YAO & ARTUSIO'S

ANESTHESIOLOGY

PROBLEM-ORIENTED PATIENT MANAGEMENT

Seventh Edition

Editor-in-chief

FUN-SUN F. YAO, MD

Professor, Department of Anesthesiology
Weill Medical College of Cornell University
Attending Anesthesiologist
New York Presbyterian Hospital
New York, New York

Associate Editors

VINOD MALHOTRA, MD
Professor of Anesthesiology and
Professor of Anesthesiology in Clinical Urology
Weill Medical College of Cornell University
Vice-Chair for Clinical Affairs
Department of Anesthesiology
Clinical Director of Operating Rooms
New York Presbyterian Hospital
New York, New York

MANUEL L. FONTES, MD
Professor of Anesthesiology and Critical Care
Duke University Medical Center
Durham, North Carolina

Care has been taken to confirm the accuracy of the information presented and to describe generally accepted practices. However, the authors, editors, and publisher are not responsible for errors or omissions or for any consequences from application of the information in this book and make no warranty, expressed or implied, with respect to the currency, completeness, or accuracy of the contents of the publication. Application of the information in a particular situation remains the professional responsibility of the practitioner.

The authors, editors, and publisher have exerted every effort to ensure that drug selection and dosage set forth in this text are in accordance with current recommendations and practice at the time of publication. However, in view of ongoing research, changes in government regulations, and the constant flow of information relating to drug therapy and drug reactions, the reader is urged to check the package insert for each drug for any change in indications and dosage and for added warnings and precautions. This is particularly important when the recommended agent is a new or infrequently employed drug.

Some drugs and medical devices presented in the publication have Food and Drug Administration (FDA) clearance for limited use in restricted research settings. It is the responsibility of the health care provider to ascertain the FDA status of each drug or device planned for use in their clinical practice.

To purchase additional copies of this book, call our customer service department at (800) 638-3030 or fax orders to (301) 223-2320. International customers should call (301) 223-2300.

Visit Lippincott Williams & Wilkins on the Internet: at LWW.com. Lippincott Williams & Wilkins customer service representatives are available from 8:30 am to 6 pm, EST.

This book is dedicated
to
Joseph F. Artusio Jr., MD
who
has taught us
not only to be good anesthesiologists
but also
to become better persons.

CONTENTS

Contributing Authors xi
Preface xix
Acknowledgments xxi

SECTION I
The Respiratory System
1

CHAPTER 1 Asthma and Chronic Obstructive Pulmonary Disease 1
Fun-Sun F. Yao

CHAPTER 2 Bronchoscopy, Mediastinoscopy, and Thoracotomy 30
Alessia Pedoto
Paul M. Heerdt
Fun-Sun F. Yao

CHAPTER 3 Aspiration Pneumonitis and Acute Respiratory Failure 51
Manuel L. Fontes
Sean Garvin
Fun-Sun F. Yao

CHAPTER 4 Lung Transplantation 90
Nanhi R. Mitter
Charles W. Hogue, Jr.

SECTION II
The Cardiovascular System
111

CHAPTER 5 Ischemic Heart Disease and Coronary Artery Bypass Grafting 111
Nikolaos Skubas
Anita L. Cave
Manuel L. Fontes
Fun-Sun F. Yao

CHAPTER 6 Valvular Heart Disease 183
Natalia S. Ivascu
Gregg S. Hartman

CHAPTER 7 Pacemakers, Implantable Cardioverter-Defibrillators, and Cardiac Resynchronization Therapy Devices 217
Alan Cheng
Fun-Sun F. Yao

CHAPTER 8 Thoracoabdominal Aortic Aneurysms 240
J. Mauricio Del Rio
Jeffrey G. Gaca
Mani A. Daneshmand
Madhav Swaminathan

CHAPTER 9 Abdominal Aortic Aneurysm Repair 277
Anup Pamnani
Lori A. Rubin

CHAPTER 10 Hypertension 308
Manuel L. Fontes
Fun-Sun F. Yao

CHAPTER 11 Cardiac Tamponade 335
Manuel L. Fontes
Nikolaos Skubas
James Osorio

CHAPTER 12 Heart Transplantation and Subsequent Noncardiac Surgery 364
Jeff T. Granton
Davy C. H. Cheng

CHAPTER 13 Ischemic Heart Disease and Noncardiac Surgery 382
Shamsuddin Akhtar
Marbelia Gonzalez
J. Patricio Escandon
Paul G. Barash

SECTION III
The Gastrointestinal System
415

CHAPTER 14 Intestinal Obstruction 415
Joseph Tjan

CHAPTER 15 Liver Transplantation 431
Vivek K. Moitra

SECTION IV
The Nervous System
453

CHAPTER 16 Brain Tumor and Craniotomy 453
Kane O. Pryor
Hugh C. Hemmings, Jr.

CHAPTER 17 Carotid Endarterectomy 477
Maria Bustillo
Cynthia A. Lien

CHAPTER 18 Awake Craniotomy for Mapping and Surgery in the Eloquent Cortex 507
Thomas A. Moore II

CHAPTER 19 Head Injury 529
Eugene S. Fu
Jonathan Jagid
Leo T. Harris III

CHAPTER 20 Cerebral Aneurysm 551
Patricia Fogarty Mack

SECTION V
The Endocrine System
575

CHAPTER 21 Thyrotoxicosis 575
Dana L. Gurvitch

CHAPTER 22 Pheochromocytoma 591
Gregory E. Kerr

CHAPTER 23 Diabetes Mellitus 605
Mark E. Nunnally
Vinod Malhotra

SECTION VI
The Genitourinary System
621

CHAPTER 24 Transurethral Resection of the Prostate 621
Jerome F. O'Hara, Jr.
Mauricio Perilla
Vinod Malhotra
Fun-Sun F. Yao

CHAPTER 25 Kidney Transplant 649
Panchali Dhar
Peter Fleishut
Fun-Sun F. Yao

CHAPTER 26 Robotic-Assisted Laparoscopic Surgery 671
Judith Weingram

SECTION VII
The Reproductive System
705

CHAPTER 27 Placenta Previa/Placenta Accreta 705
Jill Fong

CHAPTER 28 Hypertensive Disorders of Pregnancy 734
Sharon Abramovitz

CHAPTER 29 Breech Presentation, Fetal Distress, and Mitral Stenosis 755
Jill Fong

CHAPTER 30 Appendectomy for a Pregnant Patient 778
Farida Gadalla

SECTION VIII
The Hematologic System
793

CHAPTER 31 Hemophilia and Coagulation Disorders 793
Jonathan Leff
Linda Shore-Lesserson
Robert E. Kelly

CHAPTER 32 Sickle Cell Disease 812
Chris R. Edmonds
Vinod Malhotra

SECTION IX
Eye, Ear, Nose, and Throat
829

CHAPTER 33 Airway Trauma 829
Richard P. Dutton
LaRita Yvette Fouchè-Weber

CHAPTER 34 Open-Eye Injury 843
Theresa T. Kudlak

CHAPTER 35 Laser Treatment for Laryngeal Lesions 861
Marcus Gutzler

SECTION X
Pediatrics
877

CHAPTER 36 Tracheoesophageal Fistula 877
Jacques H. Scharoun

CHAPTER 37 Congenital Diaphragmatic Hernia 888
Fun-Sun F. Yao
David Stein
John J. Savarese

CHAPTER 38 Tetralogy of Fallot 903
James A. DiNardo

CHAPTER 39 Transposition of the Great Arteries 925
James A. DiNardo

CHAPTER 40 Pyloric Stenosis 951
Aarti Sharma
Vinod Malhotra

CHAPTER 41 Inflammatory Airway Disease in Childhood: Laryngotracheobronchitis 964
Miles Dinner

CHAPTER 42 Cleft Palate 977
Aarti Sharma

CHAPTER 43 Congenital Heart Disease with a Cervical Mass in Infancy 990
Miles Dinner
Marie A. Sankaran Raval

CHAPTER 44 Patent Ductus Arteriosus and Prematurity 1005
Isobel Russell
Rajesh Bhat
Fun-Sun F. Yao

SECTION XI
Pain Management and Neuraxial Blocks
1025

CHAPTER 45 Brachial Plexus Block 1025
William Urmey

CHAPTER 46 Nerve Blocks of the Lower Extremity 1040
Jeffrey Y. F. Ngeow
David Y. Wang
Karina Gritsenko

CHAPTER 47 Complex Regional Pain Syndromes 1058
Sudhir A. Diwan
Vinod Malhotra
Neel D. Mehta

CHAPTER 48 Cancer Pain 1073
Sudhir A. Diwan
Shakil Ahmed
Neel D. Mehta

CHAPTER 49 Low Back Pain and Sciatica 1094
David Y. Wang
Jeffrey Y. F. Ngeow

CHAPTER 50 Perioperative Pain Management 1116
Anuj Malhotra
Vinod Malhotra
Narinder Rawal

CHAPTER 51 Acupuncture 1143
Yuan-Chi Lin

SECTION XII
Miscellaneous
1153

CHAPTER 52 Myasthenia Gravis 1153
Cephas P. Swamidoss
Cynthia A. Lien

CHAPTER 53 Malignant Hyperthermia 1168
Henry Rosenberg
Vinod Malhotra

CHAPTER 54 Postoperative Residual Neuromuscular Weakness and Prolonged Apnea 1184
David Kopman
Aaron F. Kopman

CHAPTER 55 Burns 1200
Michael Tjeuw

CHAPTER 56 Trauma 1221
Danielle Lindenmuth
Jaideep K. Malhotra
Ralph L. Slepian

CHAPTER 57 Scoliosis 1245
Kathryn DelPizzo
Victor M. Zayas

CHAPTER 58 Hypoxia and Equipment Failure 1270
James B. Eisenkraft
Andrew B. Leibowitz

CHAPTER 59 Electroconvulsive Therapy 1294
Patricia Fogarty Mack

CHAPTER 60 Ambulatory Surgery 1302
Kathryn E. McGoldrick

CHAPTER 61 Magnetic Resonance Imaging 1326
Jung Hee Han

CHAPTER 62 Morbid Obesity and Obstructive Sleep Apnea 1346
Jon D. Samuels
Fun-Sun F. Yao

Index 1387

CONTRIBUTORS

Sharon Abramovitz, MD
Associate Professor of Anesthesiology
Weill Cornell Medical College
Attending, Department of Anesthesiology
New York Presbyterian Hospital
New York, New York

Shakil Ahmed, MBBS
Assistant Professor of Clinical Anesthesiology
Weill Cornell Medical College
Assistant Attending, Department of Anesthesiology
New York Presbyterian Hospital
New York, New York

Shamsuddin Akhtar, MBBS
Associate Professor of Anesthesiology
Yale University School of Medicine
Yale-New Haven Hospital
New Haven, Connecticut

Paul G. Barash, MD
Professor of Anesthesiology
Yale University School of Medicine
Attending, Department of Anesthesiology
Yale-New Haven Hospital
New Haven, Connecticut

Rajesh Bhat, MD

Maria Bustillo, MD
Assistant Professor of Clinical Anesthesiology
Weill Cornell Medical College
Assistant Attending, Department of Anesthesiology
New York Presbyterian Hospital
New York, New York

Anita L. Cave, MD, FRCPC
Fellow in Cardiothoracic Anesthesiology
Cornell Weill Medical College
New York Presbyterian Hospital
New York, New York

Alan Cheng, MD
Assistant Professor of Medicine
Johns Hopkins University School of Medicine
Director, Arrhythmia Device Service
Johns Hopkins Hospital
Baltimore, Maryland

Davy C.H. Cheng, MD, MSc, FRCPC, FCAHS
Distinguished University Professor and Chair
Anesthesia and Perioperative Medicine
University of Western Ontario
Chief, Department of Anesthesia & Perioperative Medicine
London Health Sciences Centre and St. Joseph's Health Care London
London, Ontario, Canada

Mani A. Daneshmand, MD
Resident in Cardiothoracic Surgery
Duke University
Resident, Department of Surgery
Duke University Medical Center
Durham, North Carolina

Kathryn DelPizzo, MD
Clinical Instructor of Anesthesiology
Weill Cornell Medical Center
Assistant Attending, Department of Anesthesiology
Hospital for Special Surgery
New York, New York

J. Mauricio Del Rio, MD
Assistant Professor of Anesthesiology
Duke University
Department of Anesthesiology
Duke University Hospital
Durham, North Carolina

Panchali Dhar, MD
Assistant Professor of Clinical Anesthesiology
Weill Cornell Medical College
Assistant Attending, Department of Anesthesiology
New York Presbyterian Hospital
New York, New York

James A. DiNardo, MD, FAAP
Professor of Anesthesia
Harvard Medical School
Chief, Division of Cardiac Anesthesia, Department of Anesthesiology, Pain, and Perioperative Medicine
Children's Hospital Boston
Boston, Massachusetts

Miles Dinner, MD
Professor of Clinical Anesthesiology
Weill Cornell Medical College
Attending, Department of Anesthesiology
New York Presbyterian Hospital
New York, New York

Sudhir A. Diwan, MD, DABIPP
Associate Professor of Anesthesiology
Executive Director, The Spine and Pain Institute of New York
Staten Island University Hospital
New York, New York

Richard P. Dutton, MD, MBA
Visiting Clinical Professor of Anesthesiology
University of Maryland
Attending Anesthesiologist, Division of Trauma Anesthesiology
R. Adams Cowley Shock Trauma Center
University of Maryland
Baltimore, Maryland

Chris R. Edmonds, MD
Clinical Assistant Professor of Anesthesiology
New York Presbyterian Hospital
Assistant Attending, Department of Anesthesiology
Hospital for Special Surgery
New York, New York

James B. Eisenkraft, MD
Professor of Anesthesiology
Mount Sinai School of Medicine
Attending, Department of Anesthesiology
Mount Sinai Hospital
New York, New York

J. Patricio Escandon, MD

Peter Fleishut, MD
Assistant Professor of Anesthesiology
Weill Cornell Medical College
Deputy Quality and Patient Safety Officer
New York Presbyterian Hospital
New York, New York

Jill Fong, MD
Associate Professor of Clinical Anesthesiology
Weill Cornell Medical College
Associate Attending, Department of Anesthesiology
New York Presbyterian Hospital
New York, New York

Manuel L. Fontes, MD
Professor of Anesthesiology and Critical Care
Duke University Medical Center
Durham, North Carolina

LaRita Yvette Fouchè-Weber, MD
Assistant Professor of Anesthesiology
University of Maryland School of Medicine
Division Chief, Trauma Anesthesiology
University of Maryland
Baltimore, Maryland

Eugene S. Fu, MD
Associate Professor of Anesthesiology
University of Miami Miller School of Medicine
Attending, Department of Anesthesiology

Duke University
Department of Anesthesiology
Duke University Hospital
Durham, North Carolina

Joseph Tjan, MD
Assistant Professor of Clinical Anesthesiology
Weill Cornell Medical College
Assistant Attending, Department of Anesthesiology
New York Presbyterian Hospital
New York, New York

Michael Tjeuw, MD
Honorary Professor of Anesthesiology
Burn Center, South West Hospital
Third Military Medical University
Chongqing, China
Associate Professor Emeritus of Anesthesiology
Weill Cornell Medical College
New York, New York
Senior Consultant, Department of Anesthesia
Westmead Hospital, University of Sydney
Sydney, New South Wales, Australia

William Urmey, MD
Clinical Associate Professor of Anesthesiology
Weill Cornell Medical College
Associate Attending, Department of Anesthesiology
Hospital for Special Surgery
New York, New York

David Y. Wang, MD
Clinical Assistant Professor of Anesthesiology
Weill Cornell Medical College
New York, New York

Judith Weingram, MD
Assistant Professor of Clinical Anesthesiology
Weill Cornell Medical College
Assistant Attending, Department of Anesthesiology
New York Presbyterian Hospital
New York, New York

Fun-Sun F. Yao, MD
Professor of Anesthesiology
Weill Medical College of Cornell University
Attending Anesthesiologist
New York Presbyterian Hospital
New York, New York

Victor M. Zayas, MD
Clinical Associate Professor of Anesthesiology
Weill Cornell Medical College
Attending, Department of Anesthesiology
Hospital for Special Surgery
New York, New York

PREFACE

Important advances in surgical procedures and in the clinical practice of anesthesiology have prompted the production of a new edition of this text. The book has been published in five languages: English, German, Japanese, Chinese, and Portuguese. The remarkable popularity of the first six editions in the anesthesiology community both in the United States and abroad encouraged us to update and expand its subject matter. The seventh edition is written to further improve anesthesia management for sophisticated surgery.

As with our previous editions, *Yao & Artusio's Anesthesiology: Problem-Oriented Patient Management* was written to present a group of important clinical entities covering the most critical anesthetic problems. It is intended to provide logical and scientific fundamentals for individualized patient management.

In this seventh edition, *Yao & Artusio's Anesthesiology* is organized by organ systems into 12 sections consisting of 62 chapters. Each chapter begins with a brief case presentation, followed by essential problems of each disease covering four areas: (1) pathophysiology and differential diagnosis; (2) preoperative evaluation and preparation; (3) intraoperative management; and (4) postoperative anesthetic management. Using a question-and-answer format, the book is designed to stress anesthetic problems and to give the anesthesiologist the opportunity to organize his or her own ideas of patient care. A reasonable answer, with updated references, follows each question.

To maintain the fresh quality of the textbook, approximately one-third of the seventh edition consists of new chapters or contributions by new authors. All pediatric chapters from different organ systems are regrouped to the new section of Pediatric Anesthesia to reflect the importance of this unique subspecialty. The text originally reflected the clinical experience of the Department of Anesthesiology at Weill Cornell Medical College–The New York Presbyterian Hospital. In this edition, experts from other prestigious institutions have contributed their invaluable opinions to make this book more universally acceptable and applicable. The material in the book is prepared for the education of the resident and the practicing anesthesiologist; it also serves as a review source for continuing education and for preparing for board examinations and recertification. The question-and-answer format, combined with current references, enhances its educational value.

We welcome comments, criticisms, and suggestions for future editions.

ACKNOWLEDGMENTS

I wish to express my personal gratitude to the individual contributors. This book would not have been possible without their hard work and dedication. I am grateful to the associate editors: Vinod Malhotra, MD, and Manuel Fontes, MD, for their invaluable assistance. I would like to thank our editors at Lippincott Williams & Wilkins (Wolters Kluwer), Brian Brown, Lisa McAllister, Nicole Dernoski, and Matt Gardner for their commitment to excellence. In addition, I am especially indebted to John J. Savarese, MD, for his constructive advice and support. Above all, my deepest appreciation goes to my family, Tong-Yi, Ning-Yen, Jean-Kuan, and especially to my dear compassionate wife, Baw-Chyr Peggy Yao. Her understanding, patience, and encouragement made this book possible.

Fun-Sun F. Yao, MD

SECTION I

The Respiratory System

CHAPTER 1

Asthma and Chronic Obstructive Pulmonary Disease

FUN-SUN F. YAO

A 55-YEAR-OLD MAN

with cholelithiasis was scheduled for cholecystectomy. He had a long history of asthma and developed dyspnea with only moderate exertion. He slept on two pillows. There was no peripheral edema. Arterial blood gases (ABGs) showed the following: pH 7.36; P_{CO_2}, 60 mm Hg; P_{O_2}, 70 mm Hg; CO_2 content, 36 mEq per L.

A. Medical Disease and Differential Diagnosis

1. What differential diagnosis is compatible with these symptoms?
2. What is the prevalence of asthma?
3. What is the etiology of asthma?
4. Discuss the pathogenesis of asthma.
5. What are the predisposing factors of asthmatic attacks?
6. What is the universal finding in ABGs during asthmatic attacks: Hypoxemia or CO_2 retention?
7. What changes are seen in spirometry, lung volumes, and lung capacities during an asthmatic attack?

B. Preoperative Evaluation and Preparation

1. How would you evaluate the patient preoperatively? What preoperative workup would you order?
2. How would you distinguish obstructive lung disease from restrictive lung disease by spirometry?
3. Define normal lung volumes and lung capacities and their normal values in the average adult man.
4. What are flow–volume loops? Draw flow–volume loops in a healthy subject, in a patient with chronic obstructive pulmonary disease (COPD), and in a patient with restrictive lung disease.
5. Define closing capacity (CC) and closing volume (CV). What is the normal value of CV?
6. What are the effects of age and posture on functional residual capacity (FRC) and CC?
7. What are the effects of anesthesia on FRC and CC?
8. Why is the FRC important in oxygenation?
9. Are there methods to measure FRC and CV?
10. Give the equations for shunt ($\dot{Q}s/\dot{Q}T$) and dead space/tidal volume (VD/VT). What are their normal values?
11. Interpret the following ABGs: pH, 7.36; PCO_2, 60 mm Hg; PO_2, 70 mm Hg; CO_2 content, 36 mEq per L.
12. What are the common physiologic causes of hypoxemia?
13. Would you order any special preoperative preparations for asthmatic patients with COPD?
14. How long would you postpone elective surgery if the patient had a recent upper respiratory infection (URI)?
15. What medicines would you expect the patient to have taken in the past or be taking at the present time?
16. Would you order preoperative steroid preparation? Why?
17. What is the onset of action of intravenous steroid therapy in asthma?
18. What are the effects of H_2-receptor antagonists on patients with asthma?
19. How would you premedicate the patient? Why?

C. Intraoperative Management

1. What are the disadvantages of administering atropine to the patient with asthma?
2. If the patient had a severe asthmatic attack in the operating room before the induction of anesthesia, would you proceed with the anesthetic or postpone the surgery?
3. The patient did not have an asthmatic attack in the operating room. How would you induce anesthesia? Would you use a laryngeal mask airway (LMA) instead of an endotracheal tube?
4. Why would you use propofol for induction of anesthesia?
5. Would you use thiopental, methohexital, etomidate, or ketamine for induction?
6. Would you use lidocaine for intubation?
7. If this is an emergency surgery and rapid sequence induction is indicated, how would you induce anesthesia in this patient?
8. What is your choice of agents for maintenance of anesthesia? Why?
9. What are the mechanisms of volatile anesthetics that produce bronchodilation?

10. Why would you choose an inhalational instead of an intravenous technique?
11. Is regional anesthesia better than general anesthesia in this situation?
12. Which muscle relaxants would you use? Why?
13. In the middle of surgery, the patient developed a severe wheezing attack. How do you manage it?
14. How would you give β_2-agonists? What is their mechanism of action on asthma?
15. Would you administer aminophylline? How does aminophylline relieve bronchospasm? What is the mechanism of action? What are the toxic effects of aminophylline?
16. If the patient does not respond to the aforementioned treatment and becomes cyanotic, what would you do?
17. What are the differential diagnoses of intraoperative bronchospasm?
18. The asthmatic attack was finally relieved, and the surgery was completed. The patient was found to be hypoventilating. What are the common causes of hypoventilation? Would you like to reverse the muscle relaxant?

D. Postoperative Management

1. Would you extubate the patient with asthma while he or she was deeply anesthetized?
2. When the patient cannot be extubated early in the recovery room, how would you keep the endotracheal tube in place without causing bronchoconstriction?
3. In patients with asthma, are opioids contraindicated for postoperative pain control?
4. The patient was breathing well and was extubated. How much oxygen would you give to this patient who has asthma and COPD in the recovery room?

A. Medical Disease and Differential Diagnosis

A.1. What differential diagnosis is compatible with these symptoms?

The differential diagnoses of wheezing and dyspnea include bronchial asthma; acute left ventricular failure (cardiac asthma); upper airway obstruction by tumor or laryngeal edema; and endobronchial disease such as foreign body aspiration, neoplasms, bronchial stenosis, carcinoid tumors, recurrent pulmonary emboli, chronic bronchitis, eosinophilic pneumonias, chemical pneumonias, and occasionally polyarteritis. To differentiate asthma from other diseases with wheezing and dyspnea is usually not difficult. The triad of dyspnea, coughing, and wheezing, in addition to a history of periodic attacks, is quite characteristic. A personal or family history of allergic disease is valuable contributory evidence. A patient with long-standing asthma may develop chronic obstructive lung disease and suffer from exertional dyspnea and orthopnea. Cardiac asthma is a misnomer and refers to acute left ventricular failure. Although the primary lesion is cardiac, the disease manifests itself in the lungs. The symptoms and signs may mimic bronchial asthma, but the findings of moist basilar rales, gallop rhythms, blood-tinged sputum, peripheral edema, and a history of heart disease allow the appropriate diagnosis to be reached.

Gould BE. *Pathophysiology for the Health Professions*. 3rd ed. Philadelphia: Saunders; 2006: 393–398.

A.2. What is the prevalence of asthma?

Asthma is one of the most common chronic diseases globally and currently affects approximately 300 million people. The prevalence of asthma has risen in affluent countries over the last 30 years but now appears to have stabilized, with around 10% to 12% of adults and 15% of children affected by asthma. The prevalence in the United States is 6.7% of the population. It occurs at all ages, with a peak age of 3 years. Approximately half of patients develop asthma before age 10 and another third before age 40. In childhood, there is a 2:1 male/female preponderance, which equalizes by age 30.

The state of asthma in America: two landmark Surveys. 2009. Available from http://www.asthmainamerica.com/.

A.3. What is the etiology of asthma?

Asthma is a heterogeneous disease with interplay between genetic and environmental factors; its etiology is difficult to define. The common denominator that underlies the asthmatic diathesis is a nonspecific hyperirritability of the tracheobronchial tree. Clinically, asthma is classified into two groups: allergic (extrinsic) and idiosyncratic (intrinsic). Allergic asthma is usually associated with a personal or family history of allergic diseases, positive skin reactions to extracts of airborne antigens, and increased levels of immunoglobulin E (IgE) in the serum. Immunologic mechanisms appear to be causally related to 25% to 35% of all cases and contributory in another 33%. Idiosyncratic asthma cannot be classified on the basis of immunologic mechanisms, and it is probably due to abnormality of the parasympathetic nervous system. Bronchospasm is provoked when certain agents stimulate tracheobronchial receptors. Intraoperative bronchospasm is probably usually cholinergically mediated. Afferent receptors in the bronchial mucosa can be an initiating event, although such an event is not always identifiable. Efferent parasympathetic fibers travel to bronchial smooth muscle and can then result in bronchoconstriction by stimulation of the M3 cholinergic receptors on bronchial smooth muscle. After release of acetylcholine (Ach) at the M3 receptor, the Ach will stimulate the M2 muscarinic receptor, which is an inhibitory receptor that limits further release of Ach. Alterations of M2 receptor function may contribute to bronchospasm.

Fauci AS, Braunwald E, Kasper DL, et al., eds. *Harrison's Principles of Internal Medicine*. 17th ed. New York: McGraw-Hill; 2008:1596–1607.

A.4. Discuss the pathogenesis of asthma.

Asthma is a chronic disease characterized by chronic airway inflammation, reversible expiratory airflow obstruction resulting from narrowing of the airways in response to various stimuli, and airway hyperreactivity. The common denominator underlying the asthmatic diathesis is a nonspecific hyperirritability of the tracheobronchial tree. The basic mechanism of persistent subacute airway hyperirritability remains unknown. The most popular hypothesis is subacute airway inflammation. Even when asthmatics are in remission, bronchial biopsy reveals infiltration by inflammatory cells and epithelial shedding from the mucosa. After exposure to an initiating stimulus, inflammatory cells (mast cells, eosinophils, T-lymphocytes, macrophages, basophils, neutrophils, and platelets) and structural cells (epithelial cells, fibroblasts, and airway smooth muscle cells)

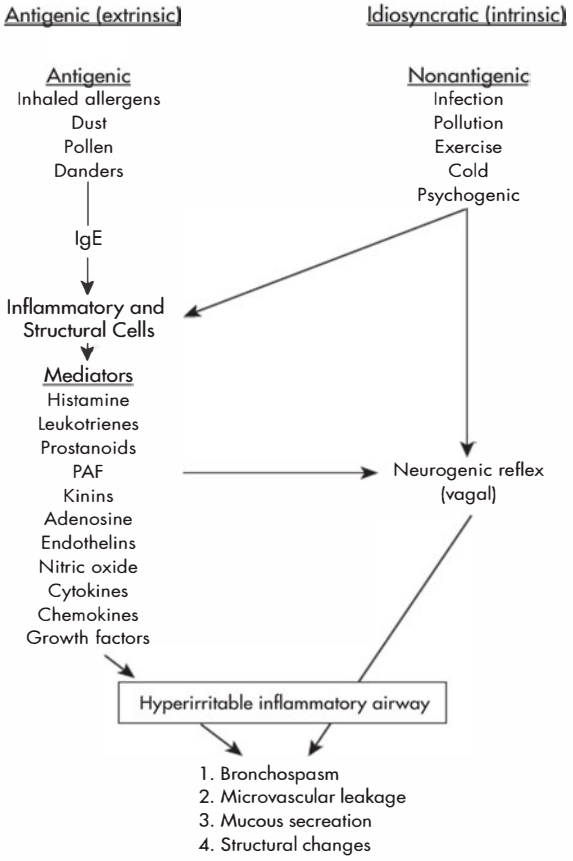

Figure 1.1 The pathogenesis of bronchial asthma. IgE, immunoglobulin E.

can be activated to release various mediators that lead to contraction of airway smooth muscle (bronchospasm), vascular congestion, increased capillary permeability (edema of bronchial mucosa), and thick tenacious secretions, thereby evoking an intense inflammatory reaction (Fig. 1.1). The net result is a reduction in airway diameter, an increase in airway resistance, decreased forced expiratory volumes and flow rates, hyperinflation of the lungs and thorax, increased work of breathing, alterations in respiratory tract muscle function, mismatched ventilation/perfusion, and altered blood gases.

Fanta CH. Asthma. *N Engl J Med.* 2009;360:1002–1014.

Fauci AS, Braunwald E, Kasper DL, et al., eds. *Harrison's Principles of Internal Medicine.* 17th ed. New York: McGraw-Hill; 2008:1596–1607.

A.5. What are the predisposing factors of asthmatic attacks?

- *Allergens*. Inhaled allergens are common triggers of asthma. Airborne allergens are able to activate mast cells with bound IgE, directly leading to the immediate release of a bronchoconstrictor.

- *Infections*. Respiratory tract infections are among the most common stimuli that evoke acute asthmatic attacks.
- *Pharmacologic stimuli*. The drugs most commonly associated with the induction of acute asthmatic attacks are aspirin, coloring agents such as tartrazine, β-adrenergic antagonists, and sulfiting agents. Aspirin and other nonsteroidal anti-inflammatory drugs (NSAIDs), such as indomethacin, mefenamic acid, ibuprofen, fenoprofen, flufenamic acid, naproxen, and phenylbutazone, make the asthma worse because of inhibition of prostaglandin G/H synthetase 1 (cyclooxygenase type 1). β-Adrenergic blockers commonly worsen asthma, and their use may be fatal. All nonspecific β-blockers should be avoided. Nevertheless, the ultra–short-acting β-1 selective antagonists landiolol and esmolol can be safely used perioperatively in patients with airway hyperreactivity.
- *Environment and air pollution*. Some types of asthma, such as Tokyo-Yokohama or New Orleans asthma, tend to occur in individuals who live in heavy industrial or dense urban areas.
- *Occupational factors*. Various compounds used in industry can cause asthma in susceptible individuals. Various names have been applied to this condition, such as meat wrapper's asthma, baker's asthma, and woodworker's asthma.
- *Exercise*. Asthma can be induced or made worse by physical exertion. The mechanism is linked to hyperventilation, which results in increased osmolality in airway lining fluid and triggers mast cell mediator release, resulting in bronchoconstriction.
- *Emotional stress*. Asthma can be induced by bronchoconstriction through the cholinergic reflex pathway.

A.6. What is the universal finding in ABGs during asthmatic attacks: Hypoxemia or CO_2 retention?

Hypoxemia is a universal finding during asthmatic attacks. However, frank ventilatory failure with CO_2 retention is relatively uncommon because CO_2 has a diffusion capacity that is 20 times higher than that of oxygen. During acute asthmatic attacks, most patients try to overcome airway obstruction and hypoxia by hyperventilation. This results in hypocarbia and respiratory alkalosis. CO_2 retention is a late finding and indicates severe and prolonged airway obstruction, as in status asthmaticus.

Fauci AS, Braunwald E, Kasper DL, et al., eds. *Harrison's Principles of Internal Medicine*. 17th ed. New York: McGraw-Hill; 2008:1596–1607.

A.7. What changes are seen in spirometry, lung volumes, and lung capacities during an asthmatic attack?

The forced vital capacity (FVC) is usually normal but may be decreased during a severe attack. The forced expiratory volume at 1 second (FEV_1) is sharply reduced, usually to less than 50% of the FVC, typically less than 40% of that predicted. The maximum midexpiratory flow rate (MMEFR) and maximum breathing capacity

(MBC) are sharply reduced as well. Residual volume (RV) is markedly increased, frequently approaching 400% of normal, and expiratory reserve volume (ERV) is moderately decreased. Therefore, FRC and total lung capacity (TLC) are increased. FRC frequently doubles.

Fauci AS, Braunwald E, Kasper DL, et al., eds. *Harrison's Principles of Internal Medicine*. 17th ed. New York: McGraw-Hill; 2008:1596–1607.

Woods BD, Sladen RN. Perioperative considerations for the patient with asthma and bronchospasm. *Br J Anaesth.* 2009;103(suppl l):i57–i65.

B. Preoperative Evaluation and Preparation

B.1. How would you evaluate the patient preoperatively? What preoperative workup would you order?

The goal of preoperative evaluation is to formulate an anesthesia plan that prevents or blunts obstruction to expiratory airflow. Preoperative evaluation requires an assessment of disease severity, effectiveness of current pharmacologic therapy, and potential need for additional treatment before surgery. Key clues to severe disease include a history of frequent exacerbation, hospital visits, use of a systemic steroid, and most importantly, prior tracheal intubation and mechanical ventilation to deal with a severe attack. In addition to routine tests such as complete blood cell count, serum electrolytes, urinalysis, electrocardiogram, and coagulation screening, special attention should be paid to cardiopulmonary function: chest radiograph; pulmonary function test results, including response to bronchodilator; and baseline ABGs. A history of allergy and symptoms and signs of cardiac or respiratory failure must be checked carefully.

Hines RL, Marschall KE, eds. *Stoelting's Anesthesia and Co-existing Disease*. 5th ed. Philadelphia: Churchill Livingstone; 2008:163–167.

Woods BD, Sladen RN. Perioperative considerations for the patient with asthma and bronchospasm. *Br J Anaesth.* 2009;103(suppl l):i57–i65.

B.2. How would you distinguish obstructive lung disease from restrictive lung disease by spirometry?

Table 1.1 summarizes the distinctions between the two types of lung diseases. In restrictive lung disease (e.g., pulmonary fibrosis and ankylosing spondylitis), the FVC is low because of limited expansion of the lungs or chest wall, although the FEV_1 is often not reduced proportionately, because airway resistance is normal. Therefore, the FEV_1/FVC percentage is normal or high.

In obstructive lung disease (e.g., emphysema), the FEV_1/FVC is grossly reduced because the airway resistance is high. MBC and MMEFR are reduced early in small airway obstruction. MMEFR is also referred to as $FEF_{25\%–75\%}$ (forced expiratory flow). MMEFR is obtained by dividing the volume between 75% and 25% of the vital capacity (VC) by the corresponding elapsed time. Unlike FEV_1, MMEFR is independent of patient effort.

Normally, FEV_1 is more than 80% of FVC and VC should be more than 80% of predicted value. The predicted values depend on body size, age, and sex. The TLC is increased in obstructive lung disease and decreased in restrictive lung disease.

Table 1.1 Differences between Obstructive and Restrictive Lung Diseases

	OBSTRUCTIVE	RESTRICTIVE
Vital capacity	N or ↓	↓
Total lung capacity	N or ↑	↓
Residual volume	↑	↓
FEV_1/FVC	↓	N or ↑
Maximum midexpiratory flow rate	↓	N
Maximum breathing capacity	↓	N

↓, decreased; ↑, increased; FEV_1, forced expiratory volume in 1 second; FVC, forced vital capacity; N, normal.

However, TLC cannot be obtained by routine screening spirometry. Normal MBC is more than 125 L per minute and normal MMEFR is more than 300 L per minute.

Fauci AS, Braunwald E, Kasper DL, et al., eds. *Harrison's Principles of Internal Medicine*. 17th ed. New York: McGraw-Hill; 2008:1588.

B.3. Define normal lung volumes and lung capacities and their normal values in the average adult man.

There are four basic "volumes" and four derived "capacities" that are combinations of these volumes (Fig. 1.2).

Tidal volume (VT) is the volume of air inhaled or exhaled during normal breathing. Normal VT is 500 mL or approximately 6 to 8 mL per kg.

Inspiratory reserve volume (IRV) is the maximum volume of gas that can be inhaled after a normal inspiration while at rest. Normal IRV is 2,000 to 3,000 mL.

Expiratory reserve volume (ERV) is the maximum volume of gas that can be exhaled after a normal expiration. Normal ERV is 1,000 mL.

