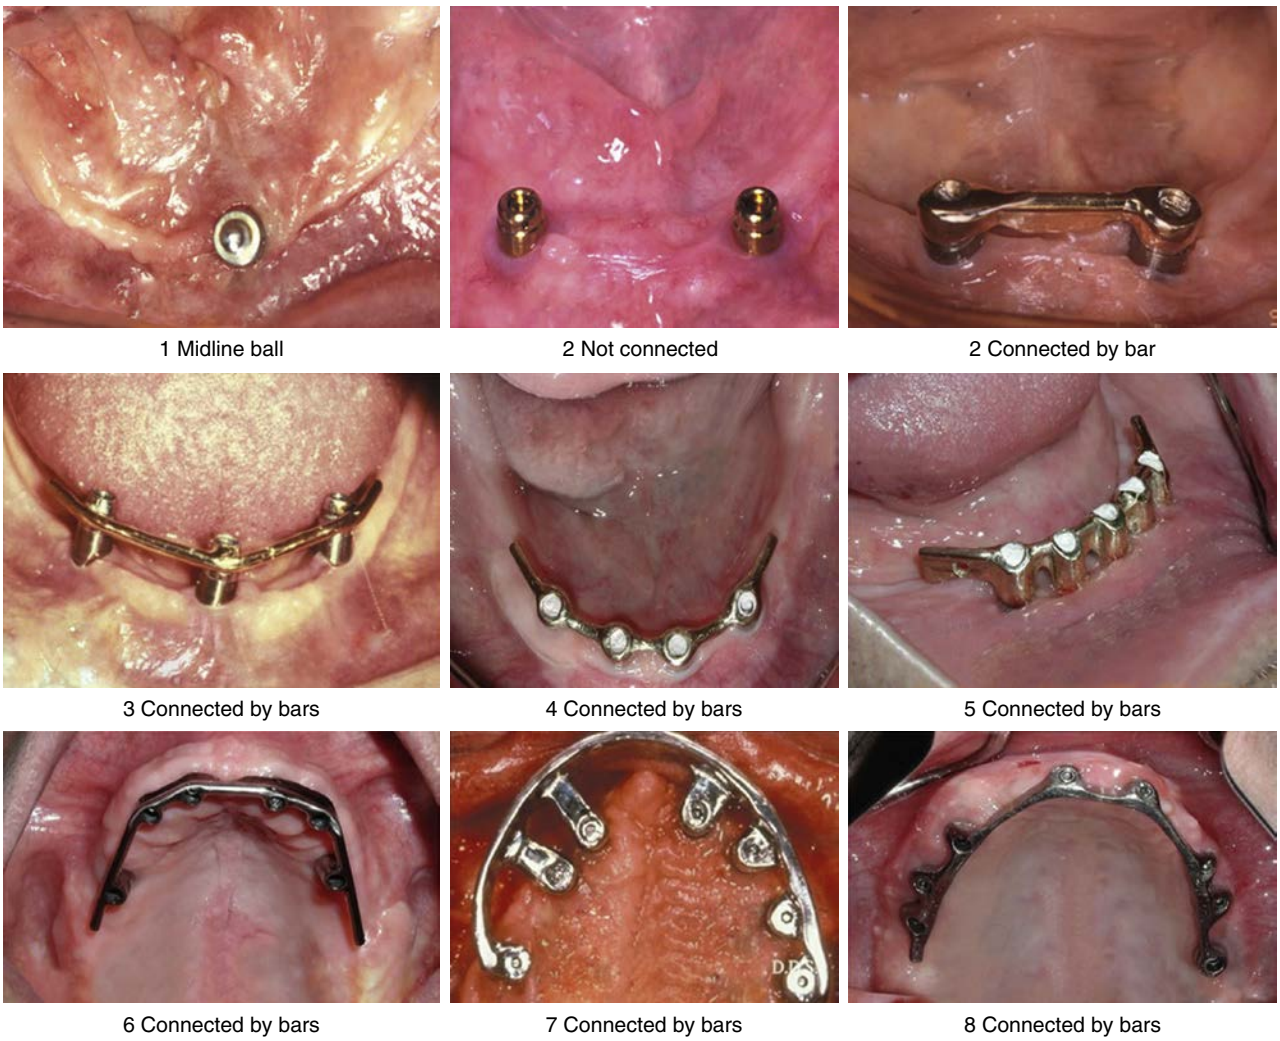
the following conditions: minimal bone height that would result in the use of shorter implants; a narrow mandibular arch; a dentulous or partially dentulous maxillary arch and sore, painful mandibular ridges because more force would be supported by the implants and bar rather than the edentulous mucosa.[27] Other criteria have been proposed that identify clinical conditions where more than two implants in the mandible may be advantageous. These conditions include the presence of a large V-shaped anterior ridge (Figure 39-11), reduced flanges due to high muscle attachments, increased occlusal forces (dentate maxilla present or parafunctional habits present), atrophic ridges that require implants of less than 3.5 mm in width or less than 8 mm in length, and patients with an extreme gag reflex.[28]

Number of Implants for Maxillary Implant Overdentures

It has been proposed that maxillary overdentures without palatal coverage (Figure 39-12) be supported by at least four implants evenly distributed around the arch and connected by a bar.[29] When there are risk factors present such as compromised quality/quantity of bone, off-ridge relations, or high applied forces, palatal coverage may improve implant prognosis.[30] Because of the higher implant loss in the maxilla,[31] Eckert[32] recommended placing at least six well-distributed implants to ensure against dramatic changes in prosthetic design.[32] Higher success rates have been reported with implants greater than 10 mm in length.[33-35] In addition, using textured implants was shown in a meta-analysis[36] to achieve stronger bone anchorage and higher clinical success rates than smooth surfaces.

Types of Implants for Implant Overdentures

In a systematic review and meta-analysis of the literature of marginal bone loss around implants retaining or supporting overdentures that identified a total of 4,200 implants from 13 manufacturers, Çehreli et al[37] concluded that there was no difference in marginal bone loss around implants retaining/supporting mandibular overdentures relative to implant type or attachment design.[37]

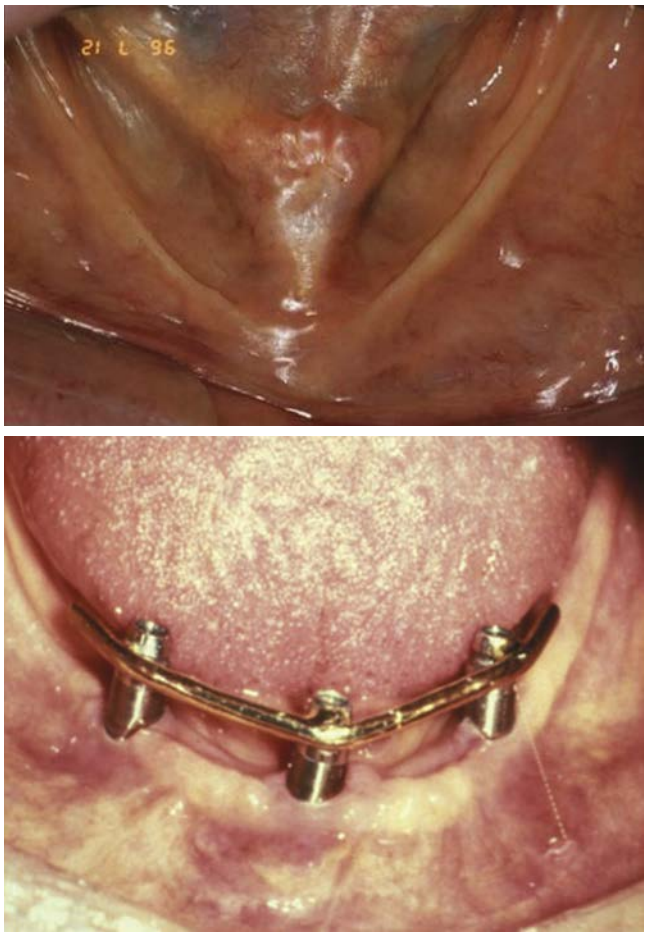


• **Figure 39-10** Possible number of implants according to each clinical situation.

Individual Versus Connected (Splinted) Implants

Several clinical studies have compared individual implants with implants connected by a bar. Study of photoelastic stress patterns indicated that individual implants with ball/o-ring attachments transferred less stress to the implants than the design that used two implants connected by a bar.[38,39] However, in an in vivo study by Kenny and Richards[39] on force transmission onto implants supporting overdentures, rigid bars were found to contribute to load sharing.[39] Greater prosthesis retention has been attained when the implants were connected by a bar than when they were separated.[40] Naert et al demonstrated that there were no biologic differences between the two designs (individual implants or connected implants) when used in the mandible.[41] Patients rated the two mandibular designs similarly in terms of their satisfaction.[41] A study by Naert et al[42] showed that after 2 to 4 years of function, 72% of the 86 implant overdentures were properly retained. However, the authors noted that the maintenance/adjustments of a bar-retained overdenture required more effort from the dentist and technician than prostheses retained by individual implants.[42] In a study by Cekic et al[43] on the effects of attachment design on strains around implants supporting overdentures, they found that the force distribution does not occur for implants supporting ball-retained overdentures, and such implants are subjected to more load than those supporting bar-retained and distal cantilevered bar-retained overdentures.[43]

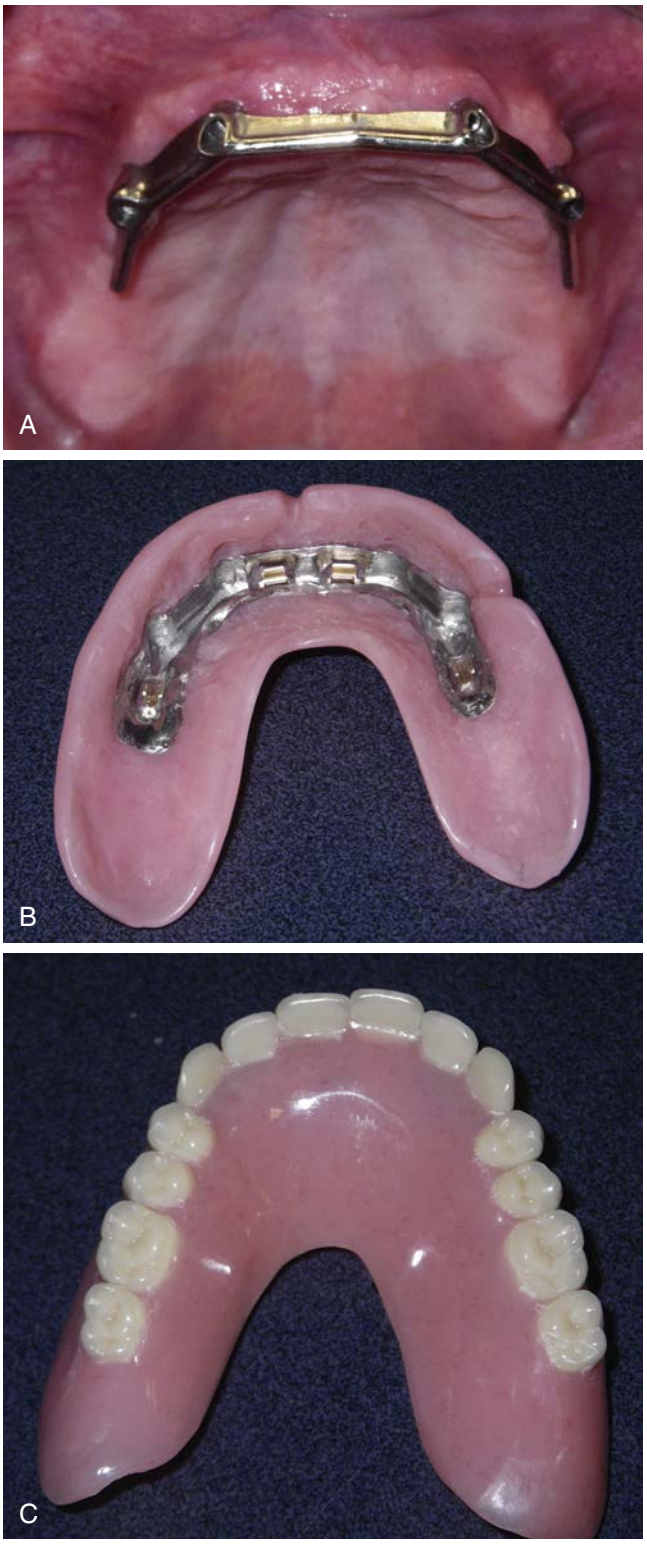
Three studies on the maxilla[42,44,45] found greater bone loss when individual implants were used. Although the number of prostheses evaluated was limited (five in one study,[44] six in another study,[42] and eight in the third study[45]), the information suggests it may be prudent to connect multiple implants in the maxilla until more definitive data become available. Even when multiple maxillary implants have been connected with a bar, increased bone loss was found to occur around some implants.[46] In a study on 5 consecutive patients with 25 textured-surface implants placed to retain overdenture prostheses, with a minimum of 4 implants per patient, these patients were followed for 12 to 48 months post-loading. None of the implants had lost osseointegration, and radiographic marginal bone levels were stable.



• **Figure 39-11** A three-implant prosthesis is indicated when the mandibular ridge is triangular in shape.

Patients were able to maintain soft tissue health around the unsplinted implants. The patients verbally indicated that they were comfortable and that their maxillary overdentures function well. It appears that unsplinted maxillary implants can be used to retain a maxillary overdenture.[47]

The controversy regarding splinted versus unsplinted anchorage systems persists due to the lack of standardization of research methodology, such as implant number, length, distribution, as well as prosthetic design, which has plagued an objective assessment of the preferred retention system for maxillary implant overdentures.[48] Using a splinted design, the type of framework may impact implant survival. A resilient design (Dolder bar) when loaded has demonstrated higher bending moments on implants than a rigid design.[49] In fact, when implant length was at least 12 mm, a lower implant failure rate and reduced incidence of prosthetic complications were demonstrated using a rigid (milled bar) design as opposed to a resilient (Dolder bar) design on the maxilla.[50,51] Posteriorly placed bilateral bars with sinus grafting procedures may allow for longer implants than an anterior array and may accommodate a sagittal discrepancy of maxillomandibular relations[51] (Figure 39-13).



• **Figure 39-12** A good indication for a maxillary overdenture without palatal coverage is when it can be supported by at least four implants, evenly distributed around the arch and connected by a bar. **A,** A four-implant CAD-CAM Hader bar in the maxillary arch. **B,** Intaglio view of the four-implant overdenture reinforced with the chrome-cobalt alloy frame. **C,** Four gold Hader clips secured in place by the denture acrylic resin. Cost, technique sensitivity, and lack of patient dexterity may be contraindications for the milled design.[50]

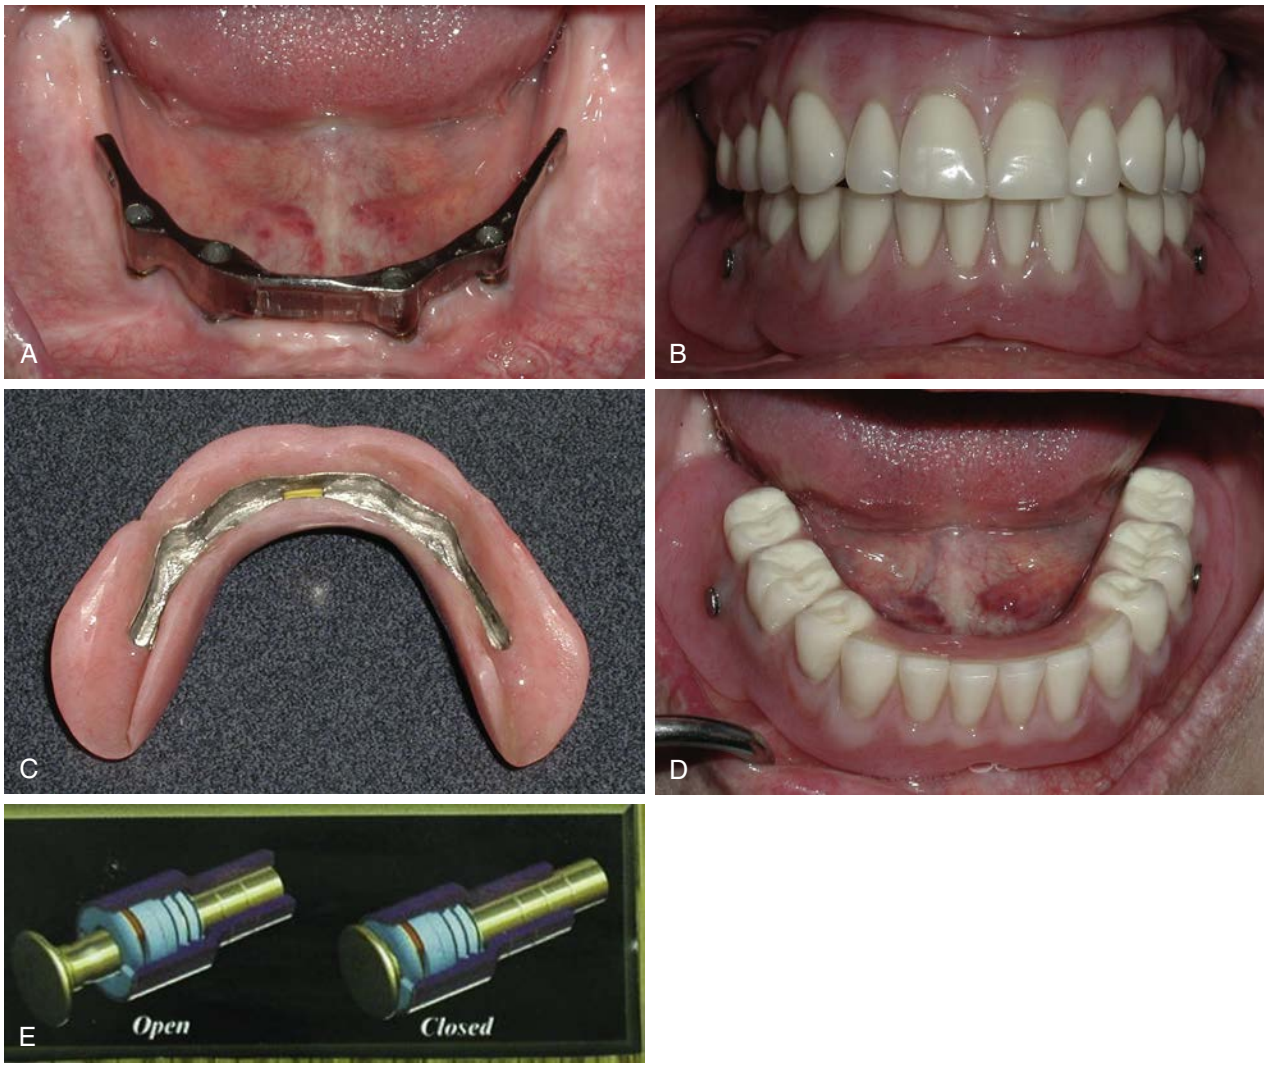
In light of the reported implant and prosthetic complications of maxillary implant overdentures, a crossover study addressed the risk/benefit calculus. When comparing patient satisfaction with a maxillary implant overdenture (with or without palatal coverage) and a newly constructed complete denture, the researchers found no significantly higher ratings in stability, retention, esthetics, mastication, or speech.[52]

Because no clear biologic advantages have been associated with the number of implants used in the mandible (individual or connected), the numerical decision should be based on retention, support, and stability requirements. For many patients, two individual implants with associated retentive mechanisms provide good patient satisfaction and the treatment is less costly than a bar overdenture. For patients with retention as a primary requirement (as evidenced by active oral musculature and functionally demanding eating expectations or anatomic or occlusal force considerations), the use of three, four, or more implants and rigid overdenture design with locking attachments system is recommended (Figure 39-14).

Payne and Solomons[53] found no significant differences were noted in the required maintenance between the bars connected to two implants and those connected to three or four implants. The maintenance requirements were greatest during the first year, with 75% of the adjustments occurring during that time.[53] One patient required 12 adjustments during the first year. Most of these adjustments were to ridge contacting areas.[54]

Location of the Implants

The implants should be located so they are contained within the normal form of the denture base and spread out around the arch. Their form and location should ideally produce no substantial changes in the dimensions of the denture base.



• **Figure 39-14** This patient has functionally demanding eating expectations, so the support and the retention of the prosthesis are a primary requirement. The use of four well spread around the arch, and rigid overdenture design with locking attachments system was made. **A,** Four-implant bar. **B,** Four-implant mandibular prosthesis in centric occlusion. **C,** Intaglio view of the reinforced mandibular overdenture. The rigid frame helps to strengthen and retain by friction the overdenture. **D,** The mandibular overdenture in place, retained by the two snap-pins and the intimate contact of the prosthesis frame and the Hader bar. **E,** Snap-pin attachments; shown in open and closed positions.

For a two-implant mandibular denture, the canine areas often serve as appropriate locations for implants. A study by Scherer et al[55] found that the lowest stress and best stability of implants in mandibular two-implant overdentures were obtained when implants were inserted in lateral incisor areas with shorter attachments and were placed parallel to the long axes of the teeth.[55] It is important to determine the location of the prosthetic teeth and the size and form of the denture base prior to implant placement. These characteristics are identified through development and the placement of a presurgical denture using conventional complete denture procedures. The clinical procedures are described later. Implants that support/retain overdentures are commonly located in the anterior area of the mouth and should be centered beneath the prosthetic teeth or slightly lingual to the center of the prosthetic teeth. When the implants are located anterior to (Figure 39-15) or substantially posterior to the teeth, the denture base has to be enlarged to encompass the implant and retentive mechanism. The enlarged base dimensions prolong the time it takes for a patient to adapt to the new prosthesis and can make the adaptation challenging. It is noted in a study that retention and stability of an implant overdenture prosthesis increase with the number of implants, when the implants are widely distributed, and the abutment.

Implant Alignment

When individual implants and retentive mechanisms will be used, placing the implants so they are parallel to each other or have their long axes nearly aligned with each other facilitates the prosthodontic phase of treatment by allowing the use of standardized components. With malaligned implants, efforts

• **Figure 39-15** This patient was complaining of poor chewing efficiency, poor esthetics, and two "bubbles" showing on speaking with these recently made prostheses. **A,** Two stud Locator abutments poorly selected on misplaced and misaligned implants. Note the poorly contoured surrounding adjacent tissues. **B,** Two-implant mandibular overdenture opposing maxillary complete denture. are commonly made to reduce the amount of resin base overcontouring and this process frequently leaves only thin areas of resin over the retentive mechanisms. The thin resin is more prone to fracture. When implants are placed posteriorly, they should be centered beneath the prosthetic teeth. Ball attachments coincided with the highest levels of retention and stability followed by Locator, o-ring, and ERA[55] (Figure 39-16). When individual implants are not aligned, custom abutments may be used to correct for implant angulation variations. Manufactured angle-correcting abutments also can be used.[56] Malalignment of individual implants with stud abutments can make prosthesis placement more difficult and the attachments are pinched more often during placement and removal, producing attachment wear and earlier loss of retention. Careful selection of attachment type is needed and depends on the ability to address the angulation problem of the implants. In one study[57] the master casts of 41 patients who had received 2 implants and ball abutment/o-ring overdentures were measured to determine the effect of implant alignment on the number of adjustments/repairs.[57] When a perpendicular relationship of the implant to the residual ridges was used as a reference angulation, implants that were inclined 6 degrees or more to the lingual or less than 6.5 degrees to the facial were associated with a significantly higher number of repairs.[57] When an implant is placed substantially out of alignment with other

• **Figure 39-16** Locator attachment has the lowest vertical height when compared with other stud attachments.

• **Figure 39-17** When implants are malaligned, a situation frequently encountered between resorbed premaxilla and posterior maxillae due to the angulation of the residual bone, the use of a CAD-CAM fabricated bar is indicated. **A,** Nonparallel implants on the final cast. **B,** CAD-CAM bar connecting all the misaligned implants. **C,** Lab analogues connected to the bar, showing the implant angulation problem. **D,** CAD-CAM bar is placed into the maxillary overdenture.

sources of retention in partially edentulous arches, the fabrication of custom components may be necessary.[56]

Castable bars or CAD-CAM milled bars have frequently been used to connect multiple implants. One of the many reasons clinicians have used bars is malalignment between multiple implants, a situation frequently encountered between resorbed premaxilla and posterior maxillae due to the angulation of the residual bone (Figure 39-17). A bar connecting multiple implants permits correction of modest implant malalignment because the screw access holes can vary in their location and orientation in the bar while still allowing the bar to possess retentive elements at the desired position(s) and angulation(s). CAD-CAM generated milled bars are being used frequently as the first choice in overdenture treatment due to their affordable cost compared with gold bars. In addition, Örtorp et al[58] investigated and compared the precision of fabrication in repeatedly produced computer numeric controlled (CNC) milled framework with conventional

• **Figure 39-18** When an implant bar is used it is advisable to reinforce the prostheses with a metal suprastructure.

castings, and demonstrated that it is possible to fabricate implant-supported frameworks by means of the computer milled technique with very high precision and repeatability.[58] When an implant bar is used, it is advisable to reinforce the prostheses with a metal suprastructure (Figure 39-18). The advantages are many: strength, optimal frictional retention, and easier reline procedures for the prostheses.

Implant Component/Retentive Mechanism: Height Above the Soft Tissue

After development of the wax trial denture, or preferably during the insertion of the presurgical complete denture, it is important to assess the vertical and horizontal base dimensions to determine the amount of space available for implant components and retentive devices before the surgical placement of dental implants (Figure 39-19). The height of implant components and retentive mechanisms should be reduced as much as possible because they weaken the prosthesis base. However, the height should be sufficient to allow bars to be fabricated in such a manner that some space is present beneath the bar. It is recommended that a 1- to 2-millimeter space be present between the underside of metal bars and the edentulous ridge mucosa. It is felt that the potential for adverse soft tissue responses is related to minimal space underneath a bar. It has also been suggested[59] in one publication that adverse responses under bars occur more often when unattached mucosa is present. In contrast, a study[60] of 62 patients found that attached mucosa was not a prerequisite for the maintenance of healthy function. Peri-implant soft tissue complications were more frequently encountered with maxillary implant overdentures and it has

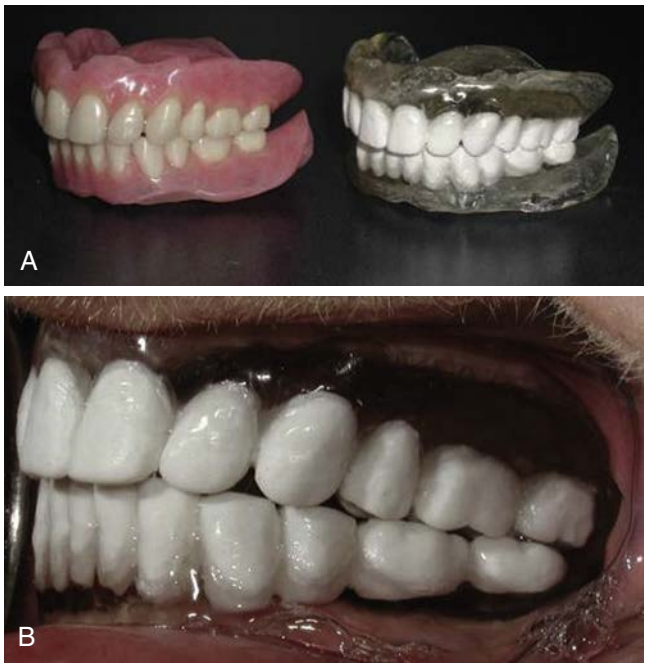
• **Figure 39-19** One way to measure the inter-arch distance needed for the selection of a stud or a bar attachment is by measuring the occlusal surface of the denture teeth to the intaglio surface of the denture.

• **Figure 39-20** Peri-implant inflammation/hyperplasia is shown here that is severe enough to require surgery.

been suggested[61] that they may be related to the reduced vertical space available in the maxilla.

Mandibular resorption frequently creates more vertical space than occurs in the maxilla, causing retentive bars to be placed closer to the soft tissue in the maxilla. It has been stated[62] that good oral hygiene is the main factor in preventing adverse soft tissue responses. Some peri-implant soft tissue complications are severe enough to require surgery. One paper reported that 11 of 25 patients had peri-implant inflammation/hyperplasia and 2 of those patients required surgery[12] (Figure 39-20).

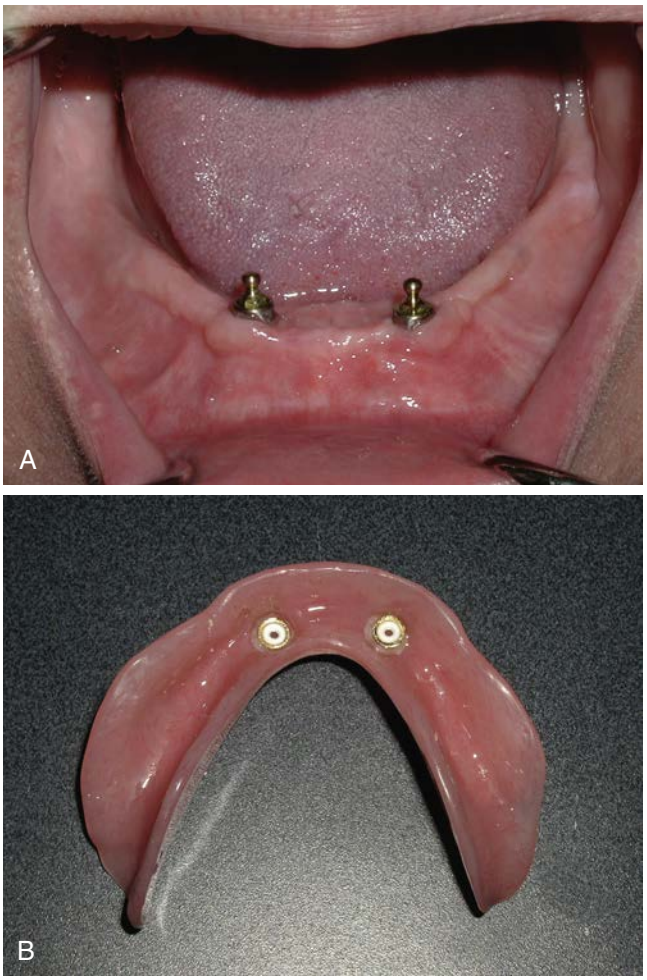
All bar and clip retentive mechanisms require an occlusocervical space of at least 12 mm (including retentive mechanism, overlying base material, and space under bars), while solitary anchors such as the Locator only require 8 to 9 mm of occlusocervical space.[63] It is advantageous to have two or more millimeters of resin thickness surrounding the retentive mechanism when possible. Available base thickness will help determine the type of mechanism that can be used. When there is not sufficient space available, a change in the type of retentive mechanism may be necessary or the base may have to be thickened or bone removal is necessary before implant placement. For diagnostic purposes, the presurgical denture can be duplicated in clear acrylic resin and used to assess available space (Figure 39-21).



• **Figure 39-21** **A,** Presurgical dentures with their duplicates. These duplicates are used as radiographic templates and later as surgical templates. **B,** Radiographic templates are placed in the mouth. They can be used also to diagnose interarch space. At the maxillary incisors only the clinical crown is missing; but at the premolar-molar area the clinical crown and soft and hard tissues are missing, and at this location the interarch space is adequate for a stud or bar attachments.

Comparison of Retentive Mechanisms

There are several types of retentive mechanisms available, including stud attachments such as Locator or ball attachments, bar(s) and clip(s), and other types of mechanical attachments such as snap pin attachments (see Figure 39-14, *A*). The choice has largely been determined by practitioner preference with bars/clips being one of the mechanisms frequently selected to support and retain overdentures when more than two implants were used. Ideally, the retentive mechanism should be positioned so it cannot be seen through the visible portion of the denture base, does not interfere with proper positioning of prosthetic teeth, and does not excessively enlarge the denture base. An in vitro comparison of the retentive properties of ball and Locator attachments for implant overdentures by Türk et al[64] demonstrated that both attachment systems showed decreased retentive forces after 5,000 insertion-separation cycles. However, after 5,000 insertion-separation cycles, locator attachments showed better retentive properties than ball attachments. When bars are used, a casting is required which increases cost and complexity. Bars have been found to provide greater retention than balls/o-rings (Figure 39-22), which may be important with patients exhibiting high functional activity and the need for maximal retention. Bars and associated retentive devices require more space within the denture base than do stud attachments. All mechanisms are subject to retention deterioration over time and the need for regular adjustment/replacement.[64] An in vitro study by Nascimento et al[65] compared the photoelastic characteristics



• **Figure 39-22** Two-implant prosthesis using a ball type attachment. This type of an o-ring ball attachment requires the implants to be placed as parallel as possible. **A,** Clinical view of the ball abutments with an adequate gingival cuff height. **B,** Intaglio view of the prosthesis showing two white clinical o-rings. (From Daher T: A simple, predictable intraoral technique for retentive mechanism attachment of implant overdenture attachments, *J of Prosthodont* 12: 202–205, 2003.)

of stress transfer around the implant in a single-implant mandibular overdenture using different types of attachments (ERA Sterngold, CNG Brazil, Conexão Brazil, Dalla Bona Brazil, Locator FL, Neodent). They found, within the limitations of the study, that the load transferred to the implant in a single-implant mandibular overdenture was evenly distributed around the implant with low stress concentration. No discernible differences were observed among the different attachment systems.[65]

Base Adaptation and Contact with Edentulous Ridge

Using a photoelastic model of a human edentulous mandible with four anterior implants, load transfer characteristics of four overdenture designs were studied.[66] Properly fitting extension bases were found to contribute significantly to even force distribution and appear to be as important as the type of retentive anchorage system in load transfer.

Base Reinforcement

When the denture base will be thin or there are heavy occlusal forces present, it may be prudent to reinforce the denture base with a metal or fiber mesh framework incorporated into the denture base or use a cast metal base (see Figure 39-13, *B*). Evaluating prosthetic tooth wear on an existing prosthesis provides an indication of the magnitude of forces present. When aggressive wear facets are noted on the prosthetic teeth of an existing denture, a hostile environment is likely to be present and the use of reinforcement may be advisable, as well as metal occlusal restorations.[67] It is also important to remember that patients who have implants can place greater occlusal force on the prosthesis than they could with their conventional complete denture. However, the maximal occlusal force applied by patients with mandibular implant overdentures was found to be less than the force developed by patients with teeth and patients who have fixed complete dentures.[68]

Occlusion, Tooth Positioning

Although there are no clinical data documenting the effect of occlusion on implant success, clinicians have felt that occlusion can affect implant success. Clinicians have frequently recommended that a balanced occlusion be used with implant overdentures, particularly when the opposing arch is edentulous. When the occlusion is properly balanced, there will be greater prosthesis stability than when the occlusion is not balanced (Figure 39-23).

Our preferences for an optimal occlusal scheme for implant overdentures is a balanced type of articulation, either a lingualized[69] or linear occlusion,[70] no matter what the opposing arch is. This will distribute the occlusal stress on multiple denture teeth instead of on one acrylic denture tooth, thus preventing fracture of the canine on a canine disclusion occlusal scheme.

• **Figure 39-23** Balanced occlusal scheme. **A,** Prostheses in centric occlusion. No centric contact from canine to canine. **B,** Right working movement. Note the working right occlusal contacts and left balancing occlusal contacts.

Synopsis of Design Guidelines[8]

- In the mandible, one symphyseal implant can be used which has been shown to be especially suitable for the geriatric population; however, when two implants are employed they can be left unattached (separate from one another) from the standpoint of implant success.
- Because of the higher implant loss in the maxilla (19%), for a palatal-less overdenture, a minimum of four implants has been proposed. It may be propitious to place at least five to six implants so that the prosthesis can still function satisfactorily should an implant be lost. Use of implants more than 10 mm long and 3.7 mm wide has been reported by clinicians to have higher implant survival for maxillary overdentures.
- In the maxilla, it is considered prudent to connect the implants together using a bar so the prosthesis can continue to function should an implant be lost. The use of a rigid (milled bar) design has been shown to reduce bending moments on loaded implants, resulting in higher implant survival and reduced prosthetic complications.
- Position the implants so they are contained within the normal form of the denture base and centered beneath the prosthetic teeth. For anterior implants, a location slightly lingual to the center of the prosthetic teeth is also appropriate.
- Align the implants so they are parallel or nearly parallel to one another whenever possible. This alignment is particularly important when individual (not connected) implants will be used.
- Minimize the height of the implant components and retentive mechanisms.
- The choice of retentive mechanism is based on personal preference and the need for maximal retention in certain patients. Bars and associated retentive devices provide the greatest retention.
- When individual implants will be used to retain an overdenture, clinicians have reported favorable results in terms of retention and longevity of the retention with Locator attachments.
- When the denture base will be thin or there are heavy occlusal forces present (parafunction), the use of metal reinforcement in the resin base will help prevent prosthesis fracture, and metal occlusal restorations will reduce denture tooth wear and loss of vertical dimension.

Clinical Procedures for Two-implant Overdenture and Three- or Four-implant Overdenture

Examination, Diagnosis, and Treatment Planning

A clinical examination, medical and dental history, panoramic radiograph, and mounted casts (with prosthetic teeth appropriately arranged and articulated) are required to plan treatment. In addition, cone beam computed tomography (CBCT) images may be needed to relate the prosthetic tooth positions to the underlying bone and vital structures.

The medical and dental history are used to identify patients more likely to experience implant failure so a thorough assessment of the risks/benefits of the treatment can be made. The history information also helps identify patients in whom implant treatment is contraindicated.

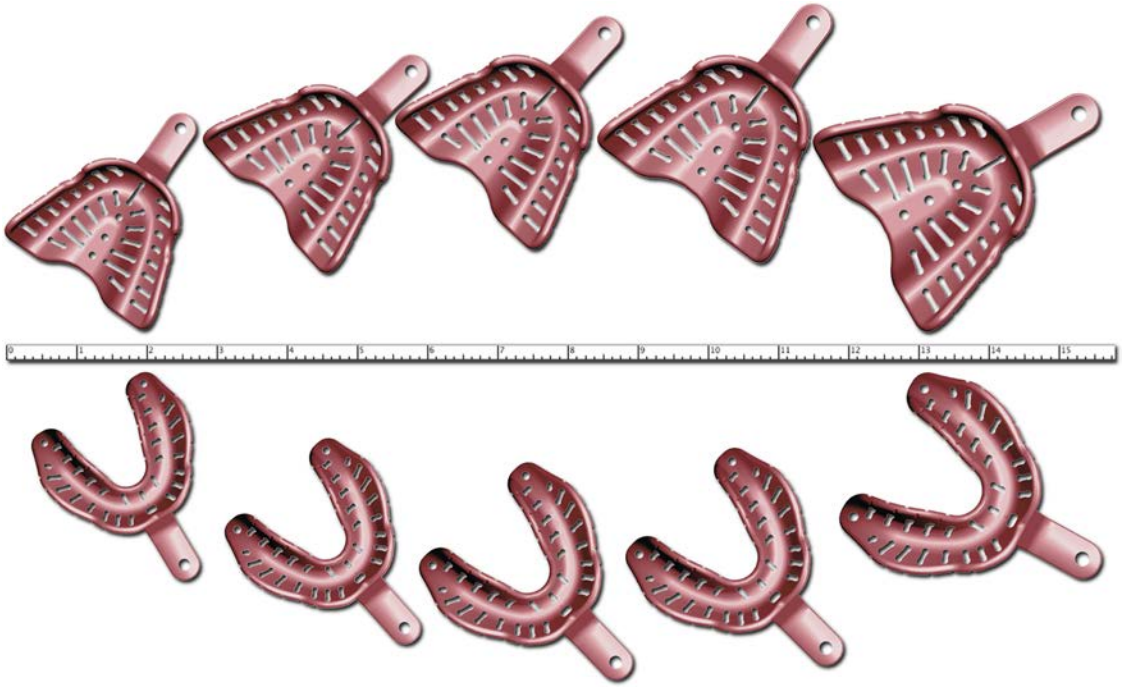
The clinical examination and radiographic information are used to evaluate bone health, bone quality, and incisocervical/occlusocervical bone dimensions in relation to the prosthetic teeth. The positions of the prosthetic teeth determine where the implants should be located. Several factors determine the most appropriate prosthetic tooth positions, including: esthetics, tooth-lips relationships, phonetics, anatomic landmarks, horizontal and vertical mandibular positions, and muscular neutrality (neutral zone) (Figures 39-24 through 39-27).

• **Figure 39-24** Accudent System 1 kit for complete denture irreversible hydrocolloid impressions.

Clinical Situation for a Two-implant Overdenture Using Locator Attachments

The presurgical complete dentures are fabricated using all the clinical and laboratory steps required to locate the most appropriate prosthetic tooth positions. Once the postoperatory check for any troubleshooting is done and no sore spots are present; a duplication of the denture is done to make a radiographic implant template using a Lang Duplicator.

CBCT radiographic series are made and evaluated. The "Rules of 10"[71] specify that for any implant-retained overdenture there must be a minimum of 10 mm of alveolar inferior/superior dimension, a minimum of 10 mm of interocclusal restorative dimension measured from the soft

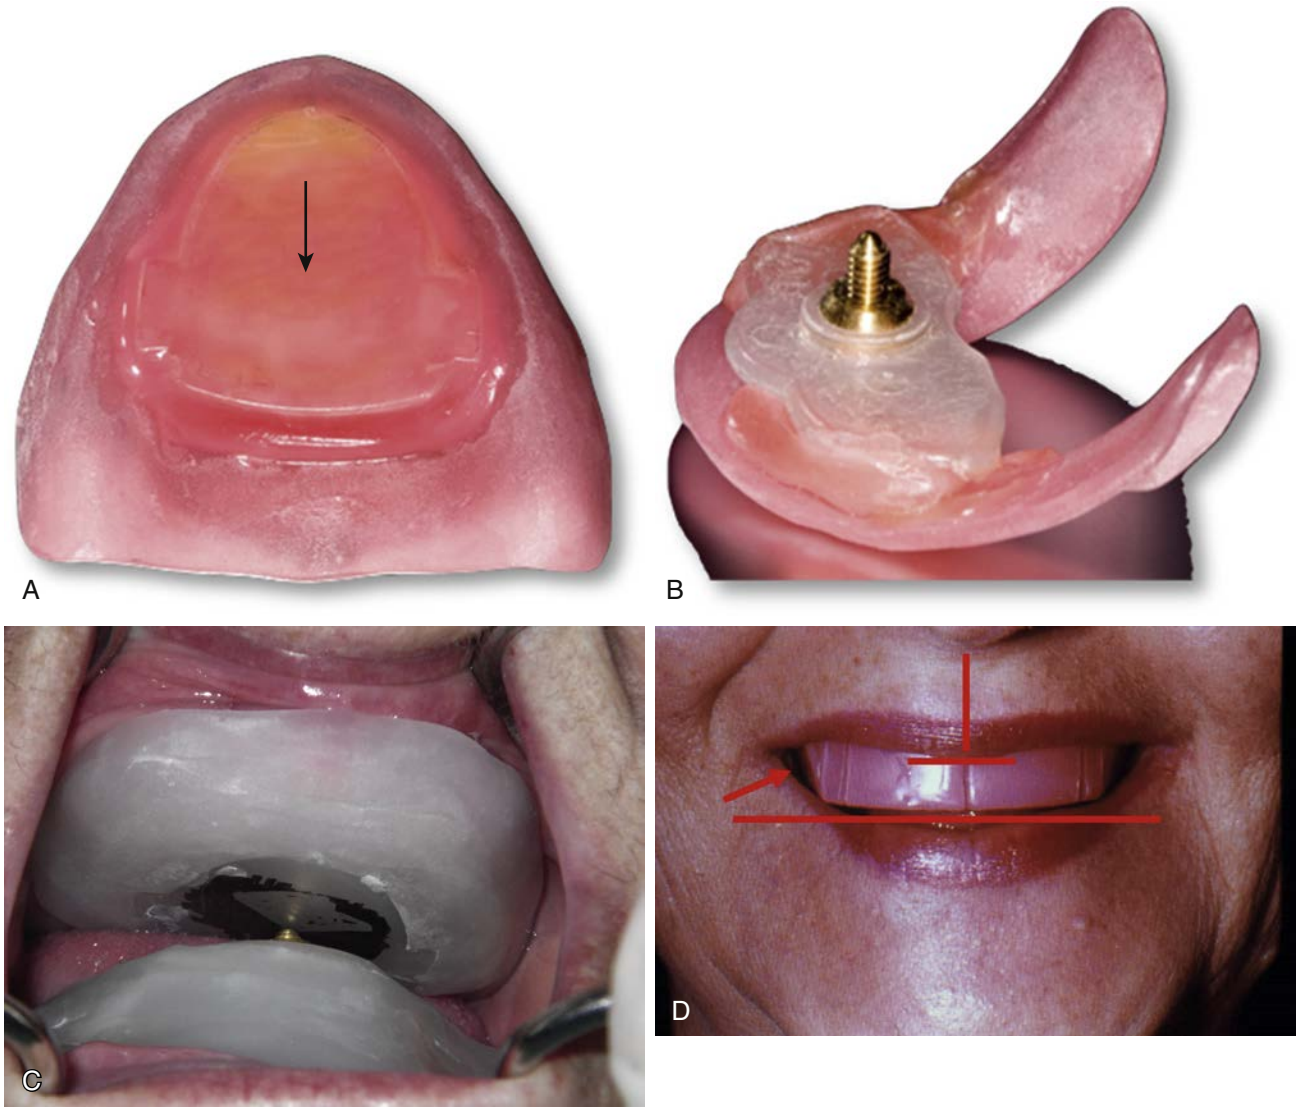


• **Figure 39-25** Massad impression trays LT for making polyvinyl siloxane impressions. These trays are placed in 170° F water, and then custom molded in the patient's mouth before making the impression.

tissue ridge crest to the occlusal plane, and at least 10 mm of anterior-posterior space between two implants.

The radiographic template is transformed into a surgical template by making occlusal holes or by making a cut-off of the lingual anterior flange where the dental implants will be placed (Figure 39-28, *A*). Then two or four implants are placed in the selected locations according to the agreed treatment plan. If the surgical technique is a two-stage technique, it is advisable to mark on the surgical template the location of the implants in case the implants are going to be submerged (see Figure 39-28, *A*). This will help in locating the implants to be exposed during the second-stage surgery (see Figure 39-28, *B* and *C*). The mandibular intaglio surface of the denture is adjusted according to the situation. An osteotomy sometimes is needed to increase the interarch space to accommodate the height of a stud attachment or a bar attachment. In this situation the use of a temporary soft liner is advisable to improve the fit during the healing phase.

Once the implants are osseointegrated and gingival tissue is healed around the healing abutments, the soft tissue height is measured with a periodontal probe after removing the implant healing abutment from each implant. The height is then used to determine the proper cuff height of



• **Figure 39-26** Massad jaw disposable recorders. **A,** Maxillary striker plate showing the gothic arch tracers. **B,** Mandibular pin reciever plate. The pin height is adjusted at the occlusal vertical dimension before making the tracing. **C,** The jaw recorders assembly intraorally showing the gothic arch tracings. The apex of the arch is the centric jaw position; it is a retruded, unstrained, repeatable, learnable position, and it is the start of all mandibular movements. **D,** During the same patient visit of jaw recording, the esthetic control base (ECB) or the maxillary wax rim is adjusted for an adequate upper lip support, for a horizontal occlusal plane, and for adequate buccal corridor. Also, the midline and the high lip line are marked on the labial surface of the ECB.

• **Figure 39-27** After a heat-cured lab reline and during the placement of the mandibular overdenture, the denture fit is improved by applying the pressure indicator paste (PIP) and adjusting the pressure areas. **A,** Few tissue contacts are showing before denture adjustment. **B,** Wider tissue contacts are achieved after a few adjustments with PIP. No contact should be present between the implant abutments and denture base during the adjustment visit. This step is important to create a denture that is tissue supported and implant retained. (From Daher T: A simple, predictable intraoral technique for retentive mechanism attachment of implant overdenture attachments, *J of Prosthodont* 12: 202–205, 2003.)

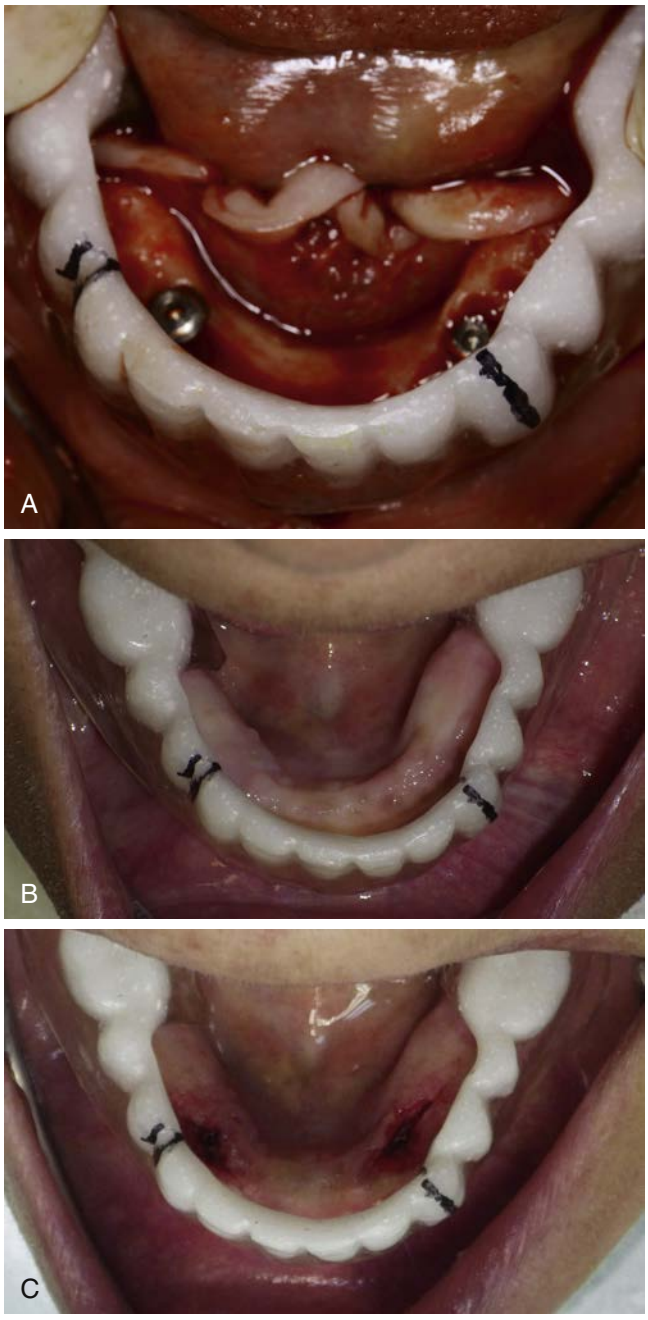
the Locator abutment that will be used. Laboratory heat-cured reline is sometimes needed and is done after placing a duplicate Locator housing over the Locator abutments. The denture is processed on a cast that includes the copy of the Locator retentive housing. The extra dimensions produce a recess in the denture (see Figure 39-27, *A*) that is large enough to permit the denture to seat over the Locator abutments and its housing with a little bit of adjustment without impingement.

In case of a bar-retained overdenture, an impression is made to generate an accurate master cast. A practical time-saving impression technique[72] with four objectives is used to achieve accuracy in a single clinical visit: (1) impression of the soft tissue, (2) impression and position of the implants, (3) registration of the maxillomandibular relationships, and (4) arrangement of the artificial teeth (Figure 39-29). Duplicate the mandibular denture twice. One is to be used as a custom tray, and is made by duplicating the presurgical complete denture by using a denture duplicator, irreversible hydrocolloid, and clear autopolymerizing acrylic resin. The second denture duplicate will be fitted over the cast and sent the CAD-CAM center to make a CAD-CAM titanium milled bar confined to the scanned duplicate denture outlines (Figure 39-30). A trial denture is made over the CAD-CAM bar and tried in the mouth and evaluated and adjusted as needed. The same procedure can be done for the maxillary overdenture.

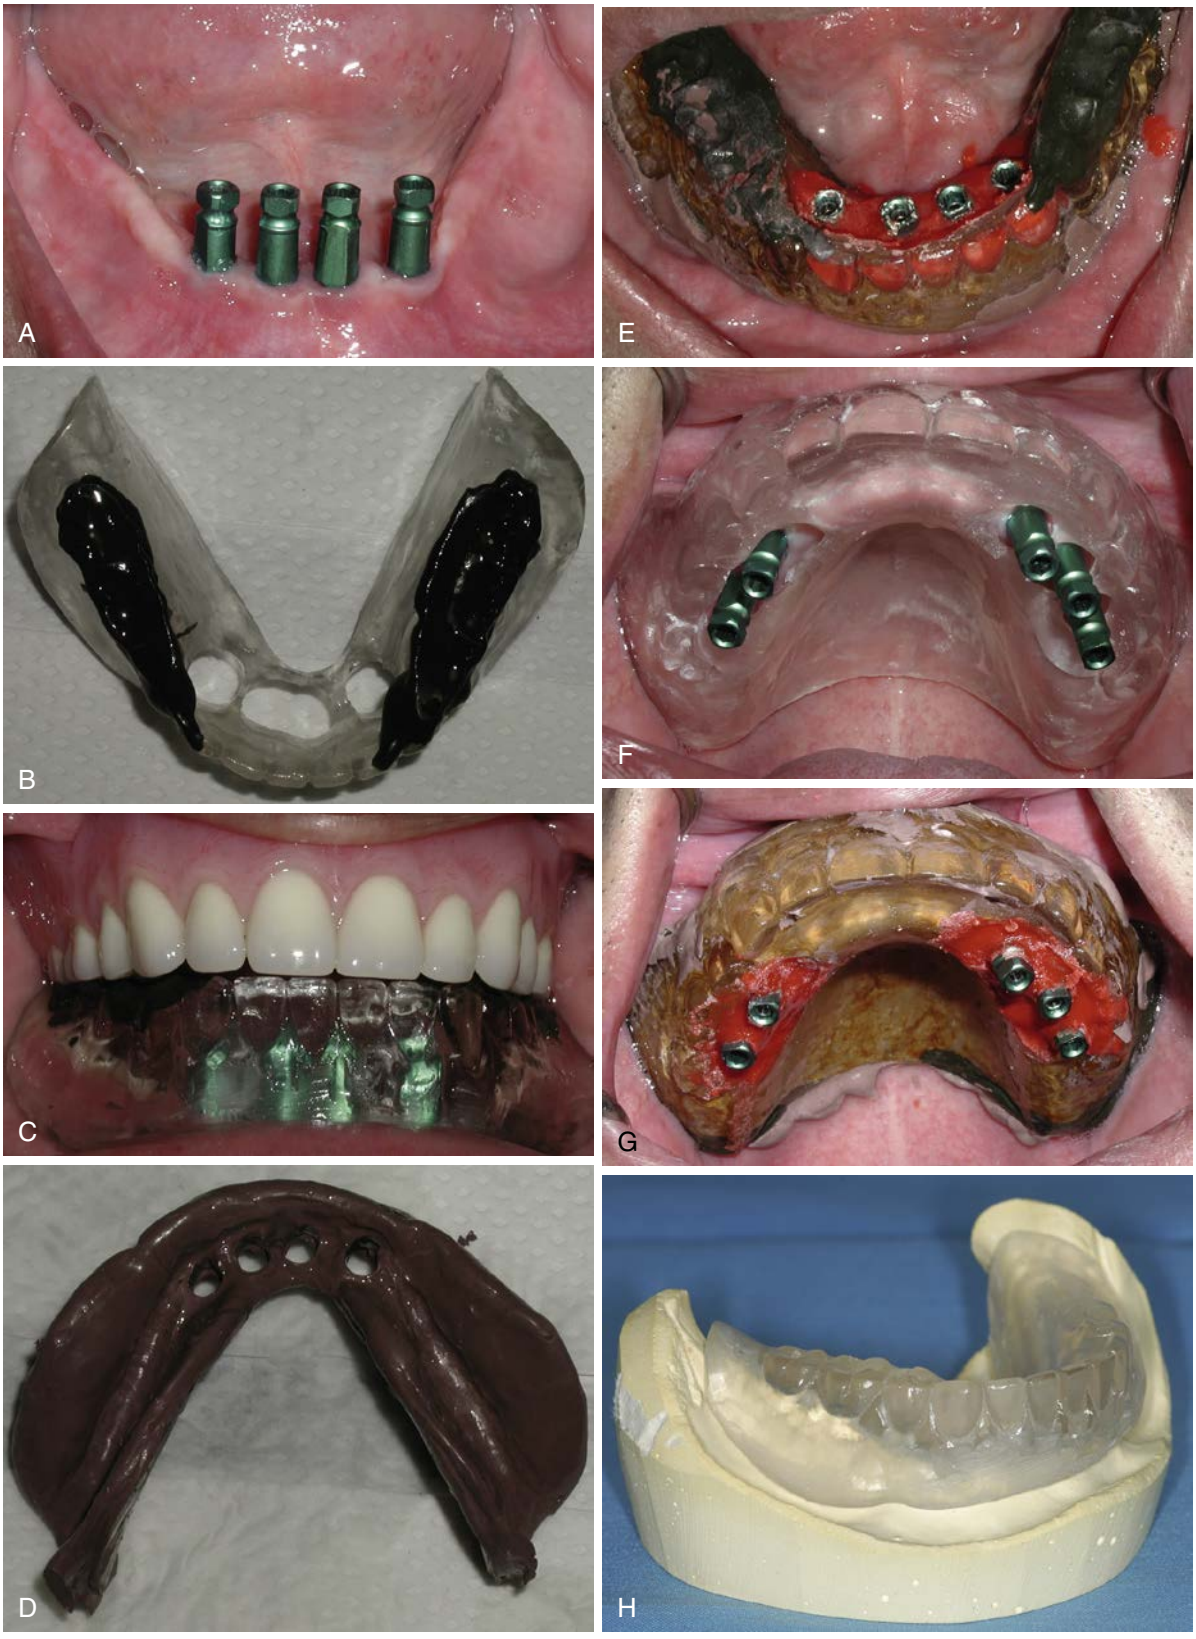
Pressure indicating paste (PIP) is used to improve the fit of the intaglio surface before attaching the denture to the implant with Locator clips. Oral hygiene and instructions must be given before dismissing the patient. The denture is placed and worn by the patient with adjustments made as needed. When stability and comfort are achieved, the retentive caps are ready to be attached to the overdenture on a separate visit. Doing this ensures that the denture is tissue supported and implant retained.

In case of a bar, the denture is processed with a metal cast base that accommodates the bar assembly. The denture is fitted over the tissue using PIP, and then the bar is placed and again the fit is checked before attaching the denture to the bar with Hader clips or with Swiss Loc NG attachments.

The prosthesis is placed intraorally so the patient can be shown how to properly seat and remove the prosthesis. The patient is then given the opportunity to demonstrate the ability to remove and reseat the prosthesis. Oral hygiene instructions will be reinforced before dismissing the patient. Various means of plaque removal from implant components and prostheses have been suggested, including manual and powered toothbrushes (Figure 39-31), interproximal brushes, dental super floss, antimicrobial rinses and gels, and subgingival irrigation systems. It is advisable to give a patient a powered toothbrush with a wide variety of brush attachments[73] (Figure 39-32) that may prove beneficial for those seeking manageable methods for maintaining the cleanliness of implant overdenture prostheses, ensuring the health of the peri-implant supporting hard and soft tissues.



• **Figure 39-28** The mandibular surgical implant template during its uses. **A,** Two implants are placed according to final destination marked by the duplicate denture used as a surgical template. **B** and **C,** After a complete implant osseointegration, the same surgical template is used to locate and expose the two implants.



• **Figure 39-29** The 4-in-1 visit for the fabrication of the master cast, the CAD-CAM bar, and the trial denture. **A,** The impression copings are placed intraorally on the implants. **B** and **C,** The presurgical denture duplicate is fitted over the impression copings, making sure that most of the length of the copings extrudes from the denture. It is advisable to add green stick modeling composition on the occlusal surfaces to secure the centric occlusion during the setup of the acrylic resin. **D,** A final tissue impression with a light bodied impression material is made in a close position in centric. Then the excess impression material is removed, making it ready for the next step. **E,** The tray is then placed and auto-polymerizing acrylic resin or composite resin is placed over it to connect the copings together and to the hard portion of the tray. The patient is asked to close in centric during the setup of the resin. **F** and **G,** The same technique can be applied to the maxillary arch. **H,** After the boxing of the impression, the final cast is made, trimmed, and articulated before separating the tray from the cast. Then the final cast and the second duplicate of the presurgical denture is sent to a dental laboratory for the fabrication of the CAD-CAM bar and the trial denture. Implants in Acquired and Congenital Defects

ALAN S. HERFORD, KATINA NGUYEN, PIER PAOLO POLI

Introduction

Both acquired and congenital defects can present unique challenges for the reconstructive surgeon. Standard reconstructive techniques may be useful for repairing the majority of these defects. More complicated deficits may require advanced techniques, such as the use of growth factors or microvascular free tissue transfer of tissue from one part of the body to another.

There are many causes for acquired defects involving the upper or lower jaws. These include major trauma that can lead to both hard and soft tissue deficits. Both benign and malignant tumors can lead to loss of tissue, requiring reconstruction. Defects that result from the removal of malignant pathology can present with unique circumstances, including loss of significant hard and soft tissue as well as the possibility of postoperative radiotherapy. These characteristics can make reconstruction of defects more challenging and thus may require a more complex reconstructive approach.

Congenital defects can affect the maxillofacial skeleton and often require reconstruction of the missing tissue in order to optimize function for the patient. One of the most common congenital defects is an alveolar cleft lip, alveolus, or palate, with an incidence rate of 1:500 to 1:700 worldwide.[1] Bony defects to the maxilla affects approximately 75% of cleft lip or cleft lip and palate patients.[1] Other congenital defects include, but are not limited to, ectodermal dysplasia and congenitally missing teeth. All of these congenital disorders contribute to missing or hypoplastic tissue discrepancies in the maxilla and/or mandible that necessitate surgical intervention to restore function and esthetics. Reconstructing these deficits in a growing child with primary or mixed dentition can present unique challenges.

Dental implants have led to increased patient satisfaction. In restoring missing tissue, the goal is to provide enough bone to place dental implants and provide the patient with a functional reconstruction. This chapter focuses on specific acquired and congenital defects. We discuss the surgical options as well as advantages and disadvantages of various reconstructive options.

Acquired Defects

Major Trauma

Car accidents, assaults, and firearm injuries continue to be a major public health problem. In particular, firearm-related injuries are the second leading cause of injury-related death in the United States, with predominance in males and young adults.[2] The mechanism of injury is important and can help determine the preferred management for a specific wound. An example is high-velocity gunshot wounds, which typically result in avulsive-type injuries with a significant blast effect. These wounds are severely contaminated and are associated with a high incidence of infection. The current trend in facial gunshot injury comprises early conservative debridement, removal of traumatic tattoos and nonviable tissues, and use of primary reconstruction, when possible.[3,4]

Surgical management of traumatic facial wounds is divided into three stages: (1) debridement, fracture stabilization, and primary or secondary closure; (2) reconstruction of hard tissues, provided soft tissue coverage is adequate; and (3) rehabilitation of the oral vestibule, alveolar ridge, and secondary correction of residual deformities and reconstruction with dental implants.[3,5] Primary treatment of injuries to bone and soft tissues of select wounds may be carried out at the time of debridement, thereby minimizing the rates of hospitalization, procedures, and complications.[6] In the past, conservative methods for treatment of wound fractures have been recommended to avoid periosteal stripping of small, partially devitalized segments.[7,8]

Primary versus Delayed Reconstruction

Facial wounds represent a complex set of challenges for the surgeon due to significant soft tissue and bone defects. After

skeletal fixation, soft tissue coverage is crucial. In the acute and subacute setting, tissue coverage depends on wound dimension as well as the overall patient status. Although some surgeons advocate free flaps, others prefer "temporary" coverage and defer lengthy definite procedures to a time when the patient has stabilized. Secondary bone reconstruction typically ranges from 3 to 12 months following revitalization of injured tissues and maturation of scars[9,10] (Figure 40-1).

Classically, surgeons selecting delayed treatment have advocated for conservative debridement of soft tissue injuries and stabilizing bony injuries. After edema has resolved and soft tissues have healed to cover the wounds, final reconstruction can be performed. However, in a review of 33 facial reconstructions, Vásconez and colleagues observed similar infection rates between delayed and immediate postgunshot wound reconstruction.[11] The delayed group also demonstrated an increased incidence of wound contracture, which resulted in significantly more structural and functional deformity. In two other comparative reviews, Gruss and Vayvada and their associates also present improved results of immediate over traditional delayed approaches. These authors proposed that fewer and less complex revisionary procedures are necessary for patients who undergo immediate definitive reconstruction.[12,13] Motamedi advocates early management of facial gunshot defects, including early primary reconstruction of bone defects using fractured segments.[14]

Decisive factors for successful bone reconstruction are the severity of the injury, the degree of destruction of the soft tissue, and the degree of bone fragmentation. Correct positioning of the arch helps establish the proper facial width and frames the face. Improper reconstruction of the arch may result in incorrect framing for the remainder of the reconstruction. When a mandibular fracture is a component of gunshot wounds, reestablishing mandibular continuity and thus restoring occlusion first is advisable. Midface and mandibular bone defects larger than 5 mm should be bone grafted.[15] The donor area is determined by the degree of bone loss as well as the need for soft tissue reconstruction. Commonly used donor sites include the iliac crest and microvascular grafts from the fibula.

The final stage of reconstruction attempts to achieve optimal functional and esthetic results. Important components of secondary revision include flap debulking, dental implant placement, and scar revision.[3,16] Although recent reports link early definitive reconstruction with a decreased need for revisional surgery, a majority of patients might request some form of revision.

Pathology

Acquired defects of the jaws are often secondary to removal of various types of pathology. A wide range of tumors with different behaviors affects the jaws, ranging from benign to malignant. Characteristics including the type of pathology as well as location and size are important when considering treatment options. Considerations for the type of tumor may help plan for a significant soft tissue defect that may affect the treatment plan. Many malignant tumors will require resections and result in a large defect of both hard and soft tissue. These patients also may require postoperative radiotherapy, which can affect the decision on which type of reconstruction should be performed.

Segmental resection of the mandible due to inflammatory disease, congenital deformities, osteonecrosis (secondary to radiation or bisphosphonate use), or benign and malignant tumors may cause considerable functional, esthetic, and social problems. Segmental resection in the anterior mandible causes the muscles of the floor of the mouth and tongue to lose their insertion to the mandible. Support of the lower lip and the chin is also lost, which can lead to inadequate lip closure with drooling. Thus, oromandibular reconstruction is mandatory to restore mandibular continuity and surrounding soft tissues with sufficient bone height and adequate muscle attachment to allow for normal function improving the oral health–related quality of life.[17]

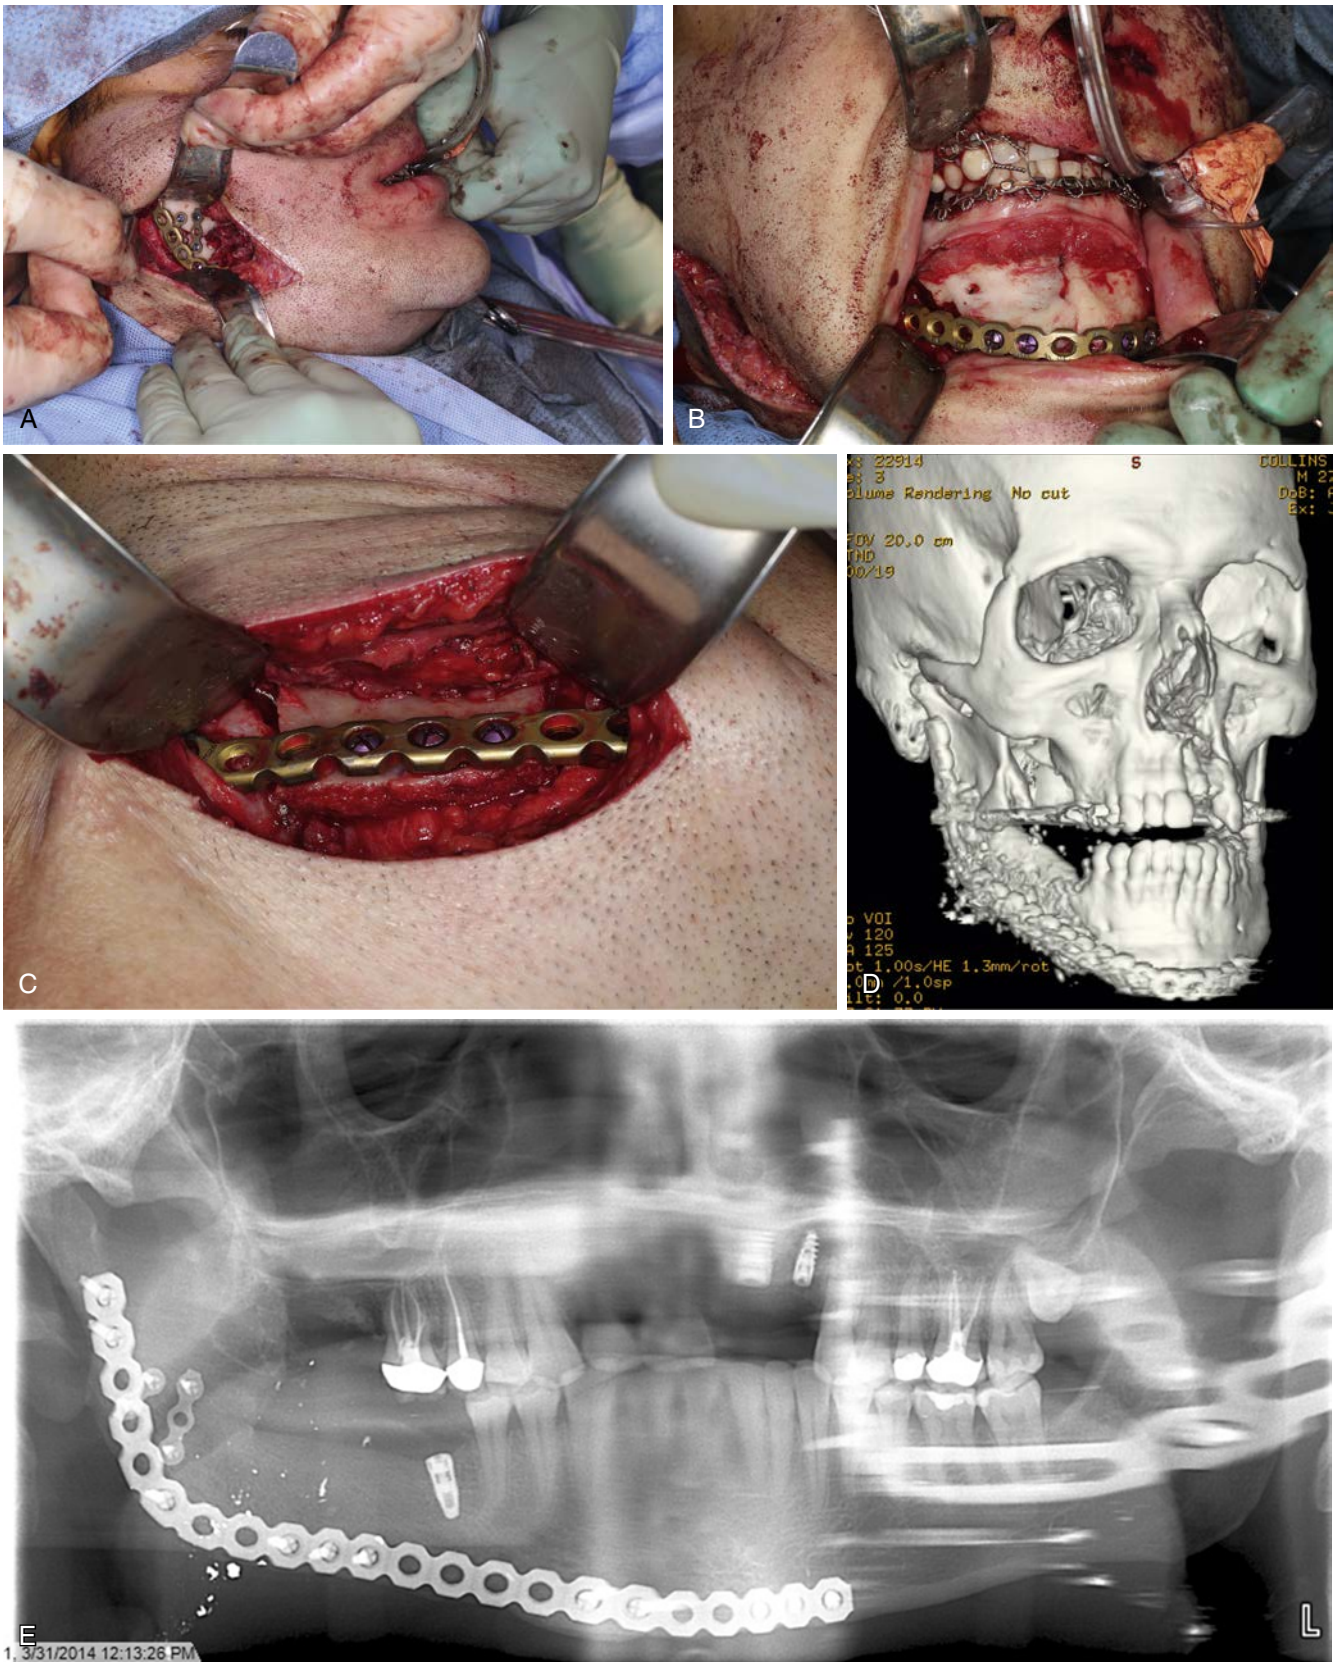
Mandibular reconstruction can be performed simultaneously with the resection or delayed, using either nonvascularized bone grafts or vascularized free flaps. The choice may be influenced by the patient's medical condition and age, quality of the vessels, vascularity of the recipient site, expected donor-site morbidity, the possible need for a two-team approach, surgeon's skills, and preference and available facilities.[18]

Grafting Options

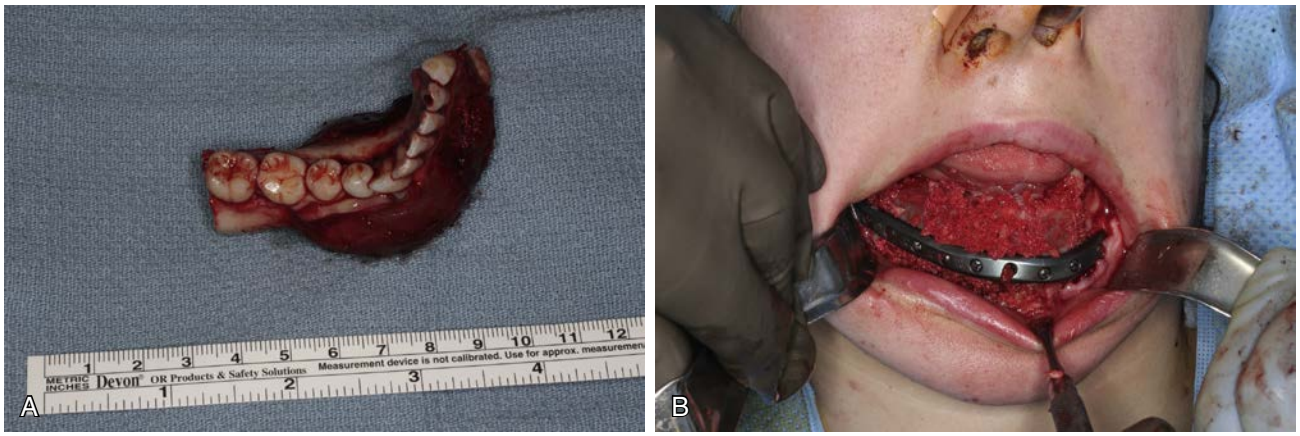
Maxillomandibular defects can be treated by a variety of techniques. Characteristics of the defect, including geometry, size, and type of tissue missing are important considerations. Patient factors such as age, health status, and need for radiotherapy are also important. For defects that involve extremely large segments of missing bone with a soft tissue defect, strong consideration should be given to the use of a microvascular free graft. The fibula is associated with a high success rate for complex defects and may be the treatment of choice. A disadvantage of reconstruction utilizing the fibula is that the mandibular height is often not as high as the native mandible and may benefit from additional grafting.

Non-vascularized Bone Grafts

Several donor sites have been used to bridge defects of the mandible. At present, cortico-cancellous block graft taken from the anterior or posterior iliac crest is considered the method of choice in cases of defects less than 5 cm and characterized by good soft tissue using an extraoral approach. There are, however, risks associated with the donor site as well as the recipient site.[19] Non-vascularized bone grafts are often used in cases of benign lesions, where watertight closure of the intraoral wound is possible and in cases where the mucosa remains intact.[18,20] For large defects, the posterior ilium donor site may be considered because it provides a large quantity of bone and exhibits less morbidity when compared to the anterior iliac crest.[21,22] The survival of these non-vascularized grafts depends largely on revascularization



• **Figure 40-1** **A,** Gunshot wound with reduction and fixation of fractures. **B,** A reconstruction plate was used to provide continuity to the jaw. **C,** Placement of an iliac crest bone graft secured to the plate. **D,** Postoperative CT showing the restored continuity of the mandible. **E,** Radiograph showing implant reconstruction of grafted area.



• **Figure 40-2** **A,** Resected bone segment. **B,** Blocks of bone are secured to the plate to aid in maintaining the mandibular height.

from the recipient site, by which the transplanted tissue undergoes resorption and deposition of new bone through the "creeping substitution" process. Grafts can be mainly cortical or cancellous in structure or a combination. Blocks of bone are often secured to a reconstruction plate to help maintain the desired height of reconstruction (Figure 40-2). Block grafts can restore continuity of the mandible as well as provide adequate height for implant reconstruction. The width of these grafts is usually sufficient to receive implants, which allows for occlusal rehabilitation; however, they are reserved for specific anatomic and clinical situations.[20]

Defects involving the anterior mandible as well as those that are grafted via an intraoral approach have been shown to be more difficult to reconstruct, with complication rates ranging from 20% to 36%.[18,23] Segmental resection in the anterior mandible causes the muscles of the floor of the mouth and tongue to lose their insertion to the mandible. Support of the lower lip and the chin may also be compromised. Intraoral wound dehiscence is a frequent complication, probably related to the intraoral approach and contamination of the wound with oral microorganisms.[24] Contamination can also occur postoperatively by leakage of saliva into the graft area, especially if rigorous suction of the wound drainage is applied.[25] The presence of dead space and a lengthy surgical procedure may also increase the risk of wound infection and dehiscence. Surgeons should therefore avoid contamination of the wound with oral microorganisms in general; if there is a communication of the wound with the oral cavity preoperatively, the mucosa should be closed with watertight sutures before placement of the bone graft. Cigarette smoking adversely affects wound healing and success of implant-related grafting procedures.[26,27] Therefore cessation of tobacco use is advised during the healing period.

Another reconstructive option is to use growth factors that are combined with a carrier. These grafts may be combined with an allograft, xenograft, or autogenous graft. When considering this type of reconstruction, note that providing a protected space for the bone formation is important for success. A titanium mesh has been described as beneficial for providing this "space maintenance."[28] RhBMP-2 (Infuse, Medtronic, Nashville, TN) has been used in an off-label manner for repair of these types of defects (Figure 40-3).

Transport distraction osteogenesis is another potential option to reconstruct segmental defects. An advantage of this technique is that both hard and soft tissues are reconstructed; however, a second surgery is required to remove the distractor. Distraction osteogenesis is also a consideration for increasing the height of the reconstructed bone secondarily (Figure 40-4).

Vascularized Free Flaps

Advancements in microvascular surgery allow a free tissue graft to be transferred with an intact blood supply to the recipient bed, due to microvascular anastomosis. Provided the graft is properly fixed, it will heal primarily at the site of the defect. Success rates of free vascularized bone flaps for the reconstruction of the mandible of 95% or higher have been reported.[29,30] No single type of free flap, however, is versatile enough to cope with the wide variety of composite mandibular defects. The choice of flap depends on several factors, including the type of bone and soft tissue (skin and/or oral) defect, vessel geometry of the donor and recipient sites, donor site morbidity, whether the patient is dentate or edentulous, need for dental implant rehabilitation, and often the type of training and individual preference of the surgical team.[20] Potentially, four donor sites are available for vascularized bone used in osseous reconstruction of the mandible: fibula, iliac crest, radius, and scapula; however, only the first two provide an adequate amount of bone for implant placement purposes. The scapula is associated with poor bone quality that may be unsuitable for dental implants, except in larger male patients.[31,32] The osseous fibular flap can provide up to 26 cm of strong cortico-cancellous bone with sufficient height to support osseointegrated dental

implants.[33] To achieve better implant:crown ratio after autogenous reconstruction of the mandible with fibula free flap, different techniques have been suggested, including the use of double-barreled reconstruction, distraction of the recipient site, and additional free bone grafting and cortico-cancellous iliac grafts (Figure 40-5). In double-barreled reconstruction, there is risk of blocking the blood supply to the graft, which causes flap failure. Distraction osteogenesis avoids issues with donor site morbidity, soft tissue limitations of the recipient site, and unpredictable graft resorption.[34]

Maxillary Reconstruction

The basic principle of reconstruction is to rebuild anatomic structures with tissue as similar as possible to that found in the resected area in order to restore not only the occlusion, but also the contours of the midface and the resulting esthetics (Figure 40-6). Various classification systems have been proposed for maxillectomy defects to predict both the functional and esthetic outcome likely to result from surgery and relate that to the method of obturation or reconstruction for each type of defect.[35] The surgical defect is classified according to the vertical dimension of the maxillectomy (Class I to IV), which relates to the involvement of the orbit and skull base and the resultant esthetic deformity.

Reconstruction depends on the amount of deficient tissue, goal of reconstruction (anatomic reconstruction vs. full dental rehabilitation), and the preexisting situation, including the presence of vessels after tumor ablation, previous surgery, and/or radiotherapy in combination with a neck dissection.[35] Obturation has been the traditional method of rehabilitation for a maxillectomy patient, but in recent years a wide variety of reconstructive options have become available.[36] Class I defects can be reconstructed without particular problems by relatively simple local flaps. With the help of microsurgical flaps, reconstruction may achieve an esthetic and functional result, which may meet the patient's expectations and demands. Composite flaps consisting of bone and soft tissue can simultaneously reconstruct the soft and hard tissue components of the defect, and later on, implants for dental rehabilitation can be inserted to accomplish a more functional and esthetic appearance, especially in the midface. The length of the vascular pedicle is an important factor, as are the thickness of the skin, muscle,

• **Figure 40-4, cont'd** **C,** Restored dentition. **D,** Postoperative radiograph.

and subcutaneous fat. Additionally, the volume of the available tissue, the durability and thickness of the bone, and the morbidity of the donor site are important factors that should be considered.[37] In comparison with other bone flaps, the fibula osteocutaneous flap is often the preferred method in large facial reconstruction, providing bone dimensions adequate for implant placement.[38,39]

Dental Implants

Osteointegrated dental implants have had a great impact on patients' quality of life following jaw reconstruction. Osseointegrated implants have afforded major advances in the reconstructive management of patients with oral neoplasms because they allow stabilization of implant-supported and implant-retained prostheses. This results in improved mastication and esthetics, as well as psychological benefits.[40,41] Implant survival rates are reported to be 81% to 99%, averaging 87% in studies ranging from 0 to 10 years in head and neck cancer patients.[42] Factors considered in selecting patients for this procedure include patient general condition, surgical timing, ablative procedure and type of graft, perioperative radiation therapy, implant placement technique, and dental prosthesis.[43]

The orofacial anatomic alterations resulting from tumor resection, regional surgery, and placement of a pedicle or microsurgical flap include an increase in thickness as a result of the skin of the flap used, insensitivity, changes in the masticatory muscles, loss of proprioceptive sensitivity and of labial vestibular space, altered tongue mobility, and irregularities in bone contour. Many patients are unable to wear removable dentures. If radiotherapy is applied, the patient will have xerostomia and mucosal atrophy, which further complicates the wearing of removable dentures because of local irritation, ulceration, and bone exposure.[40]

Patient General Conditions

The presence of inadequate mouth opening, severe periodontal disease, caries, stomatitis, or any adjacent mucosal infection may compromise osseointegration of the

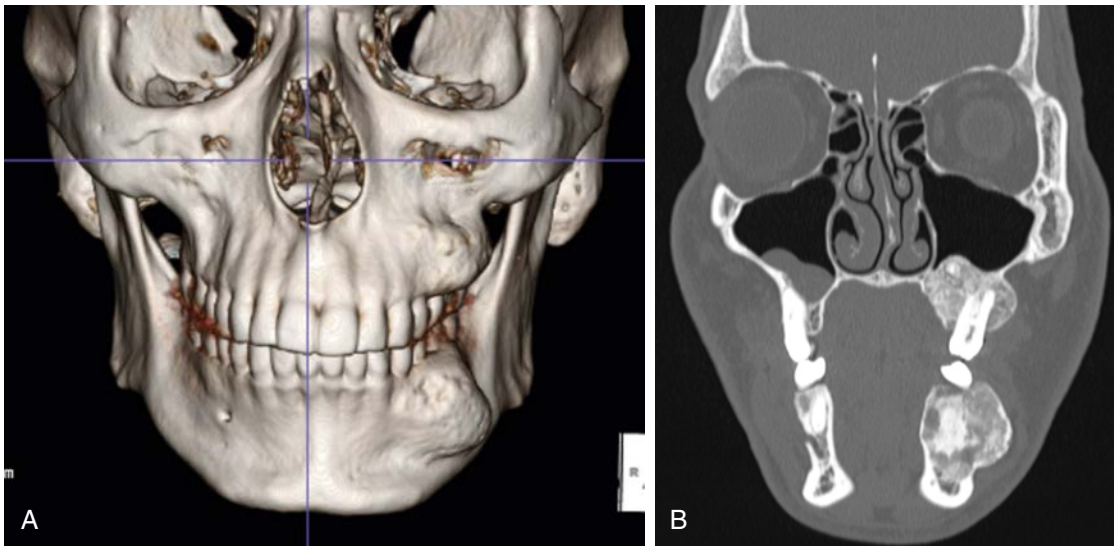
implants.[44] Meticulous oral hygiene after the surgery must be extensively explained to the patient, as this is critical for the long-term success and maintenance of dental implants. Also important are patient expectations and motivation. Understanding and cooperation are needed to continue with subsequent stages of prosthetic rehabilitation.

Surgical Timing

Implants can be placed primarily at the time of reconstruction or secondarily at a later date. Riediger described placing deferred implants in microsurgical flaps, whereas Urken and colleagues pioneered immediate implant placement at the time of free flap reconstruction.[45,46] The placement of implants simultaneously with the reconstruction increases operative time and may be less precise. This can result in minor implant misalignment, which may mean that patients must wear a removable rather than a fixed dental appliance. In addition, simultaneous implants may have to be removed in case of tumor recurrence, the incidence of which is highest during the first postoperative year.[30,47] On the other hand, proponents for primary placement of dental implants into vascularized bone grafts describe some advantages, such as eliminating one surgical



• **Figure 40-6** **A,** Radiograph showing a maxillary and mandibular tumor. **B,** Coronal radiograph showing the area of the lesions.

Continued

procedure for the patient and having better access to the bone at the time of reconstruction. The ability to obtain adequate dental ridge relationships and avoid inclination of the implants as well as the ability to achieve earlier dental rehabilitation and psychological stability are other possible advantages. Furthermore, the implantation site has not been compromised as a result of radiotherapy, thereby bypassing the need for preventive antibiotics and hyperbaric oxygen therapy prior to implantation to reduce the risk of osteoradionecrosis.[48] When dealing with malignant tumors, recurrence rate and general prognosis must be carefully considered before proceeding with simultaneous placement of osseointegrated implants together with primary reconstruction.

At the time of implant uncovering, the skin paddle can be thinned or removed and replaced by a skin graft. Finally, the dental prosthesis is secured to the implants approximately 1 month later.[49] In a recent retrospective study, with respect to implant loss in relation to postoperative radiation, no statistically significant differences were seen between implants placed during ablative surgery into free flaps as compared to those that were delayed. Both groups showed an implant failure rate of 9%.[50] This result corroborates a systematic review comparing failure rates for implants placed either before or after irradiation. Failure rates (5.4% and 3.2%, respectively) for both groups were similar and not statistically significant.[51]

Ablative Procedure and Type of Graft

Although vascularized free flaps and non-vascularized bone grafts are both widely used to reconstruct the mandible, significant differences exist when considering the reliability of each form of reconstruction. Foster and coworkers were the first to directly compare bone healing and osseointegrated implant success between vascularized and non-vascularized grafts.[30] Patients reconstructed with vascularized grafts were older and had larger defects, and most had undergone postoperative radiotherapy. The incidence of bony union in these patients was higher, they required fewer operations to achieve union, and implant success rate was significantly greater than for patients reconstructed with non-vascularized bone grafts. The significant difference in osseointegration rates between vascularized and non-vascularized grafts is believed to be related to the structure of the bone graft and to the level of osteoblastic activity throughout the graft. Because of the uneven distribution in the blood supply of a non-vascularized graft, the osteoblastic activity, which is important to bone integration, is variable. Furthermore, the graft may lack sufficient cortical bone for stabilization of the implant fixture at the time the implants are placed in the graft. When vascularized grafts are used for mandibular reconstruction, the time span from tumor resection to the completion of the dental restoration is significantly shorter than when non-vascularized grafts are used, particularly if dental implants are placed at the time of the mandibular reconstruction (10 vs. 21 months, respectively). A trend for reduced implant survival in fibula free flaps as compared with the native mandible and maxilla (91.8%, 97.4%, and 97.8%, respectively) was reported; however, this difference did not reach statistical significance.[43]

Irradiated Patients

Besides surgery and chemotherapy, radiotherapy is an essential part of treatment in patients suffering from head and neck cancer. After radiotherapy, the vascularization and regenerative ability of irradiated tissues decreases and the process of osseointegration may be impaired. Initial changes in the bone caused by radiotherapy arise from direct injury to the remodeling system.[52] Radiation results in damage to the osteoclasts and decreases proliferation of bone marrow, collagen, and blood vessels.[53] Furthermore, vascular injury

induces endarteritis with decreased microcirculation, as well as thrombosis with a progressive occlusion and obliteration of small vessels. With time, the bone marrow shows hypocellularity and hypovascularity with marked fibrosis and fatty degeneration.[52,54] These changes often lead to compromised bone healing and reduced viability that affects integration of the dental implant in bone.

Radiotherapy was initially considered a contraindication for placement of osseointegrated implants in patients with cancer.[55] Subsequently, high survival rates of implants placed in irradiated bone were reported, reinforcing the safety of placing implants in patients who have received radiotherapy as part of their treatment.[56-58] Survival rates of 92.6% and 96.5% for implants placed in patients with and without

irradiation were reported, respectively. Implant losses in patients with irradiation occurred mainly because of peri-implant infection or asymptomatic peri-implant bone loss and consecutive integration loss. A meta-analysis, including studies published from 2007 and 2013, compared implant survival between non-irradiated and irradiated native bone with a follow-up of at least 5 years. It revealed no statistically significant difference in implant survival. On the other hand, a meta-analysis of the implant survival between the irradiated native bone and the irradiated grafted bone indicated a statistically significant higher implant survival in the irradiated native bone compared with the irradiated grafted bone (72% to 100% vs. 54% to 98%, respectively). Hence, a coincidence of grafted bone and radiotherapy is a negative prognostic factor regarding implant survival.[59] Implant survival is significantly influenced by the location, the incidence of bone resection surgery in the jaw, and the irradiation dose. Visch and colleagues observed that: (1) implants inserted into the maxilla and mandible showed a significant survival difference (59% and 85%, respectively) due to differences in bone quality, bone volume, and vascularization; (2) a significantly lower survival rate was found for implants inserted into jaws treated with bone resections compared with that of implants inserted into jaws that did not undergo bone surgery (61% and 83%, respectively) because bone resections can result in unfavorable prosthetic circumstances by producing bulky and soft areas; (3) implants inserted into locations irradiated with greater than or equal to 50 gray have a significantly lower survival rate than implants in locations that are irradiated with less than 50 gray (73% and 84%, respectively).[60]

For implant osseointegration, clinical experience suggests that implants should be placed at least 6 months after the end of the consolidation period for non-vascularized grafts, and implant loading should be delayed 6 months after implant placement.[59,61] A secondary technique might allow better assessment of oral function, disease status, and possible recurrences and assists in achieving successful osseointegration in the irradiated jaw.[41,56] Esser and Wagner recommended a minimum interval of 9 to 12 months from radiotherapy to implant placement.[62] In a recent systematic review, post-implantation radiation therapy had a slightly better overall dental implant survival rate (92.2%) than pre-implantation radiation therapy (88.9%). However, this could not be verified statistically because of the marked differences in the numbers of studies reported in each group.[63] Thus, recommendations for an optimal time interval between radiotherapy and implant surgery are inconsistent and range from <6 months to >24 months.[64]

Hyperbaric Oxygen (HBO) Therapy

The success of implantation in irradiated bone may be improved using hyperbaric oxygen (HBO) therapy because HBO therapy results in increased oxygen tension in irradiated ischemic bone and provokes capillary angiogenesis and bone formation, improving healing capacity and, hence, the process of osseointegration.[65-67] There are, however, recent series in the literature that have reported acceptable outcomes in osseointegration of implants placed in irradiated bone without previous HBO therapy.[68,69] Despite the limited amount of clinical research available, it appears that HBO therapy in irradiated patients requiring dental implants may not offer any appreciable clinical benefits.[70] To date, more reliable studies are needed to determine a benefit for HBO therapy in preventing failure of dental implants or other serious complications, such as the death of bone in the jaw caused by radiotherapy treatment.[70]

Zygomatic Implants

In some clinical situations, including patients who underwent traumatic bone loss or resective surgery for oral cancer, there is insufficient bone to allow implant placement, or the patient may not be a candidate for harvest of a graft. Zygomatic implants may be an option for these select patients. Zygomatic dental implants are long screw-shaped implants developed as a partial or complete alternative to bone augmentation procedures for the severely atrophic maxilla. Currently, zygomatic implants are commercially available with an oxidized rough surface, a smooth mid-implant body, a wider neck at the alveolar crest, and a 55-degree angulation of the implant head.[71] Zygomatic implants can be used to fix maxillary prostheses and/or obturators as an alternative to non-implant retained obturators, local and regional flaps, and microvascular free flaps.[72] One to three zygomatic implants can be inserted through the posterior alveolar crest and the maxillary sinus to engage the body of the zygomatic bone. In order to use an anatomically and more prosthetically driven approach, the original technique has been modified by allowing an extra-sinus path for zygomatic implants. A recent retrospective study reported patient- and implant-related cumulative success rates of 97% and 98.8%, respectively, evaluating immediately loaded zygomatic implants placed in an extramaxillary manner for the rehabilitation of completely edentulous atrophic maxillae over a 5-year follow-up period, corroborating the satisfactory outcomes of the procedure.[73] Zygomatic implants can be left to heal submerged for up to 6 months, or they could be successfully loaded immediately.[74] It is believed that two zygomatic implants are not sufficient to hold a fixed denture, and that at least two additional conventional implants should be placed in the anterior portion of the maxilla. This can only be accomplished if there is sufficient bone in the anterior portion of the maxilla; otherwise, bone grafting is still needed. An alternative is to place two or three zygomatic implants in each zygoma.[75]

Contraindications to the use of zygomatic implants include acute sinus infection, maxillary or zygoma pathology, and patients unable to undergo implant surgery because of underlying uncontrolled or malignant systemic disease. Any pathology of the maxillary sinus should preferably be treated before placement of the zygomatic implant.[71] The most common and serious reported complications with zygomatic implants are sinusitis (up to 21% of patients[74]), zygomatic implant failures (up to 11% of patients[76]), and perforation

of the orbit (up to 6% of patients[77]). Other reported drawbacks included intrasinus osteitis, obstructed infundibulum, presence of an accessory ostium, and atelectasis.[78]

Despite several retrospective and prospective case series studies, no randomized controlled trials are available comparing zygomatic implants with or without bone augmentation techniques for the rehabilitation of the severely atrophic maxilla. Thus it is currently not possible to give reliable evidence-based advice to potential users with respect to the efficacy of zygomatic implants as an alternative to various augmentation procedures for severely deficient maxillae.[79]

Congenital Defects

Careful interdisciplinary treatment planning is necessary for rehabilitation of oral function in patients suffering from a congenital anomaly. There is not enough evidence to state that endosseous dental implants are a better treatment option than orthodontic gap closure in cleft patients; however, dental implants may result in a more esthetic and functional outcome in restoring the bony alveolar defect, especially in cases of unilateral cleft lip and palate. In ectodermal dysplasia patients, the considerable number of missing teeth necessitates the need for grafting and implant placement prior to prosthetic rehabilitation.

Congenitally Missing Teeth

A frequent dental anomaly is congenitally missing teeth. The most commonly missing are the maxillary lateral incisors, followed by the third molars and the mandibular first premolars[80] (Figure 40-7). Approximately 120 different syndromes are associated with missing teeth, such as ectodermal dysplasia, cleft lip and palate, and Down syndrome.[80] Missing teeth, especially in the anterior region, may affect esthetics and function, thus requiring surgical interventions, such as bone grafting and dental implants.

Cleft Lip and Cleft Lip and Palate

The alveolar cleft may affect the developing dentition and contribute to the collapse of alveolar segments. Failure to repair this defect in a timely manner may give rise to future issues of esthetics and function. Issues that may arise include oral-antral fistula, speech pathology, lack of bone support for anterior teeth, dental crowding, fluid reflux, anterior-posterior and transverse discrepancy of the maxilla, and facial asymmetry.[81] The reported incidence of missing teeth in the permanent dentition of cleft patients is approximately 30% to 50%, which is a sixfold higher rate than in non-cleft patients.[81] Although alveolar bone grafting has been widely accepted, there is still controversy as regards to the technique, timing, and bone grafting material.

Surgical Timing

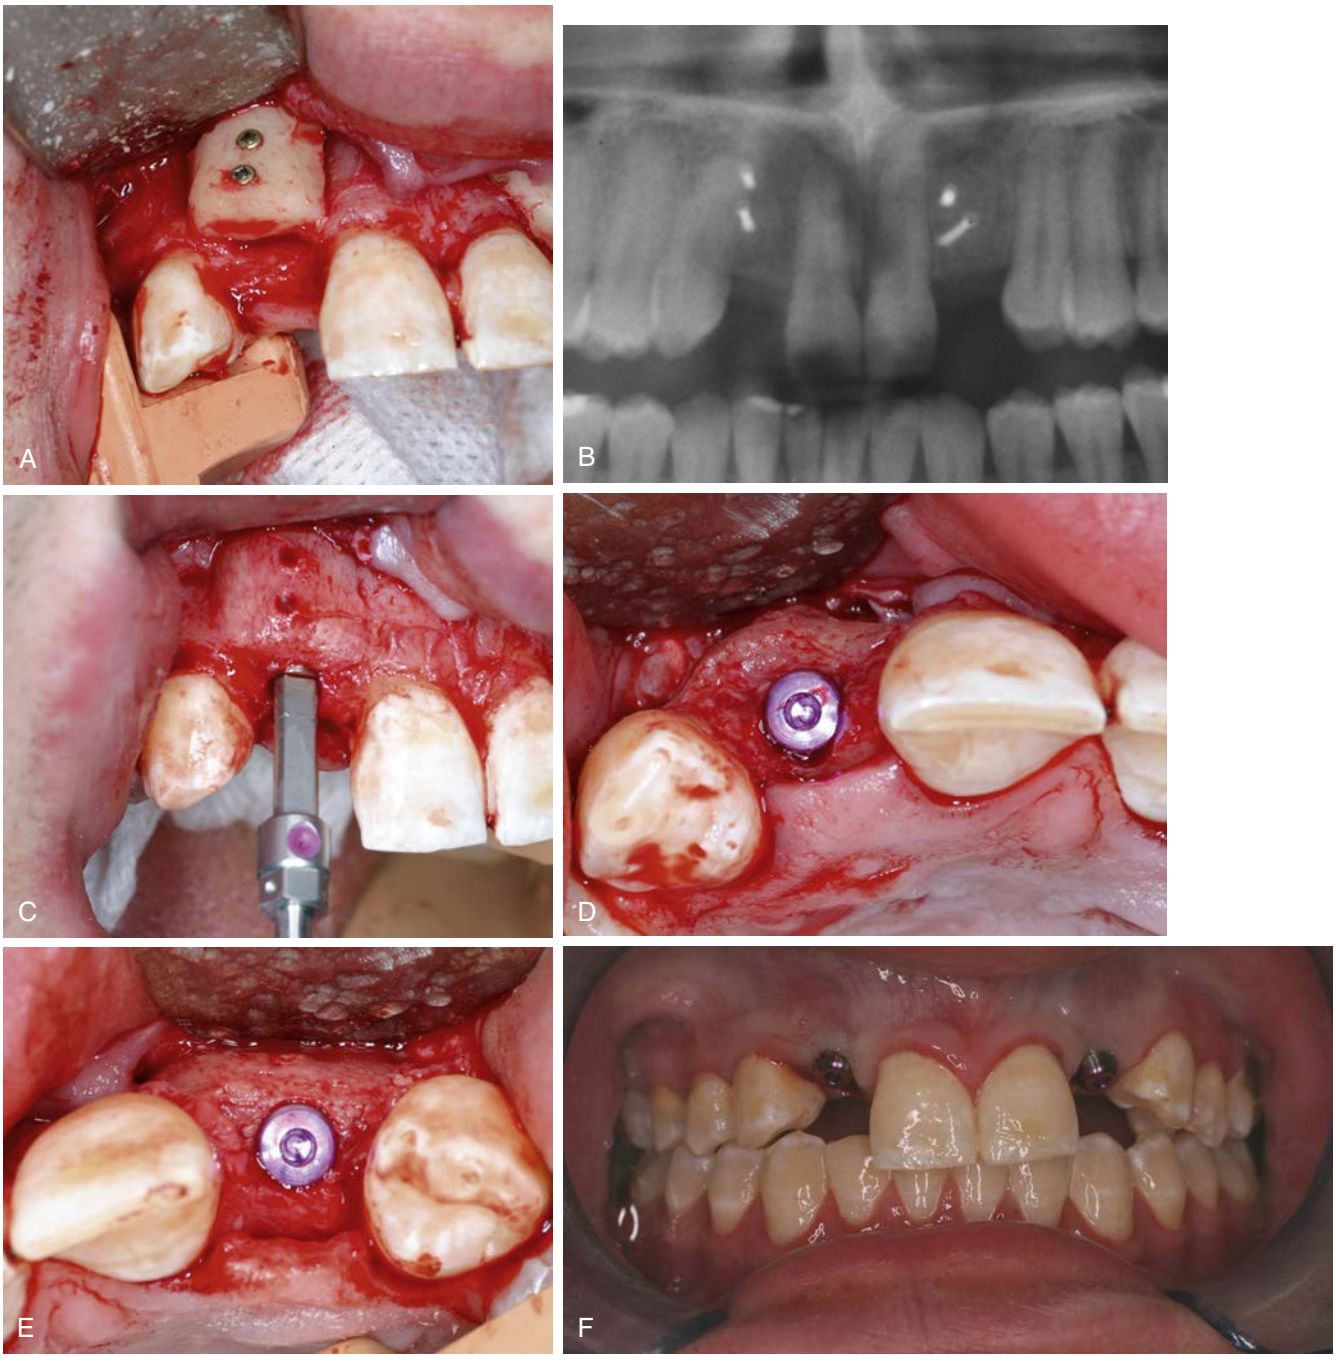
The optimal time for bone grafting is controversial. Boyne and Sands described the steps of surgical grafting with chronological nomenclature based on age of the patient.[82] Primary bone grafting occurs when the patient is younger than 2 years of age. Early secondary bone grafting is carried out in patients between the ages of 2 and 5 years old. Secondary bone grafting occurs in patients more than 5 years of age. Tertiary bone grafting occurs when the patient has reached the age of 17 years. Adverse effects may occur with primary bone grafting, which include developmental defects affecting maxillary growth, severe crossbite, and poor alveolar morphology with unerupted or unsupported teeth.[83] Early secondary bone grafting improves orofacial development. The most commonly used method today is secondary bone grafting. The optimal age for secondary grafting is often described as being between 8 and 11 years old during mixed dentition, which should coincide with when the maxillary canine is approximately two-thirds developed.[83] Even with this accepted standard of care, there is still controversy as to the age at which the secondary bone grafting should take place, the type of bone graft, and whether orthodontic intervention should take place before or after the surgery.[84] Bone grafting materials such as hydroxyapatite or lyophilized bone are not suitable for cleft grafting because the materials do not allow tooth eruption, teeth are unable to migrate into the graft site, and teeth cannot be orthodontically shifted into the space.[85]

Secondary Bone Grafting Procedure

During the secondary bone grafting procedures, the following are the general steps. Initially, mucoperiosteal flaps of the palate and vestibular surfaces of the maxillary segments are made to expose the alveolar bony defect. The mucosa is inverted in order to establish the floor of the nose. Next, the graft is packed into the defect. All flaps will be sutured together to close the oral layer over the bone graft in the cleft site. An alternative to harvesting autogenous bone is to consider the off-label use of recombinant human bone morphogenetic protein-2 (rhBMP-2) combined with a collagen sponge, thus minimizing morbidity by eliminating the need for a secondary harvest site[86] (Figure 40-8).

Benefits of Secondary Bone Grafting

Grafting of the alveolar defects gives bony support to the teeth adjacent to the cleft and greatly enhances the follow-up orthodontic treatment. It gives a bony base for eruption of teeth in the line of the cleft and prevents drifting of proximal teeth into the cleft with subsequent premature loss. It provides union to the maxillary arch and reestablishes alveolar bone contour. This provides support for arch width and minimizes collapse of the maxillary arch. The maxillary segments are stabilized for the maintenance of the dentition and mastication. The oronasal fistula is eliminated to improve oral hygiene as well as speech. And above all, it provides the bony support needed to either place dental implants to restore the function and esthetics of the patient or move the laterals medial to substitute for a missing lateral incisor.[87]



• **Figure 40-7** **A,** Placement of a ramus graft to restore missing lateral incisor. **B,** Postoperative radiograph. **C,** Placement of a dental implant. **D,** Implant in place on the right. **E,** Implant in place on the left. **F,** Osseointegrated implants.

Implants in Cleft Patients

Conventional treatment of the cleft lip and cleft lip and palate patient is usually with a fixed or removable prosthetic reconstruction. An alternative treatment option is bone grafting followed by subsequent dental implant placement. Implant placement is best done when orofacial growth is completed to ensure the best functional outcome. The issue with placing implants in a cleft patient is the lack of quality mucoperiosteum for reconstruction, and the fact that previous surgeries may have caused scar tissue in the desired implant site, which may affect the esthetics of the overall outcome in the anterior maxilla. Additional bone grafting is often necessary prior to implant placement to ensure adequate bone volume (Figure 40-9). The survival rate of implants is lower in cleft patients than in non-cleft patients. A systematic review has shown that 5-year implant survival rates for cleft patients are approximately 80% to 96%, with a mean of 88.6%.[85] Simultaneous tertiary bone grafting with immediate implant placement is not recommended;

• **Figure 40-10** **A,** Inadequate ridge width in patient with ectodermal dysplasia. **B,** Preoperative radiograph.
Continued

a study showed that results were unfavorable in 43% of cases with approximately 86% partial bone loss.[88]

Ectodermal Dysplasia

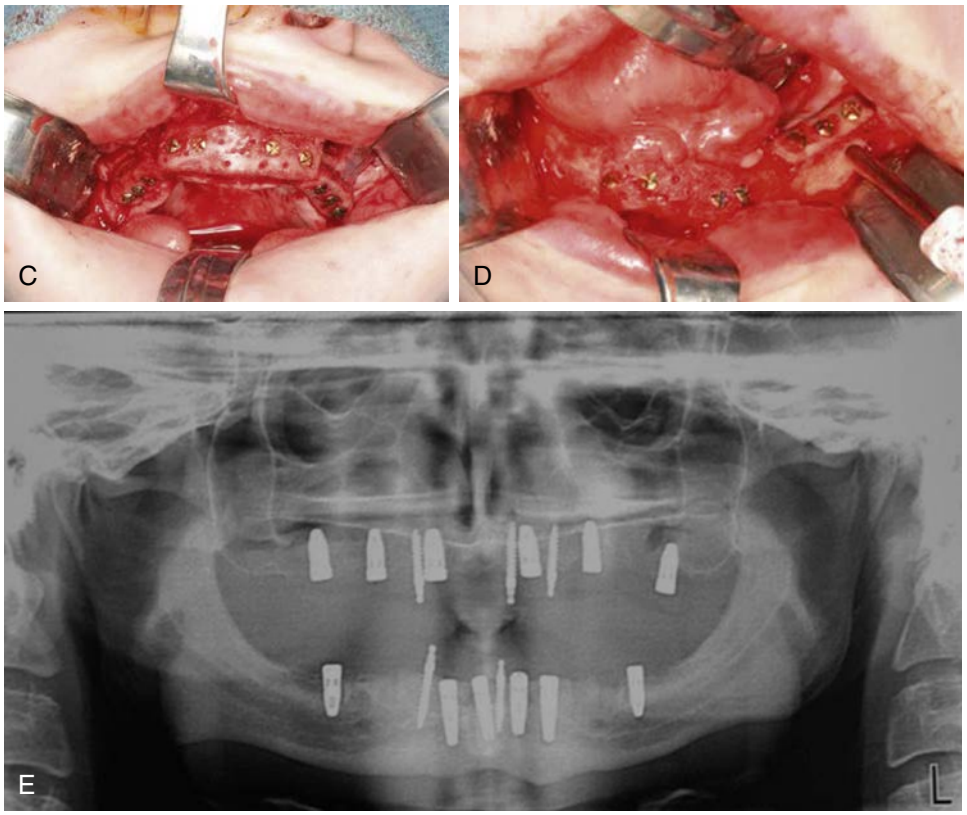
Ectodermal dysplasia is an inherited disorder that is classified into two major types: hypohidrotic ectodermal dysplasia (HED) and hidrotic ectodermal dysplasia. HED is the more common type of ectodermal dysplasia, with an incidence rate of 0.63 per 10,000 people.[89] The typical clinical presentation of the HED patient includes the following characteristics: sparse hair, "saddle" nose, thick and protruding lips, "bat ears," a juga forehead and chin, missing or misshapen teeth, and wrinkling and pigment deposition around the ear and orbital areas.[90] Patients with anodontia often have maxillary hypoplasia, mandibular prognathia, bony atrophy of the jaws, and/or facial concavity.[91] If there is an unfavorable jaw relationship, orthognathic surgery may also be indicated. The congenital absence of teeth often results in bony atrophy with insufficiency in jawbone height and width, making it difficult to place dental implants to rehabilitate the dental occlusion.

Bone Grafting

The available methods for bone augmentation of severely atrophied jaws of HED patients include the options that are used for any patient with severe atrophy of the jaws (Figure 40-10). In a study by Lamazza and colleagues, it was noted that multiple bone augmentation procedures, onlay block graft for horizontal and distraction osteogenesis for vertical, were necessary to achieve sufficient bone volume.[92] Autogenous bone block grafts are often harvested from the iliac crest. Advantages of distraction osteogenesis are that it does not cause damage to healthy tissue and does not necessitate a second donor site. The recommended time to place endosseous implants is 3 to 6 months following bone augmentation.

Dental Implants

Most HED patients suffer from oligodontia or anodontia and require multiple implants to be placed. The recommended treatment for the patient is to have an



• **Figure 40-10, cont'd** **C,** Bone grafts secured into place in the maxilla. **D,** Bone grafts secured into place in the mandible. **E,** Postoperative radiograph.

implant-supported prosthetic appliance. This will help achieve the best esthetic outcome, as gingiva-colored porcelain can be used to recreate a more natural contoured result.

In a recent study of 179 implants placed in ectodermal dysplasia patients, the 3-year success and overall implant survival rate was 97.2%.[93]

Summary

Grafting and dental implants can provide a predictable way to restore both congenital and acquired defects. Each patient presenting with a defect should be evaluated systematically and an individualized technique chosen that will give the best and most successful result. Dental implants have resulted in improved outcomes for countless patients.

Three-Dimensional Imaging and Digital Workflow Protocols for Dental Implants and Bone Grafting

SCOTT D. GANZ

Introduction

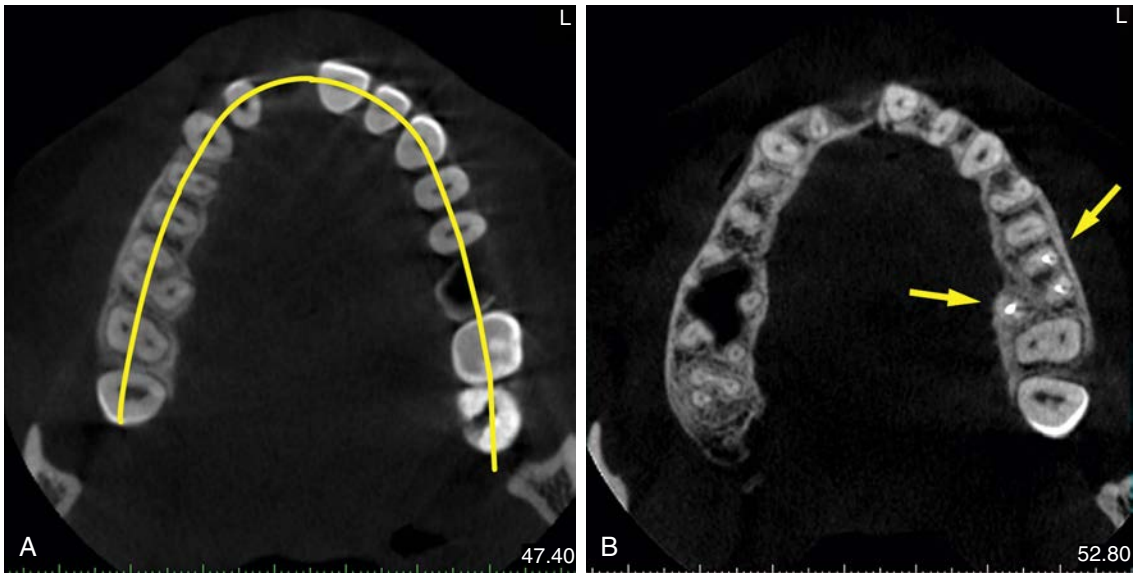
The use of three-dimensional (3D) imaging modalities and interactive treatment planning software has evolved into highly effective, useful, and essential tools for surgical and restorative intraoral reconstructive dentistry. The ability to visualize patient anatomy based on 3D data from CT/CBCT (computed tomography/cone-beam computed tomography) provides clinicians with invaluable diagnostic capabilities for assessing potential implant receptor sites, identifying pathology, determining location and proximity of vital adjacent structures, and ascertaining the need and planning for bone grafting applications. The continuation of the diagnostic phase based on imaging modalities, can result in three different protocols of treatment as previously defined by the author. The first has been termed *diagnostic-freehand.* The clinician should first visualize the patient's anatomic data in all available views including panoramic, cross-sectional, coronal, sagittal, axial, and 3D reconstructive volume. Using the interactive features of the software to interpret the CT/CBCT, non-distorted measurements can be made; implant positions can be planned; communication can be established with the patient, implant team, and dental laboratory technician; and the surgical intervention is completed using a free-hand technique based on the clinician's personal level of experience. The second protocol, termed *template-assisted,* takes the information from the Digital Imaging and Communications in Medicine (DICOM) dataset and interactive treatment planning software to fabricate a surgical guide or template. There are three basic CT-derived template designs: bone borne, tooth borne, and soft tissue/mucosal borne. The templates provide guidance for the drilling sequence for implant placement. The third protocol, termed *full template guidance,* provides the most accurate and precise link between the original plan, the surgical guide, drill sequence, and the delivery of implants directly through the template based on manufacturer-specific surgical components. These protocols summarize the use of digital dentistry solutions for the assessment of implant receptor sites, and the placement of implants.

The use of surgical templates generated through interactive treatment planning software is not new. However, the overall use of surgical guides is still quite infrequent because of several factors: (1) the need to have a CT/CBCT scan; (2) the ability to properly understand and use the interactive treatment planning software for diagnosis; (3) the fact that clinicians may not be educated on how to use software tools for proper planning of dental implants; (4) the extra time required for the planning process and (5) the fabrication of the surgical guides at a distant site; (6) and the added expense related to the template fabrication and (7) obtaining the necessary instrumentation from the implant manufacturer to complete a guided surgery procedure. Despite these barriers, the importance of 3D diagnosis, use of surgical guides, and the acceptance of guided surgery procedures is increasing as the demand for more accurate and restoratively driven outcomes are increasing. In addition, the use of surgical templates is not limited to the placement of dental implants. New protocols and surgical templates have been designed to accurately reduce bone (bone reduction template) and facilitate bone grafting procedures as well. Use of this ever-expanding technology can only be beneficial for our patients, who require accuracy, precision, and consistency with dental implant placement and bone grafting procedures, to improve long-term quality of life while reducing complications.

Case Examples: Anterior Maxillary Deficiency

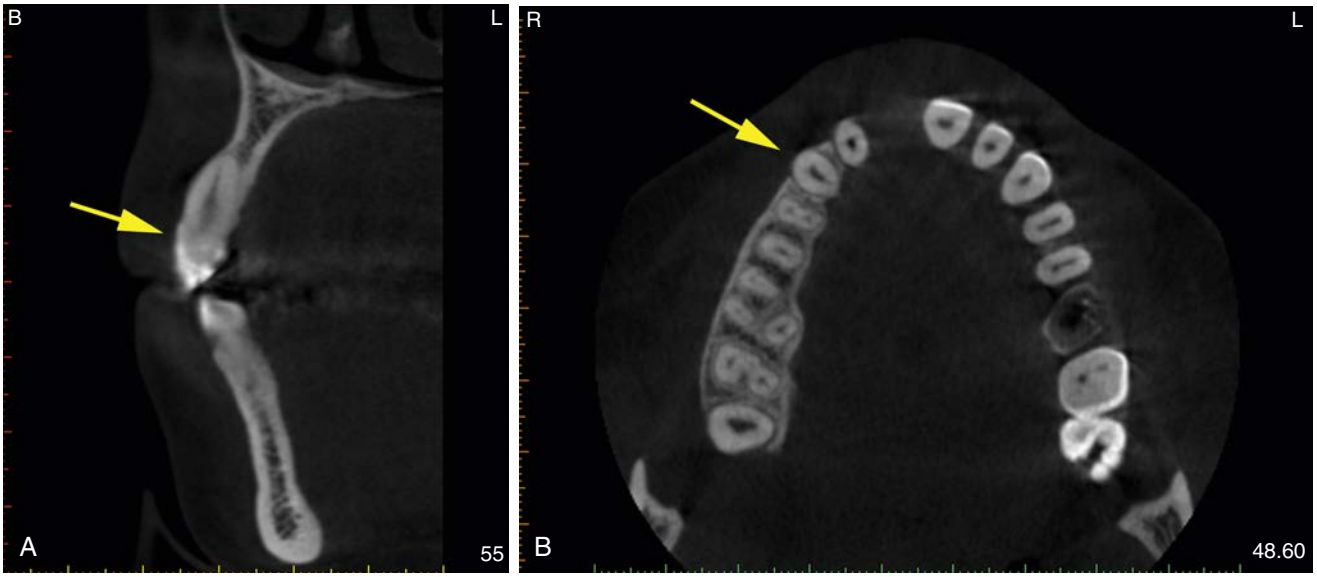
Three-dimensional CT/CBCT imaging analysis should begin with a review of the information contained within the scan data. Clinicians should institute a similar approach

• **Figure 41-1** The panoramic reconstructed image provides for a general assessment of the maxillomandibular relationship.

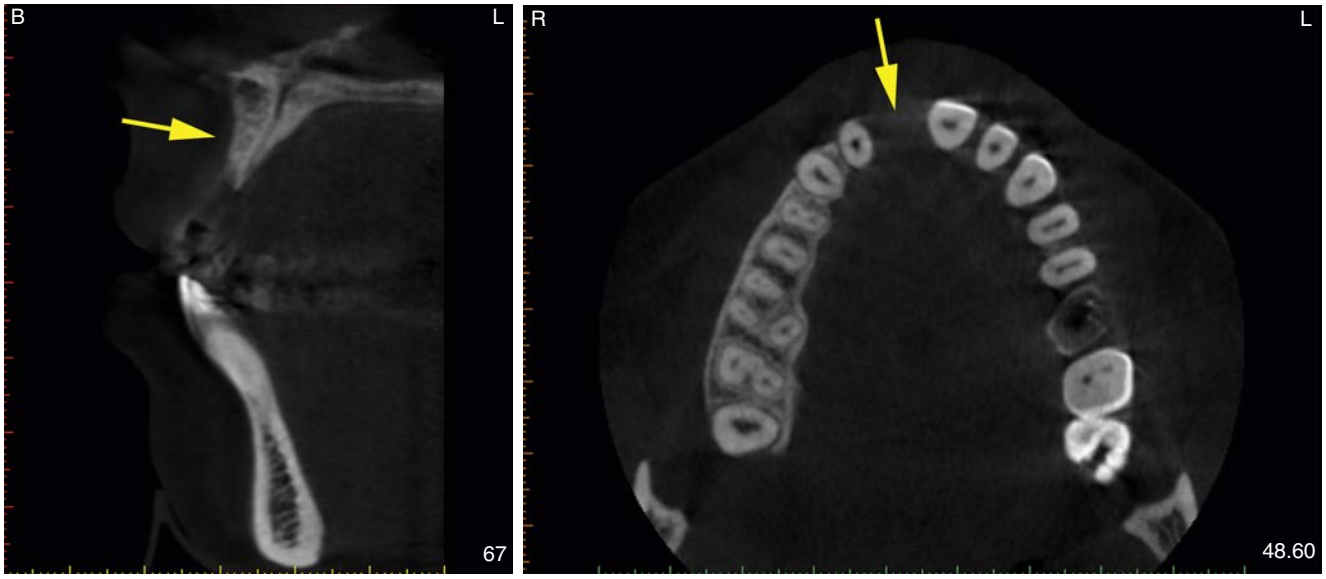


• **Figure 41-2** **A,** The panoramic view is contingent on the position of the "panoramic curve." **B,** This image reveals the buccal-palatal bone dimension and the gutta percha present in the maxillary left first molar tooth.

or protocol for the proper evaluation of each patient's individual anatomic presentation. It is important to understand that despite differences in the particular software application used, each should allow for inspection of slices in many views, including the panoramic, coronal, sagittal, cross-sectional, axial, and 3D reconstructed volumes. The panoramic reconstructed image provides for a general assessment of the maxillomandibular relationship, teeth and roots, which may be present or absent, the nasal cavity, bilateral maxillary sinuses, interarch space, location of the mental foramina, and sometimes the path of the inferior alveolar nerve (Figure 41-1). In this case, the patient's chief complaint, region of interest (ROI), and rationale for the CBCT scan was a single missing right maxillary central incisor tooth. The panoramic view is contingent on the position of the "panoramic curve," which can be automatically generated or manually positioned within the axial slice to aid in the visualization of region of interest (Figure 41-2, *A*). In addition, the horizontal slice related by the axial image can be changed in a superior or inferior direction to facilitate inspection of the entire anatomy captured by the scan (see Figure 41-2, *B*). Note that in Figure 41-2, *A,* the root morphology can begin to be appreciated without too much information about the width of the alveolar bone, whereas Figure 41-2, *B,* reveals more of the buccal-palatal bone dimension and even shows the gutta percha present in the maxillary left first molar tooth *(yellow arrow)*.

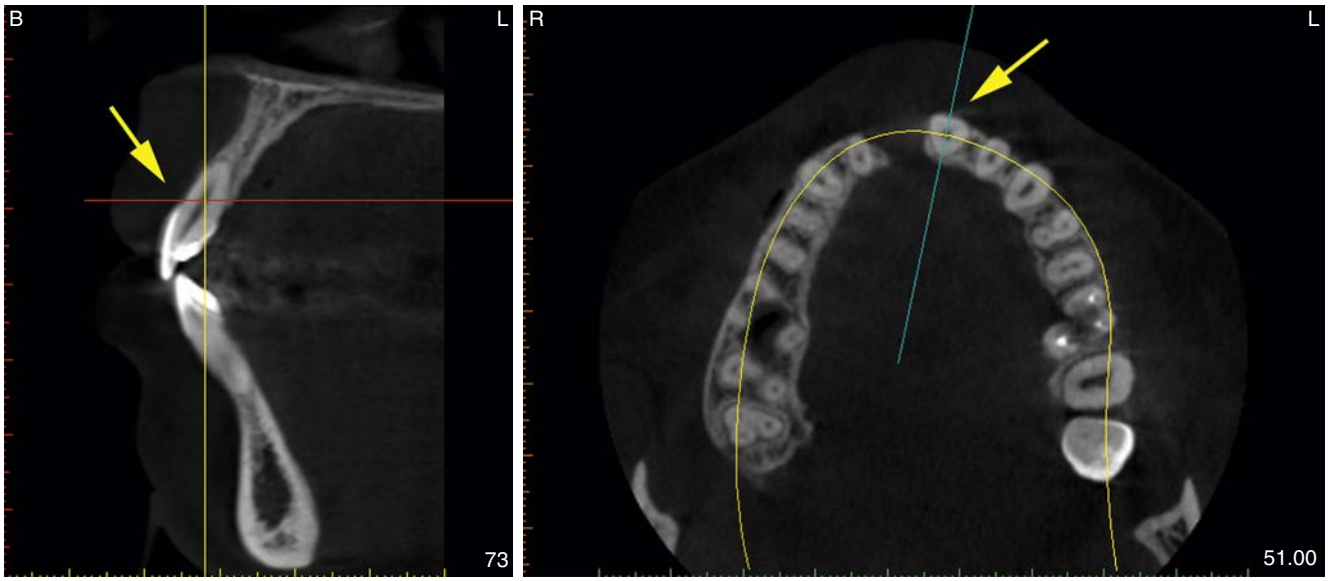


• **Figure 41-3** **A,** The cross-sectional slice of the right maxillary cuspid tooth *(arrow)*, and the axial slice **(B)** reveals almost no bone on both the facial and palatal aspect of the root.

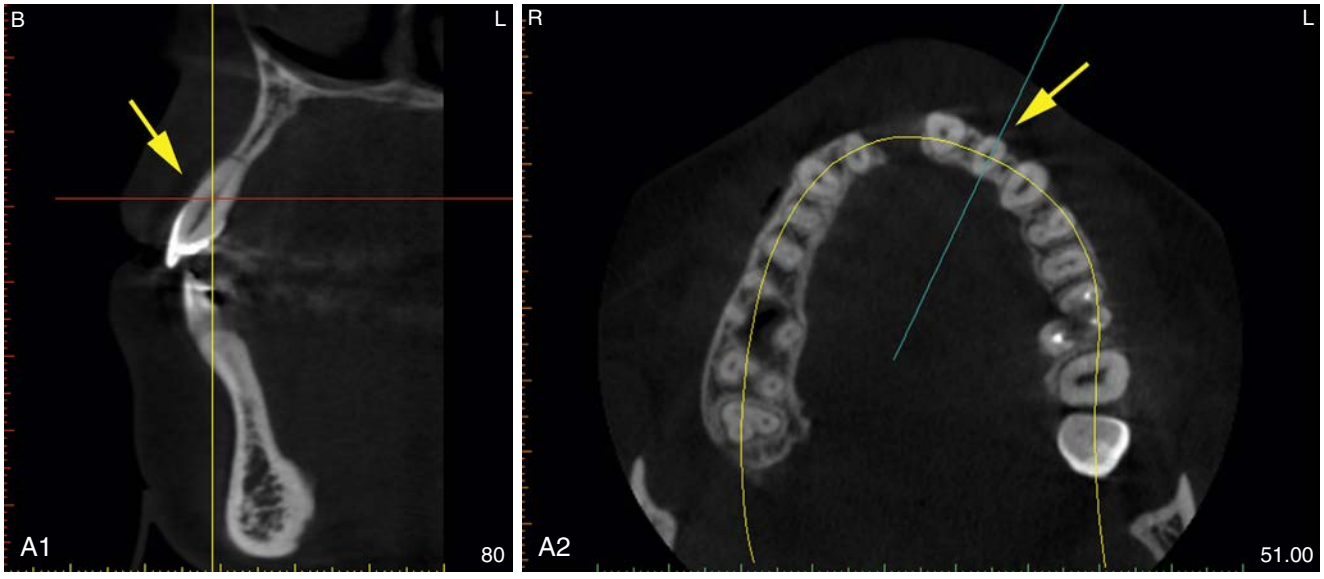


• **Figure 41-4** The missing right central incisor shows a total lack of alveolus, and insufficient support for an implant *(arrows)*.

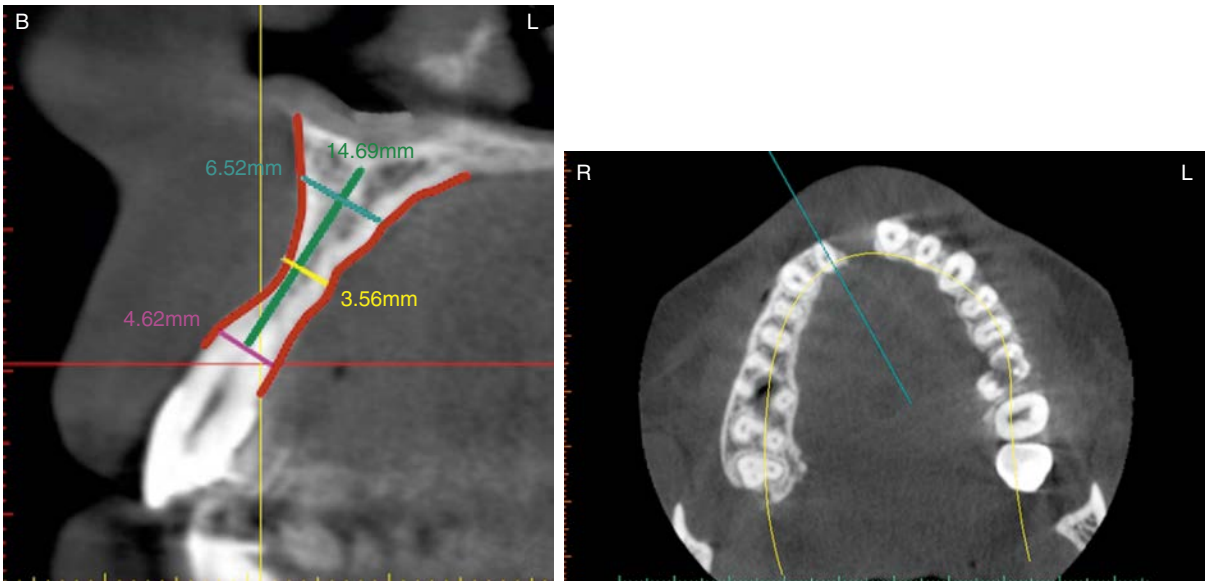
The panoramic reconstructed image is an interactive representation of the maxilla and mandible based on the CBCT scan dataset and provides only a two-dimensional view. The teeth and roots may appear to be surrounded with bone; however, the actual volume of bone cannot be accurately assessed. Although viewing slices of the 3D scan separately and individually is important, the ability to assess multiple images simultaneously allows clinicians to assimilate the information in a more meaningful and synergistic manner. The cross-sectional slice of the right maxillary cuspid tooth *(yellow arrow)* and the axial slice seen in sequence reveal almost no bone on both the facial and palatal aspect of the root (Figure 41-3). The lack of bone contained in the alveolar housing is amplified by the finding that there is minimal bone width superior to the root apex *(red arrow)*. The original region of interest, the missing right central incisor, shows a total lack of alveolus and insufficient support for an implant *(yellow arrows)* (Figure 41-4). Following the surrounding teeth in the maxillary arch (from right to left) reveals a similar pattern of insufficient bone volume for the left central incisor *(yellow arrows)* (Figure 41-5). The loss of alveolus is most pronounced when evaluating the maxillary left lateral incisor (Figure 41-6, *A*). The tooth root seemed to be balanced on top of the alveolar crest without any bone support (Figure 41-6, *B*). The interactive 3D software



• **Figure 41-5** The surrounding teeth in the maxillary arch (from right to left) reveal a similar pattern of insufficient bone volume for the left central incisor *(arrows)*.



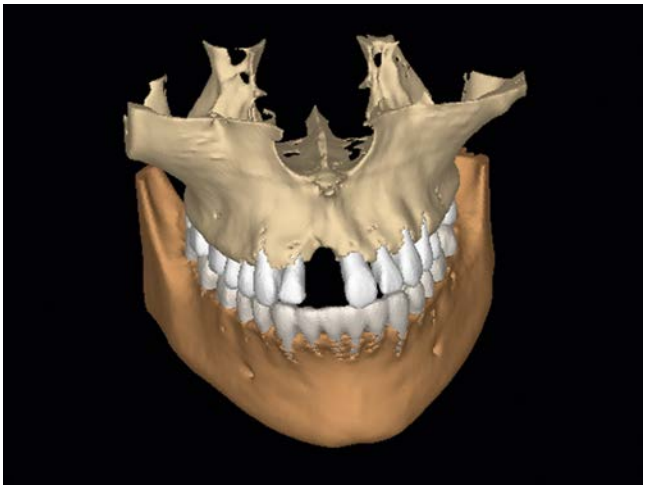
• **Figure 41-6** **A,** Two images show the loss of alveolus as more pronounced when evaluating the maxillary left lateral incisor *(yellow arrows)*. **B,** The tooth root seemed to be balanced on top of the alveolar crest without any apparent supporting alveolar bone.



• **Figure 41-7** The width of the right maxillary lateral incisor root measured near the crest of the alveolus (4.62 mm), at the middle of the alveolus (3.56 mm), and at the widest area of the alveolus superiorly (6.52 mm). The height of the ridge was measured to be 14.69 mm.

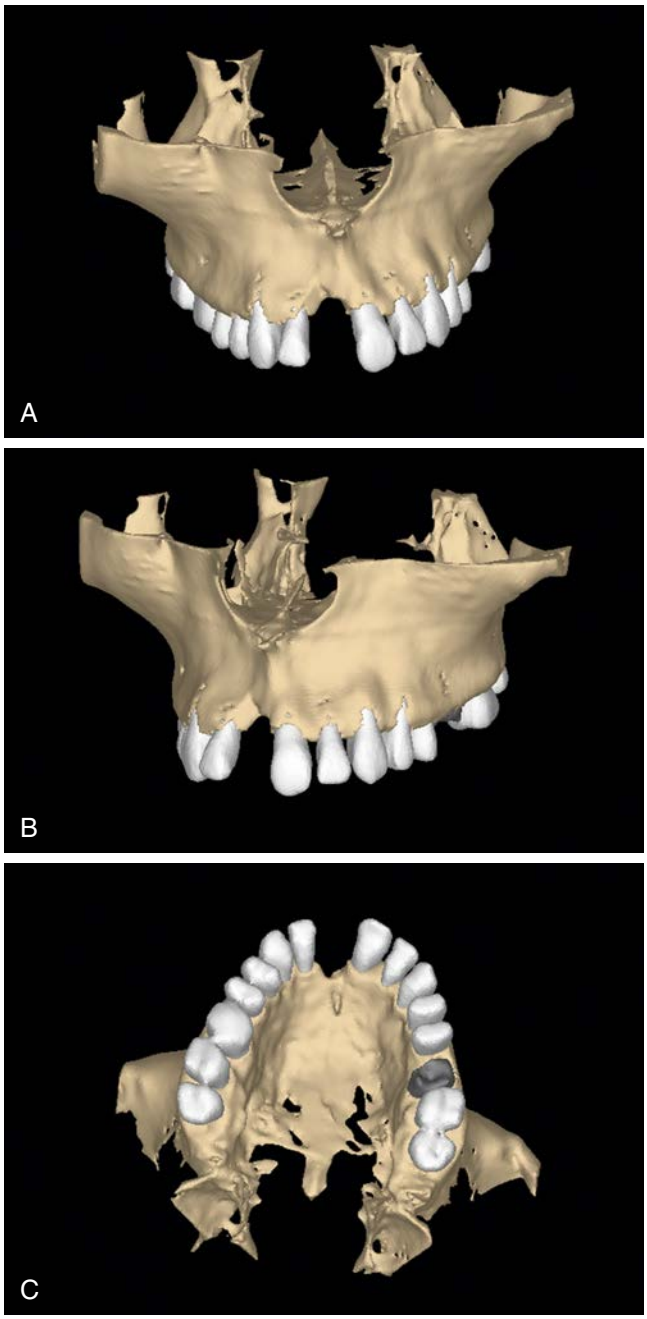
provides specific tools for undistorted measurements of the existing anatomy, which is helpful when determining the appropriate treatment options. Figure 41-7 reveals measurements of the width of the right maxillary lateral incisor root near the crest of the alveolus (4.62 mm), at the middle of the alveolus (3.56 mm), and at the widest area of the alveolus superiorly (6.52 mm). The height of the ridge was measured to be 14.69 mm. The valuable measurements become part of the "blueprint" or architectural plan for the proposed treatment.

As computing power has increased, so has the ability to manage the large DICOM dataset from the CT or CBCT imaging device. The powerful graphics cards available for desktop workstations, portable notebooks, and even tablet computers allow the datasets to be quickly processed for rendering of 3D volumetric images even with large field-of-view (FOV) sensors. The large FOV devices provide adequate height and width to capture the entire maxillary and mandibular arches in occlusion (Figure 41-8). The bony defect and loss of volume in the area of the maxillary right central incisor can be completely visualized. If the mandibular arch is removed, the maxilla can be rotated completely in all views to better assess the regions of interest (Figure 41-9). Images can and should be enlarged to improve diagnostic capabilities. The quantity of bone volume loss and width of remaining bone can be further appreciated in Figure 41-10. Each volume should be assigned a level of opacity that can be varied to reveal underlying structures, a process defined by the author as "selective transparency." By managing the root opacity and changing the level of translucency of the bone, the roots can be clearly visualized (Figure 41-11, *A*), along with the path of the incisal nerve (see Figure 41-11, *B*).



• **Figure 41-8** Largefield-of-view devices provide adequate height and width to capture the entire maxillary and mandibular arches in occlusion seen in the three-dimensional volumes.

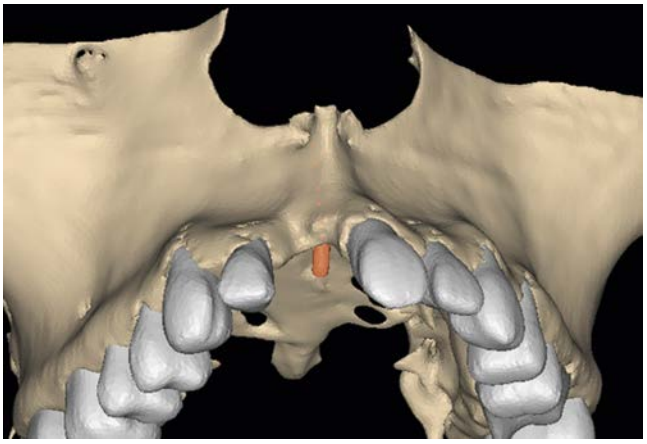
It should be noted that when the initial DICOM data is processed, the software may in many cases be able to create beautiful and visually pleasing 3D reconstructed volumes. However, problems often occur when there are existing crowns or metal within the FOV, resulting in what has been termed "scatter" artifact. This scatter can mask underlying anatomy in critical regions that clinicians need to analyze, diminishing the diagnostic information that can be gleaned from the scan. Therefore the interactive treatment planning software must have the ability to help remove or diminish scatter artifact to improve the interpretation of the data within the diagnosis and planning phase. The process can be facilitated through ancillary superimposition of intraoral scan data or optical scans



• **Figure 41-9** **A,** The bony defect and loss of volume in the area of the maxillary right central incisor can be completely visualized. **B-C,** The maxilla can be rotated completely in all views to better assess the regions of interest.

of stone casts that do not have scatter, which can exceed the surface accuracy inherent in the original scan data, as an additional aid for planning and the eventual fabrication of a variety of surgical templates.

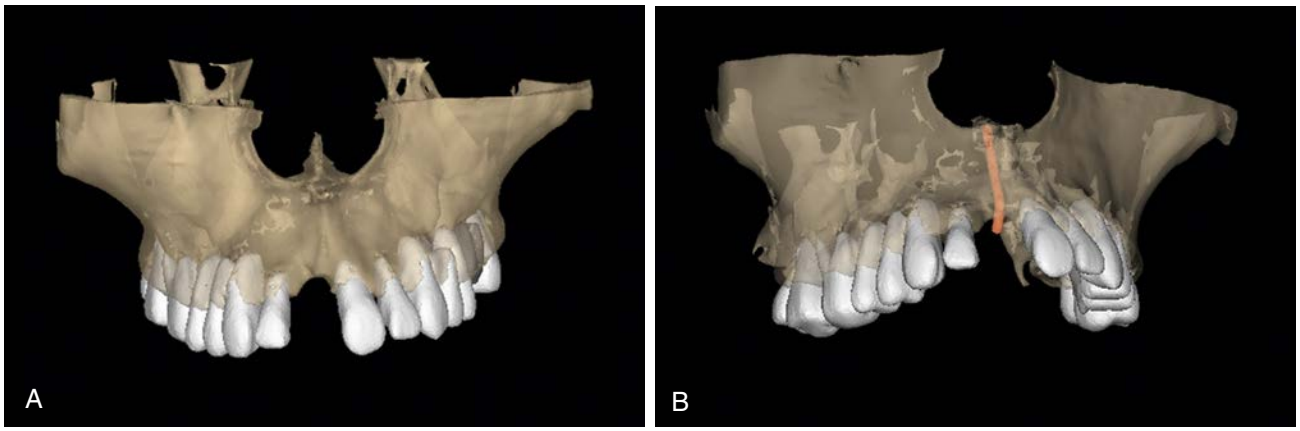
The advanced capabilities of interactive treatment planning software provide for the simulation of dental implants as well as for bone grafting procedures. These useful tools are a valuable asset for clinicians when developing treatment alternatives for their patients. When evaluating bony concavities, and the limited alveolar bone volume, one



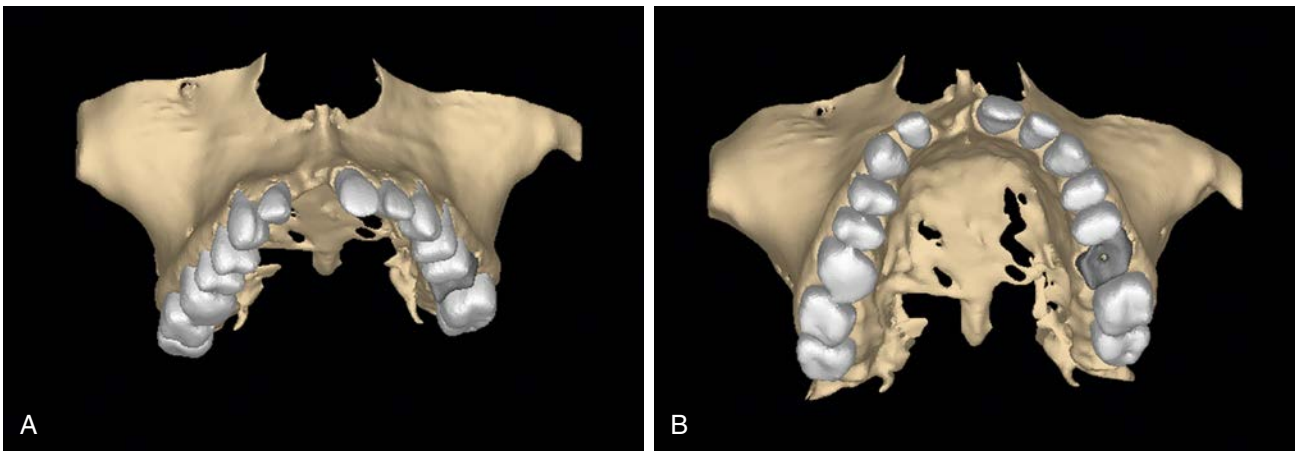
• **Figure 41-10** Image reveals the quantity of bone volume loss, width of remaining bone, and the simulated incisal nerve *(orange)*.

treatment alternative would be to improve the width of bone through grafting. Two separate grafting methods can then be used to gain adequate bone volume to allow for subsequent implant placement. The first is to use a block graft either from a sufficient autologous donor site, such as the hip, ramus, or symphysis or obtained from tissue-bank bone. The second option is to use particulate bone supported with tenting screws. The bilateral anterior facial concavities are apparent when evaluating the 3D volumetric reconstructed volume (Figure 41-12, *A*) and the amount of increased bone width required to establish a foundation for future dental implant placement (see Figure 41-12, *B*). The process of maintaining space or stabilizing block grafts can be simulated with realistic virtual components such as tenting or fixation screws (Figure 41-13). The use of selective transparency is also important when planning to place these fixation screws to avoid vital structures and potential complications (Figure 41-14). In this case, four horizontal screws were positioned to support bone within the concavities, and a vertical screw was positioned to support bone between the right lateral and left central incisor teeth (Figure 41-15). The simulation provides clinicians with an advanced knowledge of the underlying bony anatomy, and a hands-on clinical application, which may help to avoid surprises (Figure 41-16, *A*). The tenting screws should be ideally located to provide the needed support for the bone graft and placed to avoid adjacent vital structures (Figure 41-17). A bone graft with sufficient volume to fill the defect and form the foundation for implant placement was simulated using advanced bone grafting software modules (Figure 41-18).

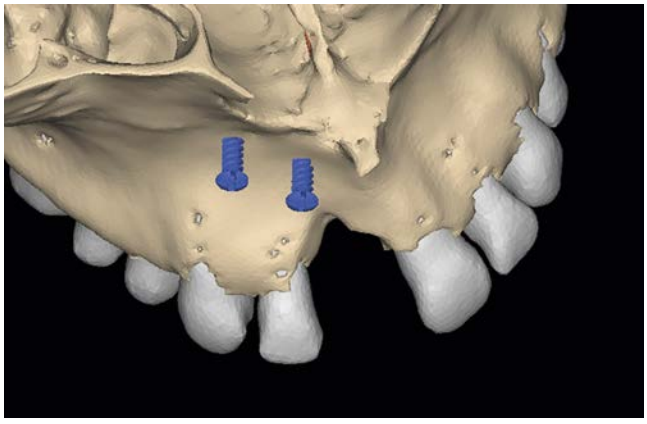
Due to the significant loss of bone support and limited long-term prognosis of the anterior natural teeth, one plan was to remove the right lateral, left central, and left lateral incisors after the bone grafting procedure was completed. It was determined that four implants could be placed within the maxillary anterior region where the bone graft was to be placed and within the residual extraction sites. Each implant was simulated with an abutment projection



• **Figure 41-11** **A,** Changes in opacity reveal underlying structures. "Selective transparency," as defined by the author, allows for changing the level of translucency of the bone so that the roots can be clearly visualized. **B,** The path of the incisal nerve.

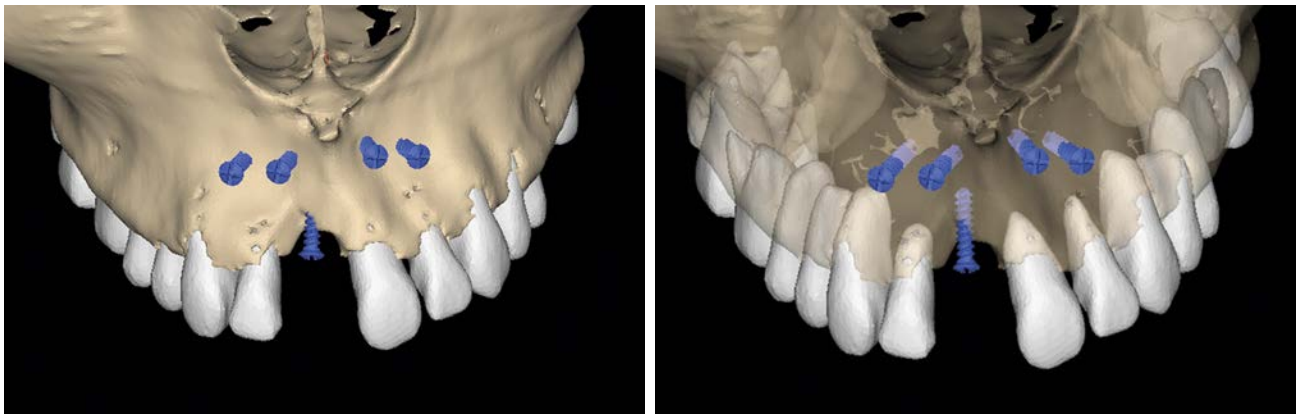


• **Figure 41-12** **A,** The bilateral anterior facial concavities become apparent when evaluating the 3D volumetric reconstructed volume. **B,** The amount of increased bone width required to establish a foundation for future dental implant placement.

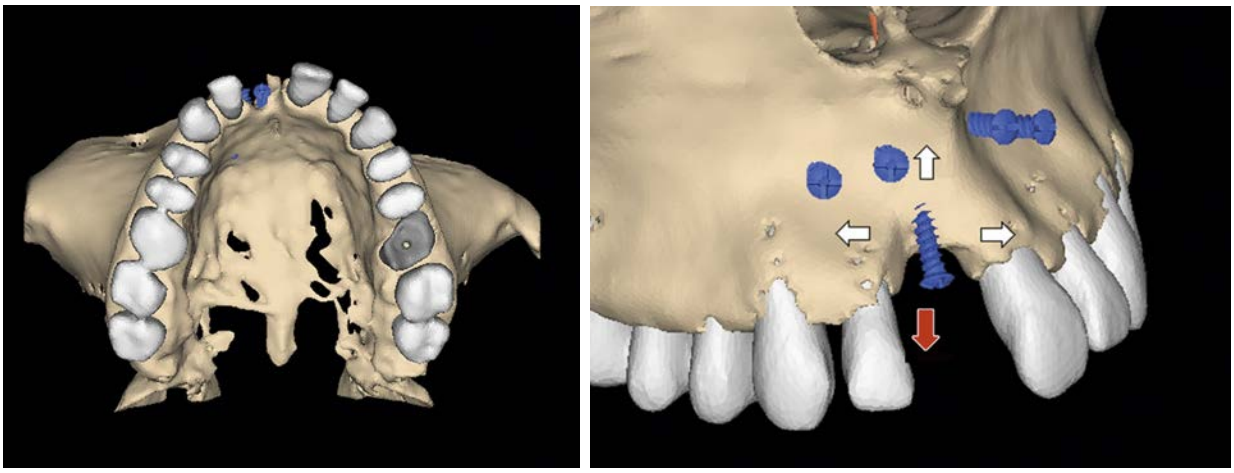


• **Figure 41-13** The process of maintaining space or stabilizing block grafts can be simulated with realistic virtual components such as "tenting" or fixation screws *(blue)*.

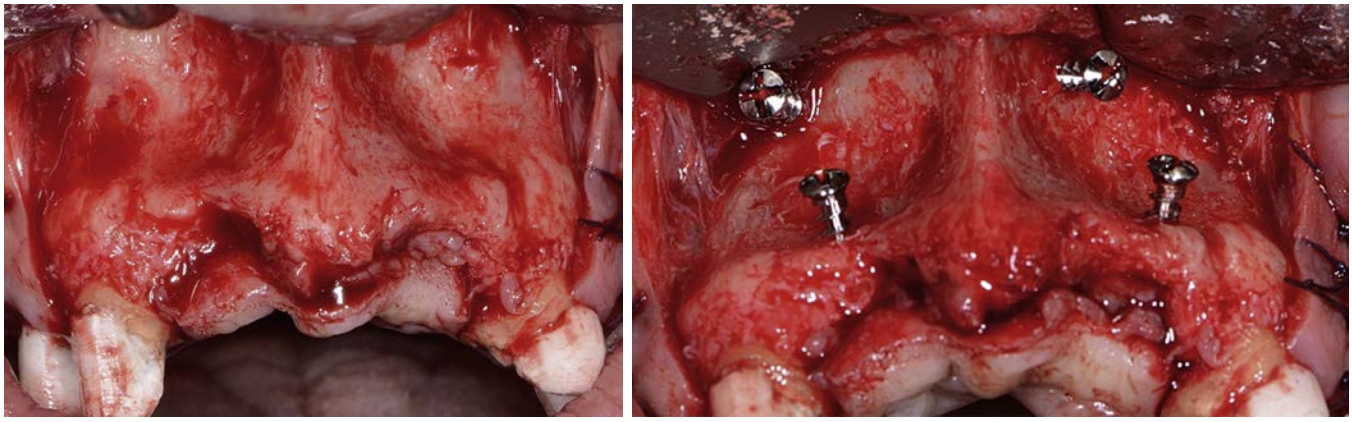
(yellow) to help define the trajectory within the restorative envelope of the existing natural dentition (Figure 41-19, *A*). Each abutment projection extended beyond the occlusal plane (see Figure 41-19, *B*), allowing the implant position to be evaluated in terms of the restorative goal, that is, screw- or cement-retained prosthetic design. The use of selective transparency combined with manufacturer-specific realistic implants and abutment projections *(yellow)* allows for a high level of planning precision. Without the bone grafting procedures, the implants could not be sufficiently fixated and would perforate the facial cortical plates (Figure 41-20). To facilitate the process of evaluating each potential implant receptor site, the DICOM data can be further manipulated through a process known as "segmentation" to virtually "extract" the anterior maxillary teeth in question (Figure 41-21). The virtual software capabilities are helpful in accurately planning the surgical and prosthetic



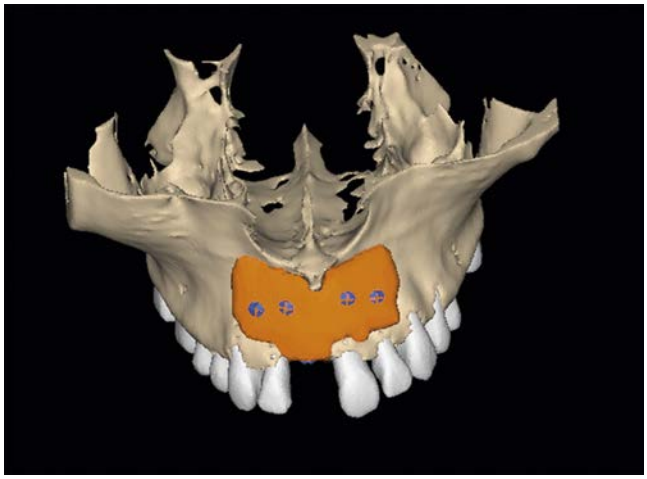
• **Figure 41-14** The use of selective transparency is important when planning to simulate the positioning of fixation screws to avoid adjacent vital structures and potential complications.



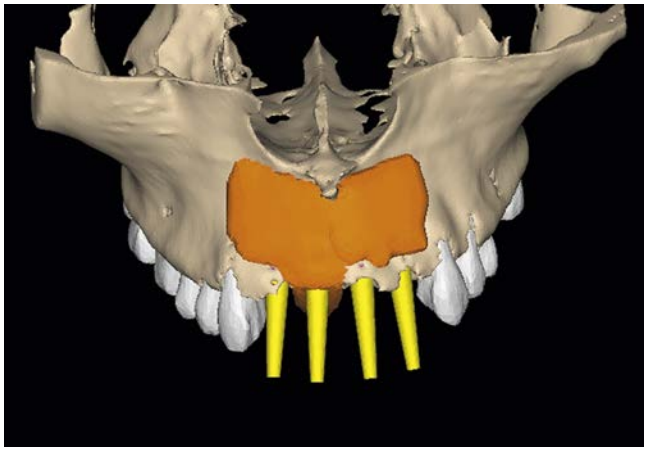
• **Figure 41-15** Four simulated horizontal screws were positioned to support bone within the bony concavities, including a vertical screw placed to support bone between the right lateral and left central incisor teeth.



• **Figure 41-16** The simulation provides clinicians with an accurate preview of the underlying bony anatomy, which may help to avoid surprises at the time of surgical intervention. (Clinical photos courtesy Dr. Aida Rebai.)



• **Figure 41-17** Tenting screws should be ideally located to provide support for the bone graft, while avoiding adjacent vital structures.



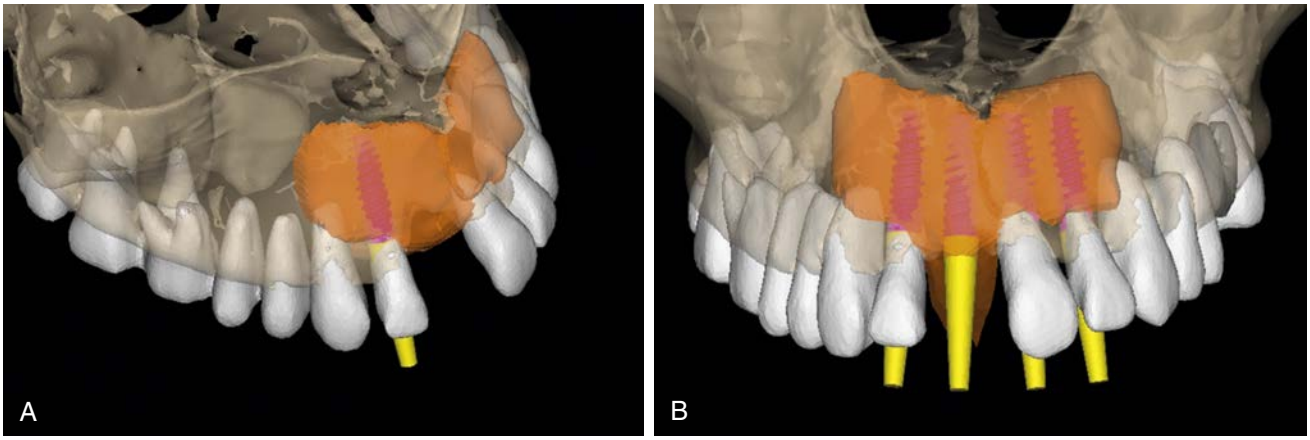
• **Figure 41-18** Using advanced software applications with a volumetric grafting module, a simulated bone graft *(orange)* is shown conformed to the facial defect, with sufficient volume to serve as the foundation for implant placement.

procedures by providing excellent visualization of the extraction sites (Figure 41-22, *A*), as well as the positions of the existing natural teeth and roots to refine the implant positioning (see Figure 41-22, *B*).

In order to achieve true restoratively-driven implant reconstruction as defined by the author, each implant requires placement within an adequate volume of bone, stability within the bone on placement, and an understanding of the definitive restorative design. Therefore the implants are simulated within the receptor site within the augmented bone of the cross-sectional slices for the right lateral incisor (Figure 41-23, *A*), the right central incisor (see Figure 41-23, *B*), the left central incisor (see Figure 41-23, *C*), and the left lateral incisor (see Figure 41-23, *D*). The plan is similar for the option of using particulate bone, block bone grafting, or tenting screws and reinforced membranes with various combination of biologic materials with the important goal of creating sufficient bone volume for implant placement. The simulated plan can be presented to the patient with the computer-generated images and shared with colleagues, members of the implant team, referring doctors, and dental laboratory technicians, providing an excellent communication tool leading to increased case acceptance. Once the plan has been accepted, the treatment can be successfully carried out with precision, and without surprises.

Biomedical Models/Stereolithography: Digital Workflow

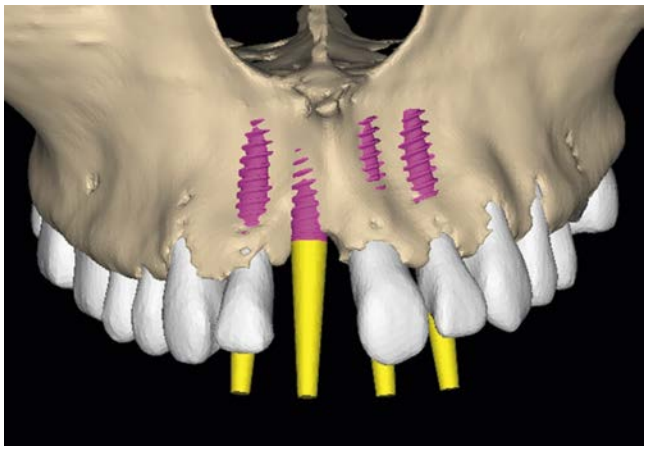
Recent technology has also provided a path from the treatment plan with simulated virtual bone grafting volumes to rapid-prototyping such as 3D printing ("additive manufacturing"), stereolithography (SLA) for hand-milling, or CAD-CAM fabrication ("subtractive manufacturing") of actual biological material for implantation. In order for



• **Figure 41-19** **A,** Each implant was simulated with an abutment projection *(yellow)* to help define the trajectory within the restorative envelope of the existing natural dentition. **B,** Each projection extended beyond the occlusal plane of the teeth.

this process to take place, the interactive treatment planning software must have the capability to export the reconstructed volumetric image dataset to standard triangulation files (STL) for the purposes of fabricating the biomedical model of the maxillary or mandibular bone and the graft shape. This process is also useful to plan the location of bone graft donor sites when autologous bone is required from the hip, symphysis, or ramus. The 3D representation of the graft volume, fixation screws, and maxillary arch can be seen in Figure 41-24, *A,* and secured to the maxilla in Figure 43-24, *B*. The reconstructed volume was first generated and then exported as an STL file to be imported into a 3D printer software application (Figure 41-25, *A*). The 3D printer can be a high-end, high-capacity, high-resolution industrial type, or the ever-evolving, lower-cost smaller devices for limited-quantity output at surprisingly high resolution, especially with SLA. In addition, the software can plan production for more than one part at a time based on the size of the build platform. The maxillary arch STL file and the separate bone graft STL file were positioned on the virtual production or build platform with the appropriate resin as seen in Figure 41-25, *B*. The stereolithography or SLA process manages a precise laser that is directed over a bath of liquid resin to solidify the resin layer by layer until the desired shape is completed. In order to complete the design process, structural elements must be incorporated to support the 3D printing process as the model is raised vertically out of the resin bath (Figure 41-26). The thinner each layer, the higher the resolution.

The simulation process can be further amplified by fabricating actual scale models of the anatomy in anticipation of the surgical procedure(s) (Figure 41-27). The deficient maxillary site can be completely visualized in the resin model (Figure 41-28). The maxillary arch and the 3D-printed bone graft shape are separate component parts used to simulate the graft placement (Figure 41-29). The simulated graft can be evaluated in terms of the desired intimate fit to the underlying facial alveolar bone (Figure 41-30). The use of rapid prototyping and 3D printing is an excellent aid to determine the size of the required donor graft material. Once the simulated graft has been fabricated in resin, the placement of fixation screws can be established on the model and with the CBCT images (Figure 41-31). The placement of the fixation screws can be therefore pre-determined within



• **Figure 41-20** Without bone grafting, implants would perforate the facial cortical plates and could not be sufficiently fixated.

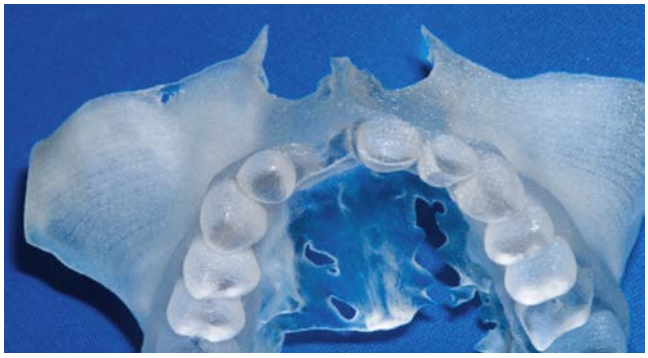
the 3D-printed resin block. Using an appropriate fixation screw kit, the entire process can be simulated extraorally to enhance accuracy of graft positioning to insure precision of fit (Figure 41-32). The occlusal view of the resin models reveals the anticipated increased width of facial bone in the anterior maxilla (Figure 41-33).

Surgical Guide Fabrication: Bone-Borne Template Maxilla

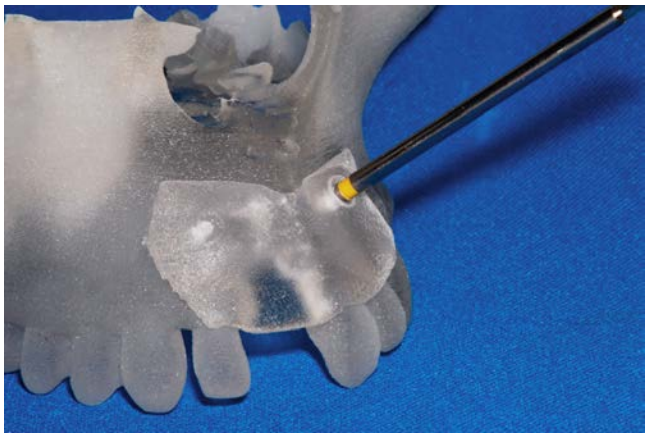
The same digital workflow applies to the fabrication of the surgical guide for dental implant placement. The diagnosis phase is important to insure that implants are placed properly within enough volume of bone, and in a position to support the desired restoration. The cross-sectional image reveals the



• **Figure 41-28** The deficient maxillary site can be completely visualized in the resin model.

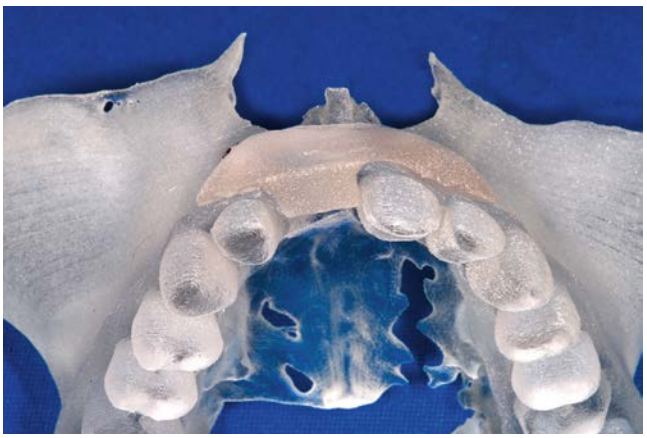
• **Figure 41-29** The maxillary arch and the 3D printed bone graft shape are separate component parts used to simulate the graft placement.

• **Figure 41-30** The simulated graft can be evaluated in terms of the desired intimate fit to the underlying facial alveolar bone.



• **Figure 41-31** Once the simulated graft has been fabricated in resin, the placement of fixation screws can be established on the biomedical model.

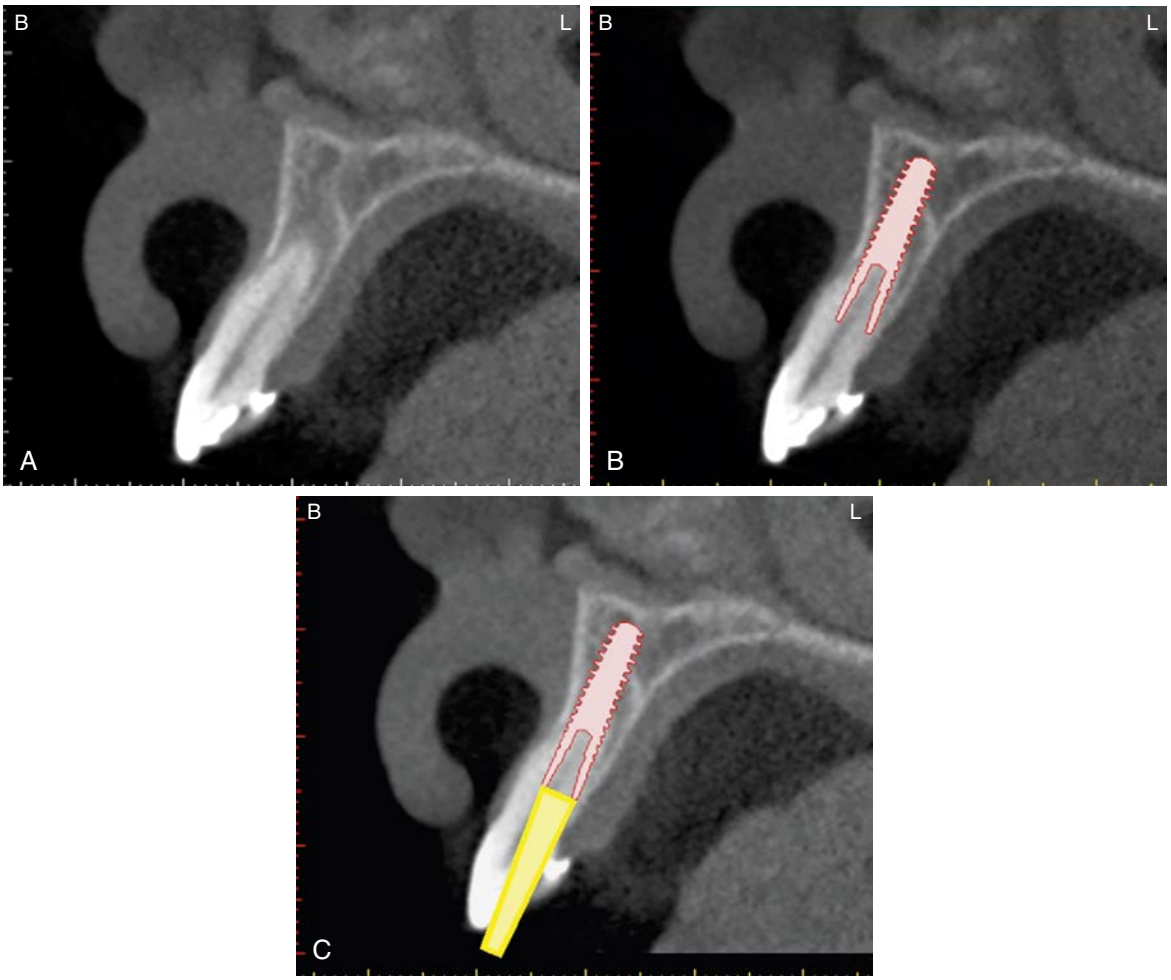
• **Figure 41-32** Using an appropriate surgical fixation screw kit, the entire process can be simulated extraorally to enhance accuracy of graft positioning and ensure precision of fit.



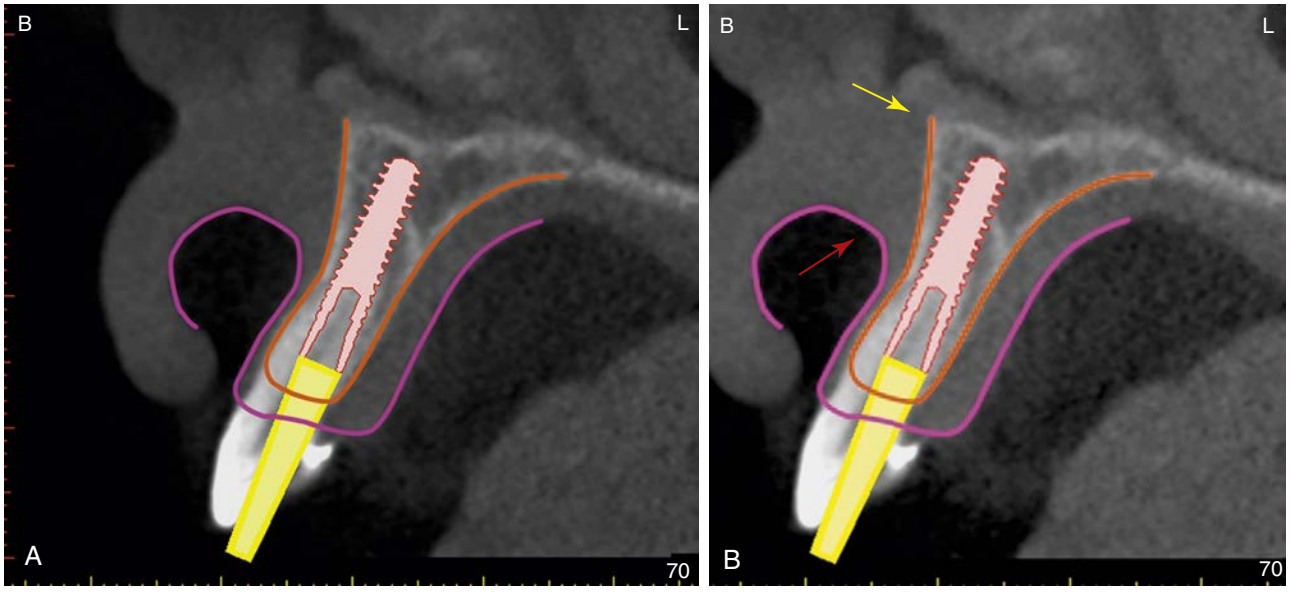
• **Figure 41-33** Occlusal view of the resin models reveals the anticipated increased width of facial bone in the anterior maxilla.

maxillary cuspid tooth with the surrounding alveolar housing (Figure 41-34, *A*). Using interactive treatment planning software, a simulated implant can be placed within the proposed implant receptor site (see Figure 41-34, *B*). However, the placement of the implant alone is not sufficient to achieve true restoratively driven implant restoration, as it does not show the link between the implant and the tooth. Therefore, in the author's opinion, it is important to create a projection from the implant body through the occlusal surface of the tooth to aid in establishing the proper trajectory *(yellow),* in anticipation of a cement or screw-retained restorative outcome (see Figure 41-34, *C*). To facilitate the diagnostic phase, the author has promoted the use of a simple cotton roll placed under the lip and into the vestibule, known as the "lip-lift" technique (Figure 41-35, *A*). Note the difference in diagnostic clarity when comparing these images to the cross-sectional images of the first case (see Figures 41-3 through 41-7). The pink line represents the soft tissue thickness over the alveolus and in the vestibule *(red arrow)* (see Figure 41-35, *B*). Using the lip-lift allows further definition of the soft tissue covering the facial aspect of the bone, and the relationship of the vestibule to the floor of the nose *(yellow arrow),* important if a flap needs to be raised for bone grafting. Advanced features contained in certain interactive treatment planning applications provide the ability to position realistic implants and implant abutments. The realistic manufacturer-specific abutment *(green shape)* can be placed on top of the implant and positioned to within the envelope of the restoration to be fabricated (Figure 41-36, *A*). The author's "Triangle of Bone" (TOB) concept maximizes the relationship between the volume of bone and an implant positioned within the receptor site to receive a cement-retained restoration. If the implant bisects the triangle as shown, it will be surrounded with the greatest volume of bone (see Figure 41-36, *B*).

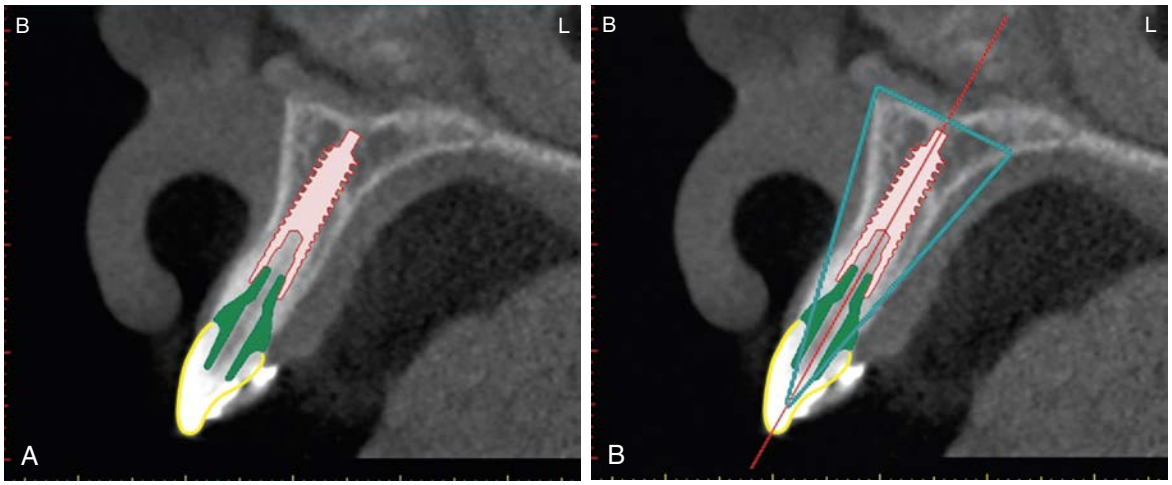
Once the implants have been planned, and the surgical guide has been completed with the interactive treatment planning software, the surgical guide design data are then exported as an STL file and sent to the manufacturing device to produce the guide. The surgical guide can then be fabricated through a CAD-CAM, 3D printing, or SLA process. The STL file is then managed within the 3D printing software and positioned on the build platform



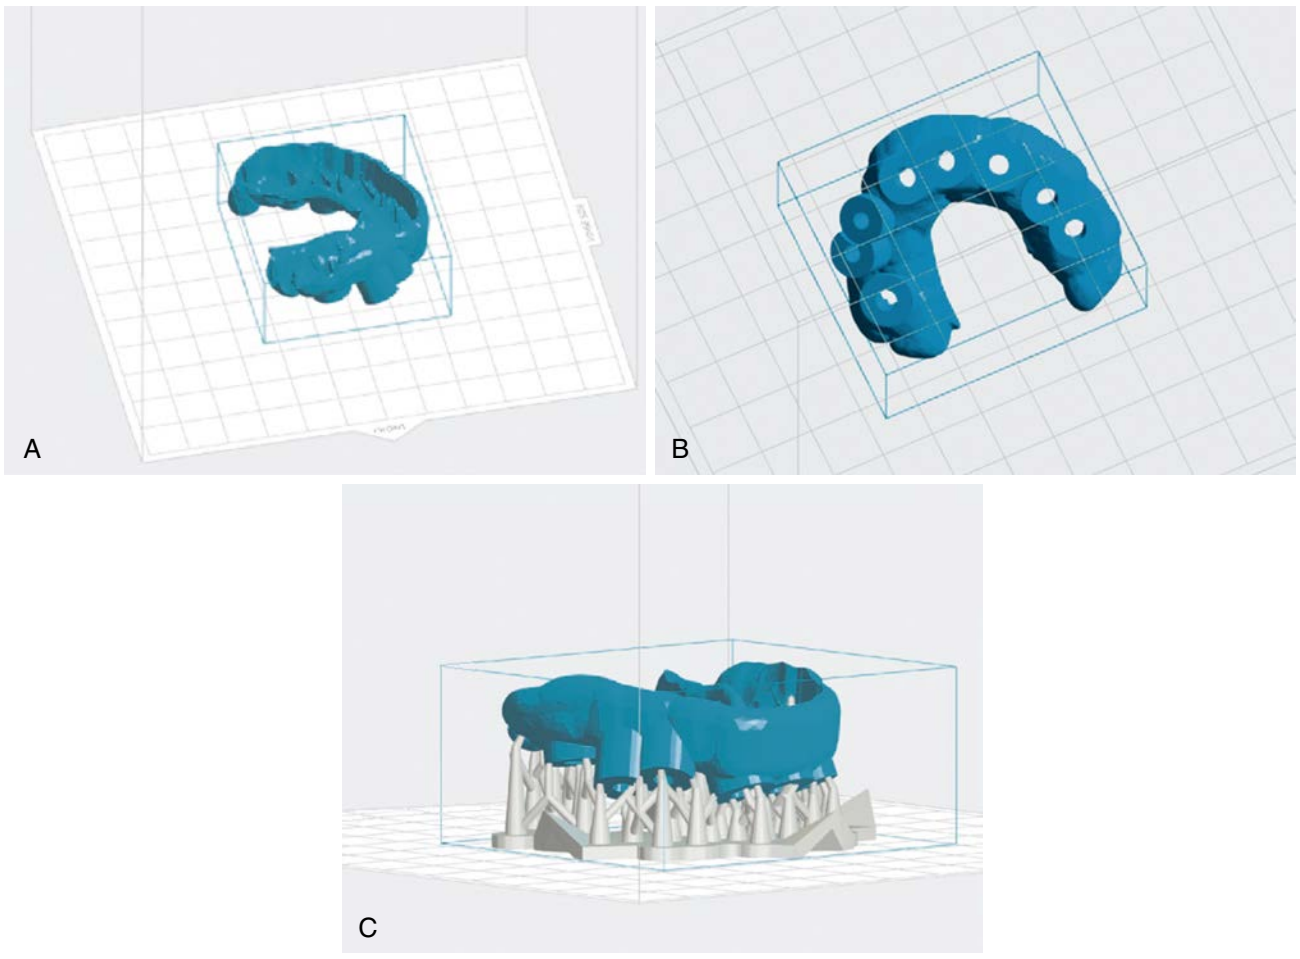
• **Figure 41-34** **A,** Cross-sectional image reveals the maxillary cuspid tooth with the surrounding alveolar housing. **B,** A simulated implant placed within the proposed implant receptor site. **C,** A projection from the implant body through the occlusal surface of the tooth aids in establishing the proper trajectory *(yellow),* in anticipation of a cement or screw-retained restorative outcome.



• **Figure 41-35** **A,** To facilitate the diagnostic phase, a simple cotton roll was placed under the lip and into the vestibule known as the "Lip-Lift" technique. **B**, The *pink line* represents the soft tissue thickness over the alveolus, and the extent of the vestibule *(red arrow)*.

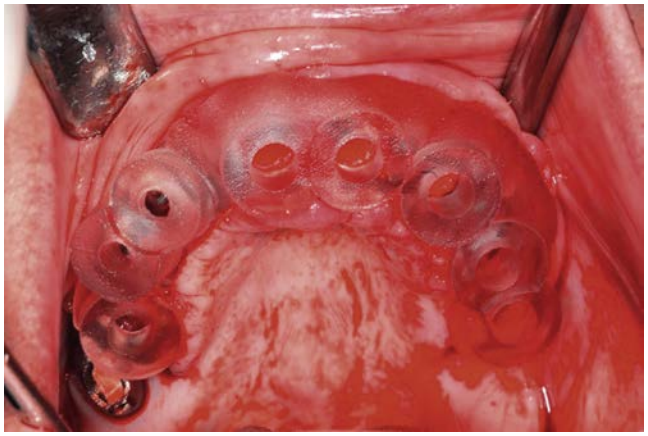


• **Figure 41-36** **A,** The realistic manufacturer-specific abutment *(green shape)* can be placed on top of the implant and positioned within the envelope of the desired restoration. **B,** "Bisecting" the Triangle of Bone to surround the implant with the most volume of bone.



• **Figure 41-37** **A-B,** The STL file managed within the 3D printing software and positioned on the build platform. **C,** The supporting structures are then formulated, and the template is printed over a period of many hours.

• **Figure 41-38** The resulting resin pattern with supporting struts which will be cut away by hand, polished, rinsed, and then sterilized for use.

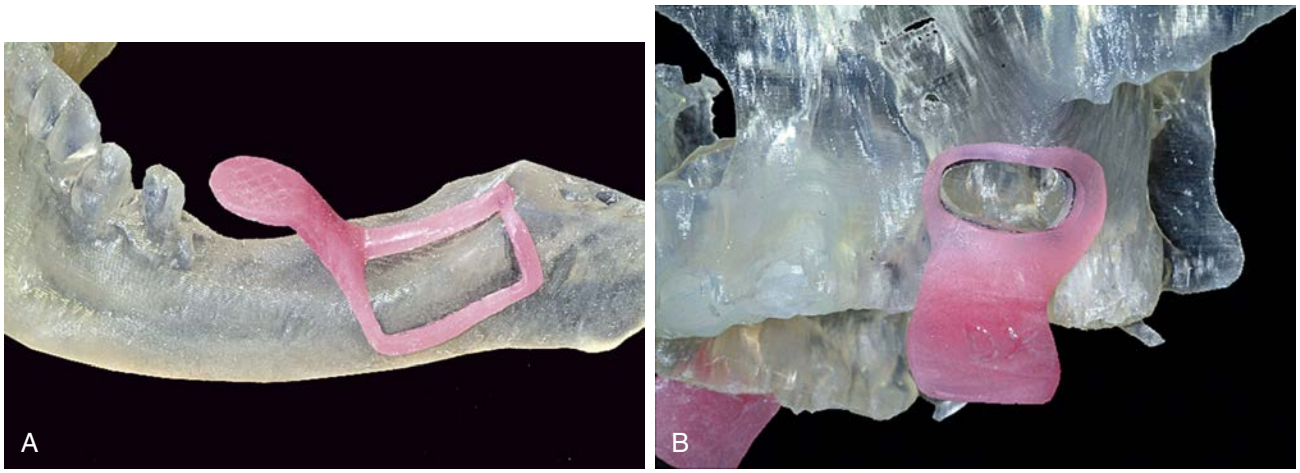


• **Figure 41-39** The maxillary bone-borne template, seen without any metal tubes, seated and ready for surgical intervention.

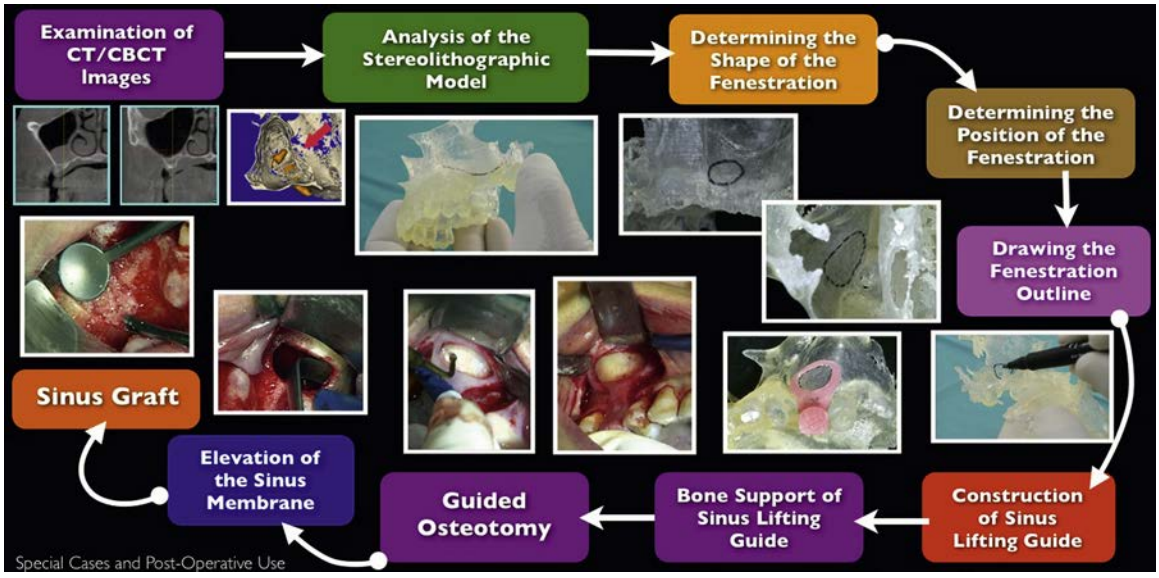
(Figure 41-37, *A* and *B*). The SLA supporting structures are then formulated, and the template is "printed" over a period of many hours (depending on desired resolution) as the laser gradually cures each layer (see Figure 41-37, *C*). The result is a resin pattern with supporting struts that will be cut away by hand, after which the pattern is polished, rinsed, and then sterilized for use (Figure 41-38). The template can be fabricated without metal guide sleeves, or metal guide sleeves can be added later. The maxillary bone-borne template, without any metal tubes, seated and ready for surgical intervention, is shown in Figure 41-39.

Innovative New Protocols: Donor Sites, Sinus Grafting, and Reconstruction Surgery

As the technology evolves, additional benefits have been derived from innovative and clinically useful concepts and protocols to enhance bone grafting procedures in preparation for placement of dental implants. The technology allows clinicians new tools to improve accuracy and efficiency and decrease surgical time and complications. To enhance grafting procedures, the mandible or maxillary bone can be fabricated through an SLA process, allowing for complete inspection of regions of interest as previously described and illustrated (see Figures 43-27 through 43-33). Once the defect has been identified and the grafting modality and region for the donor graft site has been established,



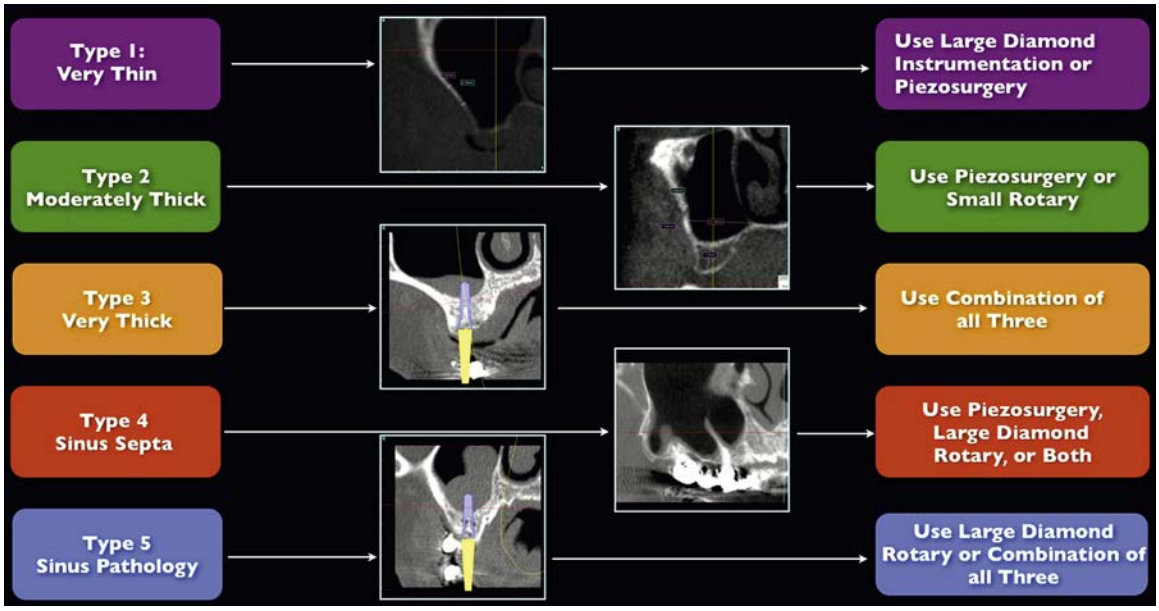
• **Figure 41-40** **A,** Once the biomedical resin model has been fabricated, the location of the donor graft site can be transferred to the model, as a "harvest guide," or **(B)** a "sinus graft guide" can be fabricated to be placed on the bone at the time of surgery to quickly and accurately transfer the position of the planned lateral window access to the maxillary sinus.



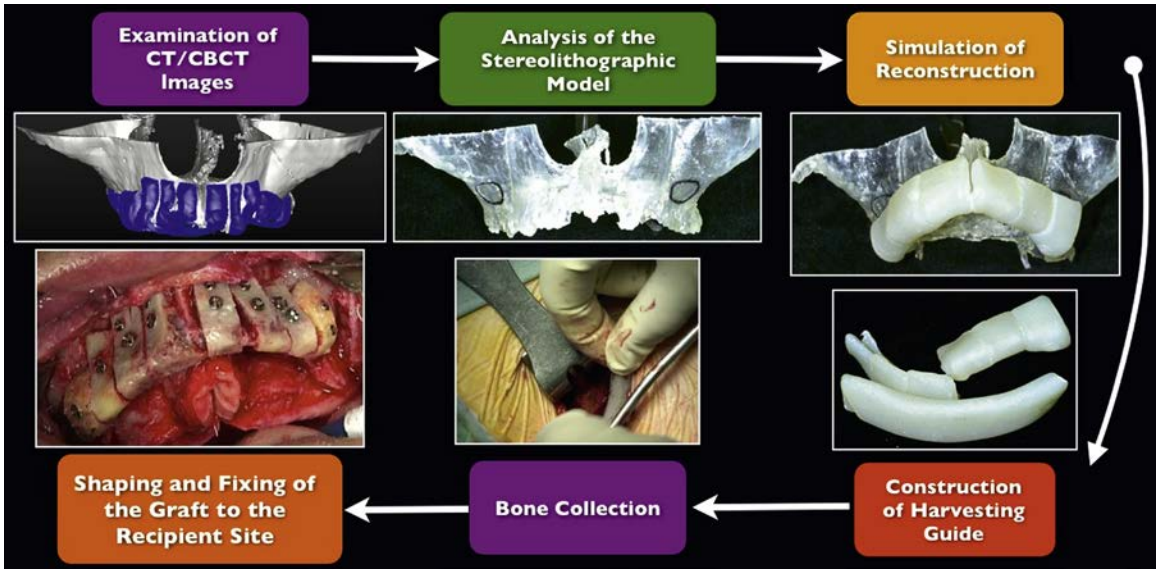
• **Figure 41-41** Protocol 1: Ganz-Rinaldi surgical protocol for sinus floor augmentation.

surgical templates can be useful to help define autologous donor graft sites, such as the mandibular ramus. Clinicians should first accurately assess potential donor sites with the 3D planning software to obtain the correct shape and volume of the donor graft while avoiding adjacent vital anatomy. Once the biomedical resin model has been fabricated, the location of the donor graft site can be transferred to the model, and a "harvest guide" can be fabricated (Figure 41-40, *A*). These concepts have been well described in the textbook *Computer-Guided Applications for Dental Implants, Bone Grafting, and Reconstructive Surgery*.

When planning for lateral window sinus augmentation procedures with 3D imaging and interactive treatment planning software, the shape and volume of the maxillary sinus can be evaluated. However, it is difficult for clinicians to transfer this information to the surgical site to determine exactly where the lateral window should be located, and the size and shape of the window fenestration to facilitate the grafting procedure. The fabrication of a biomedical model of the maxilla is useful in combination with the 3D planning software to accurately assess the position of the lateral window. Once the location has been determined, a "sinus graft guide" can be fabricated to be placed on the bone at the time of surgery to quickly and accurately transfer the position of the lateral window access to the maxillary sinus (see Figure 41-40, *B*). The Ganz-Rinaldi sinus augmentation lateral approach protocol is shown in Protocol 1 (Figure 41-41). The action flow



• **Figure 41-42** Protocol 2: Ganz-Rinaldi surgical protocol and classification for lateral sinus floor augmentation.



• **Figure 41-43** Protocol 3: Ganz-Rinaldi surgical protocol for reconstructive surgery.

describes the step-by-step process to achieve accurate location for the lateral window sinus augmentation procedure. The fabrication of sinus guides can be helpful with many different variations of the lateral window approach for single or bilateral procedures, and when septa may require two separate windows.

The use of 3D imaging can also provide clinicians with new protocols to help define and designate the proper instrumentation needed to access the sinus based on the diagnostic information gleaned from the CT/CBCT scan. The Ganz-Rinaldi sinus augmentation instrumentation protocol explains how the lateral wall thickness, bone density, presence of septa, and presence of pathology can determine which instrumentation would be appropriate to expedite the process (see Protocol 2 in Figure 41-42). The protocol describes five different categories or types of lateral sinus wall bone, and the use of three different instrumentation types: large diamond rotary instruments, piezosurgery instrumentation, or small rotary instrumentation. Finally, Protocol 3 (Figure 41-43) demonstrates the Ganz-Rinaldi reconstructive surgery protocol to simulate and then execute larger maxillofacial reconstruction with donor bone grafts and multiple recipient sites. In addition to the three presently described protocols, the Ganz-Rinaldi sinus augmentation crestal approach, harvesting protocol, and zygomatic implant protocol are presented in the textbook cited earlier.

Conclusion

The ability to visualize patient anatomy in three dimensions provides clinicians with invaluable diagnostic capabilities for assessment of potential implant receptor sites, and determination for bone grafting applications. The use of surgical templates generated through interactive treatment planning software is not new. However, the overall use of surgical guides is still quite infrequent owing to several factors: (1) the need to have a CT/CBCT scan; (2) the ability to use the interactive treatment planning software for diagnosis; (3) clinicians may not be educated on how to use software tools for proper planning of dental implants; (4) the extra time required for the planning process; (5) the extra time required for the fabrication of the surgical guides at a distant site; and (6) the added expense related to the template fabrication; and (7) the extra expense in obtaining the necessary instrumentation to complete a guided surgery procedure. Despite these barriers, the importance of 3D diagnosis, use of surgical guides, and the acceptance and adoption of guided surgery procedures is increasing to enhance one-stage, two-stage, and immediate-load/immediate restoration protocols. Use of this ever-expanding technology can only be beneficial for our patients who require accuracy, precision, and consistency with dental implant placement and bone grafting procedures to improve long-term quality of life. New and innovative protocols have been presented to illustrate the present and future potential applications of the evolving technology. Further research and case documentation is recommended to help identify further innovative concepts for diagnosis, treatment planning, surgical and restorative applications, and fabrication of surgical guides for a variety of different treatment modalities.

Peri-implant Disease and Restorative Aspects of Dental Implants

CHANDUR PREM KARL WADHWANI, BACH LE

Introduction to the Association of Residual Excess Cement and Peri-implant Disease

The debate over the advantages of screw- versus cement-retained implant prostheses has become a topic of interest within the dental community. Recent systematic reviews and consensus statements[1-4] have reported on the success and survival of these two retention mechanisms with the aim of introducing evidence-based restorative guidelines. Currently, it appears that the choice of retention in implant prostheses still mainly depends on the individual clinician's preference and experience.[1] The goal of this chapter is to give the clinician an understanding why cementation can cause issues, as well as to provide useful techniques and alternatives that may reduce the risks of peri-implant disease induced by residual excess cement.

Restorative dentists have a preference for cement-retained implant-supported restoration. Developed to mimic procedures used in traditional tooth-supported prostheses, it helped overcome issues with esthetics and occlusion, and it also has benefits related to cost, potential for a better passive fit when dealing with a multiple-unit prosthesis, and reduced chair time.[5,6] Although dentists prefer this system over the screw-retained alternative, patients, when surveyed, did not appear to have any definite preference.[7]

Along with the reported benefits of using cemented implant restorations have come some new concerns, such as cement retention in the restoration and retrievablity.[8,9]

As implant therapy has gained popularity, so has the use of the cement-retained restorative; one study reporting on the outcome of implants and restorations in general dental practice noted that 93% of the restorations were cement retained.[10] However, in the late 1990s and onward, implant site health issues began to emerge, initially restricted to clinical reports on complications associated with excess cement around crowns on osseointegrated implants.[10-18] Prospective multicenter studies were developed to compare the peri-implant soft tissue health surrounding cement- and screw-retained implant restorations. The authors concluded that the peri-implant soft tissues responded more favorably to screw-retained crowns than to cement-retained crowns.[7] Systematic reviews have also concluded that cement-retained reconstructions exhibited more technical and biological complications compared with screw-retained reconstructions.[3,4]

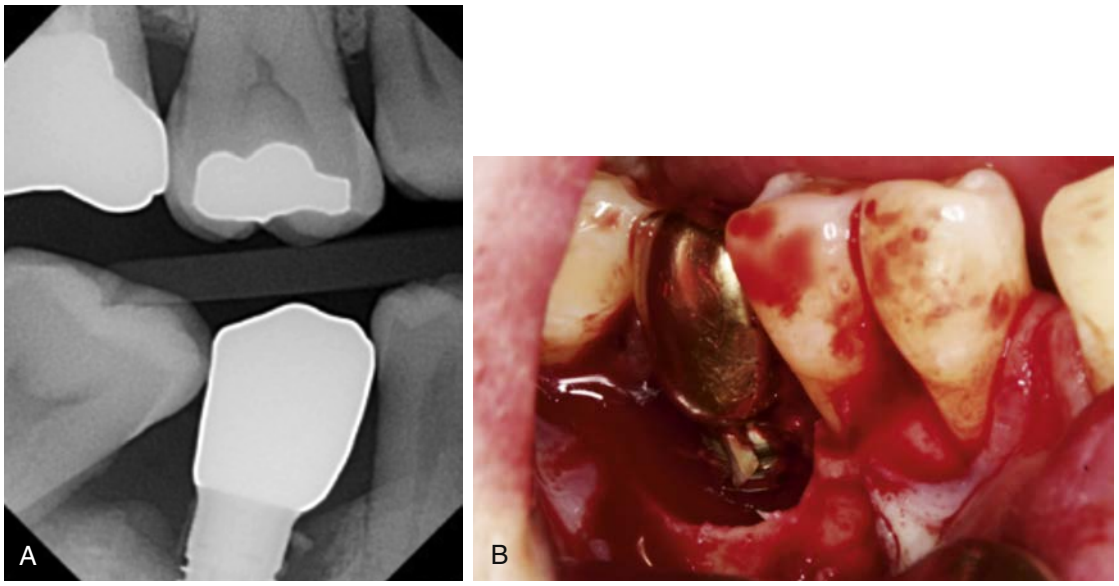
Wilson's pivotal study evaluated 42 implants in 39 patients who showed signs of inflammation (peri-implant mucositis or peri-implantitis) and reported a positive link between excess cement and peri-implant disease.[19] This endoscopic study found excess residual cement associated with 81% of diseased sites. The study also reported on resolution, suggesting that once peri-implant disease is found, the earlier the cement is removed, the more likely it is that resolution would occur. However, he also reported that the time for the disease to be discovered varied from 4 months to almost 9½ years after the crown was cemented.

Furthermore, in January 2013 the American Academy of Periodontology, under the direction of the task force on peri-implantitis, developed a position paper that highlighted residual excess cement as an etiologic factor.[20]

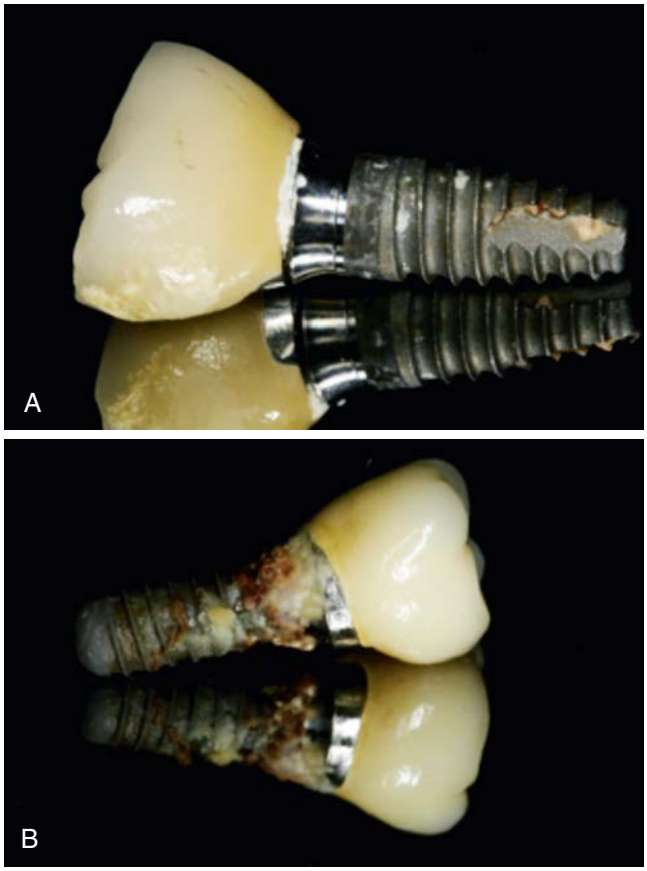
Cemented Restorations and Issues Related Specifically to Dental Implants

The tooth-supported cemented restoration has existed for well over 100 years with few, if any, biological issues related to the supporting soft and hard tissues. However, the same cannot be said when it comes to the cemented implant restoration (Figures 42-1 and 42-2).

Cement excess can elicit adverse soft tissue responses ranging from increased plaque accumulation[7] to inflammation with bleeding[13] to peri-implantitis with associated bone loss, which ultimately can result in implant failure.[10,14]



• **Figure 42-1** **A**, Radiograph indicating bone loss and peri-implantitis associated with residual excess cement. **B**, Surgical site confirming cement residue and extent of bone loss. (Courtesy Dr. Amy Fuller.)



• **Figure 42-2** Examples of failed, removed implants—residual excess cement is clearly present.

Factors such as biology of the soft tissue (hemidesmosomal) attachment to the implant, subgingival cement margin placement, poor control of cement flow, and inappropriate cement use all contribute to an increased likelihood of peri-implant disease.[21]

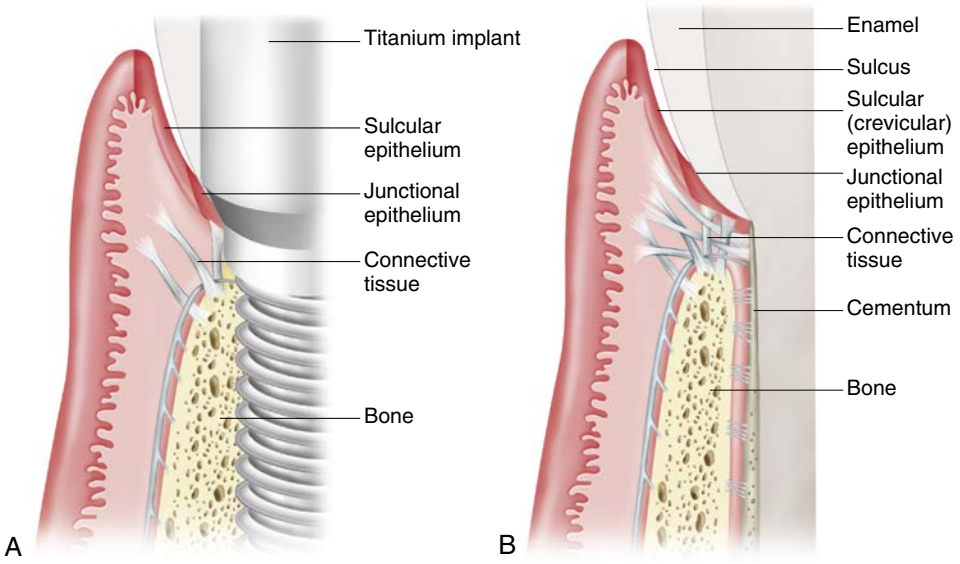
Biology of the Soft Tissue Attachment to a Dental Implant

The periodontal soft tissue attachment of the natural tooth is very different from the peri-implant soft tissue of the dental implant.[22]

Keratinized epithelium exists at the base of the gingival sulcus with a natural tooth, unlike in the case of the implant sulcus. Also, the junctional epithelium is adherent, is less permeable, and has a greater ability to regenerate around a tooth.[23] The soft connective tissue periodontium of a healthy tooth has another major biological advantage over the peri-implant soft tissues in the presence of supracrestal collagen fiber bundles. Sharpey fibers insert directly into living cementum on the root surface of the tooth (see Figure 42-1),[24] which is highly protective and serves as a seal to protect this area. The periodontal fiber bundles also form a compartment-like structure around the tooth, which localizes and limits the spread of inflammation and disease. By comparison, the soft tissue attachment to the implant site that develops through healing within a few days is far more fragile than the tissue related to a natural tooth and consists of a basic cellular hemi-desmosomal adhesion. There is no cementum associated with the dental implant, so no direct collagen fiber insertion can exist. Circumferential fibers do occur that encircle the dental implant that maintains the tissues in close apposition to the implant (Figure 42-3, *A*). This arrangement provides for a single compartment and, when inflamed, affects the implant in a generalized manner (see Figure 42-3, *B*).[22]

Implant Depth and Cement Margin Site

Again, in comparing the natural tooth with the implant site, distinct differences are noted. With natural tooth,



• **Figure 42-3** **A**, Biological attachment to a dental implant. There is no insertion of connective tissue fibers into the implant surface. **B**, Biological attachment of a natural tooth. Connective tissue fibers insert into the root apical to the junctional epithelium. (From Rose LF, Mealey BL: *Periodontics: medicine, surgery, and implants*, St. Louis, 2004, Mosby.)

preparations for a cement-retained restoration limit the cement finish line no deeper than 0.5 mm into a healthy gingival sulcus, which is still considered a compromise.[25] The prepared tooth margins also closely follow the outline of the gingival crest, moving more coronally to follow the outline of the papillae and remaining supragingival wherever possible, so the tooth site is easily accessible.

For the implant site, the soft tissue attachment tends to occur at a deeper level when compared with the soft tissue attachment in the natural dentition. When the platform (or top) of an implant is surgically placed according to the facial soft tissue crest, it is usually placed 3 mm deep. This allows for development of an emergence profile for the restoration. However, where papillae exist adjacent to this site, the scallop of the soft tissues may result in the flat top of the implant now being located 5-7 mm deep.[26] Maintaining and cleaning deeper than 4 mm is impossible with routine scaling instruments,[27] and the microbiota at deeper sites tends to favor the more pathogenic gram-negative bacteria known to cause peri-implant diseases.[28,29]

Cement extrusion from the implant crown margin site during seating can present problems with the ability to both detect and remove this foreign material. Anecdotal recommendations of acceptable implant crown margin depths of 1-3 mm[30,31] relative to the soft tissue level have been made based on esthetics. Recently, however, the ability to remove residual excess cement at different soft tissue depths has been evaluated. The influence of the cementation margin position with respect to the amount of undetected cement was reported by Linkevicius and colleagues.[32] In a prospective clinical study they compared cement margin sites that were equal with tissue level, 1 mm subgingival, 2 mm subgingival, and 3 mm subgingival. Statistical significant differences existed among the four groups: the deeper the position of the margin, the more undetected cement was discovered. The conclusions of the study indicated that, ideally, cement margins on abutments should always be visible for intraoral cementation.

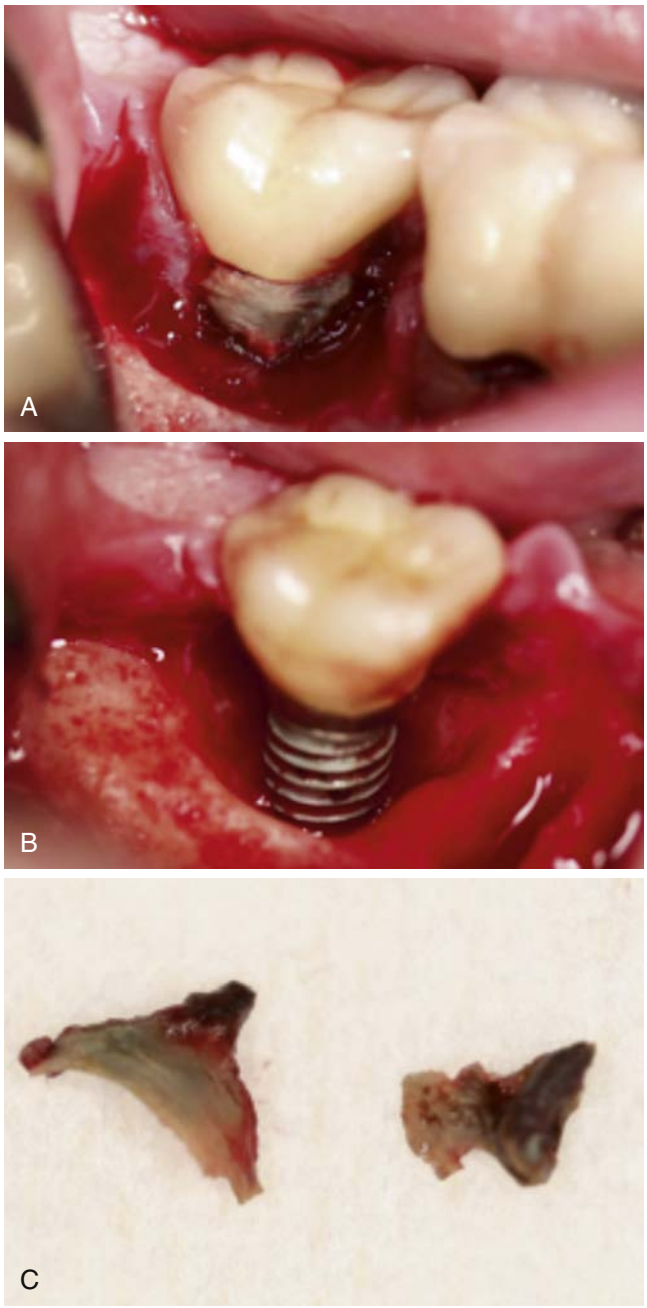
Currently, new protocols are being developed with the surgical placement of an implant now more closely related to the bone rather than soft tissue height. With the implant frequently placed even deeper to the soft tissue attachment, the removal of excess cement and routine maintenance become even more of a challenge.

Controlling Cement Flow

One of the most common procedures in restorative dentistry is the use of luting cements for crowns and bridges, which for many dentists occurs on a daily basis. As ubiquitous as cementing a crown is, it appears that most dentists have never been taught or trained on proper technique; and have little if any idea where to place the cement or even how much is required[33] (Figure 42-4).

This has resulted in little thought as to how the cement system actually works. In fact it should be considered to be an engineering-type system, essentially similar to a piston driven into a fluid chamber. The abutment behaves as a piston, the intaglio of the crown as a chamber and the fluid is cement. The clinician must now understand how the cement flows based on parameters such as cement loading site, amounts required, implant abutment design, and fluid mechanics of the material used.[34]

The factors that will then determine how the cement flows can be readily evaluated using models such as clear drinking beakers[35] or using more complex fluid dynamics and supercomputers.[36]



• **Figure 42-4** **A**, Typical example of peri-implantitis bone loss associated with residual excess cement indicating poor control over cementation technique. **B**, Cement removed. **C**, Cement remnants. (Courtesy Dr. Franco Audia.)

Studies evaluating cement flow and force of extrusion using cd-Adapco software simulations have been useful in determining the most appropriate site to place cement, which is close to the crown margin.[37] Also, the software program computed the most appropriate speed to use as the crown is seated, which should be in the order of 14 mm per second to optimize the flow of the cement. The cement used in the simulation was a resin (RelyX ARC, 3M ESPE) chosen primarily because some data existed on its flow properties. Interestingly, cement manufacturers do not commonly publish the flow properties of cement, as they, too, do not consider this process to be anything but rudimentary!

Unfortunately, because of the lack of these data, it is much more difficult for the scientist/clinician to understand how the cement will behave as force is applied.

Another feature of the study was to evaluate different abutment designs, another area completely overlooked by implant component manufacturers. When one considers that cemented abutments mimic the shape of full gold crown preparations with bevels and lute space requirements designed more than 50 years ago, it is clear there is little if any science behind the abutment form.

For the clinician this presents huge issues: most clinicians have not had any education describing the fluid properties of cement, such as Newtonian or non-Newtonian; cement manufacturers do not provide adequate information; and implant companies do not supply components where form follows function.

The better the clinician understands this system, the more likely he or she is to be able to control the cement flow and limit the extent of cement extrusion that may result in adverse effects (Figure 42-5).

Luting Material Selection

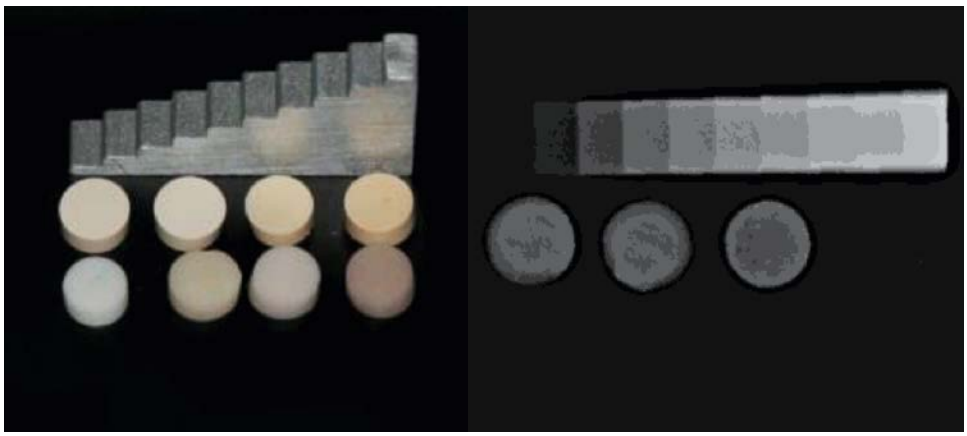
Nearly all the dental cements that exist today were primarily designed for the natural tooth, with properties often completely unrelated to the requirements for the dental implant.[38,39] One such example is caries prevention—there is no need for a fluoride component for an implant cement, and in fact it may be detrimental. Also, dentin and enamel bonding—again, there is no reason cements for implant should contain materials with these properties.

When considering problems with residual excess cement, some desirable properties for implant cements include ease of excess cement cleanup and removal, detectability on a radiograph (Figure 42-6), an antimicrobial effect against organisms that affect the health of the peri-implant tissues, assurance that it will not damage the implant or associated components, and biological inertness.[40] Table 42-1 outlines some of the more appropriate properties required of implant cements and compares these to cement properties more ideal for natural teeth.

Studies on ease of cleanup have indicated this to be especially challenging when resin cements are used with implant restorations.[41] The greater the adhesive properties a cement has for titanium, the more difficult it will be to remove if it reaches the implant itself. Also, the greater the mechanical retention of a given cement to the implant materials used, the more difficult it will be to clean up excess cement.

Many cements used for implant restoration are poorly radiopaque, which makes excess cement detection more difficult.[42] The importance of early detection and removal of this foreign material cannot be overemphasized, as it may prevent the disease process from becoming established and allow for full resolution of the site to occur.[19] Post-cementation radiographs should be standard protocol

• **Figure 42-5** Computer fluid dynamic model shows crown abutment system to be a "piston in a chamber." Modeling shows how fluid flows as the crown seats.