Residual volume (RV) is the volume of gas remaining in the lungs after a forced exhalation. Normal RV is 1,500 mL.

Vital capacity (VC) is the maximum amount of gas that can be exhaled after a maximum inhalation. VC is the sum of VT, ERV, and IRV. Normal VC is approximately 60 to 70 mL per kg.

Inspiratory capacity (IC) is the maximum amount of gas that can be inhaled from the resting expiratory position after a normal exhalation. It is the sum of VT and IRV. Normal IC is 3,500 mL.

Functional residual capacity (FRC) is the remaining lung volume at the end of a normal quiet expiration. It is the sum of RV and ERV. Normal FRC is 2,500 mL or 30 to 40 mL per kg.

Total lung capacity (TLC) is the lung volume at the end of a maximum inspiration. It is the sum of VC and RV. Normal TLC is 5,000 to 6,000 mL for an adult man and 4,000 to 5,000 mL for an adult woman.

B.4. What are flow–volume loops? Draw flow–volume loops in a healthy subject, in a patient with chronic obstructive pulmonary disease (COPD), and in a patient with restrictive lung disease.

Flow–volume loops provide a graphic analysis of flow at various lung volumes. Both flow and volume are plotted simultaneously on an X–Y recorder as subjects inspire fully to TLC and then perform an FVC maneuver. This is immediately followed by maximum inhalation as fast as possible back to TLC (Fig. 1.3). The entire inspiratory portion of the loop and the expiratory curve near TLC are highly effort dependent, and the expiratory flow at 75% to 25% of VC is effort independent. The normal expiratory flow/inspiratory flow ratio at 50% of VC (mid-VC flow ratio) is approximately 1.0. This ratio is particularly useful in identifying the presence of upper airway obstruction. In patients with restrictive lung diseases such as pulmonary fibrosis and scoliosis, a reduction is seen in FVC, with a relatively normal FEV_1. The TLC is markedly reduced, and the $FEF_{25\%–75\%}$ and mid-VC flow ratio are usually normal (Fig. 1.4). In patients with obstructive lung disease, peak expiratory flow rate, $FEF_{25\%–75\%}$, and mid-VC flow ratio are reduced, but TLC is increased secondary to the increase in RV, as shown in Figure 1.4.

A variable obstruction is defined as a lesion with influence that varies with the phase of respiration. In variable extrathoracic obstructions such as vocal cord paralysis or tracheal stenosis, during forced inspiration, the respiratory flow is reduced because the negative transmural pressure inside the airway tends to collapse the airway. During expiration, the expiratory flow is reduced far less and may be normal because the positive pressure inside the airway tends to

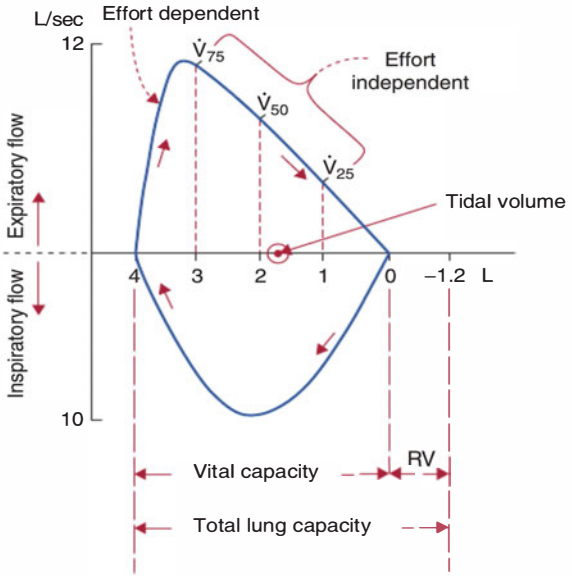

Figure 1.3 Flow–volume loop in a healthy subject. $\dot{V}_{75}$, $\dot{V}_{50}$, and $\dot{V}_{25}$ represent flow at 75%, 50%, and 25% of vital capacity, respectively. RV, residual volume. (From Goudsouzian N, Karamanian A. Physiology for the Anesthesiologist. 2nd ed. Norwalk, CT: Appleton-Century-Crofts; 1984, with permission.)

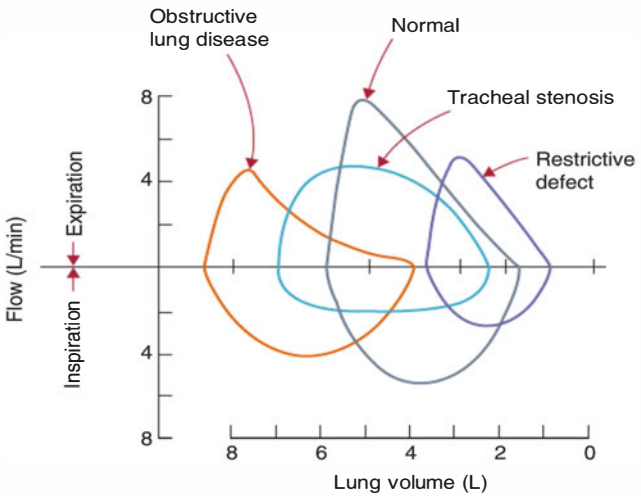

Figure 1.4 Flow–volume loops relative to lung volumes in a healthy person, a patient with chronic obstructive pulmonary disease (COPD), a patient with fixed obstruction (tracheal stenosis), and a patient with pulmonary fibrosis (restrictive defect). Note the concave expiratory form in the patient with COPD and the flat inspiratory curve in the patient with a fixed obstruction. (From Goudsouzian N, Karamanian A. Physiology for the Anesthesiologist. 2nd ed. Norwalk, CT: Appleton-Century-Crofts; 1984, with permission.)

decrease the obstruction (Fig. 1.4). On the contrary, in variable intrathoracic obstruction, the expiratory flow is markedly reduced because the high positive intrapleural pressures during forced expiration decrease airway diameter, and the inspiratory flow is far less reduced because the negative intrapleural pressure tends to increase the diameter of the airway. (Also see Fig. 21.2 in Chapter 21 Thyrotoxicosis.)

Barash PG, Cullen BF, Stoelting RK, et al., eds. *Clinical Anesthesia*. 6th ed. Philadelphia: Lippincott Williams & Wilkins; 2009:249, 1035.

Fauci AS, Braunwald E, Kasper DL, et al., eds. *Harrison's Principles of Internal Medicine*. 17th ed. New York: McGraw-Hill; 2008:1588.

B.5. Define closing capacity (CC) and closing volume (CV). What is the normal value of CV?

CC is the lung volume at which the small airways in the dependent parts of the lung begin to close. CC is the sum of CV and RV. CV is the volume above RV at which small airways begin to close during expiration. CV is the gas volume expelled during phase IV of the single-breath nitrogen test; it denotes the lung volume from the beginning of airway closure to the end of maximum expiration. Therefore, CV = CC – RV (Fig. 1.5).

In healthy young people, CV is approximately 10% of the VC, or 400 to 500 mL. CV and CC increase with age. CV is increased in patients with small airway disease and in chronic smokers.

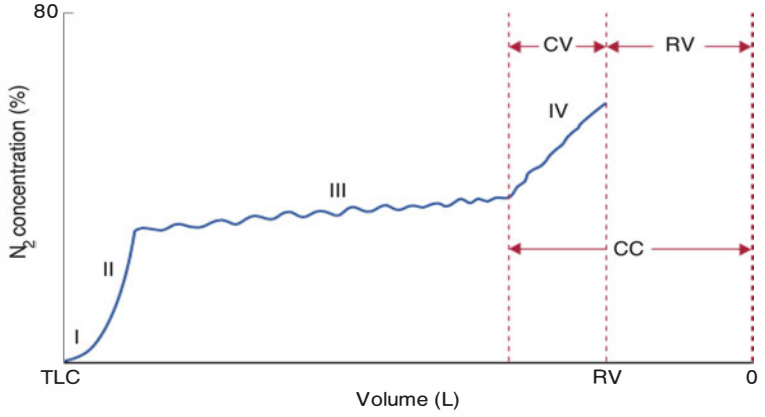

Figure 1.5 Closing volume measurement by single-breath nitrogen test. CC, closing capacity; CV, closing volume; RV, residual volume; TLC, total lung capacity.

B.6. What are the effects of age and posture on functional residual capacity (FRC) and CC?

FRC is either independent of age in adults or increases very slightly with age, increasing approximately 16 mL per year. CC, however, increases with age. Normally, CC becomes equal to FRC at the age of 66 in the upright position and at the age of 44 in the supine position.

FRC increases by approximately 30% in changing from the supine position to the upright position. CC, on the other hand, is independent of body position. It is important to remember that the effects of age on CC and posture on FRC determine whether airway closure exists.

Lumb AB. *Nunn's Applied Respiratory Physiology*. 6th ed. Philadelphia: Butterworth-Heinemann; 2005:34, 44.

Miller RD, ed. *Miller's Anesthesia*. 7th ed. Philadelphia: Churchill Livingstone; 2010:368, 377.

Rehder K, Marsh HM, Rodarte JR, et al. Airway closure. *Anesthesiology*. 1977;47:40.

B.7. What are the effects of anesthesia on FRC and CC?

During anesthesia, FRC is reduced by approximately 20% with spontaneous breathing and by approximately 16% with artificial ventilation. This is due to changes in the chest wall shape and diaphragm position. After induction of general anesthesia, a reduction occurs in the cross-sectional area of the rib cage corresponding to a decrease in lung volume of approximately 200 mL. Recent studies have consistently shown a cephalad movement of the dependent regions of the diaphragm, with little or no movement of the nondependent regions. However, the change in FRC that can be ascribed to changes in diaphragm is on average less than 30 mL.

CC was previously reported to be unchanged during anesthesia, but later studies concluded that CC reduced in parallel to FRC during anesthesia.

Wahba RWM. Perioperative functional residual capacity. *Can J Anaesth*. 1991;38:384–400.

B.8. Why is the FRC important in oxygenation?

First, when FRC is decreased to below CC, airways close in the dependent parts of the lung during certain periods of normal tidal ventilation. Airway closure results in shunting of pulmonary blood flow through the unventilated alveoli. Therefore, $\dot{Q}s/\dot{Q}T$ is increased and arterial oxygenation is decreased. Second, pulmonary circulation and alveolar gas exchange are continuous during both inspiratory and expiratory phases of respiration. Irrespective of whether there is airway closure, blood oxygenation during the expiratory phase depends mainly on the remaining lung volume, which is FRC. Therefore, when the FRC is high, blood oxygenation is better and there is more time for oxygenation before hypoxemia occurs during apnea. FRC is decreased in the supine position during general anesthesia and in patients with acute respiratory distress syndrome. Positive end-expiratory pressure increases FRC and decreases airway closure.

Lumb AB. *Nunn's Applied Respiratory Physiology*. 6th ed. Philadelphia: Butterworth-Heinemann; 2005:34, 44.

B.9. Are there methods to measure FRC and CV?

FRC may be measured by helium dilution, nitrogen washout, and body plethysmography. CV may be determined by two techniques, the single-breath nitrogen test (residual gas technique) and the bolus technique with an inert tracer gas such as helium, xenon, or argon.

Buist AS. The single-breath nitrogen test. *N Engl J Med*. 1975;293:438.

Lumb AB. *Nunn's Applied Respiratory Physiology*. 6th ed. Philadelphia: Butterworth-Heinemann; 2005:36–37, 52–53.

B.10. Give the equations for shunt (Q_S/Q_T) and dead space/tidal volume (V_D/V_T). What are their normal values?

$$Q_S/Q_T = \frac{Cc\overline{O}_2 - CaO_2}{Cc\overline{O}_2 - C\bar{v}O_2} \qquad V_D/V_T = \frac{Paco_2 - P\bar{E}co_2}{Paco_2}$$

where $Cc\overline{O}_2$, CaO_2, and $C\bar{v}O_2$ are oxygen contents in pulmonary capillary, arterial, and mixed venous blood, respectively; Q_T is cardiac output; Q_S is shunt blood; and $Paco_2$ and $P\bar{E}co_2$ are partial pressures of CO_2 in arterial blood and the mixed expired gases, respectively.

Normal Q_S/Q_T is 4% to 5%, and V_D/V_T is approximately 0.3.

Lumb AB. *Nunn's Applied Respiratory Physiology*. 6th ed. Philadelphia: Butterworth-Heinemann; 2005:33–35.

Miller RD, ed. *Miller's Anesthesia*. 7th ed. Philadelphia: Churchill Livingstone; 2010:375, 385.

B.11. Interpret the following ABGs: pH, 7.36; P_{CO_2}, 60 mm Hg; P_{O_2}, 70 mm Hg; CO_2 content, 36 mEq per L.

The fraction of inspired oxygen (F_{IO_2}) is essential to evaluate Pao_2. Assume the blood sample is obtained while the patient is breathing room air. The blood gases show mild hypoxemia and respiratory acidosis, compensated by metabolic alkalosis. The blood gases are compatible with COPD.

B.12. What are the common physiologic causes of hypoxemia?

From the shunt equation, arterial oxygen content is related to the change in pulmonary capillary oxygen content, venous oxygen content, and venous admixture. It is easier to classify hypoxemia into the following three categories.

Decreased pulmonary capillary oxygen tension

- Hypoventilation
- Low F_{IO_2}
- Ventilation/perfusion mismatch from pulmonary parenchymal change
- Diffusion abnormality (rare)

Increased shunting

- Either intrapulmonary or cardiac

Reduced venous oxygen content

- Congestive heart failure—low cardiac output
- Increased metabolism—fever, hyperthyroidism, shivering
- Decreased arterial oxygen content—anemia

Miller RD, ed. *Miller's Anesthesia.* 7th ed. Philadelphia: Churchill Livingstone; 2010:373–374.

B.13. Would you order any special preoperative preparations for asthmatic patients with COPD?

Yes. The preoperative preparation should include the following:

- Eradication of acute and chronic infection with appropriate antibiotics
- Relief of bronchial spasm with a bronchodilator
- Chest physiotherapy to improve sputum clearance and bronchial drainage
- Reversal of uncompensated or borderline cor pulmonale with diuretics, digitalis, improved oxygenation, and correction of acidemia by more efficient ventilation
- Correction of dehydration and electrolyte imbalance
- Familiarization with respiratory therapy equipment likely to be used in the postoperative period
- Cessation of smoking, if possible for 2 months, to improve mucociliary clearance and decrease sputum production
- Abstinence from smoking for 2 days (at least 12 hours), to reduce carboxyhemoglobin levels, resulting in improvement of blood oxygen content and increasing the release of oxygen in hemoglobin
- Continuation of anti-inflammatory and bronchodilator therapy up to the time of surgery
- Initiation of steroid therapy with oral methylprednisolone 40 mg for 5 days before elective surgery for patients with newly diagnosed disease, poorly compliant patients, and patients with ongoing wheezing

B.14. How long would you postpone elective surgery if the patient had a recent upper respiratory infection (URI)?

Respiratory tract infections are the most common stimuli that evoke acute exacerbations of asthma. The airway responsiveness of even healthy subjects to nonspecific stimuli is transiently increased after a viral infection. It is unclear how long surgery should be delayed following a URI because airway hyperreactivity can last 2 to

8 weeks after the infection in both healthy subjects and patients with asthma. Cohen and Cameron reported that if a child had a URI and had endotracheal anesthesia, the risk of a respiratory complication increased 11-fold. In addition, Tait and Knight found that laryngospasm and bronchospasm were significantly increased even in healthy children 2 weeks after a URI. Therefore, the recommendation is to wait 2 to 3 weeks after clinical recovery from a URI in patients with asthma even if clinical symptoms are not present. Nevertheless, a frequently cited retrospective study by Warner et al. found no increase in incidence of intraoperative bronchospasm in the patients with asthma who have had a recent URI.

B.15. What medicines would you expect the patient to have taken in the past or to be taking at the present time?

The main drugs for asthma can be divided into bronchodilators, which are for rapid relief of bronchoconstriction, and controllers, which inhibit the underlying inflammatory process. There are three bronchodilators in current use: β_2-agonists, anticholinergics, and theophylline; of these, β_2-agonists are the most effective. Inhaled corticosteroids are by far the most effective controllers for asthma, and their early use has revolutionized asthma therapy. Special attention is required if the patient has taken systemic corticosteroids. Recently, aerosol therapy has become quite popular because it provides optimal local therapeutic effects and minimizes the systemic side effects. Various relatively selective β_2-agonists (albuterol, fenoterol, terbutaline, and bitolterol), anticholinergic bronchodilators (ipratropium bromide and methylatropine nitrate), a mast cell stabilizer (cromolyn), leukotriene receptor antagonists such as zafirlukast (Accolate) and montelukast (Singulair), and various corticosteroids are now available as aerosols and are able to control most cases of chronic asthma.

B.16. Would you order preoperative steroid preparation? Why?

It is recommended that preoperative corticosteroid replacement therapy be given to all patients with known or suspected adrenal insufficiency. Patients who have been treated with systemic steroids for more than 2 weeks within the previous 6 months should also be assumed to have an unknown element of adrenocortical suppression that should be treated with full replacement therapy for major stress or surgery. The

human adrenal glands normally secrete approximately 30 mg of hydrocortisone (cortisol) per day under baseline conditions; nevertheless, under stress up to 200 to 500 mg per day may be secreted. It is reasonable to replace 300 mg of hydrocortisone per day during perioperative periods. A 100-mg dose of hydrocortisone phosphate is given intravenously before induction and during surgery. Postoperatively, hydrocortisone phosphate 100 mg intravenously is given every 8 hours for 48 hours. The biologic half-life of hydrocortisone is 8 to 12 hours. If the patient received less than 1 week of systemic steroid therapy more than 6 months previously and there are no signs of adrenal insufficiency, routine steroid preparation is not advised. However, intravenous steroid preparations should be available in the operating room in case intractable hypotension from adrenal insufficiency occurs during surgery.

The increasing emphasis on reactive airways as an inflammatory disease has led to greater appreciation of the importance of steroids in controlling the incidence of attacks and in aborting acute attacks. It has been recommended that systemic steroid preparation be used preoperatively in patients with moderate to severe asthma and a history of a need for systemic steroids in the past. One day of high-dose steroids should not significantly affect wound healing. In the face of ongoing wheezing and scheduled elective surgery, oral methylprednisolone 40 mg daily for 5 days before surgery has been shown to decrease postintubation bronchospasm. The concern that steroids will increase the rate of wound-healing problems or infection is not well founded. A study of patients with asthma treated with steroids preoperatively found no increase in the incidence of wound infections or wound-healing problems.

Woods BD, Sladen RN. Perioperative considerations for the patient with asthma and bronchospasm. *Br J Anaesth*. 2009;103(suppl l):i57–i65.

B.17. What is the onset of action of intravenous steroid therapy in asthma?

The bronchial effects of intravenous steroids are not immediate and may not be seen for 4 to 6 hours after initial administration. When severe bronchospasm does not resolve despite intense optimal bronchodilator therapy, intravenous corticosteroid administration is indicated. A loading dose of hydrocortisone 4 mg per kg is given to achieve plasma cortisol levels above 100 μg per dL, followed by 3 mg per kg every 6 hours. Alternatively, methylprednisolone, 125 mg, may be given every 6 hours.

Woods BD, Sladen RN. Perioperative considerations for the patient with asthma and bronchospasm. *Br J Anaesth*. 2009;103(suppl l):i57–i65.

B.18. What are the effects of H_2-receptor antagonists on patients with asthma?

Nathan et al. found that histamine mediates bronchoconstriction through the H_1-receptor (blocked by chlorpheniramine) and bronchodilation is mediated by H_2-receptor agonists (blocked by cimetidine). H_2-receptors are thought to be responsible for inhibitory feedback control of mediator release. Cimetidine may potentiate histamine H_1-receptor bronchoconstriction. It should be avoided in asthmatic patients. H_2-receptor antagonists also slow clearing of theophylline by inhibiting microsomal metabolism. Therefore, theophylline dosage should be decreased to avoid toxicity.

Hines RL, Marschall KE, eds. *Stoelting's Anesthesia and co-existing disease*. 5th ed. Philadelphia: Churchill Livingstone, 2008:163–173.

B.19. How would you premedicate the patient? Why?

Inhaled or systemic steroids may be given to patients with moderate-to-severe asthma to decrease the incidence of asthmatic attacks. Anti-inflammatory and bronchodilator therapy should be continued up to the time of surgery.

No good controlled studies have been performed on premedication used in patients with asthma. The patient with asthma may be premedicated with atropine and diphenhydramine. Atropine is an anticholinergic drug. It decreases airway resistance and diminishes secretion-initiated airway reactivity. Diphenhydramine is an H_1-receptor–blocking drug. It inhibits histamine-mediated bronchoconstriction and possesses a sedative effect. The sedative effect of diphenhydramine may prevent bronchospasm induced by psychological stress. Hydroxyzine hydrochloride (Vistaril) is a frequently used alternative because of its sedative, antihistaminic, and bronchodilating effects.

C. Intraoperative Management

C.1. What are the disadvantages of administering atropine to the patient with asthma?

Some physicians consider atropine relatively contraindicated because it causes drying of secretions, further plugging, and perhaps initiation of a severe attack of asthma. This assumption has proved more theoretic than real in the reasonably well-managed asthmatic patient. Moreover, atropine blocks the formation of cyclic guanosine monophosphate and therefore has a bronchodilation effect. Inhaled atropine improves FEV_1 in 85% of patients with COPD.

C.2. If the patient had a severe asthmatic attack in the operating room before the induction of anesthesia, would you proceed with the anesthetic or postpone the surgery?

First, medical treatment should be given to relieve the asthmatic attack. Elective surgery should be postponed, and the patient should be reevaluated carefully and better prepared preoperatively. In the case of emergency surgery, such as acute appendicitis, the surgery can be performed after the asthmatic attack is successfully treated. Regional anesthesia, if feasible, should be considered. During surgery, the medical treatment should be continued.

C.3. The patient did not have an asthmatic attack in the operating room. How would you induce anesthesia? Would you use a laryngeal mask airway (LMA) instead of an endotracheal tube?

The principles of anesthetic management for the asthmatic patient are threefold: to block airway reflexes before laryngoscopy and intubation, to relax airway smooth muscle, and to prevent release of biochemical mediators. Before induction of anesthesia, I like to ask the patient to take two or three puffs of albuterol from a metered-dose inhaler (MDI). Propofol 2.5 mg per kg is used for induction. Then oxygen and a potent inhalation agent, such as halothane or sevoflurane, are administered by mask to achieve adequate depth of anesthesia that suppresses hyperreactive airway reflexes sufficiently to permit tracheal intubation without triggering bronchospasm. The lesser pungency of sevoflurane and halothane (compared with desflurane and isoflurane) may decrease the likelihood of coughing, which can induce bronchospasm. Endotracheal intubation is accomplished following injection of succinylcholine or other muscle relaxants. Topical endotracheal spray of lidocaine 80 to 120 mg through a laryngotracheal anesthesia kit may be used before intubation to suppress the cough reflex induced by intubation, but the introduction of lidocaine itself may cause the cough reflex when an adequate depth of anesthesia has not been achieved.

As a supraglottic airway, the LMA seems to be suitable for patients with asthma. The LMA provides a unique opportunity for the clinician to control the airway without having to introduce a foreign body into the trachea. Therefore, it may be an ideal airway tool in the patient with asthma who is not at risk for reflux and aspiration. The patient is undergoing cholecystectomy, which may require manipulating and packing of stomach and bowels, and is at risk for regurgitation and aspiration. Meanwhile, the patient may need a nasogastric tube for gastrointestinal tract decompression. The classic LMA device (except LMA-ProSeal) is not compatible with the use of a nasogastric tube intraoperatively. I would not choose a classic LMA instead of an endotracheal tube for this procedure. Nevertheless, the introduction of the LMA-ProSeal with a gastric drain tube and larger cuff reduces both the risk for gastric inflation and aspiration of refluxed gastric contents. The LMA-ProSeal has been successfully used for laparoscopic cholecystectomy in obese patients.

C.4. Why would you use propofol for induction of anesthesia?

Propofol may be the induction agent of choice for the patient with reactive airways who is hemodynamically stable. A recent report found that induction of patients with asthma with propofol 2.5 mg per kg of body weight resulted in a significantly lower incidence of wheezing after tracheal intubation compared with induction of thiopental or thiamylal 5 mg per kg or methohexital 1.75 mg per kg of body weight. The incidence of wheezing was 0%, 45%, and 26% in patients who received propofol, a thiobarbiturate, and oxybarbiturate, respectively. Another study found that in unselected patients, propofol resulted in a significantly lower respiratory resistance after tracheal intubation than induction with thiopental or etomidate. Nevertheless, propofol-induced bronchospasm has been reported in patients with allergic rhinitis. Therefore, propofol should be used with caution in patients who are allergic.

Pizov R, Brown RH, Weis YS, et al. Wheezing during induction of general anesthesia in patients with and without asthma: a randomized, blind trial. *Anesthesiology.* 1995;82:1111–1116.

C.5. Would you use thiopental, methohexital, etomidate, or ketamine for induction?

Thiopental and thiamylal, but not methohexital and pentobarbital, have been demonstrated to release histamine. Thiopental and thiamylal are thiobarbiturates, and methohexital and pentobarbital are oxybarbiturates. This suggests that the sulfur atom is important in barbiturate-induced histamine release. Moreover, they further found that thiobarbiturates, but not oxybarbiturates, constricted guinea pig tracheas and that this constriction was mediated by thromboxane. Therefore, methohexital may be preferred as the induction agent in patients showing extreme sensitivity to histamine (asthmatics) or increased histamine releasability (atopics). Nevertheless, thiopental does not cause bronchospasm. Because it provides only a light plane of anesthesia, airway instrumentation under thiopental anesthesia alone may trigger bronchospasm. Therefore, clinically, both barbiturates have been used successfully in patients with asthma, provided that an adequate depth of anesthesia is achieved before stimulating the airway.

Etomidate does not depress myocardial function and therefore provides hemodynamic stability in critically ill patients. Although it was advertised as an ideal agent for patients with asthma, little evidence supports the claim except that etomidate does not release histamine. A study suggests that neither etomidate nor thiopental prevents wheezing after intubation, as opposed to the marked protection afforded by propofol.

Ketamine produces bronchodilation both through neural mechanisms and through release of catecholamines. In an actively wheezing patient, ketamine is the induction agent of choice, particularly when hemodynamics are unstable.

Hirshman CA, Edelstein RA, Ebertz JM, et al. Thiobarbiturate-induced histamine release. *Anesthesiology*. 1985;63:353.

C.6. Would you use lidocaine for intubation?

Intravenous lidocaine 1 mg per kg has been given 1 to 2 minutes before intubation to prevent reflex-induced bronchospasm. Topical endotracheal spray of lidocaine must be used cautiously because it may provoke reflex bronchoconstriction if adequate depth of anesthesia has not been achieved. Lidocaine infusion 1 to 2 mg/kg/hr may be used in cardiac or elderly patients with COPD whose airways need more anesthesia than their cardiovascular system can tolerate.

Although intravenous lidocaine can attenuate reflex-induced bronchospasm, recent clinical studies suggested that it may cause paradoxical bronchospasm in patients with asthma. Therefore, intravenous lidocaine should be administered with caution in these patients.

C.7. If this is an emergency surgery and rapid sequence induction is indicated, how would you induce anesthesia in this patient?

All precautions to prevent aspiration of gastric contents and asthmatic attack must be considered simultaneously. Rapid sequence induction and tracheal intubation using propofol, or methohexital, and succinylcholine are necessary to prevent aspiration, but light anesthesia may precipitate severe bronchospasm.

Ketamine 2 mg per kg may be the induction agent of choice in patients without cardiac disease who have asthma, because ketamine increases catecholamine release with resultant bronchodilation.

In patients with asthma who have ischemic heart disease, we give a moderate dose of fentanyl 5 μg per kg 2 to 3 minutes before the administration of propofol 1.5 mg per kg or methohexital 1.5 mg per kg to suppress airway reflexes and prevent tachycardia and hypertension caused by intubation.

Intravenous lidocaine, 1 to 2 mg per kg given immediately before the administration of ketamine or fentanyl, and succinylcholine are useful adjunct drugs to prevent reflex bronchospasm, particularly in an emergency situation when deep anesthesia cannot be achieved before intubation.

A full stomach should be emptied by a functioning nasogastric tube. The patient should be denitrogenated with 100% oxygen by mask. Cisatracurium or vecuronium 1 mg should be given 3 minutes before administration of succinylcholine.

If the patient has a wheezing attack before anesthesia, inhalation of β_2-agonists such as albuterol may be used as the first-line therapy for acute asthmatic attacks.

Martin DE, Rosenberg H, Aukburg SJ, et al. Low-dose fentanyl blunts circulatory responses to tracheal intubation. *Anesth Analg*. 1982;61:680.

C.8. What is your choice of agents for maintenance of anesthesia? Why?

We use inhalation agents such as sevoflurane, halothane, and isoflurane with nitrous oxide and oxygen. Sevoflurane, enflurane, and isoflurane are preferable to halothane, because halothane sensitizes the myocardium to arrhythmic effects of circulating catecholamines more than sevoflurane, enflurane, and isoflurane. However, some authorities prefer halothane and sevoflurane to isoflurane and desflurane because the latter anesthetics have a pungent odor that may cause airway irritation and trigger bronchospasm. At lower doses (<1.0 minimum alveolar concentration), the inhaled anesthetics inhibit chemically induced tracheal contractions in the order: *halothane* > *enflurane* ≥ *isoflurane* > *sevoflurane*. More recent clinical observations in humans indicate that sevoflurane at 1.1 minimum alveolar concentration may be the most effective agent, particularly in the presence of airway instrumentation. In addition, sevoflurane may have a more rapid onset of bronchodilation than isoflurane or halothane.

Desflurane has been shown to cause elevations in airway resistance and tissue mechanical parameters, with markedly enhanced airway narrowing in children with asthma or a recent URI. Therefore, desflurane should be avoided in children with susceptible airways.

C.9. What are the mechanisms of volatile anesthetics that produce bronchodilation?

The volatile anesthetics relax airway smooth muscle primarily by directly depressing smooth muscle contractility. This action appears to result from direct effects on bronchial epithelium and airway smooth muscle cells and indirect inhibition of the reflex neural pathways. The mechanisms responsible for the direct relaxation effects involve decreases in intracellular calcium, an important regulator of smooth muscle reactivity. Several intracellular mediators responsible for mobilization of calcium ions are potential sites for the action of volatile anesthetics, but the predominant mechanism appears to be inhibition of cell membrane–associated voltage-dependent calcium channels, an action that decreases entry of calcium ions into the cytosol. Volatile anesthetic–induced increases in cyclic 3′,5′ adenosine monophosphate (cAMP) cause decreases

in free intracellular calcium by stimulating efflux of calcium and increasing uptake of calcium into the sarcoplasmic reticulum. This action contributes to airway smooth muscle relaxation. In addition, volatile anesthetics reduce calcium sensitivity as a result of inhibition of protein kinase C activity and inhibition of G protein function.

Barash PG, Cullen BF, Stoelting RK, et al., eds. *Clinical Anesthesia*. 6th ed. Philadelphia: Lippincott Williams & Wilkins; 2009:434.

Miller RD, ed. *Miller's Anesthesia*. 7th ed. Philadelphia: Churchill Livingstone; 2010:563–567.

C.10. Why would you choose an inhalational instead of an intravenous technique?

First, inhalation agents such as sevoflurane, halothane, enflurane, and isoflurane have dose-related direct bronchodilator effects. Ketamine has an indirect bronchodilator effect, which is not dose related and not predictable. Large doses of morphine produce bronchoconstriction because morphine increases central vagal tone and also releases histamine. Droperidol has an α-blocking effect that may relieve bronchospasm induced by α stimulation. Meperidine was shown to have a spasmolytic effect in patients with asthma but not in experimental dogs. Fentanyl does not have a significant effect on bronchial tone.

Second, cholinesterase inhibitors can induce bronchospasm. Inhalation agents potentiate muscle relaxants; therefore, lower doses of relaxants are needed for surgery. The use of cholinesterase inhibitors to reverse the effect of muscle relaxants may be avoided or decreased.

Woods BD, Sladen RN. Perioperative considerations for the patient with asthma and bronchospasm. *Br J Anaesth*. 2009;103(suppl l):i57–i65.

C.11. Is regional anesthesia better than general anesthesia in this situation?

This issue is controversial. The use of regional anesthesia avoids the possibility of bronchospasm that may be induced by endotracheal tube stimulation. Nevertheless, if high levels of sensory and motor block are required, they may produce severe anxiety and actually incite bronchospasm. Another concern is the associated blockade of sympathetic input to the lungs. Some case reports have speculated about a resultant increase in airway resistance. Respiratory complications were reported to be quite common (83%) in patients undergoing intraperitoneal surgery who had relatively high spinal anesthesia (T6–4). Low spinal, epidural, and caudal anesthesia for surgery of the perineum, lower extremities, and pelvic extraperitoneal organs resulted in fewer respiratory complications than did general anesthesia. A study of patients with asthma demonstrated no differences between those anesthetized with high epidurals (T2–4) and those undergoing general anesthesia with ketamine and isoflurane.

Endotracheal general anesthesia is advantageous because it provides a controlled airway to deliver the desirable oxygen concentration, but the endotracheal tube may also induce bronchospasm during light anesthesia.

Woods BD, Sladen RN. Perioperative considerations for the patient with asthma and bronchospasm. *Br J Anaesth*. 2009;103(suppl l):i57–i65.

C.12. Which muscle relaxants would you use? Why?

Muscle relaxants that cause histamine release should be avoided (Table 1.2). Rocuronium, cisatracurium, and vecuronium are the preferred relaxants because the histamine released is insignificant. Vecuronium, rocuronium, and cisatracurium may be better choices of relaxants because of their intermediate action durations, allowing early recovery without reversal with an anticholinesterase, which may precipitate bronchospasm. D-Tubocurarine can cause bronchospasm by histamine release. Metocurine and succinylcholine also cause histamine release but to a lesser extent. There is no evidence that succinylcholine is associated with increased airway resistance in patients with asthma. Gallamine has minimal histamine release but has been reported to cause bronchospasm. Atracurium, mivacurium, and doxacurium in high doses increase histamine release. Therefore, they are not the relaxants of choice.

C.13. In the middle of surgery, the patient developed a severe wheezing attack. How do you manage it?

First, deepen the level of anesthesia and increase F_{IO_2}. Remember that the patient is under anesthesia and undergoing surgery. Therefore, medical intervention, such as β-agonist administration, is not the first choice of treatment. The most common cause of asthmatic attack during surgery is inadequate depth of anesthesia. The patient with asthma has an extremely sensitive tracheobronchial tree. When the level of anesthesia is too light, the patient may develop bucking, straining, or coughing as a result of the foreign body (endotracheal tube) in the trachea and then bronchospasm. First, the blood pressure is taken to ensure it is normal or high, and then anesthesia is deepened by increasing the concentration of inhalation agents, such as sevoflurane, halothane, or isoflurane, which are direct bronchodilators as well. An incremental dose of ketamine may be a quick way of maintaining blood pressure, rapidly deepening anesthesia, achieving bronchodilation, and avoiding the problem of delivering an inhaled anesthetic to a patient with poor ventilation. At the same time, oxygenation can be improved by increasing the inspired oxygen concentration and decreasing nitrous oxide. The patient should be continuously ventilated with a volume-cycled ventilator.

Second, relieve mechanical stimulation. Pass a catheter through the endotracheal tube to suction secretions and determine whether there is an obstruction, kinking of the tube, or overinflation of the endotracheal tube cuff. The cuff of the endotracheal tube can be deflated, the tube moved back 1 to 2 cm, and the cuff reinflated. Occasionally, the endotracheal tube slips down and stimulates the carina of the trachea, causing severe bronchospasm during light anesthesia. Surgical stimulation, such as traction on the mesentery, intestine, or stomach, should be stopped temporarily, because it causes vagal reflex and can cause bronchospasm.

Third, medical intervention is necessary if the previously mentioned treatment cannot break the bronchospasm or the anesthesia cannot be increased because of hypotension. The cornerstone of the treatment of the intraoperative bronchospasm is inhalation of β_2-agonists such as albuterol, which induce further bronchodilation even

Table 1.2 Histamine Release from Nondepolarizing Muscle Relaxants

MUSCLE RELAXANT	HISTAMINE RELEASE[a]
Benzylisoquinolinium compounds	
D-Tubocurarine	0.6
Metocurine	2.0
Doxacurium	>4.0
Mivacurium	3.0

Cisatracurium	None
Steroidal compounds	
Pancuronium	None
Vecuronium	None
Pipecuronium	None
Rocuronium	None
Others	
Alcuronium	None
Gallamine	None

[a] Defined as the number of multiples of the ED_{95} for neuromuscular blockade required to produce histamine release.

in the presence of adequate inhalational anesthesia. Because of rain-out in the endotracheal tube, a considerably larger dose (8–10 puffs) should be given to achieve adequate therapeutic levels. When severe bronchospasm is not resolving despite intense optimal bronchodilation therapy, high-dose intravenous corticosteroids are indicated (see sections B.16 and B.17). If bronchospasm remains refractory, epinephrine 5 to 10 μg can be given intravenously, although this has a high risk of exacerbating tachycardia and tachyarrhythmias. Alternatively, a continuous infusion of epinephrine 0.5 to 2 μg per minute in adults can provide maintenance bronchodilation with fewer adverse effects.

Fourth, bring in an intensive care unit (ICU) ventilator. Anesthesia ventilators are not designed for patients with high airway resistance. It is impossible to deliver adequate alveolar ventilation because the anesthesia circuit has too much compressible volume (tubing compliance) and the anesthesia ventilator does not have sufficient driving power. An ICU ventilator can generate inspiratory pressures as high as 120 cm H_2O. With low tubing compliance, little ventilation is wasted into the circuit. A high inspiratory flow rate allows for shorter inspiratory time with adequate time for expiration and lower auto-positive end-expiratory pressure. The major disadvantage of an ICU ventilator is its inability to use inhalational anesthetics. However, the Siemens 900D anesthesia machine incorporates an ICU-type ventilator with vaporizers and oxygen mixers. It may be ideal for this situation.

C.14. How would you give β_2-agonists? What is their mechanism of action on asthma?

In the past, it was fashionable to treat episodes of severe asthma with intravenous sympathomimetics such as isoproterenol. This approach no longer appears justifiable. Isoproterenol infusions can induce ventricular arrhythmias during halothane anesthesia. In addition, isoproterenol infusion can clearly cause myocardial damage, and even the β_2-selective agents such as terbutaline and albuterol when given intravenously offer no advantages over the inhaled route.

β_2-agonists such as albuterol, terbutaline, fenoterol, and pirbuterol may be administered through MDI adapters or small-volume jet nebulizers to the anesthetic circuit. Because MDI adapters are not very efficient in the intubated patient, 8 to 10 puffs are needed to break acute bronchospasms.

Adrenergic stimulants produce bronchodilation through action on β-adrenergic receptors. β-agonists increase intracellular cAMP by activating adenyl cyclase, which produces cAMP from adenosine triphosphate. Increased cAMP promotes bronchial relaxation and inhibits the release of mediators from mast cells (Fig. 1.6).

(From Hirshman C. Airway reactivity in humans: anesthetic implications. Anesthesiology. 1983;58:170, with permission.)

C.15. Would you administer aminophylline? How does aminophylline relieve bronchospasm? What is the mechanism of action? What are the toxic effects of aminophylline?

Currently, aminophylline is rarely used for acute bronchospasm because of its narrow therapeutic–toxic window and its relatively weak bronchodilating effect. In addition, aminophylline does not add to the bronchodilating efficacy of inhaled anesthetics.

It was formerly thought that aminophylline increases intracellular cAMP through inhibition of the enzyme phosphodiesterase, which inactivates cAMP (Fig. 1.6). However, the available evidence does not support this concept. There is increasing evidence that theophylline at lower doses has anti-inflammatory effects, which are likely mediated through different molecular mechanisms. Theophylline activates the key nuclear enzyme histone deacetylase-2, which is a critical mechanism for switching off activated inflammatory genes. The common side effects of aminophylline include nervousness, nausea, vomiting, anorexia, and headache; cardiac arrhythmias and seizures occur with high plasma levels.

Tobias JD, Kubos KL, Hirshman CA. Aminophylline does not attenuate histamine-induced airway constriction during halothane anesthesia. *Anesthesiology*. 1989;71:723–729.

C.16. If the patient does not respond to the aforementioned treatment and becomes cyanotic, what would you do?

The ABG values should be determined immediately. In a severe, prolonged asthmatic attack, there will be combined respiratory and metabolic acidosis resulting from CO_2 retention and lactic acidosis from tissue hypoxia. Hypercarbia, hypoxemia, and acidemia promote arrhythmias and impair the response to bronchodilator therapy. $NaHCO_3$ should be given to correct the acidosis, because β-agonists are not effective in severe acidosis. At the same time, bronchodilator therapy should be continued or increased. Consultation with senior staff or a physician in pulmonary medicine may be necessary.

Woods BD, Sladen RN. Perioperative considerations for the patient with asthma and bronchospasm. *Br J Anaesth*. 2009;103(suppl l):i57–i65.

C.17. What are the differential diagnoses of intraoperative bronchospasm?

The causes of wheezing and increased airway pressure include the following:

- Mechanical obstruction of endotracheal tube
  - Kinking
  - Solidified secretions or blood
  - Overinflation of tracheal tube cuff
- Inadequate depth of anesthesia
- Pulmonary edema
- Tension pneumothorax
- Aspiration pneumonitis
- Pulmonary embolism
- Endobronchial intubation
- Persistent coughing and straining
- Asthmatic attack

Hines RL, Marschall KE, eds. *Stoelting's Anesthesia and Co-existing Disease*. 5th ed. Philadelphia: Churchill Livingstone; 2008:163–173.

C.18. The asthmatic attack was finally relieved, and the surgery was completed. The patient was found to be hypoventilating. What are the common causes of hypoventilation? Would you like to reverse the muscle relaxant?

The following are common causes of apnea or hypoventilation at the end of surgery:

- Respiratory center depression by inhalational anesthetics, opioids, or mechanical hyperventilation (low $Paco_2$)
- Peripheral blockade by muscle relaxants

Because the patient has severe asthma, it is better to avoid the use of an anticholinesterase, such as neostigmine, to reverse a nondepolarizing relaxant. Neostigmine may trigger bronchospasm by cholinergic and prosecretory effects. Although atropine or glycopyrrolate given simultaneously with neostigmine may prevent bronchospasm, the action duration of neostigmine can outlast that of a vagolytic agent, especially in the presence of renal insufficiency. If reversal is required, it appears prudent to administer larger than customary doses of glycopyrrolate (>0.5 mg) or atropine (>1 mg) to minimize the possibility of bronchospasm. It is advisable to use inhalation agents to potentiate relaxants and to use smaller amounts of intermediate-acting relaxants for surgery. If spontaneous respiration is not adequate, artificial ventilation should be continued.

Woods BD, Sladen RN. Perioperative considerations for the patient with asthma and bronchospasm. *Br J Anaesth*. 2009;103(suppl l):i57–i65.

D. Postoperative Management

D.1. Would you extubate the patient with asthma while he or she was deeply anesthetized?

To avoid bronchospasm triggered by coughing and bucking caused by laryngeal and pharyngeal reflexes during emergence and extubation, patients may be extubated at surgical (deep) levels of anesthesia. However, the risks of aspiration, airway obstruction, and hypoventilation should be weighed against the benefits. With a history of severe COPD, chronic hypoxemia, and CO_2 retention, the patient was not a good candidate for extubation while deeply anesthetized. A systematic approach for emergence and extubation is illustrated in Figure 1.7. However, the guidelines do not include all possible patient-surgical-anesthetic conditions. Certainly, the practitioner's clinical judgment is of utmost importance in the decision about whether to extubate the patient.

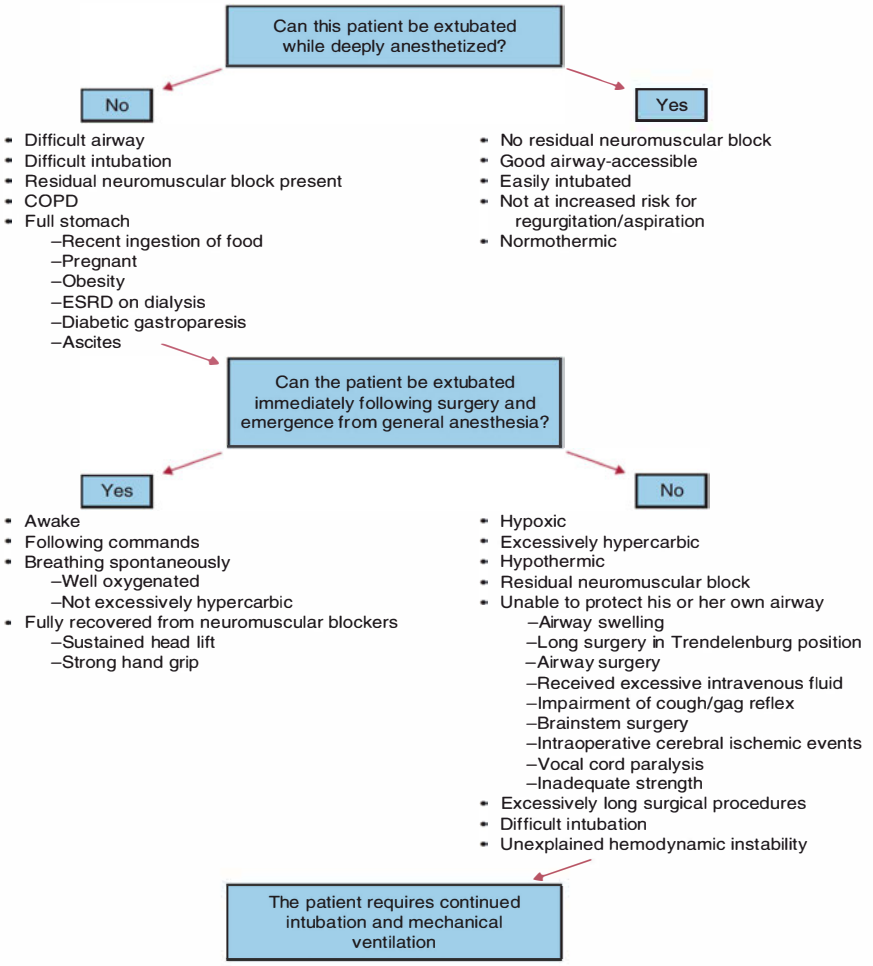

Figure 1.7 A systematic approach to emergence and extubation. COPD, chronic obstructive pulmonary disease; ESRD, end-stage renal disease.

D.2. When the patient cannot be extubated early in the recovery room, how would you keep the endotracheal tube in place without causing bronchoconstriction?

Loading doses of lidocaine, followed by continuous infusion, as described in section C.6, may be administered intravenously to prevent bronchoconstriction induced by stimulation of the endotracheal tube. β_2-agonists such as albuterol may be administered through MDI adapter to prevent bronchospasm. Alternatively, an LMA may be used to replace the endotracheal tube for control of ventilation and to avoid tracheal stimulation.

Woods BD, Sladen RN. Perioperative considerations for the patient with asthma and bronchospasm. *Br J Anaesth.* 2009;103(suppl l):i57–i65.

Hines RL, Marschall KE, eds. *Stoelting's Anesthesia and Co-existing Disease*. 5th ed. Philadelphia: Churchill Livingstone; 2008:163–173.

D.3. In patients with asthma, are Opioids contraindicated for postoperative pain control?

Opioids should be used very carefully because prolonged respiratory depression may further compromise the airway. Morphine is avoided because of possible histamine release and increased central vagal tone, which may cause bronchospasm. Meperidine may be a better choice for postoperative analgesia because of its spasmolytic action. Narcotics should be titrated carefully to control pain and not depress respiration. Poor pain control may compromise respiration because of splinting of the thoracic cage and decreased ability to cough. Paravertebral or intercostal nerve blocks, epidural analgesia, or transcutaneous electrical nerve stimulation may be used to control postoperative pain without depressing respiration.

NSAIDs precipitate acute bronchospasm in an estimated 8% to 20% of adult patients with asthma. NSAIDs block the cyclooxygenase-mediated conversion of arachidonic acid to prostaglandins, thereby shunting arachidonic acid toward the formation of bronchoconstrictor leukotrienes. Therefore, it may be prudent to avoid NSAIDs for postoperative pain control.

Miller RD, ed. *Miller's Anesthesia*. 7th ed. Philadelphia: Churchill Livingstone; 2010:786.

D.4. The patient was breathing well and was extubated. How much oxygen would you give to this patient with asthma and COPD in the recovery room?

For a small proportion of patients with COPD, the hypoxic drive might be taken away by increased F_{IO_2}. Moreover, oxygen therapy may abolish hypoxic pulmonary vasoconstriction in poorly ventilated areas, increasing blood flow to these areas and so decreasing blood flow to other lung regions with normal or high ventilation/perfusion ratios. These regions will then contribute to alveolar dead space, causing an increase in P_{aCO_2}. It is important to monitor the patient's respiration, oxygenation, and P_{aCO_2} very carefully during oxygen therapy. Venturi masks with F_{IO_2} of 0.24 to 0.4 may be used for patients with COPD. Nevertheless, adequate oxygen concentration must be used in the presence of hypoxemia. Hypoventilation can be assisted or controlled by artificial ventilation.

CHAPTER 2

Bronchoscopy, Mediastinoscopy, and Thoracotomy

Alessia Pedoto, Paul M. Heerdt, and Fun-Sun F. Yao

A 60-YEAR-OLD MAN

has suffered from cough, intermittent hemoptysis, and weight loss for 2 months. He has smoked one pack of cigarettes per day for 40 years. A chest radiograph 1 month ago revealed a right middle lobe infiltrate that was treated with antibiotics without clinical improvement. Subsequent evaluation revealed a carcinoma. He is now scheduled for fiber-optic bronchoscopy, mediastinoscopy, and possible video-assisted thoracoscopic (VATS) lobectomy.

A. Medical Disease and Differential Diagnosis

1. How is the diagnosis of lung carcinoma made? What is your prediction for the most likely type of malignancy?
2. What are the less common manifestations of bronchogenic carcinoma?
3. The patient has a long history of cigarette smoking. What is the significance of this finding?

B. Preoperative Evaluation and Preparation

1. How would you evaluate the patient preoperatively?
2. What are the pulmonary function guidelines that indicate increased risk for morbidity and mortality?

C. Intraoperative Management

1. How would you premedicate, monitor, and anesthetize this patient?
2. How many types of bronchoscopes are available and what are the intraoperative considerations of each one?
3. What are the indications for cervical mediastinoscopy? Are there potential complications?
4. The decision was made to proceed with a right VATS middle lobectomy. How would this alter your management?
5. What are the indications for single-lung ventilation and how can it be accomplished?

6. What are the contraindications to the use of double-lumen endotracheal tubes (DLTs)?
7. Would you use a right- or left-sided double-lumen tube?
8. How do you know that the tube is in the correct position?
9. How many types of bronchial blockers are available? What are the advantages and disadvantages of bronchial blockers?
10. How will systemic oxygenation be monitored during single-lung ventilation? What is the mechanism of pulse oximetry?
11. The patient was placed in the lateral decubitus position. Describe the effects of lateral positioning on pulmonary blood flow and respiration.
12. What is hypoxic pulmonary vasoconstriction (HPV)?
13. What are the effects of anesthetic agents on HPV and their clinical implications?
14. Discuss pulmonary blood flow distribution, shunt flow, and Pao_2 (F_IO_2 = 1.0) during single-lung ventilation in the lateral position.
15. How could you improve oxygenation during single-lung ventilation?
16. A right middle lobectomy was performed. Would you extubate the trachea at the end of the procedure?

D. Postoperative Management

1. What are the immediate life-threatening complications that follow lobectomy or pneumonectomy?
2. Why is it important to control postoperative pain? How would you achieve this?

A. Medical Disease and Differential Diagnosis

A.1. How is the diagnosis of lung carcinoma made? What is your prediction for the most likely type of malignancy?

The initial presenting symptoms in patients with lung cancer may be respiratory, but in the majority of cases, they are constitutional and nonspecific, mainly related to metastatic disease. Nonproductive cough, dyspnea, hemoptysis, and chest pain, along with an unresolved lung infiltrate on chest radiography should suggest carcinoma. The diagnosis and extent of the disease are confirmed by sputum cytology, bronchoscopy and endobronchial brush biopsy, biopsy of palpable lymph nodes in the neck or axilla, needle aspiration biopsy, mediastinoscopy, and possibly exploratory thoracoscopy or thoracotomy. Before any major surgical approach, an extensive evaluation is done to diagnose metastases that would contraindicate surgery.

Cancers of the lung account for 16% of all malignancies and nearly 30% of cancer deaths worldwide. Bronchogenic carcinomas represent the vast majority of lung cancers in patients requiring surgical resection and can be classified into four major types: small cell, large cell, squamous cell, and adenocarcinoma. For surgical purposes, lung tumors are classified as non–small cell or small cell. The former are amenable to surgical resection, while the latter tend to be nonresectable and are treated medically.

Further subclassification of lung tumors involves the TNM system, in which T designates tumor site, size, and local extent; N, the presence and location of regional lymph node involvement; and M, the presence of distal metastases beyond the ipsilateral hemithorax. The TNM classification is used in the staging of bronchogenic carcinomas and helps predict response to therapy. In general, small cell carcinomas that spread beyond possible resection by the time of presentation are primarily managed with chemotherapy, with or without radiation. The 5-year survival after chemotherapy and radiation with curative intent is approximately 20%. In contrast, non–small cell cancers found to be localized at the time of presentation should be considered for

primary resection. The 5-year survival depends on tumor staging, but can be as high as 85% for small tumors without regional lymph node involvement or metastases (stage I). Approximately 45% of patients present with circumscribed extrapulmonary disease or lymphatic spread to the ipsilateral mediastinal or subcarinal lymph nodes (stage IIIa). Their 5-year postresection survival is less than 20%.

A.2. What are the less common manifestations of bronchogenic carcinoma?

Other manifestations of lung tumors are primarily related to mass effects or altered metabolism. In addition to bronchial obstruction (evident in this patient) that can lead to postobstructive pneumonia, mass effects include invasion into the chest wall and pleura, compression of great vessels (e.g., superior vena cava syndrome) and heart, tracheobronchial displacement, paresis of the recurrent laryngeal or phrenic nerves as well as the sympathetic chain, and Pancoast syndrome (pain and upper extremity weakness secondary to invasion of the brachial plexus as well as the first and second thoracic and eighth cervical nerve roots). Recognized metabolic manifestations of small cell lung tumors include symptoms that resemble those of Cushing syndrome (from ectopic adrenocorticotropic hormone production), carcinoid syndrome, hypercalcemia and hypophosphatemia (resulting from ectopic parathyroid hormone or parathyroid hormone-related peptide), hypokalemia (caused by ectopic adrenocorticotropic hormone secretion), and hyponatremia (from inappropriate secretion of antidiuretic hormone and possibly atrial natriuretic factor). Neurologic paraneoplastic syndromes include Eaton-Lambert myasthenic syndrome, peripheral neuritis involving both motor and sensory components, cerebellar degeneration, retinopathy, limbic encephalopathy, and autonomic neuropathy. An autoimmune process has been suggested for these findings, and it seems to be more common in patients with limited disease.

Extrathoracic spread of the tumor can contribute to the nonspecific presentation. Structures involved include the bones, liver, adrenal glands, intra-abdominal and subcutaneous lymph nodes, brain, and spinal cord.

A.3. The patient has a long history of cigarette smoking. What is the significance of this finding?

Cigarette smoking promotes the development of chronic obstructive pulmonary disease (COPD), which includes chronic bronchitis and emphysema, and is strongly associated with an increased incidence of stroke, myocardial infarction, and cancer

(lung, oral cavity, larynx, and esophagus) compared to nonsmokers. Evidence of chronic pulmonary changes can be seen in the preoperative pulmonary function tests. Pulmonary hypertension and cor pulmonale may also occur in this patient population.

In patients who smoke at the time of surgery, there is an increased risk of postoperative complications and a higher 5-year mortality rate. Respiratory failure, pneumonia, aspiration, air leak, and atelectasis are all increased. Therefore, smoking cessation is highly recommended at the time of diagnosis. Although carboxyhemoglobin concentrations decline substantially within 12 hours of smoking cessation, it remains unclear for how long smoking must be discontinued to see a significant reduction in postthoracotomy complications. For patients undergoing cardiac surgery, a period of 2 months is suggested to see an impact on postoperative pulmonary function. This is mainly due to improved mucociliary function. In patients undergoing thoracic surgery, the benefits of smoking cessation must be balanced with the risk of local tumor growth and metastatic spread, which may preclude resectability. Four weeks has been suggested as an acceptable time by several studies in this population.

B. Preoperative Evaluation and Preparation

B.1. How would you evaluate the patient preoperatively?

Preoperative evaluation should include a complete history, physical examination, and laboratory tests (e.g., complete blood count, basic metabolic profile, coagulation study, electrocardiogram, chest radiography, and computed tomographic imaging). The main goal for preoperative evaluation is to identify in advance those patients at risk for major postoperative complications and optimize their functional status. A positive smoking history, especially if current, cough, sputum production, orthopnea, and dyspnea are hallmarks of cardiopulmonary disease and should be further investigated. An abnormal exercise tolerance, such as the inability to climb at least three flights of stairs or walk for 6 minutes, may indicate a patient with compromised response to the stress of anesthesia and surgery. The majority of patients are now admitted to the hospital on the day of surgery; therefore, a brief review of symptoms, physical limitations, interval changes, and airway anatomy should be performed before entering the operating room.

In addition to routine preoperative testing, patients scheduled for lung resection usually undergo pulmonary function testing to help define the relative risks of the planned resection. Respiratory function can be assessed by:

- **Respiratory mechanics:** Forced vital capacity (FVC), forced expiratory volume in the first second (FEV_1), and the ratio between residual volume and total lung capacity (RV/TLC).

- **Cardiopulmonary reserve:** Maximal oxygen uptake (VO_2 max), stair climbing, 6-minute walk, and shuttle walk. VO_2 max in particular is the gold standard for aerobic capacity and cardiorespiratory fitness. Patients with VO_2 max value less than 10 mL/kg/min are at increased risk for postoperative morbidity and mortality.
- **Lung parenchymal function:** Diffusing lung capacity for carbon monoxide (DLCO), partial pressure of oxygen in arterial blood (Pao_2), and partial pressure of arterial carbon dioxide ($Paco_2$). Predicted postoperative DLCO and FEV_1 less than 40% to 44% are significant independent predictors for increased postoperative morbidity and mortality.

Colice GL, Shafazand S, Griffin JP, et al. Physiologic evaluation of the patient with lung cancer being considered for resectional surgery: ACCP evidence-based clinical practice guidelines (2nd ed.). *Chest*. 2007;132:161S–177S.

Van Tilburg PM, Stan H, Hoogsteden HC, et al. Pre-operative pulmonary evaluation of lung cancer patients: a review of the literature. *Eur Resp J*. 2009;33:1206–1215.

B.2. What are the pulmonary function guidelines that indicate an increased risk for morbidity and mortality?

The reported mortality from lung resection is between 2% and 4%, mainly as a result of pneumonia, respiratory failure, bronchopleural fistula, empyema, and pulmonary embolism. Respiratory insufficiency occurs in approximately 5% of patients following lung resection and is associated with a 50% mortality rate. Advanced age and the associated increased incidence of concomitant nonpulmonary disease seem to contribute to this outcome. An increased risk of postoperative complications can be predicted by the following:

- **Spirometry:** Spirometric parameters, such as FEV_1/FVC ratio and FEV_1 (reflective of the degree of airway obstruction), as well as static volumes (such as inspiratory and total lung capacity), are used to define the severity of COPD. Several studies have indicated a strong correlation between predicted postoperative FEV_1 and DLCO and a respective increase in morbidity and mortality, especially for open procedures and extensive dissection. Concerning values are summarized in Table 2.1.
- **Arterial blood gases:** Historically, hypercapnia ($Paco_2$ greater than 45 mm Hg) was considered an exclusion criterion for lung resection. However, no independent correlation has been found with an increased mortality. Patients who are hypercapnic often have a low predicted postoperative FEV_1 and an abnormal exercise capacity, which preclude surgery. Preoperative hypoxemia (Pao_2 less than 50 mm Hg, and percentage of available hemoglobin saturated with oxygen [Sao_2] less than 90%) has been associated with an increased risk of postoperative complications. However, baseline hypoxemia can be the result of ventilatory mismatch caused by obstructive tumors that once resected may theoretically improve gas exchange.

Other factors influencing outcome include patient comorbidities and functional status, the extent and location of the proposed surgical resection, and whether the patient has undergone preoperative induction chemotherapy. An improvement in both surgical and anesthesia techniques has broadened the criteria for surgical respectability. As evident from lung volume reduction studies, patients with severely impaired pulmonary function (e.g. FEV_1 less than 1 L) can still undergo surgical resection under general anesthesia without prohibitive risk for postoperative complications. Moreover,

Table 2.1 Minimal Pulmonary Function Test Criteria for Various-Sized Pulmonary Resections

TEST	UNIT	NORMAL	PNEUMONECTOMY	LOBECTOMY	BIOPSY OR SEGMENTAL
MBC	L/min	>100	>50	>40	>25
MBC	Percentage predicted	100%	>50%	>40%	>25%
FEV_1	Liters	>4	>2.1–1.7	>1.2–1.0	>0.6–0.9
FEV_1	Percentage	>80% FVC	>50% FVC	>40% FVC	>40% FVC
$FEV_{25\%–75\%}$	Liters	>2	>1.6	>0.6–1.6	>0.6

$FEV_{25\%–75\%}$, forced expiratory volume from 25% to 75% of forced vital capacity; FEV_1, forced expiratory volume in first second; MBC, maximum breathing capacity.

the development of minimally invasive surgical techniques has raised the question of whether standard selection criteria should always be adopted.

Although preoperative pulmonary function tests are valid indices of physiologic performance, the actual predictive utility of a range of values for a single parameter is poorly defined. Overall, emphasis has been directed toward integrating multiple aspects of the preoperative evaluation (e.g., respirometry, ventilation-perfusion scanning, extent of planned resection, patient functional status) into the estimate of postoperative function. Better postoperative analgesia techniques, early ambulation, and thromboprophylaxis have all contributed to improve outcomes after major lung resection in patients at high risk.

C. Intraoperative Management

C.1. How would you premedicate, monitor, and anesthetize this patient?

Current practice in most institutions dictates that patients arrive at the hospital the day of surgery; thus, traditional oral or parenteral premedication before transport to the operating room is largely obsolete. Bronchoscopy and mediastinoscopy are generally ambulatory procedures, necessitating a relatively rapid hospital discharge. Because thoracoscopy in this patient is only a possibility, intravenous midazolam immediately on entry into the operating room would seem appropriate for anxiolysis and subsequent amnesia. In addition, a small intravenous dose (0.2 mg) of glycopyrrolate can be considered as an antisialagogue, particularly in patients who smoke.

However, the potential for tachycardia should be considered, especially in patients with coronary artery disease or atrial fibrillation.

During mediastinoscopy, intermittent compression or occlusion of the innominate artery can occur. Therefore, the blood pressure cuff should be placed on the left arm and the pulse oximeter on the right hand. In the case of innominate artery compression, a damping of the pulse oximetry trace will be evident and blood pressure measurements will remain accurate. Although rare, injury to vascular structures can occur, potentially necessitating sternotomy. Patient positioning and placement of electrocardiography leads should be considered accordingly. Arterial access is not routinely used for this procedure unless the patient has clinical indications for continuous hemodynamic monitoring. In this case, the catheter should be placed in the left radial artery as well. Body temperature should be monitored and a warming blanket applied. Despite the potential for a short procedure, elderly patients in particular can become hypothermic. Induction, maintenance of anesthesia, and muscle relaxation can be achieved with relatively short-acting agents. Propofol is usually used for induction of general anesthesia followed by rocuronium, vecuronium, or cisatracurium to facilitate tracheal intubation via a single-lumen endotracheal tube (ETT). Anesthesia can be maintained with a potent inhalational agent in oxygen or air, if oxygen saturation tolerates it, and 2 to 3 μg per kg of fentanyl often provides sufficient analgesia for the procedure. Local anesthetic can be infiltrated in the wound by the surgeon at the beginning or at the end of the procedure. Nonsteroidal anti-inflammatory drugs (NSAIDs) are used by some providers as adjuvant agents; nevertheless, the potential for bleeding in a closed space in ambulatory patients should be considered. Finally, many clinicians choose to avoid the use of nitrous oxide because of the potential for the mediastinoscope to enter the pleural space and create a pneumothorax.

C.2. How many types of bronchoscopes are available and what are the intraoperative considerations of each one?

Three types of bronchoscopes are currently in use: flexible fiber-optic, rigid ventilating, and rigid Venturi.

The flexible fiber-optic bronchoscope can be used either in sedated patients under local anesthesia (allowing examination of vocal cords movements) or under general anesthesia with a laryngeal mask airway or an ETT. For the awake or sedated examination, viscous lidocaine can be gargled to anesthetize the upper airway and a 2% or 4% lidocaine solution inhaled via nebulizer mask to reach the lower airway. Bilateral superior laryngeal nerve blocks or transtracheal block can be added. Intravenous sedation can be achieved with 0.5-mg increments of midazolam, 10 μg of remifentanil boluses or propofol infusion. Alternatively, dexmedetomidine (as a bolus of 0.5 to 1 μg per kilogram over 10 minutes followed by a continuous infusion of 0.2 to 0.7 μg/skg/hr) can also be used, its main advantage consisting of amnesia without impaired ventilation. If the oropharynx is adequately anesthetized, a laryngeal mask airway can be inserted without discomfort in sedated patients and used to assist ventilation and provide higher Fio_2 concentrations.

In contrast, rigid bronchoscopy usually necessitates general anesthesia. Although spontaneous ventilation has been used, the risk of tracheal trauma is high with coughing. If not contraindicated, muscle relaxation is usually used. The rigid ventilating

bronchoscope has a side-port adapter that can be attached to the anesthesia machine, allowing the delivery of a high flow rate. A variable air leak usually exists around the bronchoscope, so high flow rates of inspired gases or packing of the oropharynx are needed. Significant loss of volatile anesthetic into the operating room environment needs to be considered; thus, the use of total intravenous technique is a good alternative.

The rigid Venturi-effect bronchoscope relies on an intermittent high flow (20 to 60 L per minute), high pressure (50 lbs per square inch [psi]) oxygen jet to entrain air and insufflate the lungs. The jet is delivered through a reducing valve (25 psi) into a 16- or 18-gauge needle inside and roughly parallel to the lumen of the bronchoscope. Major disadvantages of this bronchoscope are the lack of control of the inspired oxygen concentration and the inability to administer inhaled anesthetics. Accordingly, anesthesia must be maintained by intravenous techniques. Inadequate ventilation (with resultant hypercapnia) can also occur.

Rigid bronchoscopic procedures can be relatively short; therefore, continuous succinylcholine infusion still remains an option for these procedures. If not contraindicated, small doses of nondepolarizing muscle relaxants can also be used. When followed by another procedure (such as the mediastinoscopy scheduled for this patient), an intermediate-duration nondepolarizing muscle relaxant is often desirable.

C.3. What are the indications for cervical mediastinoscopy? Are there potential complications?

Cervical mediastinoscopy is usually performed to establish a diagnosis for specific lesions within the mediastinum or as a staging procedure for malignancy to determine mediastinal lymph nodes spread. If lymph nodes are positive for malignancy by frozen section, the patient is probably not a surgical candidate and the planned lung resection aborted.

Conventional cervical mediastinoscopy involves a small incision at the sternal notch for the insertion of the mediastinoscope and sampling of lymph nodes. The pleural space is generally not entered intentionally, and, therefore, a chest tube is not indicated. Occult pneumothorax can occur as a complication, so a chest radiograph is usually obtained before discharge. Complications during mediastinoscopy are relatively rare (1% to 2%) and generally result from trauma to adjacent structures (pleura, trachea, esophagus, superior vena cava, azygos vein, innominate artery, pulmonary artery, and aorta) or nerve injury (recurrent laryngeal or phrenic nerve). Should a major vascular structure be perforated, blood loss can be rapid and profound, necessitating emergent sternotomy. Because packing or vascular clamps may be applied to the superior vena cava, clinicians should always have a plan for establishing venous access in the lower extremity.

Wilson RS. Anesthesia for bronchoscopy and mediastinoscopy. In: Youngberg JA, Lake CL, Wilson RS, eds. *Cardiac, Vascular and Thoracic Anesthesia*. New York: Churchill Livingstone; 2000:660–669.

C.4. The decision was made to proceed with a right VATS middle lobectomy. How would this alter your management?

Although not uniformly regarded as necessary for lung resection, an arterial catheter will be placed in the left (dependent) radial artery. Lung isolation can be achieved via bronchial blocker placed inside or outside the existing ETT or with a left-sided double-lumen tube. Although a right middle lobectomy per se is not an absolute indication for lung isolation, the thoracoscopic approach dictates complete lung collapse to achieve surgical exposure. Because of the side of surgery and the variable take-off of the right upper lobe bronchus, the best choice for lung isolation would be a left double-lumen tube.

Single-lung ventilation is associated with certain disadvantages and complications. The most notable is the large and variable alveolar-to-arterial oxygen tension difference ($P[A\text{-}a]O_2$) that occurs as a result of continued perfusion to the nondependent, nonventilated lung. However, the incidence of severe hypoxemia and hypercarbia is relatively small and often the result of double-lumen tube malposition resulting from overinflation of the endobronchial cuff, surgical manipulation of the bronchus, or head extension or flexion during positioning. Other complications include traumatic laryngitis and tracheobronchial rupture resulting from bronchial cuff overinflation, forceful placement, or airway pathology.

C.5. What are the indications for single-lung ventilation and how can it be accomplished?

Absolute and relative indications for lung separation are listed in Table 2.2. Several techniques can be used to provide single-lung ventilation, including double-lumen tubes, bronchial blocking catheters passed outside or inside the ETT, ETTs with incorporated bronchial blocking catheters (Univent ETT), or conventional ETTs placed endobronchially. Currently, DLTs remain the most common method for achieving lung isolation. Although DLTs of variable design and material have been used in the past (e.g., Robertshaw, Carlens, and White), the models most commonly used today are disposable and made of polyvinylchloride. Such a tube was the chosen for this procedure. DLTs are available in five sizes: 28, 35, 37, 39, and 41 French (size in French = 3.14 times external diameter in millimeters or 4 times the internal diameter + 2), and two sides (right and left). Although the general rule is that average-sized men usually accommodate a no. 39 F and average-sized women a no. 37 F, there is no clear correlation between age, height, weight, and DLT size. Accordingly, some clinicians advocate the use of small DLTs in all patients. A variety of techniques have been described based on measurements of airway size derived from radiographic or computed tomographic imaging, but these have been questioned across gender and ethnicity. A properly sized double-lumen tube should pass atraumatically through the glottis, advance easily into the trachea and bronchus, and exhibit an air leak when the bronchial cuff is deflated.

Several types of bronchial blockers are available (see section C.9). Disadvantages of blockers include the fact that lung collapse can be slow, especially in patients with severe COPD, and catheter tips can be dislodged during surgical manipulation of the hilum or stapled in the bronchial stump. Bronchial blocking catheters remain a good

Table 2.2 Indications for Single-Lung Ventilation

ABSOLUTE	
1. To isolate from spillage or contamination	• Infection: Bronchiectasis and lung abscess • Massive hemorrhage
2. To control the distribution of ventilation	• Bronchopleural fistula • Bronchopleural cutaneous fistula • Giant unilateral lung cyst or bulla • Tracheobronchial tree disruption or trauma • Surgical procedures on major conducting airway (i.e., pneumonectomy or sleeve resection) • Life-threatening hypoxemia resulting from unilateral lung disease • Unilateral bronchopulmonary lavage (pulmonary alveolar proteinosis)
3. To facilitate surgical exposure	• Video- and robotic-assisted thoracoscopic surgery
RELATIVE	
1. Facilitation of surgical exposure—high priority	• Thoracic aortic aneurysm • Pneumonectomy • Upper lobectomy • Mediastinal exposure • Pulmonary resection via median sternotomy
2. Facilitation of surgical exposure—low priority	• Esophageal resection • Middle and lower lobectomies and segmental resection • Procedures on the thoracic spine
3. Severe hypoxemia resulting from unilateral lung disease	

option for lung isolation in patients who have difficult airways or when postoperative mechanical ventilation is needed. Patients with a fresh tracheostomy are also good candidates for the use of blockers.

Slinger PD, Campos J. Anesthesia for thoracic procedures. In: Miller RD, ed. *Miller's Anesthesia*. 9th ed. New York: Churchill Livingstone; 2010:1833–1841.

C.6. What are the contraindications to the use of double-lumen endotracheal tubes (DLTs)?

Placement of a DLT should be carefully considered in the following situations:

- Patients whose upper airway anatomy may preclude safe insertion of the tube (recessed jaw, prominent teeth, bull neck, anterior larynx, mandibular surgery, and neck radiation).
- Patients with lesions present somewhere along the pathway of the tube that could be traumatized, such as airway stricture or endoluminal tumors.
- Small patients for whom a no. 35 F tube is too large to fit comfortably through the larynx and a no. 28 F tube is considered too small.

- Critically ill patients who have a single-lumen tube already in place and who cannot tolerate cessation of mechanical ventilation and positive end-expiratory pressure (PEEP) for a short time.