• **Figure 42-6** Cement samples showing varying radiopacity at 1 mm thickness. Some may not be detected when in the tissues.

as well as the ability to recognize the radiographic characteristic effects of implant cement extrusion.[43]

Cement Interactions: Microbial Growth

Many studies have been undertaken to evaluate the antimicrobial effects of cements; however, they have been directed exclusively at how the materials behave in the presence of *Streptococcus mutans* and *Lactobacillus acidophilus*, which are the cariogenic microbes. [44,45] There is little if any relevance to implant restoration in which the effects of microbes that may result in peri-implant disease are completely different, and these should be the prime focus.

In 2014, Raval, Wadhwani, and colleagues published a study evaluating interactions between implant luting cements and oral bacteria linked to peri-implant disease.[46] Discs were made with a series of test cements (zinc oxide/eugenol, zinc oxide/non-eugenol, orthozinc phosphate, acrylic urethane, and resin-based cement) under aseptic, controlled conditions. Gram-negative anaerobes implicated

TABLE 42-1 Some Considerations for Material Selection Specific to Teeth and Implants Cemented Restorations

	Implant Restoration	Natural Tooth
Substructure	Metal, ceramic, acrylic	Dentin, enamel
Biologic tissue association	Peri-implant tissues	Periodontal tissues, pulp
Primary disease issue	Peri-implant disease	Caries, pulpal, periodontal
Restoration finish line	One to 2 mm below the gingival crest—often deeper	One mm below in anterior aesthetic sites, often above free gingival margin elsewhere
Cement margin	May or may not follow scallop of gingival tissues	Preparation follows gingival tissue
Need for cement seal	Questionable	Desired (prevent caries)
Anti-caries agents	May be detrimental	Desirable
Corrosion	Corrosive in contact with titanium	Not applicable
Radiopacity	Should be highly radiopaque	Similar to dentin
Microbial challenge	Bacteria found in peri-implant sites	*Streptococcus mutans, Lactobacillus* (caries producers)

From Wadhwani CP, Schwedhelm ER: The role of cements in dental implant success, part I. *Dent Today* 32(4):74-78, 2013.

in peri-implantitis were chosen: *Aggregatibacter actinomycetemcomitans* (*A. actinomycetemcomitans*), *Porphyromonas gingivalis* (*P. gingivalis*), and *Fusobacterium nucleatum* (*F. nucleatum*). The bacteria were grown in individual test wells, into which the cement discs were introduced. The concentration of bacteria was standardized for each test with measurements made using an optical spectrometer that correlated the opacity of the broth directly with the microbial content. The results indicated that zinc oxide/eugenol outperformed all other cements with regard to microbial inhibition when evaluating the test bacteria. Zinc is known to be highly effective as an antimicrobial, and when coupled with eugenol, also well known for its anti-inflammatory, antioxidative, and antimicrobial pharmaceutical properties; this is likely the reason for its effectiveness. The resin-based cements were found to poorly inhibit bacterial growth and in some instances appeared to behave as a substrate for the microbes.[46] These results have been replicated clinically, with zinc oxide/eugenol exhibiting less pathogenic microbial environments compared with resin cement.[47]

These studies indicated that cement selection should be considered with respect to how it might affect the environment into which it is placed. This may relate more to patients who are periodontically susceptible, as these patients present a greater risk of peri-implant disease[20] (Figure 42-7).

Cement Interactions: Foreign Body Reaction

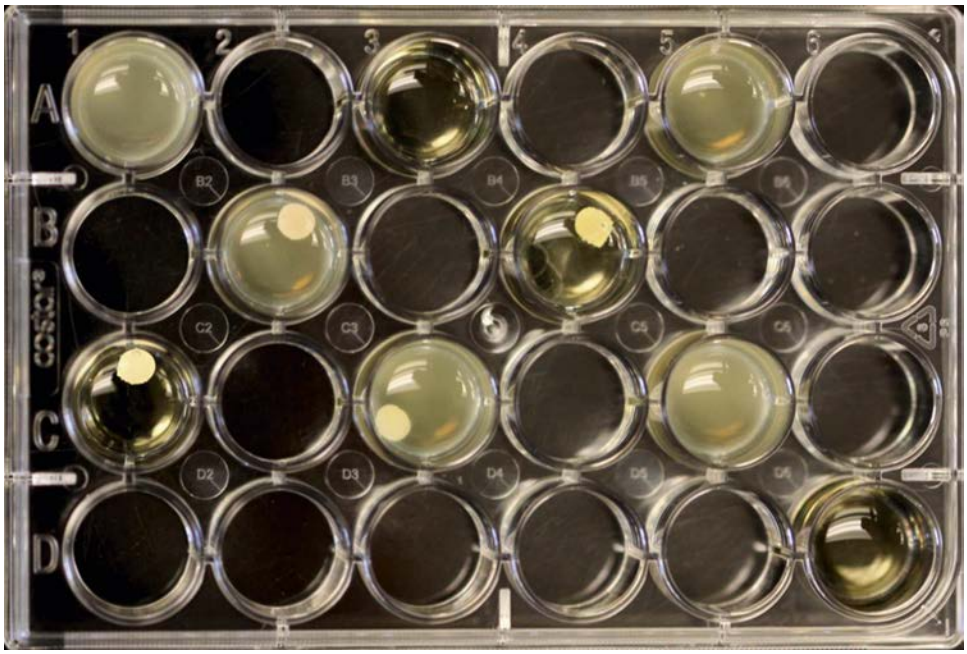
Most dentists have encountered "amalgam tattoos," which are fragments of amalgam that lodge within the tissues, often migrating into adjacent sites. Cement particles have also been reported within excised soft tissue specimens.[48-50] One study looking at human soft tissue biopsies of failed removed implants found that 19 of 36 had cement particles present. Residual cement may act as a nidus for inflammatory cells both acutely and chronically, which in turn may elicit a cascading autoimmune destructive process. How the cement particles became embedded within the tissues is speculative. It may have occurred when the crown was initially seated with the hydrostatic force disrupting the fragile hemidesmosomal attachment of the epithelium to the implant. Subsequent cement cleanup, with the dislodgement of the set particles being forced into the tissues, may also be responsible. It is also possible that the cement was forced into bleeding sites that occur when the healing abutments are removed. It is known that intercellular tears within the epithelium occur during abutment removal, and the resulting wound may be contaminated by inoculation with cements that have thin film thickness.

Cement Interaction: Allergic Response

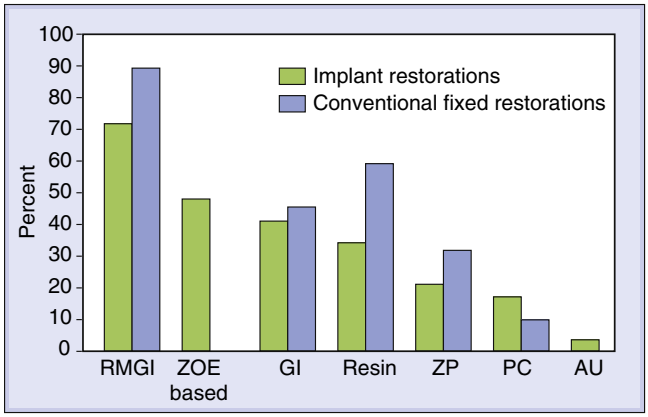
In 2010 it was reported that 73% of dental schools in the United States used a resin modified glass lonomer (RMGI) as the definitive medium for cementing restorations to implants,[42] which, interestingly, followed a similar pattern for cement selection for teeth (Figure 42-8). One of the constituents of the RMGIs is hydroxyethyl methacrylate (HEMA).[51] This material is extremely irritating to the tissues to the extent that the Material Safety Data Sheet (MSDS) advises that hands and mucosal tissue, such as eyes, be barrier protected when it is used. With implants, barrier protection is more difficult to achieve compared with the natural tooth. As the epithelial attachment adheres poorly at the dental implant site and is more permeable, it may be more susceptible to the effects of chemicals leaching out from materials.

Corrosion

The success of dental implants relates in part to the low corrosive susceptibility of the materials involved. Titanium



• **Figure 42-7** A 24-well plate with bacteria grown in media. Cement discs introduced to see how bacteria respond. Clear solutions show low bacterial content. Opaque solution indicates extensive microbial growth.



• **Figure 42-8** Definitive cements used for implant and conventional fixed restorations by prosthodontic residency directors in 2008. *AU,* Acrylic urethane; *GI,* glass ionomer; *PC,* polycarboxylate; *RMGI,* resin-modified glass ionomer; *ZOE,* zinc oxide eugenol; *ZP,* zinc phosphate. (Reprinted from Tarica D, Alvarado VM, Truong ST: Survey of United States dental schools on cementation protocols for implant crown restorations, *J Prosthet Dent* 103(2):68-79, 2010.)

appears well suited to the oral environment under most conditions.

However, recent reports have found a reactive issue with some materials commonly found in dental cements.[33,52,53] Fluoride, the ubiquitous anti-caries agent, in some forms is known to corrode titanium.[54] Corrosive elements are generally undesirable, as the surface alterations produce increased adhesion to anaerobic bacteria that produce peri-implant disease[55] and also result in reactive oxidative species being produced by the host.[56] The inflammatory response produced may be one mechanism that results in peri-implant disease. The cements identified as producing the conditions for corrosion include some polycarboxylates and some glass ionomer cements.[57] Durelon (3M-ESPE) alludes to this problem in the Instructions for Use (IFU), which is of interest as 17% of U.S. dental schools[36] admit to using it on implant restorations. This indicates the IFUs are not being followed or may not even be read.

To date no ideal implant luting cement exists—all have the potential to cause issues. However, the prudent clinician will carefully evaluate the material used, will elevate the cement margin to be readily accessible to cleaning, and will have a good biological understanding of the limitations of the dental implant.

Developing Clinical Protocols

Problems associated with cement selection and use have been described. Many of these result from the dentist considering the cementation selection and processes the same as for the natural tooth, when clearly they are not. By understanding the ideal properties required of an implant cement and how it flows, the clinician can also control cement by manipulation of the prosthesis.

If the residual excess cement can be detected and adequately removed, resolution is considered possible in many cases,[19] though this is not guaranteed (Figure 42-9). However, it is better to develop protocols that make the cementation process safer and more predictable, such as maintaining a supragingival margin on the abutment and allowing the cement extrusion site to be carefully controlled and readily accessed. Techniques such as producing a ceramic supragingival margin as part of the abutment

• **Figure 42-9** **A**, Residual excess cement located and removed. **B**, Series of radiographs showing subsequent resolution of the issues. (Courtesy Dr. Darrin Rapoport.)

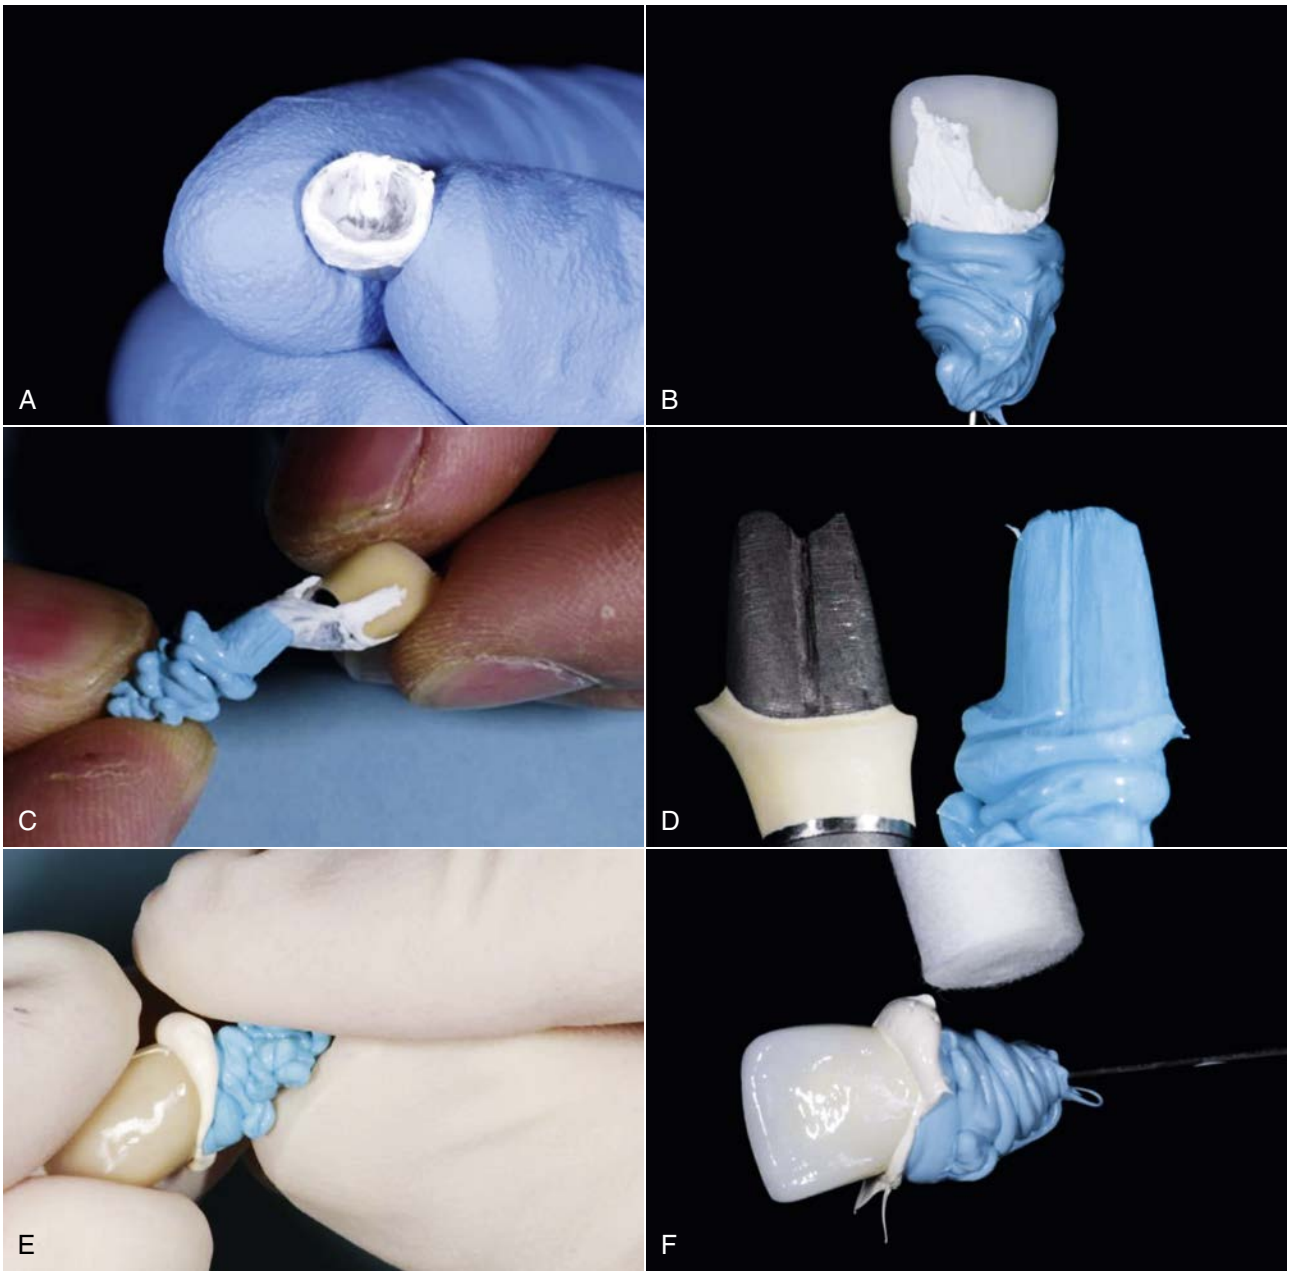
• **Figure 42-10** Implant restoration with a supragingival porcelain margin replaces maxillary right central incisor. The cement margin is easily controlled, maintaining a distance from the soft tissues.

have been described (Figure 42-10).[58] This has an added advantage in that etched porcelain can be bonded—therefore a margin on the abutment can be directly bonded to the crown material, which if done carefully can produce a seamless esthetic result. The supragingival margin also allows for the use of a barrier of PTFE (Teflon plumber's tape) to protect the soft tissues from contact with cement and other chemicals.[59,60]

Other techniques available with the use of cement are cement pre-extrusion devices, such as the copy abutment technique.[61] Here, a copy of the intaglio of the crown or cemented prosthesis is made by placing a layer of PTFE against the inside (intaglio) of the crown (Figure 42-11). This has two important functions: first, it produces a 50-µm spacer that will give close to the required volume of cement—it should be remembered that most implant restorations are fabricated with a 40- to 50-µm luting space; second, it prevents the intaglio of the crown from getting contaminated with the polyvinyl siloxane (PVS) material.

To aid the placement of the PTFE, first coat the intaglio of the crown with pure petroleum jelly, then, using a brush, carefully adapt the PTFE so it adheres to the internal surface. Using a fast-setting PVS material (e.g., Blu-Mousse, Parkell, Edgewood, NY) with a fine-tip extruder, completely fill the internal aspect of the lined crown. Aim to capture the crown margins as much as possible. Continue expressing the PVS until a handle is formed. Allow to set, then remove the copy die, remove and discard the PTFE layer, and thoroughly clean out the intaglio of the crown, ensuring that all the petroleum jelly is removed. Inspect the copy die; it should resemble the inside of the crown, yet be smaller in dimension.

When the restoration is ready to be cemented, attach the original abutment to the implant in the usual manner and



• **Figure 42-11** The custom copy abutment used to pre-extrude cement out from within the crown. The PTFE provides space for the cement lute. **A,** The internal aspect of the crown is lined with a disposable spacer material (PTFE tape works well, due to an approximate thickness of 50 microns). **B,** Fast setting polyvinylsiloxane material injected within crown until a handle is made that will become the copy abutment. **C,** Remove the copy abutment, discard the PTFE and thoroughly clean the inside of the crown. **D,** The copy abutment is similar to the actual implant abutment in form. E, Place cement within the inside of the crown, then introduce the copy abutment until it seats. This will express extra-cement outside of the mouth. **F,** Clean up excess cement, the crown is now loaded uniformly with approximately 50 micron layer of cement.

with the appropriate torque. The crown can be gross filled with cement. The PVS copy abutment is seated firmly into the crown, resulting in the extrusion of excess material. The cleanup extraorally is followed by inspection of the internal surface in which a uniform 50-µm layer of cement should exist. The crown is then cemented as usual, with minimal cleanup. Provided that all other parameters, such as cement margin height, control of seating forces, and speed of seating are controlled, the likelihood of cement extrusion into the tissues should be minimized. The technique is also suitable for multiple joined restorations, such as an implant-supported fixed dental prosthesis.

Other ways to control cement flow involve abutment modifications. The concept here is to alter the shape of the abutment so that an increase in cement held within the system results in a reciprocating reduction of cement extrusion. It was apparent that the U.S. dental schools[39] and implant component manufacturers directed clinicians to completely occlude the

screw access channel of the abutment. This site, if left partially unfilled (the screw head protected with a spacer), could act as a receptacle for cement during seating of the restoration.[61-63]

Whenever the screw channel is not sealed, there is the potential to allow cement to fill this space. Simply leaving the screw access channel open as an "open abutment" or leaving open and adding internal vent holes within the abutment walls provided a significant reduction in cement extrusion out through the margin site compared with closure of the abutment. An added benefit of manipulating cement flow within an abutment is that it significantly improves crown retention.[62,63]

The foregoing studies indicate the ability to alter cement flow by abutment modifications that are beneficial with respect to cement extrusion and crown retention effects. Although further scientific investigation is required, these seemingly easy steps can help the clinician.

Many other techniques exist that can potentially reduce cement extrusion, and the clinician can decide which is the most appropriate. Alternatively, screw-retained restorations may be chosen, especially if the surgical planning and placement has provided the ideal implant location. Although clinicians claim that esthetics and occlusal management are problematic, the skilled laboratory technician can readily overcome these issues, especially with the materials available today.[64]

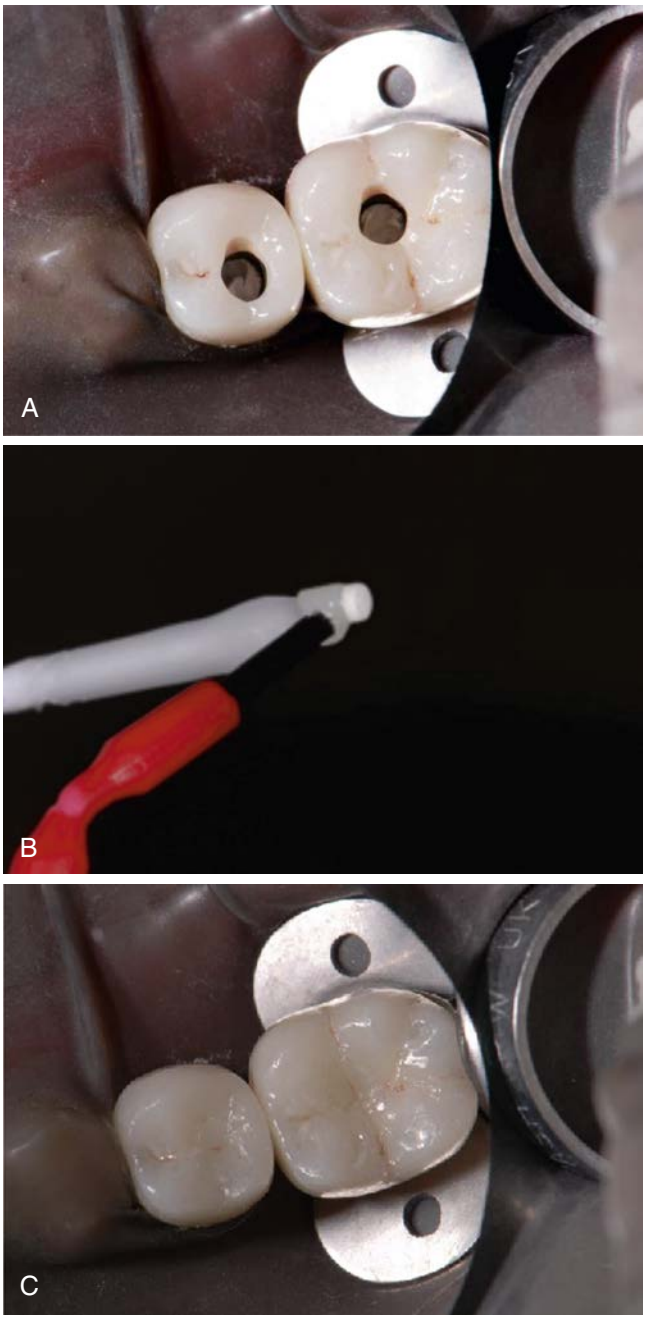
One technique is to use a hybrid cemented-screw-retained crown (Figure 42-12). This provides a relatively inexpensive solution by combining a cemented crown with a stock abutment. The crown is cemented onto the abutment; then, either drilling into the crown or having a pre-prepared screw access hole in the crown allows this hybrid restoration to be attached with a screw.[65]

Implant manufacturers are becoming more aware of the issues with residual excess cement and the risks of peri-implant disease. Some are developing novel abutments that allow angle changes, which can be used when straight-line screw access would compromise the restorative outcome.[66]

Conclusion

The interactions between excess cement and peri-implant disease are not fully understood. Biological differences in attachment between an implant and a tooth appear to be the major reason why we do not have the same issues in traditional tooth-form dentistry. This compounds the effects of cements with regard to peri-implant microbes and the potential for foreign body reactions, corrosion effects, and allergic responses. Unlike natural teeth, where little regard is given to cement selection or techniques involved, protocols need to be established that also include careful monitoring of the implant site, as peri-implantitis may take years for signs or symptoms to develop. When residual excess cement is found related to the implant site, it must be considered undesirable and an immediate response to clean the site carried out.

Alternatives to the cemented restoration exist, which can be easily implemented and planned for at the surgical stages with a team approach—the surgeon and restorative dentists working together to provide the best treatment possible for the patient.



• **Figure 42-12** **A**, Esthetic screw-retained crowns prior to aesthetic porcelain plug being cemented. **B**, Porcelain plug, which has block-out stain to prevent gray show-through of metal, being loaded with cement prior to seating. **C**, Final restoration. Esthetics are excellent, and the occlusion can also be easily managed.

Peri-implant Disease

TARA L. AGHALOO, JOAN PI-ANFRUNS

Introduction

Definition of Peri-implant Mucositis and Peri-implantitis

The use of dental implants to replace missing teeth has become a successful treatment option for millions of patients since Professor P. I. Branemark's discovery of osseointegration more than 50 years ago. Even though dental implants are associated with high success rates, they are not exempt from complications. Adell and co-workers published the first report on dental implant complications and included gingival complications such as early perforation of the mucosa, gingivitis, and fistulae.[1] Implant survival rate is very high as reported in multiple large, long-term studies;[2-7] however, when implant success is objectively evaluated, where medical risk factors are included in the analysis, or when implant survival rate is calculated per patient instead of per implant, rates are often significantly lower.[8-15]

The development of biologic complications surrounding peri-implant tissues has spawned great interest in the past decade and has been classified as two distinct processes. *Peri-implant mucositis* is a reversible inflammation of the soft tissues surrounding an implant in function with no loss of supporting bone.[16] The clinical presentation includes swelling and redness of the soft tissue and bleeding on gentle probing (<0.25 N). *Peri-implantitis* is a distinct destructive inflammatory process associated with dental implants first described by Levignac in 1965[17] and later by Mombelli and colleagues in 1987.[18] It was not until 1994 that a consensus group at the First European Workshop on Periodontology accepted the definition of peri-implantitis as a destructive inflammatory process around osseointegrated implants in function, leading to peri-implant pocket formation and loss of supporting bone. The clinical presentation of peri-implantitis includes suppuration, bleeding on probing, and deepened pockets (>5 mm).[19]

Scope of the Problem—Prevalence and Classification

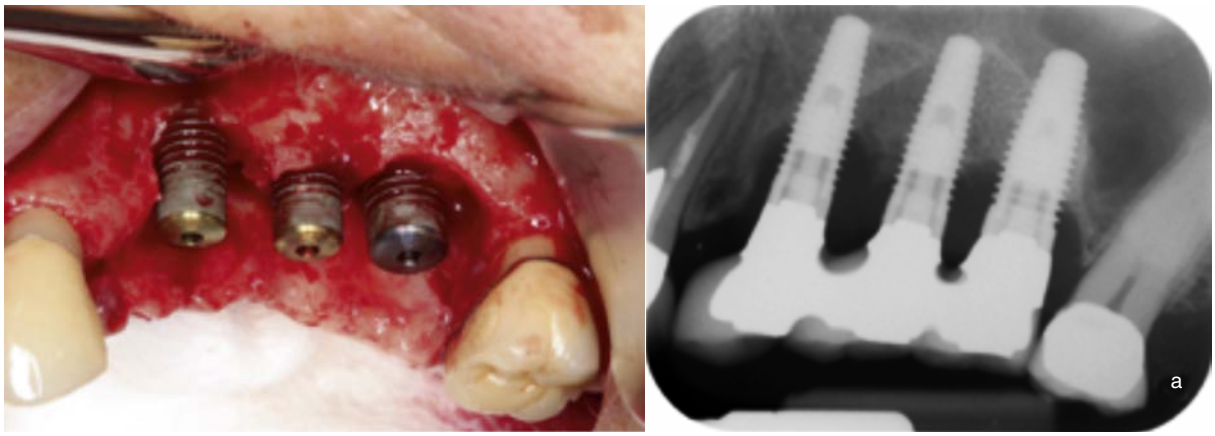
There is great variation in the literature regarding the prevalence of peri-implant mucositis and peri-implantitis, which may be due, in part, to the variety of dental implant systems available on the market. Differences in design and surface characteristics and changes at the micro and nano scale may play an important role in the development and progression of peri-implant diseases, but these factors are still under much investigation.[20,21] Moderately rough and rough implant surfaces have been shown to be more susceptible to the development of peri-implantitis, and disease progression.[22] (Figure 43-1).

Many attempts have been made to understand the prevalence or incidence of these inflammatory processes. In a recent cross-sectional report, Renvert and co-workers[23] found a prevalence of peri-implant mucositis of 80% of the subjects or 50% of the implant sites. Multiple studies examined show a widely varied prevalence of 1% to 2% to 44% with peri-implantitis.[6,23-26] Some investigators have suggested a prevalence of peri-implantitis of up to 56%.[27]

Classification of peri-implant disease has not been well standardized, other than the definitions of peri-implant mucositis and peri-implantitis. Studies that attempt to classify peri-implantitis have done so based on specific bacteria or biofilm characteristics, severity of disease, or time to disease development.[28,29] Although peri-implant diseases are diverse and complex, a universally accepted classification system is extremely important for consistent diagnosis, disease progression, and evaluation of treatment protocol effectiveness. In addition, communication with other dental and allied staff colleagues is compromised without a common classification or language. This will continue to increase in importance as implants have longer follow-up and demonstrate greater numbers and severity of peri-implant complications.

Risk Factors and Confounding Variables

A number of risk factors have been identified as important in the development of peri-implantitis. Strong evidence has been found linking peri-implant diseases with a history of prior periodontal disease, poor oral hygiene or lack of implant maintenance, diabetes, and smoking.[25,30-32] Periodontitis triggers the release of cytokines, with an



• **Figure 43-1** Peri-implantitis surrounding a three-unit fixed partial denture after 3 years of loading; clinical and radiographic appearance.

end result of attachment and bone loss. Poor oral hygiene inevitably causes plaque and bacterial accumulation, and smoking alters neutrophil activity and blood flow to the tissues and diminishes oxygen supply.[33,34] Other factors such as diabetes, alcohol consumption, rheumatoid arthritis, occlusal overload, residual cement, and genetic factors have been also identified, although with a lesser degree of evidence.[35-38]

Bacteria and Similarities/Differences between Periodontitis and Peri-implantitis

The formation of a biofilm and subsequent bacterial accumulation may play a role in the development of peri-implantitis.[39,40] These pathogens have largely been identified as gram-negative anaerobes, similar to those found in chronic periodontal patients.[41-43] In a recent cross-sectional study,[44] the authors collected samples for microbiologic analysis from three locations associated with dental implants: the peri-implant sulcus, inside the implant connection, and the gingival sulcus of adjacent teeth. A quantitative real-time polymerase chain reaction (PCR) assay was carried out for total bacterial count and for 10 pathogens. Orange complex species *Prevotella intermedia, Peptostreptococcus micros, Fusobacteria nucleatum* were most prevalent in all sites for both groups, and prevalence values were higher for the peri-implantitis group. In general, absolute loads and total bacterial counts were higher in the peri-implantitis group. Differences in prevalence between groups were more marked inside the implant connection, suggesting the implant connection as a potential microbial reservoir for peri-implant disease. The presence of peptostreptocci or staphylococci was also identified, confirming the findings of other studies that suggested the presence of certain microflora of a different nature.[39]

Prevention and Maintenance

Currently, peri-implantitis remains an unpredictable condition that is not always possible to treat and may lead to the ultimate failure of the dental implant. Therefore, it is imperative that efforts be directed toward preventing peri-implant related complications and adequate maintenance of healthy peri-implant tissues. Complications can occur at any stage during treatment. Poor patient selection, inadequate case planning, poor surgical or prosthetic execution, and lack of follow-up may lead to a higher rate of complications.[45] Identifying patients at risk, such as smokers, diabetics, or patients with previous periodontal disease is of the utmost importance.[26,30,31,46-48] Making sure that no iatrogenic risk factors for peri-implant disease exist can be verified by cleaning out all subgingival cement, preventing occlusal trauma, placing the implant in the appropriate anatomic position, and by ensuring appropriate prosthesis design and adequate space for oral hygiene.[44] In addition, providing a regular hygiene maintenance program with effective home care is paramount for continued success and prevention of peri-implantitis and mucositis.[5,49-51]

Studies and Protocols for Prevention

The prevention of peri-implantitis inherently begins with the prevention of peri-implant mucositis. A recent retrospective study showed that 43.9% patients affected by peri-implant mucositis who did not receive supportive therapy converted to peri-implantitis.[47] The measures available for prevention are delivered either by the patients themselves (toothbrush) or by a professional (hygienist), and these have been compared in a systematic review.[52] According to the review, patients were not always capable of completely eliminating the inflammatory process, although a reduction in the clinical signs of inflammation was always achieved. Similarly, the authors found that the intervention of a professional did not always achieve complete resolution. Multiple studies demonstrate the effectiveness of regular hygiene and professional maintenance to significantly decrease the prevalence of peri-implant mucositis and peri-implantitis. Simple programs such as one professional visit per year for 5 years,[49] or every 6 months for 2 years followed by yearly for 4 years,[53] are effective strategies. Even in patients with a history of periodontitis, aggressive hygiene and maintenance

programs can improve outcomes versus lack of maintenance that can increase failure and peri-implantitis.[5,25] Moreover, lack of effective home care may stem from inappropriate prosthesis design and lack of hygiene space.[44]

Education for Dentists and Patients

Even though resolution of peri-implant disease may not always be achievable, the recommendation continues to be focused toward adequate oral hygiene maintenance by the patient and regular follow-ups with the treating doctor, combined with professional hygiene services. More importantly, the focus should be on the prevention of these diseases, rather than the treatment. Oral health care providers have the obligation to educate patients on signs and symptoms of early peri-implant disease.[54] Patients should be periodically reminded and instructed on oral hygiene procedures. Dentists and allied staff also have the responsibility to continuously refresh their knowledge in all areas of implant dentistry, including implant maintenance and home care, even though there is lack of consensus for a defined preventive maintenance program and therapeutic strategy for treating peri-implant mucositis and peri-implantitis.[55]

Treatment and Outcomes

Several treatment modalities exist to address peri-implant pathologies. Despite the different approaches available, the end goal should always include:[56]

- Improvement of patient oral hygiene
- Decrease of bacterial plaque
- Decontamination of implant surface
- Bone regeneration

A number of approaches, sometimes in combination, are used to treat peri-implantitis, including mechanical debridement, local or systemic antibacterial therapy (such as subgingival chlorhexidine or local or systemic antibiotics), and open surgical debridement to remove bacteria, smooth the implant surface, and decontaminate the implant surface.[57,58] Bone regenerative procedures may also be included after debridement and decontamination. However, outcomes for these approaches are often unpredictable and difficult to assess.[58]

Nonsurgical—Debridement, Systemic and Local Antibiotics

Peri-implant mucositis, similar to gingivitis, is generally responsive to nonsurgical scaling or mechanical debridement that disrupts the biofilm on the implant.[59] Because it is reversible, further inflammation or progression can be followed up with improved oral hygiene practices and maintenance visits.[56,60] For peri-implantitis, nonsurgical debridement may be performed with plastic or metal scalers, ultrasonic devices, air-abrasive devices, or lasers. Simultaneously, the addition of antibiotic therapy (systemically or locally) has also been reported and recommended in consensus statements[56,57] (Figure 43-2).

• **Figure 43-2** Minocycline HCl available for local treatment of peri-implantitis.

In a randomized controlled trial, Buchter and co-workers[61] evaluated a local antimicrobial agent as an adjunct to manual debridement as well as manual debridement alone. Twenty-eight patients who had a total of 48 peri-implant defects were examined at baseline (week 0) and after 18 weeks. The measurements included bleeding on probing (BOP), pocket probing depths, and probing attachment levels at six sites for each tooth. For 2 to 18 weeks before week 0, all patients were treated for peri-implantitis, including motivation, oral hygiene instructions, and implant scaling with a plastic instrument. They were randomly assigned to continue with this treatment or to have additional mechanical debridement and local application of slow-release doxycycline. Patients in the test group showed a significantly greater gain in mean probing attachment levels than those in the control. Only subjects in the test group had a significant reduction in mean BOP ($P = 0.001$). Application of the biodegradable sustained release device after initial periodontal treatment resulted in a significant gain in mean probing attachment levels and a significant reduction in pocket probing depths. In another comparative study, Renvert and colleagues[62] evaluated local minocycline delivery as an adjunct to manual debridement in comparison with manual debridement with submucosal chlorhexidine application. The results showed that after a follow-up period of 12 months, a limited reduction in BOP was achieved and the mean peri-implant probing depth (PD) remained unchanged with the chlorhexidine group. In comparison, in the minocycline group, the reduction of BOP was greater and an overall improvement in the mean peri-implant PD was seen. The results suggested that the topical application of chlorhexidine may provide limited or no adjunctive clinical improvement when treating shallow peri-implant lesions as compared with mechanical debridement alone. In addition, in a recent systematic review[47] the authors concluded that the addition of systemic antibiotics and air-abrasive devices did not seem to improve the efficacy of professional hygiene treatments in the reduction of inflammation. Tang and co-workers[63] evaluated the effects of local delivery of 25% metronidazole gel and mechanical cleaning using an ultrasonic carbon fiber tip on dental implants with peri-implantitis. A total of 27 implants with peri-implantitis were randomly assigned to receiving either

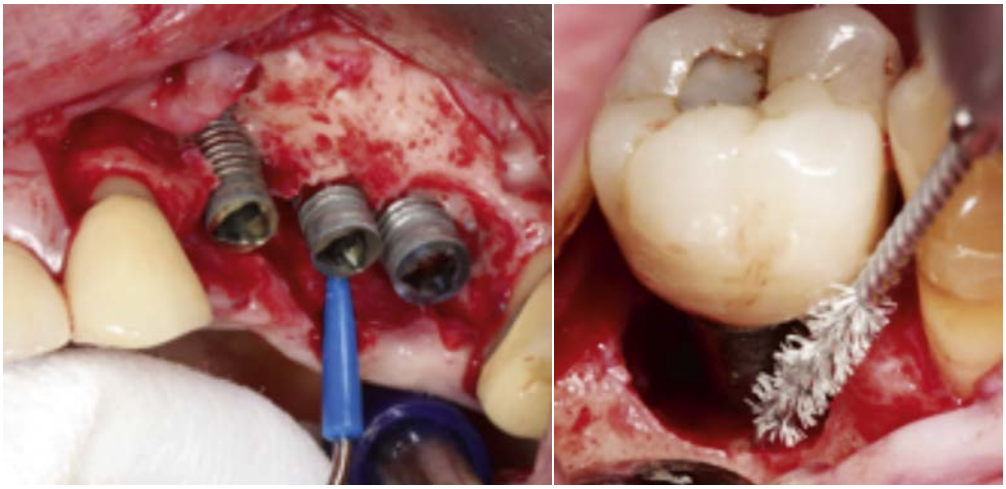
25% metronidazole gel treatment or carbon fiber tip ultrasonic scaling. A statistically significant decrease ($P < 0.05$) in BOP, enzyme analysis, and plaque index occurred in both treatment groups at all time intervals compared to baseline. Probing depths decreased in both groups, but only the metronidazole group reached statistically significant levels ($P < 0.05$) at 2- and 6-week intervals compared to baseline.

In a single blind randomized clinical trial comparing an air-abrasive device versus manual debridement, Karring and colleagues[64] treated 11 patients with at least two screw-type implants with BOP, probing pocket depth (PPD) greater than 5 mm, and at least 1.5 mm radiographic bone loss and exposed implant threads. The test sites were treated with the straight or curved flexible carbon fiber tip combined with aerosol spray of fluid polish with hydroxyapatite particles (grain size approximately 10 μm), whereas the control sites with carbon fiber curettes. Oral hygiene around both test and control implants was improved at 3 and 6 months compared with baseline. At 6 months, four of the air-abrasive–treated sites and only one site treated with curettes had no BOP. In neither the test nor control group were there any differences between baseline and 6 months regarding PPD and bone levels. In a pilot study, Schwarz and co-workers[65] compared the effectiveness of an erbium-doped yttrium-aluminum-garnet (Er:YAG) laser to mechanical debridement using plastic curettes and antiseptic therapy for nonsurgical treatment of peri-implantitis. Twenty patients with moderate to advanced peri-implantitis lesions were randomly treated with either an Er:YAG laser using a cone-shaped glass fiber tip at an energy setting of 100 mJ/pulse and 10 pps, or mechanical debridement using plastic curettes and antiseptic therapy with chlorhexidine digluconate (0.2%). Mean value of BOP decreased in the laser group from 83% at baseline to 31% after 6 months ($P < 0.001$) and in the mechanical debridement group from 80% at baseline to 58% after 6 months ($P < 0.001$). The difference between the two groups was statistically significant ($P < 0.001$). The sites treated with laser demonstrated a mean clinical attachment level (CAL) change from 5.8 ± 1 mm at baseline to 5.1 ± 1.1 mm ($P < 0.01$) after 6 months. The manually debrided sites demonstrated a mean CAL change from 6.2 ± 1.5 mm at baseline to 5.6 ± 1.6 mm ($P < 0.001$) after 6 months. After 6 months, the difference between the two groups was not statistically significant ($P > 0.05$). The study concluded that at 6 months following treatment, both therapies led to significant improvements of the investigated clinical parameters, and that laser treatment resulted in a statistically significant higher reduction of BOP than manual debridement with curettes. A systematic review comparing nonsurgical debridement with air abrasion demonstrated a significant difference in BOP but not probing pocket depth in peri-implantitis. However, control measures also improved BOP scores.[66]

Surgical—Open Debridement

In the surgical approach, or open flap debridement, for the treatment of peri-implantitis, the primary goal is to obtain access for debridement and decontamination of the infected implant surface. Animal studies have suggested that this approach may be beneficial for the elimination of the inflammatory cell infiltrate[67] (Figure 43-3).

A secondary goal in these cases is the complete resolution of peri-implantitis, including tissue regeneration and the hypothetical reestablishment of osseointegration along previously contaminated implant surfaces. The nature of the defect plays an important role in the achievement of successful bone regeneration. Circumferential-type intrabony defects may yield better results than defects lacking one or more bony walls.[68] The use of barrier membranes has also been investigated. In a longitudinal clinical study, Khoury and Buchmann[69] evaluated the outcomes of three regenerative treatment protocols for peri-implantitis. Forty-one peri-implant defects were treated with flap surgery plus autogenous bone graft alone, autogenous bone graft plus nonresorbable membrane, or autogenous bone graft plus bioabsorbable barrier. After 3 years, significant changes in mean probing depth from baseline were noted in all three groups. Three-year radiographic evaluation showed a mean



• **Figure 43-3** Open flap debridement with ultrasonic scaler and titanium brush.

bone gain in all treatment groups. Even though the differences among the three surgical treatment protocols were not significant, the treatment groups in which a barrier membrane was used exhibited more complications.

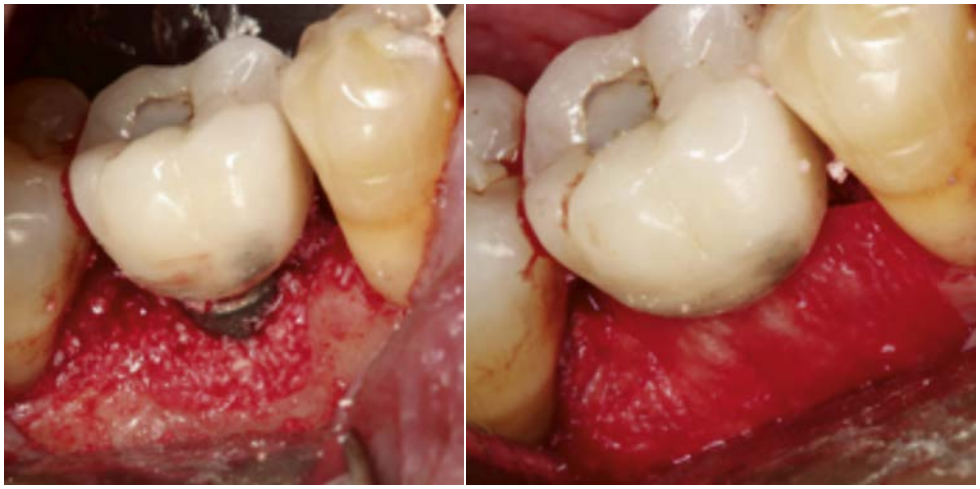
Lasers are now extremely popular for the treatment of peri-implantitis. The two most common are carbon dioxide (CO_2) and erbium-doped yttrium-aluminum-garnet (Er:YAG) lasers. The CO_2 laser is considered safe and may not negatively affect osteoblastic attachment to the implant surface.[70,71] The Er:YAG laser has bactericidal properties and can remove the biofilm without harming the implant surface.[71-73] Although some reports show promising preliminary results, long-term, controlled, comparative studies demonstrating their improved effectiveness over other methods of debridement and decontamination are generally lacking.[74-76]

Different bone graft materials have also been evaluated for the surgical treatment of peri-implantitis. Schwarz and colleagues[77,78] evaluated 6-month and 1-, 2-, and 4-year results of regenerative treatment of 22 peri-implantitis defects filled with a graft material in combination with a collagen membrane. The graft material was either a nanocrystalline hydroxyapatite or a xenograft. At 12 months, the mean PD was reduced from 6.9 mm to 4.9 mm, with a reduction of BOP from 80% to 36% in the hydroxyapatite group. In the xenograft group, the mean PD was reduced from 7.1 mm to 4.4 mm, with a reduction in the mean BOP from 78% to 29%. Higher mean probing depth reductions and clinical attachment level gains were reported at 4 years in the group treated with xenograft that was covered with a collagen membrane (Figure 43-4).

In addition to the techniques described in the nonsurgical approaches, techniques to modify the implant surface or implantoplasty are also documented. Romeo and co-workers[79,80] evaluated the clinical outcome of resective surgery and modification of surface topography (implantoplasty) with resective surgery alone for the treatment of peri-implantitis. The mean PD in the implantoplasty group decreased from 5.8 mm at baseline to 3.4 mm at 12 months, and the mean number of sites with positive BOP from 2.8 mm at baseline to 0.4 mm at 12 months. The mean recession in the implantoplasty group was increased from 0.5 mm to 2.3 mm. In the group treated with resective surgery alone, the mean PD had reduced from 6.5 mm to 5.9 mm and the mean number of sites with BOP had reduced from 2.9 at baseline to 2.7 at 12 months. The mean recession had increased from 0.2 mm to 1.4 mm. Two implants in the implantoplasty group were lost after 2 years because of mobility. The mean marginal bone level was unchanged 3 years after implantoplasty, whereas in the resective surgery group there was a mean bone loss of 1.4 mm at the mesial and 1.5 mm at the distal surfaces. Although commonly performed, results of regenerative procedures are not predictable.[81,82] It is also unclear if re-osseointegration is achieved, because it cannot be confirmed without histologic examination.

Future Directions

Even though implant dentistry has become a relatively successful treatment approach for partially and completely edentulous patients, complications continue to occur. Most implant-related complications are attributed to the failure of the osseointegration process and infection. To combat the inflammatory response from the presence of microbial biofilms, several innovative methods have been proposed. UV-mediated photofunctionalization of titanium modifies titanium implant surfaces from a hydrophobic to a superhydrophilic state and removes hydrocarbon contamination.[83] A recent report demonstrated that UV treatment of titanium surfaces can reduce attachment and monospecies biofilm formation of *Staphylococcus aureus* and *Streptococcus pyogenes*.[84] Photofunctionalization of the implant surface prior to insertion and its effect on oral bacterial attachment and biofilm formation was also evaluated.[85] UV-treated surfaces exhibited a significant reduction in



• **Figure 43-4** Peri-implantitis defect treated with xenograft and resorbable collagen membrane after decontamination.

bacterial attachment as well as subsequent biofilm formation compared to untreated ones. This treatment modality could provide additional support in the reduction of bacterial contamination for the treatment of peri-implantitis.

Nanomedicine and nanotechnology have also been evaluated for the treatment of peri-implantitis. In an experimental study,[86] the authors evaluated the antibacterial properties of silver nanoparticles deposited on titanium surfaces (Ti-nAg). Two species of bacteria, *S. aureus* and *Escherichia coli*, were used to test the antibacterial effect of the silver nanoparticles-treated surface. After a 24-hour incubation period, 94% of *S. aureus* and over 95% of *E. coli* had been killed, and the scanning electron microscopic examination of anti-adhesive efficacy showed that there were fewer bacteria attached to the Ti-nAg surface than to a control surface of untreated titanium. These data suggest that silver nanoparticle-modified titanium is a promising material that could be used as an implantable biomaterial with an antibacterial property.

Conclusions

Overall, treatment of peri-implantitis is extremely challenging, especially as patients have more medical risk factors, implant sites are more compromised with both hard and soft tissue deficiencies, prostheses are more complex and often have inadequate hygiene access, and implants are in function much longer. Focusing on prevention and early diagnosis of peri-implant diseases is an important strategy to prevent peri-implant mucositis from becoming peri-implantitis, increased severity of peri-implant bone destruction, and ultimate implant loss. Evaluating effective therapies can be problematic because research is in the early stages and mostly consists of case reports and series. In addition, combinations of multiple treatment protocols make identifying effective modalities almost impossible. As treatments become more complicated, where bone regeneration is used, results are often inconsistent and unpredictable. Evaluating outcomes of therapy also pose challenges, because objective measures are not well defined. Therefore, reaching a consensus to evaluate success of current therapies with clear outcome measures should be a priority to advance the field. Finally, continued focus on patient, dentist, and hygienist education is a key factor in prevention, diagnosis, and treatment of peri-implant disease and in maintaining implant health. Because its prevalence may continue to increase, peri-implantitis will be one of the major concerns facing clinicians practicing implant dentistry today.

Gene therapy, for oral cancer, II-678–679
General partnership, I-58–59, I-59t
Genetics
  cancer development and, II-602
  cancer treatment based on, II-622, II-625
  cell regulation and, II-603–606
  in cleft deformity, III-493–494
  craniosynostosis syndromes, III-667–669
  melanoma and, II-690–691
  oral cancer and, II-672–673
  sequencing, II-623
  in Treacher Collins syndrome, III-703–705
Geniculate ganglion, II-97
Genioglossal advancement, III-268
Geniohyoid muscle, II-784
Genioplasty, III-96–112, III-319–321
  alloplastic, III-103–104
  bony changes, III-104–105
  chin position and, III-303t
  chin repositioning, III-108f
  complications, III-319–321
  in computer-aided surgical simulation, III-35–36
  facial orientation and, III-28
  fixation devices, III-104–105
  functional, III-96–97, III-101
  history, III-2
  indications, III-97–98
  mandibular widening with, III-201
  Michelet, III-101
  model surgery and, III-60
  neurosensory disturbance, III-320
  sagittal split, III-103, III-104f–105f
  sliding, III-101–103
  for small chin, III-463b
  surgery, III-101–104
  tissue analysis, III-98
  treatment planning, III-98–101
  vertical reduction, III-111f
  wound healing failure, III-320
Gerdy's tubercle, I-457–458
Ghost cell, II-370, II-372f–373f
Giant cell granuloma, II-462–464, II-750–751, III-852
  classification, II-463t
  example, II-463f
Giant cell tumor, II-464
Gingiva
  avulsive wound, II-137
  in dentoalveolar injury evaluation, II-117, II-123t
  in fixed restoration, I-589, I-590f
  hypertrophic, III-352
  injury treatment, II-137
  minimal display, treatment for, I-585f
  miniscrew implant and, I-316
Gingival cyst, II-365, II-424
Gingival graft, I-450–451, I-450f
Gingivectomy, laser, III-348–349
Gingivoperiosteoplasty, III-498, III-562, III-584
Gingivoplasty, laser, III-352
Glabella, III-395–396
  botulinum neurotoxin for, III-440
  horizontal line correction, III-411
  innervation, III-400
  muscles, III-404–405
Glandular odontogenic cyst, II-365–368, II-369f
Glasgow Coma Scale (GCS), II-9, II-247
Glenoid fossa, II-778, II-821
Globulomaxillary cyst, II-375–376
Glogau skin classification, I-343, II-723b
Glucocorticoid deficiency, I-159t
Glutamate, I-205
Glycolic acid, for chemical peel, III-443
Glycolysis, in cancer cell metabolism, II-601–602
Glycopyrrolate
  for autogenous bone graft prophylaxis, I-451
  for pediatric patient, I-251
Glycosaminoglycans, joint function and, II-830
Gold alloy
  for abutment, I-636
  for single anterior implant, I-630–631
Gold Humanism Foundation, I-4
Golden ratio, III-13, III-14f–15f
Goldenhar syndrome, III-687, III-689f, III-694f
Goldman tip, III-376
Goode's method, chin position analysis with, III-460t–461t
Goode's method of nasal projection, III-369
Gorlin-Goltz syndrome, II-361–364, II-364b
Gorlin syndrome, II-718
Gout, II-847–848
Graft
  auricular cartilage, II-912–913
  autogenous
    after discectomy, II-912
    for temporomandibular joint surgery, II-772
  bone. *See* Bone graft
  connective tissue, I-415–416
  costochondral, II-326
  dermal, II-913–914
  for ear laceration, II-58
  failed, temporomandibular joint replacement after, II-931
  free fibula, II-326
  free gingival, I-557f
  pediculated, I-556, I-560f
  peri-implant, I-415–416
  rib, in pediatric ablative defect reconstruction, III-766–767
  for skin cancer lesion repair, II-731–732
  soft tissue. *See* Soft tissue graft
  spreader, in rhinoplasty, III-371f
  techniques and materials for, I-426–436
  tip onlay, III-374
  umbrella, III-374
  vascularized interpositional, I-558
Granuloma
  central giant cell, II-750–751, III-852
  laser excision, III-349
Grayson nasoalveolar molding appliance, III-498
Greenstick fracture, II-261
Growth, definition, III-628t
Growth factor
  bone graft and, I-431–432
  cancer cell growth and, II-612
  cell division and, II-611f
  joint function and, II-830–832
  pain management and, II-959
  in temporomandibular joint arthrocentesis, II-888
Growth inhibitory signal, cancer cell growth and, II-612–614
Growth signal
  cell division and, II-611f
  release from, II-617f
GSW. *See* Gunshot wound (GSW)
GTR. *See* Guided tissue regeneration (GTR)
Guerrero, Caesar, III-5, III-7–8
Guided bone regeneration (GBR), I-462–464
  in alveolar distraction, I-538–539
  applications, I-484–493
  case study, I-499b–500b
  complications, I-464
  defect configuration and, I-476
  history, I-475
  horizontal augmentation, case study, I-502b
  horizontal bone augmentation, I-464
  implant placement, case study, I-495b, I-497b–498b
Guided bone regeneration (GBR) *(Continued)*

Notices

Knowledge and best practice in this field are constantly changing. As new research and experience broaden our understanding, changes in research methods, professional practices, or medical treatment may become necessary.

Practitioners and researchers must always rely on their own experience and knowledge in evaluating and using any information, methods, compounds, or experiments described herein. In using such information or methods they should be mindful of their own safety and the safety of others, including parties for whom they have a professional responsibility.

With respect to any drug or pharmaceutical products identified, readers are advised to check the most current information provided (i) on procedures featured or (ii) by the manufacturer of each product to be administered, to verify the recommended dose or formula, the method and duration of administration, and contraindications. It is the responsibility of practitioners, relying on their own experience and knowledge of their patients, to make diagnoses, to determine dosages and the best treatment for each individual patient, and to take all appropriate safety precautions.

To the fullest extent of the law, neither the Publisher nor the authors, contributors, or editors, assume any liability for any injury and/or damage to persons or property as a matter of products liability, negligence or otherwise, or from any use or operation of any methods, products, instructions, or ideas contained in the material herein.

I recognize Dr. Robert E. Marx, Dr. Edward T. Lally, and the late Dr. Joseph Ashman, the three teachers who taught me oral/head and neck tumor surgery, pathology, and anatomy. My career has been most gratifying due to the education provided to me by these exemplary individuals.

Eric R. Carlson

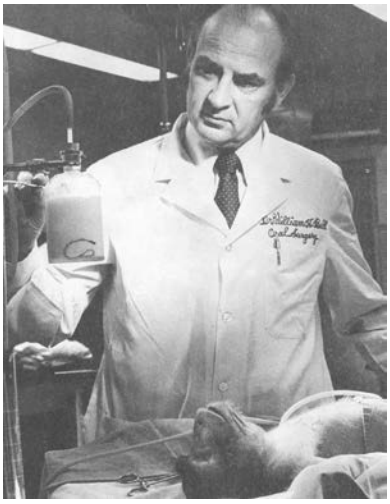
To Chester, Lady, Cheerio, Moxie, Domino, Sasha, Tuxedo, Chairman Meow, Zoey, Apollo, Ayla, Annabelle, and Atticus for enriching our lives.

Raymond J. Fonseca

As a resident I trained under Jerry Goldberg, whose practice was filled with patients suffering from TMJ disorders that few others welcomed. He would come back from early meetings of the American Society of Temporomandibular Joint Surgeons and tell tales of raucous debates over the cutting-edge knowledge, which he then passed on to us. I decided then that I wanted in on this field. When I interviewed for an academic job with Larry Peterson, he asked if I would be comfortable teaching residents to do TMJ surgery. I gave a qualified yes, and he said, "Then you will be our TMJ surgeon." And so it began. Nothing I have accomplished would have happened without the teaching, confidence, and support from these two great mentors, so I dedicate this work to Dr. Goldberg and to the memory of "Pete" Peterson.

Gregory M. Ness

In Memoriam



William H. Bell, DDS

We respectfully dedicate this edition of *Oral and Maxillofacial Surgery* to the memory of Dr. William "Bill" Harrison Bell. Matchless among his peers, Dr. Bell was an inimitable leader in surgery and medicine throughout his career.

In the early 1970s, Dr. Bell revolutionized oral and maxillofacial surgery through his landmark research on the biologic basis and clinical rationale for the Le Fort I osteotomy. In subsequent decades, he guided the hands of generations of surgeons, whether in academic medical centers across the world or through his meticulously detailed textbooks. It is a testament to Dr. Bell's always-passionate and always-persistent pursuit of excellence that his textbooks still remain contemporary decades after their publication.

While Dr. Bell was a revolutionary in our field, it is not simply in this spirit that we dedicate this book. Dr. Bell also served as an inspiration and mentor to us throughout our careers and lives, showing us always a readiness to inspire and a passion to change lives however he could. We are, quite simply, not alone in this feeling. It was this passion that compelled him to devote his life to improving patient care. It was this passion that affected so many others in our field. And it was this passion that also characterized so many areas of his vibrant and rich life—a life very well-lived.

It was an honor to learn from and know Bill. He was unwavering and uncompromising, and his love was unconditional. We know that the passion that burned in him to help others will continue to ignite the spirits of generations of surgeons to come. It will guide our hands and our actions as well.

Chapter 40: Arthrocentesis of the Temporomandibular Joint

Preface

We are excited to present the third edition of *Oral and Maxillofacial Surgery*. This three-volume text is the result of the collaboration of multiple contributors. The first edition, published in 2000, and the second edition, published in 2009, were very well-received. However, with all the advances in our profession, we felt it was time for a new edition. The section editors have done an excellent job recruiting the most knowledgeable individuals in their specific areas of expertise. The authors have submitted chapters that reflect the state of the art in their areas of responsibility.

This text is a comprehensive resource on oral and maxillofacial surgery. Every area in our specialty has been addressed. It defines the scope of the specialty. Every surgical procedure performed by an oral surgeon is covered in this text. This multi-volume text provides coverage of a wide range of issues related to surgical care, such as anesthesia, diagnostic imaging treatment planning, rehabilitation, physical therapy, and psychological considerations.

After an analysis of the changing field of oral and maxillofacial surgery, we strove to present a comprehensive, current book that covers the complete scope of our specialty. We hope that the reader appreciates and agrees with our efforts. We stated in the preface of the first edition that we hoped that our future attempts will present an even broader scope of oral and maxillofacial surgery. The fact that this edition has succeeded in that regard is a testament to the individuals who are constantly expanding the envelope.

Acknowledgments

The third edition of *Oral and Maxillofacial Surgery* is a team approach. The section editors—Eric R. Carlson and Gregory M. Ness (and myself)—were invaluable contributors to the success of this effort. They diligently pestered authors so that deadlines were almost met. This edition, like the last two, attempts to define the scope of oral and maxillofacial surgery and could not have come to fruition without these contributors.

Residents are the lifeblood of our specialty. Many have helped to contribute portions of chapters in this book. They have also provided us with friendship, dedication, intellectual stimulation, and humility, without which this book would not have been written.

Last, I would like to thank all the staff who helped to prepare these manuscripts and the editorial staff at Elsevier, who were so patient with our procrastination and meticulous in their development and editing of this book. Additionally, I would like to thank my staff—Laynee Adams, Sally Brown, Heather Early, Patty Martin, Sarah Merrill, Josie Ray, and Ashley Wood—who collectively and individually make my life so enjoyable.

Raymond J. Fonseca, DMD

Initial and Postoperative Management of the Craniomaxillofacial Trauma Patient

ALISON Y. YEUNG

Introduction

Trauma is the leading cause of mortality globally, and in the United States more than 3 million facial injuries occur each year, resulting in a large percentage of hospital admissions. Because more than 50% of patients with maxillofacial trauma have multisystem injuries as well, a thorough and efficient management strategy is crucial to optimize the care of the patient.

The goal in the management of the facial trauma patient is to restore function and esthetics while minimizing adverse events. The initial evaluation and management of the patient ensures that the appropriate treatment is rendered, whereas the focus in the postoperative setting is on an expeditious recovery with minimal complications. This chapter outlines some of the important principles in the care of the facial trauma patient in the perioperative setting. The subsequent chapters of this text will explore many of these principles in greater detail.

Initial Assessment

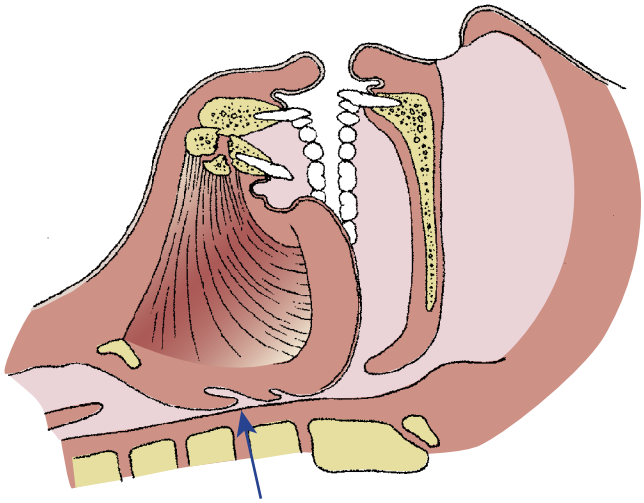
The creation of the Advanced Trauma Life Support (ATLS) course in 1978 provided a systematic approach to addressing the initial needs of the trauma patient. The principles outlined by ATLS (Box 1-1) should be applied to all trauma patients in the emergent setting, to quickly identify and treat any life-threatening injuries. However, it is rare for the oral and maxillofacial surgeon (OMS) to be the sole primary practitioner evaluating a trauma patient who presents to the hospital. A multidisciplinary approach to the management of the trauma patient has been adopted. In most situations, the trauma patient has been evaluated in the emergency room setting and the OMS is brought in as a consultant. This does not negate the need for a thorough understanding of the principles behind trauma care, as it allows the practitioner to be in sync with the efficient and effective methods of optimizing patient care in the hospital setting. In the case that the patient has been referred to you in the outpatient setting, it is important to ensure that all other systems have been evaluated and other systemic injuries have been addressed. If you are concerned that other injuries have not been thoroughly evaluated, a referral to the emergency room is warranted.

A thorough examination of the craniomaxillofacial region is typically achieved as a component of the secondary survey. However, the evaluation of head and neck injuries is tantamount to the management of a patent airway. As airway management is the first step of the primary survey in the ATLS process, it is imperative that the facial structures have stability to support patency. Hemorrhage should be controlled via compressive dressings or ligation of visible vessels. Care should be taken when packing materials or balloon catheters are placed to tamponade bleeding in the case of severe panfacial injuries involving the midface and naso-ethmoidal-orbital regions, as the cranial base can be entered and injury to the brain or orbital contents can occur. Dental prostheses, debris, and avulsed teeth should be removed to prevent aspiration or airway obstruction. Comminuted or severely displaced fractures of the mandible may result in an upper airway obstruction via the posterior displacement of the mandible and tongue base, especially when the patient is in the supine position. When integrity of the mandible is lost, increased laxity of the supporting musculature of the tongue and submental regions can obstruct the posterior oropharynx (Figure 1-1). Manual repositioning of the mandible and tongue can be helpful in relieving the obstruction, until a patent airway can be achieved by placement of

• Box 1-1 Principles of Advanced Trauma Life Support (ATLS)

1. Primary survey
   - Airway management with cervical spine protection
   - Breathing/Ventilation/Oxygenation
   - Circulation with hemorrhage control
   - Disability: Neurologic status
   - Exposure/Environmental control
2. Resuscitation and immediate intervention for life-threatening injuries
   - Normalization of vital functions
   - Imaging: AP CXR/pelvis, abdominal ultrasonography, C-spine
3. Secondary survey
   - Includes a full history and physical examination
   - Reassessment of vital signs
   - Indicated imaging obtained
   - Special procedures
4. Definitive care

AP, Anteroposterior; *CXR,* chest x-ray.



• Figure 1-1 Posterior displacement of tongue and occlusion of upper airway resulting from bilateral mandibular fractures. The *arrow* is indicating the occlusion of the posterior airway space as a result of posterior displacement of the tongue base, in association with bilateral mandible fractures. (From Hupp J, Tucker M, Ellis E: *Contemporary oral and maxillofacial surgery*, ed 6, St Louis, 2014, Mosby.)

an oral airway appliance or endotracheal intubation. The use of bridle wires to stabilize widely displaced mandibular fractures may be beneficial not only to assist in the management of a patent airway, but also to help decrease medullary bleeding as well as provide some pain relief to the patient.

The patient interview should identify the time and by what mechanism the trauma occurred. It should be ascertained whether or not the patient lost consciousness, as this can give an indication as to the degree of head trauma involved and the force sustained to create such injuries.

Mechanism of Injury

When managing trauma patients, having an understanding of the injuries sustained via various mechanisms can guide the evaluation of the patient and the rapid assessment of specific injuries. All wounds should be assessed for degree of contamination, and steps should be taken for appropriate antibacterial therapy.

Penetrating injuries result in a localized focused path of entry and exit of a sharp object. Penetrating wounds to the head and neck require a careful evaluation of the upper airway and vasculature, as direct injury to these structures can occur, in conjunction with facial bone fractures and expected soft tissue lacerations. Appropriate diagnostic studies, such as angiography or computed tomography (CT), should be completed to evaluate these anatomic structures.

Blunt trauma to the head and neck typically results in contusions and shearing forces that result in soft tissue lacerations as a result of tearing or avulsive injury. Wound margins may have extensive ecchymosis and, because of the nature of the injury, may require debridement and refining of the tissue edges to allow for improved adaptation of the margins and healing by primary intention. Facial fractures that occur as a result of blunt injury can be heavily comminuted.

Wounds resulting from gunshots follow a specific trajectory and damage pattern depending on the type of bullet and velocity. Wounds should be inspected for bullet fragments and debris that may have been fragmented and pulled into the wound. Surrounding tissue damage caused by burn injury and coagulative necrosis can have a delayed effect. Repeat evaluations should be performed to assess for progressive tissue damage.

Considerations Regarding the Medical History

A thorough understanding of the patient's preexisting medical conditions dictates the management of the patient in the perioperative period, but also allows the practitioner to better prevent postoperative medical complications, which can lead to prolonged hospital stays and increased resource utilization. Other known risk factors that tend to be commonly associated with the trauma patient can contribute to the complexity of managing craniofacial trauma.

A thorough review of the medical history, known drug allergies, and tetanus immunization should be performed, to anticipate any risks for intraoperative or postoperative complications. If the OMS becomes the primary admitting service, appropriate consultations should be considered to assist in the management of patients with complex medical conditions, such as internal medicine, infectious diseases, neurology/neurosurgery, or cardiology. The trauma literature has identified certain chronic medical conditions that have an increased risk for complications and mortality in the inpatient setting. A systematic review of data from the National Trauma Data Bank from 2002 to 2006 showed that preexisting chronic hepatic failure (cirrhosis), dialysis (end-stage renal disease), and anticoagulative therapies were risk factors for both complications and mortality. HIV/AIDS was a risk factor for the development of complications during the hospital stay. However, all other medical conditions require attention in the perioperative period to ensure patient safety. Table 1-1 outlines some common

TABLE 1-1 Common Systemic Medical Conditions and the Considerations that Should Be Made in the Management of Patients with These Conditions, in the Perioperative Setting

Medical Condition	Preoperative Considerations	Postoperative Considerations
Known cardiovascular disease (hypertension, angina/ACS, dysrhythmias, CAD, CHF, valvulopathy, etc.)	Cardiac risk assessment, plan for blood product replacement in the setting of expected high volume blood loss (maintain hemoglobin 7-8 g/dL), antiplatelet/anticoagulant reversal as needed	Consider continuous cardiac monitoring, maintain hemoglobin 7-8 g/dL
Diabetes mellitus	Cardiac and renal function should be evaluated, tight glycemic control, glycated hemoglobin value (glucose between 140 and 200 mg/dL)	Tight glycemic control, compromised immune function requiring considerations for antibacterial therapy, delayed healing, optimize nutrition
Renal failure	Be cautious in the setting of contrast use for imaging studies, renal adjustment for medication administration, evaluate for coagulopathy, consider consultation with renal service to manage the need for dialysis, evaluate nutritional status	Fluid status maintenance, renal adjustment for medication administration, be cautious with the use of nonsteroidal anti-inflammatory medications
Liver failure	Adjustment for medication administration, evaluate for coagulopathy and/or thrombocytopenia, OR positioning in the setting of ascites, evaluate nutritional status, consider consultation with medicine services for management assistance	Optimize nutrition, adjustment for medication administration as needed
Chronic obstructive pulmonary disease (COPD)	Optimize airways for the OR	Avoid prolonged ventilator assistance, aggressive chest physical therapy
Acquired/congenital coagulopathy or antiplatelet activity	Reversal/correction of coagulopathy or platelet dysfunction	Quick resumption of anticoagulant or antiplatelet therapy balanced with the concern for postoperative hemorrhage
Stroke	Antiplatelet or anticoagulant therapy reversal as needed, adjustment to OR positioning,	Aggressive chest physical therapy, consider consultation with neurology/neurosurgery services regarding the timeliness of resuming anticoagulant or antiplatelet therapy
Adrenal insufficiency	Supplemental steroid administration to prevent acute adrenal crisis, evaluate for electrolyte abnormalities	Tight glucose control in the setting of exogenous steroid administration
Immunodeficiency (HIV/AIDS), immune suppression (post-transplant)	Evaluate nutritional status, compromised immune function requiring antibacterial therapy, evaluate for thrombocytopenia, need for supplemental steroid therapy in the post-transplant patient	Delayed healing, tight glucose control in the setting of exogenous steroid administration
Dementia	Concerns in obtaining proper informed consent, evaluate nutritional status	Concerns for compliance
Substance abuse (alcohol/opiate), tobacco	Specific nutritional supplementation (thiamine, folate, multivitamin) for the alcohol dependent patient, consider prophylaxis to prevent acute substance withdrawal, administer nicotine patches as needed	Continue to monitor for withdrawal symptoms, delayed healing, optimize for early discharge, concerns for compliance
Psychiatric illness	Continue all psychiatric medications as previously prescribed	Concerns for compliance
Seizure disorder	Continue all antiepileptic medications, relative contraindication to maxillomandibular fixation	
Pregnancy	Positioning in the OR, OB/GYN consultation for continuous fetal heart monitoring	Avoid nonsteroidal anti-inflammatory medications, avoid medications with known teratogenic effects
Eating disorders	Assess for electrolyte abnormalities, dysrhythmias, evaluate nutritional status	Consider nutrition consultation

systemic illnesses and considerations that should be made in the management of the patient. All preexisting medications should be continued throughout the hospital stay. In some cases administration parameters should be delineated in the setting of medications that may affect cardiovascular stability.

Patients with chronic medical conditions have a tendency to be undernourished, which can affect healing in the postoperative period. Laboratory studies such as albumin and pre-albumin levels can help to assess nutritional status, and nutrition should be supplemented to optimize healing. Consultations with the nutrition services can be helpful in these settings.

Trauma can be a reoccurring disease process, and certain risk factors are associated with the repeat trauma patient. Alcohol and drug use have been estimated to be involved in as many as 50% to 70% of all trauma patients. The potential for acute substance withdrawal should be assessed based on quantity and frequency of use, and appropriate prophylactic measures should be taken to reduce the risk of the development of withdrawal. Alcohol has been found to affect platelet aggregation and can promote increased intraoperative bleeding. Although typically this bleeding is not profound, in the case of expected high-volume blood loss it could be a major factor.

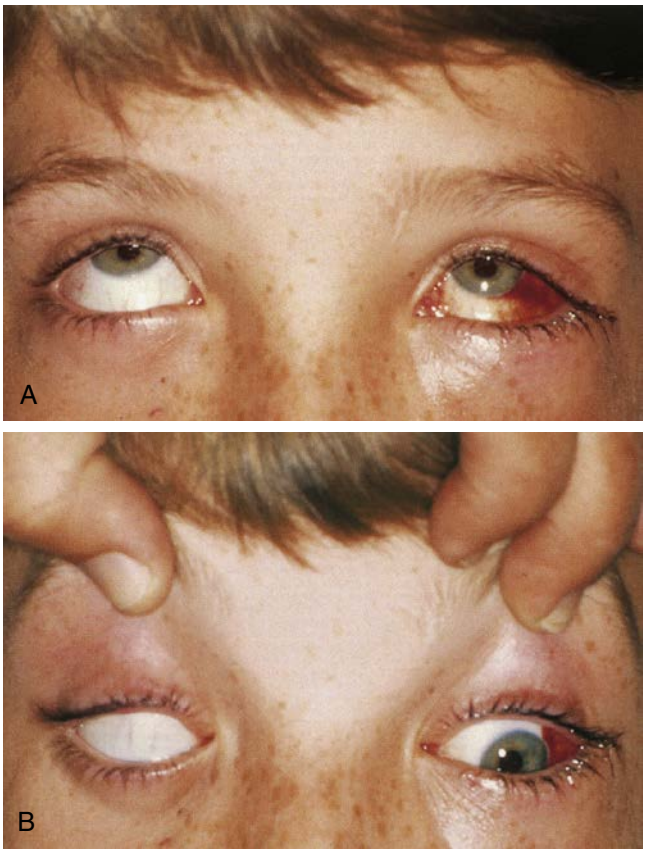
Clinical Examination

The clinical examination of the craniomaxillofacial trauma patient should be performed in a thorough and efficient manner. Every practitioner should develop an algorithm that allows adequate and consistent evaluation of facial and oral structures. The clinical exam should dictate the need for any additional diagnostic studies, which should confirm or refute the clinical suspicion of fracture.

The scalp and soft tissue structures should be directly visualized for any lacerations or abrasions. In the case of patients placed in cervical spine precautions, the assistance of others should be solicited to roll the patient while maintaining proper spinal alignment so the back of the scalp can be examined thoroughly. The OMS should be mindful of the location of lacerations in relation to underlying fractures, as decisions regarding immediate versus delayed repair of the laceration may aid in definitive fracture repair.

If lacerations to ears are extensive or there are suspected fractures to the temporomandibular joints, the tympanic membranes should be evaluated via the use of an otoscope.

The eyes should be examined for lacerations to the eyelids and any penetrating injury to the globe. If lacerations involve the lid margin, an immediate ophthalmologic consultation should be obtained to evaluate the integrity of the canalicular structures. If any fat herniation is present, a globe injury should be suspected, and again an ophthalmologic consultation should be obtained. Pupillary abnormalities should be assessed, and documentation needs to be made if dilatory medications are used to aid the fundoscopic examination. Extraocular muscular function should be examined via range-of-motion and visual-field assessment to rule out the potential for muscle entrapment involving orbital wall defects (Figure 1-2). Measurements should be made of the interpupillary and intercanthal distances, to guide repairs in the setting of naso-orbito-ethmoid complex fractures (Figure 1-3).



• **Figure 1-2** **A,** A 14-year-old patient with a left orbital floor fracture in upward gaze. **B,** Entrapment of inferior rectus muscle is the result of impingement in area of linear orbital floor fracture. In the down gaze, the patient is unable to rotate the left eye inferiorly, whereas the right eye is fully rotated inferiorly. (From Hupp J, Tucker M, Ellis E: *Contemporary oral and maxillofacial surgery*, ed 6, St Louis, 2014, Mosby.)

All facial structures should be palpated and manipulated for crepitus, mobility, or disruption of normal anatomic structures suggestive of bony fractures. Again, all suspected fractures should be confirmed against radiographic imaging.

The nasal bones should be directly palpated and the patency of the nasal airways should be evaluated. The nasal septum should be evaluated for laceration, perforations, and hematoma formation, as this could result in ischemic changes to the cartilaginous septum.

The intraoral examination should assess the dentition for fractured or avulsed teeth. The occlusion should be evaluated for any malocclusion, premature contacts, or disruption of the arch form. A determination should be made, based on discussions with the patient and the examination of occlusal wear patterns, regarding the patient's preexisting

occlusal scheme. This will provide guidance during any fracture reduction surgery to create a reproducible occlusion. Gingival or mucosal lacerations, ecchymosis of the tissues of the floor of the mouth and vestibule, crepitus while palpating the vestibule, and areas of point tenderness could be suggestive of mandibular fractures (Figure 1-4). Crepitus and ecchymosis of the maxillary vestibule could be suggestive of a maxillary fracture at the Le Fort I level or a zygomaticomaxillary complex fracture. Bimanual palpation and manipulation of the maxilla and mandible should be performed to assess for gross mobility (Figure 1-5).

Diagnostic Studies

The medical history and clinical examination should identify the need for any additional studies. Laboratory values and radiographic imaging should be discussed and ordered in conjunction with those needed by other services. Typically a complete blood count with differential, hemoglobin and hematocrit, complete or basic metabolic panel, and coagulation studies are ordered for diagnostic and preoperative planning. Although plain films can be helpful, CT is considered the standard of care for imaging the facial bones. The exception in this author's opinion is the panoramic image, which provides valuable information when evaluating a mandibular fracture. Other imaging studies such as angiography and magnetic resonance imaging (MRI) may be useful in certain situations when the vessels or other soft tissue structures need to be evaluated.

Planning for Definitive Care

Once the patient has been thoroughly evaluated and the injuries requiring treatment have been identified, a definitive plan of care needs to be devised. In the case of isolated

• **Figure 1-5** Examination of maxilla for mobility. **A,** Firm pressure on the forehead is used to stabilize the patient's head. Pressure is placed on the maxilla in an attempt to elicit mobility. **B,** A stabilizing hand can also evaluate mobility in the area of nasal bones. (From Hupp J, Tucker M, Ellis E: *Contemporary oral and maxillofacial surgery*, ed 6, St Louis, 2014, Mosby.)

facial lacerations, a decision needs to be made if the repair can be effectively achieved in the emergency or inpatient room, or if the patient needs to be taken to the operating room. Patients whose situations require better lighting, aggressive hemostasis control, large volumes of local anesthetic, complex instrumentation, or a setting better suited for the sedated patient should be taken to the operating room.

In the case of multisystem injuries, the trauma patient may make multiple trips to the operating room. Discussions with other surgical services can allow for coordinated care, so that the risks associated with general anesthesia are kept to a minimum. Positioning and sterile draping can be coordinated to allow simultaneous access to the head and neck and other parts of the body. Communication with the anesthesia staff and trauma team should be clear if the patient will remain in maxillomandibular fixation in the postoperative period, as this may play a factor in airway management. Nasoendotracheal or submental intubation techniques or a tracheostomy will be necessary in the patient remaining in maxillomandibular fixation, and length of time of expected postoperative intubation will typically dictate the technique used.

Informed consent must be obtained from the patient when possible; however, in the trauma setting this may not be feasible. In cases that necessitate a power of attorney or other designated persons, adherence to specific hospital protocols is imperative.

Preventative Measures to Optimize Patient Care in the Preoperative Setting

Hospitalized patients are at risk for the development of various adverse events directly or indirectly associated with the condition that brought them to the hospital. Minimizing the potential for these events can reduce the length of the hospital stay as well as limiting resource utilization in all patients, especially those with multisystem traumatic injuries.

The use of H2 antagonists and proton pump inhibitors can decrease gastric acid production and risk for gastrointestinal bleeding. The increased stress on the body as well as varying parenteral nutrition can promote increased gastric acid production and the potential for peptic inflammation and ulceration.

Prevention of thrombosis and a subsequent embolic event in the trauma patient is imperative. While fractures of the long bones can promote fat emboli, the non-ambulatory state of many patients puts them at risk for the development of deep vein thrombi and possible pulmonary emboli. Sequential compression devices should be used in low-risk patients, and prophylactic anticoagulant therapy in those at greater risk.

Tight glycemic control has been found to positively affect outcomes in the hospitalized patient population. Studies have identified maintaining blood glucose levels between 140 and 200 mg/dL at all times can decrease the risk for adverse events.

Postoperative Management

The postoperative management of any patient should focus on expeditious discharge from the hospital. In the case of the craniomaxillofacial trauma patient, excluding recovery from other injuries, this typically revolves around the resolution of symptoms associated with general anesthesia and the reduction of postoperative complications.

Antibiotic therapy should be tailored for each patient, taking into consideration contamination of the surgical wounds and the integrity of the immune system, balanced with the concerns for the promotion of resistant bacteria and the development of *Clostridium difficile* colitis.

Encouraging ambulation postoperatively helps to decrease the risk of thrombosis, promotes voiding of the bladder, and aids in preventing pulmonary complications. Foley catheters used intraoperatively should be discontinued as soon as possible to promote ambulation and decrease the potential for urinary retention, especially in older male patients.

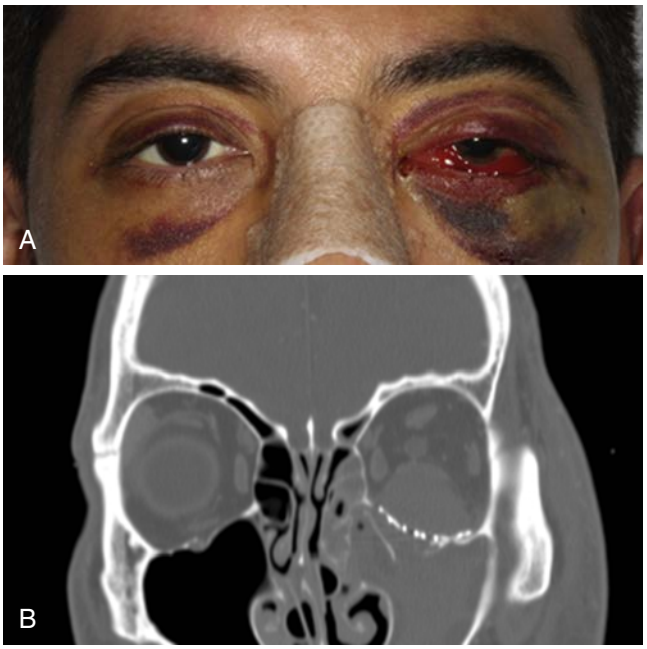
Aggressive incentive spirometry and chest therapy can help in resolving ventilator-associated atelectasis and decrease the risk of nosocomial pneumonia.

Pain in the postoperative period needs to be adequately managed to encourage a quick recovery. However, the use of intravenous medications can delay the discharge process. Transitioning the patient to oral forms of medication is important in discharge planning. Prolonged use of opioid medications has the adverse side effect of promoting constipation. With aggressive Valsalva maneuver while attempting to empty the bowels, there is an initial rise in blood pressure and stroke volume, followed by a decrease in venous return with increased intrathoracic pressure. The initial spike in stroke volume and blood pressure can promote postoperative complications associated with bleeding, such as retrobulbar hematoma formation following orbital floor repairs, or epistaxis following nasal bone reduction or other midface repairs (Figure 1-6). Administering stool softeners and laxatives in conjunction with opioid analgesics can reduce this potential and improve patient comfort.

Proper orders regarding wound care and suture removal should be provided to the nursing staff and to the patient on discharge. Wire cutters should be provided for patients placed in maxillomandibular fixation, to be carried with them at all times in the case of a medical emergency, and clear instructions should be provided on how to release the fixation if necessary.

Dietary restrictions, if any, should be specified for every patient and clearly delineated. All enteral and parenteral feeds should be resumed as soon as possible following surgery.

Instructions for follow-up should be clear and communicated to the patient and all services involved. All inpatient medications should be reviewed and confirmed against preadmission medications and any new medications required as a result of the hospital stay. Medication lists should be adjusted accordingly based on appropriate start and stop times designated by the prescribing service.



• **Figure 1-6** Postoperative hematoma formation in a patient 3 days following left orbital floor repair, who had been taking opioid pain medication for 7 days preoperatively. The patient reported straining and developing immediate sharp pain in the left eye. He reported to the emergency room, at which time evaluation noted a collection of blood in the left orbit. The hematoma was decompressed following release of the sutures used to repair the lateral canthotomy. The patient was evaluated by the ophthalmology service and had no residual visual or cosmetic defects. **A,** Proptosis associated with the left pupil. **B,** Hematoma associated with left orbital floor repair seen on coronal computed tomographic imaging.

Airway and Anesthetic Management for the Traumatized Patient

ELIE M. FERNEINI, JEFFREY D. BENNETT

This chapter focuses on anesthetic and airway considerations in the management of the patient with oral and maxillofacial surgery injuries. This chapter emphasizes the basic principle of management as well as different pre-, intra-, and postoperative anesthetic strategies.

The Importance of the Airway in Maxillofacial Trauma

The maxillofacial trauma patient can present with impending airway compromise. During the initial assessment, the airway should be assessed for patency. Maxillofacial injuries can prevent the trauma surgeon from securing an airway. An airway obstruction can be due to a foreign body, mandibular injury, maxillary injury, tracheal injury, laryngeal injury, or tongue injury, which can be compounded by hemorrhage or edema resulting from injuries to these or associated structures. The trauma surgeon must evaluate the airway using a systematic approach. This will allow the accurate diagnosis of any life-threatening or minor injury.

During this assessment, great care must be taken to avoid excessive movement of the cervical spine. Patients with maxillofacial or head trauma should be presumed to have an unstable cervical spine injury. The patient's neck should not be rotated, hyperflexed, or hyperextended. In order to minimize iatrogenic injury, the patient's neck should be immobilized until a detailed cervical spine examination and complete cervical spine radiographic series are performed and a cervical spine injury has been ruled out.[1] There is no urgency to rule out a cervical spine injury in the newly injured unresponsive patient until the patient becomes fully cognizant and can subjectively respond to the assessment.

A common error in trauma management during the primary survey involves delay in securing the patient's airway. It is important for the trauma surgeon to be comfortable and competent at airway management.[2] Maxillofacial trauma can complicate airway management both in that[3] the injuries can compromise airway integrity, resulting in poor exchange or obstruction, and[4] the soft tissue or skeletal injury may make providing respiratory support difficult.

Initial Airway Assessment

Upon initial evaluation, the airway should be assessed to ascertain patency. Any airway obstruction can prevent securing a definitive airway. The well-established approach to the ABCs (airway, breathing, circulation) is the standard approach. Is the patient able to communicate verbally? Is the patient breathing spontaneously? Does the patient have adequate oxygenation? A negative response to any of these questions will require emergent intervention to secure adequate oxygenation and ventilation. The inability to obtain control of the airway can result in irreversible brain damage due to hypoxia in as little as 4 minutes. Severe head-injury patients with a Glasgow Coma Scale (GCS) score of 8 or less usually require the placement of a definitive airway.

Airway patency does not ensure adequate ventilation. Ventilation requires adequate gas exchange with adequate oxygenation with normal function of the lungs, diaphragm, and chest wall. A rapid assessment of these components is important. Performing a detailed and rapid thoracic lung exam can aid in this assessment. Chest auscultation and percussion can help in assessing the patency of oxygenation; auscultation is the most important technique in assessing air flow through the tracheobronchial tree. Breath sounds may be decreased when air flow is decreased (due to muscular weakness) or when the transmission of sound is poor (due to pleural effusion or pneumothorax). Additionally, the chest wall should be visually inspected to rule out any chest injuries. Conditions such as flail chest or massive hemothorax, as well as tension or open pneumothorax, can compromise ventilation and oxygenation and need immediate attention.

Every trauma patient should receive supplemental oxygen. Maintaining good oxygen saturation and preventing hypercarbia are key factors. A pulse oximeter is essential

in assessing adequate hemoglobin saturation. It is essential to put the pieces together, assessing visual inspection and data obtained from monitors, and integrating that information with the history of the event. This is illustrated by the potential for a false initial assessment for a patient who may have both normalappearing skin tone and oxygen saturation secondary to carbon monoxide exposure. Capnography could be helpful in monitoring the concentration or partial pressure of carbon dioxide (CO_2). It is usually presented as a graph of expiratory CO_2 plotted against time. The capnogram is a direct monitor of the inhaled and exhaled concentration or partial pressure of CO_2 and is actually an indirect monitor of the CO_2 partial pressure in the arterial blood.

Vital signs are an important part of the assessment. Hypotension is usually indicative of hypovolemia. In fact, hemorrhage is the most common cause of shock after injury. Almost all trauma patients have an element of hypovolemia, which is indicative of hemorrhagic shock. Cardiogenic shock due to myocardial dysfunction can occur in trauma patients, especially if they sustain blunt cardiac injury, cardiac tamponade, or myocardial infarction.[5] Skin color could be an important tool in assessing perfusion and oxygenation. Checking capillary refill is a useful tool. This is the rate at which blood refills empty capillaries. Capillary refill is prolonged if it is over 1.5 to 2 seconds. Prolonged capillary refill suggests diminished localized blood flow or dehydration.

History

As appropriate, each trauma patient should have a complete history and medical examination. In many acute trauma patients, history cannot be obtained from the patient. Prehospital personnel and family members may be helpful in providing some of this relevant information. The AMPLE history is a quick mnemonic to use in evaluating the trauma patient:

A: Allergies
M: Medications (currently used)
P: Pregnancy/Past illnesses
L: Last meal
E: Events/Environment related to the injury

Knowing about the past medical history (such as medical problems, medications, and allergies) is a key factor in successfully treating the trauma patient. A patient who is on a beta blocker can have a "normal" heart rate even in hypovolemic shock. Additionally, patients on anticoagulants are prone to severe bleeding and hemorrhage. With many elderly patients on anticoagulants, a neurologic hemorrhage must be ruled out in this patient population. Physiologic changes in the gravid patient present several potential challenges. There is the potential for airway compromise associated with an increased risk of aspiration, decreased functional residual volume, and increased difficulty in intubating the airway. There are hemodynamic changes that impact fluid management, as well as the pharmacokinetics and pharmacodynamics of anesthetic and emergency agents. Many anesthetic and emergency drugs can cross the placenta and have an adverse effect on the fetus.

The mechanism of injury can provide the trauma surgeon with pertinent information about the type of injuries sustained. Blunt injuries usually result from motor vehicle accidents (MVAs), falls, and occupation-related injuries. Important prehospital information to obtain from MVA patients includes seat belt usage, direction and type of impact, steering wheel deformation, and automobile damage. The mechanism of injury can usually predict the injury patterns. For example, rear impact in an MVA will probably result in cervical spine injury and/or soft tissue injury to the neck. Penetrating injuries are usually caused by stabbings and firearms. The extent of injury depends on the region of the body affected, the path of the penetrating object, and the organs in proximity to the injury, as well as the velocity of the missile.

Physical Examination

Airway patency can affect the ability to ventilate and intubate the patient. Part of a detailed trauma examination is to recognize the problem and manage it appropriately. Airway compromise may be partial or complete. Signs such as stridor, dyspnea, tachypnea, and dysphagia may be indicative of airway obstruction. Tachypnea, additionally, could be an early sign of airway or ventilatory compromise. The patient with an altered level of consciousness is at high risk of airway compromise and will require a secure airway.

1. Soft tissue: A detailed soft tissue examination must be performed. Significant tissue avulsions or injuries may result in an ability to secure a mask and provide ventilatory support.
2. Hemorrhage: Hemorrhage can lead to airway irritation, aspiration, and laryngospasm. Pressure packing may be needed to control the bleeding. If the bleeding does not stop, surgical exploration or interventional radiology might be indicated (especially in neck trauma). Hemorrhage can result in an expanding hematoma that can compromise airway integrity. Securing an airway either via intubation or tracheotomy may be required.
3. Skeleton
   (a) Mandibular fractures are common in trauma patients. Bilateral mandibular fractures can lead to a flail mandible. This can lead to an upper airway obstruction due to posterior movement of the tongue. Lying supine can further aggravate the obstruction. Airway adjuncts (e.g., nasopharyngeal airway) may assist in supporting and maintaining airway patency.
   (b) Trauma to the midface can result in injuries to the nasopharynx and oropharynx. These fractures could be associated with hemorrhage, dislodged teeth, or unstable segments (maxilla or midface), any of which could lead to airway compromise. Posterior and downward displacement of a Le Fort fracture can result in an open bite and difficulty with mask ventilation. Displacement of a Le Fort II/III fracture can result in obstruction of the nasopharynx.

(c) Nasal fractures can lead to posterior bleeding and aspiration and thus to nasopharyngeal obstruction. Nasal intubation is relatively contraindicated in midface fractures because of the risk of the endotracheal tube entering either the cranium or the orbit. A hematoma in the oropharynx or nasopharynx can lead to partial or complete airway obstruction. A nasal septal hematoma can lead to nasopharyngeal obstruction. An urgent surgical airway may be needed if endotracheal intubation is not possible.

4. Laryngeal trauma: Hoarseness can be associated with laryngeal trauma. Laryngeal trauma is associated with the triad of hoarseness, subcutaneous emphysema, and a palpable fracture. Patients with arytenoid injury are at higher risk of aspiration. Some of the symptoms of arytenoid injury include hoarseness, dysphagia, sore throat, dyspnea, vocal fatigue, loss of vocal control, and cough.[6] A flexible endoscopically guided intubation may be helpful in laryngeal trauma. Early diagnosis of tooth aspiration in the multi-trauma patient can be difficult because aspiration is rarely considered in the absence of an acute clinical presentation. Accounting for teeth is an important aspect of the maxillofacial exam.

Injuries Affecting the Airway: Cervical Spine Injury

Cervical spine injury must be presumed in any patient with maxillofacial or head trauma. The incidence of cervical injury in the presence of facial fractures has been reported to be 1% to 6%.[7-9] Cervical spine injuries tend to occur in patients between 15 and 45 years of age and are seen more commonly in males (7:3). The most common level of fracture is C2, whereas dislocations occur most commonly at the C5/6 and C6/7 levels.[10]

The exclusion of cervical spine injuries, or "clearance," requires the exclusion of both bony and ligamentous injuries. This usually calls for a combination of clinical assessment and radiologic investigation. Clinical clearance of cervical spine injury is difficult and unreliable in patients who are unconscious or have distracting injuries to other parts of the body.

Examination of the neck includes inspection, palpation, and auscultation. The standard three-view plain film series for a c-spine evaluation includes lateral, anteroposterior, and open-mouth view. The lateral cervical spine film must include the base of the occiput and the top of the first thoracic vertebra. The lateral view alone is inadequate and will miss up to 15% of cervical spine injuries. The lower cervical spine may be difficult to examine, and caudal traction on the arms should be used to improve visualization. If the lower cervical spine is not visualized, a computed tomography (CT) scan of the region is indicated.[11,12] Thin-cut (2-mm) axial CT scanning of specific bone windows, with sagittal and coronal reconstruction, should be used to evaluate abnormal, suspicious, or poorly visualized areas on plain radiology. With technically adequate studies and experienced interpretation, the combination of plain radiology and directed CT scanning provides a false-negative rate of less than 0.1%.[12] Magnetic resonance imaging (MRI) is the gold standard for clearing the cervical spine in a clinically suspicious or unresponsive trauma patient.[13] In most trauma centers, cervical fixation is usually maintained until the patient is awake and can respond to command.

The best method of immobilization is achieved with a combination of a rigid cervical collar, a cervical/head immobilizer, and a backboard.[14] Rigid cervical collars (by themselves) limit rotation and lateral movement only to 50% of normal and flexion and extension only to 30% of normal and do not provide adequate stabilization.

Respiratory complications are common with cervical spine injuries. The severity of respiratory failure depends on the level and severity of the injury. Complete dissection of the spinal cord above C3 will cause apnea and death, unless the patient receives immediate intubation and ventilatory support. For lesions between C3 and C5, the degree of respiratory failure is variable. The vital capacity can be reduced to 15% to 20% of normal. These patients are at risk of increasing diaphragmatic fatigue due to slowly progressive ascending injury resulting from cord swelling and edema. This usually leads to decompensation and retention of secretions on day 3 to 4 post injury. Intubation and ventilation is needed to prevent respiratory failure. Patients with high cervical spine lesions have increased bronchial secretions, possibly due to altered neuronal control of mucous glands. Injuries at C5 or below spare the phrenic nerve and diaphragmatic breathing. However, expiratory reserve may be impaired secondary to accessory muscle paresis.[15]

The decision to intubate depends on several factors, including:[16,17]

- Loss of innervation of the diaphragm (e.g., phrenic nerve injury)
- Fatigue of muscles of respiration
- Failure to clear secretions
- Failure to maintain a patent airway
- History of aspiration
- Presence of other injuries (e.g., head, maxillofacial, and/or chest injuries)
- Premorbid conditions, especially respiratory disease (chronic obstructive pulmonary disease) and/or obesity

Injuries Affecting the Airway: Cervical Airway Injury

Injuries to the cervical airway may result from blunt or penetrating trauma. The incidence is usually rare. Blunt trauma to the airway either from a direct blow to the cervical airway or from severe flexion/extension injuries may result in a thyroid or a cricoid cartilage fracture.[18]

Injuries Affecting the Airway: Thermal and Inhalation Injury

Thermal and/or inhalation injury to the airway must be suspected in any patient presenting with a history

of exposure to fire or smoke. Carbon monoxide (CO) toxicity is a major problem. CO does not cause direct injury to the lungs. Its toxic effect results from a displacement of oxygen from hemoglobin-binding sites, thereby decreasing the oxygen-carrying capacity of the blood. This causes a shift of the oxyhemoglobin dissociation curve to the left. This results in tissue hypoxia because the hemoglobin binds less oxygen for transport to the peripheral tissues and is less able to unload the oxygen to those tissues. CO reacts with myoglobin to further impair oxygen uptake by decreasing facilitated diffusion of oxygen into muscle. This leads to impaired tissue oxygen availability and delivery.[19,20] Cyanide causes tissue asphyxiation through the inhibition of intracellular cytochrome oxidase. It blocks the final step in oxidative phosphorylation and prevents mitochondrial oxygen use. The organs most affected to cellular hypoxia include the central nervous system and the heart.

Inhalation injury can occur with or without evidence of burns. Burns on the face and singed eyebrows and/or facial hair are indicative of smoke inhalation. Patients with respiratory injury present with many symptoms, including minor eye irritation, cough, dyspnea, hyperventilation, tachypnea, rales, wheezing, and facial burns. This can lead to acute respiratory failure. These symptoms usually present within 6 to 24 hours post injury.[19]

Pulse oximetry is an accurate technique to monitor oxygen saturation. However, it is falsely elevated by CO. One must not rely on pulse oximetry until the carboxyhemoglobin level has reached the reference range.

Additionally, arterial oxygen tension (partial pressure arterial oxygen [PaO_2]) does not accurately reflect the degree of CO poisoning or cellular hypoxia. The PaO_2 level reflects the oxygen dissolved in blood that is not altered by the hemoglobin-bound CO. Because dissolved oxygen makes up only a small fraction of arterial oxygen content, a PaO_2 level within the reference range may lead to serious underestimation of the decrement in tissue oxygen delivery and the degree of hypoxia at the cellular level that occurs when CO blocks the delivery of oxygen to the tissues. However, arterial blood gas (ABG) measurements are still useful.

Cyanide levels correlate closely with the level of exposure and toxicity. However, these levels may not be readily available. Many hospitals send out these tests, and results may take several days to a week. Persistent neurologic dysfunction unresponsive to use of supplemental oxygen, cardiac dysfunction, and severe lactic acidosis are usually indicative of cyanide intoxication. In a setting consistent with potential cyanide exposure, empiric therapy should be started.[19,20]

Both direct laryngoscopy and fiberoptic bronchoscopy are both diagnostic and therapeutic. Visualization of erythema, edema, ulceration, and soot deposition make bronchoscopy useful in evaluating the extent of injury to the tracheobronchial tree. Additionally, fiberoptic bronchoscopy can facilitate endotracheal tube placement.[21]

Anesthetic Strategies

The goal of triage is to classify patients into various categories, identifying the urgency of treatment. Traumatized patients are divided into two major categories:

- **Those patients who require airway control as part of the resuscitation.** These patients are usually apneic or have total or near-total airway obstruction. They are identified during the primary survey and will require establishment of a patent airway. Initially, the mouth must be inspected for the presence of any foreign material. Then administration of positive pressure ventilation by mask with 100% oxygen is performed. If ventilation is unsuccessful, placement of an oropharyngeal or nasopharyngeal airway may be used to facilitate mask ventilation. The surgeon must be aware of the potential complications of these airways. The oropharyngeal airway can induce gagging and coughing. This may lead to increased intracranial or intraocular pressure and/or vomiting. The nasopharyngeal airway can lead to epistaxis, and care must be used when using it in a patient with a base-of-skull fracture. If the patient cannot be effectively ventilated, laryngoscopy and intubation must be attempted. A LMA (laryngeal mask airway) or a Combitube (double-lumen airway) may be considered in these cases.
- **Those patients who require semi-elective airway control at some time during hospitalization for surgical management of the maxillofacial injury.** These patients usually require elective intubation or, in selected situations, a tracheostomy. Intubation or a surgical airway in this situation provides a patent airway, protects against aspiration of secretions, allows positive pressure ventilation, decreases anatomic dead space, and provides a potential emergency route for drug administration.

Basic Principles of Management

Prophylaxis Against Aspiration

Trauma patients are always considered to have full stomach. This is due to multiple reasons including:

- Ingestion of food or liquids before injury
- Swallowed blood from oral or nasal injury
- Delayed gastric emptying
- Administration of liquid contrast medium

Various actions are considered to prevent aspiration:

- Administer nonparticulate antacid prior to induction
- Cricoid pressure/Sellick maneuver applied continuously during airway management
- Rapid-sequence induction (RSI)
- Avoidance of ventilation between administration of medication and intubation
- Awake intubation with or without topical or anesthetic blocks to the upper airway

Induction of General Anesthesia

There is no ideal anesthetic drug for trauma patients with hemorrhagic shock. The key to safe anesthetic management

of these patients is to administer small incremental doses of whichever agents are selected. Titration of the general anesthetic is a key factor in preventing complications. Many agents are in our armamentarium for anesthetic planning. Some of the induction agents are propofol, etomidate, ketamine, and dexmedetomidine.

Propofol is an ideal general anesthetic agent used in induction. It has a rapid onset of action as well as fast recovery from its sedative-hypnotic effects. Propofol has antiemetic effects that may be beneficial, especially for a patient who may have maxillomandibular fixation. However, propofol has some unwanted side effects in trauma patients. It may potentiate profound hypotension due to its direct myocardial depression and decrease in systemic vascular resistance. These effects can be potentiated in the elderly or cardiac patient[22] and can be exacerbated in the hypovolemic trauma patient.

Etomidate is widely used in the trauma population because of its cardiovascular stability relative to other induction agents. In fact, etomidate provides advantages for induction of anesthesia in the setting of hemorrhagic shock. In a pig model of hemorrhagic shock, its pharmacodynamics and pharmacokinetics are minimally altered in contrast to other anesthetic drugs. However, etomidate may still produce profound hypotension due to its inhibition of catecholamine release. Additionally, it can cause adrenocortical suppression. Adrenal suppression was found to last 6 to 8 hours in patients following a single induction dose of etomidate, and more than 24 hours following etomidate infusion. However, the impact of single-dose etomidate on outcomes in critically ill patients remains unclear.[23,24]

Ketamine can be used for induction in trauma patients. It is most suitable in children who are hemodynamically unstable or hypovolemic.[25] Similar to propofol, ketamine is also helpful in asthmatic patients because of its bronchodilating properties. It can result in myocardial depression. In normal patients, the effects of catecholamine release usually will mask cardiac depression and result in tachycardia and hypertension. In patients with severe hemorrhagic shock, the cardiac depression may be unmasked. This will lead to cardiovascular collapse.[26,27]

Dexmedetomidine is an agonist of α_2-adrenergic receptors in certain parts of the brain. It is indicated for sedation of critically ill or trauma patients in an intensive care unit setting. Dexmedetomidine may also be used to provide sedation for an awake intubation. Clinically it provides sedation and analgesia. It does so with minimal respiratory compromise. Dexmedetomidine is administered via a slow bolus supplemented with a continuous infusion. It is not administered with incremental boluses because of concerns about peripheral α_2-receptor stimulation, with resulting hypotension and bradycardia. Intravenous infusion is commonly initiated with a 1 mcg/kg loading dose, administered over 10 minutes, followed by a maintenance infusion of 0.2 to 1.0 mcg/kg/hour.[28]

Succinylcholine remains the neuromuscular blocker with the fastest onset (30 seconds) and shortest duration of action. Therefore, it is the agent of choice for RSI. It is especially indicated in trauma patients presenting for an emergency procedure with a potentially full stomach or who have recently eaten.

However, succinylcholine may be contraindicated in selected trauma patients:

- Burn patients: Succinylcholine must be used cautiously in burn victims (after the first 24 hours) because of increased serum potassium. The rise in serum potassium that normally follows succinylcholine administration is markedly exaggerated in burned victims. The levels can reach as high as 13 mEq/L, resulting in ventricular tachycardia, fibrillation, and cardiac arrest.[29,30]
- Crush injury: Succinylcholine must be used cautiously in patients with crush injury. The injury to the muscular tissue secondary to the crush injury results in hyperkalemia, which can be compounded with the administration of succinylcholine.
- Ocular injury: Succinylcholine must be used cautiously in patients with intraocular trauma or ocular injury. It leads to increased intraocular pressure (IOP). The increased IOP occurs within 1 minute after injection, peaks at 2 to 4 minutes, and subsides by 6 minutes.[31]
- Intracranial injury: Succinylcholine results in increased intracranial pressure (ICP). In trauma patients with head injury, succinylcholine must be used cautiously. The risk must be weighed in each individual situation.

Rocuronium can be also used safely during RSI (1 mg/kg), with an onset of relaxation of 60 seconds. Unfortunately, at this dose the duration of action will be 1 to 2 hours.[32] Sugammadex is an agent for reversing the neuromuscular blockade caused by a nondepolarizing agent such as rocuronium. Its main advantage is reversal of neuromuscular blockade without relying on the inhibition of acetylcholinesterase. Its administration is therefore associated with much greater cardiovascular and autonomic stability than the traditional reversal agents. This agent is not yet available on the U.S. market.

Maintenance of anesthesia can be achieved with a combination of inhalation as well as intravenous agents.

Advanced Airway Techniques

The maxillofacial surgeon must be aware of the different available modalities to secure the airway. These include:

1. Two-handed mask ventilation: Bag-mask ventilation is the cornerstone of basic airway management. When a second person is available to provide ventilations by compressing the bag, a two-hand technique can be used. The surgeon creates opposing semicircles with the thumb and index finger of each hand to form a ring around the mask connector and hold the mask on the patient's face. Then, the mandible can be lifted with the remaining digits.[33]
2. Combitube: A Combitube, also known as a double-lumen airway, is a blind insertion airway device (BIAD) used in the prehospital and emergency setting. It is ideal to provide an airway for the trauma patient in respiratory

distress. The simplicity of placement is a major advantage over endotracheal intubation. However, this technique has some serious but rare complications, including aspiration, esophageal perforation, and facial nerve dysfunction.[34]

3. LMA: The laryngeal mask airway (LMA) is an easy way to ventilate a trauma patient (Figure 2-1). It is a supraglottic airway device and is a good alternative to bag-valve-mask ventilation (freeing the hands of the provider with the benefit of less gastric distention).[35] The LMA is actually placed into the back of the mouth following the curve of the tongue (Figure 2-2). The rate of complications is rare (0.15%). These complications include[36,37] aspiration of gastric contents, local irritation, pressure-induced lesions, facial nerve palsies, mild sympathetic response, obstruction, and laryngospasm.
4. The laryngoscope is a useful technique to visualize the vocal cords and the glottis (Figure 2-3).
5. Videolaryngoscope: The failure of direct laryngoscopy to provide an adequate view for tracheal intubation led to the development of videolaryngoscopy. The first camera screen laryngoscope was developed by Berall in 1998. Currently, there are several manufacturers of video laryngoscopes. These include the Glidescope, McGrath laryngoscope, Daiken Medical Coopdech C-scope vlp-100, and the Berci DCI laryngoscopes. These laryngoscopes employ a variety of features, such as a monitor on the handle and/or channels, to assist in guiding the endotracheal tube into the trachea. The superior performance of video laryngoscopy in airway management where cervical spine injury is suspected has raised the question of whether these scopes should replace direct laryngoscopy in routine airway management in the trauma patient.[38]
6. Retrograde intubation is another alternative to secure an airway in the trauma patient. Under local anesthesia, a cannula is inserted through the cricothyroid membrane into the trachea, and a guide wire is then passed through the needle upward through the vocal cords into the oral cavity. The wire is then used to guide an ET tube through the vocal cords.[39]

• **Figure 2-1** Laryngeal mask airway. (From Nemeth J, Maghraby N, Kazim S: Emergency airway management: the difficult airway, *Emerg Med Clin North Am* 30(2):401-420, 2012.)