Under these circumstances, single-lung ventilation can be achieved via an endobronchial blocker or an ETT placed into a mainstem bronchus. However, using a single-lumen tube in the mainstem bronchus for lung isolation can be suboptimal. Distal airway trauma may occur, and the cuff can bulge at the carina, causing significant airway compression and potential mucosal ischemia. When placed on the right side, the right upper lobe can also be occluded by the cuff of the tube, preventing the ability to ventilate.

Brodsky JB, Fitzmaurice B. Modern anesthetic techniques for thoracic operations. *World J Surg*. 2001;25:162–166.

Campos JA. Lung separation techniques. In: Kaplan JA, Slinger PD, eds. *Thoracic Anesthesia*. 3rd ed. Philadelphia: Churchill Livingstone; 2003:159–173.

Slinger PD, Campos J. Anesthesia for thoracic procedures. In: Miller RD, ed. *Miller's Anesthesia*. 9th ed. New York: Churchill Livingstone; 2010:1833–1841.

C.7. Would you use a right-sided or left-sided double-lumen tube?

A left-sided DLT is generally preferable for most procedures because the variable origin of the right upper lobe (1.5 to 2.0 cm below carina) may complicate maintaining good placement of a right-sided tube. Nevertheless, in an institution in which the use of right-sided DLT is routine, the incidence of hypoxemia, hypercarbia, or high airway pressures was found to be the same for patients managed with left or right DLTs. The left mainstem bronchus is much longer than the right (approximately 5.0 to 5.5 cm versus 1.5 to 2.0 cm), thus providing a greater margin for error in positioning. A right-sided DLT is indicated in the case of pathology of the left mainstem bronchus, such as large exophytic lesions, tight bronchial stenosis, tracheobronchial disruption, endobronchial stent, and distortion by an adjacent tumor or a thoracoabdominal aneurysm. Other indications include left pneumonectomy or lung transplantation so that the surgical field is not encumbered by a foreign body that could be included in the staple line or prevent suturing of the donor lung. At the end of a pneumonectomy, the stump can be protected from positive pressure ventilation by leaving the tracheal side clamped until the patient returns to spontaneous ventilation; for a left lung transplant, the right lung continues being ventilated during the reconstruction phase. Right double-sided lumens are contraindicated in the case of anomalous take-off of the right upper bronchus above the tracheal carina, commonly referred to as a "pig bronchus."

Ehrenfeld JM, Walsh JL, Sandberg WS. Right- and left-sided Mallinckrodt double-lumen tubes have identical clinical performance. *Anesth Analg*. 2008;106:1847–1852.

Slinger PD, Campos J. Anesthesia for thoracic procedures. In: Miller RD, ed. *Miller's Anesthesia*. 9th ed. New York: Churchill Livingstone; 2010:1833–1841.

C.8. How do you know that the tube is in the correct position?

The position of a double-sided lumen may be confirmed by listening to breath sounds of each lung while clamping each lumen. In patients with emphysema, breath sounds may be decreased or diffuse, making auscultation difficult and unreliable. Thus, fiber-optic bronchoscopy is often helpful in confirming position before placing

the patient in the lateral decubitus position. During bronchoscopy, the tracheal cartilaginous rings are anterior and the tracheal membrane is posterior. Therefore, right versus left can be discerned by the relationship of the mainstem bronchi to the anterior cartilaginous rings and the posterior membrane (Fig. 2.1A). In addition, the right upper lobe take-off (which usually arises from the lateral aspect of the right mainstem bronchus, just below the tracheal carina) is a useful landmark when the airway anatomy has been obscured by bleeding, edema, or radiation-induced changes or has been distorted by extrinsic compression. Left DLT position and depth are confirmed by inserting the fiber-optic bronchoscope in the tracheal lumen. The entire right mainstem bronchus should be visible and the tracheal lumen orifice of the DLT should be 1 to 2 cm above the tracheal carina. When properly positioned, the upper part of the blue endobronchial cuff is visualized just below the tracheal carina in the left mainstem bronchus (Fig. 2.1B). If a right DLT is used, correct positioning is confirmed by visualization of the bronchial cuff in the right mainstem bronchus (Fig. 2.1C) and visualization of the right upper lobe orifice through a slot on the

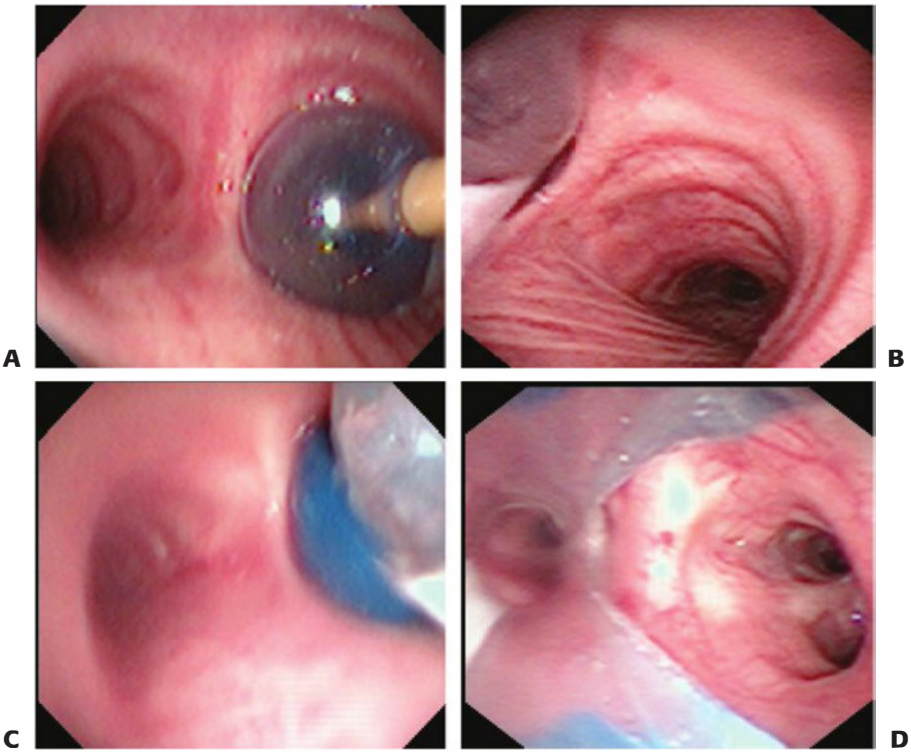

Figure 2.1 Representative bronchoscopic images of a bronchial blocker and DLT placement. **A.** Normal tracheal anatomy with cartilaginous rings anteriorly and membranous trachea posteriorly; this helps define left versus right. A bronchial blocking catheter is seen in the right mainstem bronchus. **B.** Placement of a left-sided DLT; the upper portion of the endobronchial cuff is evident as well as the orifice of the right upper lobe just below tracheal carina. **C.** Placement of a right-sided DLT; the upper portion of the endobronchial cuff is evident in the right mainstem bronchus. **D.** The orifice of the right upper lobe visualized through the slot on the lateral aspect of the bronchial side of a right-sided DLT.

lateral surface of the DLT (Fig. 2.1D). For both left-sided and right-sided tubes, the bronchoscope should also be inserted in the bronchial lumen to evaluate the distance between the tip of the tube and the distal bifurcation of the bronchus. Double lumen tube position should be reconfirmed after the patient is positioned laterally, before inflating the blue cuff and isolating the lung.

Campos JA. Lung separation techniques. In: Kaplan JA, Slinger P, eds. *Thoracic Anesthesia*. 3rd ed. Philadelphia: Churchill Livingstone; 2003:159–173.

C.9. How many types of bronchial blockers are available? What are the advantages and disadvantages of bronchial blockers?

Several blockers are available, leaving ample choice to the operator and the institution to develop a preference. Advantages and disadvantages of blockers are listed in Table 2.3.

- **Fogarty embolectomy catheters** can be used to isolate the lung, although not specifically made for this purpose. Number 7 French (7F) Fogarty catheters come with either a 12- or 20-mL high-pressure, low-volume balloon in both latex and nonlatex models. They have a metallic stylet that can be bent to facilitate endobronchial placement. In the case of dislodgment, the stylet can be reinserted and the blocker repositioned. Fogarty catheters have no communicating central channel; therefore, continuous positive airway pressure (CPAP) or suction cannot be applied intraoperatively. Ventilation should be discontinued and the ventilation circuit depressurized as long as the patient tolerates it before filling the balloon. Lung collapse then occurs by absorption of oxygen. The catheters are usually placed outside a single-lumen ETT and positioned via fiber-optic bronchoscopy (Fig. 2.1A). If placed inside the ETT, a connector such as a two-swivel adaptor is needed to facilitate insertion of both the catheter and a bronchoscope.
- **Arndt blockers** (wire-guided endobronchial blocker) are available in no. 5F, 7F, and 9F with elliptical or spherical cuffs (low pressure, high volume), the latter particularly advantageous to isolate the right lung. They are usually inserted through the ETT via a three-way connector (catheter, bronchoscope, ventilation circuit). Their positioning is facilitated by an inner wire that has a loop at the distal tip. The flexible bronchoscope is placed through the loop to facilitate positioning. The wire is then removed once the blocker is in position, leaving an inner lumen that allows for suctioning or CPAP. Once the wire loop has been removed, it can be reinserted, allowing repositioning of the blocker in case it dislodges.

Table 2.3 Advantages and Disadvantages of Bronchial Blockers

ADVANTAGES	DISADVANTAGES
• Able to use in adults and children too small to fit a double-lumen tube	• Unable to suction efficiently
• Difficult airway	• Need to be positioned via fiber-optic bronchoscopy
• If double-lumen tube contraindicated	• Difficult for right mainstem position and RUL isolation, when the take-off is too close to the carina.
• Placed inside the ETT	• Tracheal occlusion if proximal dislodgment.
• No need to change ETT in the case of postoperative mechanical ventilation	• Cross ventilation if the cuff is not completely inflated.
	• Possible stapling in the stump if not retracted at the appropriate time

ETT, endotracheal tube; RUL, right upper lobe.

- **Cohen blockers** are similar in shape to the Arndt blockers, but they use a positioning "wheel" to facilitate placement. By turning the wheel, the distal portion of the blocker deflects. The main advantage of this blocker is its placement in the left mainstem because of its steep angle. Disadvantages of the Cohen blocker include cost and the fact that the wheel is very delicate. They also come in only one size (no. 9F).
- **Univent tubes** consist of an ETT with a built-in silicon bronchial blocking catheter. The main advantage is the fact that the ETT may be left in place in case the patient requires postoperative mechanical ventilation. The main disadvantage is the bulkiness of the device. The outer diameter ranges from 9.7 to 13.7 mm (for a 6.0 to 8.0 inner diameter tube), with the potential to cause subglottic edema and stenosis in case of long-term use. The inner diameter is quite narrow, making suctioning or fiber-optic bronchoscopy difficult. The silicon blocker in the Univent is now available as an isolated item (**Fuji blocker**) that comes with a double stylet that has a preformed bend at the tip. It has a spherical cuff (ideally more suited to isolate the right mainstem bronchus) and three different sizes (no. 5F, 7F, and 9F).

C.10. How will systemic oxygenation be monitored during single-lung ventilation? What is the mechanism of pulse oximetry?

Pulse oximetry has become the hallmark for monitoring arterial oxygenation during lung resection, decreasing the need for repeated measurements of arterial blood gases. This technique uses spectrophotoelectric oximetric principles to determine oxygen saturation. Pulse oximeters are multiple-wavelength plethysmographs. The amplitude of the pulse is a function of arterial distention, hemoglobin oxygen saturation of the arterial blood inflow, and light wavelength. Hemoglobin saturation in arterial blood is the result of the ratio between the pulse amplitude of red (660 nm = deoxyhemoglobin) and infrared (940 nm = oxyhemoglobin) light. Pulsatile waveform is a characteristic of arterial blood flow, so there is no interference from surrounding venous blood, skin, connective tissue, or bone. Arterial pulsations cause changes in light absorption, which are used to calculate oxygen saturation. Adequate finger pulsation generally is lost with hypothermia of a few degrees, hypotension (mean blood pressure less than 50 mm Hg), and infusion of vasoconstrictive drugs. Dyshemoglobinemias (such as carboxyhemoglobin, methemoglobin, and sulfhemoglobin), as well as intravenous dye injection, can also affect its accuracy.

Other methods to continuously monitor arterial oxygenation include transcutaneous oxygen tension ($Ptco_2$) and arterial oxygen tension using an indwelling electrode. $Ptco_2$ requires special site preparation, airtight probe mantling, and a potentially harmful local source of heat to induce arterialization. Moreover, $Ptco_2$ fails to perfectly reflect true arterial oxygenation. An indwelling arterial oxygen electrode is inserted into the arterial line and may increase the incidence of thromboembolism.

C.11. The patient was placed in the lateral decubitus position. Describe the effects of lateral positioning on pulmonary blood flow and respiration.

In both upright and supine positions, the right lung receives approximately 55% of the total blood flow and the left lung receives the remaining 45%. In the lateral decubitus position, gravity causes a vertical gradient in blood flow distribution. Therefore, perfusion of the dependent lung is significantly greater than the nondependent counterpart. When the right lung is nondependent, it receives 45% of the total blood flow while 55% perfuses the dependent left lung. When the left lung is nondependent, it receives 35% of the total blood flow, while right lung receives 65%. Therefore, the average blood flow of the nondependent lung is approximately 40% of the total blood flow with the dependent lung being perfused with the remaining 60% (Fig. 2.2).

Respiratory Effects

The lateral decubitus position causes mechanical interference with chest wall movement, decreasing lung expansion. The dependent chest wall is constricted by the operating room table, and lateral movements are limited by the bolsters or the "bean-bag" used to hold the patient in position. Moreover, there is an increase in intra-abdominal pressure with general anesthesia and muscle relaxation, with a decrease in diaphragmatic movements. Mismatching of ventilation and perfusion in the lateral position is the result of gravity, with redistribution of blood flow toward the dependent lung and compression of the dependent lung by the mediastinum and the abdominal contents. In awake, spontaneously breathing subjects, the lower (dependent) diaphragm is still able to contract more efficiently, maintaining ventilation to the dependent lung and matching the increased perfusion. In contrast, when the patient is anesthetized, with or without paralysis, most of the ventilation is preferentially switched to the more compliant upper lung. Perfusion increases in the lower lung, resulting in an increased degree of ventilation-perfusion mismatch.

Walff KE, Aulin I. The regional lung function in the lateral decubitus position during anesthesia and operations. *Acta Anesthesiol Scand.* 1972;16:195–205.

C.12. What is hypoxic pulmonary vasoconstriction (HPV)?

HPV is an autoregulatory mechanism to prevent ventilation-perfusion mismatch and improve arterial oxygenation. The precise mechanism for HPV is still not completely

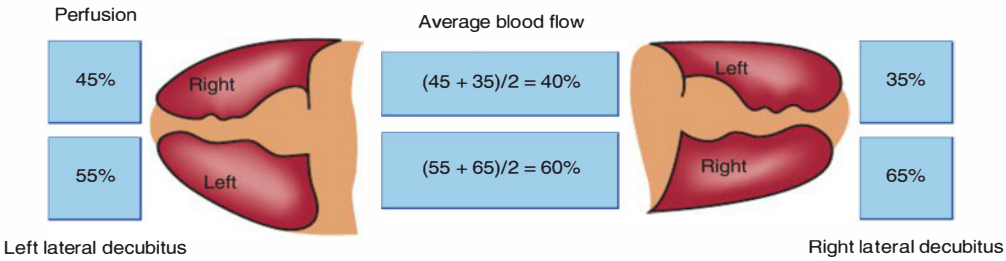

Figure 2.2 Changes in blood perfusion with the lateral decubitus position.

understood. Hypotheses include an increase in pulmonary arterial smooth muscle reactive oxygen species and activation of redox-based oxygen sensors, as well as an increase in intracellular calcium by activation of multiple pathways. HPV is triggered by a decrease in Pa_{O_2} within the lung from low F_IO_2, hypoventilation, or atelectasis. The selective increase of vascular resistance in the hypoxic parenchyma diverts blood away to the better ventilated normoxic lung, decreasing the amount of shunt flow.

Increasing evidence indicates that significant systemic oxidative stress can be elicited by hyperoxic reperfusion of a lung in which HPV has been sustained for an extended period because of the collapse produced by single-lung ventilation. Although the exact ramifications of this insult remain to be clarified, clinical data suggest an association between the magnitude of the oxidative stress and postoperative cardiopulmonary complications.

C.13. What are the effects of anesthetic agents on HPV and their clinical implications?

Several clinical studies have failed to demonstrate a decrease in HPV during single-lung ventilation and total intravenous anesthesia. Intravenous anesthetics, such as thiopental, ketamine, morphine, and fentanyl, have no direct effect on HPV, whereas propofol seems to enhance it. In contrast, inhalational anesthetics have been shown to inhibit HPV in a dose-related fashion but usually at concentrations much higher than used clinically. Other nonanesthetic drugs such as β-agonists and antagonists, calcium channel blockers, nitrovasodilators, and theophylline may influence the effects of inhalation anesthetics on shunting and arterial oxygenation during single-lung ventilation.

- The end result of an increased shunt on Pa_{O_2} depends on the absolute level of the initial shunt and the inspired oxygen concentration used. In clinical practice, nearly 100% oxygen is often used during single-lung ventilation. Even when shunt is increased, Pa_{O_2} usually remains well above 100 mm Hg and oxygen saturation and oxygen content hardly change.
- Inhalational agents inhibit HPV, but they also decrease cardiac output and oxygen consumption and may cause a decrease in mixed venous-oxygen tension. If cardiac output decreases more than oxygen consumption, there will be a decrease in Pv_{O_2}, which is a potent stimulus for HPV. A low cardiac output will result in a decreased perfusion of the collapsed lung (where there is an increase in pulmonary vascular resistance as a result of HPV). Nevertheless, the presence of chronic, irreversible vascular disease in the nondependent lung may impair HPV response.
- The presence of disease in the dependent lung will decrease the ability of accepting blood flow redistribution, thereby decreasing the HPV effect of the nondependent lung.
- Direct surgical manipulation may cause the release of vasoactive substances, such as thromboxane and prostacyclins, promoting local vasodilatation and blunting HPV, with a subsequent increase in shunt.

C.14. Discuss pulmonary blood flow distribution, shunt flow, and Pao_2 (F_Io_2 = 1.0) during single-lung ventilation in the lateral position.

When the nondependent lung is collapsed, HPV will increase pulmonary vascular resistance and decrease lung blood flow in this area. If no complicating factors exist, HPV should decrease blood flow to that lung by approximately 50%, causing a total reduction from 40% to 20% of the total. The resulting nondependent/dependent lung blood flow ratio during single-lung ventilation should be 20%:80%.

Once atelectatic, all the blood flowing into the nonventilated lung is shunt flow. Therefore, single-lung ventilation creates an obligatory right-to-left transpulmonary shunt that was not present during double-lung ventilation. If no shunt existed during double-lung ventilation (ignoring the normal 1% to 3% physiologic amount from the bronchial, pleural, and thebesian circulation), an ideal total shunt flow of 20% would be expected during single-lung ventilation. Pao_2 with a fractional inspired O_2 concentration (F_Io_2) equal to 1 should be approximately 280 mm Hg if hemodynamic and metabolic states are normal. Clinically, Pao_2 (F_Io_2 = 1) ranges from 150 to 250 mm Hg.

C.15. How could you improve oxygenation during single-lung ventilation?

When hypoxia occurs during single-lung ventilation, the goal is to optimize the match between ventilation and perfusion on the dependent lung or increase the amount of oxygen in the shunted blood of the collapsed lung.

Ventilated lung

a. Optimize ventilation

- Use 100% oxygen
- Check the position of the double-lumen tube with a fiber-optic bronchoscope
- Ventilate manually to determine whether higher or lower tidal volumes or inspiratory pressures are beneficial.
- Set minute ventilation to maintain $Paco_2$ at 40 mm Hg (hypocapnia may inhibit HPV in the nondependent lung, whereas hyperventilation may increase airway pressure and promote blood flow to the nonventilated lung).
- Apply 5 cm H_2O of PEEP. It may be beneficial if larger tidal volumes delivered manually improved arterial saturation (i.e., recruitable alveoli). Alternatively, if tidal volumes are too large, adding PEEP may overdistend alveoli that are already open and compress blood vessels, diverting blood to the nonventilated lung and worsening the shunt.
- Use two-lung ventilation intermittently.

b. Increase perfusion:
- Selective vasodilators (inhaled nitric oxide, inhaled prostacyclin PGI_2)

Collapsed lung:

a. Oxygenate shunt blood: A variety of approaches have been described but must be carefully considered for VATS procedures because most involve some degree of lung reexpansion and therefore may affect surgical visualization.
- Insufflate oxygen continuously: A flow of about 3 L per minute allowed to freely circulate will often increase arterial oxygen saturation 3% to 4%.
- Intermittent single breath with oxygen.
- Partially reexpand the nonventilated lung then keep the lumen side closed.
- Apply continuous CPAP.
- Differential CPAP to the collapsed lung and PEEP to the ventilated lung has been described, but is rarely necessary and generally impractical for VATS procedures.
- High-frequency ventilation to the nonventilated lung.

b. Decrease the shunt
- Use drugs to augment HPV (phenylephrine, norepinephrine, almitrine).
- Clamp lobar vessels or the pulmonary artery of the nonventilated lung temporarily (rarely necessary).

Brodsky J. Anesthesia, Pain, Intensive Care and Emergency. APICE 2007: Nov 9–11. Chapter 27, pages 291–298.

Slinger PD, Campos J. Anesthesia for thoracic procedures. In: Miller RD, ed. *Miller's Anesthesia*. 9th ed. New York: Churchill Livingstone; 2010:1851–1853.

C.16. A right middle lobectomy was performed. Would you extubate the trachea at the end of the procedure?

After routine lung resection, the trachea can be extubated as long as the patient meets all criteria and has adequate analgesia. If the patient cannot maintain adequate oxygenation and ventilation, postoperative mechanical support is indicated. Under most circumstances, when patients require postoperative ventilatory support, it is advantageous to change the double-lumen tube to a single-lumen ETT. Double-lumen tubes have a large outer diameter, which can cause airway edema and trauma if left in place for prolonged time. They are likely to move with patient movement, and it is difficult to suction through them. Spontaneous ventilation avoids the potential hazards of positive pressure on the suture lines of the new bronchial stump or parenchymal air leaks. The combination of modest CPAP and pressure support ventilation is usually preferable to controlled intermittent mandatory ventilation.

Higgins TL. Post thoracotomy complications. In: Kaplan JA, Slinger PD, ed. *Thoracic Anesthesia*. 3rd ed. Philadelphia: Churchill Livingstone; 2003:159–173.

D. Postoperative Management

D.1. What are the immediate life-threatening complications that follow lobectomy or pneumonectomy?

Serious complications after lobectomy include lobar collapse, massive hemorrhage caused by loosening of pulmonary vessels ligatures, bronchopleural fistula from disruption of a bronchial stump, and pulmonary torsion and infarction resulting from increased mobility of a lobe. Mediastinal shift, pleural effusion, hemothorax, chylothorax, empyema, and pulmonary edema can also occur.

Pneumonectomy can be complicated by supraventricular arrhythmias, acute respiratory insufficiency, nerve injuries (phrenic, vagus, or recurrent laryngeal) during radical hilar dissection or excision of mediastinal tumors, cardiac herniation (in the case of intrapericardial approach), acute right heart failure, and right-to-left shunting across a patent foramen ovale as a result of increased pulmonary vascular resistance and increased right ventricular pressure.

Higgins TL. Post thoracotomy complications. In: Kaplan JA, Slinger PD, eds. *Thoracic Anesthesia*. 3rd ed. Philadelphia: Churchill Livingstone; 2003:159–173.

Reed CE. Physiologic consequences of pneumonectomy: consequences on the pulmonary function. *Chest Surg Clin N Am.* 1999;9:449–457.

D.2. Why is it important to control postoperative pain? How would you achieve this?

Adequate postoperative analgesia is important not only for patient comfort, but also to minimize pulmonary complications, allowing the patient to breathe deeply, cough effectively, and ambulate. Several options are available, depending on the institution and surgical preferences.

Epidural and Intrathecal Analgesia

A trend has been shown toward a decrease in morbidity and mortality after lung resection since the introduction of regional analgesia. Thoracic or lumbar epidural analgesia may be achieved by a single injection or a continuous infusion of local anesthetic alone or in combination with an opiate. In order to reduce the volume required to produce an effect and lessen the chance of hypotension and motor weakness, the catheter can be placed as close as possible to the dermatomes to be covered. A low concentration of local anesthetic such as 0.1% or 0.05% bupivacaine combined with an opiate (e.g., fentanyl 5 to 10 μg per mL, hydromorphone 8 μg per mL or sufentanyl 0.1 μg per mL) produces synergistic effects that can reduce the sympathetic blockade that may occur with a more concentrated local anesthetic alone. In addition, the presence of local anesthetics seems to increase the affinity of the narcotic for the opioid receptors. The use of thoracic epidural analgesia with local anesthetic plus opiate has been shown to improve postoperative pulmonary function. Potential complications of thoracic epidural technique can be related to the placement (inadvertent dural puncture, trauma to the spinal cord, hematoma) or drug administration (intravascular injection of local anesthetics with resultant cardiovascular and central nervous system toxicity). In addition, clinicians should carefully consider the patient's use of long acting antiplatelet medications.

Intrathecal injection of opiates has been successfully used preoperatively or intraoperatively to provide postoperative pain relief for 18 to 24 hours. In comparison to epidural injection, intrathecal opiates (in particular morphine) are associated with an increased incidence of late respiratory depression (4% to 7% compared to less than 1% for epidural administration). The advantages of neuraxial techniques compared to systemic opiates include selective blockade of spinal pain receptors with minimal sympathetic blockade, no loss of motor function, and greater predictability of pain relief. Epidural opiates in combination with local anesthetics block the presynaptic and postsynaptic neuron cells of the substantia gelatinosa of the spinal cord by passive diffusion across the dura into the cerebrospinal fluid. The lipophilic narcotics, such as fentanyl 0.1 mg, methadone 5 mg, and meperidine 30 to 100 mg, have a relatively short onset of action (less than 12 minutes). They provide significant pain relief in 20 to 30 minutes, which can last for 6 to 7 hours. In contrast, a hydrophilic opiate, such as morphine, in a 5-mg dose, has a relatively slow onset of action of (15 to 30) minutes; provides maximal pain relief in 40 to 60 minutes; and has a duration of action of more than 12 hours. The most serious complications of epidural narcotics are early and late

respiratory depression. Other side effects include urinary retention, pruritus, nausea, and vomiting. The narcotic antagonist naloxone can reverse all the aforementioned side effects but will also reverse the analgesia, so it must be used cautiously. Overall, unlike epidural local anesthetic, epidural opioids have not been shown to decrease the incidence of postoperative respiratory complications.

Systemic Opioids and Nonsteroidal Anti-inflammatory Drugs

Systemic administration of opiates is often used alone or in combination with other modalities to control postoperative pain. Patient-controlled analgesia, often in combination with NSAIDs, can be used in the postoperative period. When used as a single modality, systemic opioids require plasma concentrations that are usually associated with sedation, potential respiratory depression, hypoventilation, cough inhibition, and reduced sighing. Even when used as patient-controlled analgesia, pain control is often suboptimal because of fluctuations in the drug plasma concentration. NSAIDs such as ketorolac, diclofenac, ketoprofen, and indomethacin can be used as adjuvants to parenteral opiates, particularly for the treatment of shoulder pain associated with chest tube placement. Potential side effects for NSAIDs include gastric bleeding, platelet dysfunction, and renal insufficiency in patients who are severely fluid restricted, especially the elderly.

Low-dose intravenous ketamine infusion (0.2 μg/kg/hr) has been used as an adjuvant in the postoperative period, especially in patients with chronic pain. Psychomimetic side effects are a possibility, but are rare at this dosage. Intravenous dexmedetomidine 0.2 to 0.5 μg/kg/hr is another alternative in the postoperative period. Its central α_2-agonism potentiates analgesia, allowing a decrease in the dose of intravenous narcotics. Hypotension and bradycardia are potential side effects.

Intercostal and Paravertebral Nerve Block

Intercostal and paravertebral nerve blocks with long-acting local anesthetics can be used to control pain after thoracoscopy or thoracotomy. In both cases, if single injections are used, they have a short duration (6 to 8 hours when bupivacaine is used). Therefore, catheters can be left in place and dosed postoperatively. Intercostal blocks can be done under direct vision by the surgeon before closing the chest cavity or percutaneously before awakening the patient. The intercostal nerves to be blocked are at the level of the incision and two or three interspaces above and below. Of the three main sensory divisions of the intercostal nerve (posterior, lateral, and anterior cutaneous nerve), the posterior branch cannot be blocked with this approach, limiting its usefulness in the case of a posterolateral incision. The quality of analgesia with this technique alone is inferior to the one achieved via the epidural route. Intercostal catheters are indicated as part of a multimodality treatment when neuroaxial blocks are contraindicated (e.g., patients on anticoagulation or tumor involvement of the epidural space) or for minimally invasive procedures. Because the rate of systemic absorption of the local anesthetic from the intercostal space is quite high, there is an increased risk of systemic toxicity.

Paravertebral blocks and catheters can be used preoperatively or postoperatively, and used in combination with parenteral opiates and NSAIDs, used as an alternative to thoracic epidural analgesia. In order to be effective, multiple levels need to be blocked. The failure rate for this technique is relatively high (6% to 10%) and can be decreased by locating the space via ultrasound guidance or under direct vision by the surgeon before closing the chest. Pneumothorax (especially if bilateral blocks are attempted), hypotension, local anesthetic toxicity because of the high vascularity of the area, and inadvertent total spinal are all potential risks. Advantages compared with epidural analgesia include less hypotension, less nausea or vomiting, and the ability to block just the surgical side.

Intrapleural Regional Analgesia

Intrapleural analgesia utilizes the percutaneous introduction of a catheter between the parietal and visceral pleura for the injection of local anesthetic. Analgesia is

thought to occur as a result of (1) diffusion of local anesthetic through the parietal pleura and the innermost intercostal muscle to the intercostal nerves (where the block occurs), (2) block of the intrathoracic sympathetic chain, and (3) direct action of local anesthetic on nerve endings within the pleura. Nevertheless, the quality of analgesia is extremely variable and unfavorable compared to that of other modalities. The local anesthetic can be lost through the thoracotomy drainage, it can be diluted by extravasated blood and tissue fluid in the pleural space, or it can be sequestered and channeled because of the decreased movements of the operated lung. Moreover, in the sitting position, the local anesthetic pools in the costophrenic angle, limiting the quality of analgesia. The use of multiple or fenestrated catheters may achieve a more even distribution over the pleura and improve the quality of analgesia. However, this technique is rarely used today.

Cryoanalgesia

Long-lasting (3 to 4 weeks up to 6 months) intercostal nerve block can be obtained by cryoablation. Two 30- to 60-second freeze cycles (−60° C), separated by a 5-second thaw period, are applied to each of the nerves selected. Although cryoanalgesia was initially shown to effectively relieve pain and improve postoperative pulmonary function, more detailed studies have revealed a significant incidence of paresthesia and postthoracotomy pain syndrome.

Transcutaneous Electrical Nerve Stimulation

Transcutaneous electrical nerve stimulation (TENS) relies on the application of brief pulses of current via electrodes to the affected area. The advantages of TENS include low cost, ease of application, and lack of undesirable side effects. Nevertheless, TENS has a weak analgesic effect. It is generally reserved for adjunctive use with narcotics to relieve mild to moderate postthoracotomy pain. It is ineffective if the pain is severe and is contraindicated in patients with pacemakers, defibrillators, and infusion pumps, because the current could produce interference.

Shoulder Pain after Lung Resection

Independently from the analgesia technique used and the surgical approach, approximately 80% of patients who have undergone lung resection complain of ipsilateral shoulder pain that is unresponsive to epidural block or systemic opioid. Possible causes for shoulder pain include referred pain from diaphragmatic irritation, chest tube placement (too far at the apex of the hemithorax), the posterior end of a large posterolateral incision, or surgical positioning in patients with arthritis. Shoulder pain usually responds to anti-inflammatory agents, and often resolves on the second postoperative day. Phrenic nerve infiltration and brachial plexus block have been used, but have the potential of causing diaphragmatic dysfunction.

CHAPTER 3

Aspiration Pneumonitis and Acute Respiratory Failure

Manuel L. Fontes, Sean Garvin, and Fun-Sun F. Yao

A 20-YEAR-OLD FULL-TERM PREGNANT WOMAN was rushed to the operating room for emergency cesarean section because of fetal distress. During emergence from general anesthesia, the patient vomited and aspirated.

A. Management of Aspiration

1. Delineate the risk factors for aspiration pneumonitis.
2. What is Mendelson syndrome?
3. What is the critical pH value and volume of aspirate to cause Mendelson syndrome?
4. How does aspiration pneumonitis differ from aspiration pneumonia?
5. You suspect the patient has aspirated; what is your initial management strategy?
6. Would you give prophylactic antibiotics?
7. Would you give steroid therapy?
8. Would you irrigate the bronchial tree with bicarbonate or saline solution?
9. How would you prevent aspiration during emergency surgery?

B. Acute Lung Injury

The patient was extubated in the recovery room. Chest x-ray films showed questionable mottled density in the posterior segments of the right upper lobe. Six hours after being transferred to the floor, she was found to be dyspneic and cyanotic. On auscultation of the chest, significant wheezing was noted, and the results of the most recent analysis of arterial blood gases showed the following: pH, 7.26; $Paco_2$, 55 mm Hg; Pao_2, 55 mm Hg; and HCO_3^-, 20 mEq per L on room air.

1. Define acute lung injury (ALI) and acute respiratory distress syndrome (ARDS).
2. What are the common causes of ARDS?
3. Describe the pathogenesis of ALI.

4. What are the radiographic findings in ARDS?
5. Describe protective-ventilation strategy in ALI and ARDS.
6. Define pulmonary compliance.

C. Mechanical Ventilation

The patient did not improve after receiving 50% oxygen through a face mask. A second arterial blood gas analysis showed the following: pH, 7.25; $Paco_2$, 50 mm Hg; Pao_2, 55 mm Hg; and CO_2 content, 22 mEq per L. The respiratory rate was 40 breaths per minute.

1. Interpret the blood gases.
2. What is your clinical plan?
3. What are the criteria for mechanical ventilation?
4. Describe the basic modes of mechanical ventilation. Discuss the advantages and disadvantages of pressure-controlled and volume-controlled modes.
5. What control mode would you select for this patient?
6. What initial ventilator settings will you prescribe for this patient (tidal volume, respiratory frequency, inspiratory oxygen fraction, etc.)?
7. Describe the potential hemodynamic effects of positive pressure ventilation (PPV).
8. What are the adverse effects of mechanical ventilation?

D. Therapeutic Approaches for Ventilatory Support

After intubation and mechanical ventilation, the oxygenation did not improve. On Fio_2, 0.7, the arterial blood gas analysis showed the following: pH, 7.30; $Paco_2$, 40 mm Hg; Pao_2, 57 mm Hg; and CO_2 content, 18 mEq per L.

1. What factors determine oxygen delivery?
2. How will you treat the hypoxemia?
3. What are the major factors governing oxygen toxicity?
4. What is the mechanism of oxygen toxicity?
5. What are your criteria to start positive end-expiratory pressure (PEEP)?
6. How does PEEP improve arterial oxygenation?
7. How would you determine the best PEEP and the optimal PEEP?
8. What are the cardiovascular effects of PEEP?
9. What is pressure-support ventilation (PSV)? Discuss its advantages.
10. Describe the rationale for prone-position ventilation and its effect on oxygenation.
11. How is liquid ventilation accomplished?
12. What are the indications and contraindications for extracorporeal membrane oxygenation (ECMO)? How many ways can it be used? What are its results?
13. What is high-frequency positive pressure ventilation (HFPPV)? What are its characteristics?
14. What are the frequencies used in high-frequency ventilation (HFV)? How are they classified?
15. What are the indications and precautions for HFV?
16. What is nitric oxide (NO)? What is the role of inhaled NO in the treatment of ARDS?

E. Weaning from Ventilatory Support

The patient's condition improved after respiratory support with 12 cm H_2O PEEP. Arterial blood gas analysis showed the following: pH, 7.45; $Paco_2$, 35 mm Hg; Pao_2, 150 mm Hg; and Fio_2, 0.75.

1. What would you do now?
2. The patient continued to improve. When would you consider weaning the patient from the respirator? Discuss the criteria for weaning.
3. Describe weaning by synchronized intermittent mandatory ventilation (SIMV), pressure support, continuous positive airway pressure (CPAP), and T-piece.

A. Management of Aspiration

A.1. Delineate the risk factors for aspiration pneumonitis.

Aspiration pneumonitis arises most often from aspiration of gastric content that is both acidic and voluminous. It can also occur from aspiration of oropharyngeal content. Several patient characteristics lead to the development of aspiration. These include:

- Neurologic dysphagia
- Disruption of gastroesophageal junction
- Anatomic abnormalities of the upper aerodigestive tract
- General anesthesia
- Poor oral hygiene
- Pharmacologic agents that alter consciousness (e.g., sedatives, antipsychotics, antidepressants, narcotics)
- Extremes of age (elderly, neonates)

The risk of aspiration pneumonitis is approximately 10% in patients presenting to the hospital after a drug overdose. This condition used to be very common in general anesthesia and accounted for most obstetric morbidity and mortality. The most recent report suggests an incidence of 1 in 3,000 patients receiving general anesthetics; however, the mortality remains very high and accounts for 10% to 30% of all deaths related to anesthesia. The elderly, particularly the nursing home population, is at increased risk of aspiration secondary to both an increased incidence of pharyngeal dysmotility and gastroesophageal reflux. Aspiration pneumonia and pneumonitis are the most common causes of death in patients with dysphagia caused by neurologic disorders, a condition that affects approximately 300,000 to 600,000 people yearly in the United States.

A.2. What is Mendelson syndrome?

Mendelson first described acute chemical aspiration pneumonitis in 1946. The triphasic sequence beginning with immediate respiratory distress, bronchospasm, cyanosis, tachycardia, and dyspnea, following with partial recovery, and concluding with a final phase of gradual respiratory recovery is characteristic of Mendelson syndrome. No signs of mediastinal shift are seen, but chest x-ray films usually show irregular mottled densities. This syndrome is due to the irritation of bronchioles by gastric hydrochloric acid, producing bronchiolar spasm, a peribronchiolar exudates, and congestion.

A.3. What is the critical pH value and volume of aspirate to cause Mendelson syndrome?

The critical pH value is 2.5. At a pH value higher than 2.5, the response is similar to that of distilled water. Maximal pulmonary damage is achieved at an aspirate pH value of 1.5. A patient is thought to be at risk when there is more than 25 mL (0.4 mL per kg) of gastric contents and the pH value of the gastric contents is less than 2.5. However, the risk of hypercapnia, acidosis, and subsequent pneumonitis may be increased if particulate matter is in the aspirate.

A.4. How does aspiration pneumonitis differ from aspiration pneumonia?

Aspiration pneumonitis generally is attributed to a chemical injury of the lungs from aspiration of gastric content (Fig. 3.1). The more acidic the pH value and the more voluminous the gastric content, the more severe the chemical burn. Food particles, independent of the acidity, also can cause a chemical injury. Aspiration pneumonitis consists of two phases: The first stage peaks within the first few hours after the aspiration and is mostly related to the caustic effect of the low pH value of the aspirate on the cells lining the alveolar-capillary interface; the second phase generally peaks at approximately 6 hours and is characterized both by infiltration of neutrophils into the alveoli and the lung interstitium and by an inflammatory process identical to that observed in other types of ALI.

Aspiration pneumonia differs from aspiration pneumonitis. It is caused by bacterial pathogens. The chemical irritation and inflammation resulting from aspiration pneumonitis may predispose an individual to developing an aspiration pneumonia. As such, the incidence of aspiration pneumonia in the population at risk (see section A.1) is much greater because a small amount of either oropharyngeal or gastric content that is colonized with bacteria is sufficient to cause injury, particularly in the elderly and the immunocompromised host. In the community, most commonly the causative organisms are indigenous oral flora. These are predominantly anaerobes (e.g., *Bacteroides* species, *Fusobacterium* species, *Peptostreptococcus* species) and streptococci. Both *Haemophilus influenzae* and *Streptococcus pneumoniae* first colonize the oropharynx and access the tracheobronchial tree and alveoli after aspiration to cause community-acquired pneumonia. In nosocomial bacterial pneumonia (i.e., aspiration in the hospital), in addition to the usual oral flora pathogens, *Staphylococcus aureus*, *Escherichia coli*, *Klebsiella* species, *Enterobacter* species, and *Pseudomonas* species may be involved. Ventilator-associated

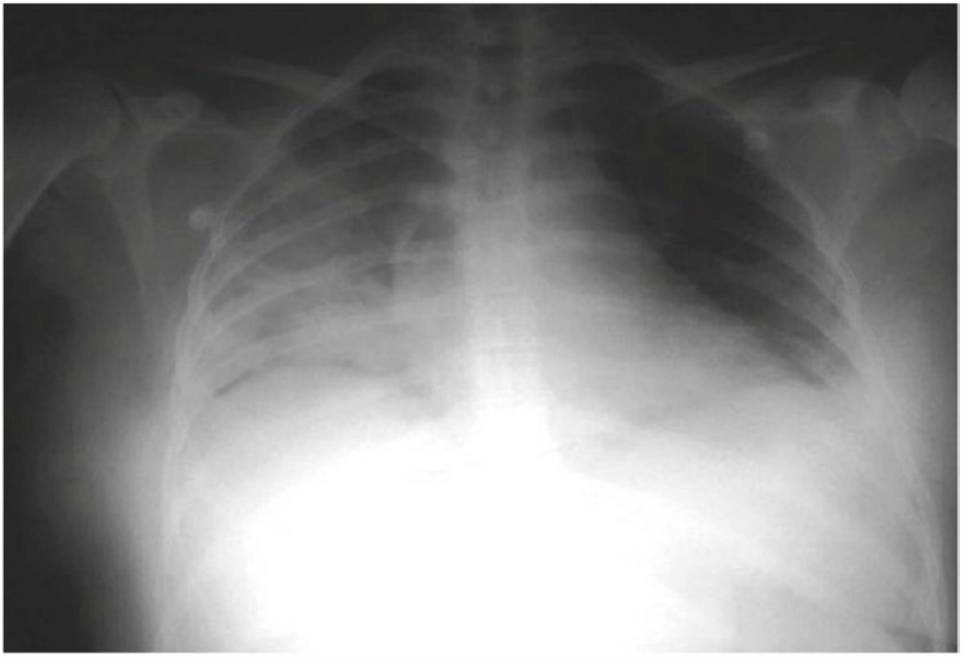

Figure 3.1 Typical radiographic findings in aspiration pneumonitis.

pneumonia may require broader antibiotic coverage. The term *aspiration pneumonia* is used specifically to describe radiographic evidence of infiltrate in a patient who is at risk of oropharyngeal aspiration. More than 50% of adults aspirate some amount of oropharyngeal secretion during sleep; however, very little sequelae arise from this for several reasons: First, the burden of virulent bacteria in "normal" pharyngeal secretions is low; second, the host is able to clear the aspirate through ciliary transport and cough reflexes; and third, the status of the immune system is noncompromised.

A.5. You suspect the patient has aspirated; what is your initial management strategy?

Rapidly tilt the operating table to a 30-degree head-down position to have the larynx at a higher level than the pharynx and to allow gastric content to drain to the outside. While an assistant maintains cricoid pressure, suction the mouth and pharynx as rapidly as possible. Next, endotracheal intubation should be performed (if the patient had been extubated) with immediate inflation of the endotracheal cuff to prevent further aspiration. Quickly suction through the endotracheal tube before administering 100% oxygen by PPV. This is to prevent pushing aspirated material beyond your reach. Suction should be brief to avoid cardiac arrest from hypoxia.

An orogastric tube should be inserted to empty the stomach. The pH value of the gastric content should be determined.

Tracheobronchial aspirate is collected for culture and sensitivity tests. Auscultation of the chest will determine whether diminished breathing sounds, wheezing, rales, and rhonchi are present. If bronchospasm is noted, β_2-agonists such as albuterol or terbutaline may be administered through metered-dose inhaler adapters to the anesthetic circuit.

The earliest and most reliable sign of aspiration is hypoxemia, which follows aspiration of even the mildest and most benign aspirate. Therefore, analysis of arterial blood gases should be performed to determine the severity of hypoxemia. Early application of PEEP is recommended to improve pulmonary function.

A.6. Would you give prophylactic antibiotics?

The initial aspirate, excluding feculent aspirate, is usually sterile and remains so for the first 24 hours. Thereafter, the aspiration pneumonitis can become aspiration pneumonia either from contamination of the initial aspirate or secondarily from aspiration of a colonized oropharyngeal secretion in a host that now has tracheobronchial and alveolar damage. Colonization cultures may demonstrate gram-positive or gram-negative superinfection or both, usually with *Escherichia, Klebsiella, Staphylococcus, Pseudomonas,* and *Bacteroides* or with anaerobes. Prophylactic antibiotic has *not* been shown to improve mortality or reduce secondary infection rates. Cultures must be taken as soon as possible after aspiration and thereafter as clinically indicated. The antibiotic therapy is given according to the sensitivity test result. Prophylactic use of broad-spectrum antibiotics may lead to drug-resistant bacterial and fungal superinfection. However, if intestinal obstruction is a possibility, antimicrobial therapy for the possibility of anaerobic and gram-negative infection may be warranted. Although data supporting the use of prophylactic antibiotics are lacking, it is not unusual for clinicians to prescribe such therapy in settings in which the host is considered immunocompromised (e.g., elderly and critically ill patients). If one or several antibiotics have been administered, prompt withdrawal should occur with laboratory or clinical evidence of no infection. In contrast, the use of antibiotics in aspiration pneumonia is unequivocally indicated (e.g., third-generation cephalosporins, fluoroquinolones, or piperacillin).

A.7. Would you give steroid therapy?

The value of systemic corticosteroids is controversial. The rationale for immediate use of corticosterowwwids is to reduce inflammation and stabilize lysosomal membranes. In addition, they have been shown to prevent pulmonary cellular damage

by protecting type II alveolar pneumocytes and to attenuate agglutination of leukocytes and platelets.

In experimental studies, the effectiveness of corticosteroid therapy appeared to be related to the pH value of aspirates. When the pH value of the aspirate was in the narrow range of 1.5 to 2.5, corticosteroid therapy was beneficial in treating acid-aspiration pneumonitis. Dexamethasone, given 0.08 mg per kg every 6 hours, decreased pulmonary water content significantly starting at 24 hours, with return to the normal range by 72 hours. When the pH value of the aspirate was less than 1.5, the pulmonary parenchymal damage was maximal. Therefore, the steroid therapy was not effective. When the pH value of the aspirate was higher than 2.5, the response was similar to that of water.

Wolfe, Bone, and Ruth found that pneumonia caused by gram-negative bacteria was more frequent after aspiration in patients treated with corticosteroids than in those who were not. Similarly, studies in animals have failed to demonstrate a beneficial effect of corticosteroids on pulmonary function, lung injury, alveolar-capillary permeability, or outcome after acid aspiration. Furthermore, because of the failure of two multicenter, randomized, controlled trials to demonstrate a benefit of high-dose corticosteroids in patients with ARDS, the administration of corticosteroids cannot be recommended.

A.8. Would you irrigate the bronchial tree with bicarbonate or saline solution?

No. In acid-aspiration pneumonitis, Bannister, Sattilaro, and Otis demonstrated that pulmonary lesions were aggravated by irrigation with sodium bicarbonate, normal saline, and sodium hydroxide. This was explained on the basis that (1) the large volume of fluid served to push the hydrochloric acid deeper into the lungs; (2) mixing of the acid and treatment solution was impossible because of the minute size of the interface; (3) hydrochloric acid probably causes damage within a very short time; (4) if equal volumes of hydrochloric acid (e.g., with a pH value of 1.6) and sodium chloride are mixed, the pH value increases only to 1.8; and (5) neutralization of hydrochloric acid with sodium bicarbonate produces heat, and a thermal burn of the bronchial mucosa may occur.

Bronchial irrigation is indicated only in the obstructive type of aspiration. Five to ten milliliters of normal saline is instilled into the tracheobronchial tree, followed immediately by suction. Bronchial irrigation is preceded and followed by oxygenation. The sequence is repeated until the aspirate fluid is clear.

A.9. How would you prevent aspiration during emergency surgery?

The following principles of preoperative preparation are of extreme importance:

- Application of gastric decompression by a wide-bore orogastric tube
- Use of regional anesthesia whenever possible
- Preoperative administration of a clear antacid, such as 30 mL of 0.3-M sodium citrate
- Premedication with anticholinergic agents, such as atropine or glycopyrrolate
- Administration of metoclopramide to stimulate gastric emptying and to increase lower esophageal sphincter tone
- Preoperative administration of an H_2-receptor antagonist or proton inhibitors (pantoprazole sodium) to decrease further secretion of additional acid
- Extubation only when the patient is fully awake

B. Acute Lung Injury

The patient was extubated in the recovery room. Chest x-ray films showed questionable mottled density in the posterior segments of the right upper lobe. Six hours after being transferred to the floor, she was found to be dyspneic and cyanotic. On auscultation of the chest, significant wheezing was noted and the results of the most recent analysis of arterial blood gases showed the following: pH, 7.26; $Paco_2$, 55 mm Hg; Pao_2, 55 mm Hg; and HCO_3, 20 mEq per L on room air.

B.1. Define acute lung injury (ALI) and acute respiratory distress syndrome (ARDS).

ARDS is the most severe form of ALI. To standardize definitions, a consensus panel of experts developed a set of criteria characterizing ARDS and ALI. The criteria include onset that is acute, bilateral infiltrates on chest radiography, hypoxemia, and no evidence of cardiogenic failure (i.e., pulmonary artery occlusion pressure < 18 mm Hg). Additionally, this group defined hypoxemia in ALI as a Pao_2/Fio_2 ratio of less than 300 mm Hg and selected a threshold ratio of Pao_2/Fio_2 of less than 200 mm Hg for ARDS, reflecting the more severe nature of the disease.

B.2. What are the common causes of ARDS?

ARDS can occur as a result of pulmonary injury arising primarily from lung pathology or secondarily from extrapulmonary processes. These include multiple trauma, massive blood transfusion, septic shock, fat or air embolism, disseminated intravascular coagulation, aspiration pneumonitis, fluid overload, burns, smoke or gas inhalation, and viral and mycobacterial pneumonia. The following conditions are also associated with ARDS: acute renal failure, oxygen toxicity, drug overdose, radiation, immunosuppression, neurogenic pulmonary edema, acute vasculitis, pancreatitis, cardiopulmonary bypass, and Goodpasture syndrome.

B.3. Describe the pathogenesis of ALI.

The histopathology reveals areas of hyaline membrane, alveolar hemorrhage, increased endothelial and epithelial permeability, and neutrophilic infiltration. Increased permeability allows passage of protein-rich plasma both into the alveolar and into the interstitial spaces, resulting in decreased lung compliance and ineffective gas exchange. As the injury process progresses, dependent lung regions beneath the diseased and edematous lung become collapsed, worsening oxygenation. Additionally, alveolar surfactant content diminishes, and its space becomes filled with fibrin and other cellular materials. Ultimately, a fibroproliferative phase is entered, whereby further destruction of the lungs occurs with varying degrees of collagen deposition and pulmonary fibrosis.

Complement activation may also play a major role in the pathogenesis of ARDS. Activation of the complement cascade through the alternative pathway by endotoxin or lipopolysaccharides results in the production of C5a complement. C5a complement causes microvascular occlusion and pulmonary granulocyte aggregation and embolization. The resultant damage to the endothelium leads to capillary leakage and pulmonary interstitial edema, ultimately producing terminal airway and alveolar edema and collapse. However, studies have shown limitations of the complement-neutrophil theory. Complement activation does not necessarily correlate with the development or severity of ARDS. ARDS can develop in patients with neutropenia, and pulmonary sequestration of neutrophils may not produce lung injury. As a result, the complement-neutrophil theory of ARDS has been expanded to include central roles for additional humoral mediators (such as endotoxin, tumor necrosis factor, interleukins, and thromboxane) and cellular mediators (e.g., the macrophage-monocyte system). The lung in patients with ARDS is now viewed as one of the organs involved in the multiorgan system dysfunction that occurs as a result of the systemic inflammatory

response syndrome. Increased mediator levels are found in bronchoalveolar lavage fluid from patients with ARDS.

B.4. What are the radiographic findings in ARDS?

The chest radiograph typically shows bilateral, fluffy involvement that initially led clinicians to think the pathology was homogenous. Now, however, pulmonary imaging techniques have provided convincing evidence that the injury is segmental. Although the increased vascular permeability is widespread and homogenous in all lung regions, both total and extravascular lung water is greatest in dependent lung regions. Computed tomography scans of patients with ARDS are several-fold more dense than those of healthy individuals and in severe cases can involve up to 80% of the lung. Based on the findings of Gattinoni et al., the lungs of patients with ARDS may be divided in thirds, wherein one-third represents a completely consolidated, nonventilated region; one-third is healthy with normal ventilation/perfusion matching; and one-third is a region that is hyperinflated with bullae formation. Contrary to previous belief, the compliance of the lung in patients with ARDS is normal for one-third of the lung parenchyma and "stiff" for the rest. The healthy portion is frequently referred to as *baby lung* and is subject to injury because of injudicious assignment of tidal volume. By selecting tidal volume on the basis of body weight (≥10 mL per kg), clinicians have overlooked the important fact that only a small fraction of the total lung in patients with ARDS participates in gas exchange. Therefore, a disproportionate share of the tidal volume will travel to the more compliant areas of the lung, subjecting it to overdistention and injury. Proponents of using lower tidal volume in ALI and in ARDS stress that utilizing a larger tidal volume in such settings is as inappropriate as ventilating an infant's lung with a tidal volume equivalent to that of an adult.

B.5. Describe protective-ventilation strategy in ALI and ARDS.

Many investigators have demonstrated a direct association between mechanical ventilation and lung injury that is independent of barotrauma and functionally and histoanatomically identical to injury observed in ARDS. ALI can occur at both low and high lung volumes (Fig. 3.2). At the lower end (below functional residual capacity [FRC]), cyclical opening and closure of alveolar units during tidal breathing may lead to lung injury from generated sheer forces. The regions most subject to this type of injury are at the interface between lung units that are edematous and nonfunctional with regions that are recruitable and mildly affected by the ARDS process. At the other extreme of lung volume, high airway pressure can cause segmental alveolar overdistention.

During the 1990s, use of a protective-ventilation strategy in patients with ALI or ARDS was shown to improve survival rates. Hickling, Henderson, and Jackson were the first to report a 60% reduction in the expected mortality for patients with

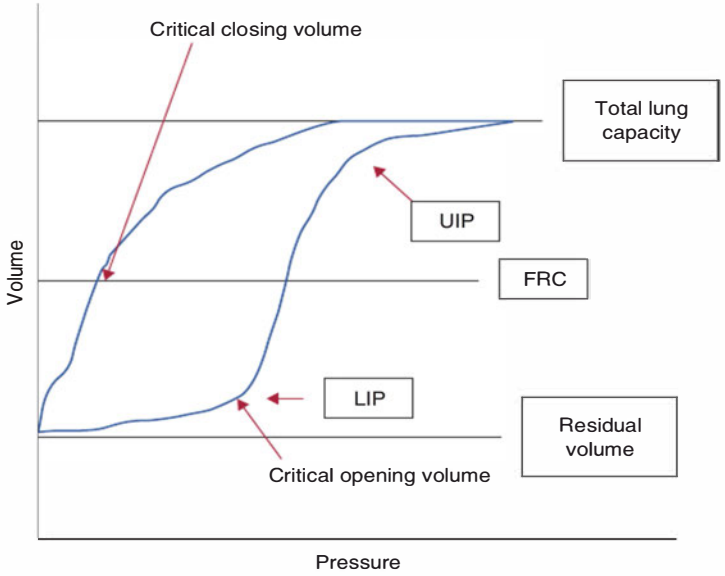

Figure 3.2 Static pressure–volume curve depicting low inflexion point and high inflexion point. On the basis of the concept of a protective-ventilation strategy in acute lung injury (ALI) and acute respiratory distress syndrome (ARDS), there are two critical regions in which pulmonary compliance is very poor. The first region is slightly above the residual volume and denotes a critical opening volume whereby recruitable alveoli have the propensity to collapse during tidal breathing. Cyclic opening and closing of these alveolar units has been implicated as a cause of ventilator-induced lung injury. On a static pressure-volume curve, the determination of this lower inflexion point (LIP) allows the clinician to set the positive end-expiratory pressure (PEEP) to 2 cm H_2O above this critical opening volume to prevent alveolar collapse and promote recruitment. The compliance of the lung markedly improves beyond this point until it reaches higher lung volumes, labeled upper inflexion point (UIP). The ideal tidal volume can be extracted from this exercise as the volume contained between the LIP and the UIP. Similarly, ideal compliance can be derived from the slope of this steep portion (region between LIP and UIP). FRC, functional residual capacity.

ARDS. In a subsequent prospective randomized trial of patients with ARDS treated by a protective lung strategy versus a conventional approach, Amato et al. also demonstrated significant survival improvement in the experimental group. The basic principles of the lung protection strategy include maintenance of lower inspiratory driving pressures (<20 cm H_2O above PEEP); use of lower tidal volumes (6 mL per kg of ideal body weight); acceptance of permissive hypercapnia over higher airway pressures; providing liberal sedation to improve patient-ventilator synchronization; and circumvention of alveolar collapse through judicious use of PEEP. Additional data suggests that early use of neuromuscular blockade to optimize ventilation and oxygenation of patients with ARDS may decrease the number of days on the ventilator and improve mortality without a significant impact on long term muscle function. PEEP maintains the end-expiratory pressure above the lower inflexion point on the static pressure–volume curve of the respiratory system (see Fig. 3.2). This contrasts to management by the conventional approach employing a tidal volume of 12 mL per kg; selection of lowest PEEP to achieve adequate oxygenation; and keeping the arterial carbon dioxide levels between 35 and 38 mm Hg. Fifty-three patients were enrolled in Amato's study (29 were assigned to a protective strategy and 24 were assigned to conventional management). After 28 days, the mortality in the protective-ventilation group was significantly reduced (38% vs. 71%). Further, the rates of weaning from mechanical ventilation were 66% and 29% for the protective-ventilation group and conventional group, respectively.

Following the work of Amato et al., a multicenter study sponsored by the National Institutes of Health (NIH), the ARDS Network, which included 861 patients, reported the same results. Briefly, 432 patients were ventilated with 6 mL per kg of tidal volume, and 429 patients received 12 mL per kg of tidal volume. The mean airway pressures were 25 ± 6 and 33 ± 8 cm H_2O. The trial was stopped prematurely after an interim analysis revealed an overall mortality reduction of 22% in the protective-ventilation group (31% vs. 39%, $P = 0.01$). This trial measured plasma level of interleukin-6 at days 0 through 3 and found it to be markedly reduced in the lower tidal volume group, suggesting fewer systemic inflammatory processes associated with the protective approach.

A recent systematic review of trials of lung protective ventilation strategy in ALI and ARDS found no difference in mortality in patients with ALI, but did find a survival benefit in the subgroup of patients with ARDS.

B.6. Define pulmonary compliance.

Lung compliance is defined as the change in lung volume per unit change in trasmural pressure gradient (i.e., between the alveolus and pleural space). Compliance is measured by adding a known amount of volume to a system and recording the pressure change. The ratio between this volume change and the respective pressure change defines compliance. The reciprocal of this relationship is called *elastance*. The lungs are said to be compliant or noncompliant depending on the pressure change that occurs after a given volume (tidal volume) is delivered. The overall lung compliance is rarely measured during clinical practice; rather, inspiratory pressures (peak airway and plateau pressures) are used to infer the status of overall compliance (lungs and thoracic). In actuality, assessing lung compliance is very difficult because different regions of the lungs exhibit different states of compliance, reflecting the heterogeneity of alveolar compliance. For example, in the upright position, the upper lung fields have the poorest compliance relative to the middle and lower lung segments. Evolutionarily speaking, blood flow is directed to lung regions that have the best compliance (i.e., the dependent regions). As described in the previous section, pulmonary compliance changes as the lung volume is increased from residual volume to total lung volume. At the extremes of volume, compliance becomes reduced. Therefore, the ideal compliance occurs at a lung volume between FRC and the resultant lung volume contributed by a normal tidal volume (7 mL per kg).

Pulmonary compliance changes with aging. Compliance is worse at the extremes of age. In addition, several disease states can compromise pulmonary compliance such as ALI, ARDS, congestive heart failure, barotraumas, neuromuscular disease, obesity, and pregnancy.

Lumb AB. *Nunn's Applied Respiratory Physiology*. 6th ed. Philadelphia: Elsevier Butterworth-Heinemann; 2005:25–33.

C. Mechanical Ventilation

The patient did not improve after receiving 50% oxygen through a face mask. A second arterial blood gas analysis showed the following: pH, 7.25; $Paco_2$, 50 mm Hg; Pao_2, 55 mm Hg; and CO_2 content, 22 mEq per L. The respiratory rate was 40 breaths per minute.

C.1. Interpret the blood gases.

The patient is demonstrating significant signs of respiratory failure. She is hypoxemic, hypercarbic, and dyspneic, and has an acid–base disturbance marked by a combined respiratory and metabolic acidosis. A 10 mm Hg rise in $Paco_2$ should have reduced the pH value by 0.08 (pH = 7.32). Therefore, a comcomitant metabolic acidosis must be present, lowering the pH value to 7.25.

C.2. What is your clinical plan?

Several approaches can be used for the initial management of this patient. A noninvasive approach using PPV by nasal or facemask can be used as a temporizing measure. Bi-level positive airway pressure is typically reserved for patients who are experiencing mild to moderate respiratory failure and who are not at increased risk of aspiration. Given this patient's presentation, the severity of respiratory failure will likely not improve rapidly. In fact, the clinical picture suggests that the patient has suffered ALI resulting in transpulmonary shunting and ineffective ventilation. The safest approach is to electively intubate the trachea and provide mechanical ventilation. Once successfully intubated, sedation can be given to allow for better patient-ventilator synchronization and comfort. If the pulmonary compliance is poor, as is commonly the case in the setting of ALI and ARDS, "deep" sedation may be required as well as muscle relaxation to facilitate gas exchange and to reduce barotrauma.

C.3. What are the criteria for mechanical ventilation?

The physiologic criteria for mechanical ventilation are as follows:

Mechanics

- Respiratory rate of more than 35 breaths per minute
- Vital capacity of less than 15 mL per kg
- Rapid shallow breathing index (respiratory rate/tidal volume–in liters) more than 200 breaths per minute per L

Oxygenation

- Hypoxia - Pa_{O_2} less than 70 mm Hg on face mask oxygen
- Alveolar–arterial oxygen gradient - P_{AO_2}–Pa_{O_2} more than 350 mm Hg on 100% F_{IO_2} or Q_S/Q_T more than 20%

Ventilation

- Hypercarbia - Pa_{CO_2} more than 55 mm Hg, except in patients with chronic hypercarbia
- Increased dead space - V_D/V_T more than 0.60

The trend of values and clinical status is important. The numerical guidelines should not be followed to the exclusion of clinical judgment. Also, frequently, the blood gas analysis results reflect what the patient's status had been at the time the sample was obtained. Depending on the time interval required to perform the analysis and to receive the result, there can be significant exacerbation or resolution in both oxygenation and ventilation, emphasizing the role of clinical judgment.

C.4. Describe the basic modes of mechanical ventilation. Discuss the advantages and disadvantages of pressure-controlled and volume-controlled modes.

Fundamentally, the various modes of mechanical ventilation, both new and old, share the following variables: trigger, control, limit, cycle, and baseline.

Trigger mode

The trigger is the first and most important component of the inspiratory phase, marking the end of exhalation. Examples of triggering mechanisms include time, flow, and pressure. In the nonparalyzed and nonanesthetized state, the patient triggers a mechanical or assisted breath by generating negative transpulmonary pressure that is sensed by the ventilator as a pressure change in the airway (Fig. 3.3). The threshold for triggering a breath (i.e., the set sensitivity) can be altered depending on the clinical setting; however, the greatest challenge in mechanical ventilation is determining the level at which sensitivity pressure should be set (usually at 1 to 2 cm H_2O). If the threshold is set too low, the ventilator will be triggered by any process that causes the airway pressure to surpass the set threshold. These include patient motion, external compression, gastric suctioning, and air leaks in the circuit or in the chest tubes. Conversely, if the threshold is set too high, the work of breathing increases; that is, to trigger every breath, the patient must make a significant effort to overcome the threshold limit for inspiratory flow to occur. At high levels of ventilatory assistance, as much as one-third of the patient's inspiratory efforts may be insufficient to trigger the ventilator. In the setting of acute respiratory failure, the inspiratory effort by the patient is approximately four to six times the normal value. This level of respiratory work frequently causes breath stacking, generating intrinsic PEEP, which in turn

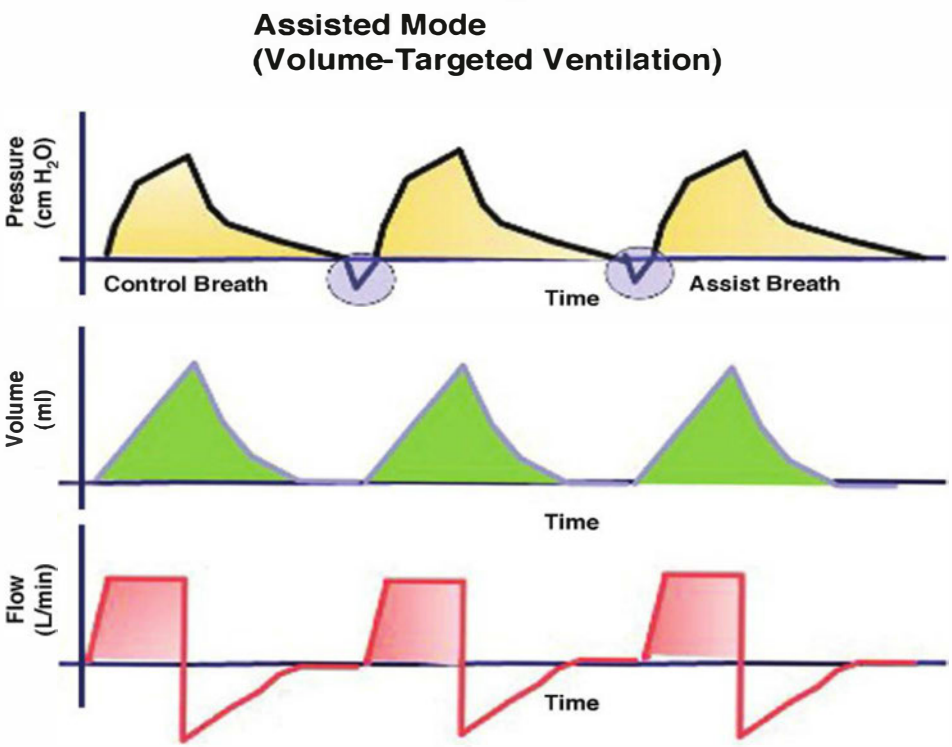

Figure 3.3 Airway pressure with corresponding lung volume and air flow tracings in assisted mode ventilation. The patient triggers a mechanical ventilation by generating negative transpulmonary pressure that is sensed by the ventilator as a pressure change in the airway.

imposes a tremendous burden on inspiratory muscle and if sustained can result in muscle fatigue and cardiopulmonary collapse.

Control mode

The delivered breath can be either pressure regulated (pressure control) or volume targeted (volume control). In the pressure-controlled mode, the amount of volume delivered is inversely related to the resistance encountered. When the resistive forces are low (i.e., normal compliance), the tidal volume for a given pressure will be relatively larger than if compliance were poor. For adults, the recommended upper limit of pressure control is 35 cm H_2O. Higher pressures may directly cause ALI or delay healing of the already injured lung. When the resistive forces are high, the resultant tidal volume may be inadequate for ventilation or oxygenation, even at high levels of inspiratory pressures. Typically, these patients have ARDS, and lower levels of arterial oxygen tension (Pao_2) are tolerated along with higher levels of arterial carbon dioxide tension (permissive hypercapnia).

Volume-controlled mode is the most common control mode used to ventilate patients mechanically. Examples include assist-control ventilation and SIMV. The ventilator will attempt to deliver a preset volume regardless of the pressure generated. For patients with poorly compliant lungs, volume-controlled mode may promote barotrauma and ALI.

Newer ventilators are capable of delivering breaths via a pressure control mode that varies the driving pressure in order to achieve a targeted tidal volume. This mode has the benefit of unrestricted flow during inspiration and automatic adjustment of inspiratory pressure in response to changes in an individual's lung compliance. Clinicians must remember that erratic inspiratory efforts by the patient may prevent the software from calculating an appropriate driving pressure for each breath. In addition, changes in compliance may be missed (especially worsening) as the ventilator will automatically increase the pressure control to get the target volume. One must be mindful to follow the trends in the ventilatory driving pressures and clinical status.

Limit mode

The limit is an essential feature in mechanical ventilation. Its variables include volume, pressure, and flow. The upper and lower limits of these variables should be preselected for each patient and adjusted in a manner consistent with the goals of the protective lung strategy employed.

Cycle mode

As discussed in the previous section, cycling has several variables: time, flow, and pressure. As such, the inspiratory phase and the expiratory phase becomes controlled. The challenge faced is in synchronizing the machine's cycling of inspiration and exhalation with the patient's "neural" respiratory cycle. Although pressure, flow, and time can be used to affect cycling, the manipulation of one or all three variables, both intrabreath and interbreath, to coincide precisely with the demands of the patient is virtually impossible (Fig. 3.4).

Baseline mode

The baseline variable is the function that is controlled during exhalation and generally indicates the level of PEEP.

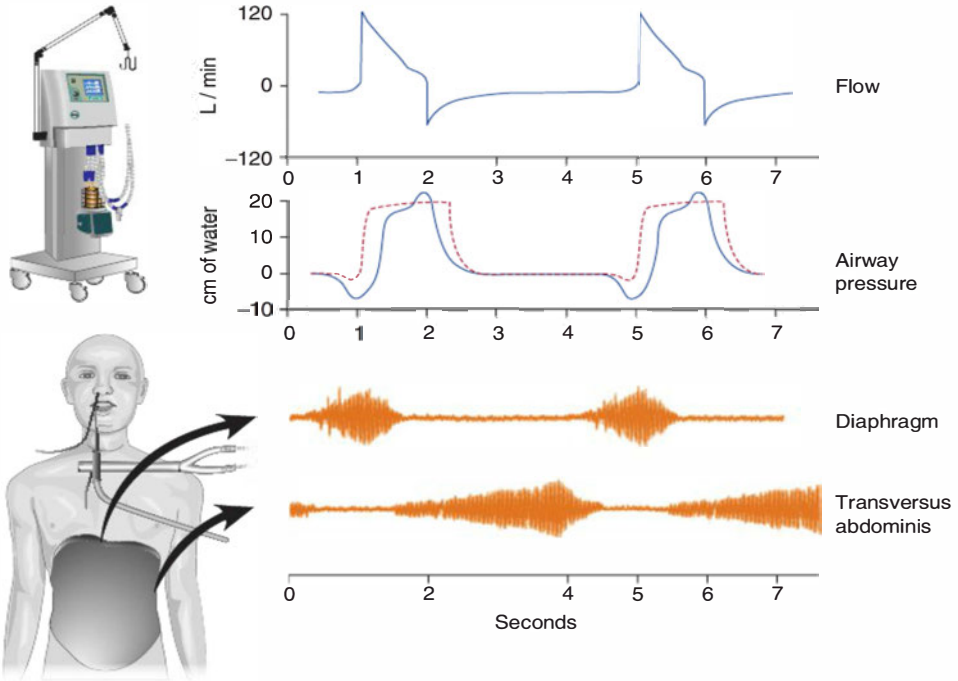

Figure 3.4 Activation of expiratory muscle during a mechanical inspiratory cycle. The airway flow, pressure, and electromyogram recording of two mechanically assisted respiratory cycles are illustrated. The start of inspiration is reflected by diaphragmatic activity that begins before the commencement of the inspiratory flow or airway pressure. The diaphragm stops contracting, marking the end of inspiratory effort. The expiratory muscle activity begins with contraction of the transversus abdominis muscle **(lower panel)**; however, the ventilator continued to deliver inspiratory flow while the patient was attempting to exhale. This illustrates a common problem with all ventilation modes that cannot fully adapt and synchronize with the patient's neuronal timing of inspiration and expiration. In the case mentioned earlier, the ventilator's inspiratory time exceeded the patient's inspiratory cycle, resulting in dyssynchrony and in some instances high airway pressure, predisposing to barotrauma. C.5. What control mode would you select for this patient?

For adult patients, volume-controlled mode most often is chosen for ventilatory management. Examples include assist-control ventilation, SIMV, and PSV. A targeted

tidal volume is selected and the ventilator will attempt to deliver this volume regardless of the pressure generated. If the resistance to ventilation is great, the pressure change can be excessive, resulting in barotrauma and ALI. Occasionally, the pressure increase is acute, reflecting some reversible condition, such as mucous plugging, bronchospasm, and patient anxiety. These conditions can be treated appropriately without having to switch to a different ventilatory mode. Alternatively, patients with ALI may have very poor compliance for which volume-controlled mode may be ineffective or prohibitive.