Surgical Airways

Emergency airway management in the trauma patient often involves a combination of factors that increase the technical difficulty of intubation and increase patient risk. These factors include:

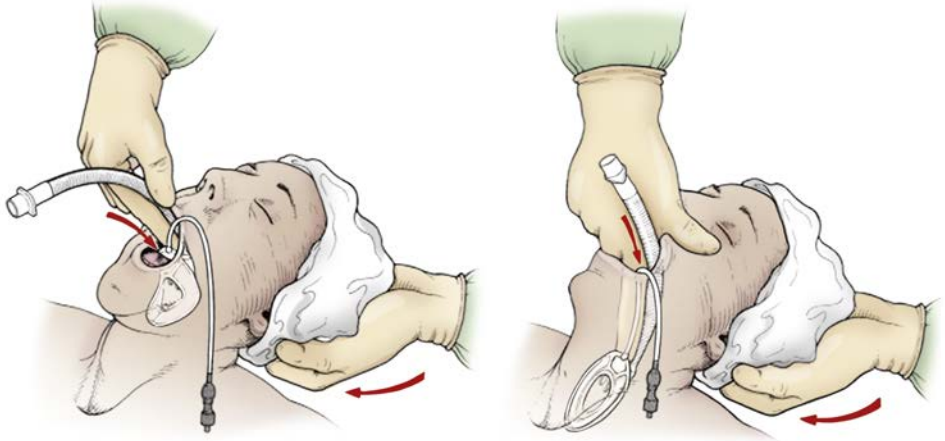
- Dynamically deteriorating clinical situation in the unstable patient
- Respiratory and ventilatory compromise
- Impaired ventilation and oxygenation
- Full stomach (increased risk of regurgitation, vomiting, aspiration)
- Increased secretions, blood, vomitus, and potential for foreign body
- Distorted anatomy

If intubation is not possible, a surgical airway is advised.

Emergency Cricothyrotomy

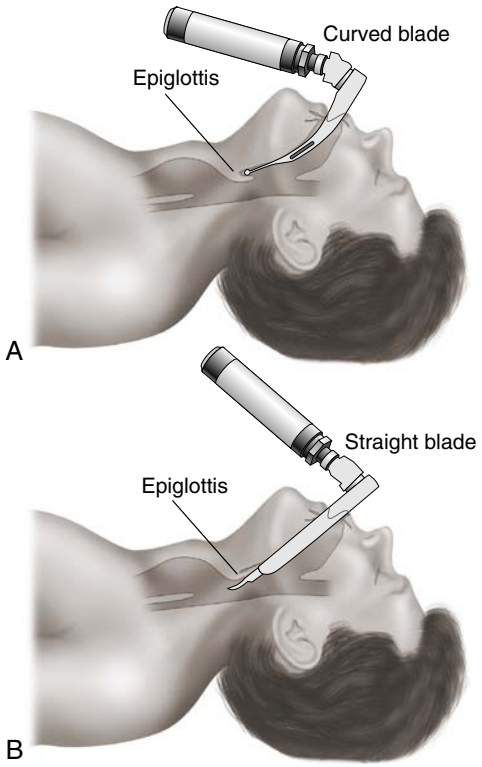
Emergency cricothyrotomy is one of the last-resort and potentially lifesaving procedures for maxillofacial trauma patients who cannot be intubated or ventilated.[40]

Traditionally, a surgical airway has been established by making an incision through the skin and the cricothyroid



• **Figure 2-2** Proper placement of the laryngeal mask airway.

membrane into the tracheal lumen, through which an endotracheal tube is inserted.[41] This method potentially has some serious complications. Several investigators have modified this technique.[42] In recent years, a number of commercial kits that include all of the necessary equipment to establish a surgical airway have reached the market. The surgeon must be familiar with the kit used at his or her trauma center.



• **Figure 2-3** Proper position of the tip of the curved **(A)** and straight **(B)** blades. (From Fonseca RJ: *Oral and maxillofacial trauma*, ed 3, Philadelphia, 2005, Elsevier.)

An experienced surgeon with exact knowledge of the anatomy and technique must perform this procedure.

The basic steps to perform a cricothyrotomy include (Figure 2-4):

1. Hyperextend the neck.
2. Identify the groove between the cricoid and thyroid cartilages as well as the cricothyroid membrane.
3. Prep the area (with Betadine) and infiltrate with local anesthetic.
4. Incise through the skin vertically with a 1.5-cm cut. Then use blunt dissection ensuring that you can see the cricothyroid membrane.
5. With a No. 22 or No. 23 scalpel blade, stab through the membrane into the trachea.
6. Rotate the blade 90 degrees, then insert a curved artery forceps alongside the blade. Remove the blade and open the forceps side-to-side. This widens the space between the thyroid and cricoid cartilages.
7. Pass a thin introducer or a nasogastric tube into the trachea (if the access is very small).
8. Run a 4-6 endotracheal tube over the introducer and pass it into the trachea.
9. Remove the introducer, if used.

The tube can stay in place for up to 3 days.

In surgical cricothyrotomy, a scalpel is used to make a horizontal incision over the lower half of the cricothyroid membrane. The only absolute contraindication to surgical cricothyrotomy is age, although the exact age at which a surgical cricothyrotomy can be safely performed is controversial and has not been well defined. Various sources list lower age limits ranging from 5 to 12 years old.[43,44] Our recommendation is to use 12 years as the cutoff age. In patients below this cutoff age, needle cricothyrotomy is indicated because infants and children younger than 12 years usually have a smaller cricothyroid membrane as well as a more funnel-shaped, rostral, and compliant larynx.[45]

Imaging in Maxillofacial Trauma

SRINIVAS SUSARLA, ZACHARY S. PEACOCK

Introduction

Imaging is a critical component of the diagnostic evaluation of a patient with craniomaxillofacial injuries. Although the history and physical examination remain the cornerstones of the initial assessment, two- and three-dimensional imaging techniques are adjuncts for diagnosis, treatment planning, follow-up evaluation, and outcome assessment.[1-11]

The interpretation of radiographic images from the traumatized face can be challenging, even for experienced practitioners. The face and cranium contain numerous critical structures, all confined into a relatively small volume. The superimposition of complex tissue layers over irregularly shaped osseous anatomy complicates the interpretation of plain radiographs. In this regard, the advent of computed tomography (CT) has significantly improved our ability to accurately diagnose, classify, and plan treatment for complex craniomaxillofacial injuries. For most patients with upper facial or midfacial injuries, multi-detector CT scanning (MDCT) is the standard for evaluation.[1,2,12-19] MDCT allows for visualization of the craniofacial skeleton in several planes (coronal, axial, sagittal), three-dimensional reformations, rapid image acquisition with limited requirements for patient positioning, and, more recently, advanced virtual treatment planning. Patients with a clinical examination concerning for mandibular or dental injury without concomitant midfacial or upper facial injury may, in certain circumstances, be adequately imaged by plain film techniques alone.[20-22]

In this chapter, we describe the detailed anatomy of the facial skeleton and predictable patterns of injury based on skeletal support structures, and offer a précis on radiographic identification of regional and complex injury patterns. Although management of specific facial fractures is discussed in detail elsewhere, indications for operative management are often based on a combination of clinical and radiographic findings. As such, this chapter briefly touches on common clinical findings and their correlation to radiographic findings, as well as implications for management.

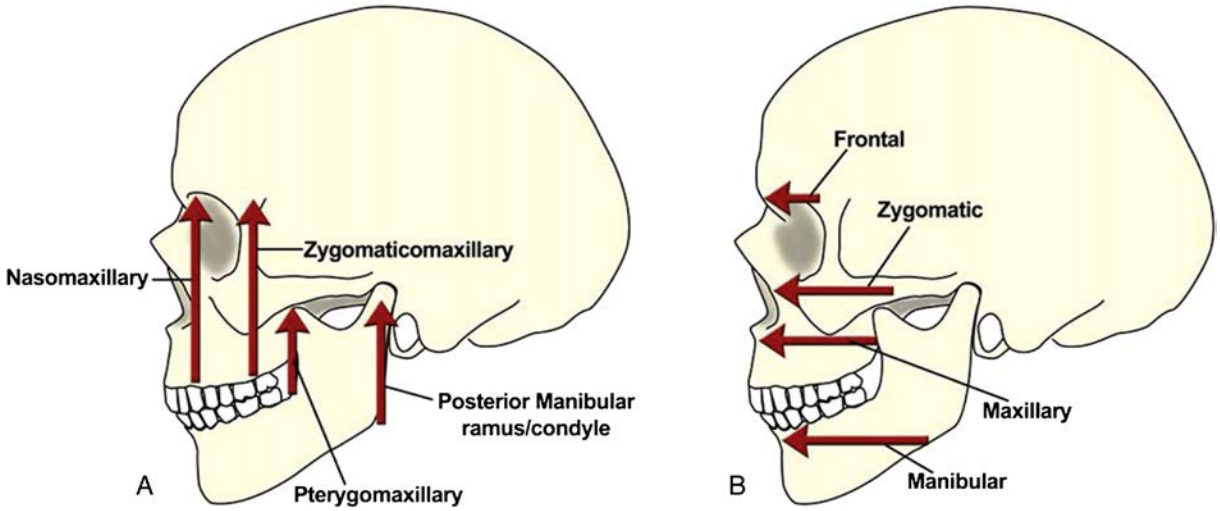
Image Acquisition

Proper diagnosis of fractures of the maxillofacial skeleton requires high-resolution images, ideally formatted in the axial, sagittal, and coronal planes.[1-6] Over the past 15 years, there has been an increased emphasis on the use of three-dimensional reformations for diagnosis and management.[13-18] Standard parameters for scanning should include a narrow slice thickness (e.g., 0.625 mm on a 64-slice scanner), with the field of view extending from the vertex of the skull to the hyoid bone.[1,2] Axial reformations should be performed in both bone and soft tissue windows, with a maximum thickness of 1.25 mm. Coronal and sagittal reformations allow for further elucidation of displacement, angulation, and rotation and should be performed universally. The 0.625-mm source images are necessary for producing high-resolution three-dimensional reformations.[1-4]

In patients with isolated mandibular fractures without clinical suspicion for midfacial or upper facial injuries, two plain film views (e.g., panoramic radiograph with anterior-posterior radiograph) can be adequate. There are classically described plain film imaging techniques for specific mandibular fractures that can be used in the appropriate clinical context (see section on Mandibular Fractures for details).

Image Interpretation

Akin to clinical evaluation of the patient with facial injury, radiographic interpretation can be daunting, particularly for complex injuries. The clinician should take a systematic approach to interpreting the images and proceed in the same fashion with each patient. It is imperative that the clinician recognize that even "simple" injuries may have contre-coup components (e.g., mandibular body and contralateral body/subcondylar fractures). Similarly, one should



• **Figure 3-1** **A**, Vertical buttresses of the facial skeleton include the nasomaxillary, zygomaticomaxillary, pterygomaxillary, and condyle-ramus unit of the mandible. **B**, The frontal bone, zygomatic arch and body, maxilla and mandible make up the horizontal buttresses. (From Fonseca RJ, Barber HD, Powers MP, Frist DE, editors: *Oral and maxillofacial trauma*, ed 4, Philadelphia, 2013, Saunders.)

not be overwhelmed by a seemingly complex injury. A systematic evaluation ensures that no area is overlooked and that a full correlation between the physical findings and imaging occurs, regardless of the mechanism of injury or state of illness of the patient.

One proposed approach for interpreting such images is a "top to bottom" approach. For the purpose of image interpretation, the craniofacial skeleton can be organized into five distinct regions: (1) orbital, (2) nasal, (3) zygomatic, (4) maxillary, and (5) mandibular.[1,23,24] Maxillofacial injuries commonly involve several regions and several contiguous structures within regions. The facial skeleton is composed of several horizontal and vertical buttresses, which act to distribute force away from vital structures, leading to predictable patterns of injury. The horizontal buttresses of the face are the frontal, zygomatic, maxillary, and mandibular buttresses. These areas transmit anterior-posterior forces. The vertical buttresses of the face include the nasomaxillary, zygomaticomaxillary, pterygomaxillary, and mandibular ramus/condyle. Each region of the facial skeleton is supported by a combination of horizontal and vertical buttresses (Figure 3-1).

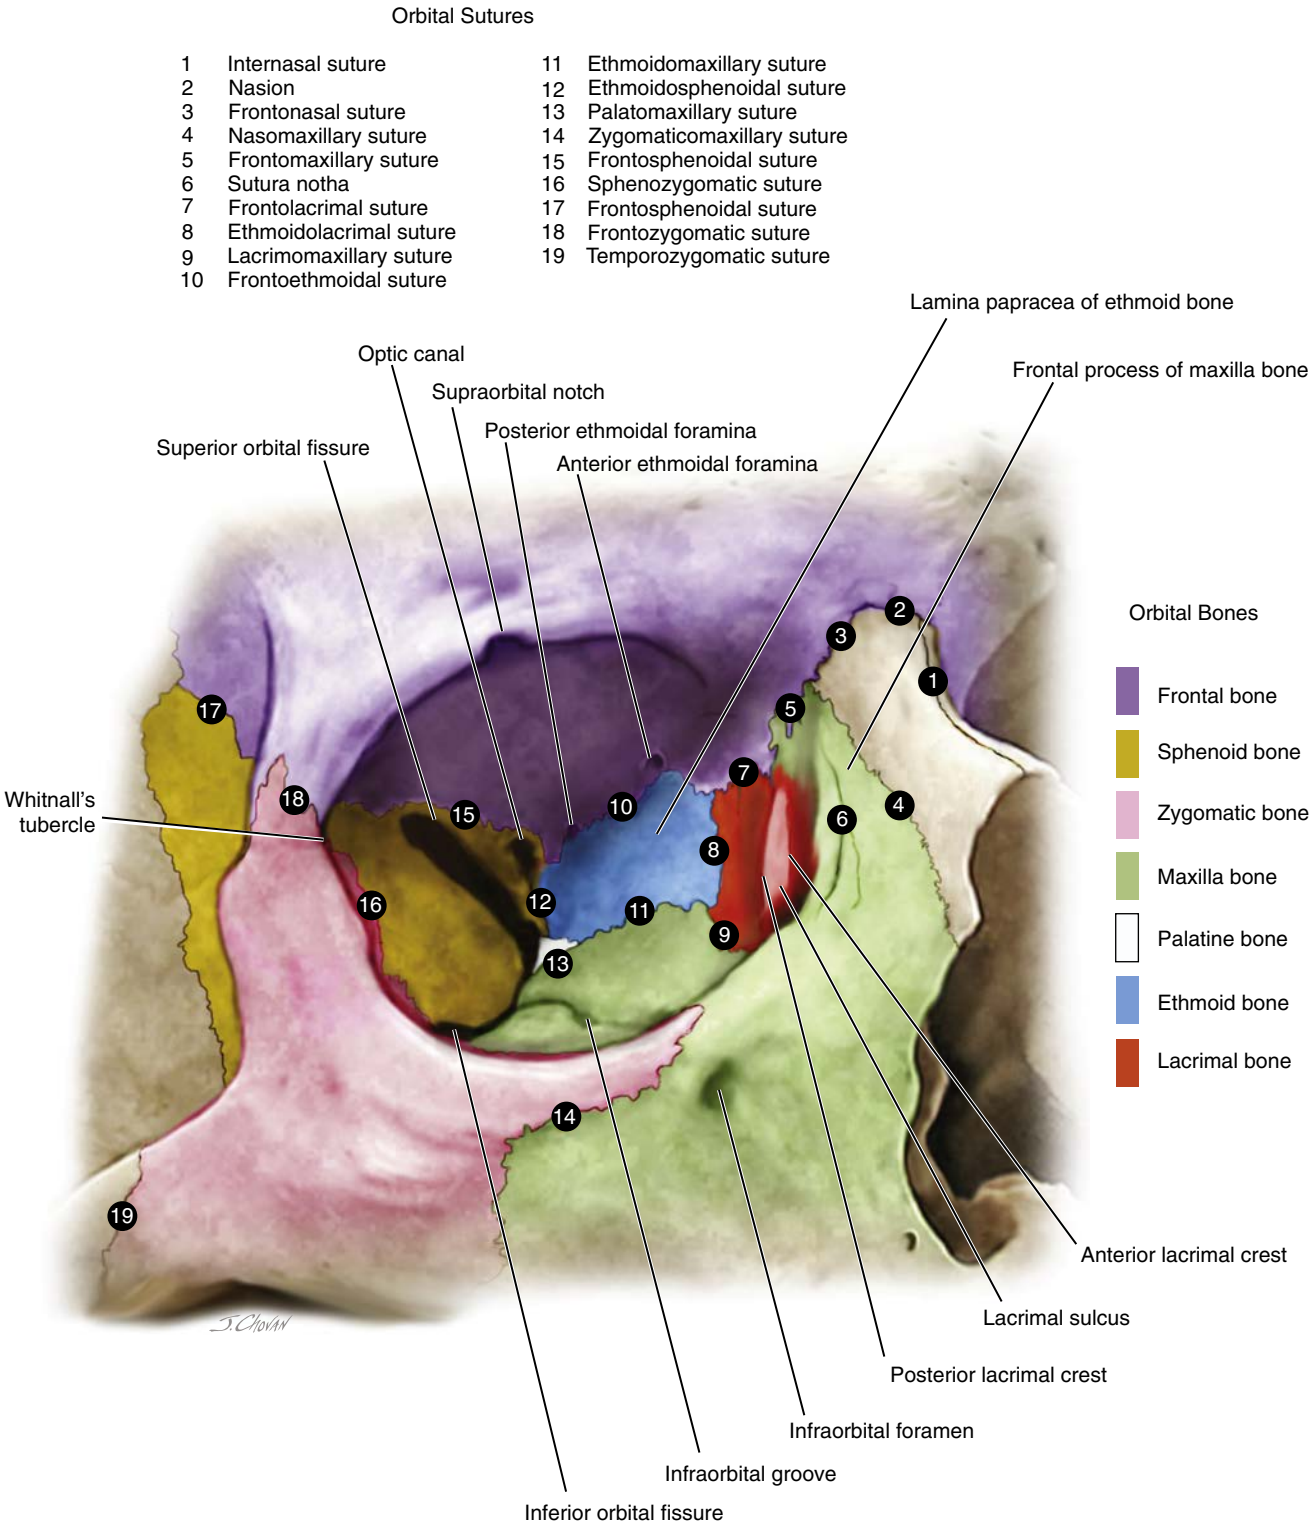
The orbital region includes the conical bony orbit and its contents (extraconal soft tissues, globe, extraocular muscles, nerves, vessels). The bony orbit proper is composed of seven constituent bones: the frontal, zygomatic, ethmoid, palatine, lacrimal, maxillary, and sphenoid (Figure 3-2). The external orbital skeleton (i.e., orbital rim) is primarily formed from the frontal bone, zygomatic bone, and maxilla. All seven bones contribute to the structure of the internal orbital skeleton, including the orbital roof, floor, and medial and lateral orbital walls. The orbit is horizontally supported by the frontal and zygomatic buttresses, as well as the supra- and infra orbital rims. It is supported vertically by the nasomaxillary and zygomaticomaxillary buttresses. This strong external framework of the external orbit prevents significant displacement of the osseous structures and affords significant protection to the globe and brain. Conversely, significant displacement of the orbital skeleton (e.g., displaced Le Fort III fracture) suggests a high-energy injury and should merit consideration for concomitant intracranial or cervical spine injury.

The nasal region is formed by the paired nasal bones, lacrimal bones, maxilla (frontal processes), nasal septum, and ethmoid sinuses. Horizontal support comes from the zygomatic buttress and the infraorbital rim. Vertical support comes from the nasomaxillary buttress and medial orbital wall.

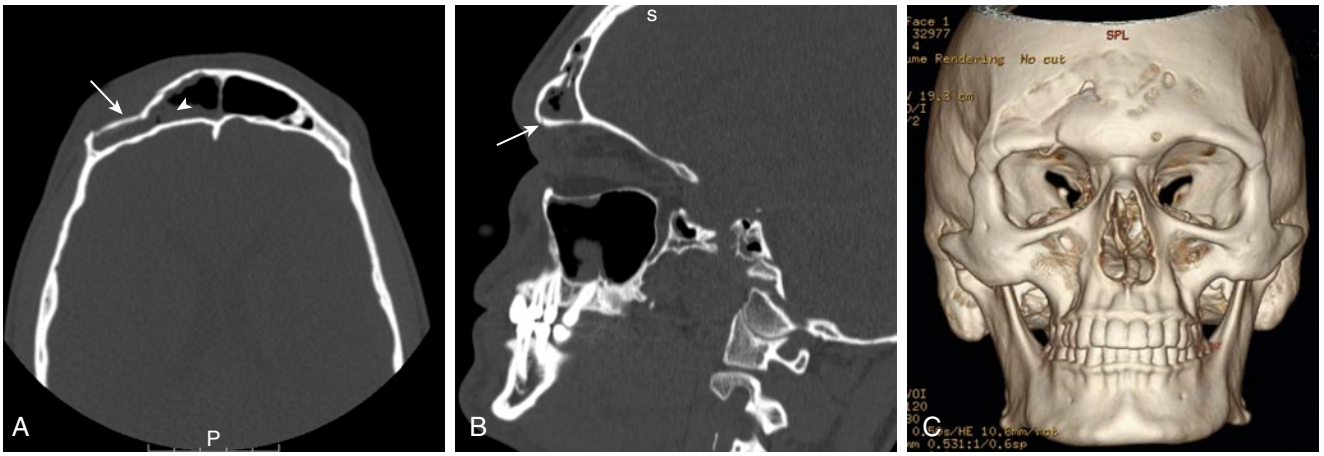
The midface is primarily composed of the zygomatic and maxillary regions. The zygomatic region serves to connect the temporal, maxillary, and sphenoid bones and has a significant role in midfacial projection. Fractures of the zygoma will disrupt one or more of these connections. The zygomatic region is supported horizontally by the zygomatic arch, infraorbital rim, and zygomatic body. Vertical support is from the frontozygomatic pillar, lateral orbital rim, and zygomaticomaxillary buttress.

The maxillary region includes the maxilla proper, the maxillary alveolus (including the upper dental arch), and the hard palate (palatine process of the maxilla and the palatine bones). This region is supported horizontally by the maxillary buttress and vertically by the nasomaxillary, zygomaticomaxillary, and pterygomaxillary buttresses. Various patterns of Le Fort injuries will disrupt these buttresses.

The mandibular region is composed of the mandible proper and the mandibular alveolus. The mandible proper includes the temporomandibular joint and the cortical mandible. The mandibular alveolus includes the lower dental arch. The mandible is the only mobile portion of the facial skeleton, articulates with the skull base via the bilateral temporomandibular joints, and has no rigid connection



• **Figure 3-2** Seven bones make up the orbit and periorbital region. The orbital rims are part of the strong vertical and horizontal buttresses and include the frontal bone, zygoma, and maxilla. The internal orbit is composed of thin bones prone to fracture. Fractures that go through the orbital walls include orbital blow-out fractures, Le Fort II and III, and naso-orbitoethmoid fractures. (From Kademani D, Tiwana P, editors: *Atlas of oral and maxillofacial surgery*, ed 1, Philadelphia, 2015, Saunders.)



• **Figure 3-3** Frontal sinus fracture affecting anterior table only. **A**, Axial image shows depression of the anterior table (*arrow*) on the right side with fluid within the sinus (*arrowhead*). The posterior table is intact. **B**, Sagittal image demonstrates comminution of the anterior table extending to the superior orbital rim (*arrow*). **C**, Three-dimensional reformat shows the depression of the anterior table and extension to the orbital rim.

to the remainder of the craniofacial skeleton. The mandible is a self-contained unit, which has significant implications for injury patterns and management. The mandible is supported by the ramus/condyle unit vertically and the mandibular buttress horizontally.

A systematic approach to reading the maxillofacial CT is to start at the most superior portion of the scan and scroll through the axial slices from superior to inferior on the axial cuts.[1-5] For inexperienced clinicians, it is often helpful to have a pen and paper handy to document the fractures visualized on a particular view. Next, the clinician should scroll through the sagittal (lateral to medial) and coronal (anterior to posterior) views, again documenting the visualized fractures. With experience, one will be able to transpose fractures identified in one plane into the other two, assembling a three-dimensional construct of the injured skeleton. Finally, once the fracture inventory is assessed, the clinician should summarize the findings in terms of patterns of fractures rather than isolated elements of fractured bones. Descriptions in the latter format are cumbersome and unlikely to be helpful for clinical decision making.

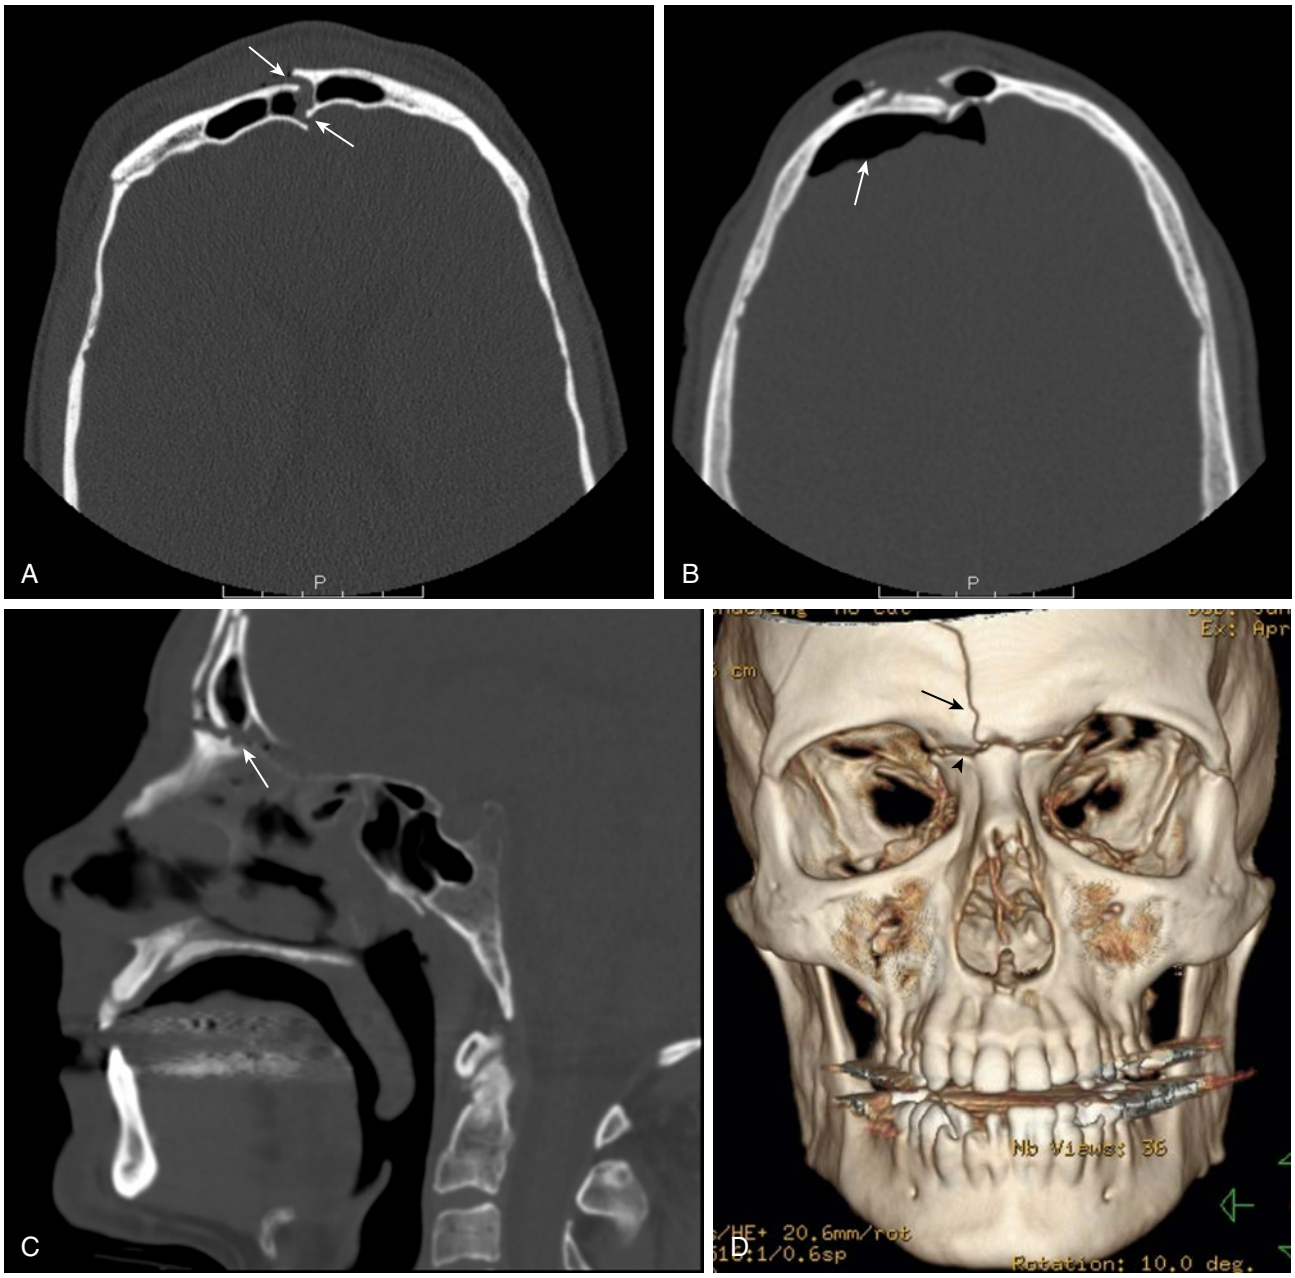
Facial Fracture Patterns

The presence of anatomic buttresses within the facial skeleton not only is useful for segmentalizing the anatomy, but also can serve as a guide for predicting patterns of facial injury, based on the direction of force and magnitude of impact. The need for careful clinical evaluation and meticulous physical examination cannot be overemphasized. Seemingly small soft tissue injuries can often mask significant skeletal injury, due to the dispersal of forces along the facial buttresses. Similarly, massive soft tissue injuries often have significant underlying skeletal injuries that follow predictable patterns to disperse the force of injury away from the brain and spine.

Because facial fractures can and often do involve several contiguous bones or several regions of the facial skeleton, there is little utility in describing fractures on the basis of the bones involved (e.g., fracture of the anterior and posterior walls of the maxillary sinus, zygomatic arch, frontzygomatic suture, and orbital floor). Instead, the clinician should be familiar with patterns of injury and the bones involved (e.g., zygomaticomaxillary complex fracture). Familiarity with the typical pattern and location of facial fractures makes each evaluation more efficient and clinically useful.

Frontal Bone Fractures

Although the frontal bone is not typically considered a primary bone of the facial skeleton, it is often involved in patients sustaining high-energy head injuries and is managed by the specialist treating maxillofacial injuries (Figures 3-3 and 3-4).[25-28] The frontal bone forms the prominence of the forehead and contains the frontal sinus. The frontal sinus divides the frontal bone into an anterior portion (anterior table) and posterior portion (posterior table). The anterior table lies immediately adjacent to the soft tissue of the forehead, and an anterior table injury should be suspected in patients with forehead lacerations. Isolated injuries of the anterior table without deformity, however, are not generally serious and often can be managed non-operatively. On axial views, an air-fluid level within the frontal sinus is suggestive of a frontal sinus injury. Higher energy mechanisms often result in fractures of both the anterior and posterior tables, which are more serious because of potential involvement of the central nervous system. The communication between a nonsterile cavity (frontal sinus) and the intracranial space defines these injuries as compound fractures, requiring, at minimum, antibiotic



• **Figure 3-4** Frontal sinus fracture affecting both anterior and posterior tables. **A**, Axial image shows displacement of anterior and posterior tables (*arrows*) and **B**, pneumocephalus (*arrow*) behind a fractured posterior table. **C**, Sagittal image shows fracture through the anterior and posterior table at the start of the nasofrontal duct. **D**, Three-dimensional image showing displacement of the right frontal bone posteriorly (*arrow*) and the disruption at the inferior aspect of the frontal sinus and nasofrontal suture (*arrowhead*).

TABLE 3-1 Variations of Frontal Sinus Fractures and Clinical Significance

Type	Significance
Isolated anterior table	Displacement > width of anterior table requires open reduction
Posterior table fracture	Considered a compound skull fracture and may result in CSF leak. Antibiotic treatment typically required
Naso-frontal duct involvement	Requires operative intervention to obliterate sinus

treatment. In non-displaced fractures of the frontal sinus, pneumocephalus is a key finding indicative of posterior table involvement. Cerebrospinal fluid rhinorrhea suggests dural disruption, which may occur if the fracture extends along the floor of the anterior cranial fossa, through the cribriform plate. Limitation of extraocular movement, visual acuity changes, or forehead and upper eyelid ecchymosis are physical findings associated with frontal bone fractures involving the orbital roof.

An adequate description of a frontal sinus fracture should include the status of the anterior and posterior tables, as well as the patency of the nasofrontal duct (Table 3-1).[28] Isolated anterior table fractures often require open reduction if there is an aesthetic deformity or if the displacement is greater than the width of the anterior table. Fractures with posterior table involvement generally require neurosurgical consultation. Displaced posterior table fractures require open treatment, which may include cranialization of the frontal sinus. If the nasofrontal duct is obstructed/non-patent, the sinus should be obliterated.

Orbital Fractures

As mentioned previously, the orbit is composed of seven bones of varying size and shape and is rigidly connected to the frontal bone, cranial base, and midface. As such, fractures of the orbital skeleton may occur either in combination with other facial fractures (e.g., frontal sinus, zygomatic, nasal) or in isolation (e.g., orbital floor). Orbital fractures should be suspected in patients who sustain injuries to the forehead, zygoma, maxilla, or nose. Commonly used terminology for internal orbital fractures includes "blow-in" and "blow-out" injuries.

Blow-in fractures are those in which the orbital roof is displaced inferiorly into the orbit, usually from a direct blow to the supraorbital rim or via transmitted forces from a blow to the forehead. Such injuries may propagate posteriorly within the orbit, resulting in involvement of the orbital apex. Several critical cranial nerves (CN II, III, IV, V_1, and VI) travel through the orbital apex, and an orbital apex injury can manifest clinically as visual acuity changes, ophthalmoplegia, or corneal anesthesia.[29] Alternatively, edema or hematoma within the internal orbit can increase the intraorbital pressure, compromising the intraorbital neurovascular structures. Orbital roof injuries may also involve the anterior cranial fossa, and pneumocephalus may be seen on imaging.[29]

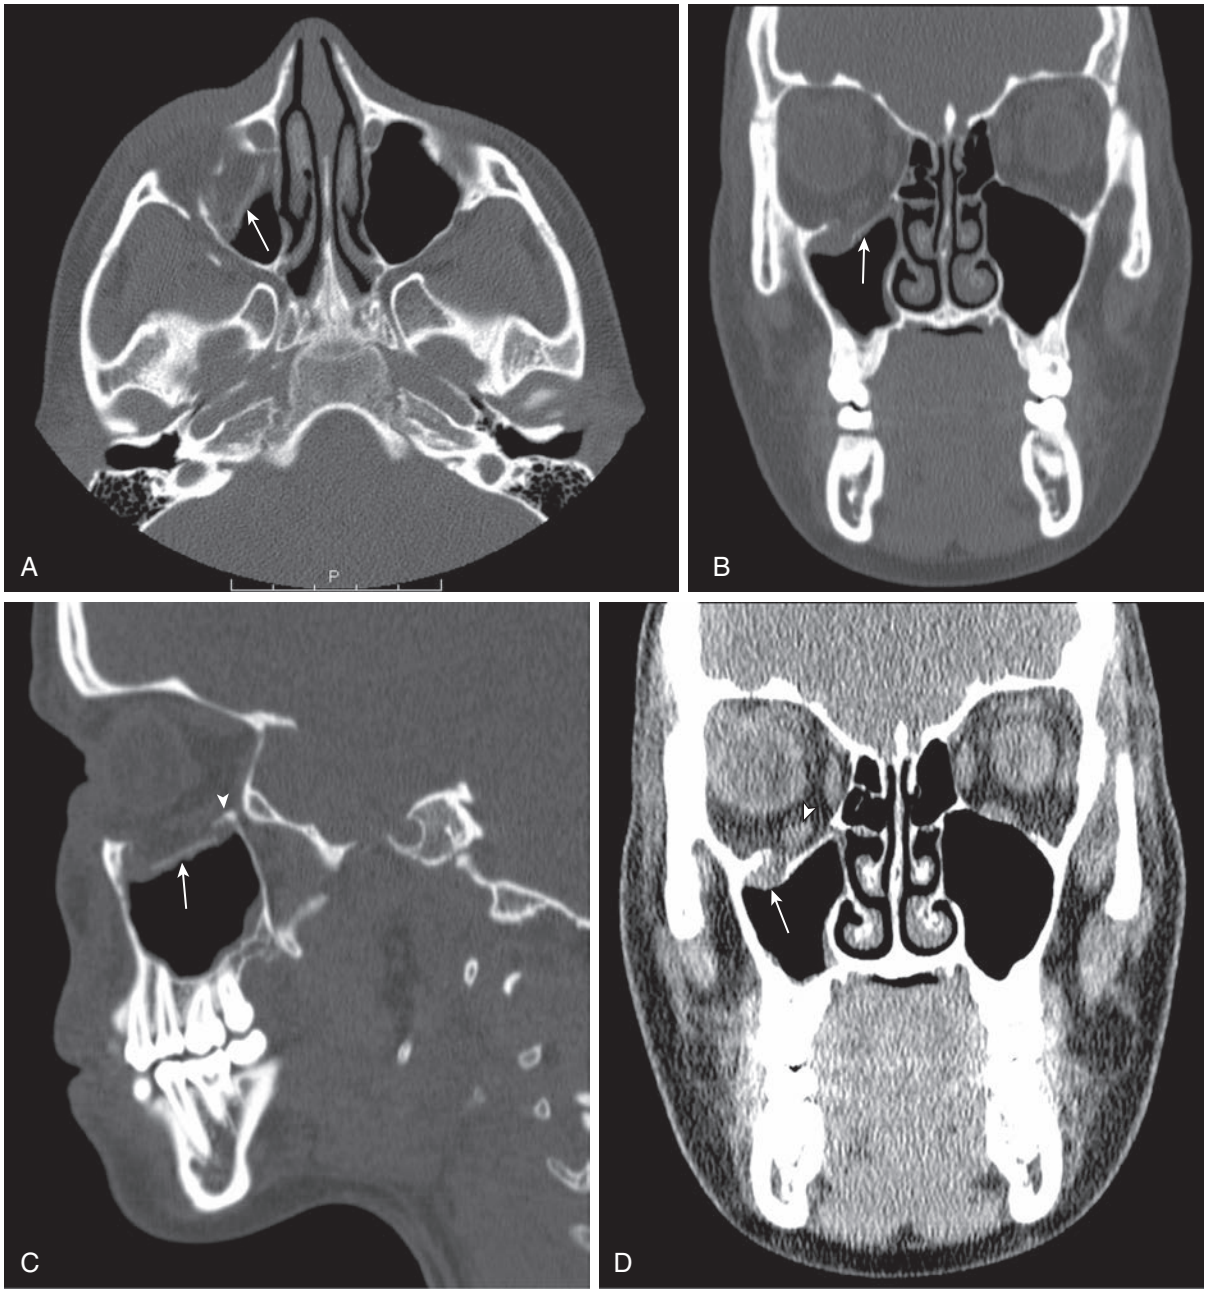
Blow-out fractures are those in which the orbital floor and/or medial wall are fractured and displaced into the surrounding air-filled spaces (i.e., the maxillary and ethmoid sinuses/nasal cavity) (Figure 3-5).[30-32] CT imaging in the axial, sagittal, and coronal planes is essential for accurate diagnosis, as axial cuts may miss orbital floor fractures and sagittal cuts may miss medial wall fractures. The appearance of the orbits should be symmetric, rounded, and smooth, with interruption in the cortex only at the bony articulations. By definition, the infraorbital rim is intact in a blow-out fracture. Theoretically, the force of the injury is transmitted to the internal orbit directly or indirectly via an increase in intraorbital volume, resulting in fracture of the thin medial wall or orbital floor. The contents of the orbit can herniate into the associated air-filled spaces.

Clinical indications for repair of orbital wall fractures are entrapment or enophthalmos. Herniation of extraocular muscle tissue (i.e., inferior or medial rectus muscles) may result in entrapment and limited extraocular movement (Figure 3-6). This occurs most commonly with small, narrow fractures, where the muscle can become impinged within the fracture.[1,2-31] An abrupt kink in the muscle is sometimes seen with such entrapment. Sagittal reformations are particularly helpful for visualizing entrapment of the inferior rectus in the orbital floor, and coronal reformations are useful for medial rectus entrapment in the medial wall. Larger fractures of the floor and medial wall generally do not result in entrapment but have a higher risk of subsequent enophthalmos.

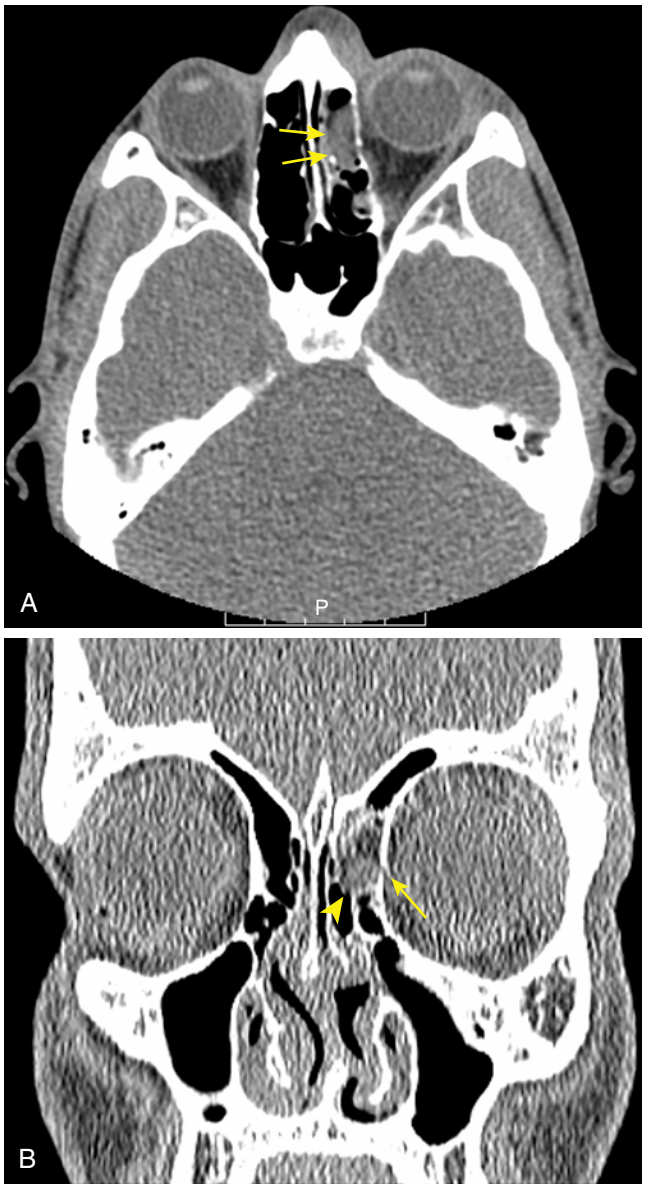
Zygomatic Fractures

Direct blows to the prominence of the cheek or lateral midface can result in injury to the zygoma and its articulations.[33-35] Disruption of the articulations between the zygoma and the temporal, maxillary, and sphenoid bones are generally more common than intra-zygomatic fractures due to the density of the zygomatic body, although high-energy injury injures can lead to comminution of the zygoma (Figures 3-7 and 3-8). These injuries are commonly known as "zygoma," "zygomatic complex," or "zygomaticomaxillary complex" (ZMC) fractures. Diagnosis of ZMC fractures relies on accurate identification of the frontozygomatic, sphenozygomatic, zygomaticomaxillary, and temporozygomatic sutures. Diastasis at any of these articulations should raise suspicion for a ZMC fracture. Coronal and sagittal views afford evaluation of the orbital floor, which is often disrupted at the articulation of the zygoma with the maxilla and sphenoid.

Lateral blows to the face may result in isolated zygomatic arch fractures (Figure 3-9) that may result in a depression of the area anterior to the glenoid fossa. These can be seen on plain films such as the submentovertex or Waters' views, but are best seen on CT scan.



• **Figure 3-5** Orbital blow-out fracture. **A**, Axial views can often be unrevealing, but in this image a fragment of orbital floor is displaced into the sinus (*arrow*) along with orbital tissue. **B**, Coronal image shows downward displacement of the thin orbital floor (*arrow*). **C**, Sagittal image shows inferior displacement of the orbital floor into the maxillary sinus (*arrow*). A posterior shelf has been maintained (*arrowhead*). **D**, Coronal image with soft tissue window shows the displacement of orbital fat (*arrow*), but the inferior rectus remains in the orbit (*arrowhead*).



• **Figure 3-6** Fracture of the medial orbital wall with medial rectus entrapment. No lateral movement was possible with forced duction. **A**, Axial image (soft tissue window) shows entrapment of the medial rectus (*arrows*) through a minimally displace medial wall fracture (trapdoor). **B**, Coronal image (soft tissue window) shows a crack in the medial wall (*arrow*) with the entire medial rectus in the ethmoid sinus (*arrowhead*).

Clinical signs and symptoms of ZMC fractures include loss of cheek prominence, paresthesia in the infraorbital region, trismus with zygomatic arch involvement, and ocular findings if there is significant orbital floor involvement. Aesthetic deformities with displacement, trismus, extraocular muscle entrapment, visual acuity changes, or persistent infraorbital paresthesia secondary to impingement are indications for operative management.

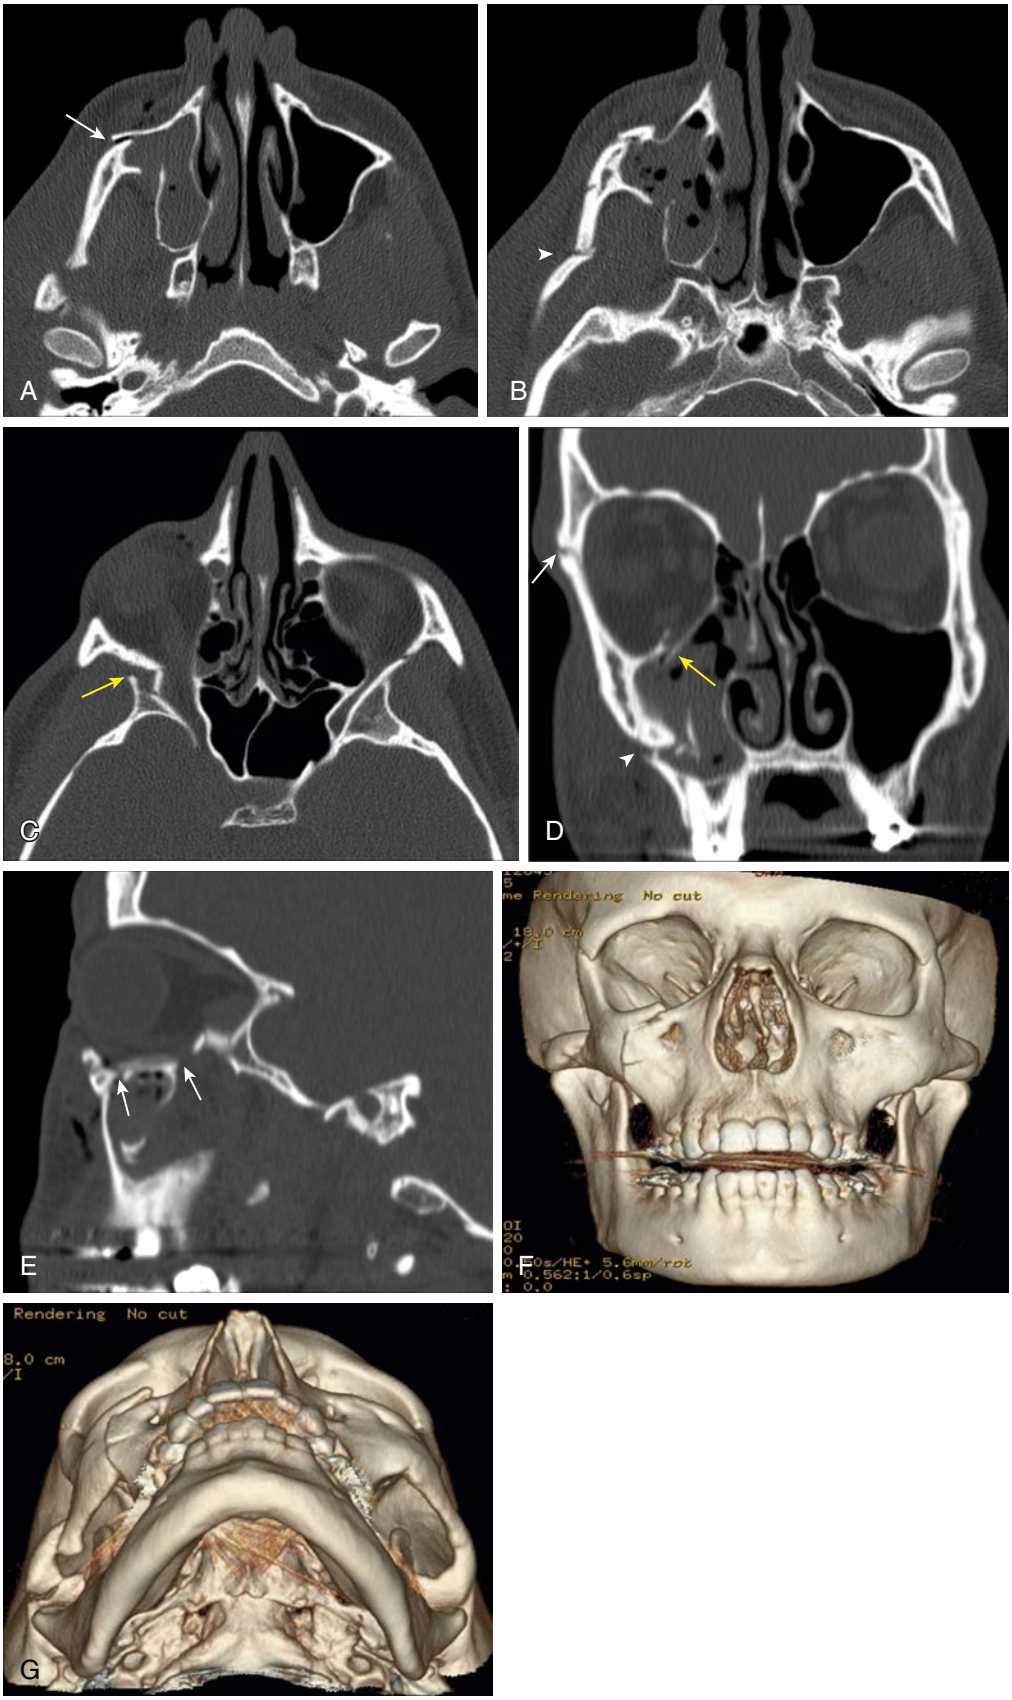
ZMC fractures have long been classified according to the system of Knight and North (Table 3-2).[35] These surgeons used plain film images to classify ZMC fractures according to the vector of displacement and bony integrity of the zygoma proper. The system hierarchy was based on the stability following closed reduction, with type I fractures (non-displaced) being the most stable, types II and + V generally stable following reduction without fixation, and type III, IV, and VI fractures being the least stable and requiring some form of fixation. It is currently accepted that all displaced ZMC fractures require some form of reduction with or without fixation. More recent classification systems, based on CT imaging, have been useful in establishing the necessity for surgical treatment (see Table 3-2).[33]

Nasal/Naso-orbito-ethmoid Fractures

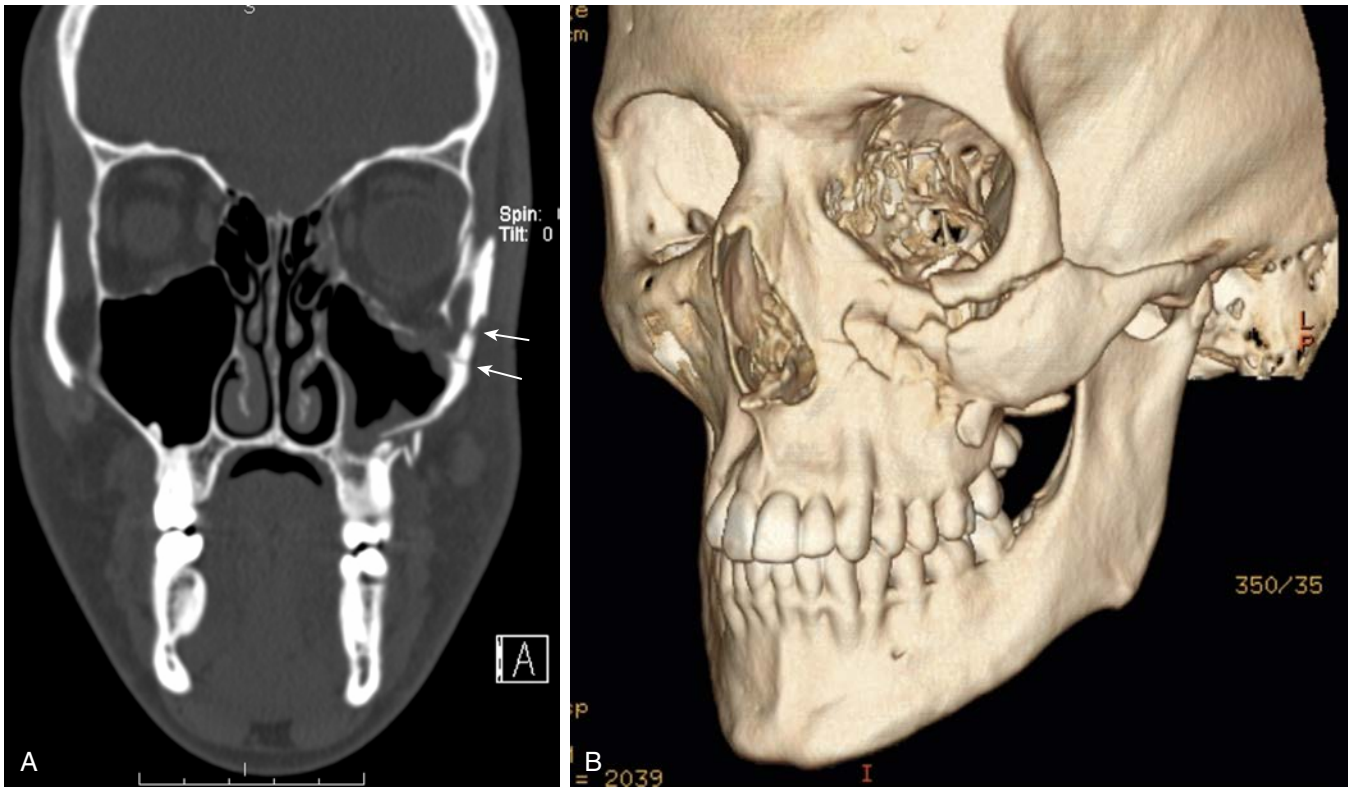
Fractures of the nasal region can be broadly classified into those that are isolated to the nasal bones proper and those that involve the naso-orbito-ethmoid (NOE) complex. Isolated nasal fractures are relatively common, because of the prominence of the nasal dorsum and its relatively weak bony support (Figure 3-10).[36-38] Patients presenting with isolated nasal fractures will often complain of perinasal swelling and tenderness. Signs include deformity over the nasal dorsum, epistaxis, nasal instability, or crepitus. For low-energy injuries, these features may be transient and there may be a delay in presentation; their absence does not exclude the possibility of nasal injury. As a corollary, old fractures of the nasal bones may appear similar to acute fractures on imaging. The absence of a recent history of trauma or signs of injury (edema, pain, crepitus, etc.) is inconsistent with an acute injury.

The majority of isolated nasal fractures occur as a result of force vectors directed from the lateral aspect.[48] Subsequently, displacement of the nasal bones typically occurs inferiorly and laterally, sometimes with displacement of the nasal septum or fracture of the frontal processes of the maxilla. Disruption of the anterior cartilaginous septum may be associated with fractures of the anterior nasal spine. A stratified classification scheme for nasal fractures has been proposed by Rohrich and Adams and may assist the clinician with management (Table 3-3).[37]

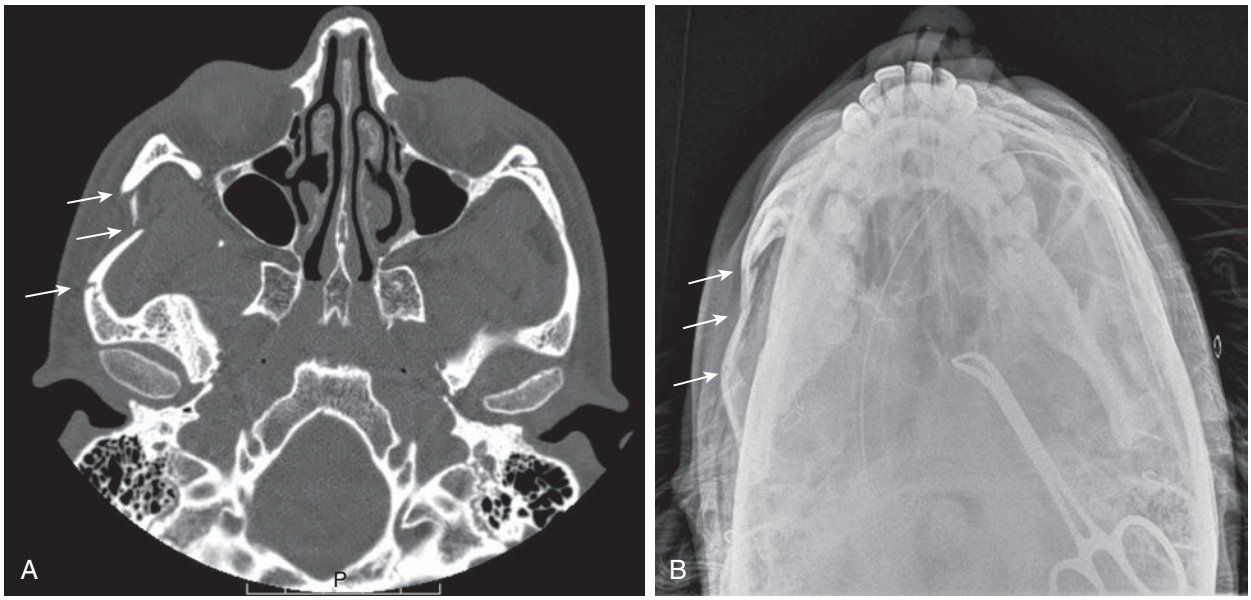
High-energy forces transmitted to the nasal region may result in NOE complex fractures (Figure 3-11). The NOE complex represents the bony union of the nasal and orbital regions and includes the nasal and ethmoid bones as well as the infraorbital rims and orbital floors. The history is typically consistent with a high-velocity or high-energy injury; concomitant intracranial or cervical spine injury should be exonerated. Although the typical clinical presentation is an amalgam of findings that can be seen with either nasal or orbital fractures, there are some specific clinical findings for NOE fractures. Telecanthus, an increase in the distance between the medial canthi, is mechanistically related to NOE fractures in that the medial canthal tendon is a critical anatomical component of the zone of injury. Injury to the medial canthal tendon may also manifest as a positive "bowstring" sign or "traction test." Other signs may include bilateral periorbital ecchymoses ("raccoon eyes," present with associated skull base fracture), epiphora (present with associated nasolacrimal system injury), or cerebrospinal fluid (CSF) rhinorrhea (nasofrontal duct injury).



• **Figure 3-7** Zygomaticomaxillary complex fracture, Type B; Knight and North type IV. **A**-**C**, Axial images show fractures through the articulations of the zygoma: zygomaticomaxillary (*arrow*), zygomaticotemporal (*arrowheads*), and zygomaticosphenoid (*yellow arrow*). **D**, Coronal image shows a minimally displaced fracture through the zygomaticofrontal suture (*arrow*), zygomaticomaxillary buttress (*arrowhead*), and orbital floor (*yellow arrow*). **E**, Sagittal image shows the disruption of the orbital floor at the junction of the zygoma to the maxilla and sphenoid (*arrows*). **F-G**, Three-dimensional reformats highlight the medial rotation of the right zygoma and disruption at all four articulations.



• **Figure 3-8** Comminuted zygomaticomaxillary complex fracture Type C; Knight and North type VI. **A**, Coronal image shows fractures within the body of the zygoma (*arrows*). **B**, Three-dimensional left three-quarter view shows the disruption of the zygomatic body and its articulation with the maxilla.



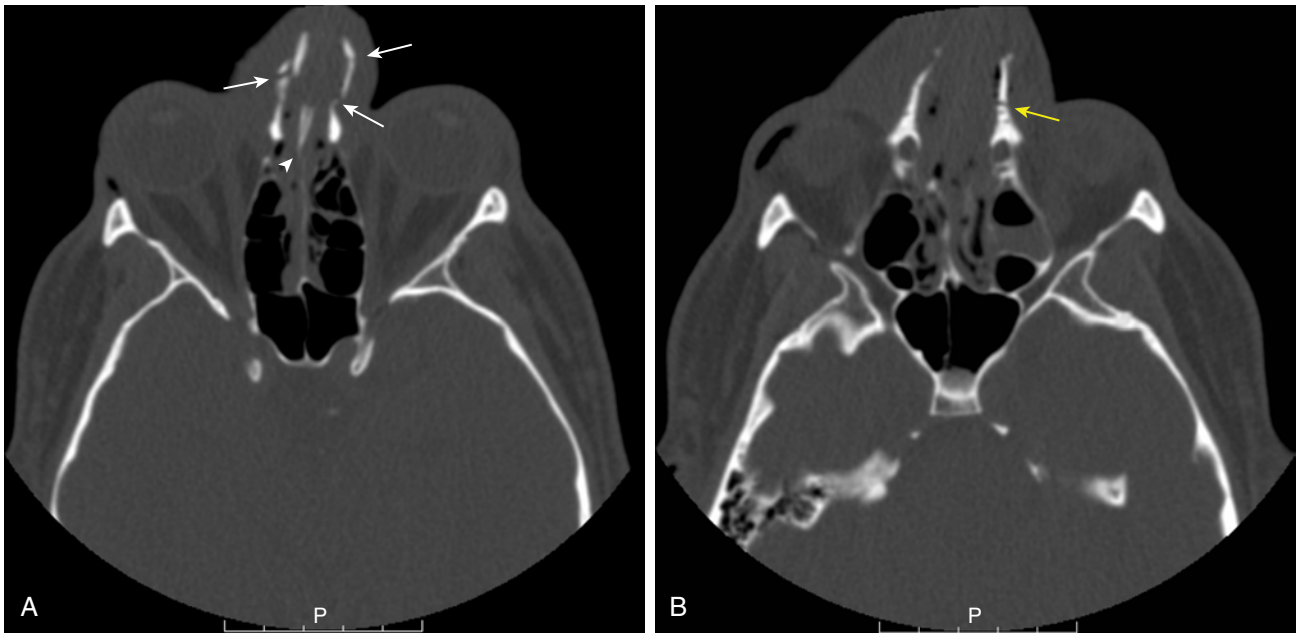
• **Figure 3-9** Zygomatic arch fracture. **A**, Axial image showing the classic three-fracture pattern (*arrows*) forming the letter M. **B**, Submentovertex plain film can also diagnose or determine adequacy of reduction after closed treatment. *Arrows* mark the fracture sites.

TABLE 3-2 Classification of Zygoma Complex Fractures

Type	Characteristics
A	Fracture limited to one zygomatic pillar: zygomatic arch, lateral orbital rim, or infraorbital rim
B	Fracture of all four zygomatic articulations with displacement
C	Multi-fragment fractures including comminution of the zygoma body

Knight and North Classification

Type	Description	Preferred Treatment
I	Non-displaced	Observation
II	Isolated arch	Observation or closed reduction
III	Depressed, non-rotated	Open reduction ± fixation
IV	Medially rotated	Open reduction ± fixation
V	Laterally rotated	Open reduction ± fixation
VI	Complex, comminuted	Open reduction + fixation



• **Figure 3-10** Nasal fractures. **A-B**, Axial images demonstrate comminution and displacement of the bilateral nasal bones (*arrows*) and through the perpendicular plate of the ethmoid (*arrowhead*). The left fracture occurred at the nasomaxillary suture (*yellow arrow*).

Markowitz and colleagues developed the most frequently used classification system for NOE fractures, based on the integrity of the medial canthal tendon (MCT) (Table 3-4, Figure 3-12).[39] Type I fractures involve a large central fragment with preserved attachment of the MCT; type II fractures involve comminuted fragments, but with a preserved MCT; type III fractures are the most severe (and difficult to treat), as they involve a comminuted NOE complex with MCT involvement.

Maxillary Fractures

Fractures of the maxilla are among the most well described injuries to the facial skeleton. Le Fort's seminal work on these injuries remains the foundation for modern diagnosis and management (Figure 3-13).[40] Clinical examination is typically notable for malocclusion and intraoral ecchymosis (commonly along the buccal mucosa or palate). Even non-displaced fractures can be

TABLE 3-3 Nasal Fracture Classification System

Type		Characteristics
I	Simple	Unilateral
II		Bilateral
III	Comminuted	Unilateral
		Bilateral
		Including frontal process of maxilla
IV	Complex	Associated with septal hematoma
		Associated with open nasal laceration
V		Associated with naso-orbito-ethmoid or midface fracture

uncomfortable for patients, and they may report a malocclusion even if an obvious malocclusion is not evident on examination.[23]

The Le Fort I-III level fractures are accepted as standard terminology for fractures of the maxilla alone, with involvement of the nasofrontal complex, or total craniofacial disjunction, respectively. The unifying feature of all levels of Le Fort fractures is fracture of the pterygoid plates.[41] A fracture of the pterygoid plates almost always indicates a fracture at one of the Le Fort levels.[1,41] Maxillary fractures may occur in isolation or with concomitant injury to the nasal, zygomatic, or orbital regions; may be unilateral or bilateral; and may be varied in severity (e.g., left-sided Le Fort I fracture with a right-sided Le Fort III fracture). As such, imaging of such suspected injuries requires careful assessment of the orbital, nasal, frontal, and zygomatic regions and assessment of laterality.

The Le Fort I fracture is a simple maxillary disjunction, separating the maxilla from its connection to the skull base, zygoma, and nasal septum (Figure 3-14). The classical fracture pattern will propagate from the pyriform rim and lateral nasal wall to the pterygomaxillary fissure, extending across the intervening bone by fracturing the anterior and posterior walls of the maxillary sinus. There is often a simultaneous fracture of the nasal septum. Clinically, the maxilla may be mobile, with the hard palate and alveolus mobile relative to the remainder of the midface.

The Le Fort II fracture is also known as a pyramidal fracture because the fracture lines may form a distinct triangular shape when viewed in the coronal plane (Figure 3-15). The Le Fort II pattern extends from the pterygoid plates superiorly and anteriorly, terminating at the nasofrontal suture. The intervening bony segments along the line of fracture are the lateral and anterior walls of the maxillary sinus, the orbital floor, and the medial orbital wall. Clinically, mobilization of the maxilla will result in tactile mobility at the nasofrontal suture.

"Craniofacial disjunction" is a synonym for the Le Fort III fracture. This is the most severe form of maxillary fracture, with a fracture line that propagates from the pterygoid plates superiorly to involve the zygomatic arch, lateral orbit, orbital floor, medial orbital wall, and nasal bones. As a result, the midfacial skeleton becomes separate from the skull base. Clinically, the mobilization of the maxilla will result in simultaneous mobilization of the lateral and inferior orbit.

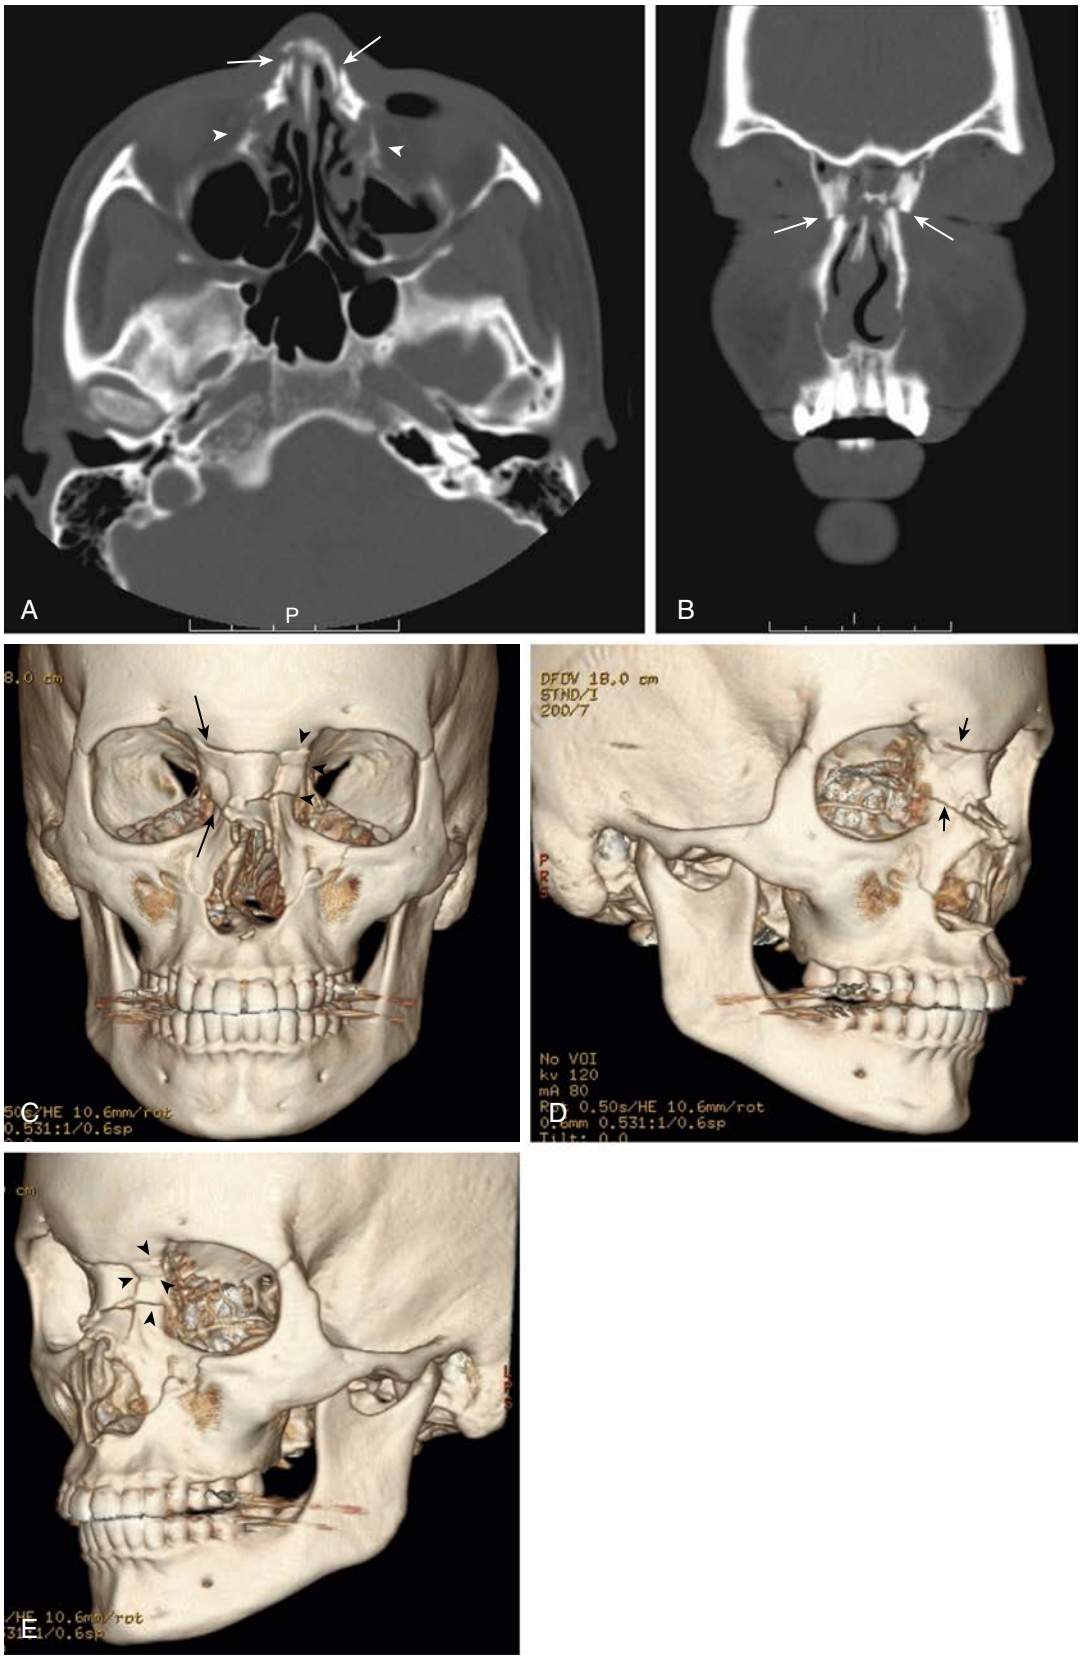
A less common form of maxillary fracture that is independent of the Le Fort schema is the palatal fracture, or sagittal maxillary fracture.[42,43] In this fracture pattern, the fracture propagates along the sagittal or parasagittal planes of the hard palate, separating the maxilla into right and left symmetric segments or greater and lesser asymmetric segments. A malocclusion due to widening of the maxilla is often present. Associated fractures of the alveolar ridge, nasal septum, and maxillary sinus walls are common. Physical examination may be notable for missing or mobile teeth within a mobile alveolus. If there are teeth missing that were not otherwise known to be missing prior to injury and are not identifiable on clinical exam or facial imaging, a plain radiograph of the chest should be performed to exclude tooth aspiration.

Mandibular Fractures

The only mobile bone within the facial skeleton, the mandible is a complex, U-shaped structure with bilateral articulations with the skull base. With its prominent position in the lower face, the mandible is also among the most frequently fractured facial bones.[44-47] Almost half of all patients with maxillofacial injuries have a fracture of the mandible.[47] Given their frequency and the potential complexity of management, any clinician treating patients with maxillofacial injuries should be well-versed in the various radiographic methods for diagnosis of mandibular fractures. Although there is no universally accepted classification scheme for mandibular fractures, an adequate clinical description will include location, pattern, and displacement.

For the purposes of localization of zone of injury, there are six distinct regions of the mandible that are commonly fractured: the condyle/condylar neck, ramus, angle, body, symphysis/parasymphysis, and alveolus (Figure 3-16). The most common location for mandibular fractures is the mandibular body, defined as the region between the distal aspect of the mandibular canine and the distal aspect of the mandibular second molar.[44] The condylar/subcondylar region is the next most frequent, followed by the angle and symphysis/parasymphysis. Isolated injuries to the alveolus and coronoid process are relatively rare, with only the former readily apparent on clinical examination. The most often misdiagnosed or undiagnosed fractures are condylar fractures, particularly intracapsular fractures. This latter finding has important implications for management, as an undiagnosed and untreated intracapsular fracture can result in temporomandibular joint ankylosis.

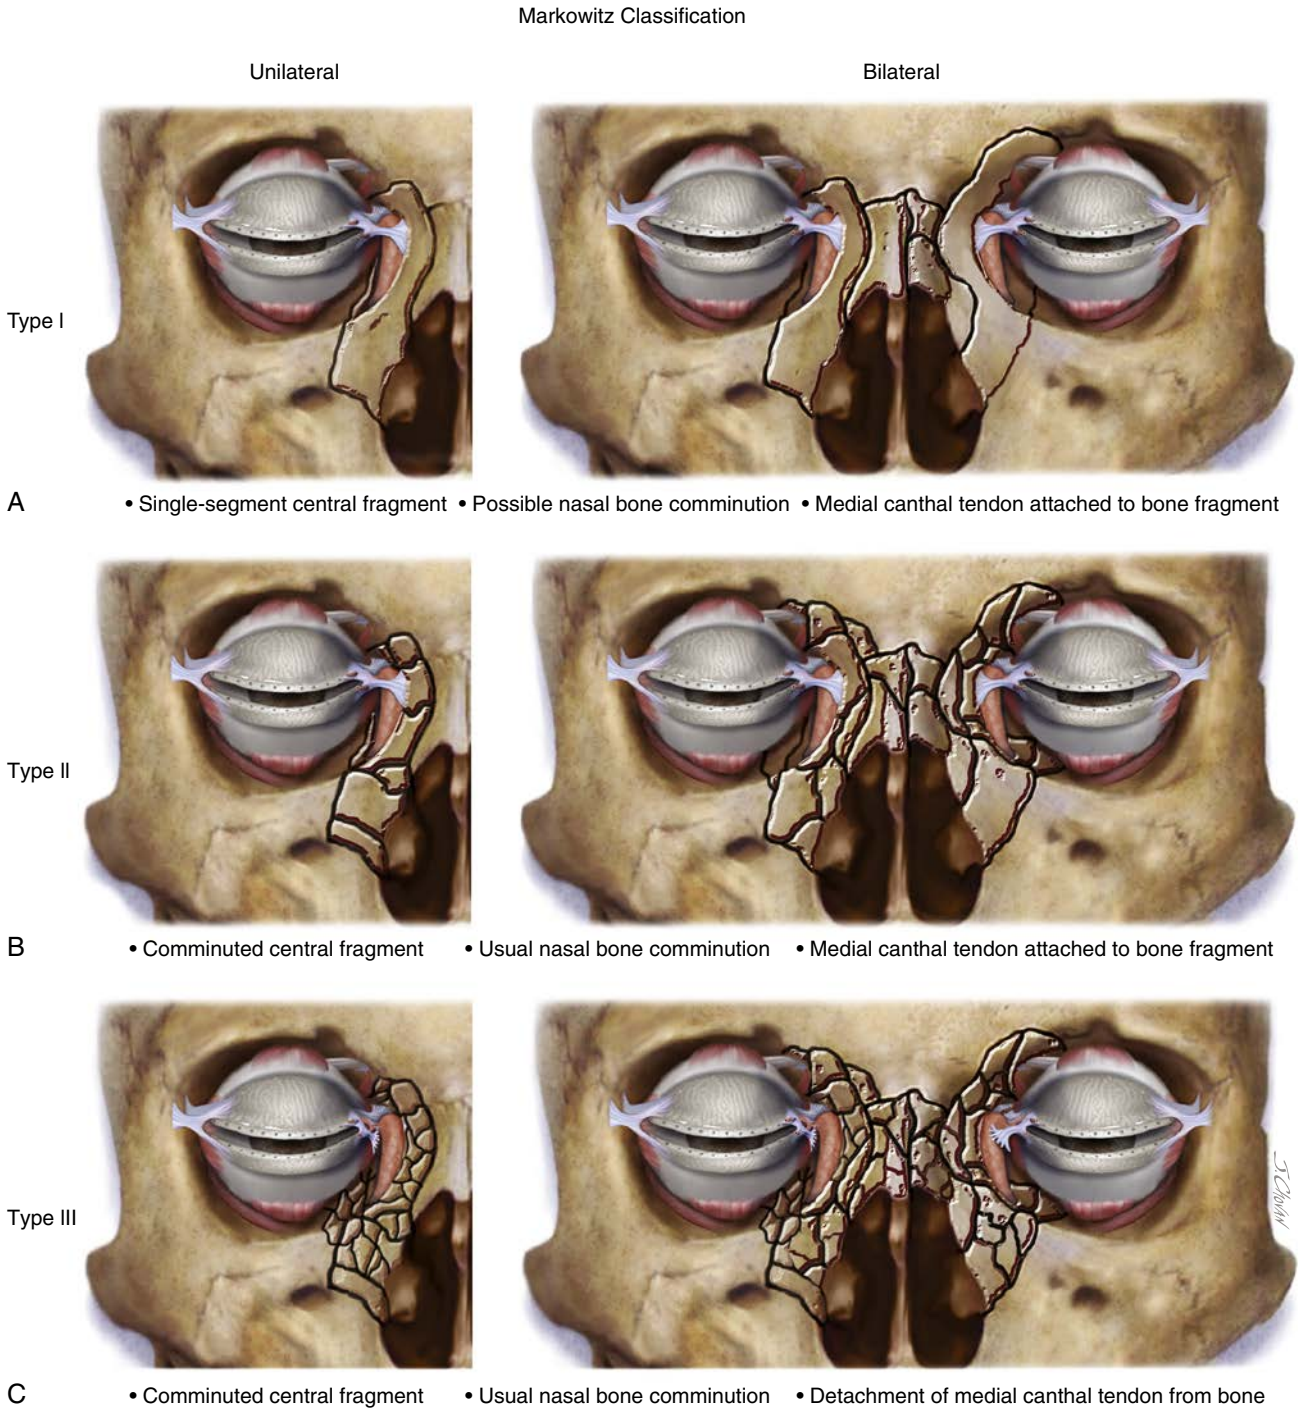
Knowledge of mandibular biomechanics and fracture patterns is required to carefully evaluate imaging in a



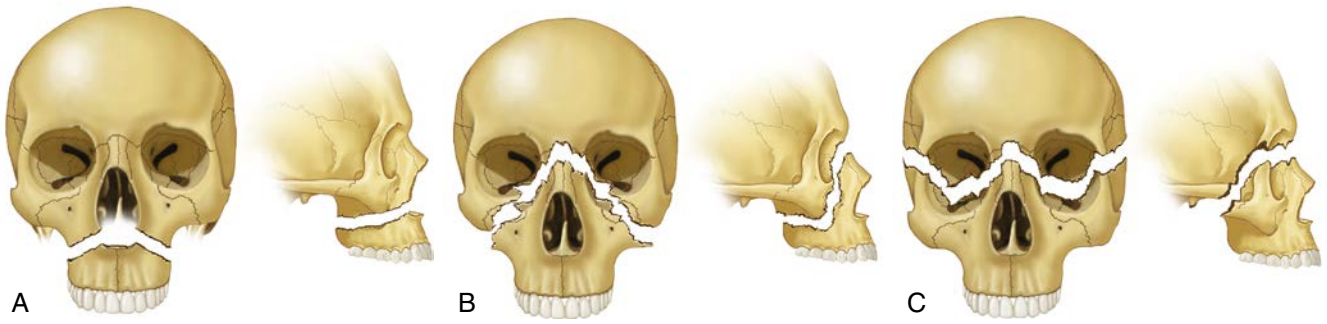
• **Figure 3-11** Naso-orbito-ethmoid (NOE) fracture: type I on right, type II on left. **A**, Axial view shows bilateral nasal bone fractures (*arrows*), disruption of the ethmoid sinus and medial wall of orbit (*arrowheads*). **B**, Coronal image displaying lateral displacement of the nasal processes of the maxilla with displacement laterally (*arrows*). **C**-**E**, Three-dimensional frontal (**C**), right (**D**), and left (**E**) lateral show the right-sided fractures (*arrows*) (type I) and comminution of the left side (*arrowheads*) (type II).

TABLE 3-4 Naso-orbito-ethmoid Classification System

Type	Characteristics
I	Single non-comminuted central fragment, no medial canthal tendon disruption
II	Comminution of central fragment, no medial canthal tendon disruption
III	Comminution of central fragment with medial canthal tendon disruption



• **Figure 3-12** Naso-orbito-ethmoid (NOE) fractures can be classified into three types. **A**, Type I fractures have a large central fragment containing the medial canthal tendon (MCT). **B**, Type II fractures have comminution of the central fragment, but the MCT remains attached. **C**, Type III fractures have comminution and disruption of the attachment of the MCT. (From Kademani D, Tiwana P, editors: *Atlas of oral and maxillofacial surgery*, 1e, Philadelphia, 2015, Saunders.)



• **Figure 3-13** Le Fort fractures display classic fracture patterns along three levels. **A**, The Le Fort I fracture occurs along the anterior maxilla extending from the pyriform rims posteriorly through the maxillary sinus to the pterygoid plates. **B**, Le Fort II fractures are referred to as pyramidal when bilateral, as they extend from the nasofrontal suture through the medial orbital wall, floor, and infraorbital rim down to the pterygoid plates. **C**, Le Fort III fractures extend from the nasofrontal suture laterally and include the zygomas, resulting in a craniofacial dysjunction. (From Fonseca RJ, Barber HD, Powers MP, Frist DE, editors: *Oral and maxillofacial trauma*, 4e, Philadelphia, 2013, Saunders.)

patient with a suspected mandibular injury. Because of the U-shape of the mandible, forces applied to a single area of the bone will be transmitted along its contour proximally and distally. This often results in simultaneous fractures of the mandible and contre-coup injuries. Common patterns of fracture include fractures of the angle and contralateral body, bilateral angle fractures, and angle with contralateral subcondylar fractures.

From a biomechanical standpoint, fractures of the mandible are classified as favorable or unfavorable based on the relationship of the fracture trajectory relative to masticator muscle pull. Horizontally favorable fractures are those in which the fracture trajectory is perpendicular to the long axis of the masseter and medial pterygoid fibers. In this pattern, muscle pull will act to reduce the fracture. Horizontally unfavorable fractures are those in which the fracture orientation is parallel to the vector of muscle pull, resulting in displacement with muscle contraction. Vertically favorable fractures are those in which the fracture line, as viewed in the axial plane, is parallel to the medial pterygoid fibers. Unfavorable fractures will be oriented perpendicular to the medial pterygoid muscle fibers (or parallel to the lateral pterygoid fibers).

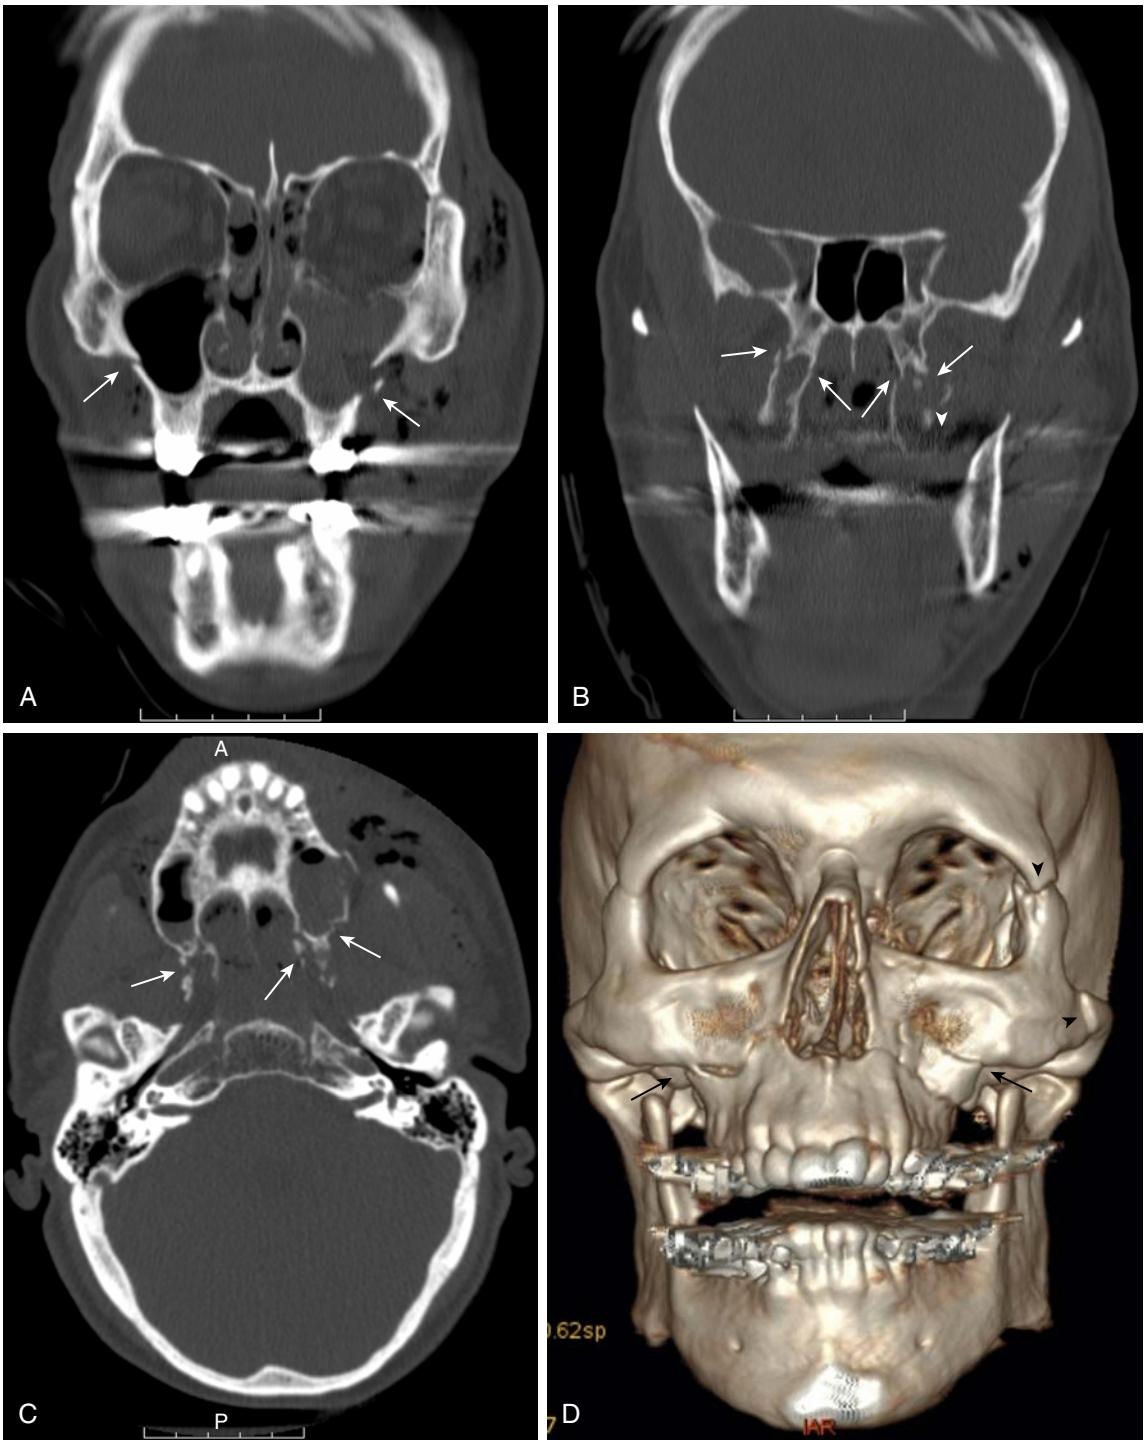
A rare pattern of injury that is of extreme clinical importance is the bilateral parasymphysis pattern, in which the genioglossus muscle attachment is in a single, centralized piece of bone, not attached to the remainder of the mandible. In this setting, the central segment is a "flail segment" that may allow for glossoptosis and airway embarrassment.

Although the majority of patients with facial injuries consistent with mandibular fractures will be imaged with MDCT, isolated mandibular fractures remain one area where plain film imaging may be adequate for diagnosis and management.[48] Regardless of the modality used for imaging, it is our practice to include a panoramic radiographic evaluation on all patients with mandibular injuries. There are two important reasons for this: (1) There are rare documented cases in which mandibular fractures were missed on facial CT due to the orientation of the fracture relative to the CT slice orientation, and (2) most patients with mandibular fractures will be followed with some form of imaging to assess healing for removal of fixation and/or resumption of regular dietary activities. With increasing concerns about cumulative radiation doses, plain film imaging is the modality of choice for following patients, and thus the initial assessment should include a plain film for baseline evaluation.

An isolated mandibular series is useful for imaging patients with a suspected mandibular fracture and no other facial fractures and can be particularly helpful if there is availability of panoramic radiography is available and a CT scan is not clinically necessary. The mandibular series consists of a Towne's view, bilateral oblique views, and posterior-anterior views of the mandible. The Towne's view (anterior-posterior) is an excellent method of visualizing the mandibular condyles/subcondylar region. Oblique views are generally adequate for visualizing the mandibular body, angles, and ramus. The posterior-anterior view is excellent for visualizing the symphysis and parasymphysis.

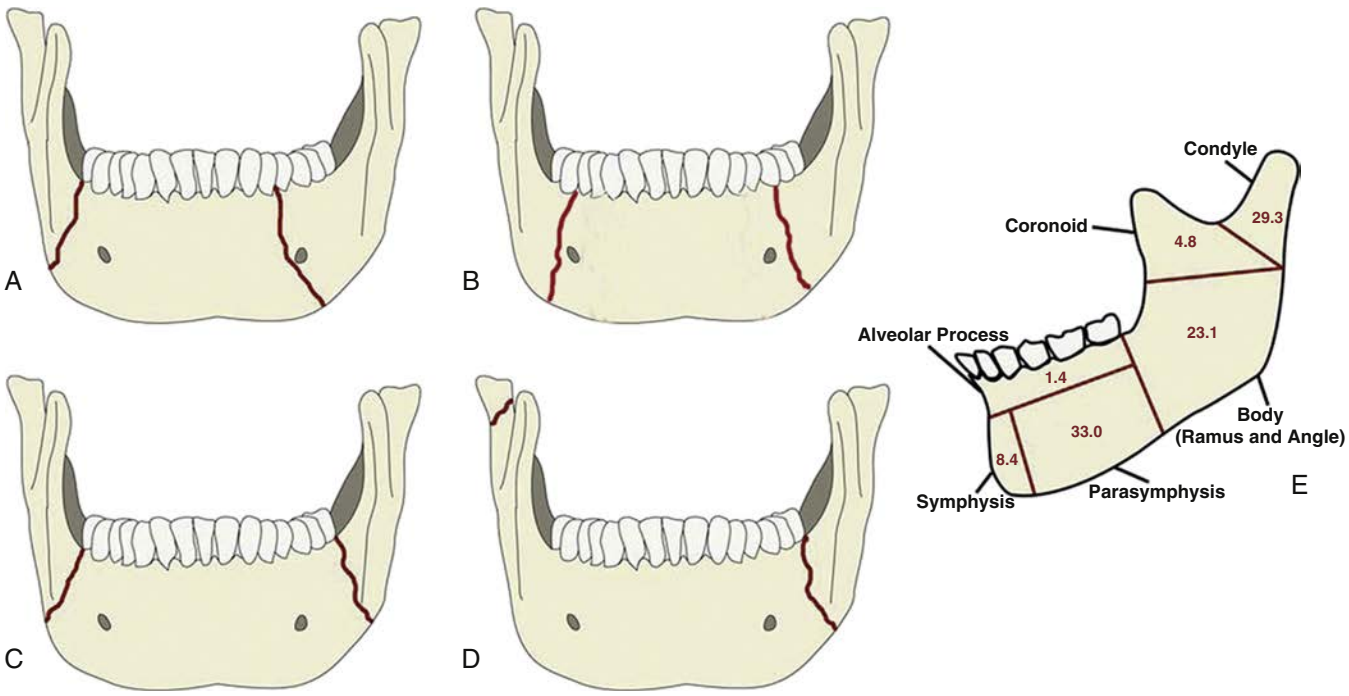
Condylar Fractures

Trauma to other parts of the mandible generally directs force toward the temporomandibular joint and often results in fractures of the condylar process or subcondylar region. Fractures to the area are divided into intra- and extracapsular fractures. Intracapsular fractures are more common in children and can be easily missed on plain films. Fractures that occur below the condylar head within the condylar neck down to the sigmoid notch are considered extracapsular or subcondylar. Unilateral subcondylar fractures often occur with contralateral angle or parasymphysis fractures. A blow to the chin may result in bilateral condylar fractures along with a fracture of the symphysis. The fractured condyles can be displaced in any direction but are often anteromedially displaced due to the pull of the lateral pterygoid muscle (Figure 3-17).



• **Figure 3-14** Le Fort I fracture. **A**, Coronal image shows bilateral fractures through the lateral wall of the maxillary sinuses just above the dentoalveolar segment of the maxilla (*arrows*). **B**-**C**, Coronal image (more posteriorly) and axial image show fractures through the bilateral pterygoid plates (*arrows*). **D**, Three-dimensional reformat showing the fractures extending from the pyriform apertures posteriorly toward the pterygoid plates (*arrows*). There is a concomitant zygomaticomaxillary fracture (*arrowheads*).

• **Figure 3-15** Le Fort II fracture. **A**-**C**, Coronal images moving anterior to posterior show fractures through the nasofrontal suture (*arrows*), pyramid-shaped combination of fracture (*lines*) through the orbital floor and lateral wall of the maxillary sinus, and pterygoid plates (*yellow arrows*). **D**, Axial image showing the pterygoid plate fractures (*arrows*).



• **Figure 3-16** Pattern and incidence of mandibular fractures **A**, Parasymphysis and contralateral body. **B**-**C**, Bilateral body and angle fractures, respectively. **D**, Mandibulary body and contralateral condyle. **E**, Incidence (%) of fractures by location. (From Avery LL, Susarla SM, Novelline RA. Multidetector and three-dimensional CT evaluation of the patient with maxillofacial injury, *Radiol Clin North Am* 49(1):183-203, 2011.)

Plain films can demonstrate disruption of the posterior margin of the condylar neck or loss of vertical height of the condyle-ramus unit (see Figure 3-17, *A*). Intracapsular fractures can be missed and are best found via CT scan (Figure 3-18). Missed intracapsular fractures can have significant articular consequences, particularly in children.

Coronoid Process and Ramus Fractures

Fractures involving the coronoid process and/ramus are rare, accounting for less than 2% of mandibular fractures.[47] The coronoid is protected by the zygoma and arch, whereas the ramus is relatively dense compared to the adjacent subcondylar region and mandibular angle, which are far more commonly fractured.

Mandibular Angle Fractures

Fractures of the mandibular angle are among the most common mandibular fractures. Inherent weaknesses at the mandibular angle, such as the third molar, make the region prone to fracture with blows to the contralateral parasymphysis or ipsilateral mandibular body. The fracture usually extends superiorly from the retromolar region in the area of the third molar posteriorly toward the mandibular angle and is easily detected on plain films such as the panoramic radiograph or ipsilateral lateral oblique view.

Mandibular Body Fractures

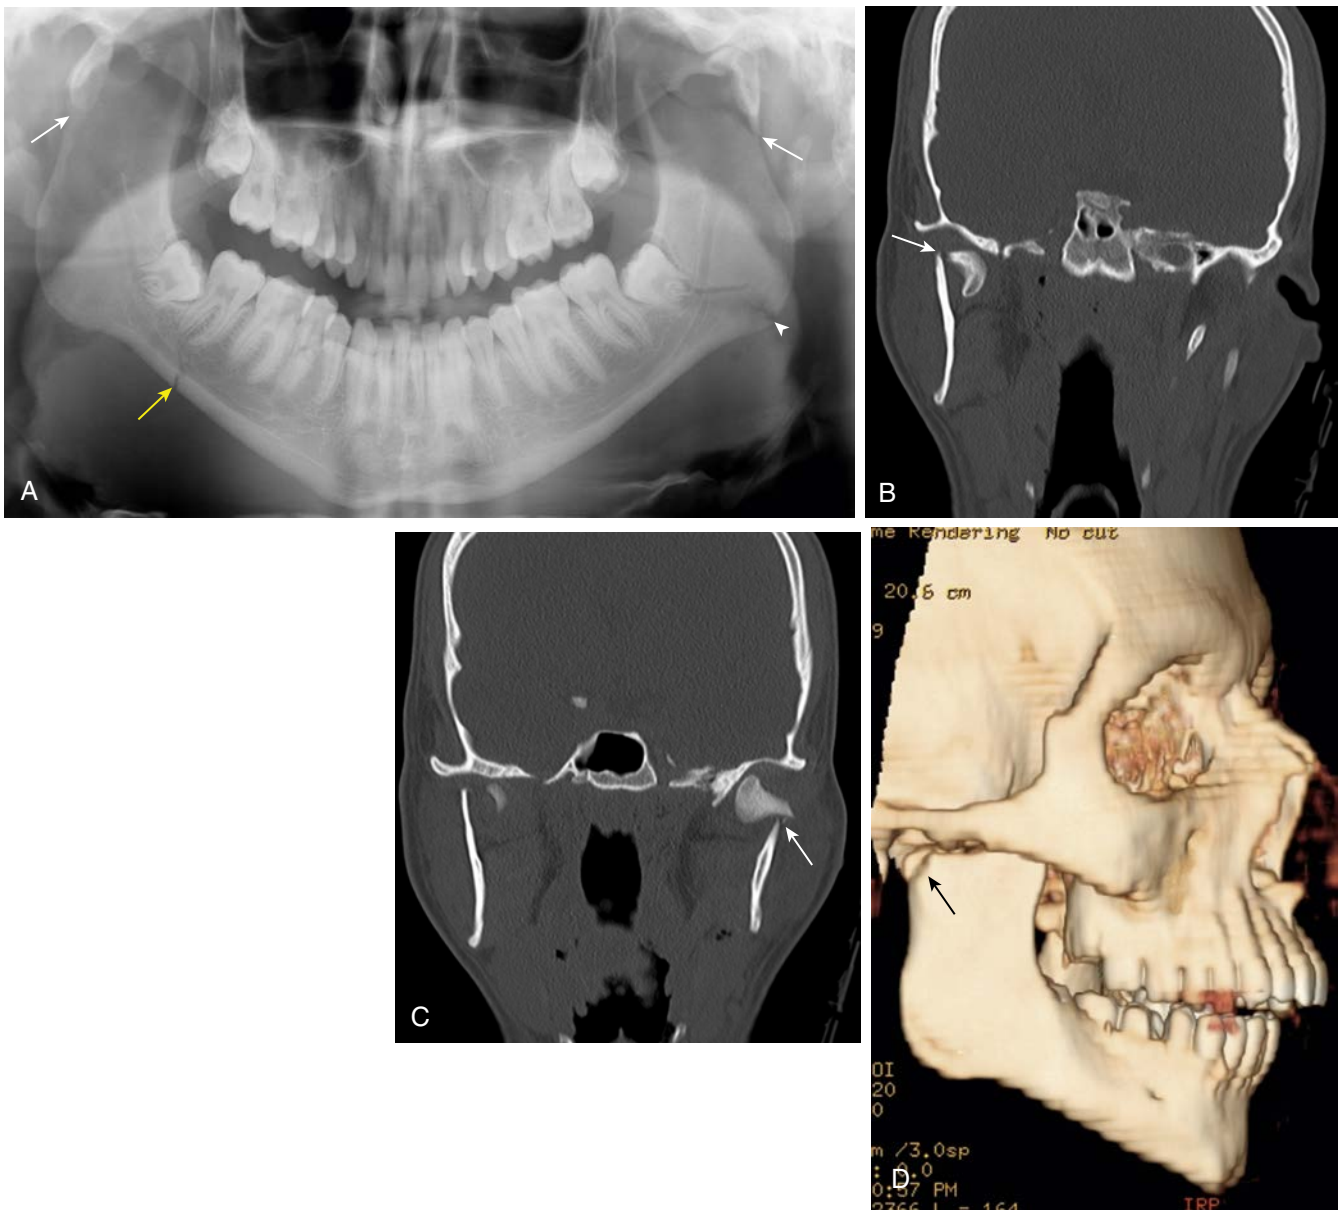
A blow to the ipsilateral mandibular body commonly results in a fracture that traverses through existing teeth. This often results in a step-off the occlusion at the site of fracture and are generally considered compound fractures (Figure 3-19). Edentulous mandibles are particularly prone to mandibular body fractures (Figure 3-20) due to atrophy of the posterior mandibular alveolus with early loss of mandibular teeth.

Mandibular Symphysis Fractures

Mandibular symphysis and parasymphysis fractures occur in the areas between and including the mental foramina. Fractures in this area are often oblique and can be missed on a plain films. The clarity of the image of the mandibular parasymphysis in a panoramic radiograph is variable because of the narrow focal trough. A CT scan is often needed to appreciate the presence and direction of the fracture.

Pathologic Fractures

Mandibular fractures can result from inflammatory or neoplastic processes affecting the structure and integrity of the mandible. Osteoradionecrosis of the mandible can progress to the inferior border and result in a pathologic fracture (Figure 3-21, *A*). Weakening of the mandible after removal of deeply impacted mandibular third molars can lead to

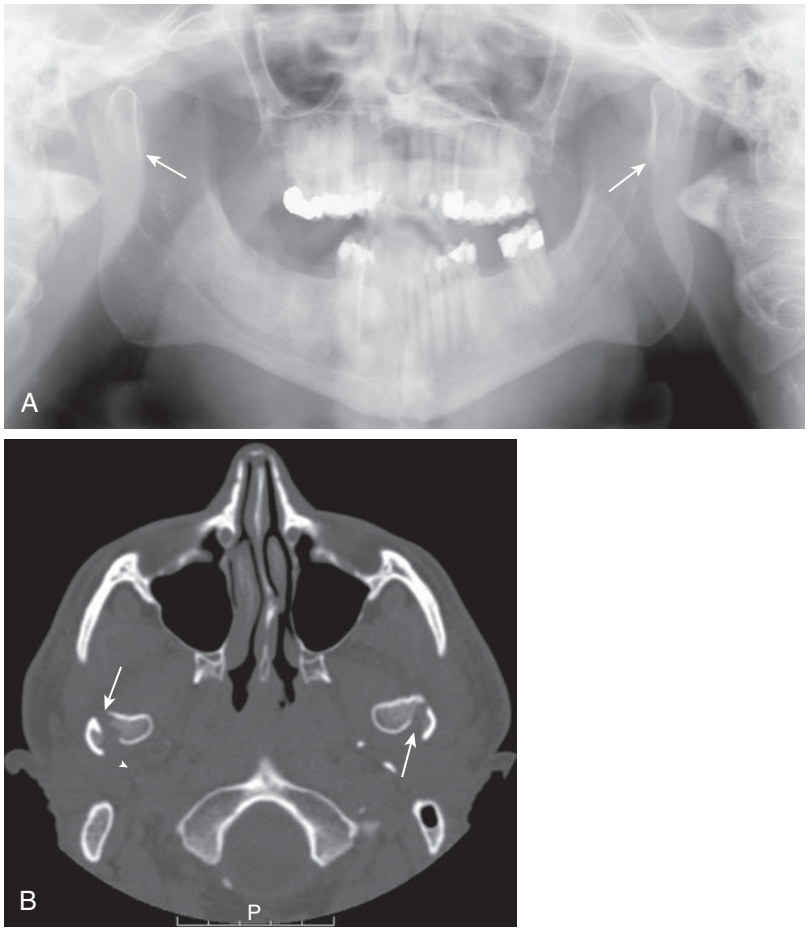


• **Figure 3-17** Multiple mandible fractures. **A**, Panoramic radiograph shows loss of continuity of the bilateral posterior ramus (*arrows*) indicating subcondylar fractures. Fractures are also seen of the left angle (*arrowhead*) through the impacted third molar and right body (*yellow arrow*). **B**, Coronal image shows high right subcondylar fracture with medial displacement of the condylar head out of the glenoid fossa (*arrow*). **C**, Coronal image shows low subcondylar fracture (*arrow*) also with medial displacement. **D**, Three-dimensional view highlights the high right subcondylar fracture with loss of ramus height (*arrow*).

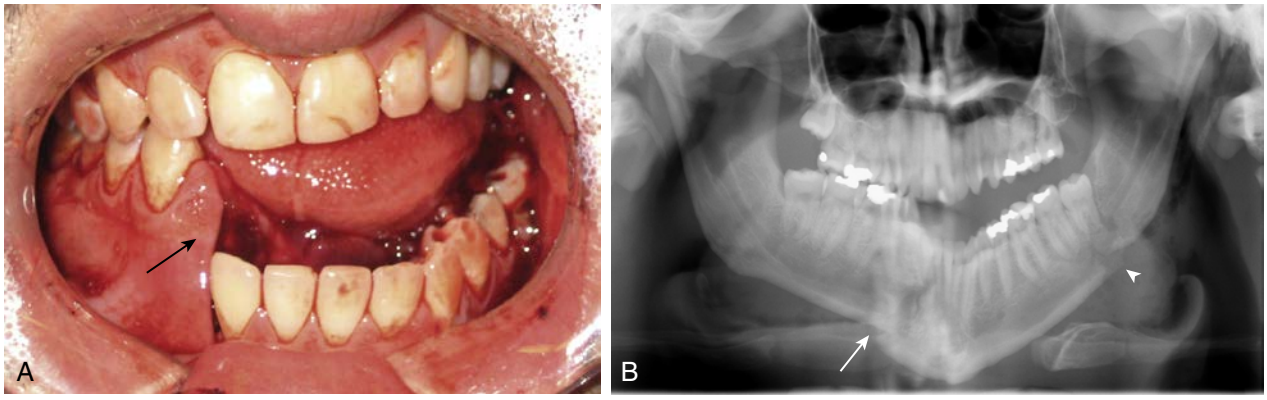
pathologic fracture, particularly in those patients where the third molar makes up a large portion of the vertical height of the mandible (see Figure 3-21, *B*, *C*).