Some alternative modes of mechanical ventilation combine pressure control that is volume compensated or vice versa. Examples include pressure-regulated volume-controlled ventilation, proportional assist ventilation, adaptive support ventilation, and many other combinations of volume control, volume support, pressure support, and pressure control. These alternative modes attempt to improve patient comfort and synchronization with the ventilator. Older modes were overly simplistic, and incorrect assumptions were made regarding the role of ventilatory assistance. The concept was to make the ventilator the "boss" and allow it to drive the respiratory cycles. The important insight gained from today's clinical research is that the ventilator should be a "helper" aimed at assisting the patient in a manner determined by the patient.

C.6. What initial ventilator settings will you prescribe for this patient (tidal volume, respiratory frequency, inspiratory oxygen fraction, etc.)?

Initially, an attempt will be made to ventilate the patient with a volume-controlled mode. The tidal volume will be set at 5 to 8 mL per kg, respiratory frequency at 10 breaths per minute, F_{IO_2} of 70%, PEEP of 10 cm H_2O. The limits for alarming will be standard. After this initial setting, an arterial blood gas analysis should be performed to determine the adequacy of ventilation and oxygenation. Should lung compliance be poor, large tidal volumes must be avoided, which will predispose the lungs to barotrauma. The patient should be adequately sedated, and both the patient and the ventilator should be examined to rule out correctable causes of elevated inspiratory pressures. Alternatively, a pressure-controlled mode can be selected to ensure the driving pressure (plateau or mean airway pressure) does not exceed 35 cm H_2O. The PEEP level should be adjusted to improve oxygenation. A Pao_2 level of more than 60 mm Hg is acceptable, and the level of $Paco_2$ can rise in excess of 60 or 70 mm Hg (permissive hypercapnia). Treating the ensuing acidemia, particularly, respiratory acidemia no longer is recommended, unless the pH value becomes less than 7.20. The use of sodium bicarbonate is reserved for profound acidemia. Once administered, this agent is chemically converted to byproducts that include H_2O and CO_2. The latter can diffuse easily through the cell membrane to make the intercellular milieu more acidotic.

Chatburn RL. Understanding mechanical ventilators. *Expert Rev Respir Med.* 2010;6:809–819.

C.7. Describe the potential hemodynamic effects of positive pressure ventilation (PPV).

During spontaneous inspiration, air is delivered to the lungs by generating a pressure gradient between pleural (negative pressure) and atmospheric pressures (1 atmospheric pressure). During exhalation, the reverse process occurs and air is expelled as pleural pressure increases (never positive) and the rib cage recoils, returning lung volume to FRC. The hemodynamic consequence of physiologic breathing is minor but is associated with alterations in systemic blood pressure. For example, during inspiration, blood flow to the right ventricle is promoted and blood flow to the left side of the heart is diminished. This results in a decrease in stroke volume and systemic systolic pressure (approximately 5 to 10 mm Hg). In contrast, during positive pressure inspiration, the ventilator applies positive pressure to overcome alveolar pressure. Overall, transthoracic pressure increases, impeding or diminishing venous return to the heart. Both the right and the left ventricular output can decrease depending on the thoracic compliance, intravascular volume status, and biventricular function; that is, PPV will cause a decrease in cardiac output and blood pressure when the overall lung compliance is poor, the intravascular volume is inadequate, and/or ventricular function is compromised.

The hemodynamic consequences of both spontaneous pressure ventilation and PPV may be profound and may have opposite effects on cardiovascular stability in different patient populations. Therefore, no firm rules apply about the specific response that will be seen in all patients and under all conditions. Some generalities, however, are probably reasonable. In patients with markedly increased work of breathing, hypervolemia, or impaired left ventricular pump function, the institution of mechanical ventilatory support can be life saving because of its ability to support the cardiovascular system, independent of any beneficial effects that mechanical ventilation may have on gas exchange. In patients with decreased pulmonary elastic recoil, increased pulmonary vascular resistance, hypovolemia, or airflow obstruction, the institution of mechanical ventilatory support may induce cardiovascular instability, which if not corrected can lead to total cardiovascular collapse.

The initiation of intermittent positive pressure ventilation (IPPV) is associated with a decrease in cardiac output and in arterial blood pressure in patients without significant lung consolidation. Cardiac output and stroke volume decrease as the peak airway pressure increases. There is also a decrease in cardiac output with increasing inspiratory/expiratory ratios. IPPV increases intrathoracic pressure, resulting in decreased venous return and cardiac output. Patients with healthy lungs behave differently from patients with significant cardiopulmonary disease. When pulmonary compliance decreases, the transmission of airway pressure to intrathoracic pressure decreases. Patients with more rigid lungs can tolerate higher airway pressures.

IPPV decreases transmural pulmonary artery pressure without a change in pulmonary vascular resistance. The systemic vascular resistance increases slightly when IPPV is begun. The decrease in cardiac output during IPPV is rarely of any clinical significance because it is compensated by an increase in peripheral vascular resistance in nonanesthetized patients. When patients are hypovolemic, the decrease in blood pressure can be significant.

C.8. What are the adverse effects of mechanical ventilation?

Physiologic complications

- Decreased cardiac output resulting from increased intrathoracic pressure
- Respiratory alkalosis from hyperventilation
- Increased venous admixture ($\dot{Q}s/\dot{Q}T$) from prolonged low tidal volume ventilation

Pulmonary complications

- Infection
- ALI
- Barotrauma/pneumothorax, mediastinal, interstitial, and subcutaneous emphysema in 10% to 15% of adults
- Oxygen toxicity if the inspired oxygen concentration is more than 60%
- Atelectasis caused by immobilization and ineffective humidification

Complications from endotracheal intubation

- Endobronchial intubation, kinking, or obstruction, cuff leak
- Nasal damage from nasal intubation, epistaxis, fractured turbinates, septal perforation, partial loss of alae nasi, nasal synechiae
- Laryngeal damage and edema, vocal cord paresis and granulomas, laryngotracheal membranes, subglottic fibrotic stenosis
- Tracheal damage and tracheal erosion, tracheoesophageal fistula, tracheomalacia, tracheal stenosis
- Complications from mechanical device malfunction

D. Therapeutic Approaches for Ventilatory Support

After intubation and mechanical ventilation, the oxygenation did not improve. On F_{IO_2}, 0.7, the arterial blood gas analysis showed the following: pH, 7.30; P_{aCO_2}, 40 mm Hg; P_{aO_2}, 57 mm Hg; and CO_2 content, 18 mEq per L.

D.1. What factors determine oxygen delivery?

Oxygen delivery is dependent on blood flow (cardiac output) and the content of oxygen carried in blood (hemoglobin and dissolved oxygen). The actual amount is reflected by the following formula:

$$\text{Oxygen delivery} = CO \times [(1.34 \times Hgb \times Sa_{O_2}) + (0.0031 \times Pa_{O_2})]$$

where *CO* is cardiac output; *Hgb,* hemoglobin content in blood; Sa_{O_2}, percent arterial oxygen saturation; and Pa_{O_2}, partial pressure of oxygen dissolved in blood.

Based on this formula, oxygenation can be improved by several modalities. First, it is important to determine where the physiologic derangement lies. If the cardiac output is inadequate, the appropriate therapy should be to improve the elements of cardiac output (rate and rhythm, preload, contractility, and afterload); next, should the hemoglobin content be too low, the patient should undergo a transfusion with red blood cells; last, oxygen delivery to the lungs and uptake should be maximized. The latter can be accomplished by increasing the inspired oxygen concentration, increasing the level of PEEP, and by other maneuvers that will improve ventilation/perfusion matching and decrease intrapulmonary shunting (e.g., chest physiotherapy, prone position, bronchodilators, and diuresis).

Ginosa Y, Pizov R, Sprung C. Arterial and pulmonary artery catheters. In: Parrillo J, Bone R, eds. *Critical Care Medicine, Principles of Diagnosis and Management*. St. Louis: Mosby-Year Book; 1995:27–49.

D.2. How will you treat the hypoxemia?

The arterial blood gas analyses suggest that the patient is hypoxemic but is adequately ventilated and has a component of metabolic acidosis. As discussed previously, it is *not* appropriate to correct this level of metabolic acidosis with sodium bicarbonate or to attempt to hyperventilate the patient and induce respiratory alkalosis. The underlying problem producing the hypoxemia is lung injury from the aspiration pneumonitis, whose effect has led to significant intrapulmonary shunting. The F_{IO_2} is set at 0.7. The most appropriate maneuver is to increase the PEEP level, ensure good patient-ventilator synchronization (i.e., the patient is not fighting the ventilator), and avoid excessive tidal volumes or inspiratory driving pressures. Other ventilatory modalities that can be applied include inverse-ratio ventilation, pressure-controlled ventilation, prone position, use of NO, jet ventilation, and partial liquid ventilation (PLV).

D.3. What are the major factors governing oxygen toxicity?

Oxygen toxicity is governed by the duration of exposure, the partial pressure of oxygen, and the susceptibility of the individual to pulmonary oxygen injury. The degree of toxicity is related to the partial pressure, but not to the percentage of oxygen inspired, as demonstrated during U.S. space flights, where astronauts tolerate 100% oxygen for 2 to 4 weeks at a tension of 250 mm Hg. Systemic oxygen toxicity is related to arterial oxygen tension, whereas pulmonary oxygen toxicity depends on alveolar oxygen tension. Retrolental fibroplasia (retinopathy of prematurity) in the premature neonate has been reported after exposure to Pa_{O_2} at more than 80 to 150 mm Hg for a few hours. Pulmonary toxicity can develop after prolonged exposure to oxygen at concentrations between 0.5 and 1.0 atmospheres. It must be emphasized that the adult patient can generally tolerate 1 atmosphere of oxygen partial pressure for at least 24 hours. Moreover, there is no evidence that clinically relevant pulmonary oxygen toxicity occurs in humans at inspired partial pressures less than 0.5 atmosphere. Lastly, no patients should ever experience life-threatening levels of hypoxemia to avoid possible oxygen toxicity.

D.4. What is the mechanism of oxygen toxicity?

The free-radical theory of oxygen toxicity proposed in the early 1960s has garnered a great deal of recent experimental support and is now accepted as the most probable molecular-level explanation for oxygen toxicity. Various highly reactive and potentially cytotoxic free-radical products of oxygen are generated metabolically in the cell. These short-lived O_2 metabolites, including superoxide anion (O_2^-), hydroxyl radical (OH), hydrogen peroxide (H_2O_2), and singlet oxygen (O^-), have been shown to be capable of effects such as inactivation of sulfhydryl enzymes, interaction with and disruption of DNA, and peroxidation of unsaturated membrane lipids with resultant loss of membrane integrity. The cell is also equipped with an array of antioxidant defenses, including the enzymes superoxide dismutase, catalase, glutathione peroxidase, vitamin E, and ascorbate. Under hyperoxia, the intracellular generation and influx of free radicals is believed to increase markedly and may overwhelm the detoxifying capacity of the normal complement of antioxidant defenses, with resultant cytotoxicity.

The pathology of oxygen toxicity is nonspecific and consists of atelectasis, edema, alveolar hemorrhage, inflammation, fibrin deposition, and thickening and hyalinization of alveolar membranes. There are exudative and proliferative phases. Capillary endothelium is damaged early and plasma leaks into interstitial and alveolar spaces. Pulmonary surfactant may be altered. Type I alveolar lining cells are injured early, and bronchiolar and tracheal ciliated cells can be damaged by 80% to 100% oxygen. Resolution of exudative changes, hyperplasia of alveolar type II cells, fibroplastic proliferation, and interstitial fibrosis occur with recovery or with the development of tolerance to oxygen. Total resolution is possible if the initial hyperoxia is not overwhelming.

D.5. What are your criteria to start positive end-expiratory pressure (PEEP)?

The role of PEEP in mechanical ventilation is evolving. Previously, it was reserved for patients who had significant pulmonary pathology and hypoxemia. Either in apparently healthy lungs or in disease lungs, there can be significant heterogeneity in alveolar compliance and ventilation. Therefore, at normal levels of PEEP (physiologic), while in the supine position, alveolar components can collapse during tidal breathing, particularly, when there exist underlying comorbid states (e.g., ALI, ARDS, chronic obstructive pulmonary disease [COPD], congestive heart failure, obesity, and general anesthesia). To prevent cyclical closure of alveolar units and to ensure that the lung volume is maintained at or slightly above FRC, PEEP should be instituted accordingly. One should not wait for physiologic or laboratory evidence of inadequate gas exchange to initiate PEEP. Five to 10 cm H_2O is often sufficient and is not associated with hemodynamic disturbances. In the setting of ALI and ARDS, application of PEEP is essential for achieving adequate oxygenation.

Petrucci N, Iacovelli W. Lung protective ventilation strategy for the acute respiratory distress syndrome. *Cochrane Database Syst Rev*. 2007.

D.6. How does PEEP improve arterial oxygenation?

The mechanism is related to an increase in the FRC and redistribution of extravascular lung water. The FRC expands linearly with increases in the end-expiratory pressure, usually at a rate of 400 mL or more for each 5 cm H_2O of end-expiratory pressure; however, recruitment of alveolar units is both variable and unpredictable in patients with ARDS. This increase in FRC represents alveoli that remain open and available for gas exchange during all phases of the respiratory cycle. The increase in FRC improves the relationship between FRC and closing capacity and therefore decreases intrapulmonary shunt or venous admixture.

PEEP therapy changes the distribution of interstitial lung water but does not directly decrease lung water. PEEP facilitates the movement of water from the less compliant interstitial spaces (between the alveolar epithelium and capillary endothelium, where gas exchange occurs) to the more compliant interstitial spaces (toward the peribronchial and hilar areas). This redistribution of interstitial lung water improves oxygen diffusion across the alveolar-capillary membrane, resulting in increased arterial oxygenation. Approximately 25% of patients with ARDS are unresponsive to increases in PEEP as measured by an increase in Pao_2.

D.7. How would you determine the best PEEP and the optimal PEEP?

Suter, Fairley, and Isenberg described best conventional PEEP in 1975. The best PEEP is defined as the level of PEEP with the highest oxygen transport, which is the product of cardiac output and oxygen content. This PEEP correlates with the highest

total respiratory compliance, the highest mixed venous oxygen tension, and the lowest V_D/V_T. Arterial oxygen tension and intrapulmonary shunt are not good indicators of the best conventional PEEP. They continue to improve even after this level has been reached. Oxygen transport decreases after the best PEEP is reached, because the cardiac output decreases.

Civetta, Barnes, and Smith described optimal high PEEP in 1975. It is defined as the level of PEEP with the lowest intrapulmonary shunt and without compromising cardiac output. The PEEP used in this report is high, more than 25 cm H_2O, whereas the PEEP in the article by Suter, Fairley, and Isenberg is more conventional, ranging from 5 to 20 cm H_2O. However, the concept of best or optimal PEEP has evolved over the years. More recently, the endpoint for PEEP application is the lowest level of PEEP that provides an adequate Pa_{O_2} at an F_{IO_2} of less than 0.5. Increasing PEEP beyond this level to obtain optimum values for various other endpoints, such as the production of maximum oxygen transport, maximum static pulmonary compliance, shunt less than 15% to 20%, minimal arterial end-tidal Co_2 gradient, decreased mixed venous oxygen tension, and minimum F_{IO_2} will not be clinically helpful and may be harmful.

D.8. What are the cardiovascular effects of PEEP?

The cardiovascular effects of PEEP depend on the severity of respiratory failure, the level of PEEP, the intravascular volume, the contractility of the heart, and the pulmonary vasculature. In healthy subjects without respiratory failure, PEEP decreases cardiac output mainly because of increased intrathoracic pressure resulting in decreased venous return. PEEP also causes pulmonary parenchymal overdistention, which makes the lung come in close contact with the left ventricle, changing compliance and interfering with ventricular function. In addition, PEEP increases pulmonary pressure and resistance, resulting in right ventricular dilation, which causes an intraventricular septum shift toward the left ventricle. The leftward septal shift decreases left ventricular diastolic filling, resulting in decreased stroke volume and cardiac output. Also, unilateral pulmonary hyperinflation may initiate neural reflexes, resulting in a decreased cardiac output and heart rate. Moreover, humoral depression of myocardial contractility may also be observed. The aforementioned deleterious effect of PEEP is more apparent in individuals with limited cardiovascular reserve. Although PEEP is applied only at the end of expiration, in actuality, the alveolar and transpulmonary pressures are highest during inspiration (driving pressures exceeding 20 to 30 cm H_2O in some patients) and are associated with the greatest negative hemodynamic effects.

In persons with respiratory failure, PEEP, up to optimum levels, usually increases or does not change cardiac output because of an increase in oxygenation with resultant improvement of cardiac performance. Cardiac output decreases when PEEP exceeds the individual's optimum PEEP. Hypotension during PEEP therapy may be exacerbated by hypovolemia.

In patients with underlying left ventricular failure and left ventricular diastolic pressure of more than 18 mm Hg, PEEP may increase cardiac output by increasing coronary arterial oxygen content, augmenting systolic function, or reducing venous return. The decreased venous return may produce a shift in the Starling curve to filling pressures associated with better myocardial function.

D.9. What is pressure-support ventilation (PSV)? Discuss its advantages.

PSV is pressure-limited, flow-controlled PPV during which each spontaneous inspiratory effort is assisted by mechanically maintaining a predetermined inspiratory pressure plateau throughout inspiration. Whereas PSV is most often flow cycled, both pressure and time can be secondary cycling mechanisms. That is, pressure support can cycle to the exhalation phase when flow decelerates to a ventilator-determined level or to a pressure-determined level and/or when the inspiratory time has reached a predetermined level. PSV can be used for patients who are breathing completely spontaneously or who are being supported with IMV (Fig. 3.5), and it can be used for patients receiving CPAP.

PSV, which is an adjunct form of ventilatory support, is controlled with a microprocessor incorporated into the mechanical ventilator's circuit. When the patient makes the initial inspiratory effort, a very sensitive pressure transducer detects the slight negative pressure change and application of a constant support pressure is begun. Pressure is applied continuously throughout inspiration at the value selected by the operator.

The advantages of PSV are as follows:

- Achieving larger tidal volumes with lower airway pressures
- Decreasing work of breathing
- Improving spontaneous breathing patterns, including decreased respiratory rate, longer expiratory phase, and better synchrony with mechanical ventilation
- Promoting weaning from mechanical ventilation because of decreased respiratory muscle fatigue

Although theoretic advantages and safety of the mode in appropriately monitored patients support its use, few clinical studies have documented the efficacy of PSV.

D.10. Describe the rationale for prone-position ventilation and its effect on oxygenation.

The concept of improving oxygenation and gas exchange in patients with ARDS was proposed more than 30 years ago. The mechanisms for improvement in oxygenation in the prone position are unclear, and whether such physiologic benefit alters outcome is equally unknown. For gas exchange to improve, several respiratory processes must occur: (1) better matching of ventilation and perfusion in those lung regions affected by either too little perfusion but normal ventilation or normal perfusion but inadequate ventilation; (2) improvement in pulmonary diffusion capacity of oxygen and carbon dioxide (i.e., reduced interstitial edema and inflammation); (3) improvement in mobilization and delivery of these gases from the tissues to the lungs (better cardiac output and end-organ function); and (4) reduction in ventilator-induced lung injury in the prone position as compared with supine. In ARDS, the whole lung is affected by endothelial and epithelial hyperpermeability with resulting edema. In the supine position, dependent lung regions are subjected to a relatively greater regional pleural pressure gradient secondary to the forces of gravity acting on the ribcage, the diaphragm, the abdomen, the heart, and the mediastinal structures. Such increases in transpulmonary pressures overstretch normal alveoli, cause epithelial and endothelial disruption, and induce a state of pulmonary edema. Studies of animal models of ALI have shown that while in the supine position, high levels of PEEP are required to

maintain the injured and surfactant-depleted alveoli open. Failure to do this promotes ventilator-related lung injury. Additionally, perfusion of these dependent regions may be reduced from regional compression by the weight of the edematous upper lung units and from the effects of hypoxic pulmonary vasoconstriction. In contrast, positioning the patient prone allows for a more uniform gravitational gradient for alveolar ventilation and redistribution of alveolar ventilation to dorsal lung regions. Several other processes may account for the observed improvement in physiologic parameters in the prone position:

- The airway orientation is such that it tends to promote drainage of airway liquids toward the airway opening while in prone position and toward the dorsal regions when lying supine
- Redistribution of perfusion along a gravitational gradient to less injured lung regions
- Increased FRC
- Change in regional diaphragm motion

Pelosi et al. measured the change in thoracoabdominal compliance in the supine versus the prone position and compared this to changes in oxygenation. They found a direct correlation between improvement in compliance in the prone position and improvement in oxygenation that was most likely attributed to positioning the more rigid ribcage and vertebrae in the superior position while splinting the mobile anterior chest by the mattress. This maneuver favored redistribution of ventilation to the dorsal lung segments and alveolar recruitment.

Voggenreiter compared the effects of intermittent prone ventilation in 22 patients (11 of whom had severe and moderate posttraumatic lung injury and 11 had ARDS). Statistically significant improvements in respiratory parameters were observed in the prone position relative to the supine position for the following variables: (1) oxygenation; (2) $P_{AO_2} - P_{aO_2}$ and $\dot{Q}_S/\dot{Q}_T$; (3) total static lung compliance; and (4) reduction in pulmonary densities.

Prone position can improve oxygenation in patients with ARDS, and it may decrease the incidence of ventilator-associated pneumonia. The benefit appears to most in a subgroup of the most severely ill patients, in whom, it may it also lower mortality.

A recent meta-analysis found an improvement in hypoxia and decreased mortality in patients with ARDS who were ventilated in the prone position, albeit with a higher risk of complications, including pressure ulcers, endotracheal tube obstruction and chest tube dislodgement. In summary, prone position ventilation may improve oxygenation in 60% to 70% of people. Because not everyone will respond, a brief test of the prone position is recommended to assess responsiveness. The optimal duration of this treatment, and the repeat benefit of successive trials, is not currently known.

D.11. How is liquid ventilation accomplished?

Kylstra, who demonstrated that salt solutions could be saturated with oxygen at high pressures, first introduced the concept of fluid breathing in the 1960s. In 1966, Leland Clark uncovered that both oxygen and carbon dioxide were soluble in fluorocarbon liquids. The earlier methods of liquid ventilation with fluorocarbons met limited success as a result of impurities and chemical compositions of the fluorocarbons that caused ALI. Advances in perfluorocarbon (PFC) technology, however, have led to the development of improved generations of oxygen carriers that incorporated nontoxic substances. The PFC compounds are inert organic chemicals produced by replacement of fluorine for hydrogen in specific sites within the carbon chain. These agents do not undergo metabolism in the body and are eliminated through the pulmonary, gastrointestinal, and renal systems.

The proposed mechanisms for both improvement in oxygenation and hastening of recovery from ALI include a high solubility coefficient for oxygen and carbon dioxide relative to hemoglobin and a density that is twice that of water. As such, replacement of the FRC by PFC eliminates the alveolar membrane-air-liquid interface, reduces surface tension in the surfactant-depleted lung, and physically maintains the alveoli open. Because of its high density, it tends to gravitate toward the more dependent lung region that is most affected by lung edema and ALI. This effect stabilizes alveolar units in these regions and aids in alveolar recruitment. The use of PLV with PFC may alter regional blood flow by diverting blood from dependent to nondependent lung regions, thereby improving ventilation/perfusion matching (i.e., fluid PEEP). An additional benefit of PLV is the displacement of alveolar proteinaceous edema, inflammatory cells, debris, and other mediators from the alveolar spaces that are less dense.

Several clinical trials investigating the effect of PFC for PLV have shown a dose-dependent improvement in oxygenation. Leach et al. studied the efficacy of PLV using perflubron—an 8-carbon PFC—in 13 premature infants with severe ARDS in whom conventional therapy using various modalities, including surfactant replacement, had failed. An amount of PFC equaling the infant's FRC was infused endotracheally while standard mechanical ventilation was maintained. Within 1 hour after installation of PFC, the Pao_2 increased by 138% and the dynamic compliance improved by 61%. Whereas the duration of PLV was 24 to 72 hours and no direct complications occurred during the trial, the overall mortality rate was 50%. In 2001, Schuster et al. investigated whether or not the distribution of PFC in PLV is inhomogeneous, resulting in either inadequate improvement or deterioration in oxygenation, particularly during the first 24 hours after initiation of PLV. Inhomogeneity in distribution may arise from regional obstruction of airway components by (1) cellular debris, edema, and inflammatory factors; (2) local destruction of lung parenchyma; and (3) regional uptake of the PFC by blood. In this study, the chest radiograph of 16 patients who had received PLV for 48 hours were reviewed. The best predictor of inhomogeneous filling was the initial dose of PFC (10 mL per kg as compared with 20 mL per kg). Although other investigators have shown a dose-dependent improvement in oxygenation, several others have confirmed the findings of Schuster et al.

PLV has been combined with several ventilatory approaches to maximize oxygen delivery. Suh et al. showed, in an animal model of ALI, that PLV has a dose-dependent increase in Pao_2 with PEEP or proning as compared with volume-controlled mechanical ventilation mode. Additionally, lung histology revealed significantly less hyaline membrane formation in the PLV group, suggesting that this modality of ventilation allows the lungs to heal after an acute injury process. Relative to lungs from conventionally ventilated animals, similar histologic findings have been described whereby

the use of PLV resulted in less alveolar hemorrhage, decreased lung fluid accumulation, and diminished neutrophilic infiltration. This anti-inflammatory benefit may be attributed to the mechanical lavage of alveolar debris by the PFC and by a direct effect on alveolar macrophages. Despite these proven benefits, the use of PFC for PLV remains investigative for management of ARDS and ALI. Additional larger randomized clinical trials addressing the efficacy and safety of PLV need to be performed before any definitive recommendation can be made.

D.12. What are the indications and contraindications for extracorporeal membrane oxygenation (ECMO)? How many ways can it be used? What are its results?

ECMO should be used for patients in severe acute respiratory failure with potentially reversible lung disease, who are dying of severe hypoxemia despite maximal conventional ventilatory care (e.g., tracheal intubation, mechanical ventilation with high PEEP, diuresis, chest physical therapy, antibiotics, normothermia or mild hypothermia, sedation, paralysis, and increased oxygen concentration). Indications for ECMO by the NIH are as follows: Pao_2 less than 50 mm Hg for more than 2 hours with FIO_2 of 1.0 and conventional PEEP; and a Pao_2 less than 50 mm Hg for more than 12 hours with FIO_2 of more than 0.6 and conventional PEEP. Active bleeding is the only absolute contraindication to use of the artificial lung. The three routes for ECMO are as follows: venovenous perfusion from the inferior vena cava by way of the femoral vein to the oxygenator and then to the superior vena cava; venoarterial perfusion from the femoral vein to the oxygenator and then to the femoral artery; and venovenous arterial perfusion from the femoral vein to the oxygenator and then to both the internal jugular vein and the femoral artery.

A collaborative study on ECMO has been completed under the auspices of the National Heart, Lung, and Blood Institute of the NIH. The results of this controlled study are as follows:

- Compared with the control group of conventional respiratory therapy, ECMO did not improve mortality (90%), and the predominant cause of death was still progressive respiratory failure.
- ECMO did not affect the progress of disease (or lung pathology in those patients who died) any differently from conventional respiratory therapy.
- Although ECMO is an effective means of short-term life support, its clinical application for the treatment of ARDS is not appropriate or economically justified.

However, the recent randomized controlled study of 180 patients in the United Kingdom (CESAR trial) that referred patients with respiratory failure to a specialized facility with an ECMO-based management protocol demonstrated an overall improvement in survival (63% vs. 47%) with an acceptable economic cost.

D.13. What is high-frequency positive pressure ventilation (HFPPV)? What are its characteristics?

HFV was originally used as a technique to provide adequate oxygenation and alveolar ventilation for rigid bronchoscopy and laryngeal surgery. Since that time, the literature is replete with clinical applications of HFV. The major characteristics of the ventilatory pattern of volume-controlled HFPPV are as follows:

- A ventilatory frequency of approximately 60 to 100 per minute and an inspiration/expiration ratio of less than 0.3
- Smaller tidal volumes and therefore lower maximum and mean airway and transpulmonary pressures, yet a higher FRC than in conventional PPV
- Positive intratracheal and negative intrapleural pressures throughout the ventilatory cycle
- Less circulatory interference than in IPPV and/or continuous positive pressure ventilation
- Reflex suppression of spontaneous respiratory rhythmicity during normoventilation
- Decelerating inspiratory flow without an end-inspiratory plateau
- More efficient pulmonary gas distribution than in IPPV and/or continuous positive pressure ventilation

Sjostrand U. High frequency positive-pressure ventilation (HFPPV): a review. *Crit Care Med*. 1980;8:345–364.

D.14. What are the frequencies used in high-frequency ventilation (HFV)? How are they classified?

HFV is a generic term encompassing any form of mechanical ventilation operating at a frequency at least four times higher than the natural breathing frequency of the subject being ventilated.

Smith categorized HFV into three groups:

- HFPPV, 60 to 110 per minute
- High-frequency jet ventilation, 110 to 400 per minute
- High-frequency oscillatory ventilation (HFOV), 400 to 2,400 per minute

Froese summarized HFV into five groups as shown in Figure 3.6.

Sjostrand, in Sweden, first introduced HFPPV. It was administered with a very low compliant ventilator with high gas flow rates. This produces a flow profile with rapid upstroke to a high peak flow rate, followed by a passive expiration. Because it is a closed circuit, there was no entrainment of additional gas during inspiration.

High-frequency jet ventilation delivers a small tidal volume at a high flow rate by means of a narrow orifice at an adjustable drive pressure, rate, and inspiratory time or I/E ratio. Gas is regulated by a solenoid or fluidic mechanism. Because jet flow is

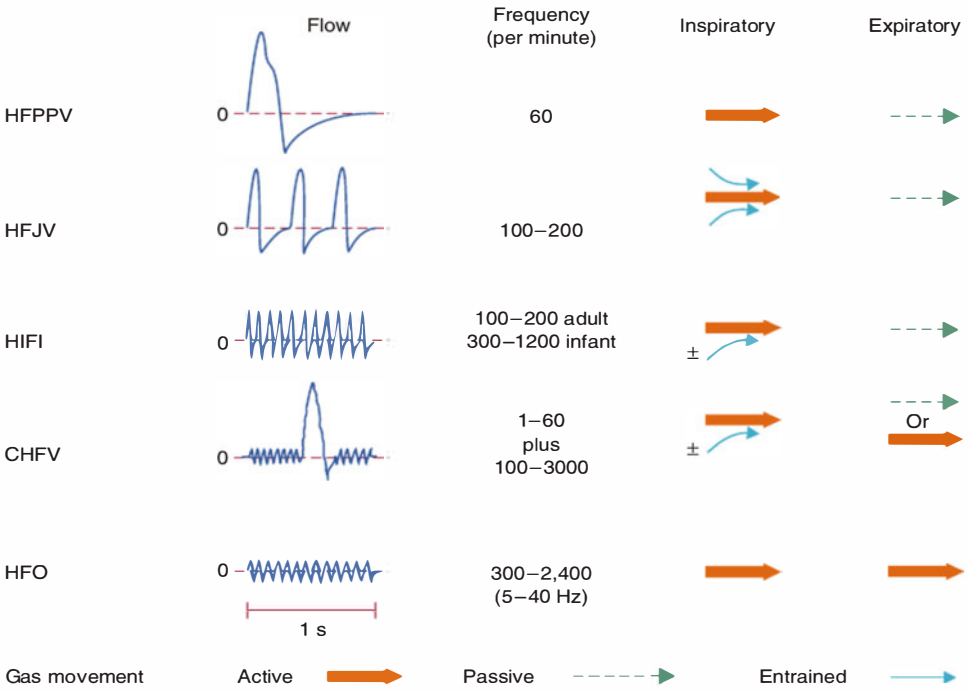

Figure 3.6 Summary of features of several commonly encountered high-frequency modalities. See text for details. CHFV, combined high-frequency ventilation; HFJV, high-frequency jet ventilation; HFOV, high-frequency oscillatory ventilation; HFPPV, high-frequency positive pressure ventilation; HIFI, high fidelity. (From Froese AB. High-frequency ventilation; uses and abuses. *ASA Refresher Courses in Anesthesiology.* Park Ridge, IL: American Society of Anesthesiologists, 1986:127–138, with permission.)

delivered to a small-lumen tube, entrainment occurs due to subatmospheric pressure created at the distal end of a cannula. Exhalation occurs around the tube or through another lumen and is passive. Frequencies are commonly 100 to 200 per minute, occasionally up to 400 per minute.

High-frequency flow interrupters are closely related to jet ventilators. Gas from a high-pressure source is "chopped" into pulses by a rotating ball valve and directed into the lung. The frequencies are usually 100 to 200 per minute in adults and 300 to 1,200 per minute in infants.

CHFV means combined high-frequency ventilation. Combined approaches usually superimpose some form of HFV onto backup conventional mechanical ventilation. The reported combinations vary considerably, with the slow component ranging from 1 to 60 per minute, and the fast component being delivered at 100 to 3,000 per minute.

HFOV is delivered by an oscillator-type ventilator consisting of a rotary-driven piston to produce to-and-fro movement of gas within the airway. Unlike all the other modalities, during HFOV the ventilator actively drives both inspiratory and expiratory flows.

D.15. What are the indications and precautions for HFV?

The indications for HFV include the following:

- Respiratory failure with bronchopleural fistula, tracheoesophageal or bronchoesophageal fistula, barotrauma, pulmonary fibrosis, and pulmonary hemorrhage, because of low airway pressure with HFV.
- Anesthesia for special procedures, such as bronchoscopy, laryngoscopy, tracheal reconstruction over a T-tube, and laser resection of a bronchial lesion, because HFV uses a small cannula for ventilation, leaving adequate room for surgeons to operate.
- Anesthesia for open thoracic surgery because of a moderately expanded lung and minimal respiratory movement with HFV.
- Improving oxygenation in adult and infant respiratory distress syndrome when hypoxemia persists in spite of maximal conventional ventilatory support.
- Enhancement of CO_2 elimination when conventional mechanical ventilation has been unable to support adequate CO_2 elimination despite multiple adjustments of ventilator settings in situations such as persistent fetal circulation in the neonate. HFV could prove advantageous in achieving a respiratory alkalosis by hyperventilation at low peak and mean airway pressures.

The precautions with HFV include the following:

- HFV must never be used in a situation in which expiratory outflow of gas from the lung is impeded. Under such circumstances, lethal barotrauma can occur.

- HFV should never be used with inadequate humidification, because serious tracheal injury may occur.
- HFV system pressure should be accurately and appropriately sampled and monitored in order to drive an automatic shutoff mechanism so gas entry into the lungs can be terminated immediately if an overpressure situation occurs.
- HFV should never be used without adequate training.

D.16. What is nitric oxide (NO)? What is the role of inhaled NO in the treatment of ARDS?

In 1987, endothelium-derived relaxing factor was identified as NO. NO produced by the endothelium diffuses into vascular smooth muscle where NO activates soluble guanylate cyclase. The subsequent increase in intracellular cyclic guanosine monophosphate causes smooth muscle vasodilation. Endothelium-independent nitrovasodilators such as nitroglycerin and nitroprusside also act through guanylate cyclase activation to directly release NO.

Inhaled NO is a selective pulmonary vasodilator. NO is not effective during systemic administration because it is rapidly inactivated by hemoglobin. Therefore, inhaled NO may diffuse from the alveoli to pulmonary vascular smooth muscle and produce pulmonary vasodilation without systemic vasodilation because any NO that diffuses into blood will be inactivated by hemoglobin. Inhaled NO has been shown to be effective in treating primary pulmonary hypertension, as well as decreasing pulmonary hypertension and improving oxygenation after mitral valve replacement and in the newborn with persistent pulmonary hypertension.

Pulmonary hypertension and hypoxemia universally occur in ARDS. Pulmonary hypertension in ARDS may be due to active vasoconstriction from local alveolar hypoxic pulmonary vasoconstriction and other vasoconstrictor mediators. Hypoxemia in ARDS is due to ventilation/perfusion mismatch, intrapulmonary shunting, or anatomic shunting. Intravenous pulmonary vasodilator therapy with agents such as nitroglycerin, nitroprusside, prostaglandin E, prostacyclin, adenosine, and nifedipine produces small reduction in pulmonary artery pressure but large reduction in systemic blood pressure and arterial oxygenation. The adverse effect on oxygenation is primarily due to reversal of hypoxic pulmonary vasoconstriction. On the contrary, inhaled NO may decrease pulmonary hypertension and improve oxygenation in patients with ARDS because inhaled NO may be distributed according to ventilation so the associated vasodilation increases blood flow to well-ventilated alveoli.

Rossaint et al. published the first major report of the use of inhaled NO in patients with ARDS. They found that inhaled NO (5 to 20 parts per million [ppm]) effectively decreased pulmonary hypertension and improved oxygenation. In a subsequent study, they showed that inhaled concentrations of only 60 to 250 parts per billion could increase Pao_2 by 30%. These concentrations had little or no effect on pulmonary artery pressure. The other major study by Bigatello et al. demonstrated that inhaled NO produced dose-related decreases in pulmonary artery pressure with 50% of the maximal effect occurring at 5 ppm. Inhaled NO also increased oxygenation, but dose-response effects could not be demonstrated.