Pediatric Facial Fractures

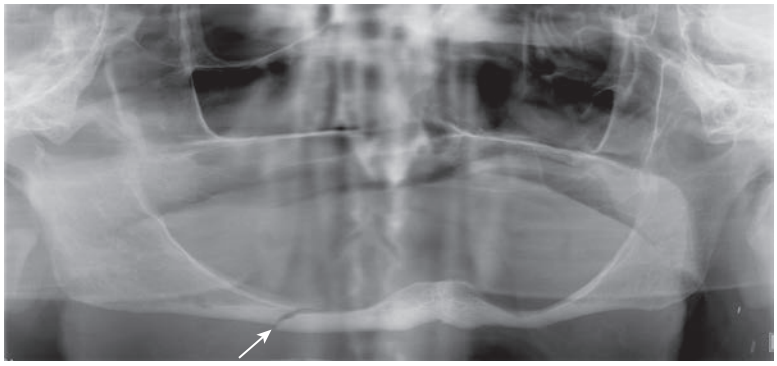
Growth is a confounding variable in the biomechanics of the facial skeleton. The growing facial skeleton has different stress points than the mature facial skeleton, and patterns of fractures are consequently different in children compared to adults.[49-51] Nasal fractures are the most common type of facial fracture in children, but mandibular fractures remain the most frequent cause of hospitalization, as they almost always necessitate some form of treatment. The distribution of mass within the pediatric facial skeleton (prominent cranium, non-pneumatized sinuses within the maxilla) results in more frequent injuries to the condylar/subcondylar regions (Figure 3-22) of the mandible and the frontal bone/orbital roof, with less frequent injuries to the midface.[51,52] When midfacial injuries do occur, they do not follow the



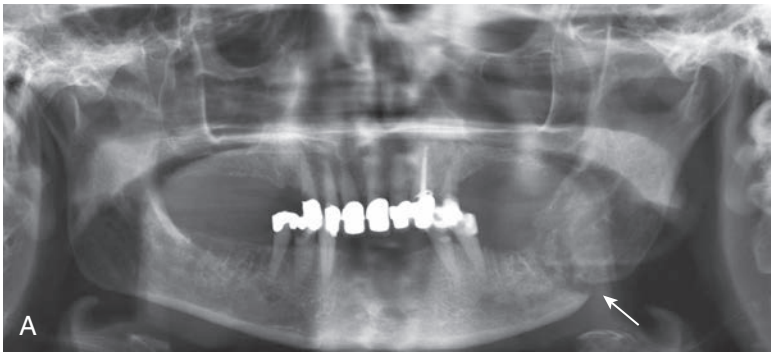
• **Figure 3-18** Bilateral mandibular condyle fractures (intracapsular). **A**, Panoramic radiograph shows disruption of the condylar head with displacement anterior to the articular eminences bilaterally (*arrows*). **B**, Axial image confirms intracapsular condylar fractures with displacement of the bilateral medial poles (*arrows*). The ramus heights are not substantially changed, and the malocclusion was subtle.

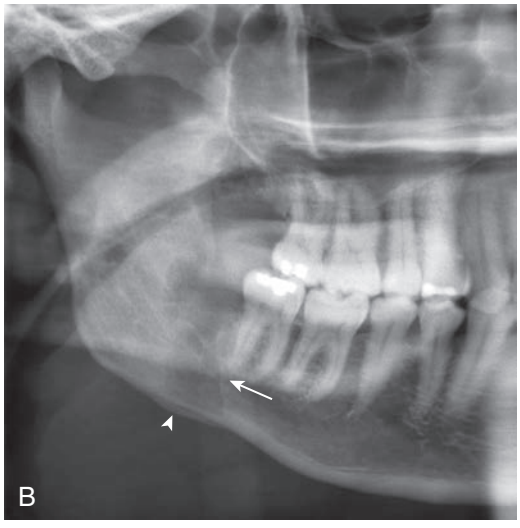


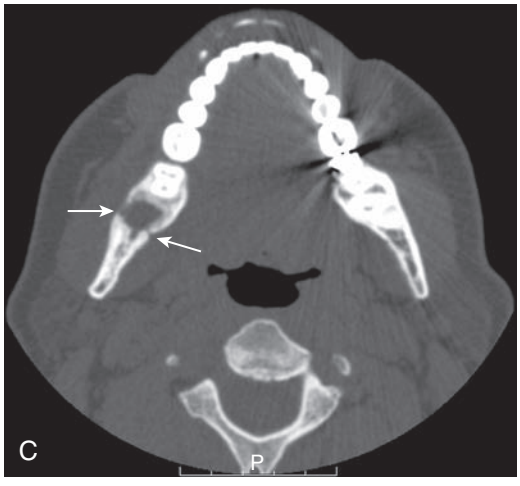
• **Figure 3-19** Mandibular body fracture. **A**, A stepoff in the occlusion (*arrow*) indicates a fracture between the teeth and represents a compound fracture. **B**, Panoramic radiograph demonstrating right mandibular body fracture (*arrow*) and left mandibular angle fracture (*arrowhead*).



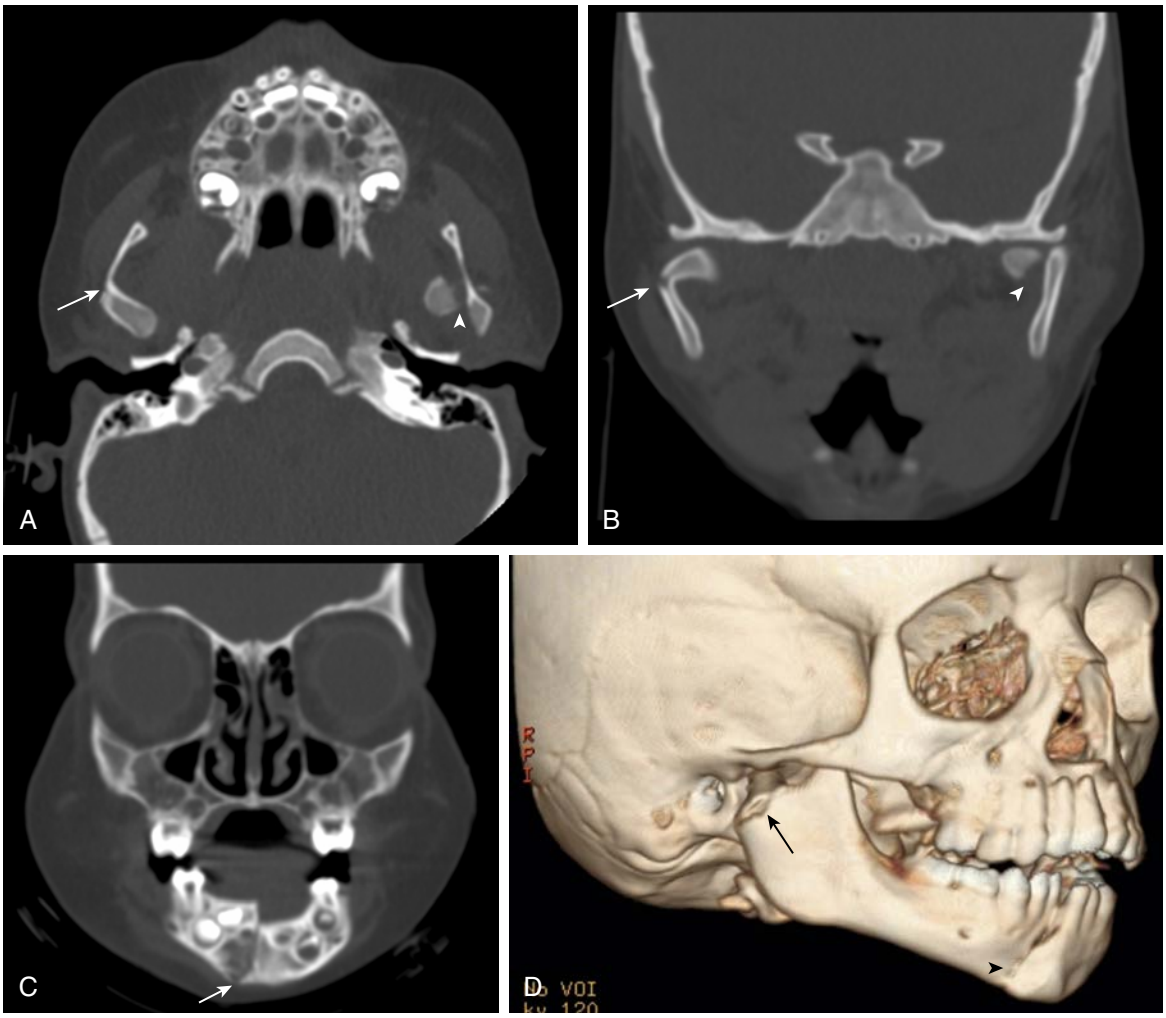
• **Figure 3-20** Fractures of edentulous mandibles typically occur in the region of the mandibular body (*arrow*) after longstanding edentulism of the posterior mandible.







• **Figure 3-21** Pathologic fractures occur in compromised areas. **A**, Osteoradionecrosis has progressed to the inferior border and resulted in a pathologic fracture of the left mandibular body (*arrow*). **B**, After extraction of a deeply impacted third molar, the patient had persistent pain. A panoramic radiograph showed a linear radiolucency (*arrow*) and periosteal reaction (*arrowhead*). **C**, Axial CT image confirmed pathologic fracture through the third molar extraction socket (arrows).



• **Figure 3-22** Pediatric mandibular fractures. **A-B,** Axial (**A**) and coronal (**B**) image shows right subcondylar fracture that is medially displaced with bending without displacement of the medial cortex (*arrows*) along with left intracapsular condyle fracture (*arrowheads*). **C**, Coronal image showing displaced symphysis fracture through tooth buds (*arrow*). **D**, Three-dimensional view of right subcondylar fracture (*arrow*) and symphysis fracture (*arrowhead*).

typical patterns described by Le Fort. Rather, they are more obliquely oriented across the zone of injury. Incomplete ossification of the facial skeleton results in bending in response to stress, with resultant greenstick or incomplete fractures.

Though there are reasonable concerns regarding the use of CT scans in children, CT imaging is the most accurate method of diagnosing facial fractures within this population. Clear discussions between the emergency personnel, surgeon, and radiologist are required to identify the most appropriate method of imaging for a particular injury presentation. Most institutions have diagnostic protocols for low-dose CT imaging for pediatric patients. Such protocols should be used whenever possible.

Children with facial injuries may, unfortunately, be victims of abuse.[49-51] If there is a suspicion of abuse, a skeletal survey to identify other injuries or old injuries in distant parts of the body is required and should be discussed with the radiologist.

Craniomaxillofacial Fractures with Associated Cervical Spine or Intracranial Injury

Among patients who present with facial trauma, 4% to 10% will have concomitant cervical spine injuries and up to 50% will have concomitant intracranial injuries.[53-56] Fractures of the frontal bone and orbital roof are associated with increased incidence of craniocervical injuries. Severe bilateral midfacial injuries are associated with skull-base injuries and death. Unilateral fractures of the nasal, orbital, zygomatic, and maxillary regions have been associated with skull-base fractures and intracranial injuries. Isolated mandibular fractures are associated with cervical spine injury. These associated patterns of injury should prompt the treating clinician to consider additional CT imaging of the cervical spine and head in patients who present with facial trauma.

Summary

Diagnostic imaging has a critical role in the management of facial trauma. Advances in imaging continue to improve the diagnosis and management of maxillofacial trauma.

Soft Tissue Injuries of the Face, Head, and Trunk

PHILLIP N. FREEMAN, JAMES W. WILSON, KEVIN C. GAMS

Facial wounds are among the most commonly encountered problems in emergency departments (ED). Approximately one third of all lacerations occur in adults between the ages of 19 and 35 and predominantly in male patients, with approximately 50% occurring in the head and neck.[1-3] Injury patterns vary greatly, with trips and falls commonly causing isolated soft tissue injuries such as laceration and contusions mainly in children and the elderly.[4] Violence and motor vehicle accidents are among the most common causes of injury in individuals aged 15 to 50 years old.[3-5] Violence is most frequently by sharp injury from glass, knives, and wooden objects. In the United States motor vehicle collisions are the most prevalent cause of soft tissue damage to the face. More than 146,000 patients annually require hospital attention for facial soft tissue trauma.[6] Human and animal bites make up a small but significant percentage of soft tissue injuries. Burns, although infrequent compared to other wounds, also make up a small but significant percentage of facial wounds.

Initial Evaluation

Evaluation and management of trauma patients requires the advanced trauma life support (ATLS) protocol with a primary trauma survey followed by a secondary assessment for concomitant injuries.

A comprehensive head and neck exam should be performed to assess the extent of hard and soft tissue injury to determine the appropriate steps in management. All wounds should be evaluated for depth, size, and status of the wound for contusions, abrasions, crush injury, viability of the wound edges, and contamination. During the assessment period or during treatment of other injuries, the wounds should be kept moist with gauze soaked in saline until final management. Hemorrhage associated with most head and neck wounds may be substantial but can usually be controlled with local measures of pressure and ligation, or electrocautery when vessels are directly visible and can be isolated with a forceps. Persistent bleeding should be evaluated by direct pressure for inspection to prevent damage to other vital structures.

Injured and exposed structures should be identified, evaluated, and documented, with particular attention to cranial nerves V, VII, and XII. This is critical in the conscious patient and must be done prior to the use of any local or general anesthetic. A nerve stimulator may be helpful to stimulate the appropriate muscle groups in the nonparalyzed patient under general anesthetic. If a nerve has been damaged, appropriate microsurgical techniques should be used to attempt to restore continuity and ultimate function of the nerve. Always inquire about functional deficits that existed prior to the injury.

Parotid duct injuries should be suspected in any patient with lacerations extending from the pretragal region to the middle half of the upper lip. In patients with a suspected parotid duct injury, the duct should be cannulated intraorally at the level of the second maxillary molar and visualized through the wound. The authors' preference for cannulation is the use of a J-wire followed by an intracatheter placed over the J-wire. If ductal injury is poorly visualized in the wound, liquids such as propofol or methylene blue may be injected into the duct to assess the location of the injury.

Exposed cartilage that cannot be covered initially should be dressed with mafenide acetate (Sulfamylon) 5% or silver sulfadiazine cream. As well, neurovascular structures that cannot be covered should be dressed with nonadherent dressings such as Xeroform gauze or Adaptic gauze with or without bacitracin ointment. Abrasions and superficial burns can be dressed with Adaptic gauze and bacitracin. Deep wounds that cannot be closed can be dressed initially with hydrogel bandages, normal saline Kerlix dressings or iodoform gauze until definitive closure can be obtained. Eyelid avulsion wounds require immediate ophthalmic

antibiotic ointment and an occlusive eye shield to prevent exposure keratopathy.

In isolated soft tissue injuries emergent airway stabilization is rarely indicated. However, in patients with soft tissue injuries that need tracheostomy there is a high associated mortality (11.5%) and a significantly longer hospital stay than in patients with craniofacial fractures.[7] The difference is primarily attributed to neurologic injury, which requires delay of soft tissue repair until after the patient is stabilized. All patients should be assessed for concomitant intracranial, craniofacial, ophthalmologic, and cervical spine injuries. Documentation of the timing and mechanism of injury as well as postinjury signs and symptoms such as loss of consciousness, nausea, and vomiting should be used to guide assessment and management. Increased vascularity of most craniofacial structures limits the risk of infection relative to delays in treatment.[8,9] Time from injury to repair was initially thought to be associated with an increased risk of infection but recently has been shown to be not specifically related to incidence of infections. Berk, Osbourne, and Taylor found that wound age was of little concern in wounds located on the scalp and face.[8] Factors such as diabetes, wound contamination, length greater than 5 cm and location are important risk factors for wound infection.[8]

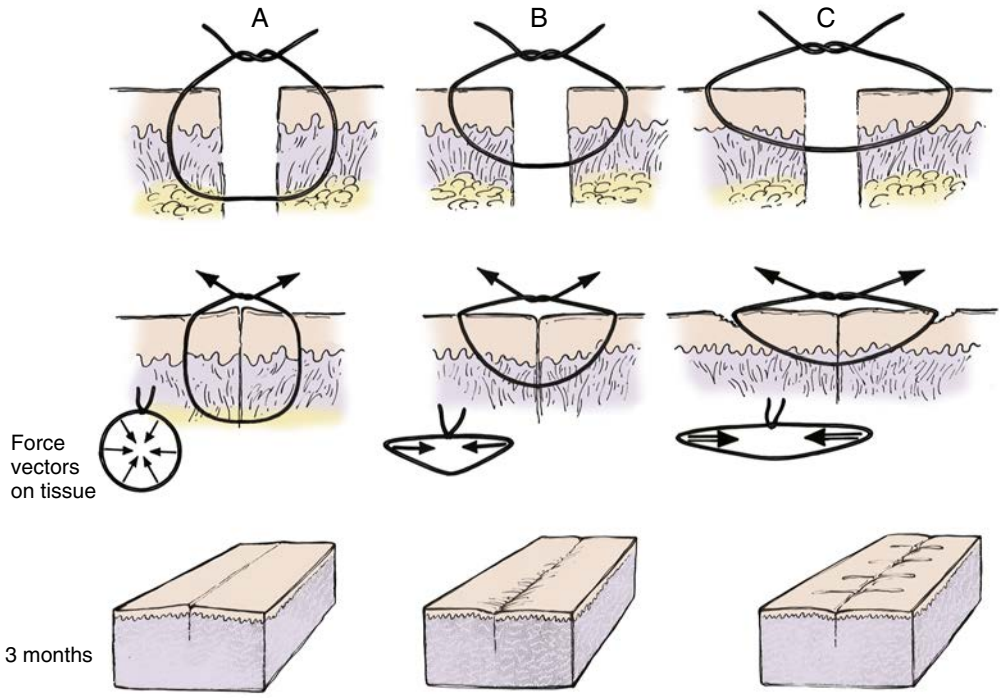
Improvements in decontamination by pressure irrigation over the past 30 years may have led to improved outcome.[10] It is also critically important to assess the mechanism of injury, as certain injuries that are associated with significant debris or wound contamination have been associated with increased incidence of infection. Impact crush injuries, for example, are as much as 100 times more susceptible to infection than are wounds caused by shear force.[11,12] Such wounds require pressure irrigation (< 15 psi) and debridement of all nonviable soft tissue to prevent postoperative infection. Also, photographs prior to injury are useful in identifying preexisting deformities and facial morphology.

Suture Technique and Suture Materials

Wound closure requires a variety of surgical techniques depending on the location of the wound, depth of the wound, anatomy of the wound margins, and presence of tissue edema.

Simple wound closure requires placement of sutures at the proper level in a trapezoidal fashion to create wound eversion. This principle applies to placement of subcutaneous sutures as well. Improper placement results in wound inversion (Figure 4-1). Multiple cutaneous suture techniques may be employed to accomplish the task of wound eversion as shown in Figure 4-2.

Simple wound closure that results in eversion and approximation of wound margins with subcuticular sutures

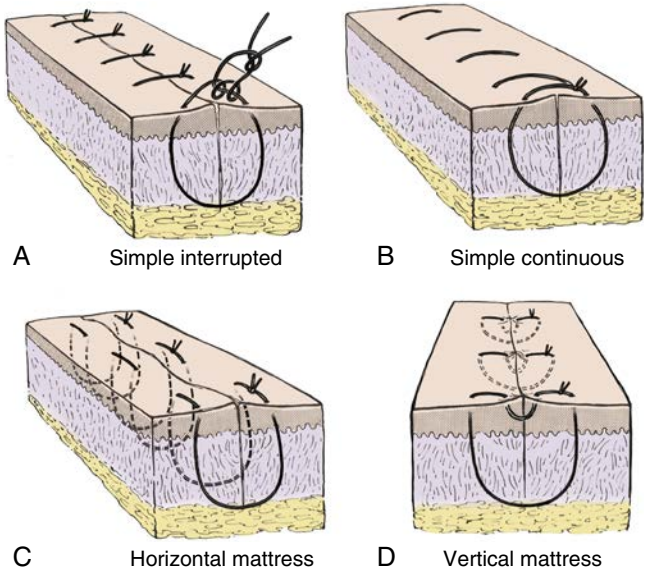


• **Figure 4-1** **A**, Proper placement of cutaneous suture showing equal distribution of tension along entire wound edge. Everted surgical would edges provide esthetic result. **B**, Improper placement of cutaneous suture with surgical bit too far from skin edge and too superficial. This creates vector forces that are greatest in a horizontal direction and produces inverted wound. **C**, Improper placement of cutaneous suture farther from skin edge with more superficial surgical bite. Force vectors on wound are greater in a horizontal direction and create more wound inversion. Additionally, permanent suture marks result in areas of pressure necrosis where wound closure tension is greatest. (From Sykes MJ, Byorth PJ: Suture needles and techniques for wound closure. In Baker SR, Swanson NA, editors: *Local flaps in facial reconstruction*, St. Louis, 1995, Mosby, p 56, Fig. 8, with permission.)

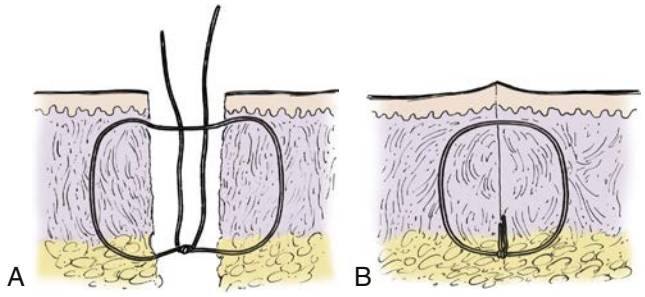
can be supported with paper tape for final closure, as seen in Figure 4-3. Paper tape alone may be used for closure of wounds that are superficial to the subcutaneous level, especially in pediatric patients.

In complex wounds, multilayered closure is required to eliminate dead space and provide wound eversion. This can be accomplished with either an interrupted suture or continuous suture technique as shown in Figure 4-4.

Closure of wounds with skin of unequal thickness requires placement of subcuticular sutures that maximize the cutaneous level and frequently requires modification of cutaneous suture placement (Figure 4-5). Staple closure may be used in a variety of circumstances but is most commonly used in the cutaneous closure of scalp. The proper placement of deep sutures and skin staples is demonstrated in Figure 4-6.



• **Figure 4-2** **A**, Simple interrupted suture. **B**, Simple continuous suture. **C**, Horizontal mattress suture. **D**, Vertical mattress suture. (From Sykes MJ, Byorth PJ: Suture needles and techniques for wound closure. In Baker SR, Swanson NA editors: *Local flaps in facial reconstruction*, St Louis, Mosby, 1995, p 57, Fig. 9, with permission.)



• **Figure 4-3** Schematic diagram of deep suture placement. Placement of deep sutures should eliminate dead space and accomplish wound edge approximation and eversion. (From Sykes MJ, Byorth PJ: Suture needles and techniques for wound closure. In Baker SR, Swanson NA editors: *Local flaps in facial reconstruction*, St Louis, Mosby, 1995, p 56, Fig. 7, with permission.)

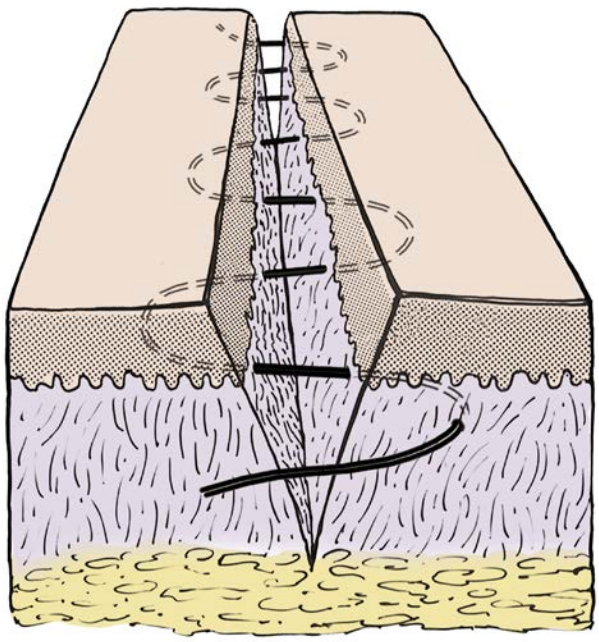
Understanding suture ideal characteristics for both absorbable and nonabsorbable materials is important in selecting the proper suture. There is no ideal suture for all wounds, therefore taking into consideration the ideal characteristics of suture material is important for selection of each particular wound. Box 4-1 lists the ideal suture material characteristics.

Familiarity with suture material terminology gives the surgeon a better understanding of suture material characteristics. This enables the surgeon to choose the suture best suited for the purpose at hand. Table 4-1 lists suture terminology. An excellent regional guide for suture selection is in Table 4-2.

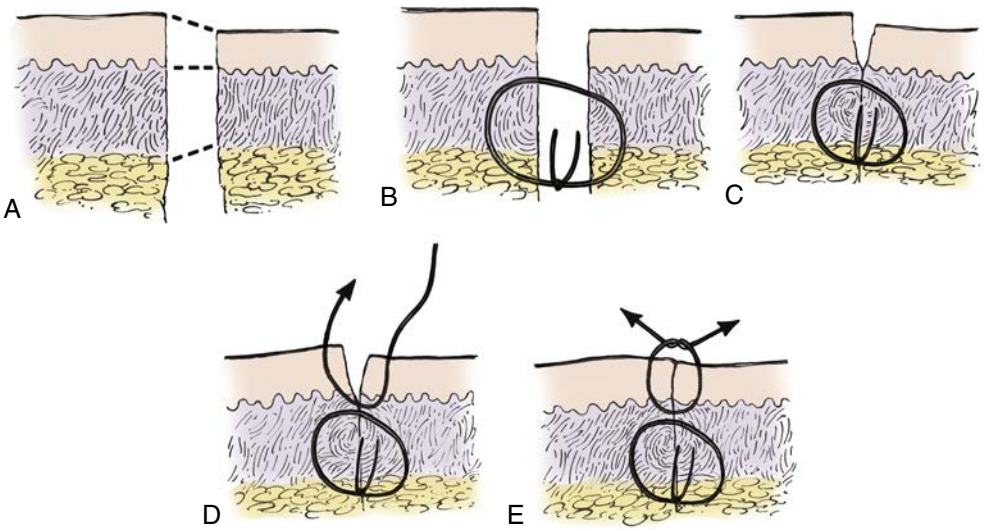
Suture materials are divided into natural fiber and synthetic fiber materials. Natural fibers are absorbable, although silk and cotton are extremely slow to be degraded over a period of several years and therefore considered to be nonabsorbable. Listed in Table 4-3 are natural materials and some of their characteristics, including tensile strength and absorption profile.

Synthetic fiber materials can be either absorbable or nonabsorbable. Absorbable synthetic fibers are polymers that degrade by hydrolysis and therefore cause less inflammation than natural fiber sutures. Listed in Table 4-4 are the absorbable synthetic suture materials and some of their characteristics, including tensile strength and absorption profile.

Synthetic nonabsorbable suture materials such as nylon and Prolene have long been the gold standard for cuticular closure. Nylon has a high level of elasticity and retains the



• **Figure 4-4** Intracuticular continuous suture. Cross-section of skin shows continuous suture at level of dermis to achieve maximal wound edge eversion. (From Sykes MJ, Byorth PJ: Suture needles and techniques for wound closure. In Baker SR, Swanson NA editors: *Local flaps in facial reconstruction*, St Louis, Mosby, 1995, p 58, Fig. 10, with permission.)



• **Figure 4-5** **A**, Schematic diagram illustrating two skin edges of unequal thickness. **B** and **C,** Placement of deep sutures in mismatched tissue to achieve maximal cutaneous alignment. Note suture is placed in dermis at deeper plane of thinner skin edge. **D** and **E,** Placement of cutaneous sutures in mismatched tissue to achieve maximal tissue eversion. (From Sykes MJ, Byorth PJ: Suture needles and techniques for wound closure. In Baker SR, Swanson NA editors: *Local flaps in facial reconstruction*, St Louis, Mosby, 1995, p 58, Fig. 11, with permission.)

most tensile strength of all synthetic materials. Prolene has the most pliability and knot-holding characteristic and is excellent for cuticular closure as well as vascular repair and approximation. Other synthetic suture materials have varied use as subcutaneous sutures for permanent holding characteristics. Table 4-5 lists the nonabsorbable synthetic suture materials and some of their characteristics.

Needle selection can be simplified into three categories: tapered, reverse cutting, and taper cutting. Further needle shapes are important for their particular utility and are divided based on their arc of curvature. Commonly used needles for wound closure include tapered for deep sutures and reverse cutting for skin closure. Tables 4-6 and 4-7 include needle types and shapes with their applications. Tissue sealants will be discussed in the section on postoperative wound care.

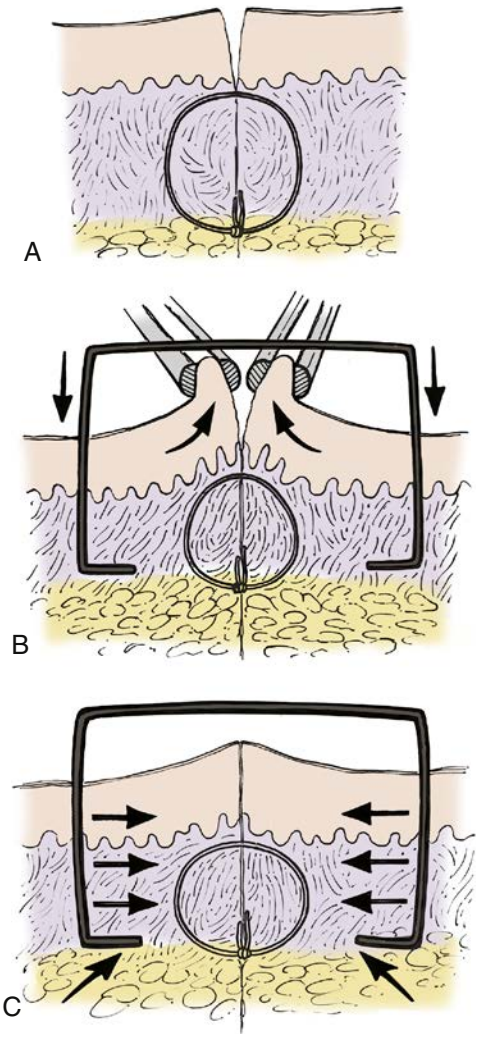
Principles of Wound Closure

Crikelair[14] listed the Halstedian fundamentals of surgical wound closure that apply to the management of any skin wound. These principles are: (1) place incisions to follow tension lines and natural folds in the skin; (2) handle tissue gently and debride only as much as necessary to ensure an adequately clean bed; (3) ensure complete hemostasis; (4) eliminate tension at the skin edges; (5) use fine sutures and remove them early; and (6) allow time for scars to mature before repeat intervention.

Wound closure requires a variety of surgical techniques for managing closure depending on the location of the wound, conformation of the wound (linear vs. curvilinear), depth of the wound, wound margins, and presence of abrasion, contusion, or avulsion. Isolated soft tissue wound closure should be performed as soon as possible, even with significant concomitant injuries. This approach has been shown to have improved postoperative esthetic outcomes.[14,15] Ideally, closure of facial soft tissue injuries should occur within the first 8 hours after injury. Soft tissue swelling associated with delay in wound closure can obscure anatomic landmarks and make primary closure more difficult. Closure in the ED requires meticulous cleaning of debris under nerve block with local anesthesia prior to closure.[16] Contraindications to primary closure in the ED include extensive lacerations, tissue closure that would result in significant tension, wounds that require complex tissue rearrangement, significant wound contamination, concomitant injuries that require general anesthesia (duct and nerve injuries), and inability to achieve adequate hemostasis or visualization in the ED setting. Wounds covering facial nerve or parotid duct injuries should be closed only after operative management of the deeper injury is complete.

Most lacerations can be treated using regional nerve blocks with small quantities of local anesthesia containing epinephrine and supplemented with 1:100,000 epinephrine solution where additional vasoconstriction is needed.[16] Pediatric patients who do not tolerate injection of local anesthesia may require conscious sedation for proper management of soft tissue injuries larger than 3 centimeters in length.

Optimizing wound healing through proper acute wound management involves removal of harmful debris/necrotic tissue, exploration for underlying injuries, control of bacterial burden, and multilayered closure. If wound contamination is present, wounds can be cleaned with a surgical antiseptic, preferably chlorhexidine gluconate.[17,18] Care must be taken not to scrub the wound because this can increase inflammation and result in poor esthetic outcome. Copious irrigation



• **Figure 4-6** **A,** Deep tissue approximation required prior to placement of surgical staple. **B**, Tissue forceps approximating and everting skin edge during application of surgical staple. **C,** Appearance of surgical wound after appropriate placement of surgical staple. Note equal and well-distributed horizontal vector forces on tissue edge after appropriate placement. (From Sykes MJ, Byorth PJ: Suture needles and techniques for wound closure. In Baker SR, Swanson NA editors: *Local flaps in facial reconstruction*, St Louis, Mosby, 1995, p 59, Fig. 12, with permission.)

should be performed in all contaminated wounds and any wounds treated more than 6 hours after injury. Irrigation volumes of 50 to 100 mL per cm of laceration length have been reported to be appropriate for contaminated wounds. Clean, uncontaminated wounds treated early do not benefit from irrigation.[19] Pressure irrigation, which has been shown to improve decontamination of wounds, can be performed in the ED setting using a 35-cc syringe and an 18 gauge catheter. Longmire[21] found that pressures of 13 psi, generated by using a needle and syringe, were effective in reducing inflammation and infection when compared to irrigation using a bulb syringe associated with lower pressures. Pressures of 8-12 psi in the wound are believed to overcome the adhesive forces of the introduced bacterium.[20] After cleansing, all irregular wound edges and devitalized tissues should be debrided. In cases such as crush injuries where the extent of injury is unclear, tissues should be loosely approximated until the wound viability is assured.

• BOX 4-1 Ideal Suture Material Characteristics

- Minimal tissue injury
- Minimal tissue reaction
- Ease of handling
- High tensile strength
- Favorable absorption profile
- Resistance to infection

Marcus BC: Wound closure techniques. In Baker SR: *Local flaps in facial reconstruction,* ed 2, St Louis, 2007, Mosby.

Several key principles are necessary to achieve an optimal result when primarily closing traumatic wounds. First, a layered closure is critical to obliterate dead spaces and also to relieve tension on the epidermal layer. Deep closure can be accomplished with a variety of suture materials. Absorbable suture, generally 3-0 and 4-0, are appropriate for muscle layers, 4-0 or 5-0 absorbable sutures are appropriate for dermal closure, and 5-0 to 7-0 nonabsorbable monofilament sutures are used for skin layers. Cyanoacrylate tissue adhesive such as Dermabond (Ethicon) or use of Steri-Strips (3-M) are appropriate in pediatric patients with uncomplicated, clean lacerations as they have been shown to be time saving, cost effective, and are less painful for the patient.[21,22]

Ideally, definitive repair of bony and soft tissue injuries can be achieved in a single operation, as successive operations rarely improve functional outcomes.[23] In high-velocity or blast injuries, primary soft tissue closure is frequently not possible due to the need for multiple debridements. Clinically superior outcomes result from early soft tissue reconstruction, which prevents significant contracture and provides better coverage for later osseous reconstruction.[24] The presence of contamination has not been associated with an increase in perioperative or long-term complications, therefore contamination should not be considered a contraindication to this treatment approach.[25] Computed tomography angiography (CTA) is needed to evaluate recipient vessels for free flap reconstruction in patients with complex wounds. If palpable pulses are not appreciable and recipient vessels lie in the zone of injury, then CTA is the definitive method to evaluate vessel patency and integrity.

Management of Special Anatomic Units

The general principles apply to most facial lacerations, however, areas with specific facial anatomy require additional consideration. These areas include the esthetic units and subunits of the face (Figure 4-7) as well as the adjacent soft tissue needed for reconstruction. Scalp, although not considered an esthetic unit, also deserves special consideration due to the importance of its hair and the esthetic consequences from injuries.

TABLE 4-1 Suture Material: Definition of Terms

Absorbable Suture

Undergoes progressive loss of mass or volume (does not correlate with loss of tensile strength

Breaking Strength

Limit of tensile strength at which material (or tissue) failure occurs

Capillarity

Extent to which absorbed fluid is transferred along the strand

Elasticity

A measure of a suture's ability to regain its original form and length after deformation

Fluid Absorption

Ability to take up fluid after immersion

Knot Pull Tensile Strength

Breaking strength of a suture material, which can be 10% to 40% weaker after deformation by knot placement

Knot Strength

Amount of force necessary to cause a knot to slip, which is directly proportional to the coefficient of static friction and plasticity of a given material

Memory

A suture's inherent capability to return to or maintain its original gross morphologic shape; it is a function of elasticity, plasticity, and diameter

Nonabsorbable Suture

Undergoes no significant loss of mass or volume (does not correlate with retention of tensile strength

Plasticity

A measure of a suture's ability to deform without breaking and to maintain that new form after relief of the deforming force

Straight Pull Tensile Strength

Linear breaking strength of suture material

Suture Pullout Value

Limit of strength of a particular tissue as measured by the force applied to a loop of suture at which tissue failure occurs

Tensile Strength

A material or tissue's ability to resist deformation and breakage

Wound-Breaking Strength

Limit of tensile strength of a healing wound at which wound separation occurs

Coefficient of Friction

A numeric value that quantifies a material's surface characteristics that act to resist motion against another surface

Marcus BC: Wound closure techniques. In Baker SR: *Local flaps in facial reconstruction,* ed 2, St Louis, 2007, Mosby.

TABLE 4-2 A Regional Guide to Suture Selection

Region	Cutaneous Suture	Subcutaneous/ Fascia Suture	Comments
Eyelid and periorbital	#6-0, #7-0	#4-0, #5-0	Minimal tensile strength requirements Esthetic concerns at a premium
Nose and pinna	#5-0, #6-0	#4-0, #5-0	Small tensile strength requirements Esthetic concerns at a premium
Lip and vermilion	#6-0	#3-0, #4-0	Moderate tensile strength requirements due to highly active region Esthetic concerns at a premium
General facial and anterior neck	#5-0, #6-0 #4-0, #5-0	#3-0, #4-0	Moderate to high tensile strength requirements due to regional mobility Significant esthetic concerns
Nasal and oral mucosa	#3-0, #4-0	#3-0, #4-0	Moderate tensile strength needed due to tissue mobility May select based on ease or no need for removal No esthetic concern
Scalp and posterior neck	#3-0, #4-0	#2-0, #3-0	Tensile strength needed for moderate to heavy tissue and very mobile region Minimal esthetic concern
Superior trunk	#2-0, #3-0	#2-0, #3-0	Tensile strength needed for heavy tissue in a relatively mobile area
Major musculocutaneous flaps	#4-0, #5-0	#1-0, #2-0, #3-0	Maximal tensile strength needed because sutures are often under significant tension May require long-term tensile strength

Marcus BC: Wound closure techniques. In Baker SR: *Local flaps in facial reconstruction,* ed 2, St Louis, 2007, Mosby.

TABLE 4-3 **Natural Fiber Sutures**

Name	Source	Special Processing	Filament	Relative Tensile Strength*	Tensile Strength Profile†	Absorption Profile‡	Tissue Reaction	Ease of Use§
Absorbable								
Plain gut	Highly purified (nearly 100%)	None	Twisted	2	75% at 7 days	70 days proteolysis

Scalp

Scalp lacerations frequently bleed profusely due to the extensive blood supply and require good visualization to gain hemostasis. Head CT should be performed to rule out skull fractures prior to closure of scalp lacerations. Lacerations that are extensive are therefore better repaired in the operation room under more controlled conditions. Scalp lacerations with defects smaller that 3 cm can be closed primarily in most cases. Larger defects may require galea scoring to allow laxity for closure. Closure of the galea is important to achieve proper approximation of overlying soft tissue. Failure to close galea frequently results in a step defect in the scalp as illustrated in (Figure 4-8). Options for closure of larger defects in hair bearing areas include local rotational or advancement flaps, skin grafts provided pericranium is intact, burring the outer table when pericranium absence exposes bleeding bone to allow granulation tissue to form a vascular bed for skin grafting, and rotation of adjacent intact pericranium, galea, or temporoparietal fascia for a vascular base for skin graft coverage. This can later be followed with staged tissue expansion of the hair bearing areas for definitive scalp reconstruction. Pedicle flaps or free tissue transfer can be performed for large defects that cannot be managed solely with tissue expansion. Avulsion wounds of the scalp that are a result of blunt or shear forces have poor prognosis due to the vascular intimal damage that propagates proximal and distal within the vessels, and in such cases microscopic revascularization is generally unsuccessful. However, in large scalp avulsion injuries attempts should be made to revascularize when possible because reconstruction of hair bearing areas remain difficult without like tissue.

Forehead

Lacerations of the forehead should be comprehensively evaluated with special attention to cranial nerves V and VII. This is critical in the conscious patient and must be done prior to the use of any local anesthetic. Closure of wounds should follow the general principles described previously using conservative debridement and multiple layered closure. Avulsion defects that are smaller can be managed with rotational flaps or advancement local flaps based off the supraorbital or supratrochlear vessels. Larger tissue defects can be closed with split-thickness skin grafts followed by secondary tissue expansion for improved management of color and texture match with forehead skin. In cases where the entire esthetic unit is avulsed, skin grafting can result in an acceptable outcome without further treatment with distant flaps which often have poor color and texture match.

Eyelid

Management of eyelid lacerations requires accurate identification of injury to all components of the eyelid. This involves upper lid, lower lid, medial canthus, lateral canthus, tarsal plates of upper and lower lid, levator aponeurosis, and lacrimal apparatus, as well as thickness of the injury and loss of tissue.[26] Timing of closure is not a critical factor owing to the excellent tissue vascularity in the periorbital area and in most cases a delay of 12 to 36 hours will not alter the outcome of the primary closure. Simple lacerations are closed anatomically in layers based on the tissues injured.[27] Closure materials include 5-0 and 6-0 plain gut for conjunctiva and orbicularis followed by 5-0 or 6-0 fast-absorbable plain gut or 6-0 nonabsorbable sutures for skin closure.

Lacerations of the lid margin and tarsal plate must be approximated anatomically and the lid margin everted with vertical mattress sutures using 6-0 silk to prevent notching (Figure 4-9). In lower lid lacerations anatomic approximation and support are important to prevent ectropion. The use of an orbicularis muscle sling sutured to lateral orbital rim using 5-0 Vicryl provides excellent support when laxity is present during repair. In upper lid lacerations levator aponeurosis integrity is important to establish to prevent postoperative ptosis. Presence of orbital fat implies a beach of the orbital septum indicating possible damage to the underlying levator palpebrae superioris muscle (Figure 4-10).

• **Figure 4-8** Poor outcome from scalp repair as a result of failure to close the galea in an anatomic closure.

When necessary, anatomic approximation of the aponeurosis with the tarsal plate can be performed with 6-0 or 7-0 polyglactin sutures placed central, medial, and lateral.[27] Medial lid lacerations require evaluation of the lacrimal ducts and canaliculi and appropriate ophthalmologic consultation for repair. Partial-thickness loss greater than

• **Figure 4-9** **A,**Through and through upper eyelid laceration managed with **(B)** closure of the palpebral conjunctiva using 6-0 plain gut with knot buried below conjunctiva. This is followed by tarsal plate repair with 6-0 polyglactin and skin closure with 6-0 polyprolene. Care must be taken to approximate margin anatomically and evert the gray margin using a horizontal mattress suture with 6-0 or 7-0 silk.

50% of either upper or lower lid requires full-thickness skin graft. Donor sites from the contralateral eyelid when adequate skin exists or postauricular (as opposed to retro auricular) full-thickness skin from the contralateral eyelid when available provide satisfactory match in thickness and color. Donor site deformities need to be prevented in both sites when using this technique. Local advancement flaps can be used in full-thickness tissue loss greater than one third of the upper lid in combination with lateral canthotomy and cantholysis. Greater loss of tissue may require myocutaneous flaps, whereas eyelid loss in excess of one half of the lid may require lid-sharing procedures of additional grafting, or both can be used for closure of defects up to 50% of the lid length (Figure 4-11). Avulsion injuries of eyelid can be repaired primarily if the horizontal length is less than one fourth of the upper lid or one half of the lower lid. Lower lid defects that are larger require lateral canthotomy and cantholysis or tarsal strip to allow for tension-free closure. A variety of single pedicle or bipedicle myocutaneous flaps from the apposing eyelid have been described for reconstruction of both upper and lower lid avulsion defects. Complete or near complete avulsion of upper and/or lower eyelid defects require switch flaps, composite flaps, cheek flaps, or forehead flaps. In complete upper and lower lid avulsion wounds it is critically important to protect the eye from further injury. Ophthalmic antibiotic ointment and protective shields should be employed for protection followed by early reconstruction. Establishment of medial and lateral canthus attachments is necessary to provide lid contour for globe protection.

Complete eyelid reconstruction can be achieved using microvascular transfer of dorsalis pedis with septal cartilage[28] or radial forearm flaps with palmaris longus tendon.[29] With severe injuries involving loss of the globe a complete prosthetic eye constructed by a maxillofacial prosthodontist is an excellent option and should be considered.

Lateral and medial canthus injuries occur frequently in lid injuries when lacerations in the adjacent area are full thickness. Repair requires primary canthopexy or canthoplasty when possible, but with more extensive injuries alternative repair may become necessary. Lateral canthus can be recreated with suture repair of the lower lid tarsus to the lateral orbit placed inside the rim. Medial canthus lacerations frequently involve the canaliculi or lacrimal apparatus and should be addressed with ophthalmologic consultation and the Jones dye test. A Jones I test can be performed using fluorescein dye placed in the eye and assessed for the presence of fluorescein in the nose after 5 minutes. If dye is present in the nose, a functional lacrimal apparatus is present. Without dye present, a Jones II test is performed by irrigating the nasolacrimal system with saline and having the patient expectorate the irrigation solution into a basin, where it is then checked for the presence of fluorescein. In the absence of a lacrimal apparatus injury, repair of the medial canthus is done with a method similar to that used in repair of Type III nasoorbitoethmoidal (NOE) injury.

Nose

Principles for repair of the nose are similar to those that apply to other special anatomic areas. With simple lacerations, anatomic approximation is performed using 5-0 chromic for mucosal lacerations and 5-0 or 6-0 nonabsorbable sutures for skin. The skin and soft tissues of the nasal tip and alar rim tend to be thick and relatively stiff, making primary closure of these regions more difficult. When cartilage lacerations are present, simple approximation with

• **Figure 4-10** Eyelid lacerations that appear innocuous with small skin loss as shown in **A** need to be explored as shown in **B**. As seen in **B**, there is a discontinuity of the levator aponeurosis and conjunctival laceration. Complete ophthalmologic exam needs to be performed before completion of repair. **C,** Completion of repair of the levator aponeurosis with 5-0 polydioxanone followed by repair of palpebral conjunctiva with 6-0 plain gut. This is followed by repair of the lid skin with advancement flap for final lid repair.

• **Figure 4-11** Complete loss of full-thickness lower lid as seen in **A**. Reconstruction with Hugh's tarsoconjunctival flap for posterior lamella and anterior lamella reconstructed with full-thickness skin graft from ipsilateral postauricular skin **(B).** Tarsoconjunctival flap is similar to an Abbey flap for lip reconstruction, however, division in inset is performed at 3 weeks.

monofilament absorbable sutures can prevent collapse of nasal ala and tip and improve esthetic outcome. The authors' have found that splinting significant lacerations that involve the alar margin and lower lateral cartilage with intranasal packs and external splints can reduce scar formation that results in external valve stenosis (Figure 4-12).

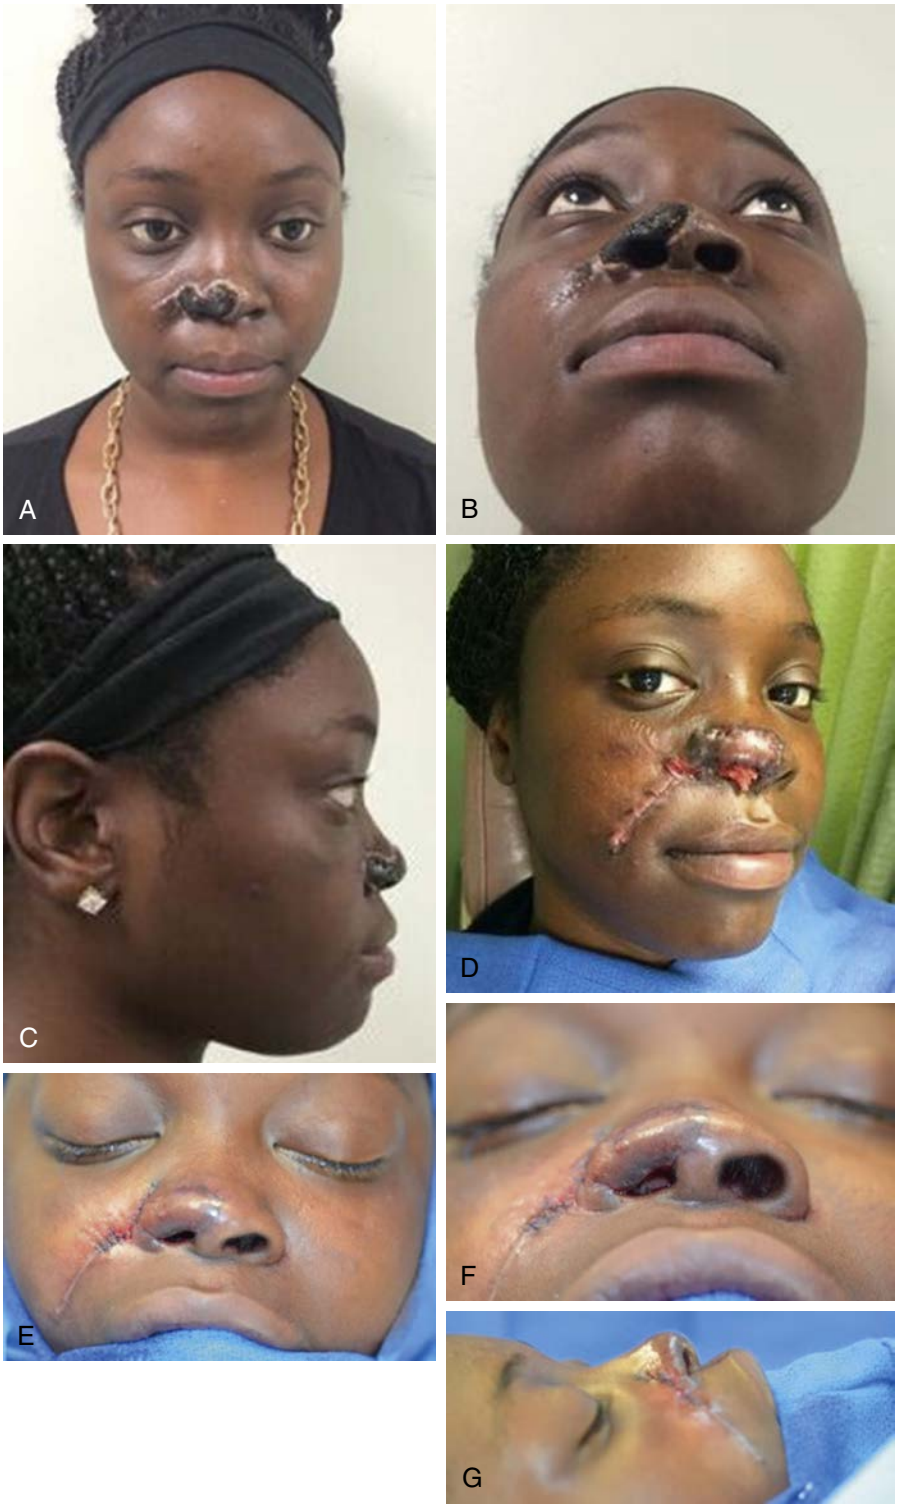
With tissue loss, successful reconstruction of soft tissue defects requires addressing all osseocartilaginous injuries or defects. Multiple algorithms have been devised for the evaluation and reconstruction of nasal defects.[30,31] Opinion varies with regard to reconstruction of the esthetic subunits of the nose. In the past, general consensus was that if a defect greater than 50% of a subunit is compromised, then the remainder should be excised so that the entire subunit can be reconstructed. Opinion is now shifting in favor of retaining as much of the anatomic structures of the nose and doing only esthetic subunits of the nose.[32] Partial-thickness defects over subunits with thinner skin can be closed using postauricular full-thickness skin grafts with reasonable esthetic outcome. Thicker skin defects of nasal tip and alae can be reconstructed with retroauricular full-thickness skin grafts; however, a better option is preauricular full-thickness grafts, which have better thickness and color match. With larger defects involving more than just tip, local and regional flaps such as dorsal nasal, cheek advancement, nasolabial, and paramedian forehead flaps are used for repair (Figure 4-13).

Extensive avulsion of soft tissue resulting from high-velocity projectiles or amputation from mechanical devices that cannot be closed with local or regional flaps requires bone graft and free flap reconstruction and often produces less than desirable esthetic results. In such cases, as with total avulsion of eyelid and ear defects, total nasal prosthetic reconstruction by a maxillofacial prosthodontist is an excellent option (Figure 4-14).

Lips

Anatomic landmarks are key to proper management of lip lacerations in restoring esthetics, motor function, and sensory function. Identification and marking of key landmarks such as the vermillion border, Cupid's bow, and commissure prior to injection of local anesthesia is important. Alignment of vermillion border is critical to the final esthetic outcome because the human eye can detect as little as 1 mm of discrepancy in vermillion continuity. Simple lacerations of the lips can be managed using the basic principles of wound closure. After thorough irrigation and wound debridement, closure of skin can be performed using 4-0 polyglactin or polydioxanone suture for deep tissue and intradermal approximation with 6-0 permanent monofilament skin sutures. If lip mucosa only is involved, irrigation and debridement is performed followed by closure with 3-0 or 4-0 chromic gut in a single layer fashion. Through and through lip lacerations should be closed from inside out. Following irrigation and debridement, mucosal closure can be performed with 3-0 or 4-0 chromic gut in a running locking fashion creating a watertight seal. If necessary, several interrupted sutures can be placed for proper anatomic alignment prior to placement of the running suture. Irrigation is performed extraorally to minimize oral bacterial contamination. Approximation of muscle with interrupted 3-0 or 4-0 polyglactin or polydioxanone is followed by intradermal approximation with 4-0 or 5-0 polyglactin or polydioxanone. Skin approximation should be accomplished with intradermal sutures to align the epidermis and prevent tension, followed by closure of skin with 6-0 cuticular sutures.

• **Figure 4-12** **A,** Complex nasal laceration with tacking suture used for temporary closure before definitive repair in the operating room. Repair requires minimal debridement and multiple layered anatomic closure. Extensive laceration with upper lateral cartilage avulsed from nasal bones, septum separated from upper lateral cartilages, septum fractured and separated from upper and lower lateral cartilages, and left lateral crus of lower lateral cartilage transected seen in **(B)**. Complete repair with suture repair of septum and lower lateral cartilage with 5-0 polydioxanone, transnasal repair of mucosa with 5-0 chromic, and layered closure of skin with 4-0 polygalactin and 5-0 polypropylene seen in **(C)**.



• **Figure 4-13** Composite loss of nasal tip involving portions of lateral crus, caudal septum, and nasal tip skin and mucosa **(A-C).** Patient at 1 week postoperative after reconstruction with nasolabial flap with auricular cartilage grafts from conchal bowl for medial and lateral crus reconstruction, and bipedical nasal mucosal flap for intranasal lining **(D).** Patient seen immediately postoperative following modification of the nasolabial flap inset to reestablish an esthetic nasofacial groove **(E-G).** Note the marked improvement of the nasolabial scar at 6 months.

Lip wounds may suggest significant tissue loss on first impression; however, by a careful approximation, it becomes apparent in many cases that most if not all of the tissue is present. When avulsion wounds exist in the lips it is important to assess the quantity of missing tissue. The lower lip is functionally more important than the upper lip because it maintains oral secretions and prevents drooling. The lower lip can tolerate up to one third loss of tissue and still be managed with primary closure. Upper lip avulsions are similar, with the exception of reestablishing normal Cupid's bow and philtral column anatomy. Esthetic outcome from upper lip loss is much less desirable than in the lower lip.

• **Figure 4-14** Patient with prosthetic nose following traumatic loss of all external nasal tissue.

Management of lip avulsion wounds can be accomplished with lip switch procedures such as the Abby-Elslander and reverse Abby-Elslander technique for defects of upper and lower lip, respectively. Lip switch procedures have major advantage in that lost tissue is replaced with like tissue. Bilateral and unilateral Karapanzic flaps can be employed for larger avulsion defects greater than one half the lip length, with the ultimate outcome dependent on the neurovascular supply of the lip for its functional maintenance.

In significant loss of upper and/or lower lip from large avulsion wounds such as gunshot wounds, it is often necessary to create lip tissue from distant free tissue transfer. Microvascular reconstruction with radial forearm and anterolateral thigh (ALT) can provide necessary tissue for lower lip with good outcome.[33,34]

Ears

Lacerations of the ear typically involve both skin and cartilage because of the thin nature of ear skin and its strong adherence to the underlying cartilage. As with all facial lacerations, the basic principles of wound management apply. Debridement of cartilage should be kept to a minimum because extensive cartilage removal results in significant deformities. Simple lacerations require skin closure only with skin adherence acting as a splinting mechanism. Permanent nonabsorbable sutures are used in most cases, but in young children and infants fast-absorbing gut is preferable.

Complex lacerations that lack support from cartilaginous injury require cartilage sutures. Absorbable monofilament 5-0 sutures such as PDS are preferable due to its absorption properties (Figure 4-15). Suture knots should be placed on the posterior of the cartilage repair, as knots on the anterior surface are visible and frequently become exposed. This is due to the tighter adherence of skin on the anterior surface versus the posterior skin. Following complex repair of ear

• **Figure 4-15** **A,** Complex forehead, lateral eyelid, cheek laceration, abrasion, contusion. Repair required copious irrigation, debridement of foreign material and nonviable severely contused cheek tissue with preservation of frontal branch of cranial nerve (CN) VII followed by multiple layered repair of soft tissue reapproximation with 5-0 polydyoxalene and multiple 6-0 prolene seen in **(B)**. Postoperative wound dressings included Bacitracin, adaptic gauze, 4-by-4 gauze, and Tegaderm occlusive bandage for management of the abrasion.

lacerations it is wise to apply a contouring bandage to provide support as well as prevent hematoma or serosa formation under the skin, which can result in a cauliflower ear deformity. The authors' preference for contour bandages is bacitracin-saturated cotton ball that can be placed into the contours of the ear from conchae to helical fold. Once the contours are filled, applications of 4-by-4 gauze front and back are placed followed by a mastoid bandage, as shown in Figure 4-16. The bandage is kept in place for 5 to 7 days.

Partial loss of ear skin can be repaired with split-thickness skin grafts taken from the contralateral ear postauricular skin. Adequate splinting to prevent hematoma and seroma is essential for survival of the graft (Figure 4-17). Lacerations that result in near avulsion should first be assessed for arterial inflow as well as venous outflow. In partial amputation with relatively large pedicle, the prognosis is good following conservative debridement and meticulous repair. If the pedicle is narrow, the chance of venous congestion is much higher. When outflow is inadequate, venous micro anastomosis is necessary. If unsuccessful, leech therapy can be used until adequate outflow channels are established (Figure 4-18). Pressure on the ear should be avoided during this period. As with complete avulsion of the scalp, mechanism of injury is a strong predictor of success. Injuries that are sharp avulsion have much better success of revascularization than those that are shearing and crushing in nature.

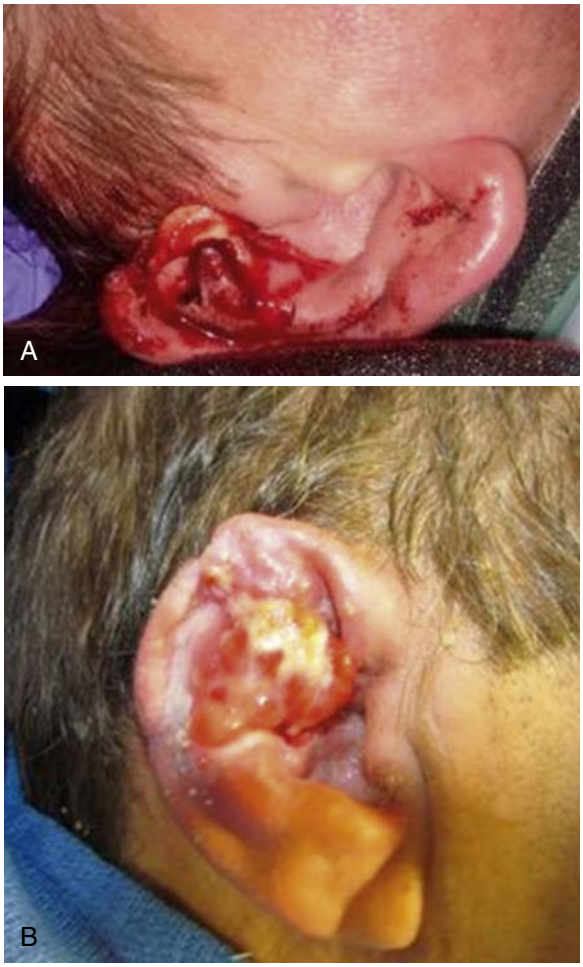
In complete traumatic loss of the ear excellent results can be obtained by implant-retained auricular prosthesis (Figure 4-19).

• **Figure 4-16** Mastoid bandage placement provides excellent support and compression over ear repairs and reconstructions. Bandage consists of cotton balls saturated in antibiotic ointment and placed in the contours of the ear anatomy followed by 4-by-4 gauze behind and covering the ear. This is followed by Kerlex wrapped as shown and tied in place over the forehead with suture or umbilical string.

Parotid Duct

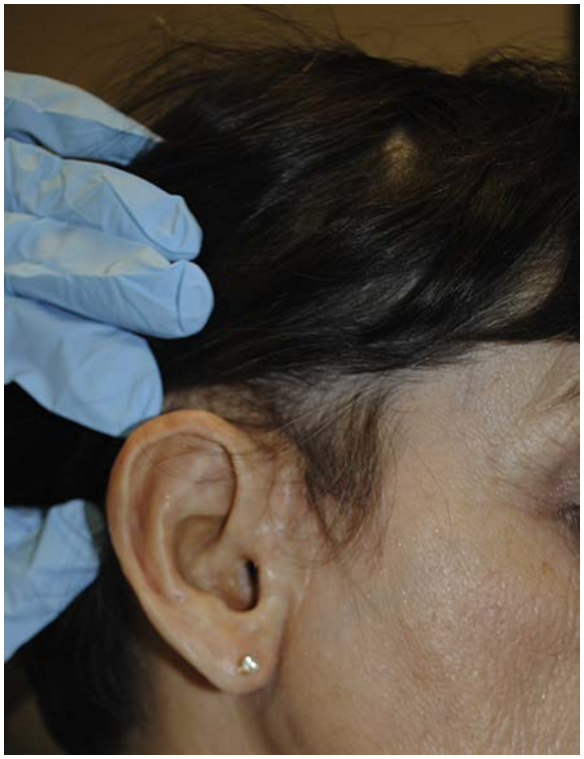
Lacerations of the cheek that lie in a line from the tragus to the ipsilateral mid-upper lip and extend deep to the superficial muscular aponeurotic system (SMAS) need to be explored for parotid duct injuries and facial nerve injuries.[35]

Lacerations through parotid fascia in this area have high probability of duct injury. Cannulation of Stinson's duct, located adjacent to the first molar tooth, should be done and visualized in the open wound. Cannulation can most easily be performed with a J-wire and followed by a catheter placed over the J-wire. Injection of materials such as methylene blue or propofol allows documentation of duct injury. Direct visualization is difficult without adequate lighting and hemostasis, therefore this type of laceration repair should be done in the operating room. If duct laceration is within the hilum of the gland, stick tie suture ligation should be placed in the hilum, followed by ligation of the distal stump of the duct. If the ductal injury is more distal, anastomosis should be performed over the catheter with 8-0 nylon under microscopic or loop magnification. The catheter should be sutured in place intraorally and left



• **Figure 4-17** Ear partial skin avulsion seen in **(A)** before repair. Split-thickness skin graft reconstruction placed over pericondrium but without adequate splinting failed. The wound was allowed to granulate resulting in a cauliflower ear deformity seen in **(B).**

• **Figure 4-18** **A,** Near complete avulsion of ear. **B,** Superior pedicle with marginal blood supply after reattachment showing moderate cyanosis. **C,** Leech therapy applied to attempt for adequate venous outflow.



• **Figure 4-19** Excellent esthetic reconstruction with complete auricular prosthesis following total loss of auricle.

for a minimum of 2 weeks. Antibiotics and antisialogogues should be prescribed.

Sialocele is not uncommon with duct or gland injury. Initial management is with pressure dressing and antisialogogues.[36]

Facial Nerve

Laceration of the facial nerve can result from penetrating injuries to complex facial lacerations that involve structures deep to the SMAS (superficial musculoaponeurotic fascia). Complete examination of all branches of the facial nerve function should be performed on initial exam. If injury is proximal to the parotid gland, the main trunks of facial nerve may be involved and must be repaired. The use of local anesthesia should be delayed until the function of the facial nerve has been established. Injuries proximal to a vertical line drawn from the lateral canthus require exploration and repair. If anterior to the parotid gland, the branches of facial nerve are examined under loop magnification or operating microscope. The nerve stimulator is useful for identification of the distal segment within 48 hours of injury. After 48 to 72 hours, the distal nerve segments will no longer conduct the impulse.[37] Early microscopic epineural and perineural repairs with 9-0 or 10-0 nylon result in the best clinical outcomes and therefore should be the primary objective if facial nerve transection is identified. If both proximal and distal ends cannot be identified, suture tags should be placed for future exploration. (A more in-depth discussion is beyond this chapter and will be deferred.)

• **Figure 4-20** Penetrating neck injury dissecting in a subcutaneous level that extends for the mandibular border to below the level of the cricoid cartilage anteriorly and posterior to the sternocleidomastoid muscle. Computerized tomographic angiography was negative.

Neck

Penetrating injuries to the neck in the past have been classified according to the zone involved: zone I extends from the level of the clavicles and sternal notch to the cricoid cartilage, zone II extends from the cricoid cartilage to the angle of the mandible, and zone III extends from the angle of the mandible to the base of the skull. Injuries to the neck can involve deep structures affecting the vascular, respiratory, digestive, neurologic, endocrine, and skeletal structures. If injury of major vessels is suspected, computerized tomographic angiography (CTA) should be performed before exploration (Figure 4-20). Imaging triage can now accomplish what operative or selective evaluation could not: a safe and noninvasive evaluation of critical neck structures to identify or exclude injury based on trajectory, the key to penetrating injury management. A comprehensive physical examination combined with CTA is adequate for triage to effectively identify or exclude vascular and aerodigestive injury after penetrating neck trauma.[38]

Postoperative Care

Routine use of antibiotics should not necessarily be employed as a component of postoperative care in most facial lacerations; however, antibiotic prophylaxis is recommended in patients with prosthetic joints, patients at risk for endocarditis, patents receiving corticosteroid therapy,

TABLE 4-8 Characteristics of Tetanus-Prone Wounds

Clinical Features	Tetanus-Prone Wounds	Nontetanus-Prone Wounds
Age of wound	More than 6 hours	6 or fewer hours
Configuration	Stellate wound	Linear wound
Depth	More than 1 cm	1 cm or less
Mechanism of injury	Missile, crush, burn, or frostbite	Sharp surface (eg, knife)
Signs of infection	Present	Absent
Devitalized tissue	Present	Absent
Contaminants (dirt, feces, soil, saliva)	Present	Absent
Denervated or ischemic tissue or both	Present	Absent

From Edlich RF: Principles of emergency wound management, *Ann Emerg Med* 17(12):1284–1302, 1988, with permission.

and in immune compromised patients (e.g., diabetes mellitus, HIV, chemotherapy).[39] Other risk factors for infection include increased age, puncture wounds, impact wounds, presence of foreign bodies in the wound, heavy contamination, jagged wound edges, lacerations deeper than the subcutaneous layer, and wide gaping lacerations. These categories should strongly be considered for antibiotic therapy.[40-42] Through and through lacerations involving oral mucosa require clinical judgment. The choice of antibiotics should contain an active agent against staphylococci and β-hemolytic streptococci, such as a first-generation cephalosporin or penicillinase-resistant penicillin.[43] Wounds that have gross contamination and/or delay in time of wound closure should be considered for antibiotic therapy. A controlled study by Ichikawa found baseline wound infection rates that varied by degree of contamination: 2.6% in clean-contaminated, 5.8% in contaminated, and 20.8% in dirty wounds. Tetanus prophylaxis should be given according to the patient's immunization history (Tables 4-8 and 4-9).

Current CDC guidelines recommend a tetanus vaccine for wound management based on vaccination history and wound severity. All patients with an unknown vaccination history or who have received fewer than three doses should receive a tetanus diphtheria vaccine (Td). Inadequately vaccinated patients with anything other than a clean, minor wound should also receive tetanus immune globulin (TIG). Patients who have received three or more tetanus vaccines prior to the injury only need Td vaccination if their previous dose was more than 10 years ago for clean, minor wounds or 5 years for other wounds.

TABLE 4-9 Recommendations for Tetanus Prophylaxis

	DTP* (0.5 mL IM)	TIG (250 U IM)	TD¶ (0.5 mL IM)	TIG (250 U IM)
History of adsorbed tetanus toxoid (for children < 7 yr)				
Unknown or < 3 doses	Yes†	Yes‡	Yes†	Yes
3 or more doses	No¶	No	No¶	No

NOTE: All dog and cat wounds should be considered tetanus-prone wounds.
*Use diphtheria, tetanus (DT) if pertussis vaccine is contraindicated.
†The primary immunization series should be completed.
‡Administer in contralateral extremity.
¶Use diphtheria, tetanus, pertussis (DTP) for children <7 years old (DT if pertussis vaccine is contraindicated); TD is preferred to T if patient is ≥ 7 years old.
¶Yes, if > 5 years since last dose. (More frequent boosters are unnecessary and may accentuate side effects.)
§ Yes, if the routine immunization schedule has lapsed or if more than 5 years since last dose of tetanus toxoid.
IM, intramuscular; *TIG,* tetanus immune globin.

Animal and Human Bites

Animal and human bite wounds are common and can cause significant morbidity and even mortality.[44] Types of bite wound injuries can be classified as abrasion, puncture, laceration, and avulsion. The majority of animal bite wounds are caused by dogs, with approximately 800,000 bite wounds per year in the United States, followed by cat wounds at 400,000 per year, and then human bite wounds[45,46] (Box 4-2). Appropriate wound management is the single most important factor in preventing infection in this patient population, and increasingly, dog bite wounds are a source of litigation due to improper management.[45,47]

Most dog bite wounds occur in children. The head and neck is the most common site of injury in children younger than 9 years old, whereas in children 10 years or older the

• BOX 4-2 Dog Bite Statistics

- 77.5 million dogs in the United States
- 4.5 million dog bites each year
- 1 in 5 bitten; 885,000 require medical attention
- Half of these are children:
  - Age 5 to 9 years; mostly boys
  - Face, head, and neck: 50% to 70%
- Adult victims, 5% to 15%: face, head, and neck
- In 2012, 27,000 underwent reconstructive surgery
- Most dog bites occur in or close to home and known to child/family

TABLE 4-10 Retrospective Review of Bite Wounds for 2013 at Memorial Hermann Hospital TMC Houston, Texas

Soft Tissue Injuries	Total: 90	Hard Tissue Injuries	Total: 5
Face	31	Skull	1
Eye	18	Nasal	1
Lip	16	Dental	1
Scalp	11	Jaw	2
Nose	6		
Neck	5		
Ears	3		

extremities are the most commonly involved site[48] (Table 4-10). Dog bites occur most frequently in the victim's home and the dogs are most often known by the victim. Dog bite forces can vary considerably from 310 kPA to nearly 31,700 kPA in trained attack dogs.[49] Due to the high bite forces with these injuries, the possibility of underlying bony injury must not be overlooked.

Due to their rounded teeth and strong jaws, dog bite wounds are often crush-type injuries.[50] The wounds are most often polymicrobial with *Pasturella multocida*, *Pasturella canis*, *Streptococcus* species; *Staphylococcus* species and *Capnocytophagia canimorus* being the most commonly isolated pathogens[50] (Box 4-3). Amoxicillin/clavulanic acid (Augmentin) provides coverage for some penicillin-resistant *S. aureus* species and *Pasturella* species and is the preferred prophylactic antibiotic[49] (Box 4-4). Whether empirical prophylaxis is required for all bite wounds is unclear based on available literature; some authors argue for routine prophylaxis and others for prophylaxis in only high-risk cases.[51,52] Due to the rich vascular supply of facial tissue, immediate closure of bite wounds is typically safe even with old

• BOX 4-3 Microbiology of Bites

- Oral flora of dog and skin of human
- Common pathogens in order of prevalence:
  - *Pasturella multocida*: soft tissue inoculation, septic arthritis, osteomyelitis
  - Staphylococci
  - Streptococci
  - Anaerobic bacteria
  - Capnocytophaga: sepsis, meningitis

• BOX 4-4 Empiric Intravenous Antibiotic Therapy

Options for empiric gram-negative and anaerobic coverage include:

- Monotherapy with a beta-lactam/beta-lactamase inhibitor:
  - Ampicillin-sulbactam 3 g every 6 hours 50/mg/kg/dose (based on ampicillin component) every 6 hours
  - Piperacillin-tazobactam 4.5 g every 8 hours 125 mg/kg/dose (based on piperacillin component) every 8 hours
  - Ticarcillin-clavulanate 3.1 g every 4 hours 50 mg/kg/dose (based on ticarcillin component) every 4 hours
  - A third-generation cephalosporin in such as ceftriaxone 1 g IV every 24 hours

PLUS

- Metronidazole 500 mg IV every 8 hours (Metronidazole 10 mg/kg/dose every 8 hours)

OR

- A third-generation cephalosporin in such as ceftriaxone 100 mg/kg/dose every 24 hours

• Box 4-5 Rabies

- Neurotropic viruses: rhabdoviridae family
- Animal quarantine
- Rare in United States: 47 deaths from 1990 to 2005
- Geographic variation: U.S./Mexico border
- Wound care: Soap and water; povidone iodine, rabies vaccines; rabies immune globulin

injuries.[53] Grossly contaminated crush wounds with delayed presentation (> 24 hours) deserve careful consideration of primary versus delayed closure. Good lighting, sterile technique, thorough irrigation of wounds using tap water or normal saline, removal of foreign bodies, and debridement of tissue are the mainstays of wound management. Cultures are indicated only in grossly infected cases.[49] The CDC recommends observation of healthy animals for 10 days and human vaccination only if the animal shows symptoms of rabies. In unprovoked bites or animals demonstrating other rabid behavior immediate vaccination is recommended[54] (Box 4-5). Tetanus immune globulin and toxoid are recommended in bite victims who have had two or fewer primary immunizations. Tetanus toxoid alone is recommended in

• **Figure 4-21** Superficial dog bite wound management. Initial wound management includes copious irrigation with normal saline, when contaminated, followed by debridement of all nonviable tissue. Wound cultures are only necessary when wound is infected. In dog bite wounds, prophylaxis consists of oral amoxicillin clavulanate for 3 to 5 days and tetanus immune globulin and tetanus toxoid as listed in Tables 4-8 and 4-9. Primary closure can be performed in noninfected wounds.

patients who have completed the primary immunization series but have not received a booster within 5 years.[55]

Some differences but many similarities exist between cat and dog bite wounds. Cat bites are more likely to cause a puncture injury with deep penetration, leaving only a small opening through which fluids can drain.[49] For this reason, cat bites are associated with a twofold higher risk of infection than dog bites.[49,50] Bacteria commonly isolated from cat bite wounds include: *P. multocida, Bartonella henselae* (the causative organism of Cat-scratch disease), *Streptococcus*, and *Staphylococcus* species. Copious irrigation of wounds with normal saline or tap water is recommended along with primary closure in the majority of cases. As with dog bite wounds, Augmentin is the prophylactic antibiotic of choice with good coverage of the most common pathogens.[49] Clindamycin should not be used alone due to poor coverage of *Pasturella* species. Similar tetanus and rabies prophylactic measures are recommended.

Human bite wounds often compress the skin, but rarely cause avulsion injuries as in dog or cat bites. However, left untreated, open human bite wounds can cause significant morbidity.[49] The most common pathogens associated with human bites include *Streptococcus* and *Staphylococcus* species as well as anaerobic bacteria *Eikenella*, *Fusobacterium*, *Peptostreptococcus*, and *Prevotella*. The prophylactic antibiotic of choice is Augmentin. Clindamycin should not be employed due to poor coverage against *Eikenella* spp.

Several cases are presented to illustrate the nature and management of these bites. Superficial dog bite wound management includes copious irrigation with normal saline, close inspection, debridement of nonvital tissue, use of appropriate antibiotic therapy, application of rabies and tetanus toxoid protocol, and primary closure in noninfected wounds (Figure 4-21).

Complex dog bite wounds by their nature involve greater loss of tissue, larger surface area, and damage to underlying structures such as bone, glands, nerves, and muscle. Two concepts should be kept in mind for pediatric patients. First is to achieve closure of the wound with either approximation or skin grafts in order to minimize scar tissue (Figure 4-22). In this case extensive undermining was done, which resulted in excessive tension on the surface. Although there was dehiscence early, at 8 months there was appreciable improvement eliminating the need for revision. In addition, by not using aggressive flap procedures one keeps more options on the table for use at a later time.

Another concept for pediatric patients is that the soft tissue scars tend to grow with the patients. Individual judgment is needed to choose between early or late revision. Certainly, degree of disfigurement and psychological needs must be factored in. Figures 4-23 and 4-24 represent a case where wide scar bands occurred following reapproximation of tissue where excessive tissue was lost initially. At 1 year, a decision was made for excision of the scar with advance flap closure. The results 6 months later helped mitigate the patient's psychological distress.

In cases where there is extensive loss of tissue and late sequela will result in major deformities, local flaps, and in some cases free flap reconstruction, should be considered. Loss of major parts of special anatomic structures such as nose, eyelids, and ears requires such management. Early nasal reconstruction with local flaps such as nasolabial or axial pattern forehead flaps results in superior esthetic outcomes than when management is delayed. Axial pattern forehead flaps can provide coverage of tissue loss of multiple esthetic units (Figure 4-25), whereas nasolabial flaps are limited to isolated reconstruction for smaller areas. Eyelid avulsion wounds require early intervention in order to protect vision. In extensive avulsion wounds of both upper and lower eyelid, local cheek flaps similar to the Mustarde flap can be used for lower eyelid reconstruction. Axial pattern forehead flaps or radial forearm free flap reconstruction can be used for upper lid reconstruction (Figure 4-26), resulting in less scar contracture and improved esthetic appearance. The reader is encouraged to review multiple reconstructive options for complex avulsion wounds of special anatomic areas prior to deciding on which method will be the best.

• **Figure 4-22** Reapproximation of tissue. This case is an example of a complex wound with gaping margins and partial avulsion **(A)**. In this case, extensive wound undermining is done with tight closure **(B)**. Although dehiscence occurred at one year postoperative, it is much improved **(C, D).** An important concept for pediatric wounds is obtaining wound closure by whatever means necessary (undermining, or skin grafts) because of positive impact to reduce the amount of scarring.

• **Figure 4-23** Wound (**A**), immediate closure (**B**), and one year postoperative (**C**).

• **Figure 4-24** A, Scar excision at 12 months post operative. B, Wound closure under minimal tension after extensive undermining prior to closure. C, Appearance at 18 months postoperative without revisions. Use caution in determining timing for revision. Revision is necessary because of wide scar ban.

Facial Burns

Facial burns produce significant changes in the physical features that are central to the human being. Features of facial expression, communication, feeding, phonation, and special sensory altered by burns can change the patient's entire individual identity. Early evaluation and management is critical in order to maintain or restore facial features essential to identity. There are many types of burns caused by different mechanisms, such as thermal, radiation, chemical, or electrical. Burns can occur at temperatures above 48 °C and are time dependent. Burn injury is classified based on the level of the injury to the skin.

First-degree burns would be similar to a sunburn and can produce mild to moderate pain depending on the level of burn. First-degree burns affect only the epidermis, or outer layer of skin. The burn site is red, painful, dry, and with no blisters. Long-term tissue damage is rare and usually consists of an increase or decrease in the skin color.

Second-degree burns involve skin and superficial dermis and are referred to as "partial thickness." Second-degree burns involve the epidermis and part of the dermis layer of skin. The burn site appears red, blistered, and may be swollen and painful. Partial-thickness burns may be further divided into superficial and deep depending on the level. Typically, second-degree burns form fluid-filled blisters, which result in the separation of the epidermis and dermis and produce moderate to intense pain.

Third-degree burns refer to full-thickness skin and extend though the dermis into subcutaneous tissue and classically are insensate and pale to translucent in appearance. Third-degree burns destroy the epidermis and dermis. Third-degree burns may also damage the underlying bones, muscles, and tendons. There is no sensation in the area because the nerve endings are destroyed. Third-degree injuries are beyond the scope of this chapter and the reader is encouraged to review more comprehensive literature for details.

Because the face involves orifices with both respiratory and gastrointestinal tract epithelium, it is essential to evaluate all areas in the advanced trauma life support (ATLS) secondary survey. Airway evaluation should include observation for signs of singed nasal hair, nasal and oropharyngeal soot, erythema of the oropharynx, carbonaceous sputum, dysphonia, stridor, dyspnea, rhonchi, and wheezing. Initial arterial blood gas (ABGs) and chest x-ray (CXRs) should be done as a baseline. Fiberoptic evaluation of the airway should be performed and, if clinical signs and symptoms of the above are present, intubation should be performed for airway protection. Oropharyngeal exam may show similar findings of edema, erythema, or carbonaceous material with signs of dysphagia. Ophthalmology examination should be performed to evaluate for singed eyelash and brow hair, lid edema and blistering, conjunctival edema and injection, corneal exam, visual acuity, and funduscopic exam. Incidence of ocular injury in facial burns approaches 27%.[56,57]

Evaluation of ears, nose, and eyelids for deep partial-thickness and full-thickness burns dictates specific treatment protocol.

Management

Prevention of airway compromise and death caused by pulmonary injury from facial burns should be the first priority. Humidified 0_2 by face shield, elevation of head of bed, and suction for excess secretions should be initiated early. Simultaneous to pulmonary resuscitation, attention should be given to fluid resuscitation. Burn resuscitation is beyond the scope of this chapter and the reader is encouraged to review literature that deals with such.

In the acute phase, gentle debridement of loose skin and debris should be performed and antiseptic soap (TechniCare Surgical Scrub Care-Tech Laboratories, Inc.) should be used to clean and decontaminate the burned skin. Reduction in the bacterial count with antiseptic soap reduces the risk of conversion of burn wound depth from bacterial infection. The use of chlorhexidine gluconate offers optimum antisepsis, rapid onset of action, and broad spectrum coverage for gram-positive, gram-negative, and virucidal activity.[58]

The use of topical antimicrobials that control and limit burn wound antimicrobials ideally should be broad spectrum; should exhibit long duration, low toxicity, and good penetration; and should be inexpensive and easy to use. By providing good penetration and broad-spectrum coverage, topical antimicrobials prevent conversion of burn wounds from zone of stasis to zone of coagulation necrosis, thus reducing the need for debridement and subsequent grafting.

Topical agents commonly used are silver preparations such as silver sulfadiazine, silver nitrate, and Acticoat (Smith Nephew, Hull, UK). Mafenide acetate (Sulfamylon, Bertek Pharmaceuticals, Morgantown, WV), a sulfonamide, provides fast, deep penetration with excellent antimicrobial spectrum. Antibiotic preparations such as Neosporin, Polysporin, and Bacitracin are the most commonly used agents for superficial burns. Polysporin and Bacitracin in combination with enzymatic debriding agents provides clean burn wounds in partial-thickness burns and results in outcomes superior to those obtained by silver sulfadiazine.[59] However, the use of enzymatic debriding agents in facial burns remains controversial and produces variable results.[60] Multiple alternative methods have been described including amnion,[61] honey,[62,63] sucralfate,[63] beta glucans,[64] and aloe vera.[65] Aloe vera appears to accelerate the sound healing process in both first- and second-degree burns compared to traditional topical treatments. Cadaveric allografts appear to be a superior biologic dressing for superficial and deep partial-thickness burns when compared with traditional management with silver sulfadiazine.[66] Bioengineered skin substitutes have also been compared to traditional management and show similar efficacy.

Once wound closure is achieved, early rehabilitation is begun before scar formation demonstrates hypertrophy. Therapeutic intervention includes pressure garments, masks, and orthotic devices. Such pressure devices improve scar maturation and redistribution of collagen fibers. Compliance with such devices is the primary challenge in the rehabilitative phase; however, without adequate post-burn rehabilitation outcomes are universally less than desirable.

The most common form of facial compression is the use of a mask in combination with compression garments. Openings are made in the garment and mask for nasal obturators and oral commissure spreaders to give continuous pressure in this area. Garments and masks are worn for up to 1 year or more, with modifications made every 6 to 8 weeks to maintain adequate compression. Garments and masks are removed only for short periods for bathing, eating, oral hygiene, and exercise.

Recent developments in the management of burn scars with the use of fractionated CO_2 laser have shown promise in early outcomes. Further studies need to be conducted to compare the efficacy of different rehabilitative modalities.

Diagnosis and Management of Trigeminal and Facial Nerve Injuries

THOMAS SCHLIEVE, MICHAEL MILORO, ANTONIA KOLOKYTHAS

Introduction

The face and perioral regions are among the body regions with the highest density of peripheral nerve receptors, and this feature makes neurologic disturbances less tolerable in the head and neck than other body parts. The 5th (trigeminal) and 7th (facial) cranial nerves innervate the vast majority of structures involved in sensation and function of the face. The trigeminal nerve is the largest cranial nerve, with three main divisions including the ophthalmic, maxillary, and mandibular branches. It is a mixed motor (special efferent and proprioceptive) and sensory (general afferent) peripheral nerve. Injury to the peripheral branches of the trigeminal nerve can be devastating because of the effects on speech, deglutition, mastication, and taste, as well as impact on social interactions. The facial nerve innervates the muscles of facial expression in addition to providing taste sensation and parasympathetic stimulation to the lacrimal, submandibular, and sublingual salivary glands. Damage therefore not only is cosmetically and functionally cataclysmic but has detrimental effects on psychological, social, and economic well-being.

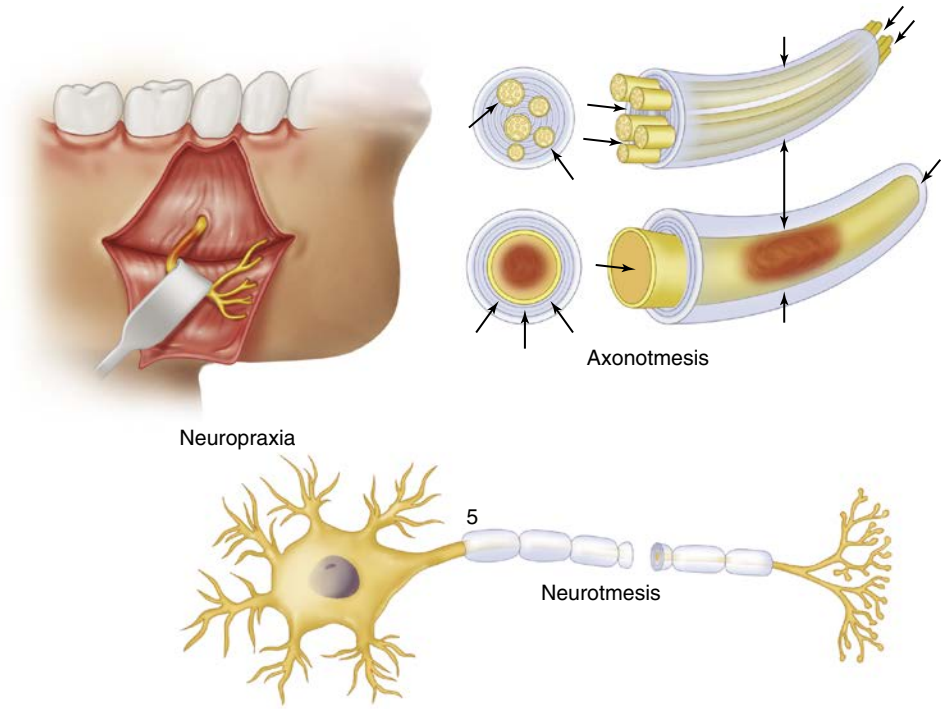
Unfortunately, injury to the trigeminal and facial nerve can occur rather easily from trauma, infection, or pathology, or from commonly performed procedures in the maxillofacial region. Throughout their careers, oral and maxillofacial surgeons often encounter patients with trigeminal and/or facial nerve injuries and should be proficient in diagnosing and managing these cases appropriately because successful outcomes from nerve injuries are critically time-sensitive. In this chapter the following topics are presented: an overview of the anatomy of the trigeminal and facial nerve; a basic overview of peripheral nerve microanatomy to assist the reader's understanding of the events following injury and a nerve's regenerative properties; the available imaging modalities; several potential causes of nerve injury; and the neurosensory testing available for appropriate evaluation and classification of nerve injuries. Finally, the treatment of trigeminal and facial nerve injuries and the expected outcomes are discussed.

Classification of Nerve Injuries

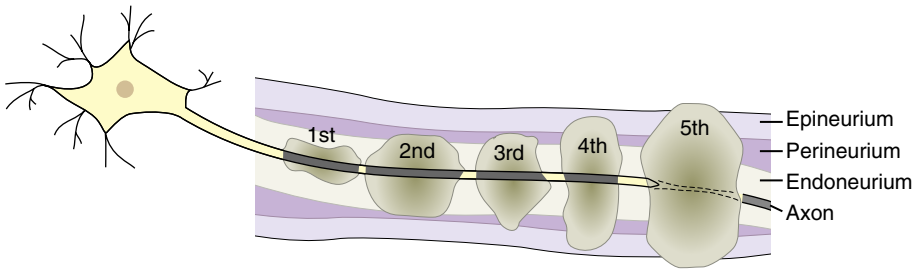
Several complex cellular events occurring in and around the nerve structure are responsible for the response to trigeminal and facial nerve injury and are required for the regeneration and restoration of neurosensory function. Two nerve injury classification schemes, Seddon and Sunderland, are described and provide for a correlation between the clinical symptoms and the histologic changes observed within the nerve structure at the time of injury. Seddon's classification is based on the time between injury and recovery and the degree of recovery, whereas Sunderland places an emphasis on the specific histologic degree of damaged neural structures.

Seddon Classification System

The Seddon classification system includes three levels of nerve injury (Figure 5-1): neuropraxia, axonotmesis, and neurotmesis.[1] In neuropraxic injuries, the integrity of the axon is maintained, and the injury indicates a local conduction block from a transient anoxic event due to acute vascular interruption of the epineurial or endoneurial vasculature. Neuropraxia is usually the result of a mild nerve manipulation, traction, or compression injury and is characterized by a reversible conduction block, with a favorable outcome and complete recovery within days to weeks of the event. No axonal degeneration occurs in neuropraxic injuries, and damage is confined to the endoneurium only. Axonotmesis involves axonal damage, corresponds to degrees II-IV Sunderland injuries, demonstrates variable



• **Figure 5-1** Seddon classification system including examples of neuropraxia with nerve stretching; axonotmesis with variable degrees of axonal injury; and neurotmesis with nerve transection. (From Fonseca RJ, Walker RV, Barber HD, et al: *Oral and maxillofacial trauma*, ed 4, St Louis, 2013, Saunders.)



• **Figure 5-2** Sunderland classification system showing the five degrees of nerve injury with progressive injury beginning with damage confined within the endoneurium (1st degree injury) and extending outward to the perineurium (2nd degree), then through the perineurium (3rd degree), and to the epineurium (4th degree), and finally through the epineurium with discontinuity (5th degree). (From Fonseca RJ, Walker RV, Barber HD, et al: *Oral and maxillofacial trauma*, ed 4, St Louis, 2013, Saunders.)

degrees of demyelination and axonal injury, and therefore, spontaneous recovery varies significantly in this category of injuries. More details are provided in the following discussion of Sunderland's classification of nerve injuries. Finally, neurotmesis implies complete or near-complete nerve transection that includes epineurial discontinuity. Spontaneous recovery is unlikely, whereas neuroma formation is common.

Sunderland Classification System

Sunderland revised and further subclassified nerve injuries in 1951 and described a five-degree classification system (Sunderland's degree I-V nerve injury) based on histologic findings of the degree of nerve involvement[2] (Figure 5-2). A first-degree Sunderland injury is the same as Seddon's neuropraxia described earlier, and was further divided by Sunderland into three types based on severity and recovery time. First-degree Type I injury is the result of nerve manipulation that causes transient blood supply interruption that, once restored, allows for full sensory recovery after only a few hours. First-degree Type II injury involves intrafascicular edema formation, from fluid exudate or transudate, as a result of moderate traction or compression on the nerve. Sensory recovery follows edema resolution within a few days. First-degree Type III injury results from more aggressive nerve manipulation and may involve segmental demyelination with recovery requiring a few days to weeks.[3] Second-degree injuries involve axonal and myelin interruption with an intact endoneurium, epineurium, and perineurium, allowing for axonal regeneration. Recovery is a relatively slow process and may take up to 1 year for

TABLE 5-1 Classification of Nerve Injuries and Associated Findings

Injury Type	Histologic Findings	Response	Recovery Pattern	Recovery Rate	Treatment
First degree (Seddon neuropraxia)	Transient ischemia, anoxia, ± segmental demyelination, intrafascicular edema	Conduction block	Complete	Fast (hours to weeks)	None indicated
Second degree (Seddon axonotmesis)	Axon and myelin interruption (intact endoneurium, perineurium, & epineurium)	Wallerian degeneration distal to injury	Complete	Slow (weeks)	None indicated
Third degree	Injury involves endoneurium (intact perineurium & epineurium)	Wallerian degeneration and some degree of neuron cell death	Variable	Slow (weeks to months)	Nerve exploration may be considered
Fourth degree	Injury involves endoneurium and perineurium	Wallerian degeneration, neuron cell death, neuroma formation and intrafascicular fibrosis	None	Spontaneous recovery not likely	Microneurosurgery
Fifth degree (Seddon neurotmesis)	Complete nerve transection, continuity disruption	Wallerian degeneration, cell death neuroma, fibrosis	None	No spontaneous recovery possible	Microneurosurgery

complete return to normal sensation, but is possible because of the intact supporting connective tissue structures. These injuries are caused by traction or compression on the nerve. In third-degree injuries, the endoneurium is involved in the injury while the epineurium and perineurium remain intact. The usual etiologies are the same as for first- and second-degree injuries, and some spontaneous recovery is expected. Complete recovery is unlikely, and surgical exploration may be considered. Fourth-degree injuries caused by traction, compression, needle injection, or chemical injury lead to disruption of the endoneurium and perineurium, while the epineurium remains intact. These injuries are associated with a poor potential for spontaneous recovery and a high probability of neuroma formation and intraneural fibrosis. Surgical intervention is required for these injuries, especially if there is no improvement within 3 months following the injury. A fifth-degree injury in Sunderland's classification system corresponds to Seddon's neurotmesis. It implies nerve transection, avulsion, or laceration with complete disruption of all components of nerve organization with little to no chance of spontaneous recovery. Extensive fibrosis, neuroma formation, or neuropathic changes occur in these serious clinical situations, and microneurosurgery is indicated. In cases of witnessed nerve transection, immediate surgical intervention is warranted. Table 5-1 summarizes the types of injuries, corresponding histologic changes, responses, recovery pattern, rate of recovery, and recommended treatment.

Axonal and Cellular Response to Injury

Nerve injury involves several events and variable responses, but the basic process of nerve healing remains the same and involves a sequence of degeneration followed by regeneration.[4,5] Within hours of axonal injury, a series of events occur at the primary site of injury, as well as at the distal and proximal portions of the axon and the cell body. The changes within the cell body and the nerve fiber proximally depend on the proximity of the injury to the cell body as well as the severity of the injury. Within 6 hours of the injury, the metabolic rate of the cell body increases significantly. This results in edema and migration of the nucleus toward the periphery of the cell body, upregulation of the rough endoplasmic reticulum (Nissl substance), and increased protein synthesis. These events are collectively known as chromatolysis and represent the histologic correlation of RNA and protein synthesis, a programmed event intended to ensure cell survival that peaks within 14 to 21 days following acute injury.[6-14] Chromatolysis signals the proliferation of perineural glial cells that, along with macrophages, phagocytes, and Schwann cells, begins the cleanup process of cellular debris at the injury site.[4,5,15]

When the injury involves the axonal fibers (Sunderland II-V grade injuries), a series of molecular and cellular events occur, either simultaneously or consecutively, and collectively result in wallerian degeneration.[16] These events occur throughout the distal nerve trunk as well as the small portion of the proximal end close to the injury site. The distal portion of the axon becomes edematous, so its ends are sealed, while the myelin that surrounds the axon breaks down into droplets.[17] The debris is phagocytosed by Schwann cells with enhanced proliferation and activity levels as well as recruited macrophages. These events, which are a prerequisite for nerve regeneration to occur, are initiated within hours of the injury and are completed within 1 week following the nerve injury.[18-24] Neural degeneration occurs in both the distal and proximal nerve ends, so the final result is empty endoneurial tubes that act as conduits for nerve regeneration; these tubes are present up to the site of the injury.[17,21,25-27]

Proximally, the transected axon forms sprouts, or axonoplasmic extensions, that mimic the axon growth cones observed during embryonic neural development. Several substances produced by neural and supportive tissues are required, and these ultimately lead to the growth and regeneration of the axon toward its receptor target.[20,28-31] Each axon may have as many as 50 collateral axonal sprouts. The high proliferative activity of the Schwann cells noted during these phases is thought to be required for the production of new myelin that will host the new axon. This theory has been challenged by Yang and colleagues, who demonstrated that Schwann cell proliferation may not be an absolute requirement for nerve regeneration, but rather that this is achieved via existing Schwann cells that survive the insult but do not divide, and that the regeneration is axon-driven and axon-dependent, as opposed to a predominant Schwann cell influence.[19]

In any case, if these processes take place in the appropriate chronological order, spontaneous nerve regeneration will be achieved. In cases when there is interruption or unfavorable sequencing of these events, the outcome will be failure of reinnervation of target receptors and possible neuroma formation. Neuromas represent a disorganized mass of collagen fibers and nerve sprouts that are randomly oriented.[32-36] Neuromas can be of the following types: amputation (stump neuroma), neuroma-in-continuity (central or fusiform neuroma) (Figure 5-3), or lateral (lateral exophytic, or lateral adhesive neuroma) (Figure 5-4). Neuromas may be painful or asymptomatic, and histologic differentiation between the two clinical scenarios is not possible. What appears to distinguish the painful and non-painful neuromas is their neurophysiologic properties.[37-39] Last, consideration must be given to the mechanism of injury and the resultant nerve injury. For clean lacerations of the nerve, primary repair is usually indicated, but for avulsive-type injuries, a delayed primary repair is preferred. A delayed primary repair is typically performed at 21 days following the injury, as this allows time for the area of injury to become defined macroscopically, levels of neurotrophic and neurotropic factors are at their highest, and the nerve is most amenable to repair.

Trigeminal Nerve Anatomy

Macroanatomy

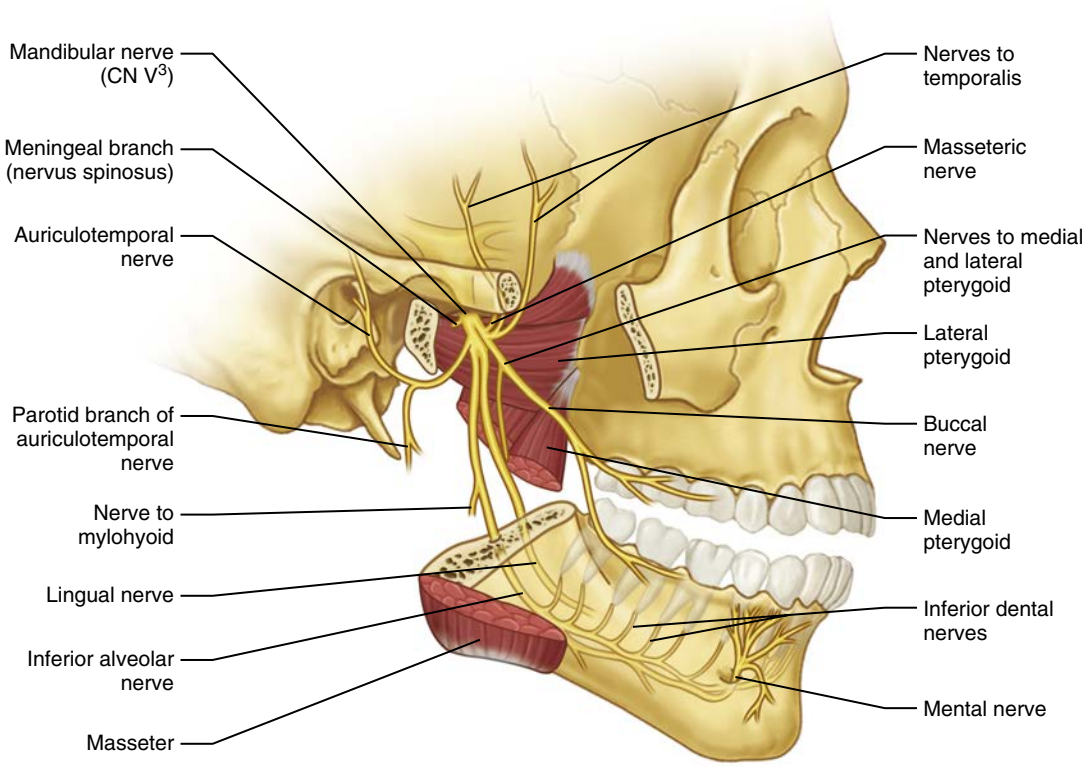
Inferior Alveolar Nerve

The largest of the three branches of the mandibular division of the trigeminal nerve (V3) descends between the medial pterygoid muscle and the medial ramus and enters the mandible at the mandibular foramen (Figure 5-5). At the lingula (the bony landmark for the mandibular foramina along the medial surface of the ramus), the inferior alveolar nerve (IAN) has the greatest diameter of 2.4 ± 0.4 mm. At the mandibular foramen, the IAN diameter is 2.0 ± 1.1 mm. The mental nerve exits the mandible at the mental foramen, and the course of the bony canal appears to be fairly predictable.[40-42] Between the mandibular foramen, where the IAN enters the mandible, and the second premolar region, the IAN follows an S-shaped course. The nerve is most lateral in the third molar region and then approaches the lingual plate in the first molar region. In the premolar region, the IAN returns toward the buccal cortex before exiting the mandible through the mental foramen.

In their study of the mandibular canal, de Oliveira and colleagues analyzed the bi- and tridimensional position of the canal through multiplanar computed tomographic (CT) scan morphometric analysis and provided useful average distances of the canal to the buccal and lingual cortices, the inferior border, and the alveolar ridge. The locations of the mandible for the measurements were selected to represent areas of commonly performed maxillofacial procedures associated with high risk for nerve injury, specifically extraction of third molars, sagittal split osteotomy, and dental implant placement. The authors did not find significant differences between the right and left sides, whereas in edentulous patients the typical values were lower in females than in males, and in older patients (ages between 51 and 75 years) than in younger individuals (ages 25-50 years).[43]

According to Cutright and co-workers, the mental foramen was found to be apical to the second premolar in about 51% of the cases. It was noted that in whites the foramen was located between the premolars, whereas in blacks it was located distal to the second molar. In addition, the group noted small but significant differences between males and females for the three studied foramina (mental, infraorbital, and supraorbital).[44] In the sagittal plane, the course of the IAN in the mandible begins superiorly and lingually at the lingula, approximately 10 mm from the sigmoid notch, and it reaches its lowest point at the first molar-second premolar region, with the distance from the inferior border of the mandible of 7.5 mm ± 1.0 mm, where it splits into the incisive and mental nerve branches. The incisive dental branch continues forward toward the incisors, whereas the mental nerve ascends and loops backwards for a variable distance (3-7 mm) to exit at the mental foramina through the buccal cortex.[45,46]

Classically, the mental nerve is described as having two branches (range between one and four branches) with the largest being the labial branch running on the orbicularis oris



• **Figure 5-5** Regional anatomy demonstrating the peripheral trigeminal nerve system. (From Fonseca RJ, Walker RV, Barber HD, et al: *Oral and maxillofacial trauma*, ed 4, St Louis, 2013, Saunders.)

muscle fibers, and a smaller mucosal branch that runs posteriorly on the buccinator muscle fibers. The labial branch innervates the lip and chin mucosa and overlying skin, and it may re-enter the mandible to innervate the mandibular incisors and even cross the midline,[47] The mucosal branch innervates the buccal mucosa and gingiva of the mandible as far posteriorly as the first and second molar where cross innervation with the buccal nerve may occur. Throughout its course in the mandible, the IAN provides branches for innervation of the mandibular teeth.[48]

Lingual Nerve

The lingual nerve (LN) branches from the posterior division of the third division of the trigeminal nerve, medial to the lateral pterygoid muscle, and it is located medial to the IAN. It supplies sensory and special sensory function to the anterior two thirds of the ipsilateral tongue, floor of mouth, and lingual mandibular gingiva. The LN is joined by the chorda tympani as it passes through the pterygotympanic fissure, which provides taste (anterior two thirds of the tongue) and carries special visceral afferents (preganglionic parasympathetic fibers from the facial) to the submandibular and sublingual glands. Kim and associates, in their study of the topographic relationship of the LN and IAN at the infratemporal fossa and paralingual space in 32 cadaveric hemi-sectioned heads, noted four patterns of furcation between the two nerves in relationship to the sigmoid notch and the lingula (Table 5-2). In addition, the group measured the distance of the bifurcation to stable bony landmarks, including the foramen ovale and the hamulus. The bifurcation was identified to occur on average 14.3 mm (range: 7.8-24.1 mm) inferior to the foramen and 16.5 mm superior to the tip of the hamulus (range: 4.9-24.3 mm).[49] This variation in the bifurcation patterns between the IAN and the LN, as well as the collateral nerve branches at the retromolar region identified in 81.2% of the cases in the study by Kim and colleagues, is thought to contribute to the reported failure rate of mandibular anesthesia.[49,50]

TABLE 5-2 Types of Furcation of IAN and LN

Type of Furcation between IAN and LN	Level of Furcation between Sigmoid Notch and Lingula	Percentage per Type
Type I	Separation occurs above notch and inferior to otic ganglion	65.6% (21/32)
Type II	Separation occurs below notch and at superior half of distance between notch and lingula	28% (8/32)
Type III	Separation occurs below notch and at inferior half of distance between notch and lingula	3.1% (1/32)
Type IV	Separation occurs in a plexiform pattern	6.3% (2/32)

IAN, Inferior alveolar nerve; *LN*, lingual nerve.

The LN then passes into the pterygomandibular space between the ramus and the medial pterygoid muscle, where it is surrounded by mesoneurial fat throughout its course. It enters the oral cavity over the superior pharyngeal constrictor, styloglossus, and mylohyoid muscles at the anterior border of the medial pterygoid muscle. As the nerve approaches the third molar region, it courses from a more lateral to a more medial position following the oblique flaring of the ramus. The exact location of the LN at the third molar region has been studied extensively, with some controversial findings between cadaveric studies, clinical observation during third molar surgery, and high-resolution magnetic resonance imaging, with regard to its proximity to the mandible.[51-58] Table 5-3 summarizes the reported distances and relationship of the nerve to the mandible at the third molar region. In this location, the nerve has a diameter between 2.0 and 5.0 mm and may be round, oval, kidney-bean shaped, elliptical, or ribbon-like in cross section, with a predominance of one shape versus another varying among the studies.[49,56,58]

At the second molar region, the LN crosses Wharton's duct from a lateral to medial direction traversing below the duct and hypoglossal nerve in the submandibular triangle. The nerve in this location gives off the preganglionic parasympathetic fibers (from the facial nerve) to the submandibular ganglion. These fibers are transected during submandibular gland excision so the gland can be released from the nerve. It has been reported that the risk of LN injury during submandibular gland excision or sialodochoplasty of the Wharton's duct ranges between 1.4% and 4.8%, and the nerve is in danger from both intraoral and extraoral approaches.[59-62]

After looping under Wharton's duct, the LN passes upward onto the genioglossus muscle and enters the oral tongue muscular substance. With the exception of one or two large branches that proceed toward the tip of the tongue, all other branches to the tongue and adjacent lingual mucosa and gingiva are of small diameter (generally no more than 1-2 mm). The larger branches provide the greatest density of innervation to the tip and medial portions of the anterior two thirds of the tongue, compared to the posterolateral, dorsal, and ventral portions, and this difference is developmentally driven.[63]

Buccal Nerve

The buccal nerve (BN) is a branch of the mandibular division of the trigeminal nerve that carries sensory fibers to the lower buccal sulcus, gingival, buccal, and cheek mucosa and may contribute to the cutaneous supply of the cheek. The nerve travels between the two portions of the lateral pterygoid muscle, beneath or through the lower part of the temporalis muscle deep to the mandible, then crosses over the external oblique ridge at the anterior border of the masseter muscle and merges with the same branch of the facial nerve. It is this

area where the nerve crosses over the external oblique ridge that places it at risk for injury, most commonly from third molar surgery. A rare variation that supports the IAN as the origin of the BN is described by Turner, Singh, and Jablonski and their colleagues, who identified the nerve exiting the mandible through a small foramen at the retromolar fossa.[64-67] As the nerve reaches the surface of the buccinator muscle, it divides into a superior division that supplies the muscle and an inferior division that provides the sensory innervation of the mucosa, as stated earlier.

Hendy and colleagues, in their study of the course and relationships of the BN in 20 cadaveric specimens, noted the following: The nerve was found to have 4 to 8 major branches with a mean number of 3 branches where it crosses the external oblique ridge. The nerve trunk was found to cross the ridge as close as 3 mm from its deepest concavity of the external oblique ridge in 70% (14 of 20) of specimens. In the remaining cases, the distance ranged between 7 and 12 mm below that point. The authors postulated that the nerve is at risk from incisions in this region even if these are placed as far away as 12 mm from the external oblique ridge. The variation of the branching patterns of the nerve, in addition to the high mechanosensory threshold noted on the buccal mucosa, may result either in a small area of damage or in the injury going unnoticed by the patient.[66,68,69]

Infraorbital Nerve

The infraorbital nerve (ION) is a major branch and the termination of the second division of the trigeminal nerve that emerges on the face via the infraorbital foramen. The foramen is on average 2.7 cm from the facial midline and 6 to 8 mm from the inferior orbital rim. In males the foramen is larger than in females, with some differences in the distances from the midline and infraorbital rim identified in anatomic studies.[44,70] In the study by Kazkayasi and co-workers, a single foramen was found in 90% of cases, two canals in 5%, and three canals in the remaining 5%. The shape of the canal was found to be oval in 30%, round in 40%, and semilunar in 30% of cases.[71] The ION enters the orbit via the inferior orbital fissure and transverses the orbital floor in the infraorbital canal (IOC) for 22 mm. The canal may not be complete, as the cortical thickness of its roof ranges between 0.1 and 6.0mm and thus the nerve may be exposed without a discrete superior bony wall. The combination of a groove and a canal is found in 50% of the cases, and the remainder demonstrate a complete canal.[71] Racial and gender variations have been reported in the location and shape of the foramen as well as the length of the canal.[70,72,73] After it exits the infraorbital foramen, four branches of the ION have been identified and correspond to the areas of the midface, nose, upper lip, and lower lid innervated by the nerve.[74] The ION is at risk for injury during approaches for reconstruction of the orbito-zygomatico-maxillary complex following traumatic events and during maxillary orthognathic surgery. Orthognathic-related injuries are typically transient and reversible, whereas sensory changes from entrapment of the nerve encountered in midface trauma may cause more problematic, long-term neurosensory changes.

Microanatomy

The microanatomy of the trigeminal and facial nerves is the same, with sensory and motor nerves containing myelinated and unmyelinated fibers in a ratio of 1:4. The difference between the two types of fibers is the number of Schwann cells that surround each fiber with nodes of Ranvier that permit rapid saltatory nerve conduction (Figure 5-6). In the myelinated fiber, the ratio of nerve axons and Schwann cells is 1:1, whereas in the unmyelinated fiber the Schwann cell envelops several axons. The membrane, or basal lamina, created by the Schwann cell as it wraps around the axon, runs the entire length of the axon, is called a band of Büngner (laminar myelin sheath) and is crucial in the process of nerve regeneration. Although myelin may be destroyed during the nerve injury, the Schwann cells survive and play a major supportive role in nerve recovery and repair. The length of the axon surrounded by a single Schwann cell is known as the internode, and the small area (0.3 μm to 2.0 μm) between the internodes, where the axon is not myelinated, is known as a node of Ranvier. In each node of Ranvier, diffusion of ions occurs, resulting in nerve depolarization and repolarization. This allows for the conduction of nerve impulses along the nerve fiber. Conduction occurs only between the nodes of Ranvier (saltatory conduction) and is responsible for the rapid impulse transmission noted in myelinated nerve fibers (up to 150 m/s) compared to the nonmyelinated nerve fibers (2-2.5 m/s). Typically, unmyelinated axons are also smaller, with diameters ranging between 0.15 and 2.0 μm.

Collagen provides the framework that surrounds the nerve and creates the structural architecture within the nerve (Figure 5-7). The endoneurium is the first organization of fine collagen fibers around each nerve fiber axon. Several bundles of endoneurial groups, known as fascicles, are grouped together and surrounded by a second layer of collagen fibers (and mesothelial cells) called the perineurium. The outer layer of connective tissue supporting the nerve, along with some elastic fibers, creates the external epineurium or extrafascicular epineurium. Another layer of epineurium that invests the fascicles is known as internal epineurium. The epineurium makes up 50% of the cross-sectional area of

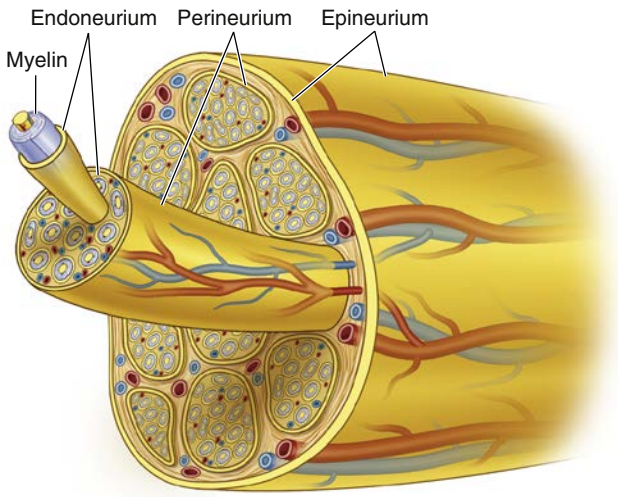
the nerve and provides some protection against compression. The final layer of connective tissue, which is continuous with the epineurium and surrounding tissue bed and is responsible for allowing some freedom of movement of the nerve, is known as the mesoneurium, or adventitia of the nerve.[75]

Peripheral nerves are often distinguished based on their fascicular pattern. A monofascicular pattern has only one large fascicle (an example is the chorda tympani); an oligofascicular pattern contains only a few fascicles (2 to 10; an example is the labial branch of the mental nerve); and a polyfascicular pattern has several different-sized fascicles, more than 10 in total (examples include the facial, IAN, lingual, and buccal nerves). The mean number of fascicles and the cross-sectional area of the trigeminal nerve branches decreases proceeding from proximal to distal nerve.[76-79]

A rich interconnecting vascular network of extrinsic and intrinsic systems provides blood supply for each neuron. The vessels reach the extrafascicular epineurium, via the vasa nervosum, after entering the mesoneurium and create a plexus that runs longitudinally at this level. The vessels continue their course toward the axon by passing in an oblique angle through the subsequent connective tissue layers and forming a longitudinally running plexus during their course at each level. This configuration allows for the individual fascicles to have their independent and rich blood supply analogous to an individual nerve fiber (Figure 5-8).[80,81] This passage of the vasculature between the layers of connective tissue may become an area of compromise within the intrafascicular layers. There are no associated draining lymphatics running with the vascular plexuses.

Trigeminal Nerve Imaging

Objective, noninvasive, radiologic imaging modalities in the preoperative assessment of the patient at risk for nerve injury, as well as a monitoring methods for post-injury and post-repair phases of neurosensory recovery, are highly desirable.[82] Radiologic assessment can be categorized with regard to the timing of the imaging period: that is, pre-injury, post-injury, and post-repair phases. Pre-injury assessment refers to the documentation of the in situ position of a nerve prior to any surgical intervention that places that nerve at risk for iatrogenic injury (e.g., third molar removal, tumor extirpation). Intraoperative monitoring of nerve function during a surgical procedure that involves a specific nerve may also be used, most commonly with functional study of nerve conduction and electrophysiologic status such as somatosensory evoked potentials (SSEP). Post-injury imaging is divided into a primary phase (i.e., following nerve injury and allowing for spontaneous neurosensory recovery without microneurosurgical intervention) and a secondary phase (i.e., following surgical nerve exploration and repair). Primary post-injury imaging may be clinically significant if it can correlate objective (radiologic) findings with subjective (clinical examination) findings, and thereby guide the need for surgical intervention, and possibly aid in treatment planning (i.e., the need for an interpositional nerve graft).



• **Figure 5-8** Schematic representation of vascular supply between the layers of the connective tissue surrounding the axon. *Red*, arteries; *blue*, veins; *yellow*, axons. (From Fonseca RJ, Walker RV, Barber HD, et al: *Oral and maxillofacial trauma*, ed 4, St Louis, 2013, Saunders.)

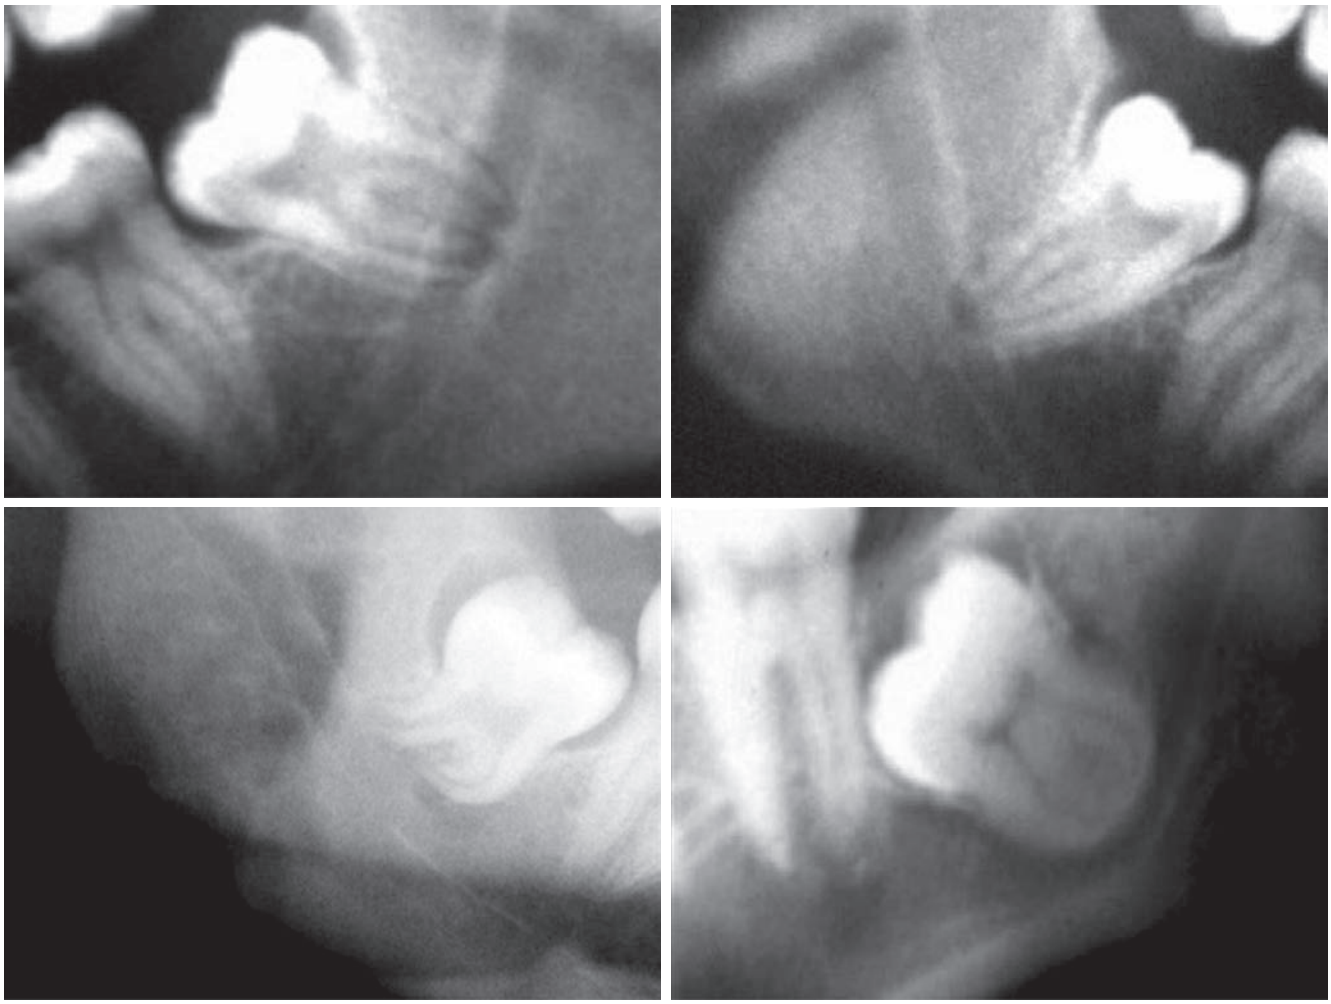
Panoramic Radiography

Preoperative assessment of the position of the inferior alveolar nerve during patient consultation has been routinely performed with the use of a panoramic radiograph. Obviously, information gained from this study is extremely limited because of the two-dimensional nature of the image, the variable magnification of the bony anatomy (for the inferior alveolar nerve), and the complete inability to visualize the position of the lingual nerve. Valuable information can be obtained from the panoramic radiograph as a stand-alone imaging modality in regard to the relationship of the IAN in the vertical plane, but not in the horizontal dimension. The most useful aspect of the panoramic radiograph is in assessing increased potential for inferior alveolar nerve injury during third-molar extraction based on the presence of several radiographic predictors[83,84] (Figure 5-9).

The post-surgery assessment of the nerve-injured patient usually includes a panoramic radiograph that may demonstrate a variety of clinically significant findings. The presence of a foreign body in the region of one or both nerves must be ruled out; these may include metallic foreign bodies from rotary instruments or amalgam particles from neighboring teeth, as well as retained tooth or root fragments following third-molar surgery. The presence of iatrogenic surgical disturbance of the nerves may be indicated by evidence of bone removal in proximity to the inferior alveolar neurovascular bundle or the lingual nerve (Figure 5-10). A panoramic radiograph or any other plain film is rarely used, however, to monitor progression following injury or repair.

Computed Tomography

The use of computed tomography (CT) in the assessment of nerve injuries is very limited. An evaluation of bone



• **Figure 5-9** Panoramic radiographs showing examples of Rood radiographic predictors of root proximity to the inferior alveolar canal, including root darkening, root narrowing, root deflection, loss of the superior white line of the canal, and diversion of the canal. (From Fonseca RJ, Walker RV, Barber HD, et al: *Oral and maxillofacial trauma*, ed 4, St Louis, 2013, Saunders.)

window attenuation images may indicate violation of the cortical outline of the inferior alveolar canal, either from implant placement or following facial trauma involving the posterior mandible (Figure 5-11), but yields little information regarding the condition of the nerve or neurovascular bundle.[85] The use of soft tissue window images for the lingual or inferior alveolar nerves is compromised by very poor detail resolution that precludes its routine application in neural assessment. Furthermore, dental artifacts often impose severe limitations on obtaining accurate information regarding the position of the LN relative to the lingual cortex of the mandible in critical areas, even in the soft tissue windows and despite with the current high-resolution image acquisition.

In 1998 cone beam CT (CBCT) technology, until then used only in angiography, was employed in the United States as a potential imaging modality for the maxillomandibular complex. The use of CBCT for presurgical evaluation of an impacted mandibular third molar and its relationship to the IAN has gained popularity over CT scans and plain panoramic radiographs[86-90] (Figure 5-12).

• **Figure 5-10** Panorex following third molar removal showing the presence of preoperative radiographic predictors of root proximity to the canal, and evidence of the use of a drill distal to the crown of the extraction site in a patient with right lingual nerve injury.

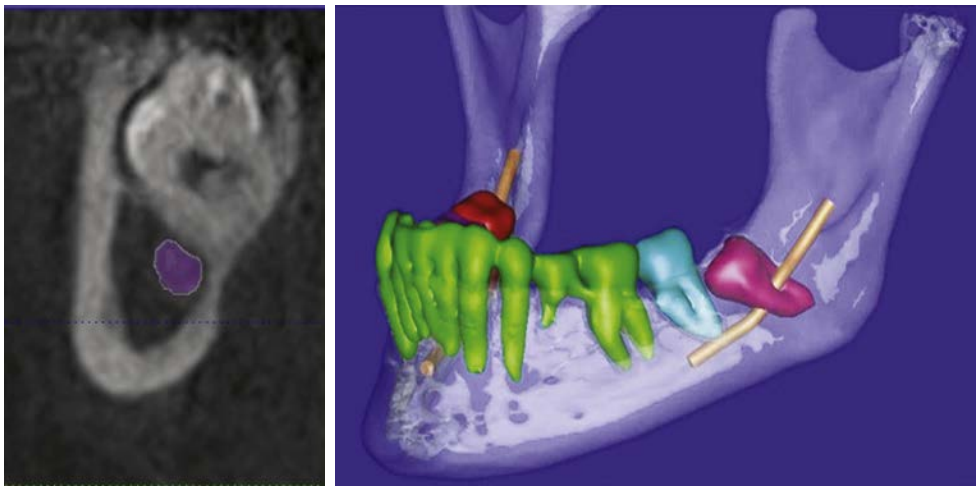
The need for accurate imaging with the lowest possible dose of radiation (following the ALARA rule: as low as reasonably achievable) seems to be well satisfied with this technology. CBCT provides the desired three-dimensional representation of the anatomic location of interest with minimal distortion compared to traditional plain films and by simpler acquisition compared to CT systems.[91,92] Similar to the panoramic radiograph, CBCT can be used for preoperative risk assessment in various dentoalveolar procedures such as third-molar surgery or dental implants and pre-prosthetic surgery.[93-95] A major limitation remains the inability to visualize the lingual nerve, as no accurate soft tissue information can be obtained with use of CBCT.

Postoperative investigation of the surgical site for examination of the integrity of the IAN canal or presence of material, tooth or root fragments, within the canal could be superior and more reliable with CT or CBCT imaging than traditional panoramic imaging. Direct investigation of the integrity of the LN cannot be reliably performed with either modality because of the limitations discussed. Disruption of the lingual cortex of the mandible at the third-molar region that may be noted in a postoperative panoramic radiograph, and may imply trauma to the LN in the region, can be reviewed in more detail with CT or CBCT. Direct comparison of pre- and postsurgical images can be made and added to the information gathered from the clinical examination to potentially assist in the decision for need of exploration in the region.

• **Figure 5-11** Coronal CT scan through a mandibular body fracture showing canal involvement. (From Fonseca RJ, Walker RV, Barber HD, et al: *Oral and maxillofacial trauma*, ed 4, St Louis, 2013, Saunders.)

Magnetic Resonance Imaging

Magnetic resonance imaging (MRI) is the method of choice for visualization of all cranial nerves (CN), and each nerve segment can be seen and examined in detail with specific sequences. Because of the complexity of the course and surrounding anatomic structures, detailed examination of the CNs is possible only with careful planning and MRI technique selection. The imaging plane, coil selection, slice selection, in-plane resolution, and use of special techniques can be tailored based on the CN and the segment of interest so the highest quality image possible is obtained. The course of the lingual and inferior alveolar branches of the mandibular division, after it exits from foramen ovale, can be followed with high-resolution contrast-enhanced T-weighted (T1W) or T1W three-dimensional fast field echo (T1W 3D-FFE) sequences in the axial, coronal, and sagittal or parasagittal



• **Figure 5-12** Cone-beam CT scan showing the proximity of the inferior alveolar canal to an impacted third molar, and 3D reconstruction of the scan to highlight the canal passing between the roots of the impacted third molar tooth. planes.[96-100] MRI is the preferred imaging modality for examination of the status of the CNs in the presence of a disease process or injury.[97,101-104]

In an attempt to document the in situ position of the lingual nerve in the third molar region, high-resolution MRI has been studied. Ten patients (20 sides) of healthy adult volunteers without prior dental surgery were imaged using an MRI sequence that enabled visualization of the lingual nerve (Figure 5-13). This study documented that the lingual nerve position, while variable, was found to be superior to the lingual crest in 10% of cases, and in direct contact with the lingual plate in 25% of cases.[56]

The application of MRI in the assessment of the trigeminal nerve post-injury is in its early trial phases. Presumably, with improved resolution, a variety of anatomic changes in the nerve could be visualized. First, a change in nerve diameter may be visualized in cases of nerve injury with wallerian degeneration of the nerve segment distal to the site of injury with an acute or gradual decrease in nerve diameter. Second, an acute change in nerve position may be seen—for example, where the lingual nerve is retracted into the region of the third-molar socket with the formation of a lateral adhesive or exophytic neuromatous segment. Third, a change in nerve shape may be able to be visualized—for example, in the case of a fusiform neuroma-in-continuity, with a change in shape of the nerve for a certain distance with return to normal shape distal to the neuroma.[105]

The application of MRI to post-injury neural assessment is hindered by a variety of factors. The degree of image resolution and magnification significantly limits precise anatomic examination of the neural elements. The ability to image the internal architecture of neural anatomy will require dramatic improvements in resolution from currently available techniques. Also, while the lingual nerve lies within soft tissue and its course is unaccompanied, the inferior alveolar nerve lies within a cortical bony conduit and is joined by an artery and a vein throughout its course.

Ultrasonography

Several reports have described the use of ultrasound and high-resolution ultrasound technology mainly for assessment of peripheral nerve lesions. This real-time advanced technology with the high-resolution probes now available can offer compound imaging without radiation and in a relatively inexpensive manner. Although ultrasonography (US) has not been employed or investigated as a potential preoperative risk assessment tool for the trigeminal nerve, it has been demonstrated to be valuable in identification and safe advancement of the needle in brachial plexus and sciatic nerve blocks.[106]

Mechanisms of Injury to the Trigeminal Nerve

Several commonly performed procedures in the maxillofacial region are associated with potential injury to the terminal branches of the trigeminal nerve.

Local Anesthetic Injection

Injury to both the IAN and LN is possible during administration of mandibular block local anesthesia. Interestingly, prolonged sensory alterations are rare, considering the number of blocks administered daily by dental professionals. The ratio of injuries to injections has been estimated at between 1:26,762 to 1:160,571, although this may not represent the actual incidence because not all cases of sensory disturbances are reported.[107,108] Harn and Durham in 1990 reported an incidence of transient sensory disturbance of 3.62%, with only 1.8% incidence of long-duration changes (over 1 year).[109] The proposed mechanisms that result in this injury are multiple, the exact cause remains unclear, and there is no reliable way of avoiding these types of injuries. Direct penetration of the nerve by the needle, hematoma formation from vessel laceration, direct laceration of the nerve from a barb on the tip of the needle after repeated injections and needle contact with cortical bone, and chemical injury from intraneural injection are reasonable possibilities.[109-111] Direct toxicity of the local anesthetic solution (specifically 4% articaine and 4% prilocaine), especially when deposited within the confines of the epineurium, has been associated with cases of sensory changes after mandibular blocks.[112-115] Box 5-1 lists conclusions that can be made based on the current understanding of injection-related nerve injuries. These cases are usually associated with only a limited distribution of neurosensory alteration, reflecting the small number of fascicles insulted or involved in this type of injury.[116]

• BOX 5-1 Clinically Based Conclusions on Local Anesthesia-Related Nerve Injuries

1. Not predictable, possibly preventable
2. Painful response upon injection (electric-shock sensation) does not always accompany an injury
3. More common in female patients
4. More commonly result in dysesthesia than hypoesthesia
5. May follow a non-anatomic distribution (involvement of more than one division of the trigeminal nerve) due to segmental demyelination
6. More common with higher-concentration anesthetic solutions (e.g., 4% articaine)
7. Surgical exploration is not indicated due to nature and location of injury
8. Lingual nerve is more commonly affected than the inferior alveolar nerve
9. Spontaneous recovery usually occurs within 8 weeks of the injury
10. Less than one third of cases lasting longer than 8 weeks will recover fully
11. Pharmacologic management is indicated for unpleasant sensations (dysesthesia)

Third Molar Surgery

Complications associated with third molar removal are the most common cause of trigeminal nerve injury reported and can occur during any stage of the actual procedure (Figure 5-14) as well as during postoperative care.[117-121] The overall incidence of IAN injury during third molar surgery is estimated to be between 0.41% and 7.5%, resulting in temporary sensory changes in 2% to 6%, and permanent disturbances in 0.5% to 2% of cases. Stretching or manipulation of the lingual nerve from tissue retraction during third molar surgery is reported to cause temporary sensory disturbances at rates from 6.4% to as high as 15%, but less than 1% result in permanent changes.[116,122-128] Several risk factors associated with increased risk of IAN injury during this procedure have been discussed in the literature and include advanced age, female gender, tooth angulation, depth and type of impaction, integrity of the lingual cortex, complexity of the procedure, and surgeon experience.[129,130] Rood and Shehab in 1990 described seven radiographic predictors of potential proximity of a third-molar to the IAN on panoramic radiograph that may be helpful in the decision-making process regarding extraction versus more conservative approaches such as coronectomy or observation.[84] These radiographic predictors include darkening, deflection, or narrowing of the tooth root; diversion, narrowing, or interruption of the white line of the IAN canal; and a dark or bifid root apex. The most significant radiographic findings of potential nerve injury included root darkening, root deflection, and interruption of the white line of the IAN canal. It is important to note that subsequent studies have reported controversial findings, in both support and opposition of the value of these radiographic predictors in nerve injury (Figure 5-15).[131,132] In any case, these radiographic findings are neither highly sensitive nor specific for nerve injury.

• Figure 5-14 Diagram showing possible iatrogenic injury of the inferior alveolar nerve during extraction of a deeply impacted third molar. (From Hupp JR, Ellis E, Tucker MR: *Contemporary oral and maxillofacial surgery*, ed 5, St. Louis, 2008, Mosby.)

Dental Implant Surgery

With the wide utilization of dental implants for dental rehabilitation throughout the world, injury to the IAN is a fairly common occurrence with a 0% to 40% reported incidence of nerve injury due to implant placement, depending on location (Figure 5-16); and, patient management can be problematic.[133,134] The IAN, in particular, is at risk in the molar region as well as anterior to the mental foramen, especially in edentulous patients because of the associated alveolar ridge resorption. In addition, the surgeon should consider the anterior extension, or genu, of the neurovascular bundle beyond the foramen when placing dental implants in this region. These injures can result from surgical exposure, during preparation of the osteotomy site, or at the time of implant placement. Mechanical compression of the neurovascular bundle can result from overextension of and canal violation during the osteotomy. This can cause infracture of the cortex of the canal at the site and direct pressure on the IAN (Figure 5-17). Alternatively, bleeding within the canal from a laceration of the inferior alveolar vein or artery with an implant drill can cause pressure similar to a compartment syndrome. Finally, direct compression on the neurovascular bundle following restoration of the implant and mastication or prior clot formation and subsequent ectopic calcification may occur. Although extensive literature is available regarding the use of modern imaging modalities for treatment planning in implant dentistry, data are lacking on the most appropriate modality for nerve injury risk assessment, as discussed earlier.[42,134-139]

Management of these injuries is tailored individually based on the mechanism of injury and may involve implant removal as soon as such an event is recognized, or the use of pharmacologic therapy as indicated for dysesthesia. Immediate implant replacement with a shorter implant may be considered, but it is dependent on the exact cause of the trauma and the need or lack of need for nerve canal exploration as well as the timing and recognition of the occurrence.[117,134,140-143]

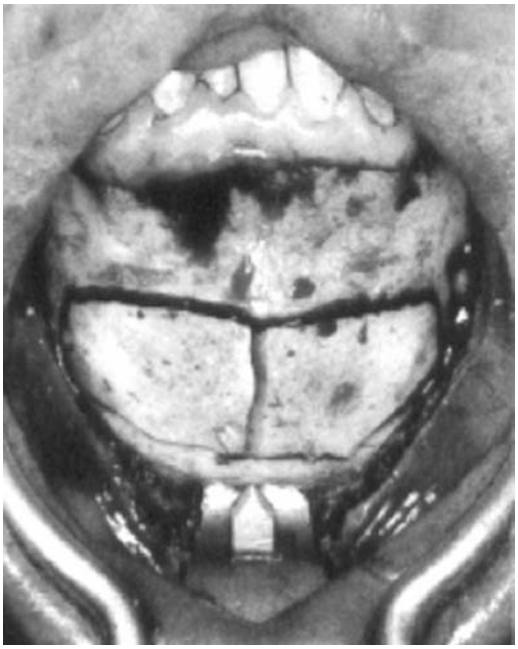
• **Figure 5-17** Panorex showing the distal implant placed within the confines of the inferior alveolar canal in a patient with inferior alveolar nerve paresthesia. (From Fonseca RJ, Walker RV, Barber HD, et al: *Oral and maxillofacial trauma*, ed 4, St Louis, 2013, Saunders.)

Procedures aimed at augmenting the alveolar bone height in the posterior mandible or improving the site to facilitate implant placement, such as bone grafting, distraction osteogenesis (DO), or IAN nerve lateralization carry their own risks for nerve injury. During bone harvesting from the mandibular ramus (Figure 5-18) or chin region (Figure 5-19), the IAN or mental nerves could be inadvertently injured, especially when a large area requires augmentation. When small, single tooth-sized grafts are harvested and appropriate preoperative radiographic examination of the area is undertaken, this risk appears to be minimal.[144] The same branches of the trigeminal nerve are at risk when securing autogenous or allogeneic bone graft material at the recipient site, either from direct compression of the nerve from the graft or from hardware (plates and screws) used to secure the graft in place. Distraction osteogenesis (DO), another method employed for alveolar ridge height augmentation, may lead to nerve injury, again either at the time of the osteotomy or directly from the device used for the distraction. The actual response of the IAN to the DO process has been studied in animal models, and it has been shown that several events occur at the cellular level, including activation and proliferation of Schwann cells as well as a limited degree of axonal degeneration and regeneration. The result is minor nerve injury that is reversible with no long-term sequelae.[145-147]

• **Figure 5-18** An example of a ramus graft procedure that places the inferior alveolar nerve at risk for injury due to its lateral location in this region of the mandible. (From Fonseca RJ, Walker RV, Barber HD, et al: *Oral and maxillofacial trauma*, ed 4, St Louis, 2013, Saunders.)



• **Figure 5-19** An example of a genial bone graft harvest that may sacrifice the incisive branch of the inferior alveolar nerve and result in paresthesia to the anterior mandible dentition. (From Fonseca RJ, Walker RV, Barber HD, et al: *Oral and maxillofacial trauma*, ed 4, St Louis, 2013, Saunders.)

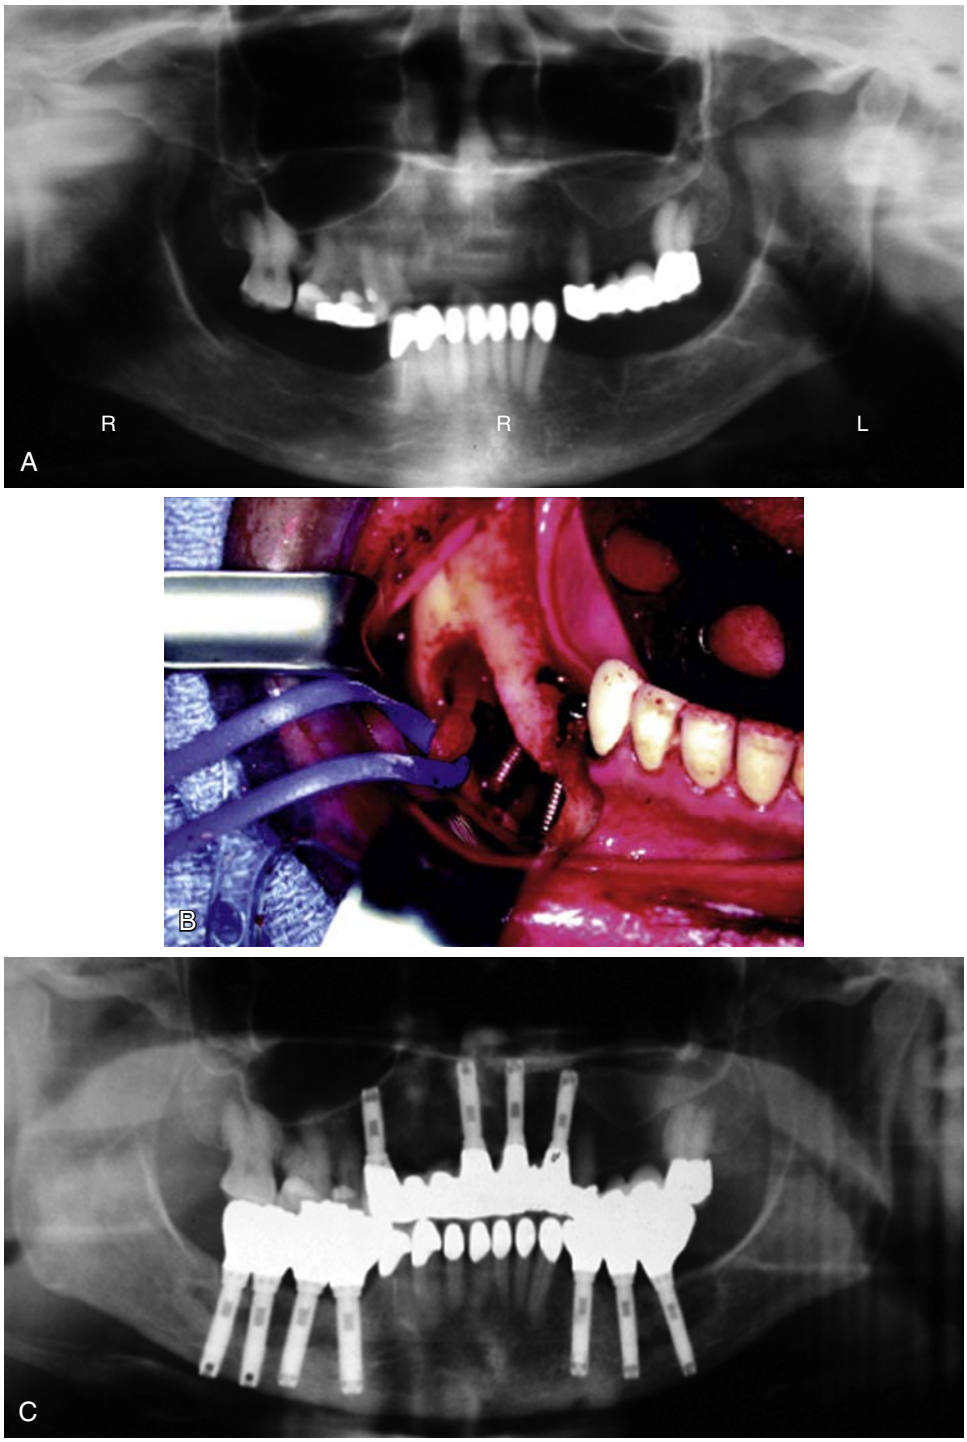
Nerve lateralization for facilitation of implant placement is a viable option in select cases. With this approach, the lateral cortex of the mandible is removed and the IAN is exposed and lateralized so that implants of adequate length can be placed (Figure 5-20). The procedure inevitably causes some neural trauma, but the injury is "controlled," while the risk of compartment syndrome is eliminated along with risk of direct injury to the neurovascular bundle from the implant placement itself. The procedure is associated with a high incidence of neurosensory changes, some permanent, but with excellent implant stability, success, and high patient satisfaction.[148-154] If the nerve lateralization procedure requires release of the mental nerve from the mental foramen, then the incidence and degree of neurosensory dysfunction is increased over a transposition of the nerve posterior to, and not involving, the mental foramen. Recovery after nerve lateralization should be expected within 3 to 6 months, although up to 30% to 40% of patients, especially older individuals, may experience long-term neurosensory dysfunction.[154] The use of piezosurgery in a cadaveric study (10 sheep mandibles with 20 lateralizations) showed no disturbance of structures beyond the epineurium, and the overall degree of injury was found to be less than when the procedure was performed with conventional burrs.[155]

Maxillofacial Trauma

Maxillofacial trauma and surgery for the correction of facial injuries may result in disturbances of the peripheral branches of the trigeminal nerve in the vicinity of the traumatic injury. The overall incidence of neurosensory impairment has been reported to be 70.9%. In cases of nondisplaced fractures, the incidence was found to be 54.4%, while a significant increase was noted in displaced fractures of 88.2%. As expected, cases of direct injury had 100% neurologic impairment.[156] Fractures of the mandible may result in neurosensory alterations due to laceration, traction, or compression of the IAN from bony segment displacement (Figure 5-21) or treatment of the fracture with iatrogenic

injury to the nerve canal (Figure 5-22). Similarly, midface fractures or soft tissue trauma, lacerations, or avulsions may violate the infraorbital canal and damage the ION, leading to transient or permanent sensory alterations[156-159] (Figure 5-23). In a study by Kloss and colleagues, hypoesthesia of the ION was found in 10% of single, and 16% of multiple, midface fractures.[160]

Reduction of fractures with alignment of segments and removal of loose bony segments that impinge on the nerve will assist in spontaneous neurosensory recovery.



• **Figure 5-20** **A,** Panorex showing posterior mandibular edentulism with insufficient bone height above the canal and inadequate interocclusal clearance for implant placement. **B,** Nerve repositioning procedure results in a neuropraxic injury in a controlled fashion during implant placement. **C,** Panorex showing bilateral inferior alveolar nerve repositioning with restored implants that engage the superior and inferior borders of the posterior mandible for stability. (From Fonseca RJ, Walker RV, Barber HD, et al: *Oral and maxillofacial trauma*, ed 4, St Louis, 2013, Saunders.)

Unfortunately, treatment of facial fractures may cause further injury to branches of the trigeminal nerve due to nerve retraction or inadvertent placement of plates and screws.

Orthognathic Surgery

Neurosensory alterations are common sequelae of orthognathic surgery for correction of dentofacial deformities, especially mandibular procedures.[161] During sagittal split osteotomy (SSO), the IAN and LN can be injured at several locations and during the various steps of the procedure. These include during medial dissection at the lingula region, during the actual osteotomy procedure, or during mobilization or fixation of the segments. If the IAN is found to be located in the proximal segment after the osteotomy, then it may need to be mobilized, and this may cause further injury. The location of the IAN in relationship to the inferior border of the mandible, the ramus height, the dentofacial deformity to be corrected, and the patient's age and gender have all been associated with various incidences of neurosensory disturbances.[162-165] In addition, the incidence of neurosensory alterations during mandibular orthognathic surgery has been found to increase with intraoperative complications, most commonly unfavorable splits.[166] Furthermore, IAN sensory alterations appear to occur more frequently with additional procedures (e.g., genioplasty in addition to SSO), but these are transient, and spontaneous full recovery is usually reported within 6 to 12 months.[161,167,168] Interestingly, a substantial difference has been demonstrated between subjective and objective findings regarding sensory alterations after SSO with normal sensation reported in 73.7% of osteotomy sites, while objective testing revealed normal sensation in only 34.2% of cases.[169]

During maxillary or midface procedures, the ION is at risk for injury, most commonly due to soft tissue flap retraction rather than direct injury, and results in sensory changes of the upper lip, cheeks, lateral aspect of nose, and infraorbital region. Based on the nature of the injury (traction, compression, or pressure), full recovery is expected and usually achieved without intervention.[168] Segment fixation with plates and screws could theoretically cause direct injury to the ION or LN from bicortical screw overpenetration (Figure 5-24), but this is an event that is easily avoidable with adequate exposure, visualization, and protection of the nerve.

• **Figure 5-21** Panorex showing an open displaced unfavorable left mandible angle fracture. Note the displacement of the inferior alveolar canal. (From Fonseca RJ, Walker RV, Barber HD, et al: *Oral and maxillofacial trauma*, ed 4, St Louis, 2013, Saunders.)

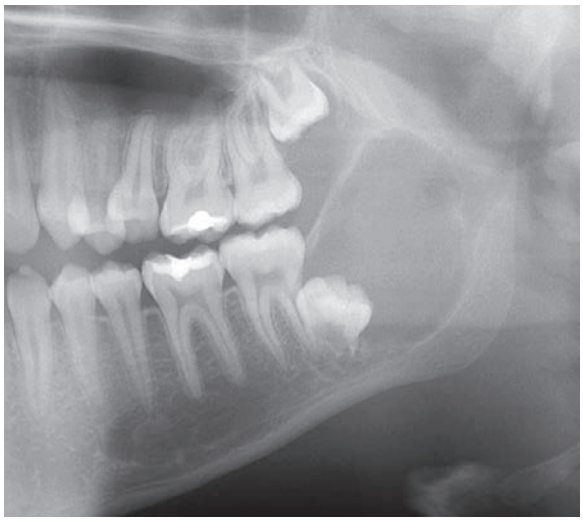
Maxillofacial Pathology

Several odontogenic and non-odontogenic cysts and tumors may be found in the nerve-bearing segment of the mandible in intimate relationship with the IAN. These can result in displacement or encompassment of the canal (Figure 5-25). This also applies to tumors of the maxilla in the vicinity of the IOC. Benign pathology usually is not associated with neurosensory disturbances with the exception of neural or vascular tumors originating from the involved neurovascular bundle (Figure 5-26). On the contrary, malignant lesions usually will be associated with sensory changes, as is the case with specific pathology (e.g., adenoid cystic carcinoma with neurotropism), in cases of tumors with aggressive behavior, when the IAC is invaded by the tumor, or the tumor has caused a pathologic mandible fracture (Figure 5-27). Infectious processes are similarly associated with neurosensory changes if they involve nerve-bearing areas of the jaws but usually spontaneously resolve with resolution of the infection (Figure 5-28).

Treatment of maxillomandibular pathology often involves extensive bone and soft tissue resection that may include the IAN, mental nerve (MN), or ION and result in permanent anesthesia in the distribution of the corresponding resected nerve. On occasion, nerve pull-through procedures or utilization of adjuncts such as enucleation and curettage with cryotherapy, have been advocated for some tumors in an effort to minimize morbidity associated with alternative treatments and associated permanent neurosensory disturbances. These approaches remain somewhat controversial with regard to the associated risk of recurrence and can be in conflict with the basic oncologic principles for management of these tumors.[170-178]



• **Figure 5-25** Panorex of a keratocystic odontogenic tumor causing displacement of the left inferior alveolar canal without paresthesia. (From Fonseca RJ, Walker RV, Barber HD, et al: *Oral and maxillofacial trauma*, ed 4, St Louis, 2013, Saunders.)

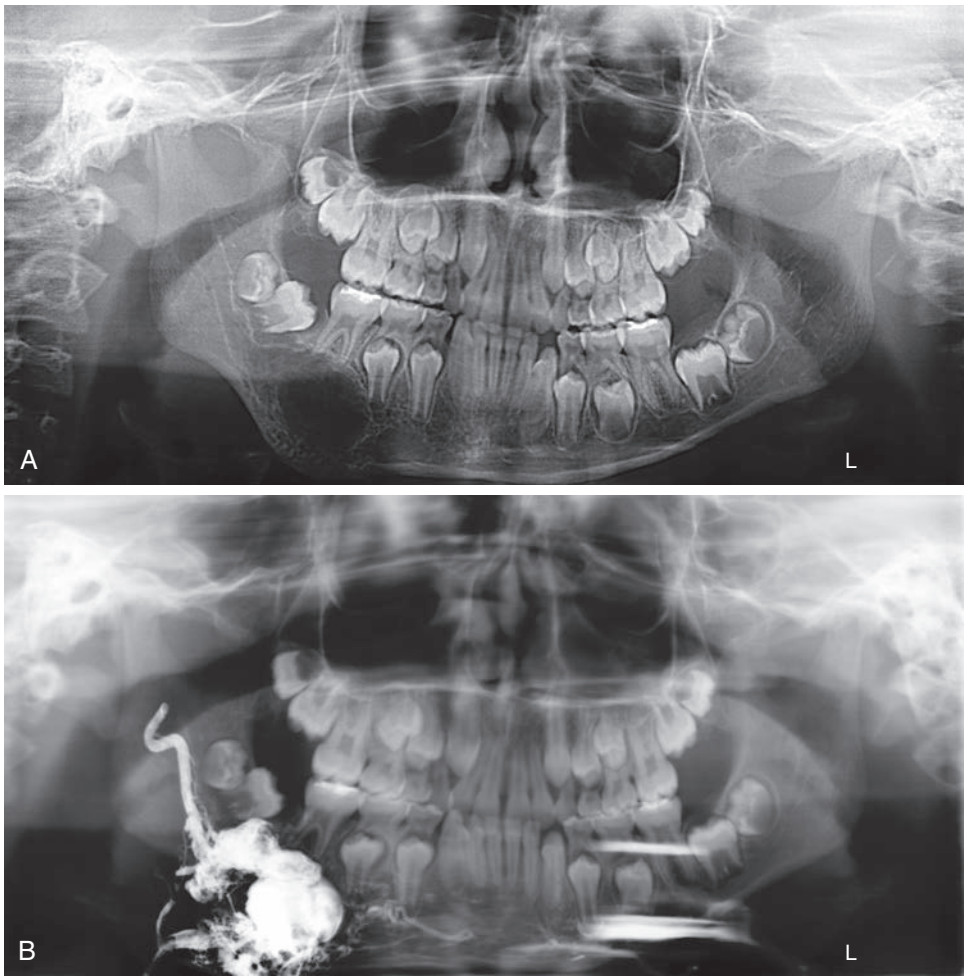
Endodontic and Chemical Injury

Endodontic therapy and periapical root surgery may place the IAN at risk for injury. The nerve may be injured by physical disruption with a file by overinstrumentation of the canal(s), by apicoectomy procedures, or by physical compression from extrusion of the filling materials used (Figure 5-29). The other mechanism of injury is that of chemical neurotoxicity, which may result from the use of certain root canal medicaments to treat the canal(s). These types of IAN injuries can be due to mechanical or chemical factors, or both, and can result in a foreign body reaction or granuloma formation in the canal that may impede spontaneous neurosensory recovery. Unfortunately, these injuries are difficult to manage, with variable success following microneurosurgery, and a large proportion of these injuries may manifest clinically as dysesthesia. For extrusion of potentially neurotoxic root canal filling materials into the IAC, prompt exploration, decompression, and debridement of the foreign material may be beneficial in preventing long-term sequelae.

In addition to root canal medicaments, many other chemical agents are potentially neurotoxic; these include tetracycline, Surgicel (oxidized cellulose), and prolonged exposure of the nerve to Carnoy's solution (a solution of ferric chloride, glacial acetic acid, chloroform, and ethanol).

Clinical Neurosensory Testing

The use of universally accepted terminology is crucial when discussing nerve injury, and it is imperative that the appropriate terms be used to describe and document each case for communication between clinicians, determination of management strategies, and medicolegal reasons (Box 5-2). In addition, a detailed description, including but not limited to nerve mapping and photographs of the region affected by



• **Figure 5-26** **A,** Panorex of an arteriovenous malformation of the right mandible involving the inferior alveolar canal. **B,** Panorex of the same patient following arteriography with embolization. (From Fonseca RJ, Walker RV, Barber HD, et al: *Oral and maxillofacial trauma*, ed 4, St Louis, 2013, Saunders.)

injury should be documented in each patient and used to quantify the initial presentation and, most importantly, to follow the progress of the area of involvement (Figure 5-30).

A detailed history and clinical examination along with objective testing that includes the use of specific neurosensory testing (NST), pain questionnaires, and visual analogue scales are crucial in the assessment of the patient who has sustained trauma to the trigeminal nerve. Attention to details regarding the onset of symptoms, events associated with the current complaints, and changes, including worsening or improvement, requires careful documentation and plays a critical role in the treatment decision-making process.[117,158,179,180] Descriptive terms used by the patient to qualify their symptoms need to be documented in the chart exactly as stated by the patient.

In a critical evaluation of the accuracy of NST to accurately diagnose trigeminal nerve injuries, Zuniga and co-workers demonstrated that for LN assessment, NST had superior sensitivity and specificity compared to examination of the IAN. In addition, IAN findings were associated with a high incidence of false-positive and false-negative results—23% and 40%, respectively.[181] This was subsequently supported in a recently published comparison between clinical NST and current perception thresholds.[182] NST should be performed in patients with neurosensory changes to determine the degree of sensory impairment, monitor recovery, and assist in decision making as to the need for surgical intervention. The clinical neurosensory testing protocol involves mechanoreceptive fiber testing performed first (two-point discrimination, static light touch, directional discrimination, and vibratory sense), followed by nociceptive fiber testing (pain stimuli and thermal discrimination). Testing should be performed in the same manner and sequence on each occasion, in a quiet, calm, comfortable environment with the patient in a semi-reclined position. It is important that the clinician explain in detail the tests that will be performed and assure the patient that there will be no pain involved. An uninvolved normal site should be used to establish a baseline control site and to demonstrate the tests about to be performed. Marking can be done directly on the patient's face with erasable markers, on photos obtained prior to testing, or on drawings on standard recording forms if available. If the marking is done directly on the face, the patient needs

• BOX 5-2 Select Terminology for Sensory Alterations

Allodynia: Pain due to a non-painful stimulus
Analgesia: Absence of pain from a painful stimulation
Anesthesia: Absence of any sensation from a painful or non-painful stimulation
Dysesthesia: Abnormal sensation, spontaneous or evoked, that is unpleasant
Hyperalgesia: Abnormal response to a painful stimulus
Hyperesthesia: Increased sensitivity to stimulation; excludes special senses
Hyperpathia: Increased reaction to a (repetitive) stimulus
Hypoalgesia: Diminished pain in response to a painful stimulus
Hypoesthesia: Decreased sensitivity to stimulation; excludes special senses
Neuralgia: Pain in the distribution of a nerve or nerves
Paresthesia: An abnormal sensation, spontaneous or evoked, that is not unpleasant

to be photographed, and all photos, drawings, and forms must be kept in the records for documentation purposes and for future reference and comparison.

The clinical neurosensory testing protocol (Figure 5-31) begins by outlining the area of sensory disturbance, using brush-stroke directional discrimination to differentiate between the normal and the affected area. Brush-stroke directional discrimination is performed with a camel-hair brush or a fine sable brush that is stroked across the affected area at a constant rate, and the patient is asked to indicate the direction of movement. The correct number of responses out of 10 is recorded. Static two-point discrimination is performed next using any device that allows for measurement between two points, and these tips should be blunt, not so sharp as to stimulate the nociceptive fibers. The closest distance at which the patient can discriminate two points versus one point at both the control and injured site is recorded. If the findings at this level of testing, brush stroke and two-point discrimination (Level A testing), are normal, no further testing is required. The patient injury can be classified as Sunderland first-degree injury. If the findings are abnormal at level A, testing proceeds to the next level. Level B testing involves contact detection and is performed with von-Frey hairs or Semmes-Weinstein monofilaments of several diameters reflecting the stiffness of the filament and the force required to deflect it on contact. The narrowest filament consistently detected by the patient is recorded for the control site and the involved site. Level A and B testing examines the integrity of the large myelinated A-alpha and A-beta fiber types. If Level B testing is normal, no further testing is required, and the patient is considered mildly impaired, representing a Sunderland second-degree injury. If findings are abnormal at Level B, then testing proceeds to the next level. This involves pinprick nociception and thermal discrimination, and it evaluates smaller myelinated A-delta fibers and unmyelinated C fibers. A 30-gauge needle, in the absence of a pressure-sensitive device, can be used for pinprick testing, with care not to cause injury to the skin or mucosa, and an all-or-none response may be recorded. For thermal discrimination, there are specialized Minnesota thermal discs or simpler options such as ice or hot water on a cotton swab. Suprathreshold thermal testing has been shown to be valuable in the assessment of iatrogenic injuries to the IAN and LN.[183] Normal responses at Level C testing imply a moderate impairment (Sunderland third-degree injury), whereas abnormal findings may be consistent with either severe impairment with an increased thermal threshold or a decreased nociceptive response (Sunderland fourth-degree injury) or lack of response to pinprick or temperature with complete anesthesia (Sunderland fifth-degree injury).[117]

Pain as a result of nerve injury can be assessed with a simple visual analogue scale or with a more complex McGill pain questionnaire. This can also be used for evaluation of altered sensation and is a useful tool for continuous monitoring of progress. Direct or indirect injury to the LN may cause taste alteration that can be a significant component of the patient's subjective complaints. Taste requires special testing that may involve the entire mouth or be localized; however, it is generally difficult to assess taste alterations, and there is poor correlation between degree of injury, alteration in taste, and response to surgical intervention.[117,184-187] Taste can be evaluated with 5% saccharose (sweet), 5% saline (salt), 5% citric acid (sour), and 0.5% quinine hydrochloride (bitter).[186]

Indications for Microneurosurgery

Careful patient assessment and collection of information from neurosensory testing are crucial in the decision-making process for treatment recommendations and the need for

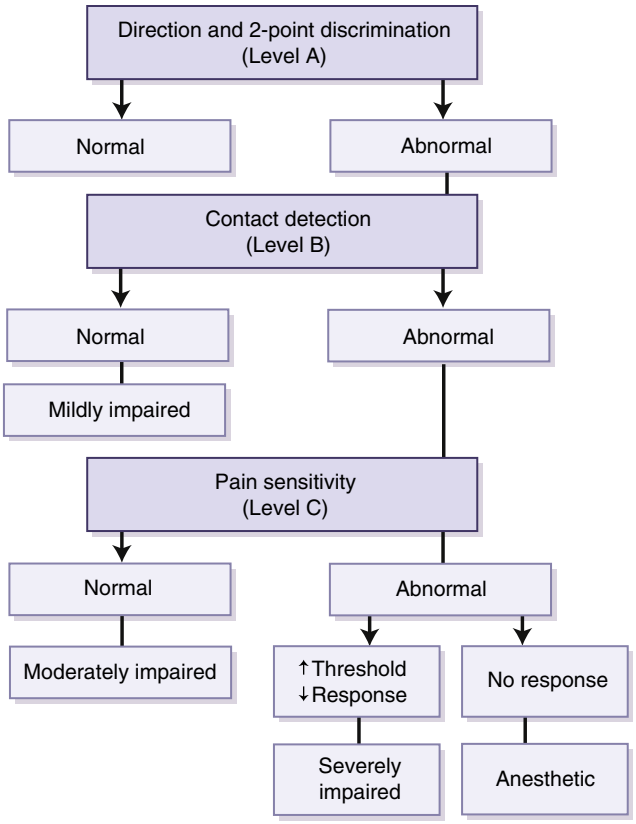
• **Figure 5-30** Facial photographs with the areas of involvement marked are useful for monitoring progression. (From Fonseca RJ, Walker RV, Barber HD, et al: *Oral and maxillofacial trauma*, ed 4, St Louis, 2013, Saunders.)

surgical innervation (Table 5-4). With the exception of an observed nerve transection that requires immediate surgical repair, successful treatment of all other injuries requires a balance of timing to allow for potential spontaneous recovery without delaying timely microsurgical intervention. The complex events surrounding nerve injury with degeneration and regeneration distally, proximally, and centrally make timing of intervention critical when it is indicated.[188-191]

Clinical neurosensory testing, along with subjective findings, should guide and dictate appropriate treatment. When improvement is documented during periodic nerve testing, surgery is not yet indicated. Microneurosurgery is also not indicated in cases of central neuropathic pain, or most cases of dysesthesia or unpleasant sensations, and consideration should be given to pharmacologic management of these difficult clinical scenarios. If persistent paresthesia is documented in subsequent visits, then referral to a surgeon with expertise in microneurosurgery is prudent. Although several timing guidelines regarding surgical intervention exist, the scientific evidence to support them is limited.[192] It is generally accepted that prolonged delay may decrease the success of microneurosurgical repair. Regardless of the exact timing, indications for microneurosurgery include a witnessed nerve transection, no improvement of significant hypoesthesia (more than 50% compared to control site), the presence of a foreign body, neuroma formation, progressive worsening of hypoesthesia or dysesthesia, and intolerable subjective hypoesthesia.[193] Intervention for LN paresthesia should be considered earlier (1 to 3 months post injury) than for the IAN (3 to 6 months post injury), because the inferior alveolar canal provides a conduit to spontaneous nerve regeneration, whereas the LN lies in soft tissue. This may explain why IAN injuries have a higher rate of spontaneous recovery than LN injuries (Box 5-3). Some studies have indicated that no surgical intervention should be considered longer than 1 year post injury, because distal end organ neurotization is less likely, although others suggest that timing is less important and improvement can be achieved when microneurosurgery is performed after 12 months.[117,193]

Microneurosurgery for Trigeminal Nerve Injuries

Microneurosurgical procedures are best performed in the operating room under loop magnification or with use of an



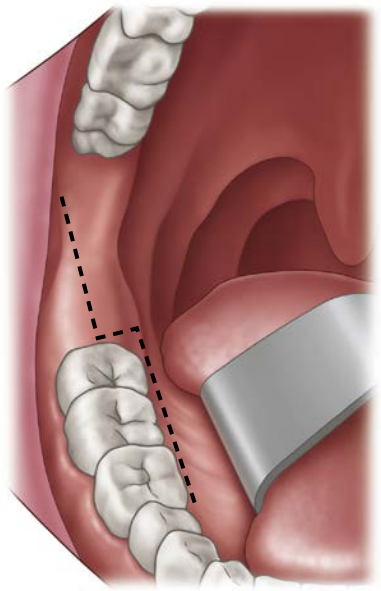
• **Figure 5-31** Clinical neurosensory testing algorithm. Level A testing (brush stroke direction and two-point discrimination) is done first, and if normal, the exam is normal (Sunderland 1st-degree injury). If Level A testing is abnormal, Level B testing with contact detection is performed, and if normal, the exam is mild impairment (Sunderland 2nd degree injury). If abnormal, Level C testing (pinprick and thermal discrimination) is done, and if normal, the exam is moderate impairment (Sunderland 3rd degree). If Level C is abnormal, then the patient is either severely impaired (Sunderland 4th degree) or, with no response to testing, is considered anesthetic (Sunderland 5th degree). (From Fonseca RJ, Walker RV, Barber HD, et al: *Oral and maxillofacial trauma*, ed 4, St Louis, 2013, Saunders.)

TABLE 5-4 Indications of and Contraindications for Microneurosurgery

Indications
Complete anesthesia
Less than 50% residual sensation (Sunderland III, IV, V)
No improvement within 3 months after injury
Observed nerve transection
Early dysesthesia (neuroma formation)
Intolerable subjective paresthesia
Contraindications
Continuing improvement in sensation
Late dysesthesia (especially IAN)
Central neuropathic pain
Complex regional pain syndrome
Trigeminal neuralgia
Atypical facial pain
Anesthesia dolorosa

• BOX 5-3 Recommended Time Frame for Microneurosurgery, When Indicated

Lingual nerve: 1-3 months after injury
Inferior alveolar nerve: 3-6 months after injury



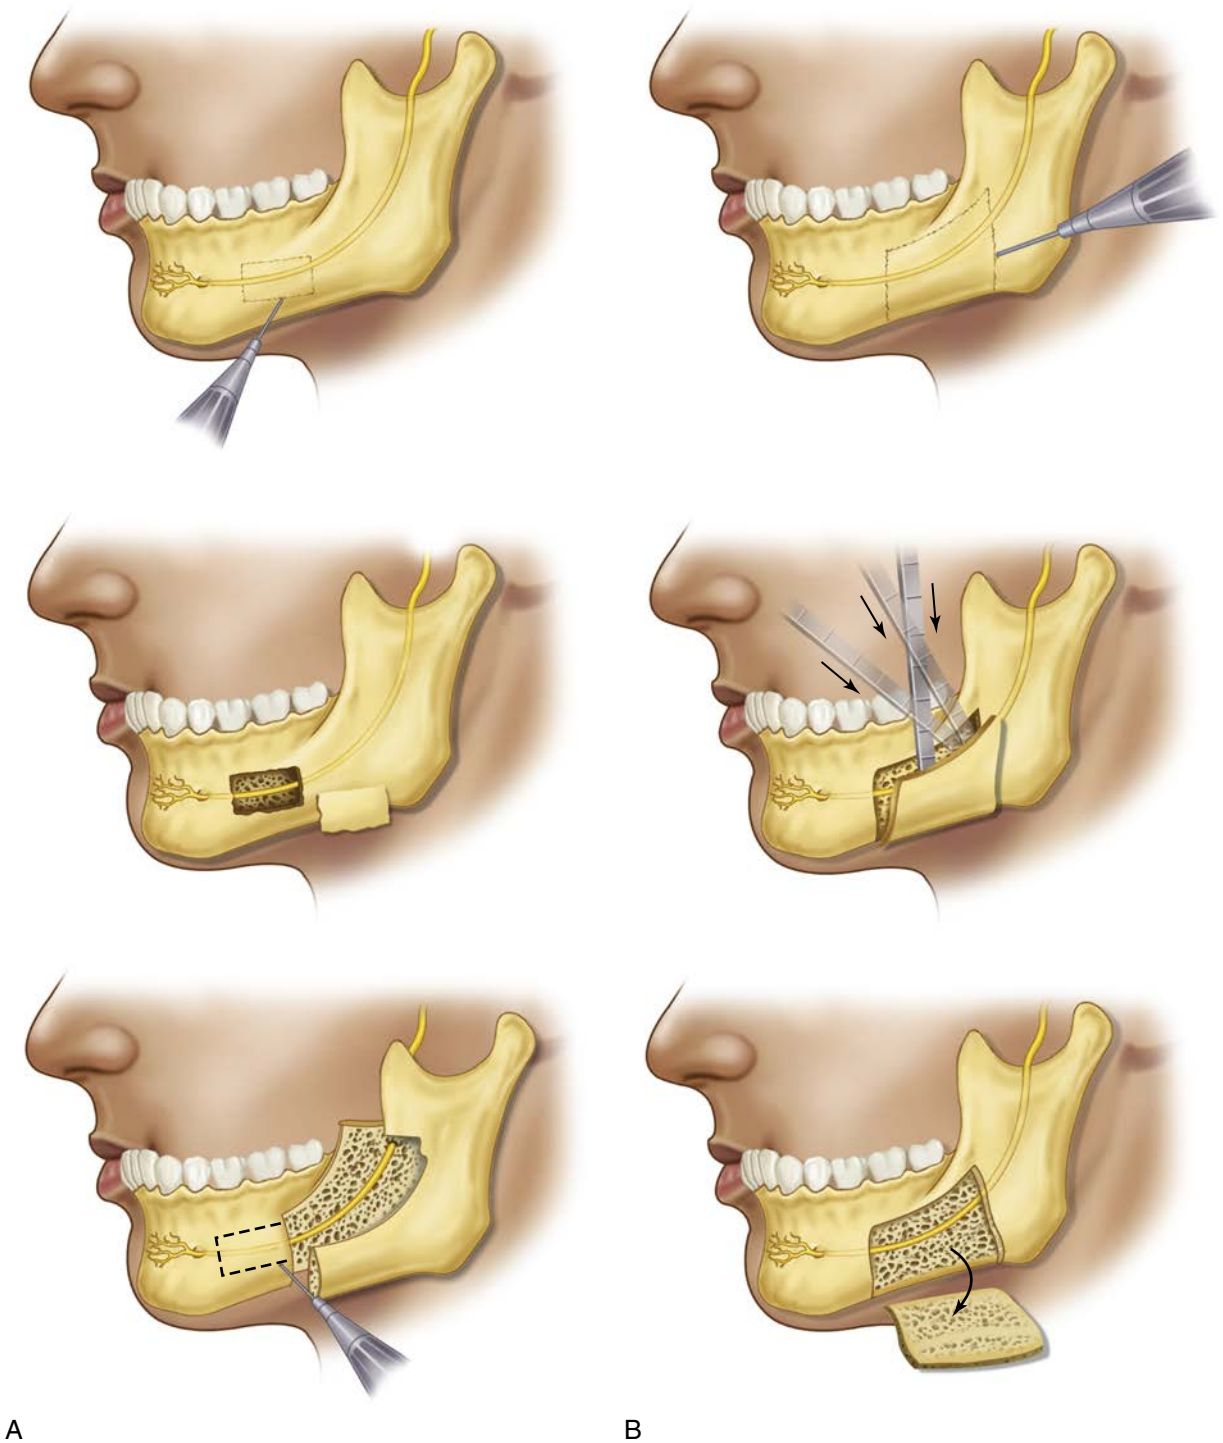
• **Figure 5-32** Diagram showing surgical access for lingual nerve repair using a lingual gingival sulcus approach with posterolateral extension. (From Fonseca RJ, Walker RV, Barber HD, et al: *Oral and maxillofacial trauma*, ed 4, St Louis, 2013, Saunders.)

operative microscope. Surgical exposure to assess the IAN, LN, MN, and ION can be easily performed via intraoral approaches, and in these cases surgical loop magnification maybe more practical than a microscope. There is a clear esthetic benefit from intraoral approaches, but these may be more challenging based on the site of the injury.[117] The more proximal the injury, the more challenging the access is; for example, a LN injury at the third molar region is more challenging to repair than an IAN in the mental foramen area. The individual patient anatomy, surgeon experience, mechanism of injury, and location of the injury are further considerations when deciding the most appropriate surgical approach.

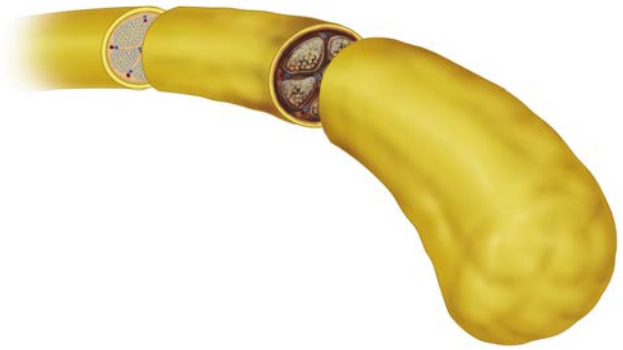
The LN is approached intraorally via a paralingual or lingual gingival sulcus incision (Figure 5-32). The paralingual incision allows for small incision and direct visualization of the nerve, but it may be more challenging to identify the nerve stumps after transection because of retraction into the soft tissues. The latter approach involves a longer incision with anterior and posterior releases, but there is less risk of retraction of the nerve endings during dissection.[194] For the IAN (and MN), a vestibular incision with identification of the mental nerve and lateral decortication to expose a portion of the IAN is usually adequate to mobilize the mental nerve for repair. In cases of restricted mouth opening, an extraoral approach may be required. Once the mandible is accessed, the IAN is approached via lateral decortication

techniques (Figure 5-33).[195] Access to the ION can be accomplished transorally via a maxillary vestibular incision at the time of maxillary or zygomaticomaxillary complex fracture repair. Alternatively, a lower lid, transconjunctival, or subciliary incision may be more suitable and an osteotomy around the infraorbital canal may be required for nerve isolation.[76,194]

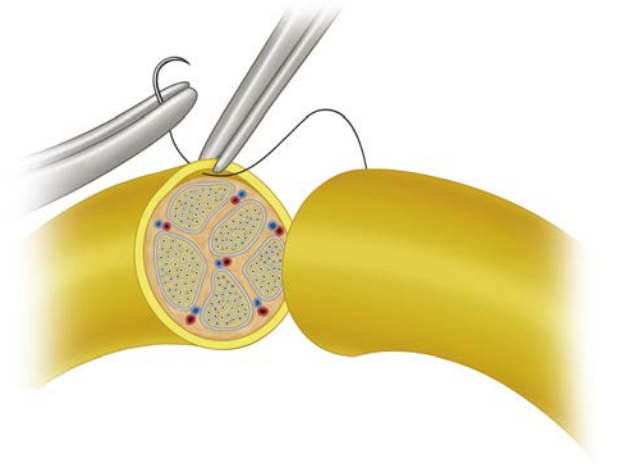
Dissection of the nerve from the surrounding tissue bed for inspection and further manipulation is the next step and is termed external neurolysis (EN). For the LN this may involve microdissection of the neurovascular bundle from surrounding scar tissue, whereas for the IAN it may imply the need for decortication of the IAC and lateralization of the IAN. Separation of the nerve from scar tissue that may be responsible for



• **Figure 5-33** **A,** Diagram of techniques for inferior alveolar nerve access, including isolated decortication, or a sagittal split osteotomy, with extension to the mental foramen if necessary. **B,** Diagram of technique described by Miloro (see Ref. 195) for wide access to the inferior alveolar nerve via a complete lateral decortication window that may be replaced to protect the nerve repair site.



• **Figure 5-34** Diagram showing preparation of the nerve stump with serial 1.0 mm resections to remove scar tissue (neuroma) and ensure that normal healthy neural tissue is encountered prior to the neurorrhaphy procedure. Failure to debride the nerve stumps adequately will result in failure of neurosensory recovery. (From Fonseca RJ, Walker RV, Barber HD, et al: *Oral and maxillofacial trauma*, ed 4, St Louis, 2013, Saunders.)

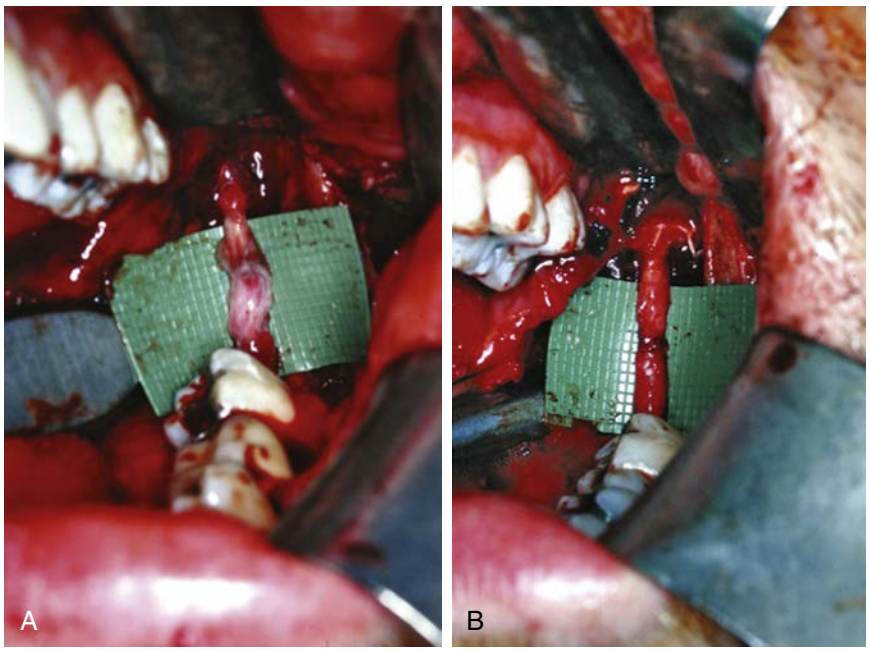


• **Figure 5-35** Diagram showing direct neurorrhaphy with epineurial sutures. (From Fonseca RJ, Walker RV, Barber HD, et al: *Oral and maxillofacial trauma*, ed 4, St Louis, 2013, Saunders.)

restriction or compression leading to a conduction block and prevention of spontaneous recovery may be all that is required. In cases of short duration of symptoms (less than 6 months) or if nerve compression from scarring is less than 25% of the nerve diameter without neuroma formation, EN may provide definitive treatment.[117,193,196,197] EN is performed under loop magnification; once completed, an examination of the nerve is performed and the need for additional intervention is determined. If foreign material or bone or tooth fragments are identified, they should be removed at this stage.

Several injuries may cause intraneural scarring that results in neurologic deficits while nerve continuity is maintained.[198] In such cases, internal neurolysis (IN) is indicated and requires opening the epineurium for fascicular examination. Because of the sparse amount of epineurium in the trigeminal nerve branches, this may lead to further fibrosis and iatrogenic scarring. Caution should be exercised when making the decision to proceed with IN, since it may cause worsening of the condition.[117] Several types of IN are described based on the exact tissue manipulation performed: epifascicular epineurotomy, epifascicular epineurectomy, and intrafascicular epineurectomy that are of progressive complexity, involve tissue removal, and are of questionable benefit for the trigeminal nerve system.[117,192,193]

In cases of neuroma formation, excision followed by restoration of nerve continuity is required. Careful examination of the nerve stumps to be anastomosed is crucial so that healthy nerve tissues are repaired, and scarred and necrotic nerve stumps are completely removed at 1.0-mm resection increments until normal tissue is encountered (Figure 5-34). For a direct neurorrhaphy, epineurial suturing with three or four 7.0 or 8.0 nonreactive sutures (nylon) is adequate for the trigeminal nerve (Figure 5-35).[199] Coaptation is the alignment of individual fascicles during direct repair, and this is difficult if not impossible with a polyfascicular nerve such as the trigeminal.[200,201] Nerve mobilization for tension-free closure is critical and may require dissection in proximal and distal directions (Figure 5-36) or,



• **Figure 5-36** Clinical example of a left lingual nerve neuroma **(A),** and following resection of the neuroma and direct repair with epineurial sutures **(B)**. (From Fonseca RJ, Walker RV, Barber HD, et al: *Oral and maxillofacial trauma*, ed 4, St Louis, 2013, Saunders.)

additionally, in the case of the IAN, sacrifice of the terminal incisive branch to allow further release and mobilization of the IAN.[200]

Cases of nerve injury that result in nerve continuity defects or prevent primary tension-free repair will require indirect repair with interpositional grafting (Figure 5-37). Traumatic avulsive injuries, pathologic conditions involving the nerve, or extensive neuroma resection at the time of nerve repair are common reasons for these continuity defects of the nerve. When nerve mobilization is not adequate to allow tension-free primary repair, then interpositional grafts may be required. The donor site selection for a nerve graft depends on several factors that include diameter and fascicular pattern, correlation of neural function, and donor site morbidity. Usual donor sites for trigeminal nerve repair include the greater auricular and sural nerves because of ease of access and relatively low donor site morbidity with relatively tolerable anesthetic areas.[79,117,193,194,201] In fact, the sural nerve may be the preferred autogenous nerve graft because it matches most closely with the diameter and fascicular pattern of the trigeminal nerve system and it results in an area of minor donor site paresthesia (Figure 5-38).[202] The greater auricular nerve diameter is approximately 50% of the trigeminal nerve diameter, and therefore its usefulness may be limited to cable grafting (multiple grafts) for the trigeminal nerve. Additionally, the harvest would result in a facial scar as well as an area of deficit in the facial region that is less tolerable to patients than the donor site deficit of the lateral foot that results from sural nerve harvest.

Alternatively, several other materials may be used for indirect neurorrhaphy via entubulation techniques, including alloplastic tubes (Silastic, expanded polytetrafluoroethylene,

polyester, polyglycolic acid polymer), vein grafts,[203] and allogeneic nerve grafts (Figure 5-39). The use of alloplastic tubes is attractive because it eliminates donor site morbidity. Unfortunately, there has been no consistency in the reported clinical outcomes with these entubulation techniques, and therefore, this is not a standard technique for management of trigeminal nerve injuries with continuity defects. Vein grafting, on the other hand, has been successfully used for this purpose with results comparable to primary repairs in small defects of less than 5 mm.[204-209] Following surgical intervention, periodic follow-up with repeat NST to evaluate response to treatment is required, and sensory reeducation exercises may be used to augment spontaneous neurosensory recovery.

Outcomes of Trigeminal Nerve Injury and Surgical Intervention

Injuries to the peripheral branches of the trigeminal nerve may be associated with impairment of speech, taste, or mastication and impact on quality of life. Long-term effects of these injuries are not very well documented in the literature. In a recent effort to elucidate this subject, Pogrel and colleagues attempted to obtain information from patients several years following nerve injury via a telephone survey. Despite the poor 20% response rate, patients did report long-term difficulties with jobs, relationships, depression issues, speech, and eating problems. It was reported, however, that patients noted general improvement over time, with 8% describing complete recovery. It is unclear from this study if this represents true neurosensory recovery or adaptation to the altered status of the nerve, yet the authors were in support of surgical intervention when indicated.[188]

Based on the literature in this area, the success of microneurosurgical reconstruction of trigeminal nerve injuries could be estimated to be between 30% and 50%, for all degrees of injury and types of reconstruction, with higher success rates achieved when primary repair is performed.[117,210-212] However, gap repair with an autogenous sural nerve graft may provide a better outcome because the graft itself provides a rich source of Schwann cells and neurotropic and neurotrophic factors to an area of injury that can assist in the degeneration and regeneration process of neural recovery.[202] Factors contributing to the variability of reported success rates relate to inconsistencies in documentation and standardization as well as heterogeneity with regard to etiology of the injury, specific medical or surgical intervention, experience of the surgeon, timing of intervention, length of follow-up, neurosensory testing methods used, method of reporting results, and criteria used to evaluate and define a successful outcome. In a retrospective review of outcomes in 51 patients who underwent microneurosurgical intervention, the following observations were reported: (1) repairs performed less than 10 weeks (early repairs) from the injury appeared to do better than late ones; (2) improved sensation for both IAN and LN can be achieved with microneurosurgery in select cases; and (3) carefully selected patients do benefit from trigeminal nerve microneurosurgery.[210] There is a consensus that a need exists for more data in this area in the form of a prospective, randomized, multicenter clinical trial with standardization in diagnosis and management of trigeminal nerve injuries.

Facial Nerve Anatomy

Macroanatomy

The facial nerve contains approximately 10,000 fibers, of which 7000 are myelinated fibers innervating the facial musculature, with the remaining 3000 fibers providing sensation, taste, and parasympathetic secretomotor functions to the submandibular, sublingual, and lacrimal glands. The facial nerve is described as having three distinct segments: intracranial, intratemporal, and extratemporal. The intracranial segment is that portion of the nerve from the brainstem to the internal auditory canal (IAC). It is made up of two components, a motor root and nervus intermedius carrying sensory, preganglionic parasympathetic fibers, and special afferent sensory fibers. These two components join before becoming the intratemporal segment to form the common facial nerve. Within the caudal pons, motor fibers supplying the lower face cross to the contralateral motor nucleus. The majority of fibers supplying the musculature of the upper face also cross over to the contralateral motor nucleus; however, some fibers do not cross and continue to travel in the ipsilateral motor nucleus. The incomplete crossover of the fibers innervating the upper face results in forehead sparing, often indicative of a central etiology to facial paralysis. The nervus intermedius will provide sensation to the posterior concha and external auditory canal (EAC), taste sensation to the anterior two thirds of the tongue, and secretomotor innervation of the minor salivary, submandibular, sublingual, and lacrimal glands. The intracranial segment of the facial nerve is approximately 24 mm in length.[213,214]

Intracranial Segment

The intratemporal segment begins at the porus acusticus of the IAC and is divided into four portions as it travels to exit the stylomastoid foramen and become the extracranial portion. The first of four intratemporal segments is the meatal portion. This segment is 8 to 10 mm in length and extends from the porus acusticus of the IAC to the meatal foramen of the IAC.[213,214] Traveling in the anterior superior portion of

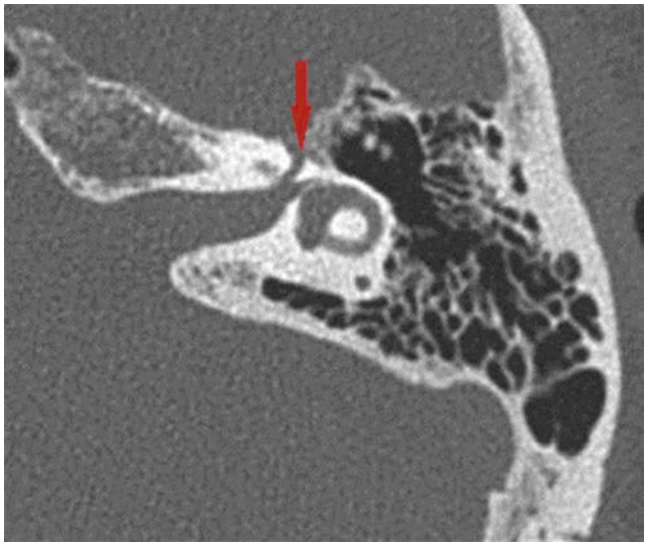
the IAC, the facial nerve is separated from the cochlear nerve anterior inferiorly by a horizontal segment of bone and the superior vestibular nerve posterior superiorly by a vertical segment of bone; it passes by the posterior inferiorly located inferior vestibular nerve. Running within the IAC is the anterior inferior cerebellar artery. A branch of this artery, the labyrinthine artery, supplies blood to this region of the facial nerve.[215]

Intratemporal Segment

The bony canal of the facial nerve begins the second segment of the intratemporal portion, the labyrinthine segment, which is the shortest segment (3-5 mm) and extends from the fundus to the geniculate ganglion. It is within this portion that the facial never runs through the narrowest portion of the IAC (0.68 mm) (Figure 5-40).[213] It is hypothesized this narrow canal is the culprit in facial nerve compression due to Bell's palsy and other causes of facial nerve edema. As the labyrinthine segment ends at the geniculate ganglion the facial nerve gives off its first branch, the greater superficial petrosal nerve (GSPN) (Figure 5-41). The GSPN carries preganglionic parasympathetic fibers from the superior salivatory nucleus to the pterygopalatine ganglion, where it synapses and postganglionic fibers join the maxillary branch of the trigeminal nerve to innervate the lacrimal gland and minor salivary glands of the nose and palate.[215]

The third segment of the intratemporal portion of the facial nerve, the tympanic segment, extends from the geniculate ganglion to the second genu (Figure 5-42). It begins with a 75-degree bend at the geniculate ganglion (first genu). This 8- to 11-mm segment passes superior and lateral to the oval window, inferior to the lateral semicircular canal, and then makes a second turn at a 95- to 125-degree angle (second genu) to become the mastoid segment. The tympanic segment has the highest rate of bony dehiscence (40% to 75%).[215,216]

The fourth and final segment of the intratemporal portion of the facial nerve, the mastoid segment, exits the temporal bone at the stylomastoid foramen approximately 10 to 14 mm from its origin at the second genu (Figure 5-43).[213,215] It gives off two branches, chorda tympani and the nerve to the stapedius muscle. Chorda tympani passes



• **Figure 5-40** Labyrinthine segment (fallopian canal) of the intratemporal facial nerve segment (*red arrow*). Narrowest point in the course of the facial nerve canal.

• **Figure 5-43** Mastoid segment of the intratemporal facial nerve segment (*red arrow*).

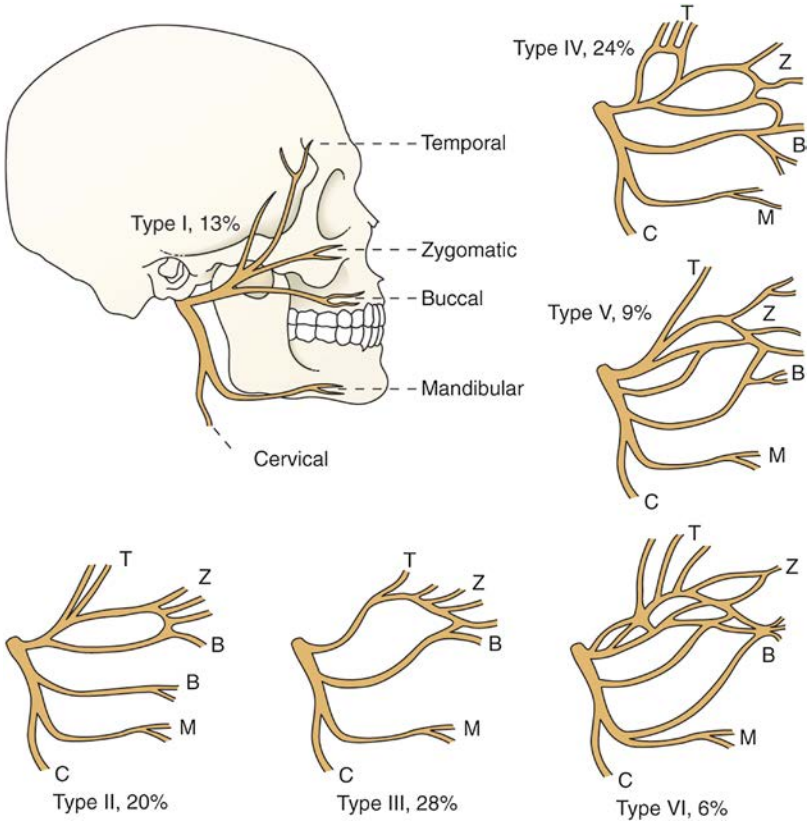
through the petrotympanic fissure and into the infratemporal fossa, where it joins the lingual branch of the trigeminal nerve before reaching the submandibular ganglion. Postganglionic fibers innervate the submandibular and sublingual glands as well as providing taste sensation to the anterior two thirds of the tongue.

Extratemporal Segment

The extratemporal segment of the facial nerve begins at the stylomastoid foramen, which is located posterolateral to the styloid process and anteromedial to the mastoid process. Before entering the substance of the parotid gland, the posterior auricular nerve and branches to the posterior belly of the digastric and stylohyoid muscle divide from the facial nerve. The posterior auricular branch divides into an auricular and occipital branch innervating the external auricular and occipital belly of the occipitofrontalis muscle, respectively. The facial nerve then travels between the digastric and stylohyoid muscles, superficial to the styloid process, and enters the substance of the parotid gland, dividing the parotid into a superficial and deep lobe. At an anatomic point located approximately 1.3 cm from the stylomastoid foramen, the pes anserinus (Latin: goose foot), the facial nerve divides into its two main branches, the temporofacial and cervicofacial.[217]

Various surgical landmarks are available to assist in locating the main trunk of the facial nerve. Prior to locating the nerve, exposure of several important anatomic landmarks should be completed. This includes exposure of the mastoid process, sternocleidomastoid, posterior belly of the digastric muscle, tympanic bone, and EAC. The main trunk of the facial nerve is located midway between the cartilaginous tragal pointer of the EAC and the posterior belly of the digastric muscle. It lies approximately 1.0 to 1.5 cm deep and slightly anterior and inferior to the tip of the external canal cartilage (tragal pointer). Additionally, the facial nerve is 1.0 cm deep to the medial attachment of the posterior belly of the digastric muscle to the mastoid. The tympanomastoid suture line is located approximately 6 to 8 mm lateral to the stylomastoid foramen. Additionally, as dissection proceeds, a branch from the occipital artery may be encountered. This artery lies in close proximity to the facial nerve trunk, and further dissection should be made with caution.[218,219] If the main trunk of the facial nerve cannot be located or its path traced proximally, retrograde dissection of one of the branches of the facial nerve may be necessary.

The temporofacial and cervicofacial trunks then divide into the final five branches of the facial nerve (temporal, zygomatic, buccal, marginal mandibular, and cervical) with various reported branching patterns and no predominant pattern (Figure 5-44).[220] The temporofacial trunk always gives rise to the temporal and zygomatic branches, whereas the cervicofacial trunk always gives rise to the marginal mandibular and cervical branches. The variation in branching patterns is due to the origin of the buccal branch as well as the presence of cross innervation. Cross innervation between the zygomatic and buccal branches is noted in



• **Figure 5-44** Variations in the branching pattern of the facial nerve. (From Townsend C, Beauchamp RD, Evers BM, et al: *Sabiston textbook of surgery*, ed 19, St Louis, 2013, Saunders.)

more than 70% of cases, whereas cross innervation between the temporal or marginal mandibular nerve to other facial nerve branches occurs in fewer than 15% of cases.[221]

The temporal branch of the facial nerve is described as crossing the zygomatic arch within or deep to the temporoparietal fascia approximately 0.8 to 3.5 cm anterior to the EAC and most commonly demonstrating two branches.[222] The course of the temporal branch has been noted to fall between two lines: a superior line connecting the upper tragus to the highest forehead crease, and an inferior line connecting the lower tragus to the lowest forehead crease.[223] In an axial high-resolution MRI study, Miloro and co-workers determined the mean distance from the most anterior aspect of the external acoustic meatus to the posterior ramus of the temporal branch was 2.12 ± 0.21 cm.[224] It innervates the frontalis, orbicularis oculi, corrugator supercilii and the anterior and superior auricular muscles. The temporal branch of the facial nerve also acts as the efferent limb of the corneal reflex.

The zygomatic branch of the facial nerve travels within the parotid gland until its exit approximately 30.71 mm (16.2-45.64 mm) anterior to the tragus and is located a mean vertical distance of 19.29 mm (5.7-28.72 mm) from a line connecting the lateral palpebral commissure and the tragus. It most commonly consists of two branches (69.7%) or three branches (25.8%). The nerve follows a path deep to the zygomaticus major and orbicularis oculi muscle and is located beneath the superficial fascia following its exit from the anterior border of the parotid. It innervates the medial head of the orbital portion of orbicularis oculi muscle, the depressor supercilii muscle, and the oblique head of the corrugator supercilii muscle.[225]

The buccal branch of the facial nerve exits at the anterior border of the parotid, generally noted to be 35 mm (21-53 mm) anterior to the tragus and along the transverse axis of the zygomatic arch, most often as a single branch located inferior and traveling parallel to the parotid duct. When multiple branches are noted exiting the parotid, the most common pattern is to have a branch superior and inferior to the parotid duct, with the superior portion crossing over the duct a variable distance from its emergence. In 100% of specimens, the entire course of the buccal branch of the facial nerve is below a line drawn from the tragus to ala nasi.[226,227] Innervation of the buccinator, levator labii superioris, risorius, levator labii superioris alaeque nasi, levator anguli oris, nasalis, orbicularis oris, depressor septi nasi, and procerus muscles is provided by the buccal branch of the facial nerve. For the majority of the paired facial muscles, innervation is from the deep aspect. The buccinator, levator anguli oris, and mentalis are the exceptions to this pattern.

The marginal mandibular branch of the facial nerve is located within or deep to the superficial layer of deep cervical fascia as it courses anteriorly and innervates the depressor labii inferioris, depressor anguli oris, and mentalis muscles. The location of this nerve in relation to adjacent structures has been extensively studied.[228-230] The marginal mandibular nerve is located above the inferior border of the mandible anterior to the facial artery in 100% of cases. Posterior to the facial artery, it is located above the inferior border in 81% of cases, and in the remaining 19% the marginal mandibular nerve is located up to 1.75 cm below the angle of the mandible with a reported average distance of 1.2 to,1.5 cm below the mandibular angle.[228-230] In addition, the marginal mandibular nerve is located superficial to the facial artery in 100% of cases. Cross innervation with other facial nerves is rare, and therefore injury to the marginal mandibular nerve causes permanent paralysis of innervated structures. The most common branching pattern is two or more with only 28% to 32% demonstrating a single branch-up until arborization near its termination.[228-230]

The cervical branch of the facial nerve innervates the platysma muscle and branches below the angle of the mandible in all cases. It can be reliably located 1 cm below a line connecting the mentum to mastoid about the position of the angle of the mandible.[231]

Microanatomy

The microanatomy of the facial nerve is consistent with that previously described in this chapter for the trigeminal nerve with few exceptions. The facial nerve is considered to be a polyfascicular nerve, although it does not begin to demonstrate true fascicular organization until the geniculate ganglion. Distal to this point, the number of fascicles increases in a proximal to distal fashion. The temporofacial trunk demonstrates on average 13 fascicles (2-29) and the cervicofacial trunk demonstrates an average of 16 fascicles (2-23) with an average fascicle diameter of 300 μm.[232] Within the substance of the parotid gland, the average facial nerve diameter ranges from 0.3 mm to 1.6 mm.[233] Similar to the trigeminal nerve branches, the mean number of fascicles and the cross-sectional area for the facial nerve branches decrease proceeding from proximal to distal nerve.[232]

Chorda tympani most commonly demonstrates a monofascicular pattern before its fusion with the lingual nerve 1 to 2 cm below the base of the skull and just above the lower border of the lateral pterygoid muscle.[78,234] At this point, the lingual nerve has been described as having both a monofascicular and oligofascicular pattern. Shortly after joining the lingual nerve, the fibers of chorda tympani are no longer recognizable as separate entities; the fibers join the lingual nerve fascicles. This explains the lack of gustatory recovery following repair of lingual nerve injuries at the level of the third molar.[78]

Facial Nerve Imaging

The choice of imaging modality in the evaluation of the facial nerve should take into account the location and suspected cause of injury. For suspected intracranial segment pathology or when the location of pathology is unknown, contrast-enhanced MRI is the preferred preliminary imaging. When pathology of the intratemporal segment is suspected, CT with thin cuts through the temporal bone is

indicated along with the addition of MRI, depending on the type of pathology suspected. For evaluation of the extracranial segment of the facial nerve, MRI is again preferred.[215]

Computed Tomography

CT is the preferred imaging modality for pathology of the intratemporal segment of the facial nerve. As mentioned previously, this segment extends from the porus acusticus of the IAC to the stylomastoid foramen and includes four segments: meatal, labyrinthine, tympanic, and mastoid. Dedicated high-resolution CT of the temporal bone with thin cuts (0.6 mm), helical mode acquisition, and contrast when neoplastic or vascular pathology are suspected is the imaging of choice.[235] If a tumor of the facial nerve is suspected, MRI should be obtained in addition to CT, as pathology of the facial nerve within its bony canal can only be inferred based on adjacent bony erosion evident on CT. High-resolution CT of the temporal bone can detect early erosion and destruction of the facial nerve canal in addition to providing important information regarding relationships to normal anatomic landmarks such as the ossicles that are not seen on MRI.[216] This information is crucial to preoperative planning in otologic surgery and leads to a decreased rate of iatrogenic facial nerve trauma.[216]

Magnetic Resonance Imaging

MRI is the preferred imaging modality for suspected neoplastic pathology and for the intracranial and extratemporal segments of the facial nerve. Its superior visualization of the soft tissues can identify perineural spread from parotid malignancy and enlargement of the facial nerve that can be missed with high-resolution temporal bone CT scanning.[214] The normal labyrinthine, cisternal, intracanalicular, and parotid segments of the facial nerve normally do not enhance, whereas the normal facial nerve will faintly enhance in the geniculate ganglion, tympanic, and mastoid segments on gadolinium contrast MRI imaging. Increased enhancement or asymmetric enhancement of these regions should prompt consideration of inflammatory or neoplastic processes. Once the facial nerve exits the stylomastoid foramen, it is best visualized with axial high-resolution T1-weighted images using a microscopic coil.[214]

Ultrasound

Ultrasound is rarely used in routine imaging of the facial nerve. However, there are several studies that have used ultrasound to evaluate the normal size of the facial nerve or prognosis of Bell's palsy based on nerve diameter.[233,236] In a prospective controlled trial, Lo and colleagues noted that a normal ultrasound diameter of the facial nerve on the affected side in Bell's palsy had a positive predictive value of 100% for recovery of facial nerve function, whereas an abnormal value had a negative predictive value of 77% for House-Brackmann Grade II or worse facial nerve function at 3 months.[236]

Classification of Facial Nerve Injury

Injuries to the trigeminal and facial nerve are both classified according to the previously described Seddon and Sunderland classification of nerve injury. In addition, the axonal and cellular response to injury is consistent between these two cranial nerves. Please see the section on classification of nerve injuries. In regard to facial nerve injury, an additional classification system, the House-Brackmann facial nerve function grading scale, is used (Table 5-5).[237] This scale is the official scale of the Facial Nerve Disorders Committee of the American Academy of Otolaryngology–Head and Neck Surgery (AAO-HNS. It consists of grades I through VI, with VI representing total paralysis. In patients with isolated injury to a single branch, the House-Brackmann scale is of limited use, and therefore more subjective notation of injury is utilized.

Mechanisms of Injury to the Facial Nerve

Bell's Palsy

Named for the Scottish anatomist who first described it, Charles Bell, facial paralysis due to Bell's palsy is an uncommon condition with an incidence ranging from 11.5 to 53.3 per 100,000 person years.[238] The condition can be found in the pediatric population; however, its incidence is higher with increasing age and in females across all age groups.

TABLE 5-5 House-Brackmann Facial Nerve Grading Scale

Grade	Description
I	Normal facial function
II	Mild Dysfunction—Slight weakness, slight synkinesis on close inspection. Moderate to good forehead function. Complete eye closure with minimal effort. Slight smile asymmetry with maximum effort. Normal symmetry and tone at rest.
III	Moderate Dysfunction—Obvious but not disfiguring difference between sides. Noticeable but not severe synkinesis. Slight to moderate forehead movement. Complete eye closure with effort. Strong but asymmetric smile with maximum effort. Normal symmetry and tone at rest.
IV	Moderately Severe Dysfunction—Obvious weakness and/or disfiguring asymmetry. Severe synkinesis. No forehead movement. Incomplete eye closure. Asymmetric smile with maximum effort. Normal symmetry and tone at rest.
V	Severe Dysfunction—Barely perceptible motion. Synkinesis usually absent. No forehead movement. Incomplete eye closure. Slight movement at the corner of mouth. Asymmetry at rest.
VI	Total Paralysis—No movement.

From House JW, Brackmann DE: Facial nerve grading system, *Otolaryngol Head Neck Surg* 93:146-147, 1985.

There is an increased risk in pregnancy and in patients with diabetes mellitus, hypertension, obesity, and prior upper respiratory infection (URI), with 60% reporting recent URI.[238] Although a viral etiology is suspected, the diagnosis of Bell's palsy is one of exclusion. Other causes of facial paralysis should be excluded through careful history and physical examination (Table 5-6). Imaging and laboratory testing are not routinely recommended in the evaluation of patients with new-onset Bell's palsy.[238] Despite being the most common cause of facial paralysis, the true etiology of Bell's palsy is not yet fully understood. Paralysis is thought to occur due to facial nerve edema and possible resulting compression of the vascular supply to the nerve as it travels through its bony canal, specifically within the labyrinthine segment.

Bell's palsy is defined by acute, unilateral facial nerve paresis or paralysis with progression to maximum severity within 72 hours and without an identifiable cause.[238] By definition, it involves all muscle groups of one side of the face. Signs of central nervous system disease, such as extremity weakness, and signs of ear or cerebellopontine angle disease, such as hearing loss, tinnitus, or vertigo, will be absent. Patients may complain of concurrent or prodromal ipsilateral pain about the face or ear as well as exposure eye keratopathy, xerostomia, taste disturbance, and hyperacusis.

Treatment of Bell's palsy is controversial.[239,240] Clinical practice guidelines from the AAO-HNS recommend treatment of all patients with suspected Bell's palsy with oral steroids within 72 hours of symptom onset.[26] Multiple studies including randomized, double-blind, placebo-controlled multicenter trials have been published.[241-243] The findings of these studies are in accordance with the clinical practice guidelines previously mentioned. Regardless of symptom severity, all patients benefited from early initiation of oral steroids. The evidence from these studies does not support the routine use of antivirals alone or in combination with prednisone; however, the AAO-HNS clinical practice guidelines leave the addition of oral antiviral therapy as an option due to low risk and weak data unable to exclude a small benefit.[238] Surgical decompression remains controversial, and no recommendation is provided by the AAO-HNS because of low-quality evidence and a small subset of patients with specific indications who may derive significant benefits from decompression surgery.[238,244-246] In a multicenter prospective trial, Gantz and associates demonstrated a benefit to early (within 2 weeks of symptom onset) surgical decompression of the facial nerve in a subset of patients demonstrated by electroneurography and electromyography to have a higher risk of poor return of facial function.[245] A Cochrane systematic review of available evidence published in 2013 concluded that there is only very low-quality evidence, and this is insufficient to decide whether surgical intervention is beneficial or harmful. However, they did state that further research is unlikely to be performed because of spontaneous recovery in most cases.[246] Regardless of treatment approach, patients should be referred to a facial nerve specialist if at any point during recovery they develop new or worsening neurologic findings, ocular symptoms, or have incomplete facial recovery at 3 months from onset of initial symptoms.[238]

Prognosis is best in those patients with incomplete paralysis; 94% will recover completely. Most patients will show some recovery without any intervention within 2 to 3 weeks of symptom onset and continue to improve until complete recovery at 3 to 4 months. However, without treatment, up to 30% will have incomplete recovery. If improvement is noted within 2 weeks, prognosis for complete recovery is best.[239,240] Of those who do not recover completely, sequelae are slight to mild in a large majority, with only 4% being described as having severe sequelae.[240] Possible sequelae include ageusia, facial spasm, facial pain, and corneal infection/abrasion. Additionally, patients can develop synkinesis, an involuntary muscular movement occurring simultaneously with voluntary movements. An example would be a patient who has movement of the corner of the mouth when attempting to close the ipsilateral eye.

TABLE 5-6 Etiology of Facial Paralysis

Congenital	Möbius syndrome, hemifacial microsomia, Goldenhar syndrome
Birth-Related	Trauma during delivery
Neurologic	Guillain-Barré, ischemic/hemorrhagic stroke, hypertension
Bell's Palsy	Herpes simplex virus, autoimmune reaction, ischemic neuropathy, microcirculatory failure of vasa nervorum, entrapment, idiopathic
Neoplasm	Central, parotid, and acoustic tumors
Hematologic	Leukemia, hemophilia
Infection	Otitis media, Lyme disease, Ramsay Hunt, herpes simplex, Epstein-Barr virus, mycoplasma, mastoiditis
Trauma	Temporal bone fracture, blunt or penetrating trauma to the extratemporal segment
Iatrogenic	Facial surgery, otologic surgery, brain surgery

Trauma

Traumatic injury to the facial nerve can occur at any point along its course from the brainstem to the muscles of facial expression or other target organs. Blunt and penetrating trauma can directly injure the facial nerve or cause injury to adjacent structures resulting in nerve transection, edema, vascular compromise, and ischemia. The second most common cause of facial nerve injury, traumatic injuries represent 15% of all cases of facial nerve paralysis, with the most common traumatic cause being temporal bone fracture. In total, 5% of trauma patients will sustain a temporal bone

fracture. There are two subtypes of temporal bone fracture, longitudinal and transverse, although in reality many fractures are a mixture of the two. The longitudinal fracture is the most common type (70-80%) and is classified by a fracture line along the long axis of the petrous temporal bone, which is also the path of least resistance to fracture propagation in the temporal bone.[247,248] It is generally caused by a direct blow to the temporoparietal region. Fortunately, longitudinal fractures are associated with facial nerve injury in only 10% to 20% of cases, with 94% returning to normal function. Transverse fractures are described as extending perpendicular to the long axis of the petrous bone, commonly from the jugular foramen or foramen magnum to the middle cranial fossa, and involving the bony labyrinth and/or geniculate ganglion. Because of labyrinth involvement, sensorineural hearing loss and vertigo are common. These fractures are associated with high-impact frontal or occipital trauma, and up to 50% of patients will have a facial nerve injury that does not return to normal function.[247,248] Prognosis is improved for patients who present with delayed-onset facial paralysis compared to those presenting with immediate-onset paralysis.

Physical exam should include a thorough head and neck exam noting any facial asymmetry, lacerations, bruising, or hematoma. Otoscopy should be completed to check for EAC lacerations, step-offs, hemotympanum, otorrhea, tympanic membrane (TM) perforation, and vertigo or a flaccid TM on pneumatic otoscopy. Fluid should be collected in cases of suspected cerebrospinal fluid (CSF) leak and sent for beta-2 transferrin testing. In addition to imaging with high-resolution dedicated CT of the temporal bones, facial nerve conduction testing with topographic and electrodiagnostic methods is advised. The specifics of these tests are discussed later.

Treatment of facial nerve injury due to temporal bone fracture is guided by clinical and facial nerve conduction examination. Surgical nerve decompression should be performed as soon as possible (within 1 month of injury) in patients with neural degeneration of the facial nerve that is >90% by facial nerve electrogram.[248-250] Complications of facial nerve decompression include dural tears, conductive and sensorineural hearing loss, loss of vestibular function, persistent CSF leak, meningitis, and injury to the anterior inferior cerebellar artery or its branches. The technique of nerve decompression and a complete discussion of its use is beyond the scope of this text; however, further information can be obtained from multiple sources.[248-253]

Facial nerve injury due to penetrating trauma and involving the extratemporal segment of the facial nerve requires prompt evaluation and management to avoid functional and cosmetic deficits. Injuries that are proximal to a line dropped from the lateral canthus are amenable to surgical repair. Injuries distal to this line are generally not repaired due to extensive nerve arborization and cross innervation. Additionally, individual facial muscle fibers can possess multiple motor endplates arising from different branches of the facial nerve. For these reasons, facial nerve dysfunction due to injury anterior to this perceived line is likely to recover spontaneously.[254] Repair of proximal injuries is discussed in detail in later sections of this chapter.

Infection

Facial nerve injury due to infection is the third most common cause of facial nerve injury, with the most common subset of patients presenting with herpes zoster oticus (Ramsay Hunt syndrome).[254] Other infectious causes of facial paralysis include Lyme disease, acute otitis media, chronic suppurative otitis media, malignant otitis externa, infected cholesteatoma, mastoiditis, tuberculous mastoiditis, human immunodeficiency virus, and parotitis.[255-262]

Herpes zoster oticus, also known as Ramsay Hunt syndrome, is due to reactivation of latent varicella zoster virus (VZV). It presents most often in patients over age 60, although it is an important cause of facial paralysis in children 6 to 15 years of age.[256] Patients describe a prodrome of symptoms similar to Bell's palsy, with pain in and around the ear followed by facial weakness. Those patients with Ramsay Hunt syndrome will then progress to develop facial paralysis, hearing loss, vertigo, and possibly facial numbness due to involvement of the trigeminal nerve. Seventy percent of patients will develop a rash around the ear with vesicle formation and crusting. Patients with Ramsay Hunt syndrome often have more severe paralysis at initial presentation, late neural denervation, and a less favorable recovery profile than Bell's palsy. Up to 50% of patients will have persistent facial weakness or other related symptoms despite adequate treatment with prednisone and antiviral medication.[256]

Iatrogenic

Iatrogenic injury of the facial nerve is a feared complication of many head and neck procedures. Facial nerve paralysis due to iatrogenic injury results in cosmetic and functional deficits, ocular complications, diminished quality of life, and, often, malpractice litigation.[263] Injury is most common following parotidectomy procedures due to frequent but necessary manipulation of the facial nerve during surgery. Often, these are neuropraxia-type injuries, and therefore recovery is expected within a few days to weeks of the inciting event. Temporary facial nerve dysfunction occurs in 20% to 40% of patients undergoing parotidectomy; however, the incidence of permanent injury is less than 4%.[264,265] To decrease the risk of facial nerve injury during parotidectomy, many surgeons use intraoperative nerve monitoring techniques, most commonly electromyography.[264] Studies have shown a reduced rate of temporary facial nerve paralysis and an unclear benefit regarding permanent injury when intraoperative nerve monitoring techniques are utilized. Because of the rarity of permanent paralysis, sufficiently large and statistically powered studies are lacking.[264] Injury of the facial nerve during otologic procedures is relatively uncommon, with an incidence of 0.6% to 3.7% in primary surgery and 4% to 10% in revision surgery. For otologic

surgery, data on intraoperative nerve monitoring techniques demonstrate a clear and cost-effective reduction in facial nerve injuries.[264,266,267] Another possible cause of iatrogenic facial nerve injury is during temporomandibular joint (TMJ) surgery. In a review of 102 patients evaluated for iatrogenic facial nerve injury at the Massachusetts Eye and Ear Infirmary Facial Nerve Center, oral and maxillofacial surgery procedures accounted for 40% of total injuries, with TMJ surgery responsible for 27% of total injuries. The temporal branch of the facial nerve was most likely to be injured during TMJ surgery.[267] Reports regarding the risk of facial nerve injury during temporomandibular joint surgery range from 2% to 25%.[268] Repair of mandibular trauma, especially when involving the condyle or subcondylar region, is associated with a risk of temporary facial nerve injury ranging from 8% to 48%, with the buccal branch or marginal mandibular branch most likely to be injured and permanent facial nerve injury an infrequent occurrence.[269-272] Risk factors for injury to the facial nerve included fracture location at the condylar neck, fracture dislocation, and operator inexperience (<3 years).[269] Recovery time ranged from 4 to 24 weeks, and in multiple case series, no permanent facial nerve injury has been reported.[269-272]

Clinical Evaluation of Facial Nerve Injury

The evaluation of facial nerve injury, as with trigeminal nerve injury, begins with a detailed history and physical examination. Patients presenting with facial paralysis should be questioned regarding timing of onset and associated symptoms such as pain, dizziness, changes in hearing, hyperacusis, tinnitus, changes in taste, extremity weakness, prior ear or facial surgery, tick bites or travel to endemic areas, dysphagia, dysarthria, and dry eyes. Patients with extremity weakness, forehead sparing, dysphagia, and dysarthria should be promptly evaluated for central lesions as a cause of their facial paralysis or weakness. The incomplete crossover of the fibers innervating the upper face results in forehead sparing, often indicative of a central etiology to facial paralysis. These patients will maintain the ability to wrinkle the forehead and raise the eyebrows. Additional evaluation and management of patients with central etiology to facial nerve injury is beyond the scope of this text. The clinical examination of patients with facial nerve injury should also include otoscopic examination, especially in cases of blunt traumatic injury, to evaluate for signs or symptoms of temporal bone fracture such as canal laceration, step-off, TM perforation, otorrhea, hemotympanum, or a flaccid TM or vertigo with pneumatic otoscopy. The House-Brackmann grading system should be used when applicable, as it is considered the standard by the AAO-HNS; however, it should be noted that when an extratemporal source of injury is suspected, such as with penetrating trauma to the face, this scale is of limited use, and a subjective description of facial function by the examining physician is appropriate.[237,238] If temporal bone fracture, or benign or malignant pathology is suspected, appropriate imaging should be ordered. For temporal bone fractures, high-resolution dedicated CT of the temporal bones is recommended. If pathology is suspected, MRI should be ordered to better evaluate soft tissues and perineural spread. Following the history and physical exam, facial nerve testing can be ordered when appropriate. Facial nerve testing can help to determine the site and severity of injury, as well as dictating treatment and prognosis.[273,274] In cases of penetrating injury to the extratemporal segment, and when the proximal and distal cut stumps of the facial nerve are identifiable and available for repair, immediate surgical repair by primary neurorrhaphy is advised and can proceed without additional facial nerve testing.[254] Dedicated facial nerve testing is divided into two categories, topographic testing and electrodiagnostic testing.