Inhaled NO has been effective on ARDS in combination with other therapies. The combination of inhaled NO (5 to 10 ppm) and almitrine bismesylate, a potentiator of hypoxic pulmonary vasoconstriction, had additive effects on improving oxygenation in ARDS and simultaneously decreased pulmonary hypertension. Dcering et al. studied intravenous phenylephrine, 50 to 200 μg per minute, titrated to a 20% increase in mean arterial pressure; inhaled NO, 40 ppm; and the combination of phenylephrine and NO. They found that phenylephrine alone can improve Pao_2 in patients with ARDS. In phenylephrine-responsive patients, phenylephrine augments the improvement in Pao_2 seen with inhaled NO. These results may reflect selective enhancement of hypoxic pulmonary vasoconstriction by phenylephrine, which complements selective vasodilation by inhaled NO.

However, an important unsolved issue is the potential pulmonary toxicity of inhaled NO. Toxicity may be due to NO itself, or to its reactive metabolite, NO_2. NO can combine with superoxide anion to produce peroxynitrite anion, which is a powerful oxidizing agent. The effects of NO and NO_2 on repair versus fibrosis in injured lung and on pulmonary host defenses are unknown. Therefore, the effects of inhaled NO on outcome in patients with ARDS are not predictable.

Overall, a recent Cochrane analysis found a transient improvement in oxygenation in patients with ARDS receiving NO but was unable to demonstrate a mortality benefit. Additionally, NO therapy may increase the risk of renal impairment in adult patients with ARDS.

E. Weaning from Ventilatory Support

The patient's condition improved after respiratory support with 20 cm H_2O PEEP. Arterial blood gas analysis showed the following: pH, 7.45; $Paco_2$, 35 mm Hg; Pao_2, 150 mm Hg; Fio_2, 0.75.

E.1. What would you do now?

The arterial blood gas analysis suggests that the oxygenation has improved markedly; nevertheless, there continues to be significant intrapulmonary shunting and the level of PEEP remains high. Before making any drastic changes, it is important to examine the patient thoroughly to determine that in fact the lung injury is resolving and that there is no evidence of infection, systemic inflammatory involvement, and metabolic derangements. The most appropriate ventilatory change is to lower the F_{IO_2} to less than 0.5 or 0.6. This should be well tolerated. Next, the PEEP should be lowered gradually. The suggested criteria to lower PEEP level are a stable, nonseptic patient; P_{aO_2}/F_{IO_2} more than 200 mm Hg; effective compliance, more than 25 mL per cm H_2O; $P_{AO_2}-P_{aO_2}$, less than 200 mm Hg at F_{IO_2} 0.5. PEEP should not be decreased by more than 5 cm H_2O during a trial. At least 6 hours should elapse before undertaking a further attempt at lowering the PEEP level.

Tobin MJ. 1999 Donald F Egan scientific lecture: weaning from mechanical ventilation: what have we learned? *Respir Care*. 2000;45:417–431.

E.2. The patient continued to improve. When would you consider weaning the patient from the respirator? Discuss the criteria for weaning.

The criteria for discontinuance of mechanical ventilation are essentially the converse of the criteria for the institution of mechanical support and are as follows:

- Clear consciousness with adequate gag and cough reflex
- Cardiovascular stability
- Stable metabolic state without hypothermia, hyperpyrexia, metabolic acidosis, or alkalosis
- Adequate pulmonary function

Mechanics

- A vital capacity of more than 10 mL per kg or more than twice the normal tidal volume
- Rapid shallow breathing index (respiratory frequency/tidal volume) of less than 105 breaths/min/L
- A maximum inspiratory force of at least −20 to −30 cm H_2O

Oxygenation

- P_{aO_2} more than 80 mm Hg with F_{IO_2} at 0.4
- $P_{AO_2}-P_{aO_2}$ less than 300 mm Hg with F_{IO_2} at 1.0
- Q_S/Q_T less than 15%

Ventilation

- P_{aCO_2} less than 45 mm Hg
- V_D/V_T less than 0.6

E.3. Describe weaning by synchronized intermittent mandatory ventilation (SIMV), pressure support, continuous positive airway pressure (CPAP), and T-piece.

Mechanical ventilatory assistance is often an obligatory step during management of critically ill patients; however, complete withdrawal from this support represents a significant clinical problem in approximately 25% of intubated patients. Frequently employed weaning techniques have included PSV, T-piece, CPAP, and SIMV. Several studies have compared these various weaning approaches, but the results have been conflicting. Brochard et al. compared weaning by PSV, T-piece, and SIMV and found weaning by PSV to be superior to weaning by T-piece and by SIMV. In contrast, in a large multicenter trial of nonsurgical patients with diverse medical problems, Esteban et al. demonstrated that the duration of weaning by T-piece once a day was significantly less than weaning by PSV, which in turn was less than weaning by SIMV. Kollef et al. showed that a protocol-guided weaning by nurses and respiratory therapists was safe and led to extubation more rapidly than physician-directed weaning. Therefore, in addition to differences in study design, weaning modalities, and weaning techniques, there are selection and physician biases that interfere with the process of weaning. Although employment of protocol-driven weaning may control for physician bias, it is also data driven, time consuming, and costly.

Conventional T-piece technique

When the patient meets the criteria for weaning, a T-piece adapter and heated nebulizer are connected to the patient's endotracheal tube. The patient should be in a semisitting or sitting position. The inspired oxygen concentration is set at a level 5% to 10% higher than what the patient was receiving during mechanical ventilation. The vital signs and cardiac rhythm are monitored carefully every 5 to 10 minutes. Arterial blood gases are determined 15 minutes after weaning is begun and then every hour. The patient who tolerates the T-piece very well is extubated after 2 to 4 hours. Oxygen is then administered through a face mask with a heated nebulizer, at the same inspired oxygen concentration as during the T-piece trial.

The high success associated with T-piece weaning is related primarily to the fact that the clinician biases are removed from the process. In other words, the patient becomes the sole controller of his or her weaning and readiness for extubation. No guessing is involved. One is either ready or not for weaning, and the best way to determine this is to apply no support. The weaning process is very difficult because the patient's need varies on a breath-by-breath basis, such that the clinician is incapable of predicting such changes. The common error is to be too conservative, thereby prolonging the weaning process.

SIMV technique

Weaning is accomplished by a gradual decrease in the SIMV rate that the ventilator delivers, allowing the patient slowly to take over spontaneous ventilation. This system allows the patient to breathe spontaneously between the preset mechanical ventilation. This system ensures intermittent hyperinflation of the lung.

Weaning by SIMV is the least effective approach in terms of weaning time. It promotes dependence on the ventilator and can be "confusing" to the respiratory center. The delivery of the mechanical breath must coincide with the central inspiratory time. The same rule applies during exhalation. Prolonging the mechanical breath will overlap with the neural start of exhalation; that is, although the neural input is telling the patient to exhale, the ventilator continues to inflate the lungs. This is frequently seen in patients with COPD whose airway flow changes more slowly and the expiratory muscle becomes active during ventilator-induced inflation. A mismatch can also occur if the patient's inspiratory drive occurs before exhalation is complete, leading to "breath stacking."

Another important aspect of synchronization during PPV is the flow rate that changes on an intrabreath and an interbreath basis. Frequently, patients will show signs of "air hunger" and tachypnea if the inspiratory flow rate is inadequate. In most

ventilators, the flow rate is set at 60 L per minute. Too much flow is also problematic. Occasionally, the flow rate is increased to lower the inspiratory time while increasing the exhalation time. Unfortunately, the patient may respond adversely by becoming tachypneic, resulting in shortened expiratory times, which then potentiates dynamic hyperinflation (intrinsic PEEP). Several studies have shown a flow-related inspiratory termination reflex. Activating such reflexes can result in curtailing the neural inspiration producing shallow inspiratory efforts. Overall, the consequences of poor synchronization include increase in work of breathing, anxiety, patient discomfort, ineffective ventilation, and increased morbidity and mortality.

Pressure-support weaning

Pressure-support weaning can be combined with IMV and with CPAP weaning. Its proposed advantages include reducing the work of breathing, improving synchronization between the patient and the ventilator, reducing inspiratory pressures, and facilitating weaning. While on IMV, once the patient has been weaned to a minimum rate (i.e., IMV of 4 to 6 breaths per minute), the level of pressure support is gradually reduced (2 to 3 cm H_2O at a time). In some cases, this level of change is performed only once a day, whereas in other cases, the changes may be made several times a day. When the pressure-support level is at a minimum (<8 cm H_2O), weaning parameters are obtained in preparation for complete withdrawal from the mechanical ventilation. Attention to the pressure–volume and flow waveforms, which are available in most

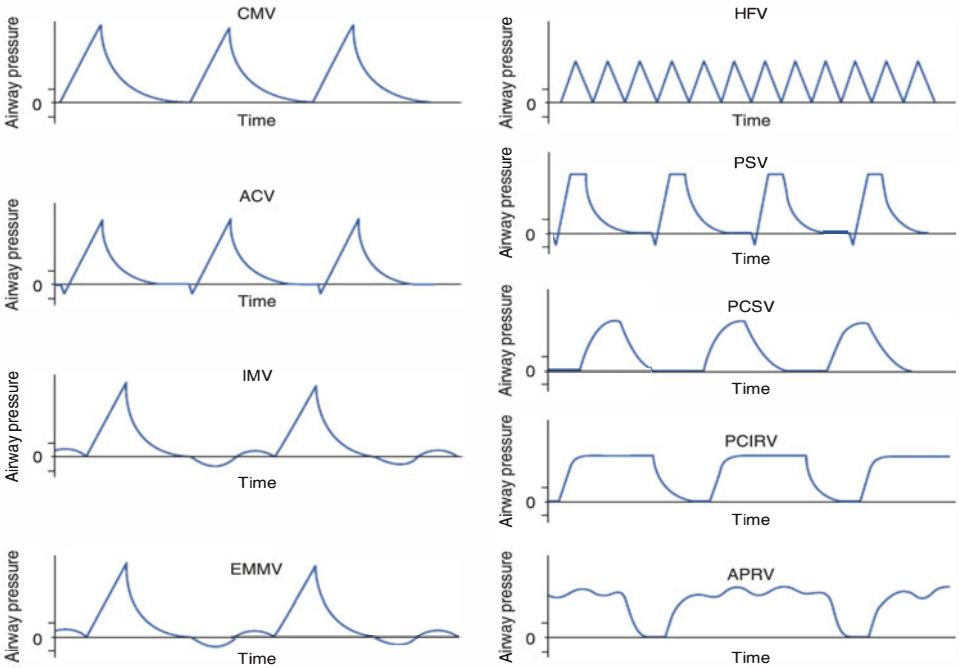

Figure 3.7 Airway pressure waveforms. ACV, assist/control ventilation; APRV, airway pressure-release ventilation; CMV, controlled mechanical ventilation; EMMV, extended mandatory minute ventilation; HFV, high-frequency ventilation; IMV, intermittent mandatory ventilation; PC–IRV, pressure-controlled inverse-ratio ventilation; PCV, pressure-controlled ventilation; PSV, pressure-support ventilation. (From Barash PG, Cullen BF, Stoelting RK, eds. *Clinical Anesthesia*. 4th ed. Philadelphia: Lippincott Williams & Wilkins; 2001:1470, with permission.)

mechanical ventilators, can facilitate the weaning process and help determine other important aspects of respiratory mechanics (Fig. 3.7).

As with IMV, the inherent problem with pressure-support weaning is the clinical biases that exist. Once again, the technology and the knowledge that allow for minute-to-minute assessment and adjustment of the dynamic environment of the patient's physiology needs are lacking. Consequently, we make predictions about the level of support the patient needs and await clinical and laboratory signs of problems or success.

Noninvasive ventilation to facilitate weaning

Noninvasive positive pressure ventilation (NIPPV) allows for patients to receive ventilatory support to decrease work of breathing, augment tidal volumes, improve gas exhange while preserving their ability to speak and cough. Additionally, NIPPV can reduce the risk of ventilator associated pneumonia. In a recent systematic review by Burns and colleagues, that examined the use of NIPPV to facilitate liberation from mechanical ventilation, the data suggested a mortality benefit and decrease in the incidence of ventilator associated pneumonia, especially in those with COPD.

Overall, difficulties with weaning can be ascribed in part to the heterogeneity of underlying pulmonary diseases and to inconsistencies in clinical practice. Data-driven approaches to weaning are often are nonpredictive of outcome and may fail to provide clinicians with signs of impending respiratory muscle fatigue. The patient's respiratory demand can vary considerably, requiring appropriate and timely ventilatory adjustments.

CHAPTER 4

Lung Transplantation

Nanhi R. Mitter and Charles W. Hogue, Jr.

A 52-YEAR-OLD WOMAN

with progressively worsening dyspnea on exertion, limitation of daily activity despite supplemental oxygen, and radiographic and spirometric evidence of severe obstructive pulmonary disease was scheduled for bilateral sequential lung transplantation. History was remarkable for 30 pack-years of smoking (although none for 10 years), mild hypertension (145/86 mm Hg), normal left ventricular ejection fraction, and osteoarthritis.

A. Medical Disease and Differential Diagnosis

1. What were the expected manifestations of severe obstructive pulmonary disease in this patient, and why is she a transplant candidate?
2. What other end-stage lung diseases can also be treated with transplantation?
3. How many lung transplantations have been performed?
4. What are the selection criteria for recipients?
5. How is the decision made to transplant one or both lungs, and does this influence preoperative management?
6. How does a single-lung transplantation differ technically from a double-lung transplantation?

B. Preoperative Evaluation and Preparation

1. What preoperative evaluation is desirable?
2. How would you premedicate this patient?
3. What vascular access is required?
4. Is preoperative epidural catheter placement advantageous?

C. Intraoperative Management

1. What special equipment is necessary?
2. How would you monitor this patient?

3. How would you induce anesthesia in this patient?
4. How would you ventilate this patient? What kind of endotracheal tube would you use?
5. How does the physiology of single-lung ventilation influence the procedure?
6. Should volatile anesthetics be avoided during single-lung ventilation?
7. At what specific points in the procedure are problems anticipated?
8. What problems are associated with the lateral position?
9. How does single-lung ventilation affect cardiopulmonary function? What are the problems of single-lung ventilation in this patient? How would you treat them?
10. How would you deal with problems related to clamping of the pulmonary artery?
11. What hemodynamic alterations would you expect during graft implantation and reperfusion? How would you correct them?
12. When is cardiopulmonary bypass (CPB) necessary for lung transplantation?
13. Should fluid administration be restricted, and are blood products commonly required?
14. Would you extubate the patient upon conclusion of the procedure?

D. Postoperative Management

1. What are the major complications after lung transplantation?
2. How is postoperative ventilation managed, and for how long is it required?
3. What special precautions should be taken when a lung transplant recipient requires general anesthesia for subsequent nonpulmonary surgery?
4. What are the long-term outcomes of lung transplantation?
5. Are there surgical alternatives to lung transplantation?

A. Medical Disease and Differential Diagnosis

A.1. What were the expected manifestations of severe obstructive pulmonary disease in this patient, and why is she a transplant candidate?

This patient suffered from increased airway resistance, reduced expiratory flow rates, and high residual lung volumes. When expiratory airway obstruction and lung hyperinflation become so severe that the chest cannot physically expand to accommodate a normal tidal volume, restrictive physiology becomes superimposed on obstructive disease. This condition is usually refractory to medical management and substantially limits daily activity. This patient's age and lack of other major systemic illness allowed her to be considered a transplant candidate.

Chronic obstructive pulmonary disease (COPD) (36%), idiopathic pulmonary fibrosis (21%), emphysema secondary to α_1-antitrypsin deficiency (7%), and cystic fibrosis (16%) are the most common obstructive disorders in adults undergoing lung transplantation. At one time, concerns about mediastinal displacement and profound ventilation–perfusion mismatch secondary to hyperinflation of the remaining native lung prevented surgeons from attempting single-lung transplantation for emphysema. However, clinical experience has demonstrated that many patients with emphysema can be successfully treated by single-lung transplantation. Because of the severe shortage of organs for transplant, single-lung procedures have been advocated as a means to increase the number of recipients. However, with 5-year survival rates after single-lung transplantation approaching only 50% and increasing experience suggesting that bilateral lung transplantation for COPD is associated with improved functional outcomes and improved long-term survival, bilateral lung transplantation emerged as a formidable (alternative)

approach to treat this patient population. The improved survival with bilateral lung transplantation may possibly be due to the later development of bronchiolitis obliterans syndrome, as well as a trend for higher quality of life score compared with single-lung transplantation. Nevertheless, although transplantation may improve quality of life for patients with severe COPD, the decision for single-lung or bilateral lung transplantation remains controversial and is based on the individual situation, taking into account regional organ allocation policies, individual center experience, and organ availability.

A.2. What other end-stage lung diseases can also be treated with transplantation?

The first successful (i.e., the patient left the hospital) single-lung transplantations were performed in 1983 for idiopathic pulmonary fibrosis. Since that time, the procedure has been applied to patients suffering from various end-stage pulmonary diseases (Table 4.1). In general, the underlying disease processes produce lung dysfunction that can be broadly characterized as obstructive, restrictive, infectious (e.g., cystic fibrosis and bronchiectasis), or vascular. As of 2008, most single-lung transplantations were performed for obstructive lung disease, followed by idiopathic pulmonary fibrosis. The most common indications for bilateral lung transplantation are cystic fibrosis and obstructive lung disease.

Reflecting a loss of lung parenchymal elasticity and compliance, end-stage restrictive disease is characterized by profoundly reduced lung volumes and diffusing capacity but relative preservation of ventilatory flow rates. Comparison of flow–volume loops representing obstructive and restrictive diseases is shown in Figure

Table 4.1 Lung Transplants Categorized by Disease

END-STAGE LUNG DISEASE	SINGLE-LUNG TRANSPLANT (% OF TOTAL)	BILATERAL/DOUBLE-LUNG TRANSPLANT (% OF TOTAL)
Cystic fibrosis	1.9	26.6
Retransplant	2.6	1.7
Idiopathic pulmonary arterial hypertension	0.7	5.4
α_1-Antitrypsin deficiency	6.5	7.6
Sarcoidosis	2.1	2.9
Idiopathic pulmonary fibrosis	29.1	14.5
Emphysema/chronic obstructive lung disease	49	25
Miscellaneous	5.2	6.6

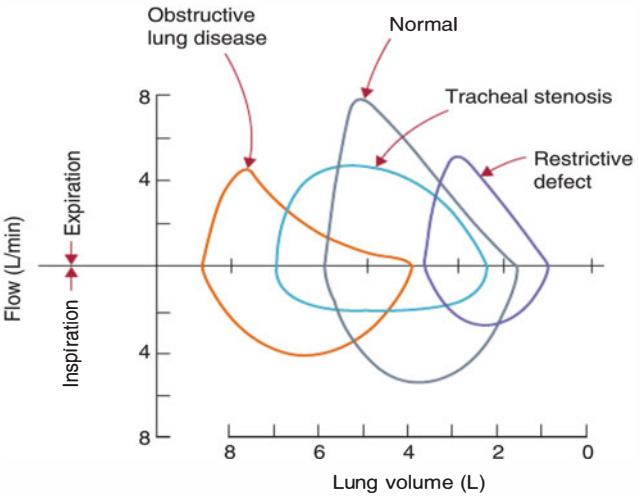

Figure 4.1 Representative tracings of flow–volume loops from a healthy individual, a patient with parenchymal obstructive disease, a patient with tracheal stenosis, and a patient with restrictive disease from parenchymal fibrosis. (Adapted from Goudsouzian N, Karamanian A. *Physiology for the Anesthesiologist.* 2nd ed. Norwalk, CT: Appleton-Century-Crofts; 1984:213.)

4.1. The underlying disease process also tends to obliterate pulmonary microvasculature, thereby chronically increasing vascular resistance, producing pulmonary hypertension, and predisposing to cor pulmonale. Most patients with restrictive disease are good candidates for a single-lung transplantation because the stiff, vasoconstricted native lung will receive relatively little ventilation and perfusion and can, therefore, usually be left without compromising the transplanted lung.

Infectious lung disease such as cystic fibrosis is the most frequent indication for lung transplantation in patients younger than 18 years. Characterized by chronic infection and the production of copious purulent secretions, patients with cystic fibrosis primarily exhibit functional abnormalities that are obstructive with increased airway reactivity. Under most circumstances, residual volumes and functional residual capacity are increased, and bronchodilators have little effect on expiratory flow rates. Because of potential infectious cross-contamination of the transplanted lung, chronic infectious disease represents a contraindication to single-lung transplantation. Nevertheless, single-lung transplantation with contralateral pneumonectomy has been performed and suggested as an alternative solution.

Pulmonary vascular disease with severe pulmonary hypertension and right ventricular dysfunction has also emerged as an indication for transplantation. Pathologically, severe pulmonary artery hypertension can result from idiopathic proximal vascular processes such as persistent pulmonary hypertension (PPH) or secondary to chronically increased pulmonary blood flow (e.g., left-to-right intracardiac shunt, leading to Eisenmenger syndrome) or pulmonary venous hypertension. Pulmonary hypertension may precipitate chronic hypoxemia if it is associated with an intracardiac defect that allows for development of a right-to-left shunt. Improved medical therapy for PPH, particularly with continuous long-term intravenous prostacyclin infusions or sildenafil, has affected the number of patients undergoing lung transplantation for this disease at some centers.

Controversy exists with respect to choice of single-lung versus bilateral lung transplantation for patients with idiopathic pulmonary arterial hypertension (IPAH).

Because a native lung can usually be left intact without compromising a transplanted lung (which will receive most of the blood flow), some patients with pulmonary vascular disease may be reasonable candidates for single-lung transplantation, with concurrent repair of any cardiac anomalies. Early reports indicated poorer functional recovery and higher mortality after single-lung versus bilateral lung transplantation for PPH. Some reports suggest the earlier manifestation of bronchiolitis obliterans syndrome in patients after single-lung versus bilateral lung transplantation, and although survival curves diverge 3 years after transplantation, controversy remains as to whether procedure type is the main cause. Some centers have adopted bilateral lung transplantation as the mainstay of treatment for patients presenting with IPAH.

A.3. How many lung transplantations have been performed?

Although the first human lung allograft was performed in 1963, transplantation of one or both lungs did not emerge as a viable therapeutic option for patients with end-stage lung disease until the 1980s. The ultimate emergence of this procedure can be largely attributed to advances in the prevention and treatment of airway complications, infections, and rejection. Since initiation of an international registry for lung transplantation in the mid-1980s, the number of procedures reported yearly rose sharply, until beginning to slow in 1993. To date, the highest yearly total was 2708 in 2008. Despite this volume, the number of patients awaiting lung transplantation continues to exceed the limited donor supply. As of the 2009 international registry, 29,732 lung transplantations had been reported worldwide.

A.4. What are the selection criteria for recipients?

In general, patients with severe end-stage lung disease are considered candidates for transplantation when their life expectancy is less than 2 to 3 years, they have minimal disease of other organ systems, and they are mentally and psychologically capable of following strict regimens for rehabilitation and immunosuppressive therapy. Specific criteria, including age, depend on the type of lung disease and whether the planned procedure is single-lung or bilateral lung transplantation. Recent data reveal that the

age of lung transplant recipients is increasing, with approximately 35% now 60 years of age and above compared to 15% in 1998. The average age of the recipient is 35.5 years. In contrast to criteria formulated when lung transplantation was in its infancy, concomitant steroid therapy, previous intrathoracic surgery, mechanical ventilation, and right ventricular failure are no longer considered absolute contraindications.

Christie JS, Edwards LB, Aurora P, et al. The registry of the international society for heart and lung transplantation: twenty-sixth official adult lung and heart-lung transplantation report—2009. *J Heart Lung Transplant.* 2009;28:1031–1049.

Myles PS. Pulmonary transplantation. In: Kaplan JA, Slinger PD, eds. *Thoracic Anesthesia.* Philadelphia: Elsevier Science; 2003:295–314.

A.5. How is the decision made to transplant one or both lungs, and does this influence preoperative management?

Single-lung transplantation is often preferred because of the extreme shortage of donor organs; nevertheless, as experience increases with double-lung transplantation and the improvement in outcomes compared with single-lung transplantation, many centers are performing double-lung transplantation more frequently. The only absolute contraindication to single-lung transplantation is infectious lung disease (e.g., cystic fibrosis and bronchiectasis), with which leaving the native lung could endanger long-term viability of the transplanted lung. As noted earlier, severe emphysema was once thought of as a contraindication to single-lung transplantation because of the probability of mediastinal shift and marked ventilation mismatch between the highly dispensable native lung and the graft. This is only rarely of clinical significance, and it is now accepted that single-lung transplantation can be successfully performed in patients with obstructive disease. Although single-lung transplantation is technically easier and advocated for more difficult recipients, such as those with prior thoracic surgery or coexisting illnesses, functional improvements are often better with bilateral lung transplantation. In addition, the status of the donor lungs further influences the decision of whether to perform a single or bilateral procedure. Finally, transplantation of two lobes from two living related donors for patients with inflammatory disease who are unlikely to survive the wait for a cadaver donor is gaining acceptance. From a practical standpoint, the decision to perform a single-lung or bilateral lung transplantation has little impact on preoperative management because both procedures necessitate the same level of preparation.

Sundaresan RS, Shiraishi Y, Trulock EP, et al. Single or bilateral lung transplantation for emphysema? *J Thorac Cardiovasc Surg.* 1996;112:1485.

A.6. How does a single-lung transplantation differ technically from a double-lung transplantation?

It is extremely important that anesthesiologists be broadly familiar with the surgical methods, because manipulation of the heart and lungs at specific points during

the transplantation can produce marked cardiopulmonary disturbances. Ideally, the anesthesiologist will anticipate these changes and adapt the anesthetic management accordingly. Description of the detailed technical aspects of lung transplantation are readily available.

Single-lung transplantation is usually performed in the lateral decubitus position through a thoracotomy incision, often with the upper leg and pelvis angled to allow groin exposure for potential femoral cannulation and CPB. In contrast, bilateral sequential lung transplantation is usually performed with the patient supine through a "clamshell" incision (bilateral anterior thoracotomies with or without transverse sternotomy). For both single-lung and bilateral lung transplantation, intermittent single-lung ventilation is required during dissection of the native lung to be removed and implantation of the graft. Once stable single-lung ventilation is established, dissection of the lung to be transplanted is initiated with isolation of the pulmonary artery. To assess the cardiopulmonary response to diverting the entire cardiac output through one lung, progressive temporary occlusion of the vessel is first performed manually; if well tolerated, the vessel is then clamped and stapled. After ligation of the pulmonary artery, the pneumonectomy is completed. Implantation of the graft begins with anastomosis of the airway. In the past, the bronchial anastomosis was wrapped with an omental pedicle, mobilized through a small abdominal incision in an effort to improve blood supply to the airway and promote healing. However, the use of a "telescoping" bronchial anastomosis has now largely obviated the need for omental wrapping. The pulmonary artery branch is then attached to the graft, followed by anastomosis of a cuff of the left atrium containing the pulmonary veins. The implanted lung is then partially inflated, air is remove from the left atrial cuff and pulmonary veins, and circulation to the organ restored.

Patients presenting for single-lung transplantation with chronic PPH of primary or secondary etiology often exhibit severe functional compromise of the right ventricle. To avoid additional right ventricular stress, many institutions choose to institute partial normothermic CPB during single-lung transplantation for PPH or in patients with severe pulmonary hypertension and right ventricular dysfunction secondary to restrictive or obstructive disease. Cannulation is typically through the femoral artery and the right atrium unless simultaneous correction of an intracardiac defect is planned. In such patients, conventional aortic and single- or double-stage atrial cannulation are performed. Implantation of the lung is otherwise performed in the same manner as described earlier.

Double-lung transplantation was first described by the Toronto Lung Transplant Group in the mid-1980s as en bloc implantation of both lungs simultaneously. The procedure is performed through a median sternotomy using hypothermic CPB, cardioplegic cardiac arrest, and single tracheal (or double bronchial) anastomosis of the trachea and main pulmonary artery. Although the procedure initially produced encouraging results, considerable limitations related to technical complexity, morbidity, mortality, and application to many patients with end-stage lung disease soon became apparent. Not surprisingly, use of the procedure declined sharply and has now been largely replaced by the bilateral sequential implantation technique, which does not uniformly require hypothermic CPB. Introduced in 1990, bilateral sequential (or bilateral single) lung transplantation has become the surgical procedure of choice when replacement of both lungs is necessary. According to the 2009 International Registry, 69% of the transplants performed were bilateral lung transplantations. As noted earlier, in contrast to single-lung transplantation, bilateral sequential lung transplantation procedures are performed in the supine position. In general, the procedure can be regarded as having two phases. First, the most severely compromised lung (as determined by preoperative ventilation–perfusion lung scanning) is removed during ventilation of the "good" contralateral lung. Implantation is achieved through a bronchial anastomosis as with single-lung

transplantation. The second lung is then removed and transplanted during ventilation of the new lung alone.

Pasque MK, Cooper JD, Kaiser LK, et al. An improved technique for bilateral single lung transplantation: rationale and clinical experience. *Ann Thorac Surg*. 1990;49:785–789.

B. Preoperative Evaluation and Preparation

B.1. What preoperative evaluation is desirable?

At most centers, an extensive physical examination, psychological evaluation, and numerous tests of cardiopulmonary function are performed before acceptance into the transplant program. This facilitates the preanesthetic evaluation that ideally is performed when the patient is first accepted into the transplant program. Familiarity with pulmonary function tests, ventilation–perfusion lung scan results, heart catheterization, echocardiographic data (including evidence of intracardiac shunts), exercise tolerance, oxygen use, and dependence on continuous pulmonary vasodilator infusion (i.e., prostacyclin) are beneficial for formulating an anesthetic plan. Although many of these parameters are regularly reassessed, the interval between evaluation and transplantation necessitates that a careful history and physical examination be performed before the procedure, focusing on signs of pulmonary hypertension and cardiac dysfunction.

Bigham M, Dickstein ML, Hogue CW Jr. Cardiac and lung transplantation. In: Estafanous FG, Barash PG, Reves JG, eds. *Cardiac Anesthesia*. Philadelphia: Lippincott Williams & Wilkins; 2001:636.

Myles PS. Pulmonary transplantation. In: Kaplan JA, Slinger PD, eds. *Thoracic Anesthesia*. Philadelphia: Elsevier Science; 2003:295–314.

B.2. How would you premedicate this patient?

As with all critically ill patients, considerations regarding preoperative sedation are governed primarily by the functional limitations imposed by the underlying disease and the potential consequences of hypercarbia and hypoxemia as a result of the sedation. Consideration must also be given to the possibility that the donor lungs will be deemed unacceptable at final inspection, and therefore the procedure is canceled and the patient discharged from the hospital. When indicated, parenteral sedation is usually chosen because of insufficient time to effectively administer oral anxiolytics. Midazolam alone or with diphenhydramine (potentially protecting the lung against drug-induced histamine release) is often sufficient. Clinically, most patients with end-stage restrictive, obstructive, or infectious lung disease are tachypneic while breathing room air and cannot be aggressively sedated. In contrast, patients with PPH and no intracardiac defect often appear reasonably normal and will benefit from sedation because of the potential for stress-related increases in pulmonary vascular resistance. Alternatively, patients with pulmonary hypertension and significant right-to-left intracardiac shunting (i.e., Eisenmenger physiology) are often cyanotic despite oxygen supplementation and may not tolerate sedation well. In addition, consideration needs be given to immunosuppression protocols and, in appropriate patients, supplemental bronchodilator therapy.

Hartigan PM, Pedoto A. Anesthetic considerations for lung volume reduction surgery and lung transplantation. *Thorac Surg Clin*. 2005;15:143–157.

Myles PS. Pulmonary transplantation. In: Kaplan JA, Slinger PD, eds. *Thoracic Anesthesia*. Philadelphia: Elsevier Science; 2003:295–314.

B.3. What vascular access is required?

Typically, a large-bore intravenous catheter and central venous access for pulmonary artery catheter placement are secured before surgery. In many centers, additional central venous cannulation is performed with a multiple-lumen catheter to provide intraoperative and postoperative venous access. For patients with chronic infectious lung disease or a history of previous intrathoracic procedures, a second large-bore intravenous catheter is often started because of the potential for brisk blood loss during dissection of pulmonary adhesions. Meticulous removal of air from venous infusion lines should be performed, particularly in patents with known or suspected right-to-left shunts. At many institutions, cannulation of a femoral artery, instead of the radial artery, is performed under local anesthesia in the operating room, because radial arterial pressures may become damped during the procedure secondary to positioning of the arms.

Hartigan PM, Pedoto A. Anesthetic considerations for lung volume reduction surgery and lung transplantation. *Thorac Surg Clin*. 2005;15:143–157.

Heerdt PM, Triantafillou AN. Anesthesia for lung transplantation. In: Flye MW, ed. *Atlas of Organ Transplantation*. Philadelphia: WB Saunders; 1995:313–318.

B.4. Is preoperative epidural catheter placement advantageous?

Pain control after lung transplantation can be critical in facilitating patient extubation and rehabilitation. Both lumbar and thoracic epidural catheters have been used for postoperative pain management. At many institutions, catheters are placed immediately before the procedure in most patients, despite the rare possibility of anticoagulation and CPB during the transplantation procedure. This practice is supported by data indicating no adverse sequelae to preoperatively placed epidural catheters, including patients who required emergent heparinization and CPB. Obvious exceptions to this approach are patients who undergo anticoagulation preoperatively or those in whom CPB is planned. Delaying placement of the epidural catheter until the postoperative period may also be a possibility.

Feltracco P, Barbieri S, Milevoj M, et al. Thoracic epidural analgesia in lung transplantation. *Transplant Proc*. 2010;42:1265–1269.

Myles PS. Pulmonary transplantation. In: Kaplan JA, Slinger PD, eds. *Thoracic Anesthesia*. Philadelphia: Elsevier Science; 2003:295–314.

C. Intraoperative Management

C.1. What special equipment is necessary?

Items necessary for lung transplantation procedures include an anesthesia machine with a ventilator capable of delivering a wide range of inspiratory/expiratory ratios, varying inspired oxygen concentrations, and differing ventilatory modes, as well as efficacy at higher airway pressures. Apparatus to deliver continuous positive airway pressure (CPAP) should be readily available, as should a fiberoptic bronchoscope to

confirm double-lumen tube positioning, provide guided airway suctioning, and inspect anastomosis. Access to transesophageal echocardiography is often beneficial, and a CPB machine should always be immediately available for lung transplantation. Although not specifically approved for this indication, an inhaled nitric oxide (iNO) delivery system is highly desirable during lung transplantation. Other drugs, including vasopressors, inotropes, and selective pulmonary vasodilators, also may be needed in these cases.

C.2. How would you monitor this patient?

Intraoperatively, hemodynamic and respiratory changes are often acute and profound, so extensive monitoring is imperative. In addition to the electrocardiogram, arterial blood pressure, and peripheral arterial oxygen saturation, pulmonary artery catheter placement is routine for lung transplantation at most institutions because of the profound changes in pulmonary and systemic hemodynamics that often occur. During single-lung transplantations, pulmonary artery catheters often migrate to the operative side after the patient has been laterally positioned even when radiographically confirmed to be in the nonoperative lung. Therefore, the surgeon should be reminded to palpate the pulmonary artery and withdraw the catheter if necessary before cross-clamping the vessel. Pulmonary artery catheters capable of measuring mixed venous oxygen saturation have become widely used. Transesophageal echocardiography is often employed during lung transplantation to evaluate right ventricular function, particularly during clamping of the pulmonary artery; to assess for intracardiac shunts; to assess the adequacy of air removal maneuvers; and to evaluate vascular anastomoses.

C.3. How would you induce anesthesia in this patient?

As with induction of anesthesia in any critically ill patent, multiple techniques have been safely used for patients undergoing lung transplantation. The only general rule is that induction be relatively gradual, because abrupt withdrawal of sympathetic tone in these patients with high sympathetic activity can result in marked cardiovascular compromise, particularly during the transition from spontaneous to mechanical ventilation. For this reason, injecting an epidural catheter with local anesthetic before induction of anesthesia can be problematic. Because effective alveolar ventilation and nitrogen washout are poor in the patient with severe obstructive lung disease and high residual volumes, prolonged (i.e., 15 to 20 minutes) preoxygenation is worthwhile, followed by a rapid-acting induction agent to shorten the excitement stage, expedite airway management, and prevent opiate-induced truncal rigidity. Thiopental, etomidate, propofol, and ketamine have all been used safely, but specific properties

of each drug in the setting of the patient's underlying disease should be considered. Thiopental, for example, may not be desirable for patients with bronchospasm or pulmonary hypertension because of a propensity for histamine release. Alternatively, the sympathomimetic properties of ketamine may preclude use in the presence of pulmonary hypertension, whereas its bronchodilating effects may be beneficial in the setting of bronchospasm. After administration of the hypnotic, fentanyl 10 to 15 μg per kg or sufentanil 1 to 2 μg per kg has been commonly used with either succinylcholine or a nondepolarizing muscle relaxant to complete induction. Benzodiazepines, scopolamine, or volatile anesthetic agents are frequently administered after induction to promote amnesia and in the case of volatile agents to promote bronchodilation.