Topographic testing is used to determine the anatomic level of a peripheral lesion through a variety of tests. A Schirmer test is used to evaluate for lesions at or proximal to the geniculate ganglion. This test evaluates tear production; because the GSPN branches just prior to the geniculate ganglion, a lesion proximal to the geniculate ganglion would result in decreased tear production. In this test, filter paper is inserted into the eye and the degree of wetting of the paper after 5 minutes is recorded. A normal result is greater than 15 mm. Severe disease would be represented by less than 4 mm of wetting. When evaluating for facial nerve lesions, if the affected side shows less than half the amount of lacrimation seen on the unaffected side, the test is considered positive. An alternative, less invasive test involves the use of fluorescein eyedrops. Drops are placed into the eye, and drainage into the nose through the lacrimal duct is expected within 2 minutes. The utility of this test in evaluating for facial nerve injuries has not been explored, as most topographic testing is rarely used since the advent of high-resolution CT and MRI to localize lesions. Stapedius reflex testing can be utilized to evaluate for lesions proximal to the stapedius nerve. An audiologist uses impedance audiometry to record the presence or absence of stapedius muscle contraction to sound stimuli of 70 to 100 dB. An absence of this reflex or a reflex with less than half the amplitude indicates a nerve injury proximal to the branch point of the stapedius nerve within the mastoid segment of the intratemporal portion of the facial nerve. Finally, taste can be evaluated through electrogustometry. This test evaluates the function of chorda tympani and would also indicate presence of an injury within the mastoid segment.

Electrodiagnostic testing includes nerve excitability testing (NET), maximal stimulation testing (MST), electroneurography (ENoG), and electromyography (EMG). Electrodiagnostic testing provides more useful information regarding function and prognosis compared to topographic testing and is more commonly used in clinical practice. All of these tests except EMG require a normal contralateral facial nerve for comparison. In NET, a stimulating electrode is placed at the stylomastoid foramen. Current is applied and the face monitored by the operator for movement. The test is repeated on the opposite side, and a difference of 3.5 mA or greater is considered significant. In

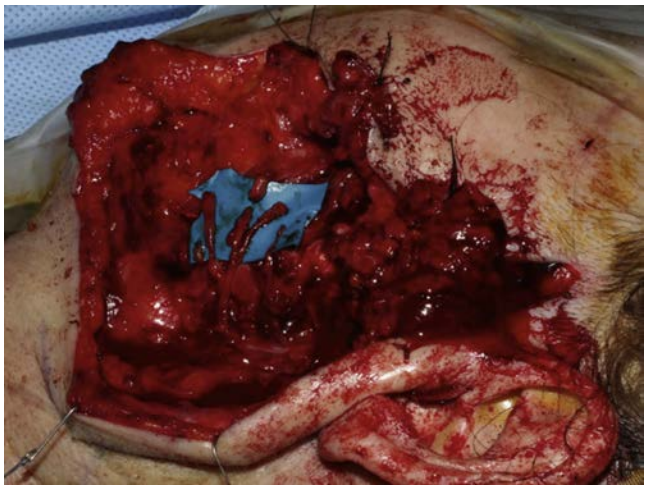
contrast to NET, which measures the minimum current for contraction, MST uses a current that produces maximal contraction of the normal side. An electrode is placed over the stylomastoid foramen of the normal side, and the current that produces maximal contraction is measured. This current is then applied to the side of suspected injury, and the response is recorded as equal or decreased (mild, moderate, severe, absent). The MST has the advantage of a lower false-negative response rate, and patients with an absent response will have incomplete recovery of function in 100% of cases.[274] Although this test is subjective, an equal or mild decrease in response has been shown to have a favorable chance of recovery, whereas a severe decrease or absent response indicates advanced degeneration with a poor prognosis and suggests that surgical intervention with decompression may be indicated.[274-276] The most accurate diagnostic testing modality, ENoG, provides quantitative analysis of the extent of nerve degeneration and is most useful 3 to 21 days after injury.[275] It is performed by placing bipolar electrodes at the stylomastoid foramen and stimulating the facial nerve. The summation potential is then recorded by electrodes placed at the nasolabial groove. A percentage of the response on the normal side of the face is calculated, and the literature states a value greater than 90% degeneration as an indication for surgical decompression of the nerve. Values less than 90% indicated expected recovery of function in 80% to 100% of patients. Disadvantages to ENoG include patient discomfort, cost, and test-retest variability due to electrode positioning.[273,275,277,278] Last, electromyography can be used to assess muscle function. EMG is more useful 10 to 21 days or more following injury when fibrillations being to appear.[275] A needle electrode is inserted into the muscle and recordings are made during rest and voluntary contraction. Six to 12 weeks prior to the return of clinically evident facial nerve function, polyphasic reinnervation potentials can be measured.[273,275] Regarding extratemporal facial nerve trauma, these tests are most often used in the postoperative period to monitor for recovery or prior to surgery when nerve transection cannot be verified.

Treatment of Traumatic Extratemporal Facial Nerve Injuries

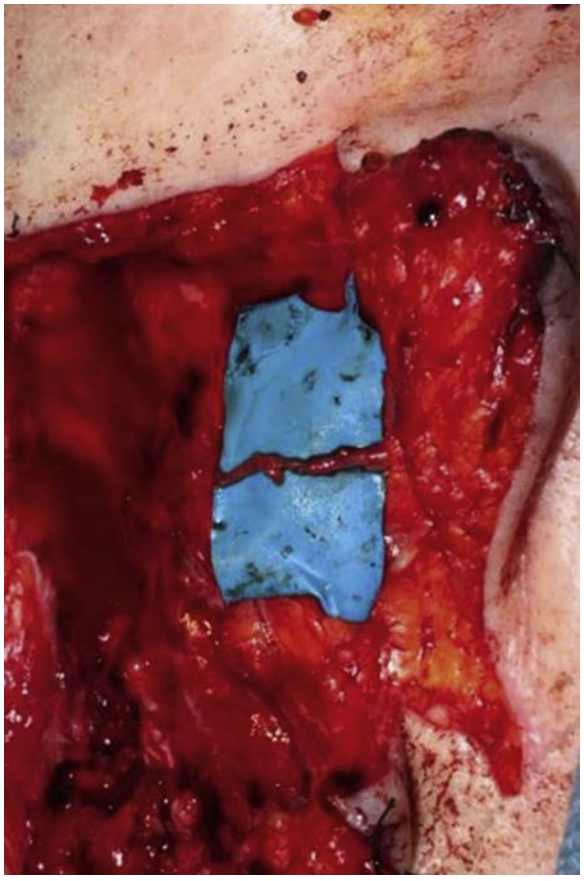
A discussion of the treatment of intratemporal facial nerve injuries is beyond the scope of this text; however, there are many injuries resources describing the indications, contraindications, and approaches for surgical treatment of intratemporal facial nerve injuries.[248-253]

Extratemporal facial nerve injuries encountered by the oral and maxillofacial surgeon are most commonly due to penetrating trauma or iatrogenic injury. In both cases, prompt recognition of injury and surgical repair are required. Early repair within 72 hours allows for nerve stimulation to identify cut distal nerve endings. After 72 hours, motor endplate depolarization is not possible, as neurotransmitter stores are depleted in the absence of antegrade axoplasmic transport.[279,280] Repair within 30 days has been shown to improve recovery of facial function.[214,281] Loupe or microscope magnification is recommended to assist in locating branches of the facial nerve and in visualizing healthy fascicles. When immediate repair is possible, the surgeon should access the facial nerve through existing lacerations or incisions (Figure 5-45). If delayed repair is carried out, a modified Blair incision is recommended. Following skin incision, dissection just below the superficial musculoaponeurotic system is carried out to create an anterior skin flap. Next, the main trunk of the facial nerve should be located using the landmarks previously described in this chapter (tragal pointer, tympanomastoid suture, attachment of posterior belly of the digastric) and the course of the facial nerve followed from proximal to distal until the site of injury is encountered. The superficial lobe of the parotid will require mobilization to identify more proximal branches; alternatively, a superficial parotidectomy may be performed to assist in tension-free repair and ease of identification. Once the area of trauma is reached (if using an existing laceration, full dissection of the facial nerve and the facial nerve trunk may not be necessary if the proximal and distal ends can be located), the facial nerve should be freed from any adhesions. Damage to Stensen's duct should be ruled out, as a salivary leak or sialocele may compromise the repair. Next, a colored background should be placed to improve visualization, and, if desired, microscopy can be used (Figures 5-46 and 5-47). The cut ends should be explored for 5 to 10 mm proximally and distally and electrical stimulation applied. A response with 0.05 mA indicates a good prognosis, and further exploration is not required. If a response is only obtained distally, further exposure is warranted prior to repair. A Victor-Meyer neurotomy instrument is then used to excise any neuroma or scarring until a normal-appearing fascicular pattern is noted. At this point, a determination should be made as to the need for any grafting or if primary neurorrhaphy can be completed. As a general rule, tension-free primary neurorrhaphy of the facial nerve can be performed if the defect is less than 17 mm.[214] The surgeon should always keep in mind that the most important

• **Figure 5-45** Severe facial soft tissue lacerations with injury to the facial nerve.



• **Figure 5-46** Proximal and distal ends of the facial nerve identified and isolated.



• **Figure 5-47** Repaired facial nerve.

prognostic factor for success is a tension-free coaptation of the nerve stumps.[214,282,283] If a tension-free repair cannot be completed, cable grafting, cross-facial nerve grafting, or crossover grafting should be considered. End-to-end anastomosis of the facial nerve is then performed with 8-0 or 9-0 nylon sutures as an epineural repair (see Figure 5-47). Most surgeons no longer perform perineural repair because of its increased technical difficulty and lack of demonstrated superiority over epineural techniques. Sutures should initially be placed 180 degrees to each other and should not be overtightened, as this can result in poor fascicle alignment and mushrooming. A loose approximation is preferred. Using the long ends to the already placed sutures, the nerve can be manipulated and rotated to allow placement of additional sutures as needed. Four sutures are typically all that is necessary to ensure alignment. The sutures are trimmed, and the wound is irrigated and closed in a layered fashion. In cases with significant gaps between the proximal and distal facial nerve stumps, superficial parotidectomy and mobilization of the branches of the parotid plexus can improve nerve mobility. Additional mobility can be obtained by decompression of the nerve from the mastoid and temporal portions of the intratemporal segment of the facial nerve by a neurotologist.[284]

When a tension-free repair is not possible, a cable (interposition) graft may be considered. Sources of allograft nerve include the greater auricular, sural, medial antebrachial, or lateral antebrachial cutaneous nerves. The greater auricular nerve is preferred because of its similar size to the facial nerve branches and location within the operative field in select cases. If more than 8 to 10 cm of graft is required, an alternative source such as the sural nerve will be necessary.[214] Facial nerve repair with a cable graft is similar to a direct repair, except that two sites of epineural suturing will be required.

If the proximal facial nerve stump is unavailable for repair, a cross-facial graft can be considered, using a contralateral facial nerve branch and nerve graft. This technique has the benefit of borrowing nerves with similar functions and can allow spontaneous and emotional facial expression without dyskinesis.[214,280] When smile reconstruction is desired, a buccal or zygomatic branch is identified and then stimulated to determine function. Multiple nerves are stimulated and mapped until a suitable donor with redundant functions is found. Use of a donor nerve that produces similar function as the injured side may decrease risk of synkinesis. A subcutaneous tunnel through the upper lip is then created to pass the graft from the normal donor side to the injured side, and tensionless epineural repair is performed on each side.[280]

An alternative technique is the nerve crossover or nerve transfer. This is most useful in cases where the contralateral facial nerve is unavailable or in the intermediate period following nerve injury, 3 weeks to 2 years. It requires an intact proximal donor nerve, intact distal facial nerve, and intact muscles of facial expression.[214,280] Possible donor nerves include the ipsilateral masseter branch of the trigeminal nerve and partial hypoglossal nerve. The ipsilateral masseter branch is advantageous because it can be used without the need for an intervening nerve graft and therefore will only have a single anastomosis. In addition, it has been noted that due to the close proximity between the facial and trigeminal nuclei in the pons, motor reeducation after this procedure is rapid. The ability to smile without active clenching has been reported in 66% to 82% of patients.[280] A partial hypoglossal donor is preferred over complete transection of the hypoglossal due to decreased morbidity. Patients with partial

transection have as little as 8% permanent tongue deficits, whereas the complete transection is associated with 100% deficit.[214,284] Patients who undergo this procedure will need significant biofeedback and motor sensory rehabilitation to learn voluntary control of movement, decrease synkinesis, and limit facial grimacing when chewing.[214]

Outcomes of Facial Nerve Injury and Surgical Intervention

Injury to the extratemporal branches of the facial nerve may be associated with impairment in facial expressions, eye protection, and oral competence, with additional effects on a patient's psychological, social, and economic well-being. The long-term effects of facial nerve injury are muscle denervation and atrophy. Immediate, primary repair of facial nerves has up to an 85% chance of acceptable recovery (House-Brackmann Grade I-III).[214,280-285] Cable grafting is associated with success rates of 54% to 80% (House-Brackmann Grade I-III), and recovery of function is first noticeable approximately 6 months after repair, with full recovery expected around 12 to 18 months following repair.[214,286-289] Cross-facial and crossover grafts are associated with success rates ranging from 25% to 82%, depending on the specific procedure performed and the definition of success, which is not standard across all studies.[214,280] In cross-facial grafting, noticeable facial movement is not evident until 9 to 12 months after surgery.[214] Factors that affect long-term results in facial nerve repair are patient age, chemotherapy or radiation treatment, nutrition status, time to repair, and underlying comorbidities such as diabetes mellitus.[214,284] When facial nerve repair and/or grafting techniques fail, static and dynamic reconstructive surgeries can be performed using static slings, regional muscle transfer, or free functional muscle transfer.[214,280]

Diagnosis and Management of Dentoalveolar Injuries

SHRAVAN KUMAR RENAPURKAR, A. OMAR ABUBAKER

Introduction

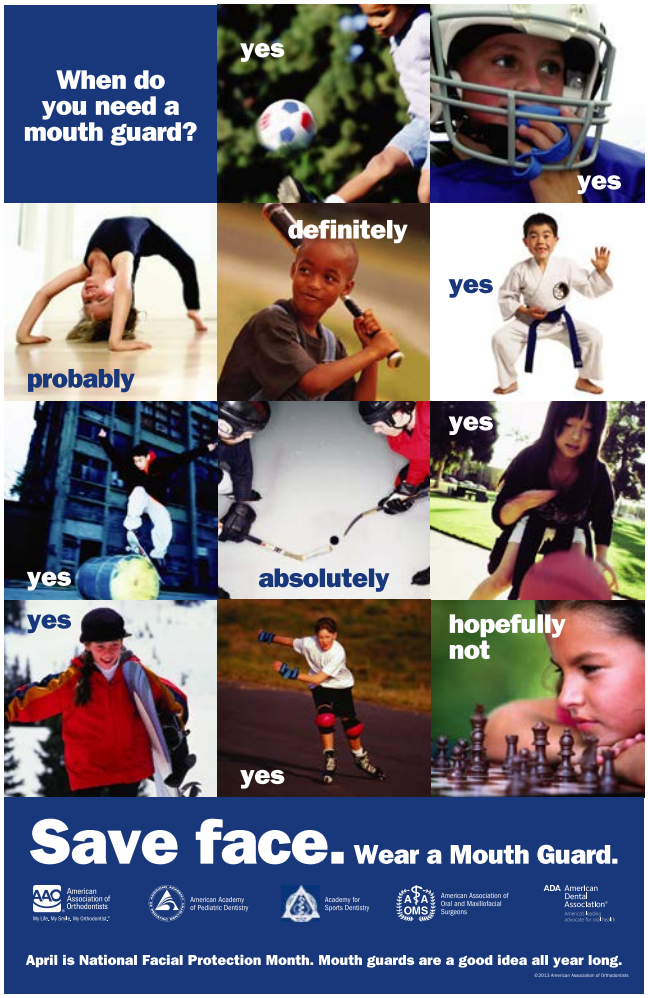
Injuries secondary to trauma are common in the facial region, and about 20% of these include injuries involving the dentoalveolar complex.[1,2] In the United States, traumatic dental injuries have been evidenced in approximately 1 of 4 adults and 1 of 6 adolescents.[3] These injuries could involve the tooth, surrounding soft tissues, and alveolar bone. In many of these patients, comprehensive management will require multidisciplinary care from various dental specialties including oral and maxillofacial surgery, restorative dentistry, prosthodontics, and orthodontics.

Isolated dentoalveolar injuries are common among children and adolescents, whereas those occurring concomitantly with other facial fractures are more common among young adults.[3-6] The reported prevalence of dentoalveolar injuries varies widely depending on factors such as age, cause of injury, country, environment, and gender. These injuries may be caused by motor vehicle accidents, motorcycles, bicycles, assaults, falls, sports, iatrogenic causes from intraoral procedures, and industrial accidents. Among preschool children and toddlers, dentoalveolar injuries are most often caused by falls, especially during the first year of life.[3,6,7] Boys have dental injury more commonly than girls.[6] A recent 12-year review estimated that across multiple studies spanning many countries, 71% to 92% of all dental trauma sustained in a lifetime occurs before the age of 19 years with a decrease in incidence after the age of 24 to 30 years.[3,7] Overall, the prevalence of dentoalveolar injuries among children with primary dentition is 11% to 30%, and among children with permanent dentition it is 5% to 20%. Boys also are affected almost twice as often as girls, with peak incidence at 2 to 4 years and 8 to 10 years.[7]

Many of these dentoalveolar injuries are underreported in trauma literature, as they are treated in an outpatient setting, in contrast to common pediatric facial fractures. The general prevalence of oral injury among pediatric patients is reported to be 5% of all facial fractures.[6]

Another cause of dentoalveolar and surrounding soft tissue injuries among children can be child abuse.[8-13] All 50 U.S. states have mandates for dentists and health care professionals to be able to identify and report child abuse and neglect.[8] When no obvious cause of the trauma is identifiable, child abuse may be suspected. In fact, roughly 50% of all physical injury associated with child abuse occurs in the head and neck region.[13] Finally, certain medical conditions may predispose a patient to dentoalveolar trauma, such as a history of uncontrolled seizures. Among children of school age, dentoalveolar injuries occur mostly on playgrounds and in bicycle accidents. In the teenage years, these injuries are most often caused by contact sports, motor vehicle accidents, and interpersonal violence. It has been stated that 33% of all traumatic dental injuries and up to 19% of injuries to the head and face are sports related.[14-16] Among adolescents with sports-related trauma, the incidence of dentoalveolar injuries is reported to be 36%.[16] Use of mouthguards has been strongly supported by the American Dental Association.[17] Extensive effort is spent on the fabrication of mouthguards, but there is no strong evidence in the literature to show their efficacy.[18] More recently the focus has been on preventive education and awareness among schools, sports authorities, and others. In addition, National Facial Protection Month, which occurs every April, has been successful in bringing attention to the prevention of sports-related injuries. This campaign has been promoted by the American Association of Oral and Maxillofacial Surgeons, as well as other dental organizations. (http://www.aaoms.org/media/april-is-national-facial-protection-month), (Figure 6-1).

Injuries to the dentoalveolar structures can present as an isolated injury or in association with multisystem injury as seen in motor vehicle accident victims. Dentoalveolar injuries



• **Figure 6-1** National Facial Protection Month in April annually has been a great way to educate patients about importance of prevention of sports-related orofacial injury.

can also result from direct trauma to the teeth or from indirect trauma from mandibular dentition forcibly closing against the maxillary dentition. If the injury is caused by direct trauma, the most likely teeth to sustain injury in both the primary and permanent dentition are the maxillary central incisors, because of their relatively exposed position**.** Large overjet, proclined incisors, and short upper lip predispose to increased incidence of dental trauma.[19] This occurs most commonly when these teeth are protruding, as in patients with Class II Division I malocclusion, an overjet greater than 5 mm, or in patients with insufficient lip closure.[20] These are followed in incidence by the upper and lower lateral incisors and the upper canines. Depending on the force of the impacted trauma, direct injury mechanisms can affect the upper or lower lip, occasionally causing laceration of the lip as well as dental or osseous alveolar fracture (Figure 6-2). Dentoalveolar injury from indirect trauma usually results from force applied to the chin, forcing the mandibular teeth against the maxillary dentition. The impact of this force often results in crown or crown-root fracture as well as condylar and/or mandibular symphysis fracture and anterior intraoral soft tissue and submental laceration (Figures 6-3 and 6-4).

• **Figure 6-2** Direct trauma to the lower lip causing a laceration in a child.

The nature of dentoalveolar injuries also varies with age, possibly because of the anatomic differences between the teeth and supporting structures of adults and pediatric patients. The lack of sinus pneumatization and higher ratio of cancellous to cortical bone, as well as the developing dentition within the facial skeleton, tend to increase the elasticity of the pediatric facial bones, making them less vulnerable to fractures. Trauma to the primary dentition most often affects the supporting structure (luxation and exarticulation), whereas trauma to the permanent dentition mostly affects the teeth themselves (causes crown fractures).[21] Only 10% of injuries to the primary dentition are crown or crown-root fractures. Seventy-five percent involve luxation or exarticulation of the tooth, compared to the incidence of mostly crown or crown-root fracture involvement in the permanent dentition.

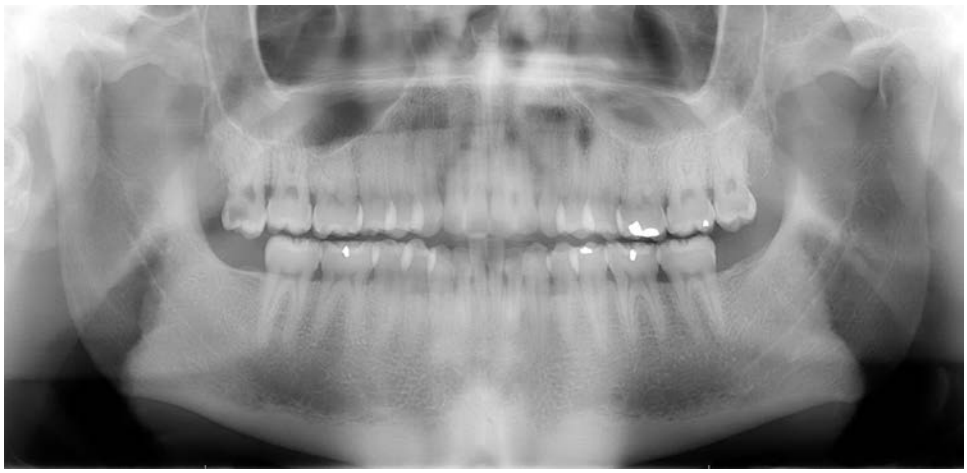
The oral and maxillofacial surgeon (OMS) is often called to the emergency department to evaluate patients who sustain orofacial trauma. The first-aid treatment is regularly performed by an OMS, and subsequent dental and restorative management is performed in outpatient setting by other dental colleagues.

Evaluation of the Dentoalveolar Injury Patient

As with any other trauma patient, the evaluation process of a dentoalveolar trauma patient should include a thorough history and comprehensive physical examination, along with any necessary radiographic examination or other diagnostic procedures.

History and Physical Examination

A thorough and systematic evaluation and diagnosis must precede management of traumatic dental injuries. In general, primary evaluation of any trauma patient must be carried out based on Advanced Trauma Life Support (ATLS) guidelines.[22] Once the systemic stability of the patient is



• **Figure 6-3** Mandibular anterior teeth luxated along with a concomitant subcondylar fracture. Dentoalveolar injuries can occur along with other facial bone fractures.

established, secondary evaluation is performed in a system wise fashion. Although dentoalveolar injuries, especially avulsive ones, are considered emergent, definitive repair of the dentoalveolar injury could be delayed until patient has been stabilized from a systemic standpoint. Results of the history and physical examination will dictate the need for diagnostic radiographs and/or special diagnostic tests such as pulp testing. Once a diagnosis is established based on clinical and radiographic evaluation, a treatment plan can be formulated. Because the length of time from injury until treatment is an important factor in determining the prognosis and outcome of dentoalveolar injury, the process of management should commence as soon as possible.[23]

History

Obtaining detailed history can provide invaluable information for the diagnosis and subsequent management of dentoalveolar injuries. However, the practitioner must keep in mind that children, in particular, do not often offer a reliable and detailed history, especially after a traumatic event. In this situation, one must depend on the accompanying adult or other eyewitnesses. The history obtained from patients with dentoalveolar injury should include the following information[24]:

1. Biographic and demographic data of the patient, including name, age, sex, race, address, and phone number.
2. The time interval between the injury and presentation. This is critical in ultimate prognosis of the teeth, especially in cases of avulsion or of tooth fracture with pulp exposure. The location of the incident or accident will help determine the degree of contamination of the wound and the indication for tetanus prophylaxis.
3. The mechanism of injury. This provides clues regarding the possibility of other injuries to suspect and evaluate via various imaging modalities. For example, a fall can cause injury to the maxillary anterior dentition, whereas a blow to the chin will often cause crown-root fractures of the premolar region with or without symphysis or condylar fractures. In children and women, if the reported mechanism of the injury does not correspond to the clinical presentation, the potential for abuse could be considered. In instances of abuse it is important that the clinician carefully document the clinical findings and the discussion with the patient and caregivers. Mechanism of injury also guides the clinician to suspect any occult injuries that may need further radiographic evaluation.
4. Information related to the event and its surroundings. This should also be recorded—for example, if any avulsed teeth, tissue, or fragments of teeth were noted at the site of the accident. Radiographic examination of the periapical tissues, chest, abdominal region, and perioral soft tissue is indicated when the preinjury dentition has

• **Figure 6-4** Gingival lacerations could be indicative of dentoalveolar fractures as well as underlying mandibular fractures.

changed in form or number. Management of partially or completely avulsed teeth by the patient should also be charted, including whether the teeth were replanted, or the storage medium used before presentation to the dentist or the emergency room. Medical events at the site of the accident are critical to note. Loss of consciousness, confusion, nausea, vomiting, or visual disturbances will indicate possible intracranial injury, which warrants neurologic evaluation. Patients who report persistence of these symptoms should be referred for emergent evaluation, and treatment of the dentoalveolar injury should be delayed until it is completed.

5. Subjective changes regarding dental occlusion as a result of the injury, which may indicate tooth displacement or dentoalveolar or jaw fractures.
6. A short medical and dental history to delineate any systemic or dental factors that can influence immediate and delayed treatment plans. Such factors include the presence of major systemic illness, especially those that may influence the treatment such as bleeding disorders and epilepsy. Also, knowledge of any previous oral and maxillofacial trauma may be helpful.

Physical Examination

An important aspect of the physical examination is the overall evaluation of the physical status of the patient. Historical findings will direct the examiner to anticipate injury patterns, thereby promoting a focused examination. As noted earlier, examination following the ATLS protocol will help identify or rule out systemic injuries in a systematic fashion. Abnormalities in vital signs may indicate intracranial injury, cervical spine injury, chest or abdominal injury, or even aspiration of an avulsed tooth. The mental status of the patient should also be assessed both by asking specific questions and by observing the patient's reaction and behavior during the history and examinations. Once a general examination is completed and a concomitant injury is ruled out, a thorough oral and maxillofacial examination is performed. Such examinations should include the following.[24]

Extraoral Soft Tissue Examinations

Lacerations, abrasions, and contusions of the face, chin, forehead, and scalp should be identified, and their depth, location, and proximity to vital structures should be established. The site of soft tissue trauma is a predictor of associated hard tissue injuries. Palpation of the temporomandibular joint and examination for range of jaw motion should be done to rule out condylar fracture.

Intraoral Soft Tissue Examination

Injuries of the oral mucosa, gingiva, lips, tongue, floor of the mouth, and cheek should be considered (see Figure 6-2). If present, such injuries should be carefully evaluated for the presence of foreign bodies, debris, and teeth or tooth fragments embedded within the tissue.[24,25] It may be necessary to debride the oral cavity of clots and debris and to stop active bleeding before completing a thorough examination.

Gingival lacerations (see Figure 6-4) are often indications of displacement of teeth, while bleeding from nonlacerated marginal gingiva often indicates periodontal ligament damage or mandibular fracture. It is important that all teeth be accounted for at this time. Missing teeth or pieces of teeth that have not been left at the scene of the accident should be considered to have been aspirated, swallowed, or displaced into the soft tissues, nasal cavity, or maxillary sinus (Figure 6-5).[24,26] Therefore, a radiographic examination of the head and neck, chest, and abdomen should be done to rule out presence of teeth or fragments into these tissues or organs.

Examination of the Jaws and Alveolar Bone

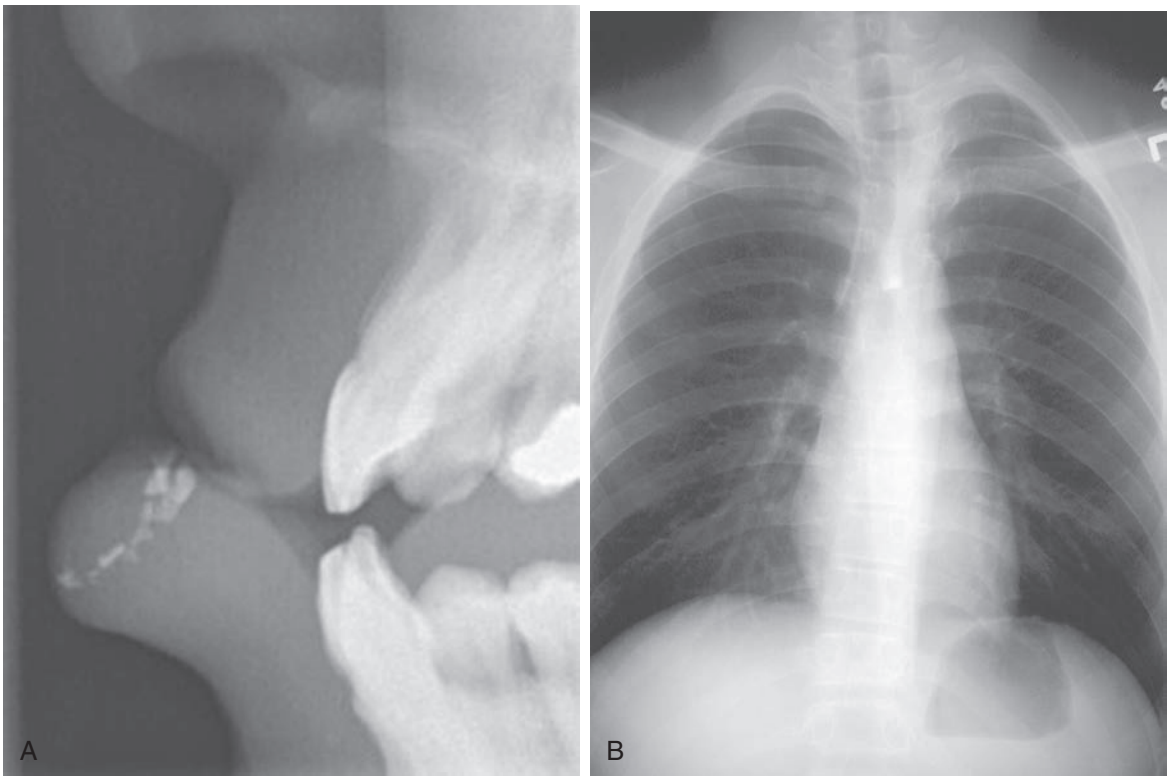
Fractures of the alveolar process protruding through the overlying mucosa are normally evident and readily detected by visual inspection. Mobility and crepitation of the palpated alveolar fracture segments confirms underlying bone injury when the overlying mucosa is not lacerated. Fractures of the jaw may be detected by presence of gross malocclusion, step-off deformities, pain, and mobility of the fractured segment to palpation. Bleeding from the gingival crevice of a tooth, vertical laceration of the attached mucosa, and submucosal ecchymosis of the floor of the mouth are other signs of jaw fracture.

Examination of the Teeth Structure

Direct examination of tooth structure is preceded by removing blood and debris from the teeth. Any infraction or fractures of the crowns should be noted. Infraction lines in the enamel can be detected by directing a light beam parallel to the long axis of the tooth. Crown fractures should be evaluated for extending into the dentin and the pulp. The size and location of pulp exposure should be recorded. Crown-root fractures in all quadrants should be evaluated as well. Changes in the color of a traumatized tooth and its translucency may indicate a pulp exposure. It is important to remember that indirect trauma leading to crown-root fractures in one quadrant is often accompanied by similar fractures in the ipsilateral opposing jaw.

Examination for Displacement of Teeth

Displacement of teeth as a result of dentoalveolar trauma can usually be readily detected by visual examination. Examination of the dental occlusion may also be helpful in detecting minor degrees of tooth movements. Although displacement of teeth as a result of dentoalveolar trauma can occur in any direction, the most common displacement is in a buccolingual direction (Figure 6-6). The direction and extent of displacement should be recorded. Lateral luxation and intrusion of teeth may present very minimal clinical symptoms because the teeth remain locked in this displaced



• **Figure 6-5 A,** Tooth fragments displaced into the lower lip. **B,** Chest radiograph showing aspirated tooth. Missing teeth or tooth fragments should be accounted for, and if they are not found, aspiration and displacement into surrounding tissues should be ruled out with imaging. (From Powers MP: Diagnosis and management of dentoalveolar injuries. In Fonseca JR, Walker RV, editors: *Oral and maxillofacial trauma*, ed 2, vol 1, Philadelphia, 1997, WB Saunders.)

position. Lingual and apical displacement of the apex of a primary tooth can interfere with its permanent successor.

Examination for Mobility of Teeth

All teeth should be tested for both horizontal and axial mobility by either manual palpation or use of a tongue blade. If a tooth does not appear to be displaced but is very mobile, a root fracture should be suspected. In such instances the location of the fracture usually determines the degree of mobility. When testing for mobility of one tooth, observing mobility of the adjacent teeth is suggestive of a dentoalveolar fracture.

Reaction to Percussion

Increased sensitivity to percussion in the absence of tooth displacement is indicative of injury to the periodontal ligament. This test can be performed by vertical and horizontal tapping of the tooth or gentle fingertip pressure when examining smaller children. A noninjured tooth should be used for control. Sound elicited by percussion, with the use of the handle of a mouth mirror, has been mentioned in the literature as providing diagnostic information.[24] An uninjured tooth will generally have a solid, metallic sound, whereas a luxated tooth will be dull. However, for this to be of any value, a quiet environment is required.

• **Figure 6-6** Buccal-palatal displacement of permanent maxillary central incisors is commonly seen.

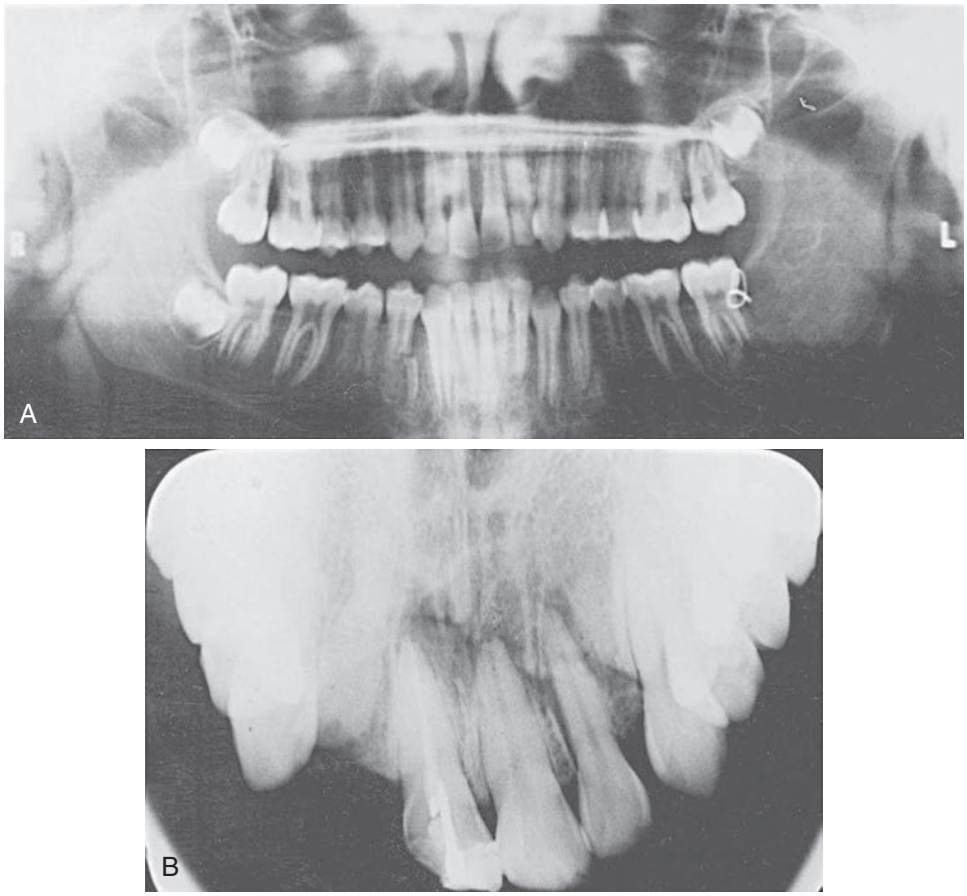
Pulp Testing

Traumatized teeth could have paresthesia and altered neurologic response, and neural recovery takes longer than vascular regeneration.[24] Currently used tooth vitality tests register the conduction of stimuli to the sensory receptors of the dental pulp. This type of vitality testing is subjective and may be difficult to perform or

relatively unreliable in the acute setting following traumatic injury. Lack of cooperation and unreliability, especially among children, and false-negative results, which are common in acute injury, diminish the usefulness of pulp testing in the acute setting. Nonetheless, pulp testing several weeks later, after revascularization and nerve repair of the pulp, may be more accurate and should be performed before endodontic therapy. It can also be beneficial and important for planning treatment. Some of the methods used in pulp testing include electric pulp testing, thermal test using treated gutta-percha, ice, ethyl chloride, carbon dioxide snow, and dichlorodifluoromethane. The low sensitivity of some of these techniques led some to search for new methods of pulp testing. Laser Doppler flowmetry has been used in recent years as a more reliable method of assessing pulpal flow and vitality. Although promising, it still remains a sensitive and time-consuming technique and is not widely used because of cost and availability.[27] Even if unreliable, pulp testing should be performed at the earliest possible time after trauma as a baseline recording and then at regular intervals of 2, 4, and 6 to 8 weeks and then 6 and 12 months.[27]

Radiographic Examination

Radiographic examination is an essential part of evaluation that helps identify injuries affecting the root portion of the tooth and the periodontal ligament, as well as status of the bone. Such information includes presence of root fracture, root infraction, and root dislocation (Figure 6-7). Concomitant jaw fractures, preexisting periapical or periodontal disease, degree of extrusion or intrusion, and teeth or tooth fragments or foreign bodies lodged in the soft tissue can also be identified.[25,26] In children and young adults, radiographic examination serves to provide information regarding the extent of root development, size of the pulp chamber and root canal, and proximity of succedaneous teeth to the injured primary tooth. Choice of radiographs should be based on history and physical examination. Radiographic imaging of dentoalveolar trauma usually consists of more than one radiograph, including intraoral periapical, occlusal, and panoramic radiographs.[28] Correctly positioned periapical radiographs (central beam of x-ray parallel to the line of fracture) provide the most detailed information to adequately evaluate root fracture and dislocation of teeth. Often multiple views (ideally three radiographs) with two



• **Figure 6-7** **A,** Panoramic radiographic examination for evaluation of dentoalveolar injury revealing a root fracture of the right mandibular first bicuspid. **B,** An occlusal radiograph showing a dentoalveolar fracture of the anterior maxilla. (From Abubaker AO, Papadopoulos H, Giglio JA: Diagnosis and management of dentoalveolar injuries. In Fonseca R, Marciani RD, Turvey TA, editors: *Oral and maxillofacial surgery*, ed 2, St Louis, 2009, Saunders.)

different vertical and three different horizontal angulations of the central beam may be necessary, especially to view root fractures. Periapical radiographs are also used postoperatively to confirm position of the root.

Occlusal radiographs are particularly useful to diagnose a root fracture, or lateral luxation with lingual displacement of the crown. Occlusal radiographs are also often made for patient comfort because they place minimal pressure on the traumatized area. They are also valuable in examining the floor of the mouth, tongue, cheek or lip lacerations for teeth or tooth fragments in the soft tissue. When occlusal radiographs or other x-ray exposure is used to examine soft tissue, a reduced radiographic exposure time is recommended.

Radiographically displaced teeth will appear as a widening of the periodontal ligament space or displacement of the lamina dura. Extruded teeth may appear as a periapical radiolucency compatible with the pattern and shape of the apical portion of the root. Lateral and extensive luxation of teeth will also appear as a widening of the periodontal ligaments. Intruded teeth often will show minimal radiographic findings or only a blurred or absent periodontal space.

If jaw fractures or fractures of the alveolar ridges are suspected, extraoral radiographs such as an orthopantomogram should be obtained. Although panoramic radiography can demonstrate fractures of the jaw, alveolar ridges, and teeth, it is best suited as a screening image for fractures of the condyle, subcondylar region, or angle or body of the mandible. The overlap of the vertebral column inhibits adequate visualization of maxillary and mandibular anterior dentition. Complex midface anatomy also limits the use of plain-film two-dimensional radiographs because of overlapping of structures. In these cases a three-dimensional (3D) imaging modality such as computed tomography (CT) or cone-beam CT (CBCT) is valuable in overcoming superimpositions while allowing a 3D evaluation. CT and CBCT both have good resolution, but CBCT have relatively less radiation exposure compared to a medical-grade CT scan. Imaging of soft tissue trauma may be better appreciated on a CT scan compared to a CBCT. Occasionally, access to or use of routine dental radiographs is limited, such as in a hospital setting and in children under the age of 2 years. CT scans have remained the gold standard for evaluation of facial bone fractures. With advent of CBCT and its availability and low cost in outpatient settings, it can be used a valuable tool in assigning both bony and dental structure injuries with higher definition and more accuracy to the nature of dentoalveolar injury.[30,31]

Classification of Dentoalveolar Fractures

Although historically there have been several classification systems in use for description of dentoalveolar trauma, each had its own advantages and disadvantages.[32-36] These systems are based on a variety of factors such as etiology, anatomy of injury, pathology, and therapy. The purpose of such classification is to provide a comprehensive and universal description of the injury for communication and treatment planning purposes. The most accepted and commonly used is Andreasen's modification of the WHO classification.[19,36,37]

Andreasen's classification[19] includes description of injuries to the teeth, supporting structures, gingiva, and oral mucosa, with some modifications to take into account anatomic, therapeutic, and prognostic considerations. This classification can be applied to both the permanent and primary dentition. In this classification system, dentoalveolar injuries are divided into four major categories: injuries to the dental tissues and pulp, to the periodontal tissues, to the supporting bone, and to the gingiva or oral mucosa. Descriptions and illustrations of the four categories are shown in Tables 6-1 through 6-4. Basic types of traumatic injuries to primary dentition are shown in Figure 6-8.[38]

Treatment of Dentoalveolar Injuries

General Considerations

An ideal outcome with treatment of dentoalveolar fractures would be to attain or preserve the premorbid functional state of teeth, bone, and gingiva; maintain esthetics; and optimize growth and development. Based on the Andreasen classification system and including the six luxation types and nine fracture types in both primary and permanent dentition, there could be 108 types or combinations of dental trauma entities. The complexity of diagnosis and management of dentoalveolar trauma has been perplexing to the clinician in making an evidence-based decision. The most recent IADT-recommended guidelines, updated in 2012, represent the best evidence based on the most current literature and expert opinion.[38] These guidelines are meant to help the clinician make acute management decisions with traumatic dental injury, but they do not substitute for comprehensive and detailed information on traumatic dental injury management as found in scientific literature and books. These guidelines have been made accessible online at http://www.dentaltraumaguide.org.

Factors to be considered in treatment planning include:

1. age of the patient;
2. cooperation of the patient;
3. primary, mixed or secondary dentition;
4. developmental state of the tooth;
5. classification and extent of the injury;
6. any concomitant bodily injuries or medical comorbidities;
7. restorability of the tooth based on decay and periodontal health; and
8. long-term restorative options.

Although every attempt should be made to preserve all of the dentoalveolar structures permanently, it is sometimes necessary to either sacrifice or only temporarily maintain teeth to facilitate future reconstruction, restoration, and rehabilitation. Therefore, deciding whether and when

TABLE 6-1 Injuries to Hard Dental Tissues and Pulp

Crown infraction	Incomplete fracture or crack of the enamel without loss of tooth substance	Uncomplicated crown fracture	A fracture confined to the enamel or involving the enamel and dentin without exposing the pulp	
Complicated crown fracture	Involves enamel and dentin with exposure of the pulp	
Uncomplicated crown-root fracture	Involves enamel, dentin, and cementum without exposure of the pulp	
Complicated crown-root fracture	Involves enamel, dentin, and cementum with exposure of the pulp	
Root fracture	Involves dentin, cementum, and the pulp	

Modified from Powers MP: Diagnosis and management of dentoalveolar injuries. In Fonseca JR, Walker RV, editors: *Oral and maxillofacial trauma*, ed 2, vol 1, Philadelphia, 1997, WB Saunders, p 333.

to remove teeth or bony segments at the initial phase of treatment should be done cautiously. Heroic attempts to maintain teeth that are otherwise unsalvageable for decay or periodontal reasons should be avoided unless they are being retained temporarily to preserve at-risk alveolar bone. Being able to maintain proper alveolar contour and bulk will often allow for a more satisfactory dental rehabilitation. Likewise, avulsed teeth that have an extremely poor prognosis when associated with alveolar fractures may be replanted for a period of time as both a means of properly reducing the fracture and as physiologic space maintainers. Such a tooth can always be removed at a later date. If root fractures are evident, clinically concomitant with alveolar fractures, the teeth are removed if it can be accomplished without compromising the alveolar segment. Otherwise, they are left in place for removal at a later date after the segment is healed. Root fractures, particularly apical third fractures, are often only discovered on postreduction radiographs taken in the dental office. These are managed in the same manner as if they had occurred without an alveolar fracture.

When dealing with alveolar fractures, debridement of bone should be conservative. The alveolar bones are highly vascular, and vitality may often be maintained by even a very small soft tissue pedicle. Therefore, an attempt should always be made to retain fragments that have soft tissue attachments. The avulsed tooth associated with an alveolar fracture may have to be rigidly splinted for 3 to 4 weeks instead of physiologically splinted for 7 to 10 days.

Use of antibiotics in dentoalveolar trauma is controversial, with limited evidence in the literature about its efficacy. Use should be at the discretion of the provider, who should

TABLE 6-2 Injuries to the Periodontal Tissues

Concussion	An injury to the tooth-supporting structures without abnormal loosening or displacement of the tooth, but with marked reaction to percussion	
Subluxation (loosening)	An injury to the tooth-supporting structures with abnormal loosening, but without displacement of the tooth	
Intrusive luxation (central dislocation)	Displacement of the tooth into the alveolar bone with comminution or fracture of the alveolar socket	
Extrusive luxation (peripheral dislocation, partial avulsion)	Partial displacement of the tooth out of the alveolar socket	
Lateral luxation	Displacement of the tooth in a direction other than axially, accompanied by a comminution or fracture of the alveolar socket	Retained root fracture	A fracture with retention of the root segment, but loss of the crown segment out of the socket	
Exarticulation (complete avulsion)	Complete displacement of a tooth out of the alveolar socket	

Modified from Powers MP: Diagnosis and management of dentoalveolar injuries. In Fonseca JR, Walker RV, editors: *Oral and maxillofacial trauma*, ed 2, vol 1, Philadelphia, 1997, WB Saunders, p 333.

consider other indications such as wound contamination, soft tissue trauma, and general medical status.[39]

The sequence of treatment of dentoalveolar fractures is an inside-to-outside approach that includes bone, teeth, and then soft tissue. Accordingly, underlying alveolar bone injuries are treated first, followed by placement or reduction of the teeth as they relate to the underlying bone, and then the soft tissues are repaired. Prioritizing treatment sequence in the presence of other more critical bodily injuries, especially in a hospital setting, may sometimes preclude optimal treatment of the dental injury. Compromises are often unavoidable for the overall good of the patient.

Treatment of Specific Types of Injuries to the Hard Dental Tissues and Pulp

Crown Infraction

An infraction is an incomplete crack in the enamel without any loss of tooth structure. These are asymptomatic; if tenderness is present, other injuries such as luxations or fractures should be suspected. The infraction can be sealed with composite resin to avoid discoloration, but otherwise no treatment is indicated. These injuries may be easily missed and may require direct transillumination to diagnose. Pulp

TABLE 6-3 Injuries to Supporting Bone

Comminution of the alveolar socket	Crushing and comminution of the alveolar socket occur, together with intrusive and lateral luxation	Fracture of the alveolar socket wall	Confined to the facial or lingual socket wall	
Fracture of the alveolar process	May or may not involve the alveolar socket	Fractures of the mandible or maxilla	Involves the base of the mandible or maxilla and often the alveolar process; may or may not involve the alveolar socket	

Modified from Powers MP: Diagnosis and management of dentoalveolar injuries. In Fonseca JR, Walker RV, editors: *Oral and maxillofacial trauma*, ed 2, vol 1, Philadelphia, 1997, WB Saunders, p 333.

TABLE 6-4 Injuries to the Gingiva or Oral Mucosa

Mucosal or gingival contusion	A bruise that is submucosal hemorrhage without mucosal break and usually produced by a blunt object
Mucosal or gingival abrasion	A superficial wound resulting in a raw, bleeding surface usually produced by rubbing or scraping of the mucosa
Mucosal or gingival laceration	Shallow or deep mucosal wound from a tear and usually produced by a sharp object

Modified from Powers MP: Diagnosis and management of dentoalveolar injuries. In Fonseca JR, Walker RV, editors: *Oral and maxillofacial trauma*, ed 2, vol 1, Philadelphia, 1997, WB Saunders, p 333.

vitality tests are not reliable at the time of injury. However, teeth with crown infraction should be evaluated periodically to monitor the status of the pulp to determine the need for or the nature of treatment at a later time. Prognosis for pulpal health is good except in cases of combination injuries with concomitant subluxation, intrusion, or concussion, which could be often overlooked in an acute setting.[39,40]

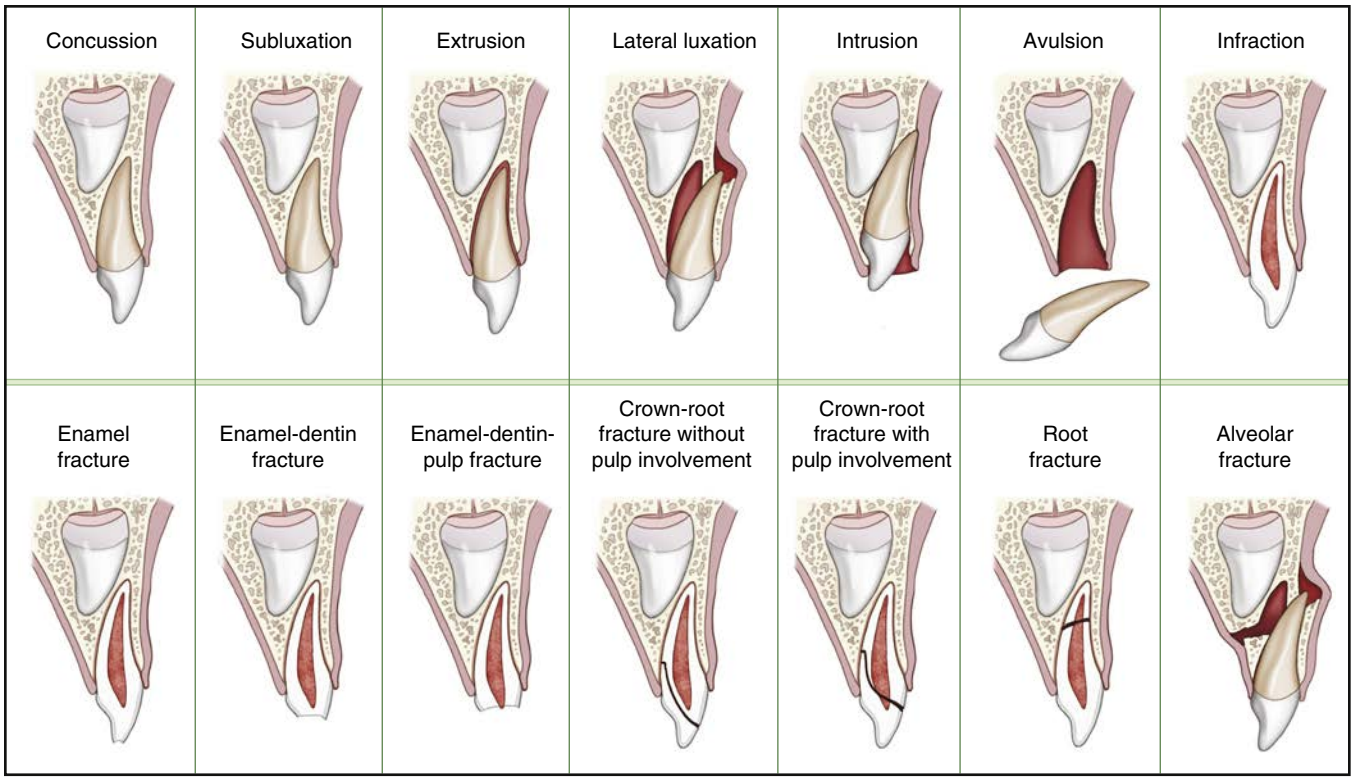
Crown Fractures

Enamel Fractures

The usual treatment for an enamel fracture is to smooth the sharp edges of the enamel or restore with composite and observe the tooth. The tooth fragment, if available, can also be bonded to the tooth. The accident impact force is not always proportional to the size of the fracture, and the pulp could later become necrotic; hence the need for periodic follow-up.

Enamel and Dentin Fractures

In permanent dentition, crown fractures account for 26% to 76% of all traumatic injuries seen in the dental office.[19] Radiographic and clinical examination is important to rule out tooth debris or fragments lodged in the soft tissue. Emergency treatment of enamel and dentin fractures is designed to reduce hyperemia and protect the pulp against any thermal stimuli or bacterial contamination. The tooth fragment, if available, can be bonded with bonding agents. A calcium hydroxide base should be placed on the exposed



• **Figure 6-8** Injuries to primary teeth. (Modified from the *Dental trauma guide 2010*. International Association for Dental Traumatology.)

dentin, followed by an immediate temporary protective acid-etch resin restoration, especially if the remaining dentin is in close proximity to the pulp. Acid-etch resin restorations should hold the calcium hydroxide in place for a sufficient length of time ideally (6-8 weeks) to allow secondary dentin formation. A light cured glass ionomer liner/base, such as Vitrebond (3M Dental Products, St Paul, MN), can be used in place of calcium hydroxide. Resin restorations should restore the contact area, prevent movement of adjacent teeth into the fractured area, and provide sufficient incisal length to prevent the tooth from moving lingually.

Concurrently, restoring crown contour will prevent overeruption of the opposing tooth. Intermediate resin restorations also allow the tooth to be pulp-tested. After allowing for secondary dentin buildup, the final acid-etch resin restoration can be placed.

Enamel, Dentin, and Pulp

The aim of treatment in cases of pulp exposure should be to preserve a vital noninflamed pulp along with formation of a biologic hard-tissue barrier.[19] Factors to be considered in treatment planning include (1) age of the patient, (2) length of time elapsed since the injury occurred, (3) size of the pulp exposure, (4) condition of the pulp (vital or nonvital), and (5) the stage of root development.

Pulp Exposure with Vital Pulp

The prognosis is best for teeth with a vital pulp exposure if the fracture is treated as soon as possible.[41] A combination injury such as luxation and root fracture increases the chance of pulpal necrosis. In young patients with immature root apices as well as with completely formed root apices, pulp capping or pulpotomy is the treatment of choice. Pulp capping is indicated in cases where there has been a small area of pulp exposure, both in roots with immature and in those with mature apices, if the patient is seen within 24 hours after the injury. Calcium hydroxide (CH) or mineral trioxide aggregate (MTA) can be used in cervical pulpotomies or partial (Cvek) pulpotomies after removal of the superficial area of inflamed and hyperemic pulp. The direct pulp cap or pulpotomy is designed to allow a tooth with an open apex or recently formed apex to complete root development (apexogenesis) and physiologic dentin apposition. An intermediate protective restoration should be placed. A tooth with a vital pulp and incomplete root formation has the best recovery prognosis. Usually teeth that have cervical pulpotomies will ultimately need root canal therapy along with a post-and-core plus a crown.[41]

If the pulp exposure is large and/or if it has been present longer than 24 hours, root canal therapy is favored. Recent studies have shown MTA to be able to form a calcific bridge without inflammation in the pulp, whereas CH showed lesser calcification and presence of inflammation in the pulps capped. MTA is growing in popularity among clinicians for apexogenesis and apexification.[41]

Pulp Exposure with Nonvital Pulp

Root canal therapy should be performed if the pulp is necrotic and there is a mature apex. Apexification procedures

should be performed if there is a necrotic pulp with an immature apex.[41] The purpose of this procedure is to provide a calcific seal at the apex prior to condensing the gutta percha. This differs from apexogenesis in which completion of the root occurs. In the apexification technique, the canal is cleansed and a calcium hydroxide paste is placed in the canal (Figure 6-9). In 3 to 6 months, the tooth should be evaluated radiographically for a calcific bridge. If bridging has occurred, a root canal with gutta percha can be done. On occasion the apexification technique might take up to 18 months and the calcium hydroxide might have to be replaced every 3 to 6 months. In successful apexification treatment, teeth do not undergo physiologic dentin apposition and they are left with thin dentinal walls. If a tooth with a successful apexification technique is injured again, the tooth would be more susceptible to a cervical-third root fracture due to the thin dentinal walls.

Crown-Root Fracture

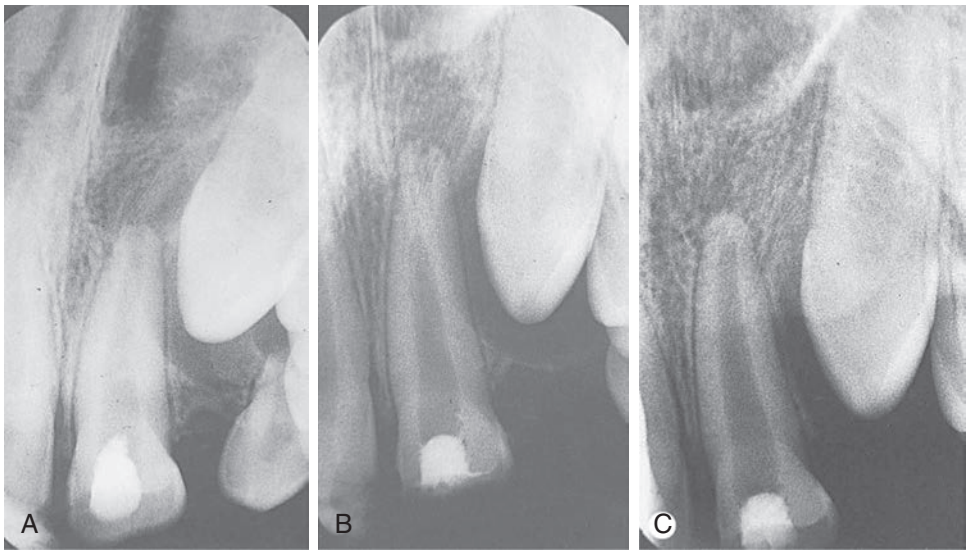
The treatment of crown-root fractures depends on several factors including the location of the fracture, the apical extent of the fracture, and whether the pulp is involved or not. Generally, emergency treatments for this type of fracture include temporary stabilization of the coronal fragment to the adjacent teeth and removal of these loose fragments before definitive treatment can be started sooner than later.[42] In fractures that are longitudinal and follow the long axis of the tooth or if the coronal fragment makes up more than one third of the clinical root, extraction is generally recommended. If the fracture line is above or slightly below the cervical margin, appropriate forms of conservative therapy can usually be employed to restore the tooth (Figure 6-10). Such therapies usually include crown-lengthening procedures or orthodontic elevation of the fracture site to provide for access for restorative margins. In young patients, treatment of this type of fracture is also influenced by whether the apex of the tooth is mature or immature. If the tooth is mature and restorable, endodontic treatment is indicated prior to restoration, whereas if the tooth is immature and the apex is open, a pulpotomy should be performed with a calcium hydroxide base and the tooth followed radiographically for closure of the apex. After such closure, definitive root canal therapy and permanent restoration can be completed.[40,42]

Root Fractures

Root fractures are relatively uncommon, with an incidence of 2.5% to 8% varying with age. They are found more commonly in adults, and they generally occur in teeth with complete root development, with the maxillary central incisor being the most common tooth.[44] Clinically, a root fracture is usually seen as an extruded tooth displaced lingually, making it difficult to differentiate from luxation injuries. Most root fractures occur in the apical and middle third and only rarely in the cervical third. Location of the root fracture plays a significant role in the prognosis of the tooth and hence in the treatment planning.[44]

Occlusal radiographs are useful for identifying the apical-third root fractures; periapical radiographs can identify root fractures at the middle and cervical thirds.

Radiographs taken immediately after an injury may not show a horizontal or diagonal root fracture. Intraoral periapical 90-degree film with central beam through the tooth can show a horizontal fracture more commonly in the cervical third of the root. In root fractures, separation of the

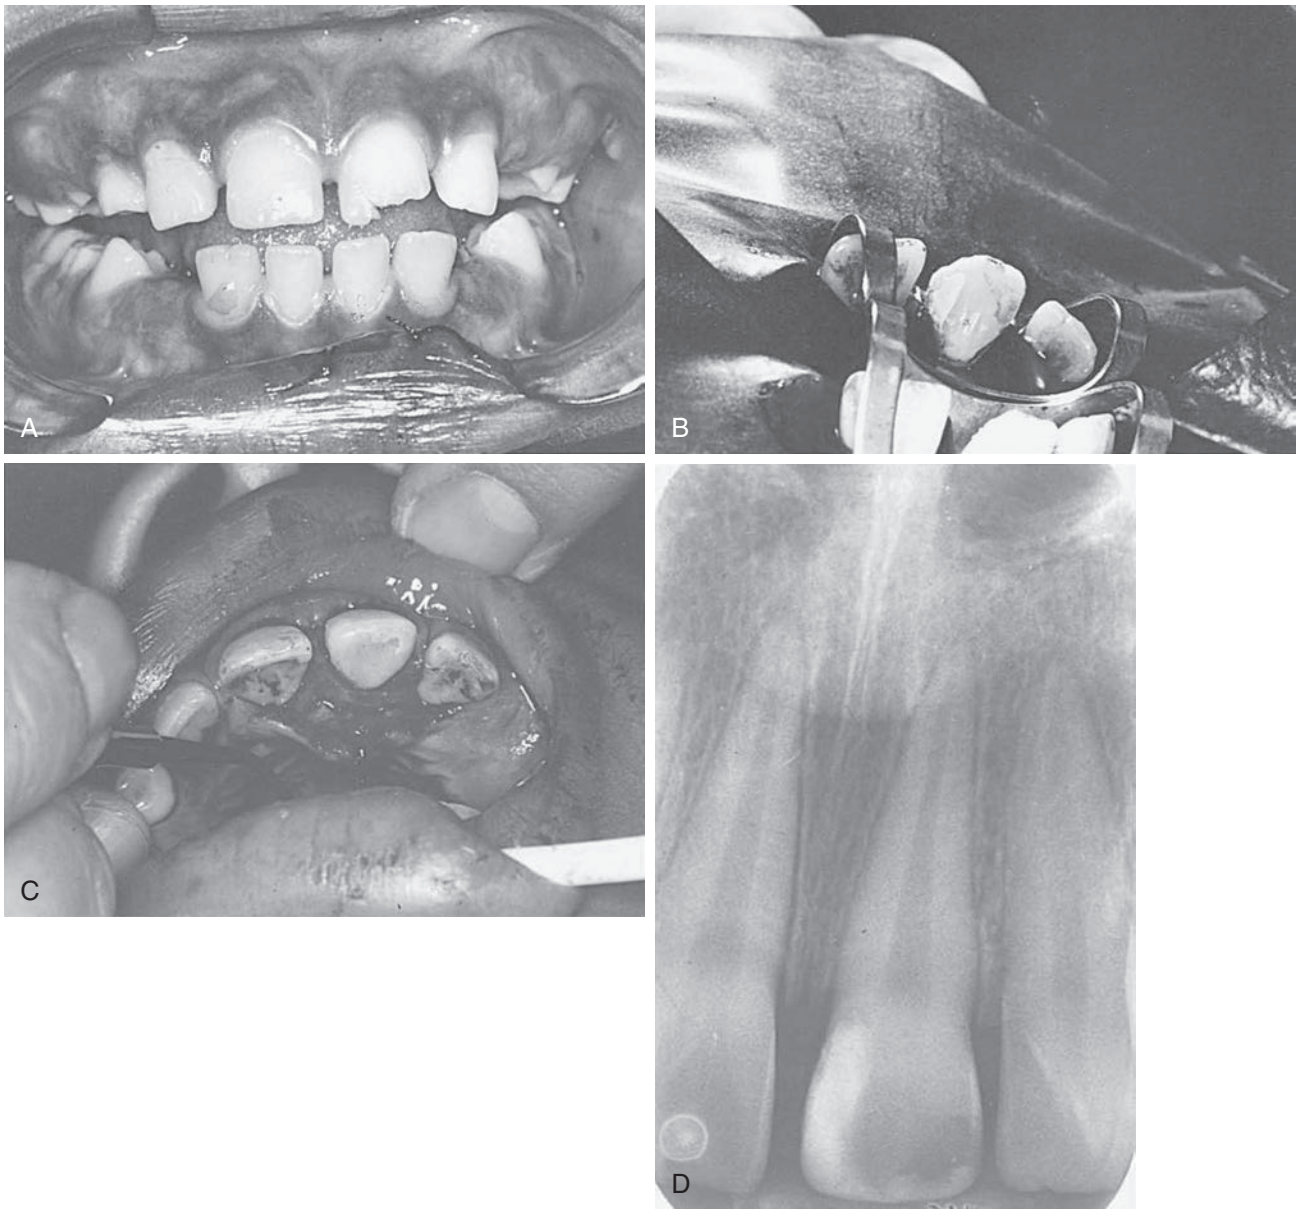


• **Figure 6-9** Periapical radiographs showing the results of the apexification procedure. **A,** A left central incisor necrotic tooth with an immature apex. **B,** The same incisor seen in Figure 6-8a after the placement of calcium hydroxide paste in the apex of the canal. **C,** Four months following treatment, note the radiopaque barrier that has formed at the apex. (From Abubaker AO, Papadopoulos H, Giglio JA: Diagnosis and management of dentoalveolar injuries. In Fonseca R, Marciani RD, Turvey TA, editors: *Oral and maxillofacial surgery*, ed 2, St Louis, 2009, Saunders.)

fragments must be substantial to appear on a radiograph. Only after a week or two, when hemorrhage, inflammation, and resorption have caused the fragments to separate, will the radiograph show the damage more conclusively. Diagonal root fractures are the most difficult to diagnose and are missed on intraoral periapical films. In suspected diagonal root fractures, a foreshortened (45-degree angulation) and an elongated (110-degree angulation) periapical film should be taken in addition to the standard 90-degree angulation.[40] Vertical root fractures in a labiolingual but not in a mesiodistal direction are easily discernible on a radiograph. Extraction is the treatment of choice in vertical root fractures because of nonrestorability.

Root fractures in the apical third without mobility require minimal treatment to avoid further trauma and improve the prognosis. The basic principle of treatment of root fractures with mobility consists of apposition of the fractured segments with flexible splinting for 4 weeks to 4 months for cervical-level root fractures. Splinting for 4 months is necessary because the repair of root fractures is similar to the repair of bone fractures, except slower.[41]

The treatment philosophy for cervical-third root fractures has changed significantly over the past decade. Extraction of the coronal part of the fracture followed by endodontic treatment was favored. Recent data have shown that—except for cervical-half root fractures, which are very close



• **Figure 6-10** **A,** A fracture of the maxillary left permanent central incisor. **B,** Isolation of the tooth after flap surgery was done to see the extent of the fracture. **C,** The fracture restored with an acid-etch resin system. **D,** A periapical radiograph 1 year following treatment. (From Abubaker AO, Papadopoulos H, Giglio JA: Diagnosis and management of dentoalveolar injuries. to the gingival crevice—splinting and follow-up has helped the fractures heal with formation of hard tissues.[46] If pulp in the coronal segment undergoes necrosis, then orthodontic treatment of a cervical-third root fracture with removal of the coronal segment is considered.[47]

Root fractures can heal by four different modalities: (1) calcified tissue, (2) connective tissue, (3) bone and connective tissue, and (4) granulation tissue.[45] Healing by calcified tissue is usually seen in teeth with immature roots or in teeth with little or no fragment separation.[46] Radiographically, the segments are not rounded at the edges. In connective tissue healing, radiographically the segment edges are rounded, with partial or complete pulpal obliteration.[45] In healing with bone and connective tissue, each segment has its own periodontal ligament, and total calcific metamorphosis of both segments is a usual occurrence. In healing with granulation tissue, the teeth are usually loose, slightly extruded, and sensitive to percussion. The pulp in the coronal segment usually undergoes necrosis, whereas in the apical segment it is vital.

Monitoring is recommended for at least 1 year prior to determining the final pupal status in absence of other signs and symptoms.[40] Root canal therapy is withheld for apical and middle-third root fractures, until there is evidence of pulpal necrosis. Pulpal necrosis is usually seen only in the coronal segment. Increased separations of the segments with an adjacent radiolucency and tenderness to percussion are indications of pulpal necrosis. Endodontic treatment for root fractures consists of (1) pulpectomy of the coronal segment only, (2) pulpectomy of both segments, or (3) pulpectomy of the coronal segment with surgical removal of the apical segment.[48]

Treatment of Injuries to the Periodontal Tissues

Concussion

A concussed tooth is one that has received a traumatic insult but exhibits no evidence of mobility, displacement, or fracture. The tooth may be sensitive to percussion and/or exhibit symptoms of hyperemia. No treatment is recommended other than palliative therapy. If there are excessive masticatory forces on the injured tooth, taking the tooth out of function by relieving the occlusion may help. Concussed teeth may later develop a reaction to the trauma. The patient must be advised that additional treatment may be required and that the prognosis is guarded; however, the incidence of pulpal necrosis is low.[40,49]

Displacements

Displacements are classified as subluxation (loosening injury), luxation (labial, lingual, or lateral), intrusions, and extrusions (partial avulsions).

Subluxation

The tooth demonstrates tenderness to palpation with slight mobility but without evidence of displacement clinically and radiographically. No active treatment is usually necessary, but a flexible splint can be placed for up to 2 weeks for patient comfort. Patients have masticatory discomfort, which can be managed with a soft non-chew diet and relieving the occlusion. Continued observation of the tooth radiographically and by vitality testing during the follow-up period is essential. False-negative vitality tests are possible for up to 3 months, after which root canal therapy is usually necessary. This type of displacement injury has the best chance of the tooth remaining vital since the apical vessels are not displaced.

Extrusive Luxation

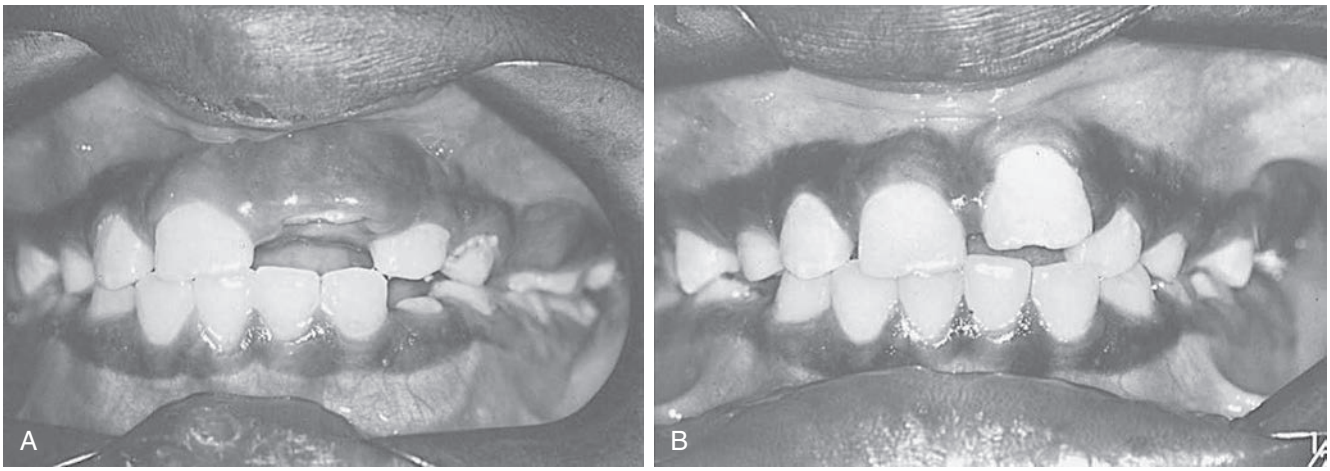
In extrusion injuries, the tooth is partially displaced from the socket, resulting in excessive mobility. Radiographic examination shows increased periodontal ligament space in the apical region. It should be repositioned in its original position using digital pressure and splinted with a flexible splint for 2 weeks. Continued clinical and radiographic observation is essential to identify pulpal necrosis and perform endodontic treatment. False-negative vitality tests are possible for up to 3 months.

Lateral Luxation

Lateral luxation is a complex injury that includes rupture or compression of the periodontal ligament (PDL), severance of the neurovascular bundle, and fracture of the alveolar walls around the tooth.[50] This causes lingual (most common), buccal, mesial, or distal displacement of the crown of the tooth. Such displacement is often painful, associated with large gingival laceration, and places the tooth in a "locked" position. The initial treatment of lateral luxation of the tooth is aimed at relieving the pain associated with this injury by repositioning and stabilizing the displaced tooth. This can usually be done by digitally manipulating the tooth to release the displaced root apex and repositioning the tooth into the proper alignment along with a flexible splint placement for 4 weeks. Repositioning of the tooth may require pressure application in the incisal direction to release the lock and return the root apex to its original location. These displacements should be followed closely to determine vitality. Such teeth may not respond normally to electric pulp testing for about 3 months. Follow-up examinations are therefore necessary, and depending on the stage of root development at the time of injury, endodontic therapy may be needed.

Intrusive Luxation

This results from apical displacement of the tooth into the alveolar bone. Intruded teeth are immobile with an ankylotic sound on percussion with minimal sensitivity. Stage of root development is a critical factor in treatment planning. In intruded permanent teeth with incomplete root development, spontaneous re-eruption is the first line of treatment (Figure 6-11). If there are no signs of re-eruption after a



• **Figure 6-11 A,** Intrusion of a maxillary left permanent central incisor with an immature apex. **B,** Six months later the tooth has partially re-erupted. (From Abubaker AO, Papadopoulos H, Giglio JA: Diagnosis and management of dentoalveolar injuries. In Fonseca R, Marciani RD, Turvey TA, editors: *Oral and maxillofacial surgery*, ed 2, St Louis, 2009, Saunders.)

month, orthodontic repositioning may be required. If the intrusion is greater than 7 mm to begin with, orthodontic or surgical repositioning or a combination should be performed. Repositioning is followed by flexible splinting for 4 to 8 weeks. Orthodontic repositioning has been shown to have better marginal bone levels compared to surgical repositioning. Root canal therapy for re-erupted intruded teeth with an immature apex should only be done if signs of pulpal necrosis develop. Time is allowed for apexification prior to definitive endodontic treatment. In general, intruded teeth with immature root formation have a better prognosis with regard to pulpal necrosis.[51]

If the tooth has completed root development, allow spontaneous eruption only if displacement is less than 3 mm.[40] If there is no sign of spontaneous eruption in 2 to 4 weeks, orthodontic extrusion is recommended. In cases of severe displacement (>7 mm), surgical repositioning to its original position either by finger pressure or with forceps is performed, followed by flexible splint for 4 to 8 weeks. The incidence of pulpal necrosis in this type of injury in general is 88%; therefore endodontic therapy is initiated 10 to 14 days after the injury.[51] Inflammatory and/or replacement resorption can occur in approximately 48% of these teeth. The depth of intrusion has been found to be a factor in the development of root resorption, with intrusions of 1 to 3 mm having the lowest frequency.[51] For intruded teeth with completed root development, there is high likelihood of pulp necrosis. Calcium hydroxide can be placed as a temporary filling, followed by definitive endodontic treatment within 2 to 3 weeks.[40]

Exarticulation (Complete Avulsion)

Avulsion involves complete displacement of the tooth out of its socket. It may occur by itself or in conjunction with alveolar fractures and/or gingival lacerations. Children between 7 and 9 years of age are more often subject to avulsion because of the unsettled condition of the periodontal ligament and low mineralization of the alveolar bone caused by continued eruption of the teeth. Usually avulsion involves a single tooth, and the most frequently avulsed tooth is the maxillary central incisor. The chances of survival of the pulp and periodontal cells in a replanted tooth are highly dependent on the extra-alveolar time and handling of the avulsed tooth, which affect the pulp and periodontal reactions.[53] Treatment must be aimed at maintaining cellular viability, which can increase the chances of successful reattachment and decrease the chances of root resorption. The tooth's pH, osmolality, and cell metabolites can be physiologically maintained by various storage media. The periodontal ligament is usually restored in 3 to 4 weeks after a prompt replantation. After an extraoral dry time longer than 60 minutes, the periodontal ligament cells become nonviable.[54] The viability of the PDL can be assessed based on the extraoral dry time, storage media, and time of replantation. The treatment plan for avulsed teeth relies on maturity of the root apex and condition of the PDL cells.

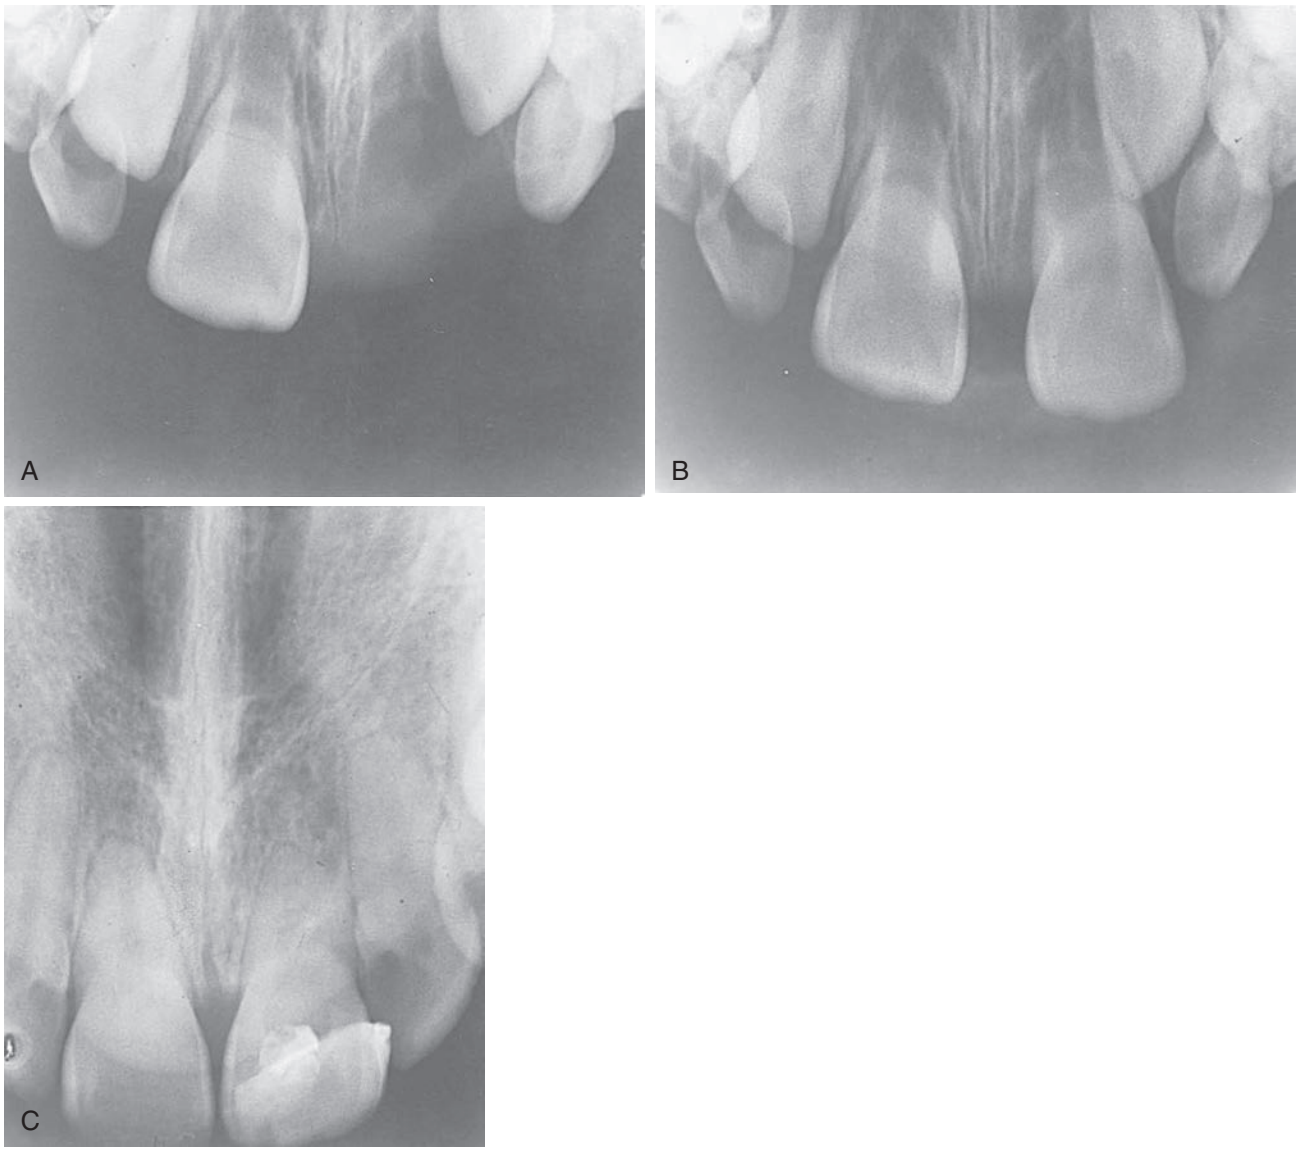
Teeth that are nonrestorable because of extensive caries or severe periodontal disease should not be replanted, except for the temporary purpose of maintaining alveolus or esthetics until a definitive replacement is planned. In teeth with a closed apex and pulp that have been replanted prior to arrival or have a extraoral dry time of less than 60 minutes and have been stored in an appropriate storage medium, replantation should be performed, with a flexible splint for up to 2 weeks. Endodontic treatment should be performed on these teeth within the first 7 to 10 days before splint removal.[54] In teeth with a closed apex that have had more than 60 minutes of extraoral dry time, the PDL is likely nonviable. Splinting can still be performed, but the patient should be informed of the poor prognosis and increased probability of eventual loss of the tooth, likely due to replacement resorption. Flexible splinting is recommended for 4 weeks. Endodontic treatment on these teeth can be

performed either prior to replantation or within 7 to 10 days after replantation. In children and adolescents, ankylosed teeth with infra-positioning can be managed with decoronation. Patients and parents should be informed about the possibility of ankylosis and indications for decoronation.

In avulsed permanent teeth with open apex that were replanted before the patient's arrival or have an extraoral dry time of less than 60 minutes, the goal of replantation is possible revascularization of the pulp. On the other hand, if the extraoral dry time was greater than 60 minutes, the long-term prognosis is poor and hence the goal is restoring the tooth for esthetic/psychosocial/functional purpose. The ultimate outcome in these teeth is ankylosis or resorption. The time period of flexible splinting is similar to that for teeth with a closed apex: 2 weeks for early replantation and 4 weeks for delayed replantation.

The overall prognosis for replanted permanent teeth in terms of continued pulp vitality is very poor. However, replanted teeth are useful during the mixed dentition stage in children even if the long-term prognosis is poor, because alveolar bone support is maintained during maxillary growth. These replanted teeth also serve as a good esthetic space maintainer, even if it is for only a few years. The central incisor also provides guidance for the eruption of the lateral incisor into its position in the arch (Figure 6-12), as would the lateral incisor for the canine.

In general, the avulsed tooth should be gently rinsed under tap water before replantation; it should not be



• **Figure 6-12** **A,** An occlusal radiograph of an avulsed immature maxillary left permanent central incisor prior to the eruption of the permanent lateral incisor. **B,** The tooth was replanted within 1 hour. The tooth has had the calcium hydroxide paste replaced every year. Seven years later the replanted tooth has served as guidance for the lateral incisor **(C).** (From Abubaker AO, Papadopoulos H, Giglio JA: Diagnosis and management of dentoalveolar injuries. In Fonseca R, Marciani RD, Turvey TA, editors: *Oral and maxillofacial surgery*, ed 2, St Louis, 2009, Saunders.)

scrubbed. If the tooth is maintained by soft tissue attachment, this attachment should not be removed. The objective is to maintain vital periodontal tissue and cementum. The tooth should be held in place either by finger pressure or by gently biting down on a handkerchief or washcloth until the patient is brought to the office or emergency room. If replantation is not possible, the tooth should be placed in the best transport medium available. The transport medium of choice is Hanks balanced salt solution (HBSS) or Viaspan.[55-57] Viaspan is used for transport organ storage. It has a pH of 7.4 with an osmolality of 320 mOsm, and vital cells were present at 7 days.[57] Hanks solution has a pH of 7.2 with an osmolality of 320 mOsm. Hanks can successfully preserve and reconstitute the periodontal ligament cells for at least 24 hours. Depleted cell metabolites can be replenished in Hanks solution.[58] Hanks solution is commercially available as Save-A-Tooth (3M Health Care) (Figure 6-13).

Milk, saliva, and saline are temporary storage media more readily available to the public; however, their effectiveness is very limited. Milk is a short-term storage medium (up to 6 hours) provided avulsed teeth are placed in it within 15 to 20 minutes. Milk only prevents cell death; it does not restore the cell's normal morphology and ability to differentiate and undergo mitosis. Milk has no ability to maintain viability after the cells have been dry stored for more than 20 minutes. Milk is a significantly better medium than saliva or water for preserving periodontal fibroblast viability and proliferative ability. If the tooth cannot be replanted immediately, it should be stored in milk if Hanks solution is not available. Storage of avulsed teeth in water or saliva should be avoided since they can damage the periodontal ligament cells and cause increased root resorption. Once teeth have been placed in Hanks solution, time is no longer as critical a factor.

Once the patient reaches the treatment facility, the tooth should be rinsed with saline. Any remaining periodontal ligament should not be removed. The alveolar socket should be debrided by saline irrigation without curettage. The blood clot should not be removed, because it will not interfere with positioning of the tooth or pulpal and periodontal healing. The tooth should be replanted and splinted as soon as possible. Manually compress the facial and lingual bony plate if spread apart. A radiograph should be taken to verify proper positioning of the replanted tooth. The need for tetanus prophylaxis should be evaluated. The value of antibiotic coverage for replanted teeth has not been clearly established by clinical studies, although experimental studies favor topical antibiotics. A 7- to 10-day course of amoxicillin is usually prescribed to prevent secondary infection from occurring and to promote wound healing.[53] The tooth should be taken out of occlusion, and the patient should not chew on it for the first month. When relieving the occlusion, reduction on the opposing teeth is preferable to avoid further pulpal injury. The patient should be instructed on gentle but thorough tooth brushing to prevent inflammation in the gingival crevice. Chlorhexidine rinses should be prescribed for gingival health, and analgesics for pain.

• **Figure 6-13** Save-A-Tooth containing Hanks balanced salt solution and a basket for placing the avulsed tooth.

Teeth with immature apices have a better prognosis than do teeth with mature apices. Immature teeth soaked in a doxycycline solution have a higher rate of pulpal revascularization than those not treated.[59] Tetracycline, in animal studies, has been also been shown to have antiresorptive properties.[60,61] If pathology is noted, thoroughly clean and fill the canal with calcium hydroxide (apexification procedure).

In 7 to 10 days the pulp should be removed and the canal filled with calcium hydroxide. The tooth can be obturated with gutta percha after 6 to 12 months of calcium hydroxide, provided there is no pathology present.

In teeth with an open or closed apex that have been extraoral for more than 60 minutes, endodontic treatment can be carried out prior to replantation or after. These teeth could be soaked in a 1% stannous fluoride solution for 5 minutes and in a 1 mg/20 mL doxycycline solution for 5 minutes. The antibiotic kills the bacteria that might remain on the root surface and has been shown in animal studies to synergize with the stannous fluoride to make the tooth more resistant to resorption.[62,63]

The two major reasons for failure of replanted teeth are inflammatory and replacement resorption (ankylosis). Inflammatory resorption is due to necrotic pulp, and replacement resorption is due to damage to the periodontal ligament. Andreasen and colleagues showed in a study on 400 replanted teeth that normal periodontal healing occurred in 24%, surface resorption in 5%, inflammatory resorption in 30%, and replacement resorption in 64% of cases.[64] Radiographically, the first signs of pulpal necrosis may be seen in 2 to 3 weeks, and inflammatory resorption could take 3 to 6 weeks up to 6 months. Inhibition of inflammatory resorption involves removal of necrotic tissue and filling the root canal with calcium hydroxide. Replacement resorption or ankylosis can be diagnosed clinically by percussion and immobility in 4-8 weeks, but radiographic evidence could take up to a year.[67] The extent of the injury, concomitant alveolar fractures, and age of the patient can affect the rate of progression of replacement resorption.[65,67] In younger patients, ankylosis alters the normal alveolar growth, resulting in infraocclusion of the replanted tooth.

There is no treatment for ankylosis as such, but to avoid extensive loss of alveolar bone from extraction of these teeth in younger children, decoronation, involving removal of the crown and the root canal filling so as to allow replacement of the remaining root with bone, has been the procedure of choice. This allows continued growth of alveolar bone coronal to the resorbing root.[68]

Radiographs should be taken in 2 weeks, 1, 2, 3, and 6 months, and then semiannually thereafter. The practitioner should also evaluate the unaffected adjacent teeth in displacement and avulsion injuries. Usually 50% of the supposedly unaffected adjacent teeth will undergo pulpal necrosis within 2 years from the time of injury. Finally, crown discoloration is common in replanted avulsed teeth.[69] This discoloration may later be treated by internal bleaching, veneers, or crowns.

Calcium Hydroxide Root Canal Fill

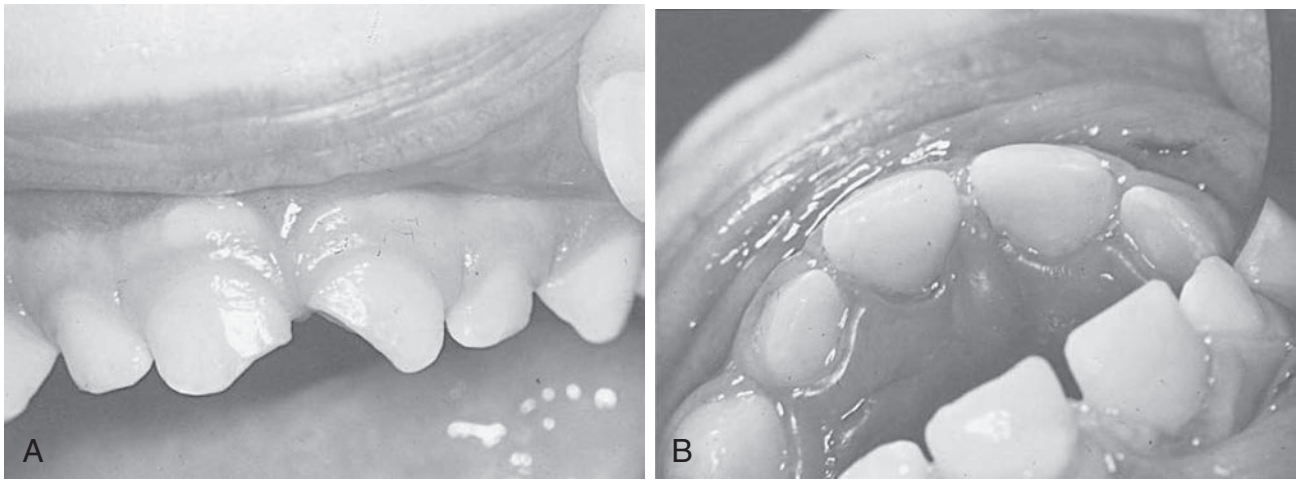
Inflammatory resorption usually occurs in teeth that have undergone severe displacement or avulsion. It appears to be related to pulpal necrosis. Removal of the necrotic pulp and the placement of calcium hydroxide in the canal appear to inhibit inflammatory resorption.[70-72] Calcium hydroxide should be used in avulsion and intrusion injuries and any luxation injury in which the tooth is displaced more than 3 to 5.0 mm. The procedure involves removal of the pulp and instrumenting the root canal thoroughly during the first or second week after the injury.[73] The canal should be filled with USP calcium hydroxide powder or Pulpdent (calcium hydroxide in aqueous methyl cellulose from Pulpdent Corp., Watertown, MA) (Figure 6-14). Filling the canal with calcium hydroxide at 1 to 2 weeks will allow initial repair of the periodontal ligament.[74] The powder may be inserted dry or made into a paste with either a local anesthetic solution, water, saline, camphorated monochlorophenol (CMCP). Because calcium hydroxide is a resorbable material, the canal should be recleansed and repacked with calcium hydroxide at 3-month intervals for a minimum of 1 year. There is no need to change the calcium hydroxide if it appears to occupy the root canal space adequately at the 3-month evaluation. If resorption is arrested or nonexistent, a gutta percha root canal can be done at the end of the year.

Treatment of Injuries to the Primary Teeth

Injuries involving primary dentition and injuries to children in general deserve special consideration. Difficulties with patient management due to lack of cooperation, as well as concern regarding underlying permanent dentition and the consequences, are some major factors affecting management. The treatment plan should aim at preventing or minimizing the injury to permanent dentition. Displacement injuries rather than fractures are more frequent in the primary dentition, in part because of the anatomic differences between a child and adult jaw in terms of bone mineralization and density. Most traumatic injuries to the primary teeth occur when the child is learning to walk, at 18 to 30 months old.[19,21,75]

Fractures of Primary Teeth

Fractures of primary teeth are less common than in the permanent dentition. Treatment of fractured primary teeth presents difficulties because of the small size of the tooth and the relatively large pulp chamber. In fractures involving enamel only, the sharp edges should be smoothed and the tooth observed. The same treatment can be provided for enamel and dentin (Class II) fracture. In severe or large fractures, calcium hydroxide/MTA and/or a light-cure glass ionomer liner/base (e.g., Vitrebond, 3M Dental Products) should be placed over the dentin followed by an acid-etch resin restoration[75,76] (see Figure 6-12). In primary teeth with fractures involving the pulp,



• **Figure 6-14** **A,** Mesioangular fractures of the maxillary primary central incisors. B, Acid-etch restorations placed using celluloid crown form. (From Abubaker AO, Papadopoulos H, Giglio JA: Diagnosis and management of dentoalveolar injuries. In Fonseca R, Marciani RD, Turvey TA, editors: *Oral and maxillofacial surgery*, ed 2, St Louis, 2009, Saunders.)

a calcium hydroxide partial pulpotomy should be performed, followed by a full-coverage restoration. Extraction of the involved tooth is the alternative option. Full coverage of all teeth that have pulpotomies or pulpectomies is necessary because the crown of the tooth is weak, usually unsupported, and is liable to fracture below the gingival attachment or crest of the alveolus.[75]

Root fractures are extremely rare. The most common root fracture occurs in the middle third of primary teeth (Figure 6-15). If the fracture is present in the apical third and the coronal segment exhibits no mobility, the tooth should be observed. If the fracture of the root occurs in the middle or cervical third, the coronal segment may be mobile and should be removed while the apical segment is left to resorb. The apical fragment should not be removed if injury to the developing permanent tooth is a possibility.[75]

If fistula, redness, or swelling appears, the tooth should be treated with pulpectomy or be removed. Teeth with zinc oxide and eugenol pulpectomies may not resorb normally and can cause displacement of underlying permanent teeth.[77] Pulpectomies should not be attempted on primary teeth with external resorption.

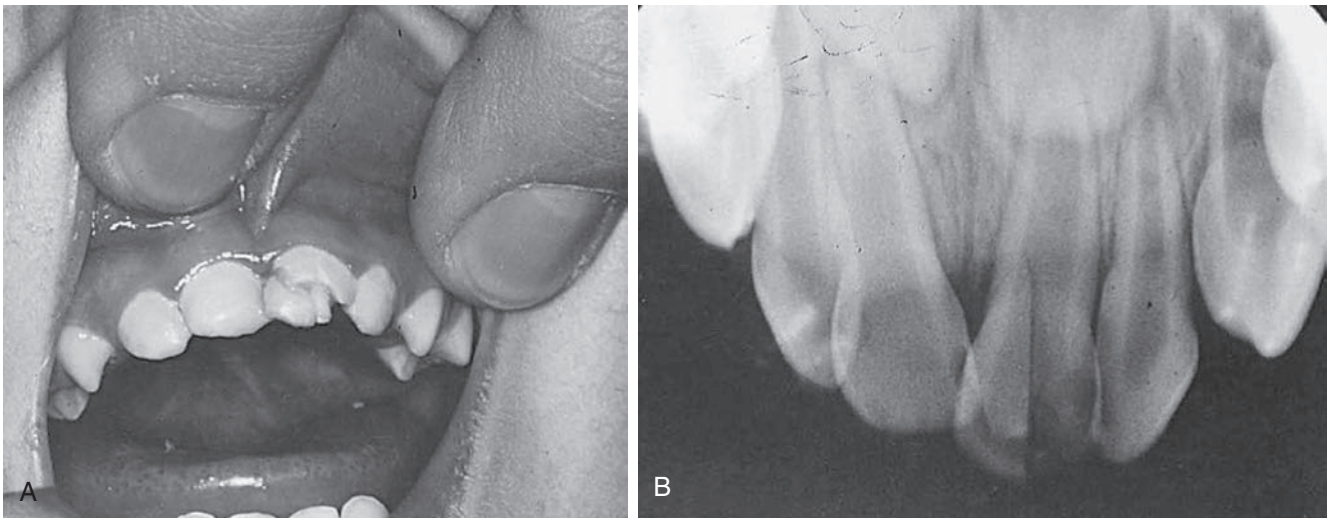
Displacements of Primary Teeth

Displacement injuries are more common in the primary dentition than in the permanent dentition. Primary teeth that have been subluxated do not need any acute treatment. They should be observed and the patient instructed about soft diet and oral hygiene measures. Treatment of displaced primary teeth depends on maturity of root formation, severity of displacement, and proximity or potential for injury to the permanent tooth bud. Laterally luxated teeth with the root apex displaced moderately in a labial direction with severe occlusal interference should be repositioned with digital pressure. Usually the tooth will snap back into position, and splinting may not be necessary. But depending on the patient's cooperation, a short period of splinting can be performed. Physiologic forces can be relied on to reposition the displaced tooth when the displacement is minimal and when there is no occlusal interference, as in the case of an anterior open bite. If the root apex is displaced into the permanent tooth, bud extraction is recommended. If a primary tooth is extruded, spontaneous realignment can happen in minimal extrusions (<3 mm) with immature root development. A tooth with a fully formed root with severe extrusion should be extracted.[75]

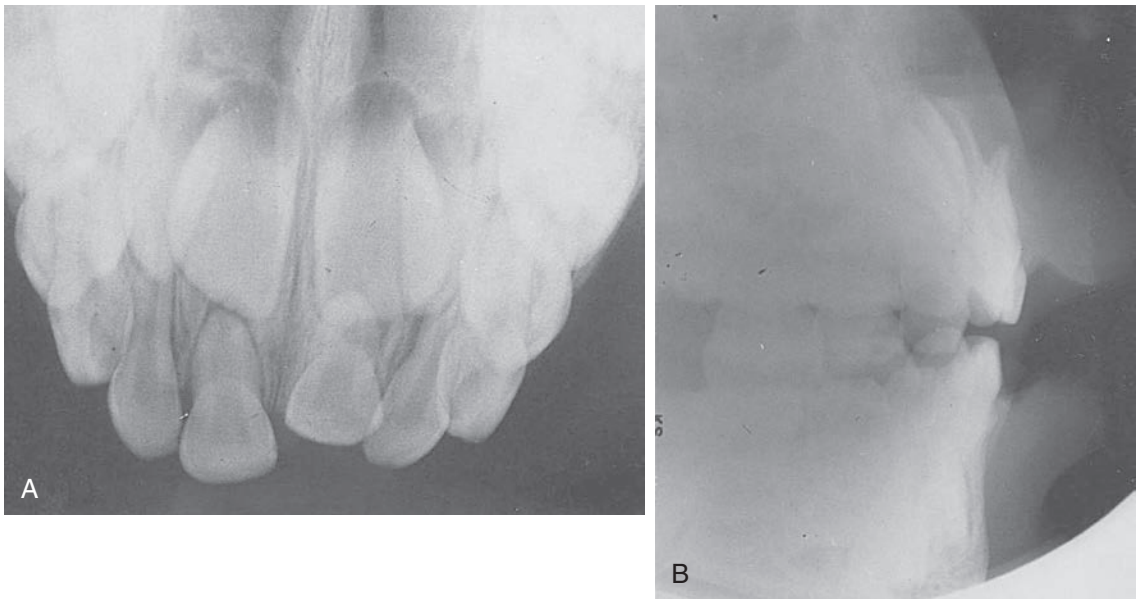
When a primary tooth is intruded, the practitioner should observe the tooth for re-eruption if the apex is displaced in a labial direction; otherwise, the tooth should be extracted (Figure 6-16). If the primary tooth has not started re-erupting within 4 to 8 weeks, it should be extracted. If acute inflammation and swelling, or inflammation of the gingiva and/or purulence from the gingival crevice, develop during the re-eruption phase, the tooth should be extracted. In primary teeth with alveolar fractures, the segment is repositioned and stabilized using a flexible splint for 4 weeks.

Replantation of primary teeth is not recommended. More importantly, the replacement of an avulsed primary tooth is contraindicated because of the increased probability of ankylosis, internal or external resorption, abscess formation, and alteration of the sequence or direction of eruption of the permanent tooth.

Premature loss of a primary incisor before the eruption of the primary canines usually results in arch perimeter loss. Primary incisors lost after the eruption of the primary canines usually result in space loss in crowded or nonspaced arches but not usually in spaced arches. However, adjacent teeth in the anterior segment can drift, which could cause an esthetic problem.



• **Figure 6-15** **A,** A vertical fracture of a maxillary left primary central incisor. **B,** An occlusal radiograph showing that the vertical fracture extends to the middle of the tooth. The tooth was later extracted. (From Abubaker AO, Papadopoulos H, Giglio JA: Diagnosis and management of dentoalveolar injuries. In Fonseca R, Marciani RD, Turvey TA, editors: *Oral and maxillofacial surgery*, ed 2, St Louis, 2009, Saunders.)



• **Figure 6-16** **A,** An occlusal radiograph showing an intruded maxillary primary central incisor. **B,** A lateral radiographic view showing the tooth displaced in a vestibular direction. (From Abubaker AO, Papadopoulos H, Giglio JA: Diagnosis and management of dentoalveolar injuries. In Fonseca R, Marciani RD, Turvey TA, editors: *Oral and maxillofacial surgery*, ed 2, St Louis, 2009, Saunders.)

Premature loss of primary incisors will not cause a delay or disruption in speech.[79-81] Parents are usually more concerned with the esthetics of the child. If the child had normal speech prior to the premature loss of the incisors, adaptation to the new environment should occur. In some cases, there may be some lisping until the eruption of the permanent incisors. Replacing the teeth with a prosthetic appliance, though not necessary for speech, will create a more normal oral environment that will foster the maintenance of previously normal speech.

A primary incisor removed before the age of 3 generally causes a delay in the eruption of the permanent successor; a primary incisor removed 1 to 2 years before its normal exfoliation time generally causes an acceleration in the eruption of the permanent successor. The eruption of the permanent successor often occurs in a more facial direction.[82]

Treatment of Injuries (Fractures) to the Supporting Bone

Fractures of the supporting bone can be divided into four types.[83]

Comminution of the Alveolar Socket

This type of fracture is usually associated with dental injuries such as lateral or intrusive displacement of teeth. Digital manipulation and repositioning of the displaced tooth is often adequate to reduce these fractures. Monitoring the pulpal status of the tooth and evidence of root resorption and ankylosis by routine follow-up is recommended.

Fractures of the Socket Wall

Fractures of the socket wall are often associated with dislocation of teeth with mobility of the buccal osseous plate and mucosal contusion. Reduction of these fractures after administration of local anesthesia can be achieved using simultaneous digital pressure over the apical area and at the lingual aspect of the crown. In case of comminuted fractures, loose fragments not attached to the periosteum should be removed and attempts to preserve the tooth should be made. After completion of the reduction, any mucosal laceration should be sutured, the involved teeth should be relieved from forces of traumatic occlusion, and the segment should be splinted for 4 weeks to allow for osseous healing. Because bone healing occurs relatively quickly in children, fixation often is unnecessary in this age group for primary dentition. The child should, however, be maintained on soft diet for 2 weeks and followed periodically to monitor pulp and tooth healing.

Fractures of the Alveolar Process

Alveolar process fractures may be isolated or may be seen in conjunction with other dental or facial injuries and with varying degrees of mucosal or gingival laceration. In most instances the fractured bony segment contains one or several teeth. These fractures occur most often in the anterior or premolar regions of children of oldest age group and adults.

The successful treatment of alveolar fractures is based on proper reduction and repositioning of the fractured segment using closed or open techniques followed by adequate stabilization to allow for osseous healing.[40] Closed reduction of dentoalveolar fractures may be accomplished with digital

• **Figure 6-17** **A,** Displaced dentoalveolar segment involving the maxillary anterior teeth. **B,** Closed reduction of dentoalveolar fractures using digital pressure on the alveolus and dental segment along with placement of a splint for stabilization.

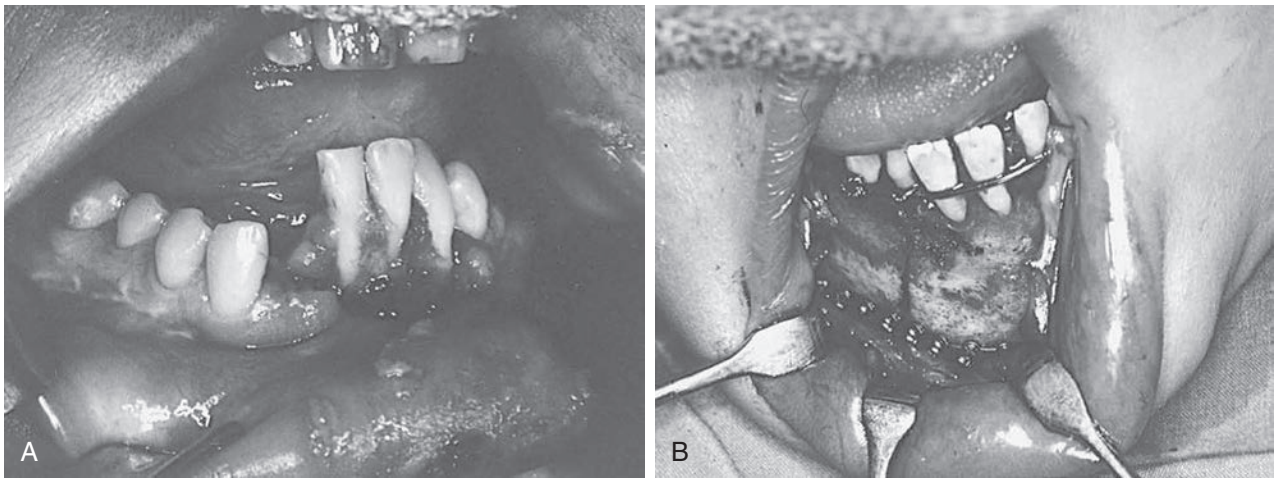
pressure on the alveolus and dental segments (Figure 6-17). The segments then should be stabilized in place using either rigid splinting of the involved teeth or other forms of splinting techniques for 4 weeks. In children this period can be reduced to 3 weeks because of rapid healing.

Although alveolar fractures can usually be reduced and stabilized in proper position using closed methods, occasionally, to reduce the segment properly and achieve adequate stabilization, it is necessary to resort to open surgical techniques. Once the fracture is reduced, it can be stabilized or fixed in a variety of ways. In most instances, one arch fixation is adequate to provide stable fixation of simple alveolar fractures. However, a splint of bonded brackets or composite resin that fixes a wire to the teeth on either side of the fracture is superior to other forms of fixation with regard to hygiene and periodontal effects—although it may be impossible in instances where a procedure needs to be done in an emergency room or at bedside, without the necessary armamentarium, facilities, or cooperation to cleanse, dry, acid-etch, and bond brackets to composite resin. In these instances, an arch bar or a Risdon or Essig wire, either alone or supplemented with autopolymerizing acrylic resin, may be the best method of fixation. If necessary, this fixation may be changed to a more optimal splint at a later date.

Processed or autopolymerizing acrylic resin splints on the palatal, lingual, or occlusal coverage are also effective methods of fixation. However, they require impressions and models to construct and thus introduce a delay in the treatment. Fixation should be maintained for 4 to 6 weeks. Patients should maintain a soft diet. Open reduction is occasionally required, especially when the alveolar segment is significantly displaced or the roots of teeth or the bone in the segment interferes with proper repositioning of the segment. A vestibular incision is made apical to the fracture line and the segment pried into position using a sharp instrument such as periosteal elevator. Occasionally, an irregular area of spongy bone may inhibit the reduction. Proper alignment of the alveolus may require removal or contouring of the obstructing segment. Once the segment is satisfactorily repositioned and the proper occlusion is verified, the segment is fixed in place using transosseous wire or a small bone plate (Figure 6-18). Condemned teeth in an alveolar fracture segment should only be considered for extraction in the acute phase if they are poorly supported or infected. In general such extractions should be delayed until bone healing is complete to prevent inadvertent removal of the entire alveolar segment with the teeth during the extraction. Antibiotic coverage with penicillin, erythromycin, or clindamycin and the use of chlorhexidine oral rinse are recommended, especially in delayed treatment and extensive associated soft tissue lacerations. Tetanus booster is usually only indicated in wounds with dirt and road debris contamination. Careful follow-up of the involved teeth should be done to monitor the vitality of the tooth.

When an alveolar fracture occurs in conjunction with a jaw fracture, the treatment should be accomplished as soon as the patient's condition is stable. Generally, reduction of the fractures and maxillomandibular fixation with appropriate wiring techniques (arch bars, Risdon wiring, etc.) are required. This should be done as soon as possible to improve the prognosis of the dental and alveolar components. Additional maneuvers, such as open reduction of the jaw fractures, may be done later, if necessary.

Avulsed injuries of the alveolus are occasionally seen in conjunction with major facial injuries. The treatment is often dependent on the anatomic location of the avulsion and its relationship to other injuries, particularly fractures. In these instances, advancement of mucosal flaps is often used to cover exposed bone, particularly areas where there are fractures. Avulsions that result in nasal or maxillary sinus openings should be closed, if flaps can be advanced, so as not to compromise treatment of other injuries or preclude a more predictable closure by conventional means at a later date. The



• **Figure 6-18** **A,** Open reduction of a displaced mandibular dentoalveolar fracture. **B,** A mucoperiosteal flap was elevated, the segment was satisfactorily reduced, the proper occlusion was verified, and the segment was fixed in place using arch wire and a small bone plate.

patient should be informed of the prognosis, especially as it applies to insurance coverage and possible litigation.

Splinting Techniques

Splinting is a form of fixation to stabilize the injured teeth in its normal anatomic position during the healing period. Importance of allowing physiologic mobility during this period of healing to avoid damage to the periodontal and pulpal healing is well known.[84-86] Requirements of an ideal splint would include:

1. Splint fabrication materials easily available in a dental office or emergency room,
2. Avoids or minimizes further trauma to the injured tooth or supporting structures,
3. Facilitates oral hygiene maintenance, avoids soft tissue irritation,
4. Stays passive and remains in its normal position throughout the immobilization period,
5. Allows physiologic movement of the tooth,
6. Does not interfere with the occlusion,
7. Allows easy access for endodontic treatment and pulp testing, and
8. Is easily removed in the dental office.

The splints that come closest to fulfilling these requirements are the acid-etch resin arch wire splint (Figure 6-19, *A*) and the orthodontic bracket arch wire splint (see Figure 6-17, *B*). These, of course, are difficult to apply when blood and saliva cannot be isolated from the field, such as in an emergency room.

A rigid splint increases the amount of external resorption and eventual early loss of the tooth.[87] For this reason, arch bars and other forms of interdental wiring are less than optimal. These types of splints also can cause orthodontic movement of the teeth, such as extrusion.

A splint should be left on for a minimal amount of time. Prolonged splinting will increase the risk of ankylosis. The optimal splinting period for a displaced or avulsed tooth is based on the type of dentoalveolar injury. Ideally, the splint should be maintained for 7 to 10 days because the gingival fibers are usually healed in 1 week, and this should provide adequate periodontal support. Alveolar bone fractures with replanted teeth may require a splint for 3 to 4 weeks, luxation may require a splint for 2 to 4 weeks, and root fractures require a splint for up to 12 weeks.

An acid-etch resin-only splint is easy to fabricate, but does not allow the teeth much mobility and is also fragile, resulting in fracture of the material. Newer multiphase resin materials (Protemp, Luxatemp) have been reported to provide semirigid splinting and retain the ease of application, oral hygiene, and patient acceptability. These do require the teeth to have fully erupted crowns with proper interproximal contact; otherwise the use of wire or fiber lines is unavoidable. A better splint is an acid-etch resin arch wire splint (see Figure 6-19, *A*).[86-88] This allows the tooth some mobility. Fiberglass instead of wires has been used in many cases, but the flexibility varies depending on the extension of the splint.[89] The wire is bent to conform to the facial surfaces of the teeth to be splinted. At least one tooth on either side of the displaced tooth or teeth must be included. The facial surfaces of all the teeth to be splinted are etched with phosphoric acid for 1 minute, after which they are washed and dried. The bonding agent is applied and a small amount of resin is placed in the middle of the facial surface over a small area. The arch wire is then passively placed in the resin. The resin material should not contact the gingiva because it will cause gingival inflammation. The practitioner must be sure that the displaced tooth is in its correct position. A radiograph should be taken to verify this after the splint is in place. The patient should be instructed in proper oral hygiene, stressing the importance of keeping the gingival crevice as well as the rest of the teeth clean.

• **Figure 6-19** **A,** An acid-etch resin arch wire splint. **B,** Luxation of maxillary permanent central incisors treated with an orthodontic bracket arch wire splint using ligature wires. **C,** Luxation of the maxillary permanent four incisors treated with an orthodontic bracket arch wire splint using AlastiK ligatures (3M) with banding of the permanent first molars for stabilization. (From Abubaker AO, Papadopoulos H, Giglio JA: Diagnosis and management of dentoalveolar injuries. In Fonseca R, Marciani RD, Turvey TA, editors: *Oral and maxillofacial surgery*, ed 2, St Louis, 2009, Saunders.)

When removing the splint, the wire can be cut between each tooth. The resin should not be removed because the replanted teeth are still loose and can be displaced. After the teeth are firmly attached in 2 to 3 months, the resin can be removed.

The orthodontic bracket arch wire splint is an excellent technique.[90,91] Acid-etch brackets are placed on the displaced tooth or teeth as well as on at least one sound tooth on either side of the displaced tooth. Sometimes it is necessary to extend this type of splint by banding the permanent first molars (see Figure 6-19, *C*). This can occur in the mixed dentition when permanent lateral incisors, canines, and/or premolars are absent or there is a deep overbite and additional teeth are necessary for stabilization. The arch wire can be either round or rectangular and is bent to conform to the facial surface of the teeth to be splinted. AlastiK (3M

Dental Products) ligatures are used to hold the arch wire to the brackets. The advantages of this splint over the acid-etch resin arch wire splint are that the practitioner can remove the elastic ligatures and the wire to check mobility of the displaced teeth. If there is excessive mobility, the splint can be replaced. New prefabricated splinting materials, such as the titanium trauma splint (TTS) with a rhomboid flat design, are being used because of ease of adaptability to the tooth (0.2-mm thickness) and increased patient comfort[92,93] (Figure 6-20).

It should be noted that a fairly high percentage of teeth involved in alveolar process fractures undergo pulpal necrosis and either internal or external resorption. This may occur even years later. The teeth must be carefully observed and endodontic intervention initiated at the appropriate time.

Treatment of Gingival and Mucosal Injuries

Injuries to the Gingiva and Mucosa

Intraoral soft tissue injuries to the gingiva and mucosa occur in the form of contusions, abrasions, lacerations, and avulsions. They are seen either alone or in conjunction with injuries to the teeth, facial bones, or alveolus.[94] Management in many instances depends on the presence or absence of injuries to these underlying structures as well as on periodontal considerations.

Contusions of the gingiva seldom require any active treatment other than appropriate oral hygiene to allow healing. These contusions are helpful in indicating possible underlying fractures of the bone and a need for further radiographic evaluation.[95] Underlying ecchymosis and/or hematoma will resolve with time without residual deformity.

Abrasions and lacerations of the oral soft tissue require thorough debridement and cleansing to remove all foreign bodies that could be potential sources of infection. Larger lacerations or avulsion injuries extending to the facial tissues should be considered for be treatment in the controlled setting of an operating room under general anesthesia. Careful oral hygiene and avoidance of thermally or chemically irritating food and drink allow for healing in a few days. Lacerations need to be repositioned without tension in correct anatomical position to avoid wound breakdown. Since the gingiva is highly vascular and necrosis is unusual, debridement when done should be extremely conservative. Antibiotic coverage and tetanus prophylaxis are considered on an individual basis depending on the extent of injury and degree of contamination of the wound. Evidence in the literature for routine use of antibiotics is limited, although most intraoral soft tissue wounds are considered contaminated by oral flora.[95] Hence the judgment for providing prophylactic antibiotics in absence of active infection is based on certain factors: degree of contamination of the wound, delay in debridement or repair, systemic indications due to immunocompromised status, and concomitant fractures. Current evidence shows benefit in use of preoperative and 24-hour postoperative antibiotics only. No benefit has been proven from prolonged use of postoperative antibiotics.[96,97]

Plain gut, chromic gut, or polyglycolic acid resorbable sutures in 3-0 or 4-0 sizes are commonly used to repair intraoral lacerations. Gut suture material is quite irritating, whereas polyglycolic acid suture is more difficult to tie and may take a long time to resorb. Less reactive nylon suture may annoy the patient by scratching the tongue, lip, or cheeks.

Avulsive wounds of the gingiva are infrequent and often are more apparent than real. After the wound is cleansed and the tissues are reassembled, presumed missing tissue may, in fact, be present. Management of an avulsive wound of the gingiva, in many respects, depends on the presence or absence of underlying injury to the alveolus or teeth. A gross alveolar fracture associated with a luxated or displaced tooth needs to be covered with soft tissue to promote healing of the fracture and/or retention of the tooth or teeth. Advancement soft tissue flaps to cover alveolar soft tissue defects will often be from non-keratinized alveolar mucosa rather than attached gingiva. Accordingly, small areas of avulsed attached gingiva, without underlying injuries, should be left to granulate and thus produce fixed gingiva, which is more periodontally desirable. Large areas of exposed bone should be covered whenever possible, even if it requires advancement of unattached gingiva.

Prognosis of Dentoalveolar Trauma

Reactions of Teeth/Surrounding Tissues to Trauma

The multiple types of dentoalveolar trauma and their combinations give rise to highly complex and variable healing scenarios. Knowledge of the basic reactions of the teeth and surrounding tissues to trauma is essential in rendering appropriate acute and follow-up care. Traumatized teeth and surrounding tissues often have an unpredictable course of healing. Ability to determine the ultimate outcome would help in fabricating the treatment plan. Basic reactions of dentoalveolar structures to trauma include healing

events related to alveolar bone, periodontal ligament (PDL), and the pulp tissue within mature and immature teeth.[98]

There are several basic healing patterns after trauma, based on events related to the tissue type involved in the injury. Alveolar bone healing events include those subsequent to acute bone loss and those secondary to ischemia and crushing. The chance of bone regeneration is good, especially in younger patients, owing to induction of bone from cells in PDL. Necrosis or loss of bone, either transient or permanent, happens more often in teeth with intrusion injuries that have mature roots.

Events related to PDL reaction can be divided into PDL loss facing the alveolar bone, loss of PDL facing the cementum, and PDL ischemia or contusion. PDL has good regenerative capacity when it is lost on the surface facing the alveolar bone. PDL loss facing the cementum and ischemic reaction lead to repair-related resorption or could result in ankylosis. Cementum tissue, when lost in cases of root fracture, is regenerated from the adjacent cementoblasts.[98]

Pulpal injuries can vary from direct pulp exposure to the oral cavity, exposure to PDL in root fractures, bacterial contamination secondary to invasion through the dentinal tubules, to partial or total severance at the apex during luxation injuries. Irrespective of the injury, there is a resultant neurovascular disturbance in the pulp to which it reacts, giving rise to responses ranging from secondary or tertiary dentin formation to inflammation, internal resorption, bone metaplasia, and infected or sterile necrosis. Response of the dentin-pulp complex varies depending on the type of injury, presence or absence of infection, root apex maturation, and origin of progenitor cells involved.

After pulp exposure from trauma, untreated exposure even after 1 week leads to superficial inflammation up to a depth of 2 mm.[99] In cases where capping is performed with a suitable material (calcium hydroxide or MTA), a hard tissue barrier is established. Healing starts with hemostasis, inflammation, proliferation, and remodeling. MTA is a promising new material for pulp capping, with reduced inflammation compared to calcium hydroxide.[100]

Luxation injuries, as discussed previously in this chapter, involve partial or total severance of neurovascular supply, resulting in ischemia. Wound healing starts at the apex and moves coronally and is significantly affected by the size of the apex. The recovery from pulpal severance includes either pulp revascularization or necrosis depending on the presence or absence of bacteria in the wound. In general the risk of pulp necrosis increases with the increase in root development. Revitalization is frequent in apical foramens larger than 1.0 mm in size, but infrequent below 0.3 mm. In teeth with a completely formed apex, in the absence of bacteria this sterile necrosis can persist asymptomatically for long periods of time. Tissue can be revascularized by ingrowth of mesenchymal cells. For example, in the case of PDL-derived progenitor cells, PDL tissue will be formed with cementum deposition on root canal walls. Dentin formation after revascularization is extensive, leading to pulpal obliteration.

Internal or root canal resorption is a rare occurrence. These are classified into root canal replacement resorption and root canal inflammatory resorption. Replacement resorption is characterized by an irregular radiolucency in the lumen of the canal. Histologically the replacement resorption is seen as a metaplasia of the pulp tissue into cancellous bone. This type of resorption usually does not progress and can be observed. Internal inflammatory resorption is characterized by an oval radiolucency that is seen histologically as transformation of pulp into granulation tissue, with giant cells in the granulation tissue resorbing the dentinal walls. Progress of this condition depends on interaction between necrotic and vital pulp, and root canal treatment is helpful if the condition is diagnosed early enough.

External resorption of the root in luxated or avulsed-replanted teeth is often the most difficult to predict. It is categorized into three types: inflammatory, surface, and replacement. Inflammatory external root resorption is related to the necrosis of pulp and is thought to be related to migration of bacteria thought he dentinal tubules into the PDL, causing inflammation and resorption.[101,102] Progressive resorption of tooth substance along with adjacent persistent alveolar radiolucency is a typical finding in inflammatory resorption. In surface resorption, the root surface shows lacunae repaired with cementum tissue. Surface resorption is self-limiting. Replacement resorption leads to ankylosis, resulting in direct union between root and bone. Disappearance of PDL space and progressive root resorption are characteristic radiographic signs.

Response to treatment and long-term success of treatment for dentoalveolar injuries are dependent on internal and external factors surrounding the individual case. Although treatment modalities can be planned and standardized, individual patient response and circumstances surrounding the treatment cannot be controlled. Factors influencing outcomes can be divided into intrinsic patient factors and extrinsic environmental factors. Patient-related factors include age, physical status, oral health including condition of the teeth and periodontium, habits of oral hygiene, mental and emotional status, and motivation to follow through with long-term follow-up examinations and necessary care. Important extrinsic factors affecting prognosis and treatment outcomes include nature of the injury, extent and severity of the injury, presence of concomitant trauma, and length of time from injury to definitive care.

Prognosis of Injury to the Primary Dentition

Primary teeth also show reactive responses in pulpal and PDL tissues. Initial reaction to trauma is pulpitis, characterized by pain and sensitivity to percussion and occurring as a result of vascular congestion.[77] This can lead to reversible or irreversible changes. Diagnosis of pulpal necrosis in primary dentition is challenging owing to unreliable pulp vitality testing.[103] Schröder found the frequency of pulpal

necrosis following luxation injuries to be similar to that for permanent teeth.[104] Color of the crown and associated radiographic indications are used to arrive at the conclusion of necrotic pulp. Discoloration of the crown following injury to primary teeth is frequently reversible, so color change should not be the sole criterion for pulpal therapy or extirpation. Hence, unlike permanent teeth, primary teeth that become discolored or darkened are not necessarily nonvital or necrotic. If the discoloration of the crown does not lighten within 3 weeks after the injury, and if radiographic signs of nonvitality including periapical radiolucency, nonobliteration of pulp, and lack of root formation are seen, pulpal necrosis is likely. A pink crown, however, usually signifies internal resorption, and the tooth should be removed. A yellowish, yellow-brown, or opaque discoloration is usually seen in traumatized primary anterior teeth that are visibly damaged. Radiographically, pulpal obliteration (calcific metamorphosis) is seen in primary teeth with a yellowish hue (Figure 6-21). The tooth usually remains vital. Primary teeth with calcific metamorphosis will usually resorb and exfoliate normally.[105]

A reversible grayish color will be seen in about 55% of the injuries to primary teeth. Studies have also shown that grayish discoloration was most often associated with pathology.[106,107] Periapical inflammation becomes evident 1 to 2 months after injury. Pulpectomy has been advocated in primary teeth with necrotic pulp.[108]

All displacement injuries to the primary teeth could potentially affect the associated developing permanent tooth buds, so careful follow-up evaluation for this sequela is required. Enamel hypoplasia in permanent dentition is the most common sequela after trauma to the primary dentition.[78] Pulp obliteration can happen in primary teeth as well, but no treatment is indicated, as these have been seen to resorb in a similar way to nontraumatized primary dentition. The crown of a tooth with pulp obliteration may show yellowish discoloration clinically, although this relationship is not diagnostic.[21] Inflammatory external or internal root resorption can occur in primary teeth and could potentially damage the developing permanent tooth buds. If any signs of resorption are noted, the teeth should be extracted.

Prognosis of Injuries to the Permanent and Developing Dentition

Isolated crown fractures involving only enamel and without associated injury to the periodontal ligament have a very good prognosis, more so if the root apex is open. The incidence of pulp necrosis is directly related to the degree of concomitant injury to the periodontium from combination of injuries. The overall incidence of necrosis irrespective of type of fracture or management is reported to be 1% to 6%. Exposed dentin may complicate the prognosis, because bacterial contamination of exposed dentinal tubules can result in infection. Both the length of time the dentin is exposed to the oral environment and the degree of dentin exposed are directly related to pulp survival. In one study, treatment for deep proximal fractures showed less chance of pulp necrosis (8%) compared to an untreated group (54%).[109] In complicated crown fractures exposing the pulp, both pulp capping and pulpotomy improve the chances of pulp survival. Pulpotomy had lower chances of resulting in pulp necrosis compared to pulp capping.[41]

The prognosis for pulpal healing after root fracture will depend on the extent of coronal fragment displacement and the stage of root development. Moreover, the location of a transverse root fracture does not affect pulp survival after injury. Repair of root fracture primarily depends on the degree of mobility and dislocation of the coronal segment and the stage of root development. Healing can occur regardless of fracture location, provided that proper reduction and fixation of the segment is accomplished.[110-113] The

In Fonseca R, Marciani RD, Turvey TA, editors: *Oral and maxillofacial surgery*, ed 2, St Louis, 2009, Saunders.)

incidence of pulp necrosis among permanent teeth with root fractures in general ranges between 20% and 55%.[114]

Although injuries to developing permanent teeth could result from proximity of the root apices of the primary teeth to the permanent tooth buds, damage to the permanent tooth buds most commonly occurs before the age of 3 years, when the permanent teeth are calcifying.[105] Intrusive and avulsion injuries at 2 years of age, occurring when the permanent tooth crown is about half formed, can result in permanent crown dilaceration. These teeth can erupt spontaneously or require surgical intervention to assist eruption.

Studies have shown a 50% (12%-69%) incidence of damage to the permanent tooth bud from displacement and avulsion injuries in the primary dentition.[78] Displacement and avulsion injuries may affect the developing permanent successor in the following way:

1. A white or yellow-brown discoloration with or without enamel hypoplasia (Figure 6-22, *A*)
2. Dilaceration of the crown (Figure 6-22, *B*) or root
3. Cessation of root development
4. Odontoma-like malformation
5. Sequestration of permanent tooth germs
6. Disturbance in eruption

The effect on the permanent tooth is dependent on its stage of development, the nature and the extent of the injury to the primary tooth, and the length of time the injury is allowed to exist in proximity to the developing tooth.[115,116] A very high frequency of disturbance in the development of permanent teeth is seen in intrusion (69%) and avulsion (52%), whereas extrusion (34%) and subluxation (27%) represent lower risks.[117,118] Any resulting infection from trauma poses another threat to the permanent teeth. Whether the various treatment modalities of removal, repositioning, pulpal therapy, or antibiotic therapy influence the prognosis of the injured primary tooth or its successor is not known.

Frequency of pulp necrosis after luxation injuries has been found to be between 15% and 59%. Key factors in determining the prognosis of these injuries are the type of luxation injury and the stage of root development at the time of injury. Teeth with mature root formation are at greatest risk of pulpal necrosis. Diagnosis of pulpal necrosis in permanent teeth after luxation injuries can vary from 6 months to up to 2 years because of difficulty in assessing radiographic signs of necrosis. Tenderness to percussion is found to be significantly related to presence of infection; however, sterile necrosis can be asymptomatic, and diagnosis is based on clinical parameters such as crown color, radiographic features, and pulpal sensitivity tests.

The greatest frequency of pulp necrosis is after intrusions, followed by lateral luxation and extrusions. In intrusive injuries, teeth with immature roots may be expected to spontaneously re-erupt over a period of several months and require little or no intervention.[52] Mature teeth are likely to undergo ankylosis if left in the intruded position. Endodontic treatment will be necessary but can be postponed until the tooth is in position.

Since the replanted tooth must revascularize the periodontal ligament, form a new periodontal fiber and gingival attachment, and finally revascularize and re-innervate the pulp, successful healing depends directly on the time from injury to replantation and the handling of the tooth (storage medium) prior to the replantation.[64-66] Consequently, avulsed immature teeth maintained in a physiologic medium before replantation will have the optimal prognosis for healing for up to 3 hours. Revascularization in replanted teeth with mature root apex is rare and mostly if carried out immediately after the avulsion. Root resorption, however, is the most frequent sequela after replantation. Factors shown to affect root resorption include length and type of extra-alveolar storage, stage of root development, and contamination of root surface. Three forms of postavulsion

root resorption have been identified.[119] Surface resorption appears to be transitional and a precursor to more severe resorption. Inflammatory resorption includes both the root surface and adjacent alveolar bone. Careful timing of root canal treatment (2 weeks post-replantation) can best arrest inflammatory resorption. Replacement resorption, which includes bony ankylosis, is the most severe form of resorptive response to avulsion and can lead to eventual loss of the tooth. Ankylosis can be usually detected in 4 to 8 weeks with a percussion test, but radiographic evidence may take up to a year. Avulsed teeth that have been replanted more than 60 minutes after the injury can be expected to eventually undergo replacement resorption. Prolonged splinting has been related to an increase in replacement resorption.

Finally, many patients with injuries of the dentoalveolar region, especially those that are avulsive, will benefit from a multidisciplinary approach to oral rehabilitation. Advances made in our specialty over the past 20 years in the areas of bone grafting, soft tissue grafting, and implantology have made the restoration of preinjury form and function the gold standard of care.

Prevention of Traumatic Dental Injury

The consequences of traumatic dental injuries are not just physical and esthetic, but psychosocial and economic as well.[6] Traumatic dental injuries are irreversible, and loss of tooth or supporting tissues could have permanent effects on the individual. Although much emphasis has been placed on various modes of prevention, including the role of mouthguards and faceguards, not all traumatic dental injuries are practically preventable, as most of them occur unexpectedly during daily activities.[120] Sports-related, iatrogenic, and fall-related injuries could possibly be prevented or reduced in severity. Contact sports have a higher incidence of dental and oral trauma based on the population and demographics, varying between 7% and 30%.[120-122] Certain preventive strategies include use of mouthguards, patient education, and modifying risky behavior. During sports and other activities in which there is a risk of falling or being hit by an object, wearing a faceguard or mouthguard still seems to be the only way to prevent or at least significantly reduce the seriousness of dental injuries. It has been reported that before the mandate to wear faceguards and mouthguards in U.S. high school football, facial and oral injuries constituted up to 50% of all reported football injuries. Subsequent to the mandate, a significant decrease was noted in reported injuries.[121] Currently, the U.S. National Collegiate Athletic Association requires mouthguards for four sports (ice hockey, lacrosse, field hockey, and football). However, the American Dental Association recommends the use of mouthguards in 29 sports/exercise activities.[122,123] Despite efforts to reduce the number of traumatic dental injuries, most current studies indicate that the overall incidence of dental trauma remains unchanged and is at a relatively high level for children and young adults. Knapik and colleagues[124] concluded from a systematic review of literature on effectiveness of mouthguards that the risk of orofacial sports injury was 1.6 to 1.9 times higher when mouthguards were not used. However, a review of this systematic review and meta-analysis shows that the studies included were of low level of evidence.[125] Hence, although mouthguards and faceguards do help reduce the incidence of sports-related injuries and those from other preventable etiologies, emphasis should be placed on education related to dental trauma and its first aid among children, teenagers, adults, and their caregivers. Controlling risks such as increased overjet or previous history of trauma in children that have been known to increase the incidence of dental trauma should be given priority.

Most of the literature on mouthguards has been focused on their fabrication and material properties rather than on their effectiveness. Mouthguards can be divided into three basic types on the basis of how they are manufactured and used[126]:

1. Stock prefabricated
2. Mouth-formed
3. Custom-made

Stock mouthguards carry the advantage of being readily available and inexpensive, and replacement is easy in case of loss. But these are not properly adapted to the dentoalveolar structures of the wearer and have to be held by occluding into them. These stock mouthguards have been reported to provide the least protection and carry the risk of falling out of the oral cavity before the impact of trauma, although there are no clinical studies to substantiate this claim.

Mouth-formed or self-adapted mouthguards (Figure 6-23) are a readily available and inexpensive alternative to custom-made mouth guards. They are two-layered, with a thick non-moldable outer layer and an inner resilient soft lining that is adapted by the wearer before use. The outer shell is adjusted to relieve the frenal attachments and flange depth, while the inner material is a layer of self-curing methyl methacrylate or silicone rubber. The other type of mouth-formed mouth guards are made of thermoplastic material that is again adapted by the user after warming the material to a set temperature while in the mouth. If adapted well, they can give a better fit than a stock mouthguard, but they carry the risk of thermal injury and improper adaptation that could potentially cause soft tissue injury.

Custom-made mouthguards (Figure 6-24) are fabricated in the laboratory on dental models of the individual's dentoalveolar structures. Many studies have shown better acceptance and comfort levels with these custom-fit mouthguards as opposed to stock and mouth-formed ones. Very few studies, however, offer clinical outcome data on the relative effectiveness of the various types of mouthguard, and the distinction is not clear and substantiated.

Use of faceguards and helmets has significantly reduced the incidence of facial injuries in certain contact sports.[121] One fact that has been noted among these youths is that although the number of oculofacial injuries has been reduced by faceguards, the number of spinal injuries has increased. More studies on their effectiveness and use are needed.

• **Figure 6-24** Custom-made mouth guards made from the dental models of a patient are more acceptable and comfortable. (From Bourguignon C, Sigurdsson A: Preventive strategies for traumatic dental injuries, *Dent Clin North Am* 53:729-749, 2009.)

Conclusions

Although dental traumatology has made significant advances, there still need for development of evidence-based practices. The lack of ethical basis for conducting large-scale, high-quality randomized controlled trials with dental trauma patients in distress is a significant obstacle to such studies. Although there have been a number of animal studies, which are a reasonable alternative, their application in humans is controversial. Most dental trauma occurs during everyday activities among children and adolescents, making them less likely to be prevented. More emphasis should be placed on educating patients, caregivers, and the general public about prompt management of dental trauma so as to reduce morbidity and long-term adverse consequences, which have physical, esthetic, emotional, psychosocial, and financial impact on the individual.

The successful launch of *Dental Trauma Guide* by the International Association for Dental Traumatology, based on the most recent literature evidence and expert opinion, is a substantial step in advancing the science. Ease of availability of information over the Internet and smartphones can help the clinician provide the best possible treatment option to the dental trauma patient. Large-scale clinical studies are needed on the effectiveness and long-term outcomes after successful management of dental trauma.

Diagnosis and Management of Mandible Fractures

JOHN S. VORRASI, DOMENICK P. COLETTI, JOHN F. CACCAMESE JR.

Introduction

Mandible fractures constitute a significant proportion of facial trauma treated in both urban and rural hospitals. Treatment of facial fractures, specifically those involving the dentition, has been a core discipline for oral and maxillofacial surgeons around the world.

The evolution of mandible fracture treatment modalities has mirrored materials advancements with the development of rigid fixation and titanium metallurgy. Our specialty has moved away from the strict adaptation of commonly held orthopedic principles, instead modifying these ideas to better suit the unique demands of the maxillomandibular complex. The mandible is a complex bony structure involving unique cranial and dental articulations, a network of opposing and specialized muscles, and supporting functions of respiration, speech, deglutition, swallowing, and facial expression. Therefore, reconstructing the mandible and restoring function can have a significant impact for patients and can also present a challenge in the setting of high-velocity blunt or avulsive injury. With advancements in the treatment methods and armamentarium for fixation, we are able to piece together and stabilize fractures using a combination of rigid and semirigid fixation. Open reduction techniques allow early but graduated return to function without adding significant morbidity for the patient. Load-bearing titanium reconstruction plates are able to stabilize atrophic and comminuted mandible fractures, while endosseous dental implants are used to restore dental injuries.

The complexity of mandible fractures varies based on pattern, degree of comminution, displacement, and favorability. The AO/ASIF (Arbeitsgemeinschaft für Osteosynthesefragen/Association for the Study of Fixation) provides guidance and forms the basis for fracture fixation techniques to restore function and premorbid occlusion and avoid complications (such as nonunion, malunion, or infection). The principles assume an understanding of bony biology and wound healing that is critical to proper treatment planning.

History of Mandible Fractures

Mandible fracture treatment has been documented for thousands of years dating back to 1650 BC, as highlighted in ancient Egyptian scrolls.[1,2] Hippocrates was one of the first individuals to describe the concept of immobilization for mandible fractures, a problem that was previously considered a hopeless disease process.[3] Circumdental wires were successfully used to reduce and immobilize mandible fractures to aid in healing.

The 13th century brought about the concept of maxillomandibular fixation by using the stable jaw to reduce the fracture of the injured jaw. This added to the notion that recreating a proper occlusion should assist in reducing fractures to their appropriate anatomic position to heal.[4] The final publication of the use of occlusion and maxillomandibular fixation for stabilizing fractures was not to come for another 200 years.[5] Chopart subsequently designed a stabilization device mimicking a modern-day vise between which the mandibular occlusal surface and the external mandible border were placed in compression. Efforts toward more stable fixation took a leap forward at the turn of the 20th century as Gilmer described metal rods wired together that spanned the fractured site.[6] In 1846, Buck was the first surgeon of record to perform an open reduction.[7] He used an iron wire to fixate the fractured segments. Dr. Robert Ivy, a military oral and maxillofacial surgeon, built on Gilmer's lead to develop the "Ivy loop" technique, placing interproximal wires in the premolar regions of both arches to reduce the occlusion.[8] World Wars I and II brought further innovation and surgical progress to treatment of facial fractures. A distinct need for predictable and safe methods for fracture repair spawned surgical units on the front lines in Germany and France, but the mainstay of care was based on closed treatment.

Open reduction and internal fixation (ORIF) was not advocated until the mid-20th century because of fear of contamination of bone and hardware. There were few attempts to advance the management beyond bandages, maxillomandibular fixation, and Gunning-type splints until the 1960s, thanks to the research of two German surgeons, Luhr and Spiessl.[9,10] The concept of compression plates made of vitallium (cobalt-chrome-molybdenum) revolutionized the fixation concept and developed into the principles advocated by AO/ASIF. The field of orthopedics and orthopedic injuries guided the initiation of rigid fixation, but developments were hampered by bulky plates and significant morbidity (reoperation, nerve damage, large facial scars, etc.).

The introduction of miniplate fixation in the 1970s by Champy and Michelete[11,12] further reduced the morbidity of open reduction and recognized the mandible as a unique structure with dynamic musculature and movements that may help or hinder fracture healing. Based on lines of osteosynthesis, fractures without comminution, complex fragmentation, or comminution could be repaired using miniplates (Figure 7-1).

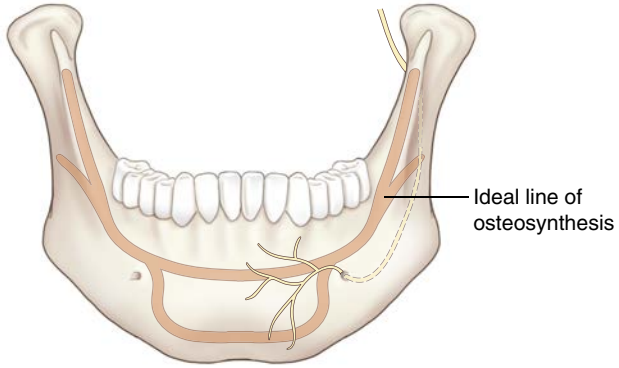
Intermaxillary fixation screws (IMFs) were introduced in the 1990s to further simplify the closed reduction technique and reduce the possibility of surgeon injuries because less wiring was now necessary (Figure 7-2).

Mandible fracture repair methods are continually evolving to optimize outcomes and minimize treatment. Recently a combination titanium arch bar with titanium bone screws introduced by Stryker allows multiple-vector, semirigid maxillomandibular fixation similar to Erich arch bars, but avoiding the tooth-borne forces. Resorbable plates using polymer materials are transitioning from cranial procedures to maxillofacial trauma, especially in the pediatric population. The biodegradable materials can maintain stability similar to miniplates in non—load-bearing areas (zygoma or midface fractures). Resorbable plates are also being used in nondisplaced angle fractures and pediatric mandible fractures as alternate means of fixation that eliminate the need for reoperative hardware removal.

Pathogenesis

In the United States, mandible fractures are largely the result of interpersonal violence, motor vehicle–related injuries, or accidents and falls.[13-15] Pathologic fractures and ballistic injuries are also seen, but with less frequency. Fortunately, with the advent of airbags and other traffic safety mandates, the incidence of motor vehicle–associated facial fractures has been reduced.[16] The populations most likely to be affected by facial fractures are male, younger than 35, in an urban setting, and of lower socioeconomic status.[17]

One of the largest retrospective studies, by Morris and colleagues in 2015, reviewed 4143 mandible fractures over a 17-year period.[18] The injury distribution by site was the angle (27.0%), symphysis (21.3%), condyle and subcondyle (18.4%), body (16.8%), multiple sites unspecified (7.1%), ramus (5.4%), alveolar border (2.9%), and coronoid (1.0%) (Figure 7-3). Injuries were typically the result of low-velocity blunt trauma. July and the summer months resulted in the highest number of mandible fractures, and 49.6% were single-site fractures.



• **Figure 7-1** Champy's lines of osteosynthesis. (From Ricardo Cienfuegos, Carl-Peter Cornelius, Edward Ellis III, George Kushner: *Mandible fractures*. AO Foundation Online Resource, 2015.)

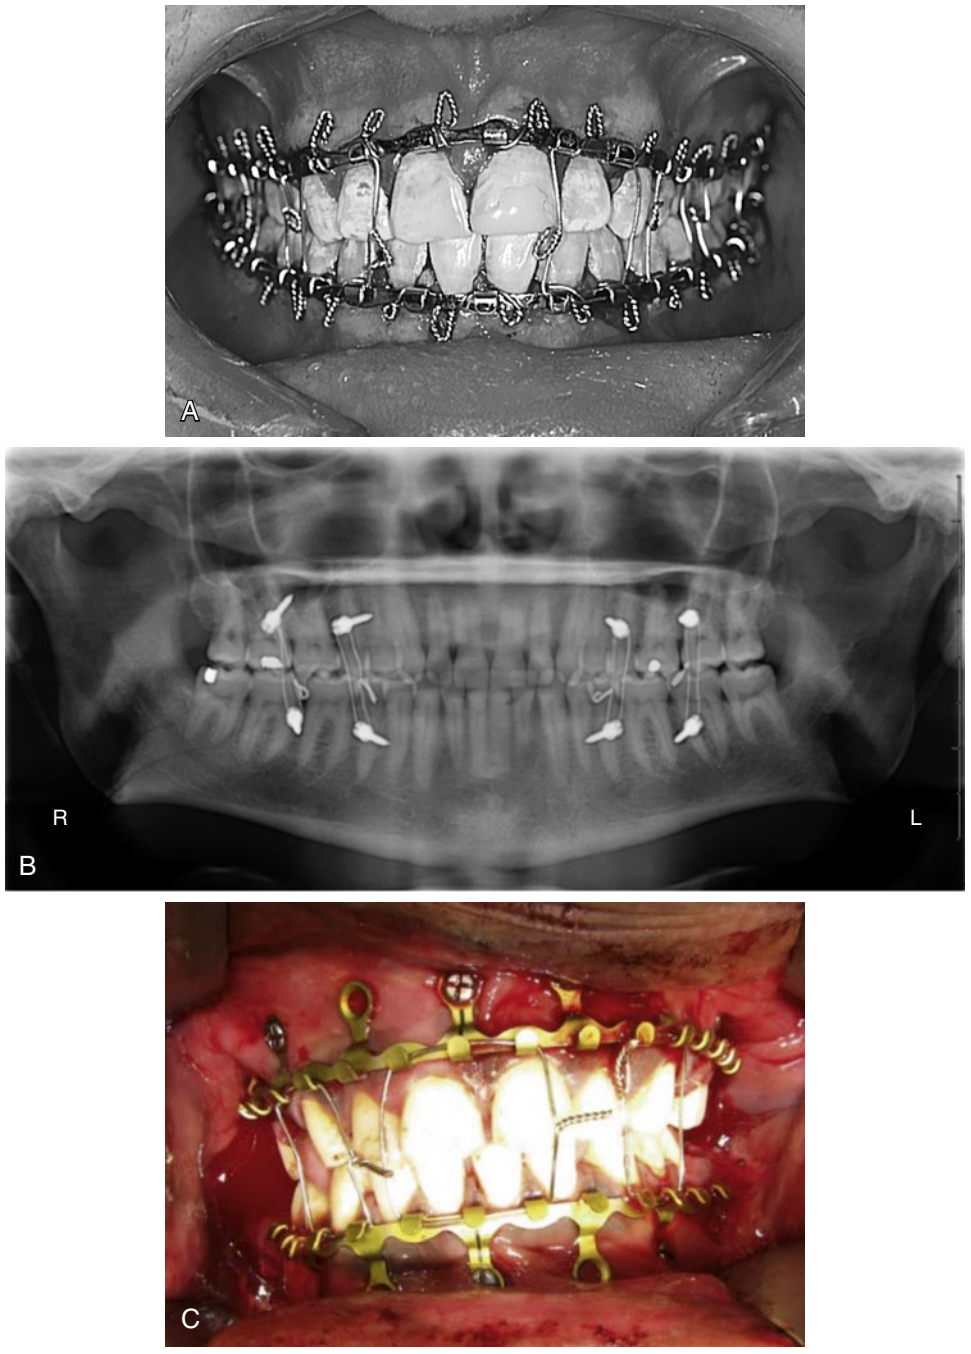
Anatomy

The mandible is one of the more complicated bones in the body in its mobility, growth, and function. The mandible has 13 muscle attachments. Within these are groups of jaw closers (temporalis, masseter, medial pterygoid), openers (digastric, lateral pterygoid), and glottic attachments (genioglossus and geniohyoid). The remaining muscles, such as the buccinator, platsyma, mentalis, mylohyoid, depressor labii inferiorius, and depressor anguli oris, can influence bone remodeling and displacement in fractures.

The temporomandibular joint (TMJ), the mandible's primary articulation with the cranial base, is a specialized system that allows two types of movement, including translation along the articular eminence and rotation within the glenoid fossa. The capsule, TMJ disc, and lateral ligaments support most of the TMJ movements. Deviation in opening or preauricular swelling may clinically indicate a TMJ injury or condyle fracture that should be investigated.

The major blood supply to the mandible develops along the inferior alveolar artery but transitions to the surrounding periosteum and muscle attachment as the body ages.[19] In the case of comminuted or atrophic mandible fractures, careful consideration of hardware location should target the highly vascular areas of the mandible (ramus and symphysis) and avoid sites with poor blood supply (the body).

The inferior alveolar nerve innervates one half of the mandibular dentition and exits at the mental foramen to supply the chin and lip soft tissue. The lingual nerve runs just inferior to the alveolus and supraperiosteal in the area of the third molar in most cases. Even with displaced fractures, this nerve rarely is injured. Nerve injuries associated with mandible fractures are discussed later in this chapter.



• **Figure 7-2** Intermaxillary or maxillomandibular fixation using **(A)** Erich arch bars or **(B)** IMF screws. **C,** hybrid system (Stryker CMF).

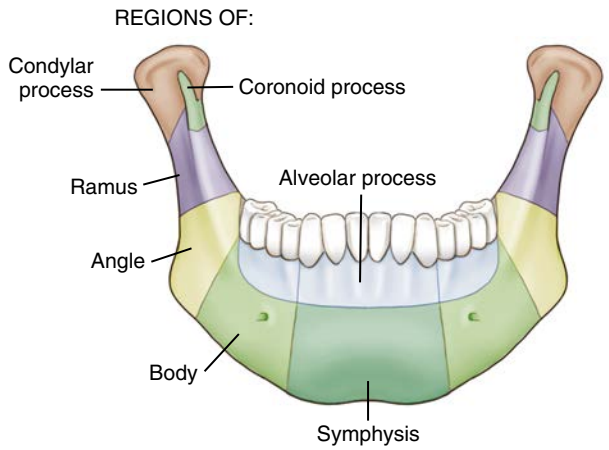
Fracture Classification

Fractures can be divided into several categories based on:
1. Location
2. Biomechanics
3. Fracture pattern

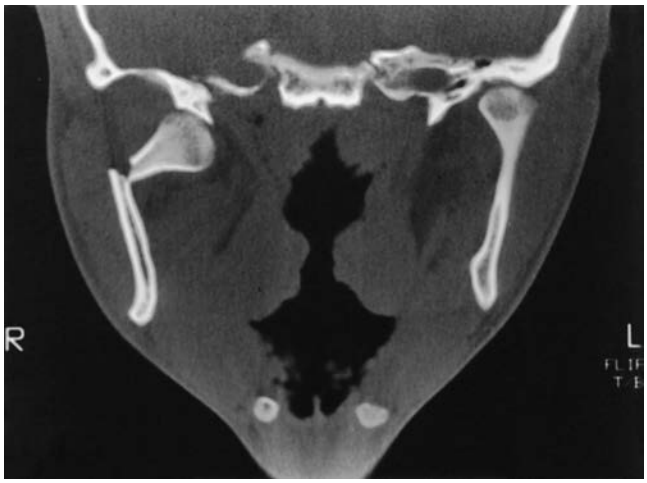
Location

The mandible is divided into anatomic subunits to better characterize the association of the dentition and associated muscle attachments with the injury.

- Symphysis: Occurring in the midline, between the central incisors.
- Parasymphysis: Area bound between vertical lines distal to the canines.
- Body: Area bound from the distal of the canine to the anterior border of the masseter muscle (the distal of the second molar).
- Angle: Area bound from the anterior border of the masseter (distal of second molar) to the posterior border of the masseter. Third molars, if present, are typically involved in angle fractures.



• **Figure 7-3** Fractures of the mandible according to anatomic region. (Adapted from Stevens M, Emam H: Mandibular body fractures. In Kademani D, Tiwana P, editors: *Atlas of oral and maxillofacial surgery*, Philadelphia, 2015, Saunders.)



• **Figure 7-4** Computed tomography (CT) scan is ideal to assess condylar fracture position and displacement.

- Ramus: Area from the posterior border of the masseter to the height of the sigmoid notch. A "subcondylar fracture" is typically within the region of the ramus.
- Condyle:
  - *Intracapsular:* A fracture of the condylar head, which is bound by the capsule (Figure 7-4).
  - *Extracapsular/Condylar neck*: A fracture from the height of the sigmoid notch to the attachment of the capsule. These fractures can be further subdivided based on their distance from the sigmoid notch. A "high" fracture is at or just below the capsule and can denote difficulty in achieving fixation. A "low" fracture is near the notch and can be fixated by conventional means.
- Coronoid: The area of the coronoid process superior to the height of the sigmoid notch.
- Dentoalveolar: A fracture of the alveolar bone and supporting root structure; it does not involve the basal bone of the mandible.

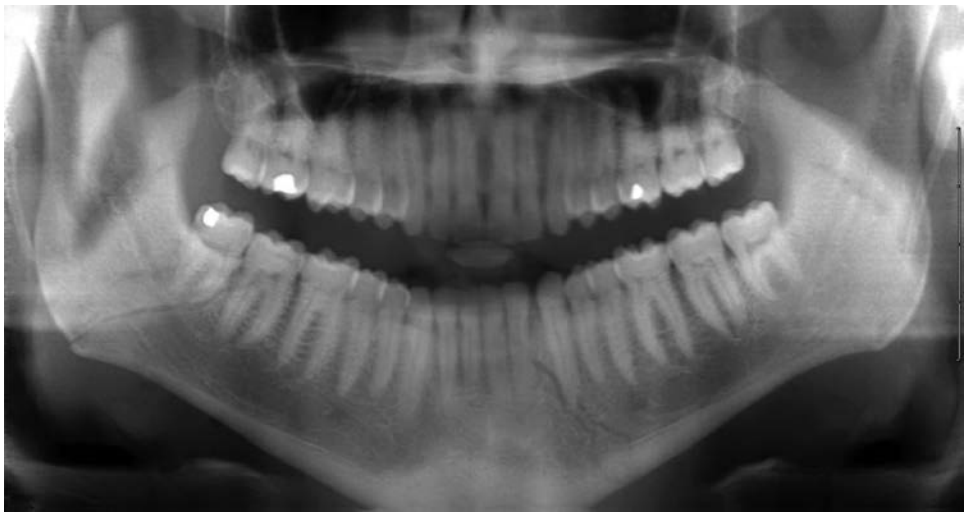
The mental foramen, the third molar/angle area, and the mandibular canine sites are particularly susceptible to fracture due to the bone density at these locations. As a result, parasymphyseal and angle fractures constitute the majority of fracture sites. The coronoid process, however, is the least common mandible fracture site because of the protective effect of the zygomatic arch and masseter muscle shielding. Condylar process fractures are the most common fracture seen in the pediatric population and are termed intracapsular or extracapsular based on the association with the temporomandibular joint capsule. Mandibular body fractures are seen most commonly with in atrophic mandibles that have lost significant bone height and width due to changes associated with premature tooth loss and aging. The body of the mandible also has limited muscle attachments as opposed to the symphysis or ramus. Muscle attachments usually have a positive impact on bone density with regard to physiologic strain and blood supply. Last, dentoalveolar fractures without complete fracture of the mandible are a unique entity requiring reduction with reapproximation to the premorbid occlusion using Erich arch bars or dental splints affixed to the adjacent teeth.

Biomechanics

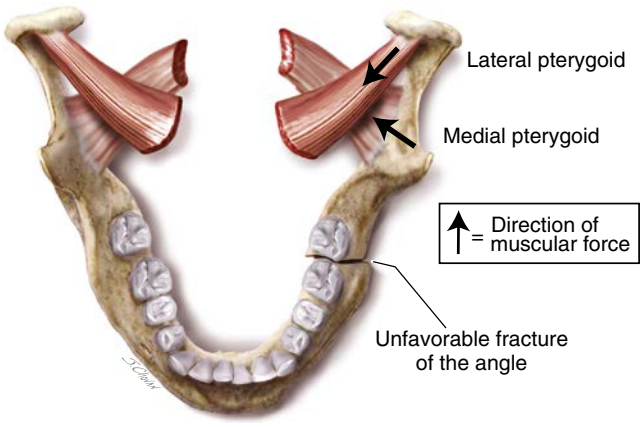
Understanding of the muscle attachments and the forces imposed on the mandible will aid the surgeon in management decisions. A mandible fracture has three forces acting on it: compression, tension, and torsion. These forces vary in magnitude depending on the location of the fracture. The muscles responsible for vertical displacement are the masseter, temporalis, and to a degree the medial pterygoid. Horizontal displacement can be caused by the lateral and medial pterygoid, and torsion by the mylohyoid, digastrics, and geniohyoid.

Displaced fractured segments are more or less well buttressed based on the vectors of muscle pull. A favorable fracture is one where the innate muscle forces have a tendency to reduce the fracture and thus contribute to buttressing. An unfavorable fracture is one in which the opposite is true, and the segments are displaced by muscle pull. This concept is most important when using closed reduction methods on fractures where the proximal segment of the fracture is wholly removed from the tooth-bearing mandible (condyle and angle fractures most typically) and the occlusion cannot be used to reduce both segments.

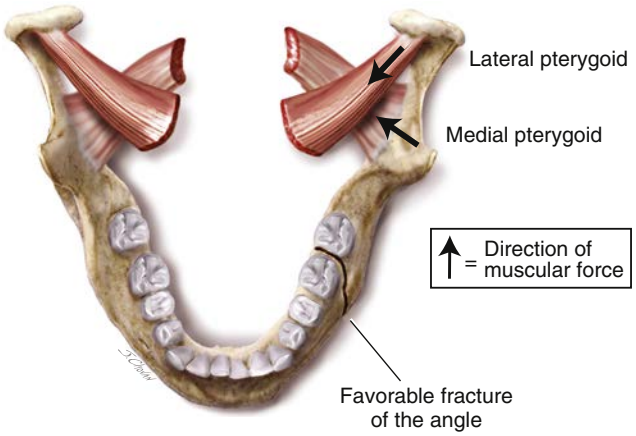
The favorability and unfavorability are described based on the plane of the films obtained; a "horizontally unfavorable" fracture is displacement noted on an orthopantomogram or Panorex (Figure 7-5). Conversely, a "vertically unfavorable" fracture is displacement noted on an anterior/posterior film. This can be confusing at times because the vectors of the muscle pull are opposite to the plane of the film. It is probably more important simply to denote whether or not a fracture is favorable or unfavorable. This feature of the fracture significantly affects the treatment plan. For example, the buttressing effect seen in some favorable fractures will make these more amenable to closed reduction and maxillomandibular fixation (MMF) (Figures 7-6 to 7-10). In contrast,



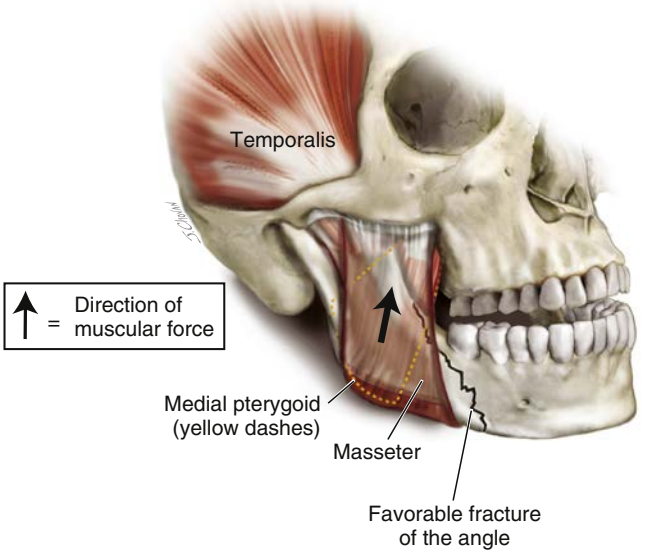
• **Figure 7-5** Panorex radiograph is an excellent modality for identifying mandible fractures. Radiograph shows a right body minimally displaced extending posteriorly to the angle of the mandible and left parasymphyseal fracture.



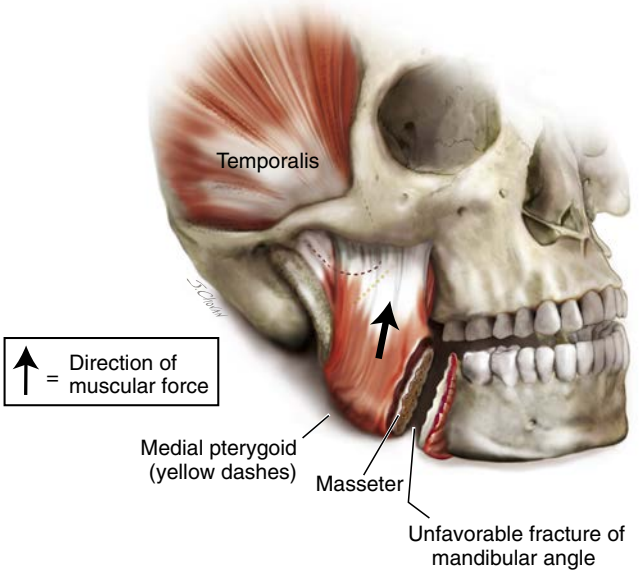
• **Figure 7-6** Horizontally unfavorable fracture.



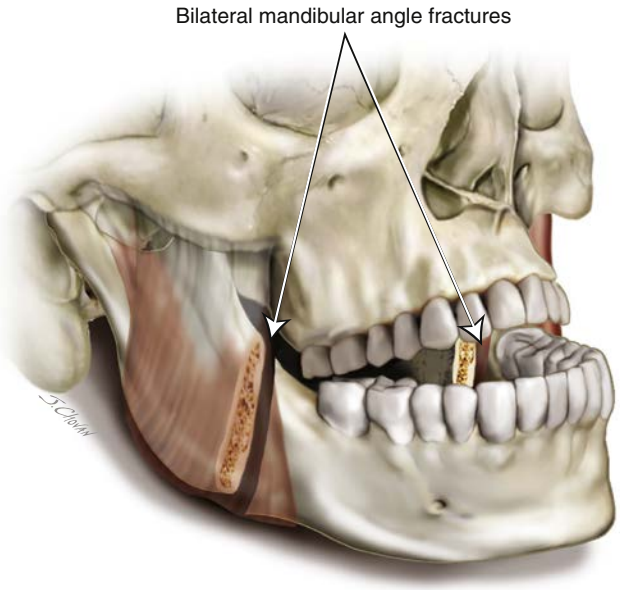
• **Figure 7-7** Horizontally favorable fracture.



• **Figure 7-8** Vertically favorable fracture.



• **Figure 7-9** Vertically unfavorable fracture.



• **Figure 7-10** Bilateral mandible fractures can create posterior displacement of the distal segment due to glottic forces. This is termed the flail mandible and may have implications for the patient's airway.

unfavorable fractures are typically more amenable to open reduction and internal fixation for lack of buttressing. The routine use of computed tomography scans in maxillofacial trauma provides better diagnostic information in terms of favorable versus unfavorable compared with traditional radiographs.

Mandibular fracture displacement is defined as:

- Favorable (stable): When the fracture line and the vector of the muscle pull keep the fracture buttressed and appropriately reduced.
- Unfavorable (unstable): When the fracture line and the vector of the muscle pull cause displacement.

Similarly, a condyle fracture can be favorable or unfavorable biomechanically. Unfavorable fractures will be either displaced or dislocated. The decision to treat a condylar neck fracture open or closed can be greatly influenced by the degree of displacement or dislocation.

- Dislocated: Where the head of the condyle is dislocated from the glenoid fossa.
- Displaced: Where the head of the condyle remains in the glenoid fossa, but the neck of the condyle has been pulled out of alignment with the ramus. This can be in any direction, but most commonly is anteromedial because of the pull of the lateral pterygoid muscle.

Fracture Patterns

- Open (compound): A fracture that has communication with the external environment via skin, mucosa, or the periodontal ligament. Any fracture involving a tooth-bearing segment is an open fracture by definition.
- Closed (simple): A fracture that has no communication to the external environment.
- Comminuted: Multiple segments of bone that are shattered, crushed, or splintered.
- Greenstick/nondisplaced: The fracture is incomplete and/or only involves one cortex.
- Pathologic: Fracture occurring from preexisting disease that has structurally weakened the bone.
- Complex (complicated): Can be either a simple or compound fracture that is associated with significant adjacent soft tissue injury.
- Multiple: Two or more fractures within the same bone, but the fractures do not communicate with each other. A mandible will fracture in at least two locations approximately 50% of the time.[18]
- Atrophic: A fracture that occurs predictably at the body (often bilateral) due to mechanical weakening because of atrophy. An atrophic mandible is defined as an edentulous mandible that has 20 mm or less in height.
- Indirect: A fracture that occurs at a site distant from the area of impact—for example, the classic "guardsman fracture," involving bilateral condylar necks and the symphysis. The point of impact at the chin creates multiple fractures, a direct symphysis fracture and indirect condylar neck fractures.
- Impacted: A fracture that has segments "telescoped" on each other.

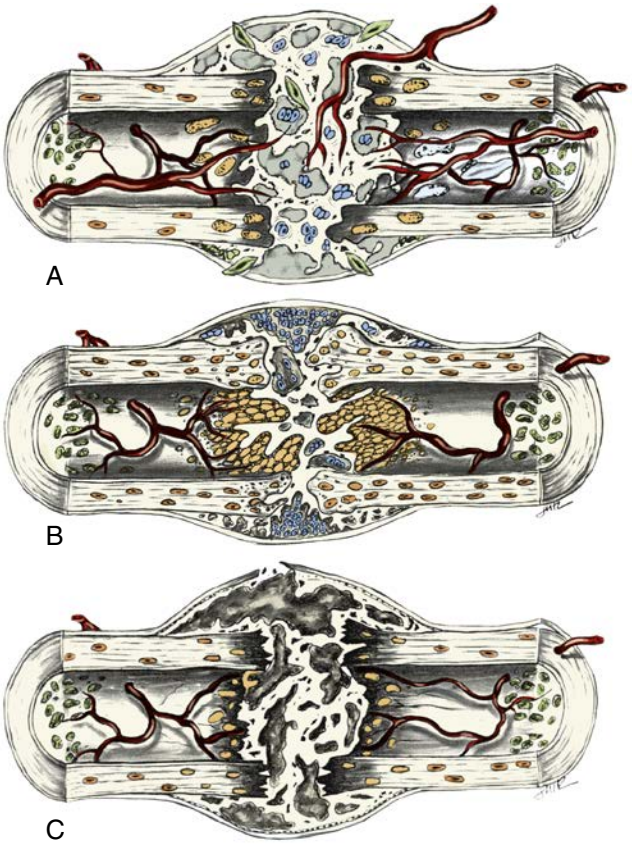
Open mandible fractures do not need to be treated with the same degree of urgency as our orthopedic colleagues would apply to open extremity fractures. Good outcomes can be expected with judicious and timely treatment, as well as with perioperative antibiotic use. In the case of open mandible fractures or mandible fractures involving tooth segments, perioperative antibiotics have been shown to be beneficial to reduce postoperative infections.[20,21] The same benefit has not been extended with the use of postoperative antibiotics.[22]

Fracture Biology

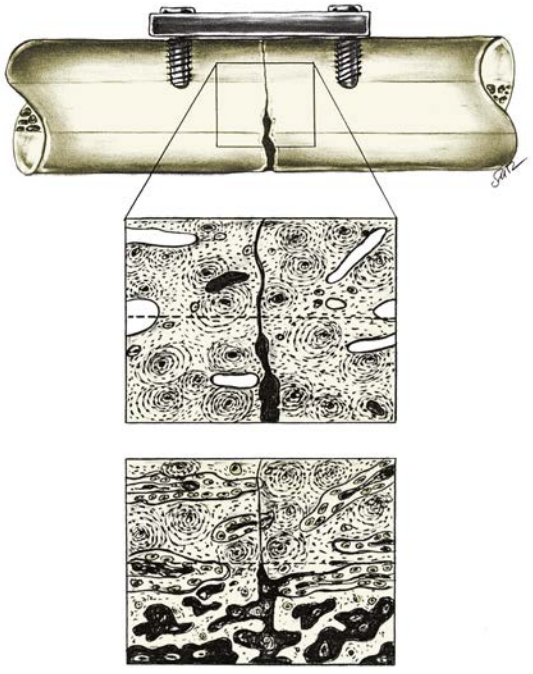
It is important for surgeons to understand the physiology of bone healing in addition to the biomechanics of facial bone function to best treat patients with any skeletal fracture. This is particularly helpful when determining the technique for fixation as well as the time allotted for the return of function. There are two processes by which a mandible fracture can heal; primary (direct) or secondary (indirect) bone healing. Either process will appropriately heal the mandible to a state that will withstand the biomechanical stress of function and form (Figures 7-11 and 7-12).

Primary healing occurs with direct contact of injured haversian systems that can remodel and form lamellar bone. The use of rigid fixation immobilizes and stabilizes well-buttressed segments to optimize contact healing without the formation of an intermediate callus. This type of healing more rapidly returns the fracture patient to the pre-injury state.

Secondary bone healing occurs with closed treatment of mandible fractures, such as when intermaxillary fixation is used for a favorable, minimally displaced angle fracture. During the healing process, a cascade of healing elements



• **Figure 7-11** Early fracture with **(A)** hematoma; **(B)** fibrocartilage callus; **(C)** hard callus. This process is common with delayed healing or secondary healing.



• **Figure 7-12** Primary (direct) bone healing on the superior portion closest to the plate due to close bone contact. Gap healing is the inferior portion as the bone is not in direct contact.

occupy the fracture site, beginning with hematoma formation and the subsequent inflammatory stage. This progresses into a soft callus and ends with remodeling. The periosteum and muscles place stresses on the fracture segments to create areas of apposition and resorption. This concept of mechanical stress dictating healing is Wolff's law.[23] If mechanical loading is placed on bone such as occurs with muscle pull, the bone will respond by remodeling and increasing in strength. This ultimately leads to equilibrium between stress and load. To achieve remodeling of the mandible to a full load-bearing state requires 4 to 6 months (less time than for long bones). The initial healing process, in order to return to normal function, typically takes an average of 4 to 6 weeks (depending on the type and severity of the fracture) and occurs in four stages.

- Inflammatory stage: The fracture causes a disruption of the vascular supply within the bone. Initially the fracture site hemorrhages, with the formation of a hematoma at the site. This is followed by an inflammatory process that involves the recruitment of macrophages, monocytes, neutrophils, and platelets. The vascular compromise initially causes necrosis of bone at the fractured edges, but a reparative process of angiogenesis ensues, as well as the formation of osteoprogenitor cells, mesenchymal cells, and fibroblasts.
- Cartilaginous stage: The initiation of a cartilaginous (soft) callus which is composed of fibrocartilaginous tissue. At the conclusion of this stage, the mobility across the fracture is eliminated.
- Bony callus stage: The conversion of the cartilaginous callus to a bony callus composed of immature woven bone, which typically occurs within 3 to 4 weeks of the injury. This is initiated by the conversion of chondrocytes to osteocytes, leading to the formation of endochondral bone.
- Remodeling stage: The return of the osseous tissue to its pre-injury state; continues for months following the injury. It is the final stage and results in the conversion of endochondral bone to mature lamellar bone.

Patient Assessment

Trauma centers evaluate and triage patients according to the principles of Advanced Trauma Life Support (ATLS). The primary survey is performed and the patient is stabilized. Soon thereafter, the secondary survey is conducted, including the craniomaxillofacial and neck examinations. Images can then be obtained based on suspicions brought about by clinical findings.

A history and physical exam are critical to managing head and neck injuries, and notes should be made concerning the mechanism of injury and loss of consciousness during the event. The physical exam should include an assessment from the skull to the clavicles for soft tissue injuries, ecchymosis, and asymmetries, as well as midline structures including the larynx and trachea. Neck zones I to III should be examined for penetrating trauma, crepitus, and hematoma.

The mandible and lower facial third should be examined and palpated for mobility, mucosal lacerations, fractured or avulsed teeth, malocclusion, bony steps or discontinuity, and any hematomas/ecchymosis of the floor of the mouth (Figures 7-13 and 7-14). The patient should be asked about paresthesia, anesthesia, or pain during the exam, and facial nerve integrity should be confirmed.

If a cervical collar is present, in-line stabilization should be used while the collar is removed for a thorough exam, so long as the patient is compliant. If a cervical spine injury is diagnosed, steps will have to be taken to immobilize the cervical spine during the definitive treatment of the facial fractures.

• **Figure 7-13** Step deformity seen with left mandibular body fracture.

• **Figure 7-14** Hematoma accompanying bilateral mandibular body fractures. The patient complained of progressive difficulty breathing and swallowing.

Imaging

The standard contemporary imaging modality is computed tomography (CT) to investigate maxillofacial trauma at the same time as other associated injuries. CT imaging highlights the bony structures better than other modalities, and three-dimensional reconstruction of the images can give the surgeon a comprehensive view of facial injuries. Level I trauma centers require access to CT capabilities, and the head/face/neck study can be included with a multisystem assessment when suspicion for injury exists. A mandible series of radiographs or a panoramic radiograph can also be ordered for centers without readily available CT. Right and left lateral oblique, panoramic, and reverse Townes views give the most thorough assessment of lower facial injury (Figure 7-15).

CT angiography can be used in the setting of blunt or penetrating neck trauma where vascular injury is suspected. Vascular injury to the common or internal carotid can influence the management of facial fractures if manipulation of the neck is contraindicated.

Treatment of Mandible Fractures

With all factors and possible implications considered, the treatment technique of mandible fractures is either open or closed. Technique decisions are based on the characteristics of the fracture as well as patient preference when appropriate. A Cochrane meta-analysis performed in 2013 by Nasser and colleagues was unable to recommend a single approach in the management of mandibular fractures without condylar involvement.[24]

Closed techniques use either tooth-borne or bone-borne stabilization to immobilize fracture segments to allow secondary healing. The keys to this technique are immobilization and approximation. This technique is reserved for patients who are capable of being placed into proper, premorbid occlusion, can be compliant, and possess no relative or absolute contraindication to a closed technique (seizure disorder, etc.). Whereas simple favorable fractures lend themselves to closed reduction and fixation, severe comminution of fractured segments may also be more appropriately treated using closed techniques to minimize devascularization of smaller bone fragments. There is evidence of cost effectiveness with closed reduction techniques, mostly due to materials and operative time.[25] The minimum time for adequate bony union is 4 to 6 weeks, but closed treatment can be extended to as long as 8 weeks with more severe facial injuries, comminution, or compromised patient healing capacity. The following appliances are commonly used for methods of maxillomandibular fixation:

Tooth-borne

- Erich arch bars
- Interdental wires (Ivy loops, eyelet wires, etc.)
- Lingual splint

Bone-borne

- Skeletal suspension wires

• **Figure 7-15** Radiographs such as these are less commonly used in major trauma centers but are useful in diagnosing mandible fractures. A mandible series showing a left angle fracture using **(A)** anteroposterior, **(B)** reverse Townes, and **(C)** lateral oblique views. **D,** A right mandibular body fracture is stabilized temporarily with a dental bridle wire. Typically this will be placed two teeth on either side of the fracture, if teeth are stable and present.

- External fixators
- Intermaxillary fixation (IMF) screws
- Hybrid systems (Stryker SMARTLock)

Erich arch bars have been the standard maxillomandibular fixation device for decades to render treatment in any number of settings: office, emergency room, or operating room. The stainless steel wire and arch bars are inexpensive compared to other methods of MMF. Arch bars are also excellent stabilizers for dentoalveolar fractures that may not be suitable for miniplates. The semirigid fixation adapts to neighboring teeth to reestablish intra-arch dimensions and contour. The arch bar can serve as a tension band to counter forces at the alveolar level while accompanying internal fixation techniques at the inferior border.

The arch bar does have several disadvantages: risk of operator or patient wire-related injury during placement, difficulty with patient hygiene, damage to the alveolar peridontium, and unintentional tooth movement or extrusion. Pediatric patients in the mixed dentition stage may be better served by other methods of closed treatment because of problems with arch bars engaging the height of contour and/or possible extrusion of deciduous teeth or underdeveloped permanent teeth. Depending on the state of developing tooth buds and the ability to use internal fixation, lingual splints, Ivy loops, eyelet wires, or skeletal suspension wires may be better options.

One of the more recent additions to the closed treatment/reduction armamentarium within the past several years has been the SMARTlock Hybrid MMF system (Stryker CMF, Kalamazoo, MI). The bone-borne titanium arch bar significantly reduces reliance on teeth for fixation techniques, similar to IMF screws but incorporates a full-arch distribution of forces similar to Erich arch bars.

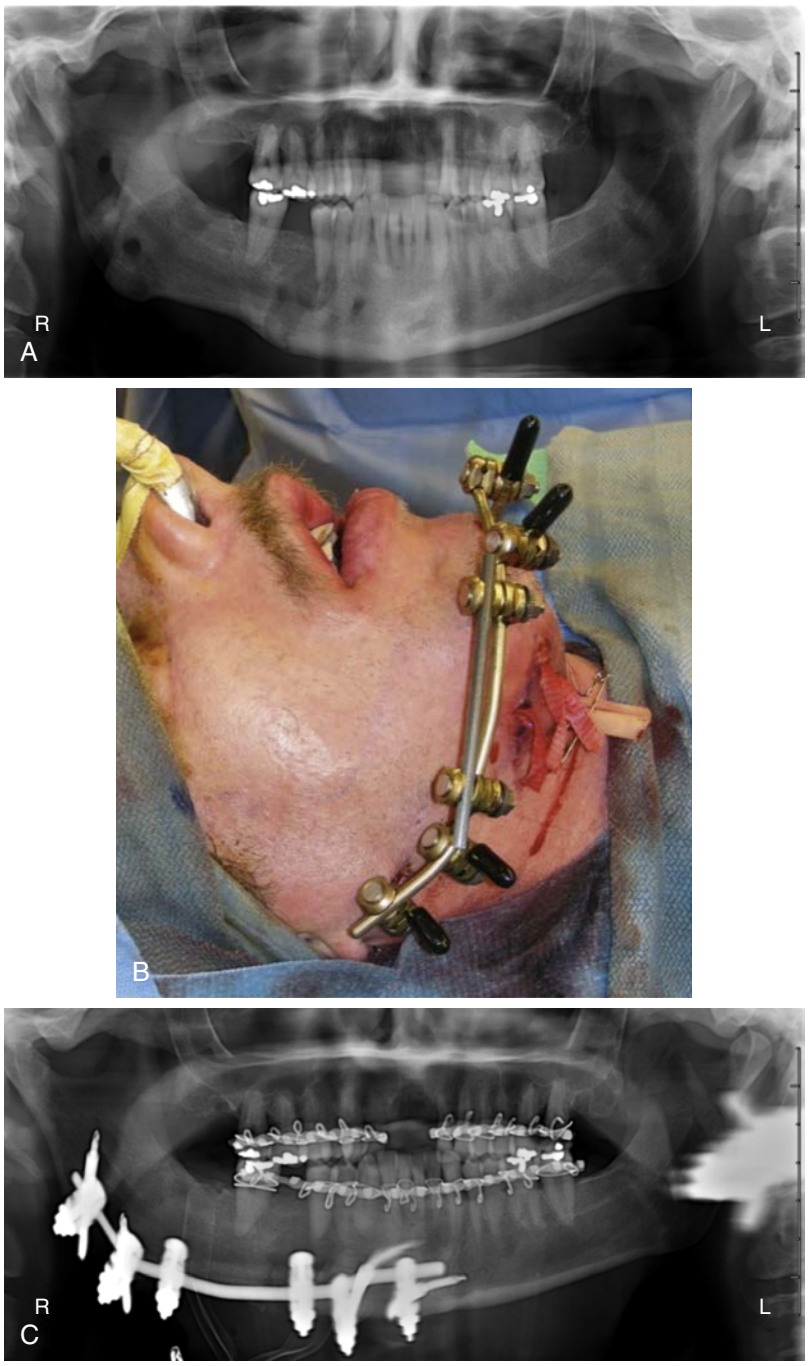
The lingual splint is a technique with which the maxillofacial trauma surgeon should be familiar. It can be useful in the pediatric patient because of the challenges posed by mixed dentition. This phase precludes the use of internal fixation for the potential damage to tooth buds and potential for changes in growth. The lingual splint can be used in adult patients with a dentition that does not provide a stable base (i.e., partially edentulous) to reliably apply MMF. Obviously this will require impressions and casts of the maxilla and mandible. This may be difficult to obtain because of pain and trismus, and it may require the patient to undergo anesthesia. Impressions can also be made complicated by the presence of significant oral soft tissue injury and edema, or by the presence of an endotracheal tube. Before the fabrication of the lingual splint, the mandibular casts may need to be sectioned in order to reestablish an appropriate arch length and alignment. The splints can have arch bars incorporated into the acrylic and can be secured to remaining teeth/mandible with circumdental and skeletal wires.

External fixation has played a significant role in the treatment of comminuted mandible fractures and the atrophic mandible fracture for a number of years (Figure 7-16). Currently, however, the use of rigid fixation and microvascular reconstructive surgery has diminished its relevance. There are occasional instances where external fixation can be used as a bridging technique. In these situations, when the surgeon is waiting for the stabilization of soft tissue or recalcitrant infection, external fixation can be used to maintain the continuity defect and form. Once soft tissue stabilization is achieved, the definitive repair can be undertaken and the external fixation removed.

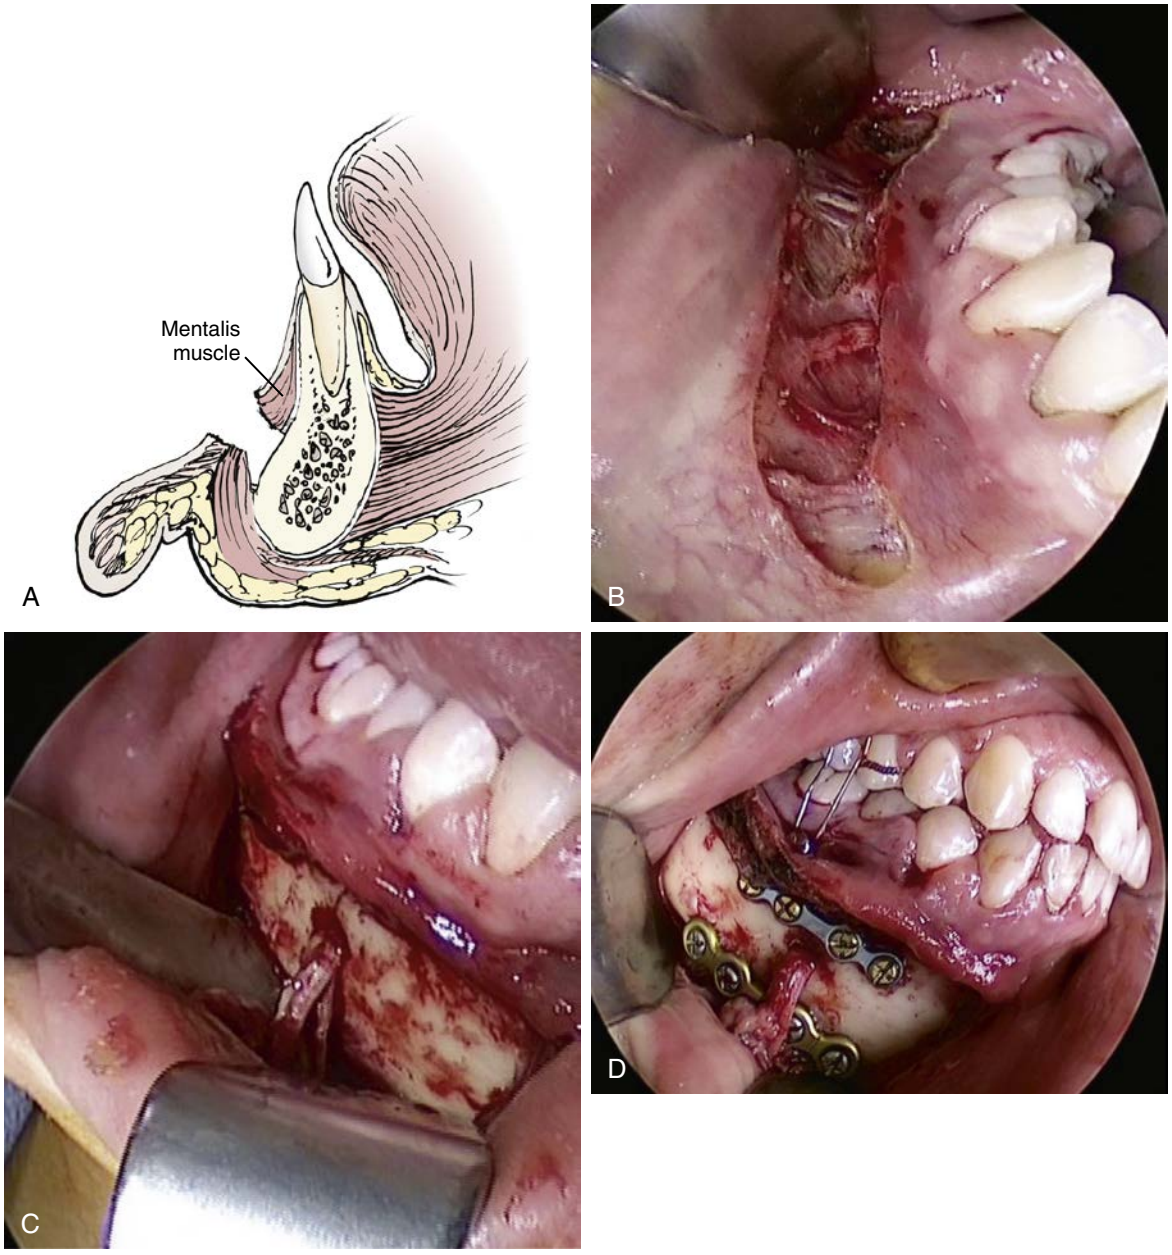
Open techniques have been revolutionized by advances in rigid fixation. Surgeons and patients appreciate an earlier return to function and avoidance of being "wired shut." Most mandible fracture segments can be accessed through oral and/or percutaneous (transbuccal) approaches. As a fracture's displacement or severity increases, the use of transcervical, retromandibular, or preauricular approaches may be warranted. Ramus and condyle fractures are typically accessed through neck and preauricular incisions; however, endoscopic approaches can be used as well.

Intraoral/Transbuccal approach (Figures 7-17 to 7-21)

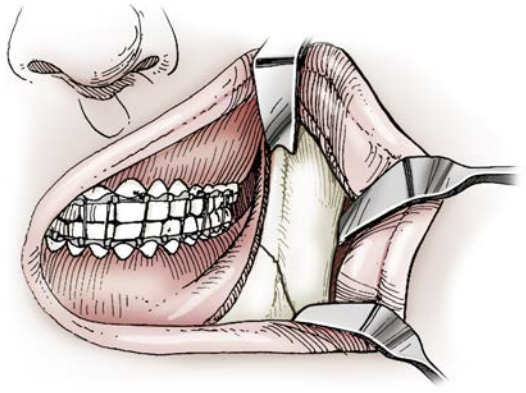
1. Local anesthetic with epinephrine can be infiltrated throughout the field to aid in hemostasis.
2. An incision is made approximately 5 to 7 mm apical to the mucogingival junction. The incision is only through mucosa to aid in identification and preservation of mental nerve branches around the canine/premolar region. The foramen itself is typically located close to the apex of the second premolar; however, preoperative assessment and localization is helpful with a panoramic radiograph or CT scan. An alternative approach can be accomplished via sulcular incisions with generous releases. This approach will avoid vestibular scarring and localization of the mental nerve along its extrabony course, but might limit access and visualization for some fractures.
3. Anteriorly, the mentalis muscle is divided, leaving a cuff of muscle for closure, and posteriorly the buccinator is elevated from the mandible. A subperiosteal dissection is performed anteriorly or posteriorly using the blunt end of a periosteal to identify the mental foramen, which will help in nerve preservation.
4. The mental nerve and its branches should be identified and preserved. Skeletonization at its bony exit may be helpful for retraction and performed by incising along the periosteum overlying the nerve using a blade and tenotomy or iris scissors. If the fracture does involve the foramen, care must be taken to avoid unnecessary nerve injury during mobilization and reduction of the fracture.
5. Any granulation, clot, or fibrous soft tissue preventing proper reduction should be removed.
6. The fracture sites should be copiously irrigated to dilute microbial contamination.
7. Before fixation, all fractures should be accessed and mobilized as described.



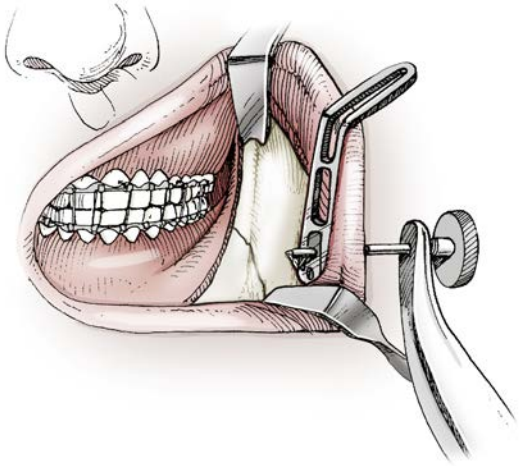
• **Figure 7-16** External fixation systems are an additional tool in the armamentarium for clinicians unable to immediately fixate segments in the setting of infection, nonunion, or noncompliance. **A,** This patient presented several weeks after sustaining a right parasymphyseal fracture with osteomyelitis and a submandibular space infection**. B,** Intraoperative photo of treatment as well as radiograph **(C)** showing fixation in place and Erich arch bars.



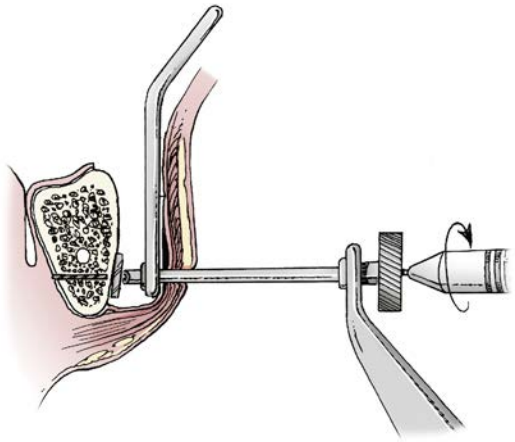
• **Figure 7-17** **A,** Path of dissection to the anterior mandible through mandibular vestibule. Mentalis muscle is incised and used later for layered closure. **B,** Access along the vestibule of the right mandible through mucosa, taking care to preserve the mental nerve. Similar vestibular access of the left angle fracture was completed. **C,** Identification, skeletonization, and protection of the mental nerve branches. IMF screw maxillomandibular fixation was used to reduce the fractures. **D,** Superior monocortical and inferior bicortical fixation is used to complete the fracture repair.



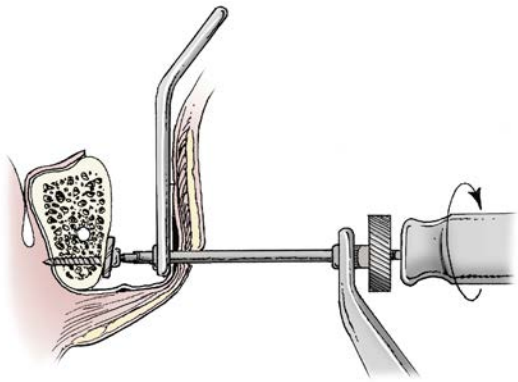
• **Figure 7-18** Transbuccal approach using subperiosteal dissection along ramus.



• **Figure 7-19** Transbuccal trocar in place with cheek retractor.

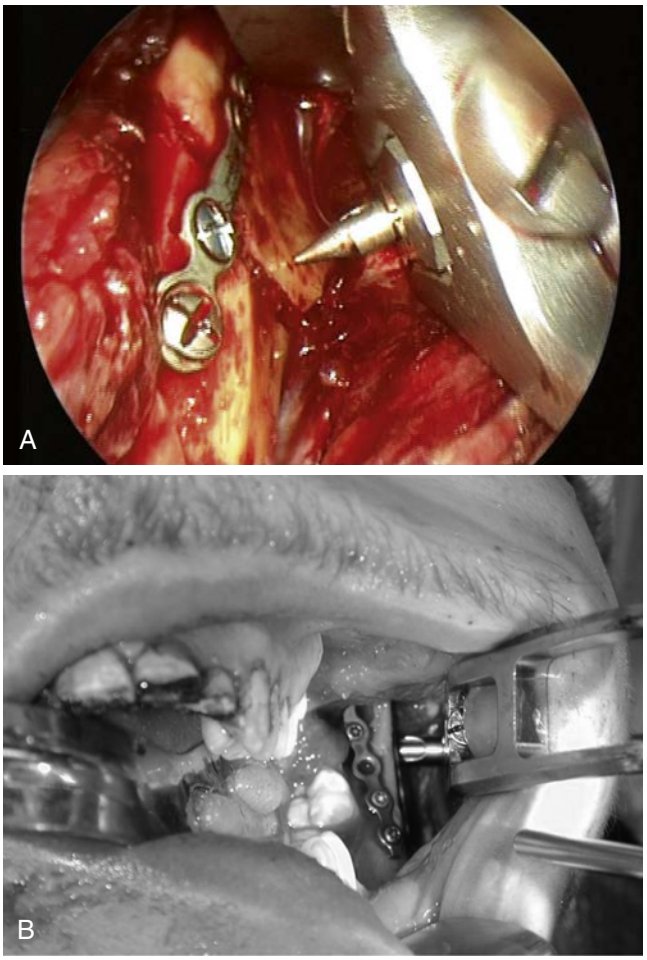


• **Figure 7-20** Preparation of inferior border bicortical plate fixation.



• **Figure 7-21** Bicortical screw placement based on accurate depth measurement to engage both cortices.

8. Fixation is then accomplished by any of several techniques. The authors prefer rigid fixation following AO/ASIF principles. Two-plate techniques place fixation along zones of tension and compression, typically a miniplate at the superior border and a fracture plate at the inferior border. Two-screw fixation is used on either side of the fracture with both plates for proper fixation. A single reconstruction plate (2.3 to 2.5 mm) at the inferior border can be used with three-screw fixation on either side of the fracture as an alternate technique. The authors prefer locking plates in the inferior border position.
9. A transbuccal puncture may be required to access more posterior body or angle plates (Figure 7-22). A cutaneous stab incision can be made through the cheek with a No. 15 blade overlying the portion of interest of the fracture. Blunt subcutaneous and trocar dissection is then carried out through the remainder of the cheek in order to manipulate the site for superior and inferior plate access both proximally and distally.
10. Resuspension of the mentalis muscle should be performed at closure to prevent a "witch's chin" deformity. Mucosa can then be closed using a continuous running 3-0 chromic gut suture.

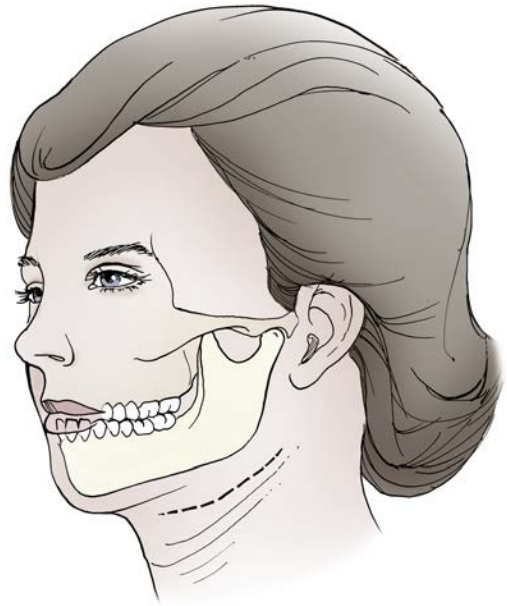


• **Figure 7-22** **A,** Transbuccal systems can be used for open reduction and internal fixation of angle and ramus fractures. The systems provide good posterior access and visualization of the fracture and fixation. **B,** Transbuccal approach to left angle.

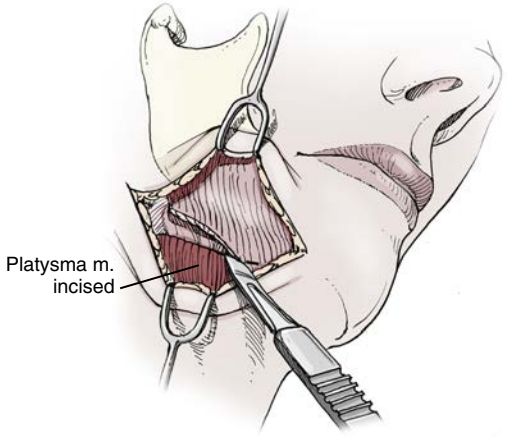
Transcervical-Submandibular Approach (Figures 7-23 to 7-28)

A skin crease is identified approximately 2 cm (or more) below the inferior border of the mandible at the approximate area of the fracture with enough extension on either side to allow for the appropriate sized plate placement and necessary retraction. If the surgeon wishes to assess the facial nerve during the procedure, muscle relaxant should be avoided after intubation. The authors prefer a high apron incision and an anatomic approach where nerve monitoring is not used.

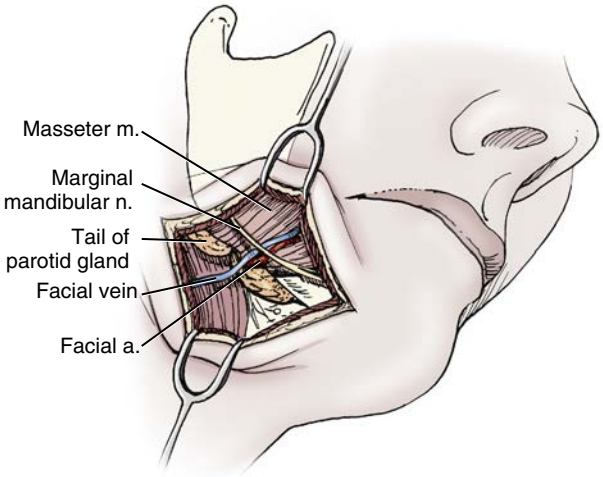
1. The skin, subcutaneous fat, and platsyma should be incised to identify the superficial layer of deep cervical fascia investing the submandibular gland. The marginal mandibular branch of the facial nerve will be deep to the platsyma and within the superficial layer of the deep cervical fascia.
2. The superficial fascia is divided at the inferior aspect of the submandibular gland, and a subcapsular dissection can be performed to protect the facial nerve. The facial vein can be divided at this point and retracted superiorly



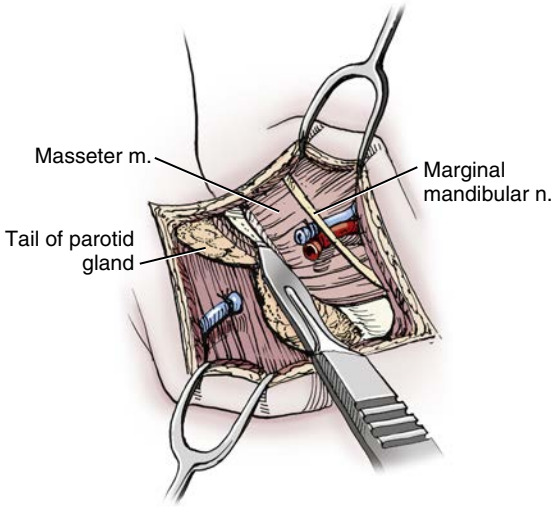
• **Figure 7-23** Extension of submandibular approach to the mandible using natural skin neck crease.



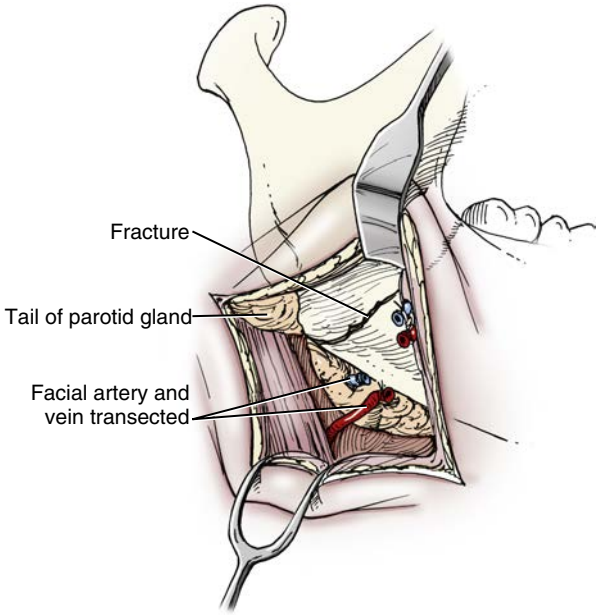
• **Figure 7-24** Incision through skin and platysma.



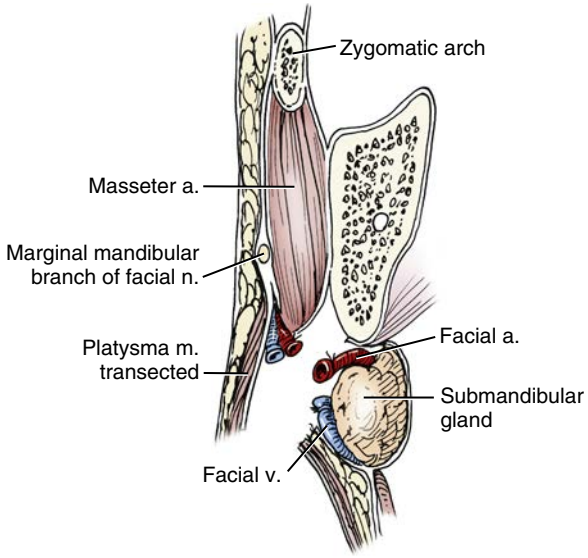
• **Figure 7-25** Dissection in subplatsymal plane to identify capsule of submandibular gland and facial vessels (artery and vein).



• **Figure 7-26** Division of the pterygomasseteric sling.



• **Figure 7-27** Identification of the fracture along a subperiosteal plane.



• **Figure 7-28** Coronal view of dissection planes.

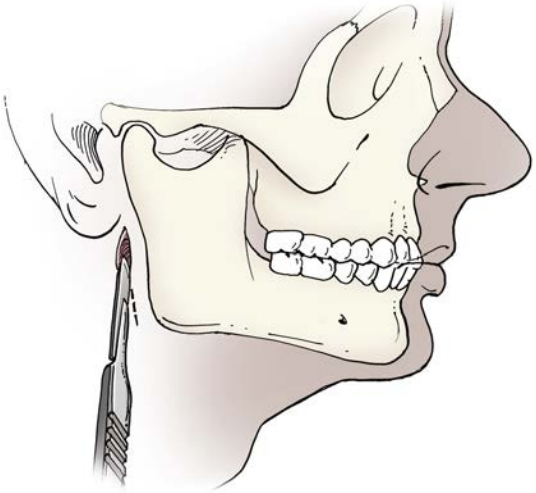
to guide dissection and protect the facial nerve (Hayes-Martin maneuver). The facial artery should be identified near the posterior aspect of the gland and isolated/divided as necessitated by access. A cadaveric study by Dingman and Grabb identified the marginal mandibular branch of the facial nerve at most 1 cm below the inferior border of the mandible 81% of the time when posterior to the facial vessels. Anterior to the vessels, the marginal mandibular branches course inferior to the mandibular border only 19% of the time.[26] Nerve simulators can be used if there is any doubt or question of the tissue dissection.

3. Anterior to the gland and facial vessels, a plane of dissection deep to the superficial layer of deep cervical fascia should direct the surgeon to the anterior digastric muscle. This can be safely dissected superiorly to its insertion at the anterior mandible.
4. Using the Hayes-Martin technique of ligating and elevating the facial vein/artery, the facial nerve is protected for direct access to the inferior border of the mandible,[27] though often the anterior course of the facial artery/veins must be encountered and managed. The pterygomasseteric sling will be encountered and is incised as needed depending on location of the fracture. The periosteum is incised at the most inferior aspect of the mandible, and a subperiosteal dissection can be developed to identify the fractures.
5. Care should be taken to avoid any damage to the mental foramen while approaching and degloving the mandible from below.
6. Once the fractures have been identified, debrided, and mobilized, the patient can be placed into MMF. The fractures may need additional reduction and immobilization with reduction forceps prior to plating. Occlusion should be verified prior to final rigid fixation. ORIF principles are followed as described earlier.
7. Closure of the platsyma over a bulb suction round drain is recommended to manage dead space and prevent hematoma formation. Resorbable suture is used for platysma and deep dermal sutures. Skin can be closed with running nonresorbable monofilament or staples.

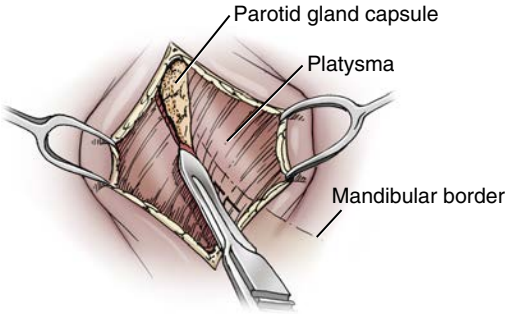
Transcervical-Retromandibular Approach (Figures 7-29 to 7-33)

A skin line several centimeters in length is marked paralleling the posterior border of the mandible 5 to 10 mm below the earlobe. The incision should be placed about 1 cm posterior to the ramus to allow elevation of the parotid gland.

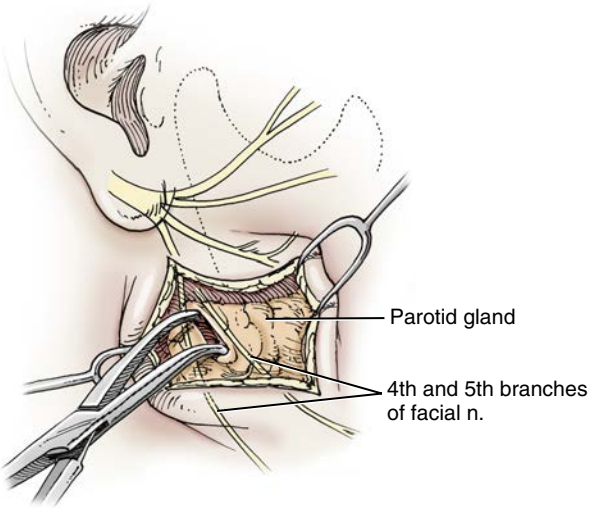
1. Skin and subcutaneous fat are incised. Platysma may be encountered and should be incised as well. Identification of the superficial musculoaponeurotic system (SMAS) that invests the parotid gland and masseter and the anterior border of the sternocleidomastoid posteriorly will guide the dissection.
2. At this point two approaches are used, depending on the surgeon and level of fracture: the transparotid for higher condyle fractures, or the sub-parotid approach for lower ramus fractures.



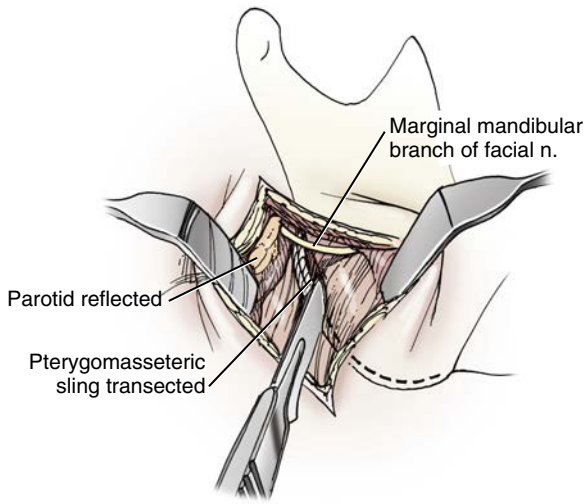
• **Figure 7-29** Retromandibular approach.



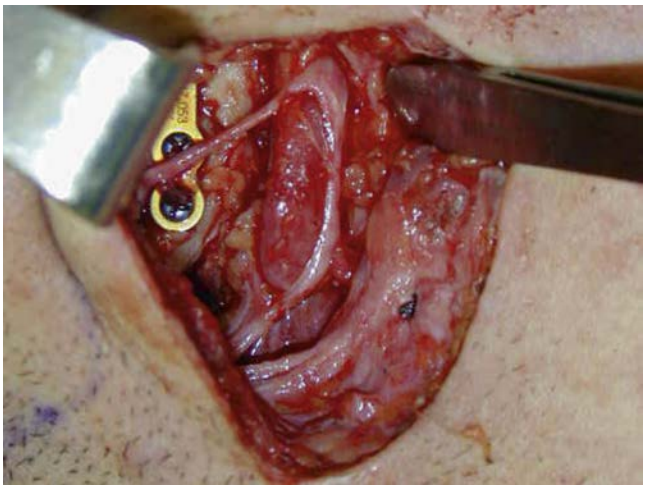
• **Figure 7-30** Incision through platysma muscle.



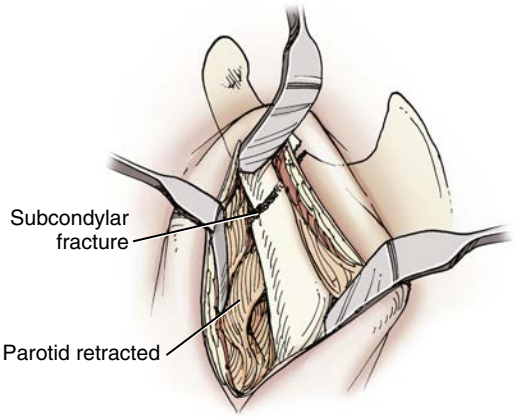
• **Figure 7-31** Dissection through the parotid bluntly to avoid facial nerve damage.



• **Figure 7-32** Incision through pterygomasseteric sling.



• **Figure 7-34** Identification of facial nerve branches (buccal and marginal mandibular).



• **Figure 7-33** Exposure of condylar or mandible fracture in subperiosteal plane.

a. The transparotid directly divides the parotid capsule, and blunt dissection is used to dissect through the gland to the mandible. The buccal and marginal mandibular branches are routinely identified and retracted to access the condyle fracture (Figure 7-34). A nerve stimulator is used to verify branches of the facial nerve, and bipolar electrocautery is used for hemostasis. Transient facial nerve injury in the transparotid approach has been documented, but function usually returns by 6 months.[28] Careful retraction of the soft tissues enveloping facial nerve branches will limit the transient paralysis postoperatively.
b. The sub-parotid approach elevates the parotid superiorly to protect the facial nerve and provide access inferiorly along the posterior aspect of the mandibular angle. This approach is better suited for lower ramus fractures but can be elevated to expose up to the neck of the condyle. In this approach, the facial nerve is still susceptible to traction injury.

3. The masseter and periosteum should be incised and elevated to identify the posterior aspect of the mandible and associated fractures. Care should be taken to stay within the subperiosteal plane to avoid damage to the retromandibular vein.
4. If the sigmoid notch is encountered, a subperiosteal dissection should be maintained to avoid damaging the masseteric branch of the maxillary artery.
5. Fractures are mobilized, debrided, and reduced. Condyle fracture reduction should be reconfirmed after establishing MMF and accomplishing reduction of all other fractures. Occasionally segments of the condyle/condylar neck will be difficult to reduce with the patient in MMF.
6. Fixation should be applied as deemed appropriate. Several condyle-specific plates are currently available that are suited to the unique contours and space limitations of the anatomic region. Watertight closure of the parotid capsule using resorbable sutures will help prevent salivary leak. A round bulb suction drain can once again aid in the elimination of dead space and avoid seroma or hematoma formation. A pressure dressing can also aid in hemostasis and prevention of a salivary leak. Platysma is reapproximated and skin closed with running nonresorbable, monofilament suture.

Endoscopic Approach

Endoscopic approaches to the subcondylar and condylar region are used to minimize facial nerve damage as well as facial/neck scars. The approach uses a sagittal split/lateral mandibular vestibule access to manipulate segments and place miniplates. A less than 1 cm submandibular incision can be used with minimal dissection deep to the pterygomasseteric sling to place the endoscope. A 3- to 4-mm Storz endoscope can be used for the procedure. As previously mentioned, mobilization and reduction techniques should be carried out, but this time using direct endoscopic view and instrumentation. Right-angle drills and screwdrivers can be used to avoid percutaneous access higher on the face.

The technique requires considerable patience and typically will increase the surgical time by 1 to 2 hours.[29] The benefit is largely a reduction in facial scars when endoscopic approaches are compared to open access, along with decreased rate of facial nerve complications.[30] More details of endoscopic approaches to mandible fractures are presented in additional chapters.

Internal Fixation Techniques

The advancements in rigid internal fixation have revolutionized mandible and maxillofacial fracture treatment outcomes and hastened return to function. There are two broad categories of fixation methods:

- Semirigid fixation
- Rigid fixation

Semirigid fixation (with or without maxillomandibular fixation):

- Champy's technique (monocortical miniplate fixation)
- Resorbable plates
- Monocortical plate fixation (non-Champy)

Maxime Champy was a pioneer of semirigid fixation techniques.[12] Using the lines of osteosynthesis, based on his understanding of torsion, compression, and tension, miniplate semirigid fixation could be placed with proper buttressing to reduce the fractures and encourage primary healing within very specific parameters of wound management (Figure 7-35). This type of fracture fixation is best used with compliant patients who have well-buttressed fractures or along with a brief period of maxillomandibular fixation.

In pediatric patients, resorbable plates can add some rigidity to the reduction of a mandible fracture without the possibility of having to remove hardware due to translocation concerns. Poly-L-lactic or polyglycolic acid are major components of the current resorbable plating systems available. These constructs are reduced to water and carbon dioxide at about 8 to 18 months, depending on the polymer material composition. Most plating companies use a proprietary polymer with similar strength and resorption properties.[31] Resorbable plates should not be used as primary load-bearing plates, but several sources highlight their use with reduced or equivalent complication rates when compared with titanium plates and screws in well-buttressed fractures[32-34] (Figure 7-36). The cost and nature of the technique can be a deterrent for some surgeons.

Transosseous wire fixation has limited use in today's realm of miniplate and rigid fixation. Occasionally with comminuted fractures, smaller fragments can be transiently realigned with wire in preparation for placement of a reconstruction plate or more stable fixation.

Rigid fixation can use a number of techniques:

- Two-plate technique (superior monocortical tension-band and inferior border bicortical compression plate)
- Reconstruction plate
- Lag screw

The two-plate technique traditionally uses a superior tension band, low-profile/miniplate (or dental arch bar) to prevent fracture distraction at the alveolar process level, while a more rigid intermediate-profile plate is placed in the compression zone at the inferior border. The superior border plate is a monocortical plate respecting the local dental anatomy. The inferior border plate is fixated with bicortical screws to maintain rigidity, immobility, and fracture reduction.