C.4. How would you ventilate this patient? What kind of endotracheal tube would you use?

After induction, the trachea is usually intubated with a left endobronchial double-lumen tube for both single-lung and bilateral lung transplantation. Use of a single-lumen endotracheal tube with either an external or an internal bronchial blocking catheter has been described but does not appear to be clearly superior to the left endobronchial tube for most procedures. Furthermore, an endobronchial tube allows for differential lung ventilation if required postoperatively. One exception to this approach has been in patients with cystic fibrosis who exhibit thick, tenacious secretions that are difficult to suction through the small-lumen suction catheters necessary for double-lumen tubes. In these patients, it is often helpful to first place a large single-lumen tube and perform extensive bronchoscopic-directed bronchial lavage and suctioning before placement of the double-lumen tube.

The transition from spontaneous to mechanical ventilation invariably produces hemodynamic alterations resulting from acute changes in intrathoracic pressure and chest wall compliance. With obstructive lung disease, mechanical ventilation magnifies airtrapping, leading to pulmonary tamponade. Varying degrees of this phenomenon should be expected during anesthesia induction. The treatment consists of intermittent apnea with an open ventilator circuit, adjustment of the ventilatory pattern to an inspiratory/expiratory ratio of 1:5 or less with moderate tidal volumes, and administration of bronchodilating drugs. Prompt restoration of blood pressure usually ensues. If hypotension persists, other causes of circulatory compromise must be excluded, including pneumothorax. With restrictive disease, higher inflation pressures and positive end-expiratory pressure (PEEP) are often required. In both patients with obstructive disease and patients with restrictive disease, optimal balance of ventilation with hemodynamic stability often necessitates tolerating a degree of hypercapnia. In patients with pulmonary hypertension, mechanical ventilation usually produces less cardiovascular disturbance if caution is exercised not to increase pulmonary vascular resistance (e.g., from hypoxia, hypercarbia, or lung hyperinflation).

C.5. How does the physiology of single-lung ventilation influence the procedure?

In laterally positioned patients, gravity helps redistribute blood away from the nonventilated lung during single-lung ventilation and lessen intrapulmonary shunt. In supine patients, this benefit is obviously lost and single-lung ventilation may not be well tolerated. In general, because of large residual lung volumes that will become filled with a high concentration of oxygen content during the initial stages of the procedure, lung recipients with severe obstructive lung disease may initially maintain oxygenation for the first 10 to 15 minutes of single-lung ventilation. However, rapid arterial desaturation may then occur once a substantial portion of the residual volume is absorbed. Alternatively, patients with restrictive lung disease and a low functional residual capacity may rapidly exhibit both hypoxia and hypercarbia. Multiple steps can be taken to improve oxygenation, including insufflation of oxygen or CPAP to the nonventilated lung, bronchoscopic-guided suctioning of the ventilated lung, careful manipulation of the ventilatory pattern, and PEEP to the ventilated lung. Differential PEEP/CPAP should be done cautiously because increased airway pressure in the ventilated lung can divert blood toward the nonventilated side. In some patients, intermittent ventilation of the operative lung may have to be performed before pneumonectomy. In general, oxygenation improves after clamping of the pulmonary artery supplying the nonventilated lung. For desaturation not responding to the usual maneuvers, tourniquets can be placed around the pulmonary artery by the surgeon as a temporizing step until dissection permits proper stapling of this vessel.

C.6. Should volatile anesthetics be avoided during single-lung ventilation?

Because of experimental evidence demonstrating inhibition of hypoxic pulmonary vasoconstriction (HPV) by the volatile anesthetic agents, some authors have suggested that these drugs be avoided in the anesthetic management of patients with end-stage lung disease requiring single-lung ventilation. Nevertheless, the true clinical significance of these experimental observations remains somewhat controversial. From a clinical standpoint, commonly used doses of isoflurane (e.g., end-tidal concentrations of $\leq$1.0) have not been empirically associated with worsening of intrapulmonary shunt and hypoxia. Therefore, isoflurane remains widely used in these patients and may actually benefit some lung recipients because of its bronchodilating properties. (See Chapter 2, section C.13.)

C.7. At what specific points in the procedure are problems anticipated?

Problems can be anticipated at the following points:

- Anesthesia induction
- Lateral positioning
- Single-lung ventilation
- Clamping of the pulmonary artery
- Graft implantation
- Graft reperfusion

C.8. What problems are associated with the lateral position?

Single-lung transplantation is usually performed in the lateral decubitus position, often with the upper leg and pelvis angled to allow groin exposure for potential femoral cannulation and CPB. Not surprisingly, position-related changes in venous return, coupled with compression of the dependent lung by the mediastinum and diaphragm, may promote systemic hypotension and ventilation–perfusion mismatch. Furthermore, pulmonary artery pressure usually tends to rise after lateral positioning, probably because of gravity-induced shifts in pulmonary blood flow distribution, vascular congestion, and increased vascular resistance.

Triantafillou AN, Heerdt PM, Patterson GA. Lung transplantation. In: Youngberg JA, Lake CA, Roizen MF, et al, eds. *Cardiac, Thoracic and Vascular Anesthesia.* New York: Churchill Livingstone; 2000:703.

C.9. How does single-lung ventilation affect cardiopulmonary function? What are the problems of single-lung ventilation in this patient? How would you treat them?

Isolated ventilation of the dependent lung is often accompanied by a marked acute increase in peak inspiratory pressure and a subsequent gradual progressive rise in pulmonary artery pressure. As noted earlier, because of the beneficial effect of gravity on redistributing blood away from the nondependent nonventilated lung, single-lung ventilation is often tolerated better from a respiratory standpoint by patients undergoing single-lung transplantation in the lateral position than those undergoing bilateral lung transplantation in the supine position. Close monitoring of right ventricular performance during conversion to single-lung ventilation is extremely important because of the increase in afterload produced by hypoxic vasoconstriction and redistribution of blood flow. Though unusual, if the right ventricle becomes hypokinetic and distended, and if the ejection fraction decreases, ventilation may have to be altered to minimize pulmonary arterial pressure.

Triantafillou AN, Pasque MK, Huddleston CB, et al. Predictors, frequency, and indications for cardiopulmonary bypass during lung transplantation in adults. *Ann Thorac Surg.* 1994;57:1248–1251.

C.10. How would you deal with problems related to clamping of the pulmonary artery?

To assess the cardiopulmonary response to diverting the entire cardiac output through one lung, progressive occlusion of the vessel is first performed manually (Fig. 4.2). Careful assessment of right ventricular function is performed with transesophageal

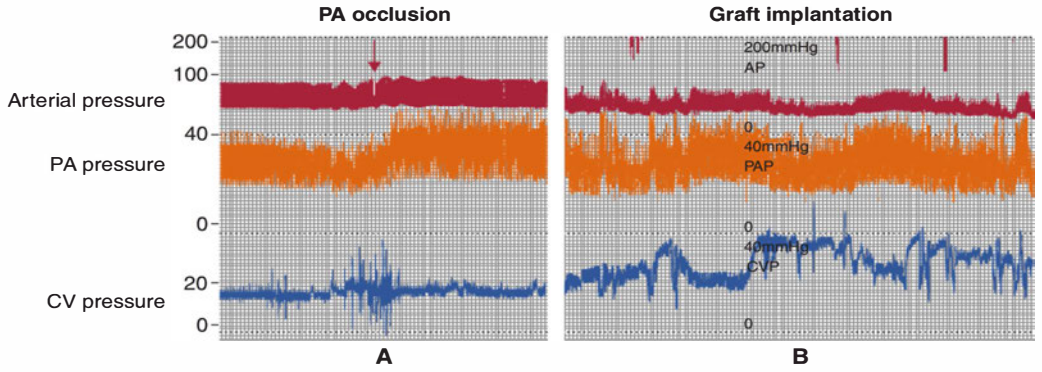

Figure 4.2 Tracings of femoral arterial blood pressure, along with pulmonary artery (PA) and central venous (CV) pressures, before and after occlusion of the left pulmonary artery (**A**) and during implantation of a left lung graft (**B**). (All pressures are in millimeters of mercury.)

echocardiography looking for evidence of right ventricular distention or hypokinesis. If well tolerated, the vessel is then clamped and stapled. If occlusion is poorly tolerated, the vessel is unclamped and a pulmonary vasodilator such as prostaglandin E_1 or iNO administered or positive inotropic infusion initiated. If severe respiratory or cardiovascular derangement persists after reclamping of the vessel despite pharmacologic intervention, heparin is administered and CPB instituted to avoid profound hypoxia or right ventricular failure. Nevertheless, for most patients undergoing single-lung transplantation, hypoxemia during single-lung ventilation and after pulmonary artery clamping is rarely a problem and right ventricular performance can be adequately maintained.

Triantafillou AN, Heerdt PM, Patterson GA. Lung transplantation. In: Youngberg JA, Lake CA, Roizen MF, et al, eds. *Cardiac, Thoracic and Vascular Anesthesia*. New York: Churchill Livingstone; 2000:703.

C.11. What hemodynamic alterations would you expect during graft implantation and reperfusion? How would you correct them?

During the process of performing the vascular and bronchial anastomoses, major disturbances on cardiac filling and rhythm can be produced (Fig. 4.2). Although often transient, systemic hypotension and pulmonary hypertension can ensue. Transient hypotension may follow the introduction of the vasodilator-containing lung graft preservatives into the systemic circulation. Incomplete removal of air from the lung can cause coronary artery air embolism, leading to transient myocardial ischemia. The latter is manifested by ST-segment elevation and regional wall motion abnormalities on transesophageal echocardiography. This condition is typically responsive to intravenous nitroglycerin while maintaining perfusion pressures with pressors. After reperfusion and subsequent ventilation of the new lung, pulmonary artery pressures and arterial blood gases should be closely monitored. Pulmonary artery pressure usually falls after reperfusion of the donor organ. If a substantial decrease is not observed, potential causes include anastomotic problems with the atrial cuff or the pulmonary artery. When pulmonary anastomotic problems are suspected, the surgeon should palpate to assess whether the pulmonary artery catheter is located proximal or distal to the anastomosis.

If a proximal location is confirmed, direct measurement of pulmonary artery pressures should be performed with a needle connected to pressure tubing handed off the operative field. Assessment of the pulmonary artery and venous flow pattern by transesophageal echocardiography can sometimes be of benefit in evaluating the adequacy of the anastomoses. Early graft dysfunction can manifest shortly after reperfusion of the first lung and may be the result of various insults. Occurring in 15% to 50% of cases, early graft dysfunction ranges in severity from modest chest radiograph abnormalities and increased inspired oxygen requirements to fulminant pulmonary edema with hypoxia and cardiovascular compromise. Immediate treatment includes adjustment of ventilation, addition of PEEP, and pulmonary vasodilators. iNO may be effective for improving oxygenation and reducing pulmonary artery pressures, and some clinicians advocate prophylactic iNO administration, although benefit of this intervention has recently been questioned. Should graft dysfunction become evident after implantation of the first lung, but before completion of the second lung transplantation, consideration should be given to initiating CPB. When severe hypoxemia persists after lung transplantation despite maximal medical therapy, including the use of iNO, extracorporeal membrane oxygenation (ECMO) may be indicated because primary graft dysfunction is the most frequent cause of perioperative mortality following lung transplantation.

C.12. When is cardiopulmonary bypass (CPB) necessary for lung transplantation?

CPB may be used electively for patients with severe pulmonary artery hypertension in whom double-lumen endobronchial tubes cannot be placed, or when visualization of hilar structures is poor. Nevertheless, in the absence of intraoperative complications, CPB is not desired because it can increase bleeding and blood product usage. It has also been suggested that CPB may aggravate postoperative lung dysfunction, although this has not been evident in cases in which lung transplantation was performed in conjunction with cardiac surgery. Nonetheless, the use of CPB has been associated with longer duration of mechanical ventilation and hospitalization, although it is difficult to differentiate whether the latter results directly from CPB or is the result of a complicated procedure that resulted in the need for it. Indications for CPB include right ventricular dysfunction not responding to medical therapy, early graft dysfunction occurring during implantation of the second lung during bilateral procedures, and surgical misadventures. Unplanned CPB is reported to occur in 12% to 46% of lung transplantation procedures, but predicting which patients may require this intervention is extremely difficult. Some report that CPB is more likely to be necessary for restrictive lung diseases than obstructive diseases.

In an attempt to derive the benefits of CPB while reducing complications, some centers advocate the use of heparin-bound ECMO systems. This approach allows for pulmonary support both during and after the procedure with minimal systemic anticoagulation.

C.13. Should fluid administration be restricted, and are blood products commonly required?

The amount of crystalloid that can be safely administered intraoperatively without adversely affecting the graft appears to be widely variable. Although efforts should be made to minimize fluid infusion intraoperatively, many patients undergoing lung transplantation require large amounts to maintain hemodynamic stability. Not uncommonly, central venous and pulmonary capillary wedge pressures of 3 to 5 mm Hg immediately after a transplantation are evident despite infusion of large amounts of crystalloid and colloid, as well as only moderate blood loss. The transplanted lung is at risk for pulmonary edema as a result of lack of lymphatic drainage and inflammatory insults, direct pulmonary trauma, and inflammatory cytokine release associated with reperfusion and organ harvest. The incidence of postoperative reperfusion pulmonary edema is described as 10% to 35%. Some reports suggest the practice of fluid restriction and low central venous pressures. In one study, central venous pressures greater than 7 mm Hg are correlated with longer intensive care unit stays and higher mortality.

Before the development of the bilateral lung transplantation procedure without CPB, patients with a history of surgery involving the lung or pleura or chronic infectious lung diseases were not deemed acceptable candidates for lung transplantation because of the anticipated excessive bleeding associated with dissecting a scarred lung after anticoagulation for CPB. Now, without the uniform requirement for heparinization, such patients are generally regarded as operative candidates. As with other surgical procedures in which hemorrhage is anticipated, continuous infusion of an antifibrinolytic has been proposed to reduce intraoperative bleeding in patients with cystic fibrosis or a history of previous intrathoracic surgery. Variables reported to increase the need for blood product usage include the use of CPB, double-lung procedures, and patients with cystic fibrosis. Transfusion therapy should remain a team decision and warrants a discussion between members of both the anesthesiology and

surgical staff. If blood products are to be administered, the anesthesiologist must know whether the patient has antibodies to cytomegalovirus and must closely check blood products to confirm they coincide with the patient's status.

C.14. Would you extubate the patient upon conclusion of the procedure?

Because of the cardiopulmonary insult associated with the procedure, the large postoperative volume shifts, hypothermia, and the frequent need for postoperative bronchoscopy, the trachea of lung transplant recipients is not generally extubated immediately after the procedure. Accordingly, unless intraoperative events (e.g., hyperinflation of the remaining intact lung) suggest that postoperative differential lung ventilation will be required, or unless functional issues such as profound oropharyngeal edema or difficult intubation are present, the double-lumen endotracheal tube is exchanged for a single-lumen tube. In many patients, the endotracheal tube change can be facilitated by use of an exchange catheter. Nonetheless, great care should be taken to not advance the catheter too far and damage the graft. It is often beneficial to perform fiberoptic bronchoscopy to examine bronchial anastomoses and aggressively suction secretions or blood after replacement of the double-lumen tube with a single-lumen endotracheal tube. As with many procedures, careful inspection of the upper airway for edema should be performed by laryngoscopy before exchange of the double-lumen endobronchial tube with a single-lumen endotracheal tube.

D. Postoperative Management

D.1. What are the major complications after lung transplantation?

Early graft dysfunction, episodes of rejection, infection, and airway complication are the major early complications of lung transplantation. Early graft dysfunction varies in severity from mild shunting and chest radiograph infiltrates to gross pulmonary edema. Management includes fluid restriction, diuretics, PEEP, iNO, and ECMO for severe cases. Immunosuppression is usually initiated before surgery, and the induction phase of therapy is continued for 5 to 10 days. The exact regimen varies among institutions but typically includes azathioprine, steroids, cyclosporine, and polyclonal antilymphocyte/antithymocyte globulins or interleukin-2 receptor antagonists. Acute rejection episodes are usually treated with intense steroid therapy and optimization of other immunosuppressant dosages. A challenge arises in differentiating acute rejection from infection as a source of shunting and chest radiograph infiltrates. Transbronchial biopsy is often necessary to make the distinction from histologic specimens. Bacterial pneumonia is the most frequent infection in the first 2 weeks. Although unusual in the first 2 weeks after transplantation, cytomegalovirus is the second most common source of infectious pneumonitis. Broad-spectrum antibiotics

are given perioperatively, and the regimen is adjusted based on the results of donor and recipient cultures. Antibiotic therapy for patients with cystic fibrosis is challenging, and the drug chosen is dictated by the patient's cultures and prior history of the organisms colonizing his or her lungs. Prophylactic acyclovir appears to be effective in reducing infections caused by herpes simplex, and trimethoprim-sulfamethoxazole is given to prevent infections from *Pneumocystis carinii*.

D.2. How is postoperative ventilation managed, and for how long is it required?

After most procedures, the fraction of inspired oxygen (F_{IO_2}) can be rapidly reduced, and weaning from the ventilator can be initiated as soon as the patient is warm and stable. An exception to this approach is the patient who has undergone single-lung transplantation for pulmonary hypertension. Because of a propensity for episodes of cardiopulmonary instability during the first 24 to 48 hours postoperatively, it is advantageous to keep these patients mechanically ventilated during this period, although increasing experience is revealing the positive effects of rapid weaning protocols in those patients who tolerate it.

Postoperatively, ventilation–perfusion mismatch and intrapulmonary shunt are often more pronounced after single-lung transplantation than bilateral lung transplantation. Not surprisingly, patients with restrictive disease usually display the best pulmonary function after single-lung transplantation, because the graft receives the majority of both ventilation and perfusion. Alternatively, after single-lung transplantation in patients with emphysema, the remaining native lung often receives a substantial portion of the tidal volume, whereas in patients with pulmonary hypertension, the native lung continues to be ventilated but receives very little blood flow. On rare occasions, differential ventilation of the transplanted and native lung is needed after single-lung transplantation for obstructive lung disease. In these situations, the double-lumen endobronchial tube is left in place and two ventilators are employed. The native lung is ventilated with low tidal volume (2 to 3 mL/kg) and rate, or even just connected to CPAP without intermittent mandatory ventilation. Nonetheless, the condition usually resolves rapidly with return of spontaneous ventilation. Postural changes in arterial oxygen saturation are often prominent in single-lung transplant recipients. In general, patients who received a single lung for pulmonary hypertension or emphysema display better postoperative pulmonary function with the "transplant side up," whereas the opposite may be true in certain patients with restrictive lung disease. The precise etiology of this response is unclear but probably reflects positional variation in ventilation-perfusion matching.

Triantafillou AN, Heerdt PM, Patterson GA. Lung transplantation. In: Youngberg JA, Lake CA, Roizen MF, et al, eds. *Cardiac, Thoracic and Vascular Anesthesia*. New York: Churchill Livingstone; 2000:703.

D.3. What special precautions should be taken when a lung transplant recipient requires general anesthesia for subsequent nonpulmonary surgery?

In general, after lung transplantation, the patient can be treated like any other ill immunocompromised patient. Recipients have subsequently undergone various surgical procedures unrelated to their pulmonary disease after lung transplantation and had few anesthetic problems. Not surprisingly, differences in the compliance and expiratory flow rates of a native and transplanted lung after single-lung transplantation for emphysema can result in alterations in intraoperative capnography. This phenomenon has been described as producing a biphasic pattern of carbon dioxide exhalation, with the first peak reflecting exhalation from the transplanted lung and the second peak exhalation from the native lung. In addition, the transplanted lung is denervated so the cough reflex is present only in the proximal native airway and mucociliary function is impaired. In contrast, hypoxic pulmonary vasoconstriction is intact after lung transplantation and central respiratory control is unaffected. Nevertheless, a blunted response to carbon dioxide may persist for patients with preoperative hypercapnia.

The major factor limiting long-term survival from lung transplantation is bronchiolitis obliterans syndrome. This progressive condition characterized by progressive narrowing of small airways must be considered in patients with prior lung transplantation presenting for surgery and anesthesia after the initial recovery phase. Other perioperative considerations for the patient with a prior lung transplant undergoing subsequent surgery are based on whether the patient was the recipient of one or two lungs. In the former case, ventilation and perfusion of the remaining diseased native lung is influenced by the functional status of the transplanted lung. For patients with obstructive lung disease, overinflation of the native lung and resultant mediastinal shift with associated ventilation and hemodynamic consequences, although rare, must be considered when employing positive pressure ventilation.

Although these patients should be assessed with the vigilance applied to patients without a history of transplantation, some points are noteworthy. Patients should be thoroughly evaluated to rule out the presence of an infection. Preoperative workup also should assess presence of renal dysfunction resulting from immunosuppressive therapy, presence of upper gastrointestinal bleeding from gastritis or peptic ulcer disease, and hepatobiliary or pancreatic dysfunction, because these are common after transplantation. Perioperative medications may also include a variety of antibiotic regimens, "stress-dose" steroids, and β-agonists because these patients may be more prone to bronchoconstriction. Aspiration precautions should also be implemented.

D.4. What are the long-term outcomes of lung transplantation?

Increased experience and improved techniques have made lung transplantation a realistic option for many patients. Nevertheless, the procedure is not without substantial risk and a favorable outcome is by no means ensured. Data suggest that survival after lung transplant is better in patients with cystic fibrosis, IPAH, sarcoidosis, and alpha antitrypsin (AAT) deficiency compared with COPD and idiopathic pulmonary fibrosis (IPF). This may be due to the fact that patients with COPD and IPF are older and have more comorbidities. Since 2009, 3-month and 1-, 3-, 5-, and 10-year survival rates after lung transplantation are 89%, 79%, 64%, 52%, and 29%, respectively. According to the registry data, the improvement in survival can be attributed to improvements in 1-year survival. Most patients who underwent bilateral lung transplantation demonstrated better survival compared with single-lung transplantation in all disease categories. Interestingly, malignancies (lymphomas early and then skin malignancies later) accounted for 12% of all deaths between 5 and 10 years after transplantation. The major cause of early mortality is graft dysfunction and noncytomegalovirus infection, and the major causes of late mortality are noncytomegalovirus infection, bronchiolitis obliterans syndrome, and rejection. Survival rates differed significantly by age, with lower short- and long-term survival in age-groups greater than 50 years of age.

Christie JS, Edwards LB, Aurora P, et al. The registry of the international society for heart and lung transplantation: twenty-sixth official adult lung and heart-lung transplantation report—2009. *J Heart Lung Transplant.* 2009;28:1031–1049.

D.5. Are there surgical alternatives to lung transplantation?

Some patients with severe emphysema who are not deemed transplant candidates may benefit from lung volume reduction surgery (LVRS) or "reduction pneumoplasty." Performed either through a median sternotomy or a bilateral thoracoscopy, the goal of LVRS is to remove up to 30% of the patient's most severely compromised lung tissue. Postoperatively, this allows the previously hyperexpanded chest and depressed diaphragm to resume a more normal shape, thereby improving chest wall mechanics and eventually pulmonary function. Nevertheless, beneficial effects of the procedure are not immediately evident, usually requiring 1 to 2 months. Furthermore, whether the improvement in pulmonary function is sufficient to warrant the risk of the procedure remains controversial. Recent data indicate that for many patients, LVRS represents a viable alternative to transplantation.

The Cardiovascular System

CHAPTER 5

Ischemic Heart Disease and Coronary Artery Bypass Grafting

Nikolaos Skubas, Anita L. Cave, Manuel L. Fontes, and Fun-Sun F. Yao

A 57-YEAR-OLD MAN

with triple-vessel coronary artery disease (CAD) was scheduled for coronary artery bypass grafting (CABG). He had a myocardial infarction (MI) 7 months ago. He was taking nitroglycerin, digoxin, metoprolol, isosorbide dinitrate (Isordil), and nifedipine. His blood pressure (BP) was 120/80 mm Hg and his heart rate (HR) was 60 beats per minute.

A. Medical Disease and Differential Diagnosis

1. What is triple-vessel CAD? Name the branches of the coronary arteries.
2. What are the indications for CABG?
3. What is percutaneous coronary intervention (PCI)? Discuss its indications, contraindications, and results.
4. What are the results of CABG?

B. Preoperative Evaluation and Preparation

1. Which preoperative tests would you order?
2. How would you evaluate the patient's left ventricular function?
3. What are the three major determinants of myocardial oxygen consumption? How are they measured clinically?

4. Which factors determine myocardial oxygen supply?
5. Would you discontinue digoxin? Why? What is its half-life?
6. Would you discontinue the β-blocker (metoprolol)? Why? What is its half-life? What is the role of β-adrenergic blockers in treating congestive heart failure (CHF)?
7. If the patient who is on metoprolol develops hypotension intraoperatively, how would you manage it?
8. What is nifedipine? How does it work?

C. Intraoperative Management

C.I. *Before Cardiopulmonary Bypass*

1. How do you monitor the patient?
2. What is the Allen test?
3. Should you monitor temperature from multiple sites?
4. How do you know that the tip of the pulmonary artery (PA) catheter is in the right ventricle (RV) or the PA?
5. What is normal pulmonary artery occlusion pressure (PAOP)?
6. Is it necessary to monitor PA pressure for coronary artery operations?
7. What are the complications of PA catheterization?
8. What are the hemodynamic consequences of myocardial ischemia (MI)? How can you detect MI? Is PAOP a sensitive indicator of MI?
9. How would you monitor electrocardiogram (ECG)? Why V_5? If you do not have precordial leads in your ECG machine, how can you monitor the left ventricle (LV)?
10. Discuss the principles and clinical applications of intraoperative transesophageal two-dimensional echocardiography.
11. How would you induce anesthesia?
12. How would you maintain anesthesia?
13. What is the better anesthetic agent for this operation—an inhalation or intravenous agent?
14. What are the cardiovascular effects of halothane, enflurane, isoflurane, desflurane, sevoflurane, morphine, and fentanyl?
15. Is isoflurane dangerous for the patient with CAD?
16. What is the cardiovascular effect of nitrous oxide (N_2O)?
17. What kind of muscle relaxant would you use? Why?
18. If ST-segment depression is seen during surgery, how would you treat it? What is the relation between perioperative myocardial ischemia and postoperative MI?
19. Would you use prophylactic nitroglycerin during CABG to prevent intraoperative myocardial ischemia or perioperative MI?
20. How would you correct hypertension?
21. How would you treat hypotension?
22. What are the indications for intravenous metoprolol, labetalol, or esmolol during surgery? How much would you give? What are the relative contraindications?
23. How would you correct increased PAOP?
24. What should you do during sternal splitting?
25. Would you monitor PAOP continuously? Why?
26. Discuss autologous transfusion and blood conservation for cardiac surgery.

C.II. *During Cardiopulmonary Bypass*

1. What anticoagulant would you give before cardiopulmonary bypass (CPB)? How much would you give? What is its mechanism?
2. What is the half-life of heparin? How is it eliminated?
3. How do you monitor heparin dosage? What is the activated coagulation time (ACT) test?
4. What is total CPB? What is partial bypass?
5. What is the purpose of venting the LV? How can it be done?
6. How many types of oxygenators are there? What are the advantages of each type?
7. What kind of priming solution would you use? How much priming solution would you use? When would you prime with blood? Why?
8. What are the advantages and disadvantages of hemodilution?
9. What kind of pumps do you use? Are they pulsatile or not?
10. How do you monitor the patient during CPB?
11. How much BP would you keep during CPB? Why?
12. How would you treat hypotension during CPB?
13. How would you treat hypertension (a mean arterial pressure [MAP] of over 100 mm Hg)?
14. How do you prepare an intravenous infusion of sodium nitroprusside, nicardipine, and nitroglycerin? What are the usual doses? Which do you prefer to use?
15. How much pump flow would you maintain during CPB?
16. How would you adjust the pump flow during hypothermia?
17. How would you adjust the pump flow during hemodilution?
18. What are the advantages of hypothermia? Does hypothermia offer neuroprotection?
19. How does blood viscosity change during hypothermia and hemodilution?
20. What are the main causes of death associated with accidental hypothermia?
21. Would you give anesthesia during CPB? Why?
22. Would you give muscle relaxants during CPB? How is the action of muscle relaxant affected during CPB?
23. How do you know the patient is well perfused during CPB?
24. How much gas flow would you use for the oxygenator? What kind of gas would you use? Why?
25. What are the disadvantages of hypocapnia during CPB?
26. The arterial blood gases and electrolytes during CPB are as follows: pH, 7.36; $Paco_2$, 42 mm Hg; Pao_2, 449 mm Hg; CO_2 content, 24 mEq per L; Na, 128 mEq per L; K, 5.8 mEq per L; and Hct, 20%. The patient's temperature is 27° C (80.6° F). At what temperature are blood gases measured? How would you correct the blood gases according to patient's body temperature? Would you treat the arterial blood gases at 37° C (98.6° F) or at patient's body temperature?
27. If the blood level of the venous reservoir is low, what would you replace it with? Blood or balanced salt solution?
28. How do you estimate the fluid balance during CPB?
29. How would you preserve the myocardium during CPB?
30. What is the cardioplegic solution? How much would you use?
31. For how long a period can the aorta be cross-clamped?

32. Why would urine become pink in some cases of CPB? What is the renal threshold for plasma hemoglobin?
33. At what temperature can the patient be weaned from CPB?
34. Why does it take longer to rewarm than to cool the patient by the pump oxygenator?
35. How would you defibrillate the heart internally during CPB?
36. Why is calcium chloride usually administered right before the patient comes off the pump?
37. If the HR is 40 beats per minute, what should you do?
38. How does the blood sugar level change during CPB? Why? Does hyperglycemia increase neurologic complications during CPB?
39. What are the effects of CPB on platelet and coagulation factors?
40. How would you prepare for termination of CPB?
41. How would you decide the need for inotropic support?

C.III. *After Cardiopulmonary Bypass*

1. How would you reverse heparin? How much protamine would you use? What are the other drugs used to neutralize heparin?
2. What is the action mechanism of protamine?
3. What are the complications of too much protamine?
4. Why did the patient develop hypotension after protamine was administered? How do you treat and prevent this condition?
5. What are the indications for intra-aortic balloon pump (IABP)?
6. What are the principles of IABP?
7. What are the complications of IABP?
8. Can PAOP represent left ventricular end-diastolic volume (LVEDV) after CABG?

D. Postoperative Management

1. What are the postoperative complications?
2. Would you reverse the muscle relaxants? Why?
3. When will you wean the patient from the respirator?
4. What criteria would you use in deciding when to wean the patient from the respirator?

A. Medical Disease and Differential Diagnosis

A.1. What is triple-vessel CAD? Name the branches of the coronary arteries.

Triple-vessel CAD involves progressive atherosclerosis of the major branches of the coronary arteries with eventual luminal obstruction and myocardial injury. The intimal disease is typically segmental but can be diffuse in severe cases. The coronary arteries are the following:

- The right coronary artery (RCA)
- The left anterior descending (LAD) branch of the left main coronary artery
- The left circumflex (CFX) branch of the left main coronary artery

The branches of coronary arteries are shown in Figure 5.1. The LAD and CFX arise from the left main coronary artery (LMCA). The sinus node is supplied by the RCA in approximately 50% to 60% of human beings and by the left CFX artery in the remaining 40% to 50%. The atrioventricular (AV) node is supplied by the RCA in 85%

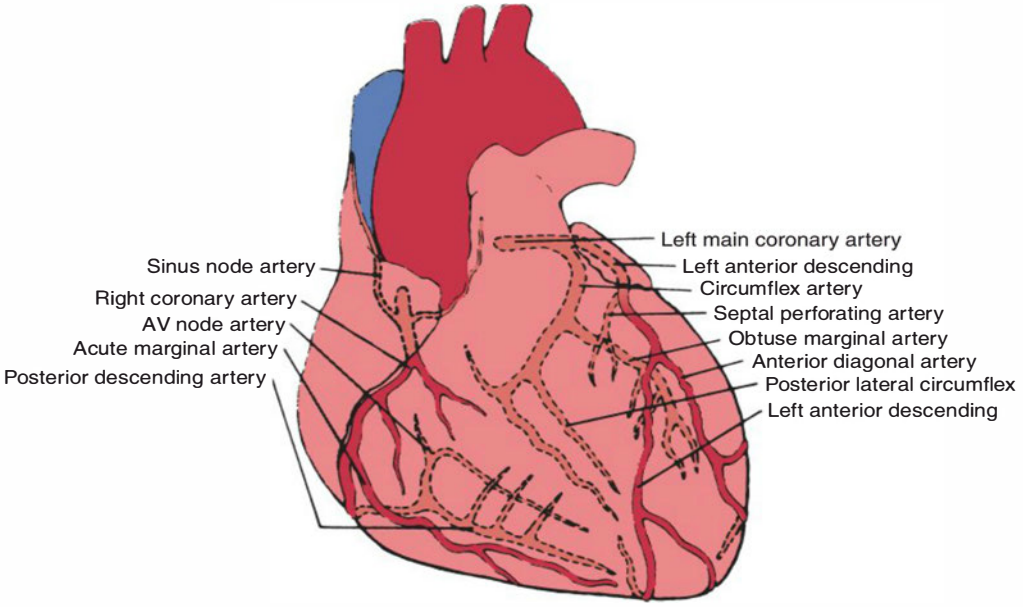

Figure 5.1 Branches of the coronary arteries.

to 90% of humans and by the left CFX artery in the remaining 10% to 15%; therefore, the RCA is dominant in 85% to 90% of patients. The most common arteries for coronary bypass grafting are LAD, obtuse marginal (branch of CFX), and posterior descending (branch of RCA) arteries.

Libby P, Bonow RO, Mann DL, et al., eds. *Braunwald's Heart Disease, A Textbook of Cardiovascular Medicine.* 8th ed. Philadelphia: Saunders Elsevier; 2008:465.

A.2. What are the indications for CABG?

The indications for CABG are the need for improvement of the quality or duration of life. Patients whose angina is not controlled by medical treatment or who have unacceptable side effects with such management should be considered for coronary revascularization.

The candidates for CABG are usually older patients with more diffuse CAD and decreased left ventricular function. The indications for CABG are as follows:

- Unstable angina pectoris or episodes of prolonged myocardial ischemia
- Persistent angina pectoris, despite optimal medical therapy
- Repeated episodes of myocardial ischemia following MI
- Prinzmetal angina (variant angina) with coronary artery obstruction
- High-grade LMCA obstruction, double- or triple-vessel obstruction, or proximal LAD artery obstruction
- Acute MI, cardiogenic shock, intractable ventricular arrhythmias
- Stable angina pectoris that interferes with desired lifestyle

Libby P, Bonow RO, Mann DL, et al., eds. *Braunwald's Heart Disease, A Textbook of Cardiovascular Medicine.* 8th ed. Philadelphia: Saunders Elsevier; 2008:1353.

A.3. What is percutaneous coronary intervention (PCI)? Discuss its indications, contraindications, and results.

PCI has developed rapidly since its introduction by Gruentzig in 1977. It is now an acceptable method of treating selected patients who have angina pectoris. This technique involves the passage of a small (3 French) catheter into the involved coronary artery and through the stenosis. With the balloon portion of the catheter straddling the stenosis, inflations are performed that result in enlargement of the stenotic lumen. The luminal widening is achieved by a controlled injury involving, to a varying degree, plaque compression, intimal fissures, and medial stretching. Next, coronary stents are introduced to maintain long-term patency. The stents are either bare-metal (cobalt–chromium alloy) or drug-eluting stents (DES).

PCI has redefined who is candidate for elective surgical myocardial revascularization. The indications for PCI have changed during the recent past. With the current available technology, PCI is considered a therapeutic option in any individual with disabling ischemic symptoms despite good medical therapy and focal obstructive coronary disease regardless of cause. The indications for PCI are as follows:

- Isolated discrete proximal single-vessel disease
- Proximal double-vessel disease
- Post-CABG with new stenotic lesions or stenosis at distal anastomosis
- Restenosis following PCI
- Contraindications to CABG
- Coronary stenosis following cardiac transplantation
- Occluded vessels within the last 6 months and less than 15 mm in length
- Poststreptokinase therapy for revascularization

PCI is contraindicated in the following:

- Left main CAD in which the distal vessels are not protected by at least one completely patent large collateral vessel
- Multivessel disease with severe diffuse arteriosclerosis
- Absence of a discrete obstructing lesion
- Absence of a formal cardiac surgical program within the institution

The results of PCI are as follows: The primary success rate is approximately 90%. The primary weakness of the procedure is restenosis, at a rate of approximately 30%, 6 months after the procedure. Dilatation can be repeated with a 90% success rate. The artery tends to remain patent after the second angioplasty. With the introduction of coronary stents, which act as a metal scaffold, the restenosis rate after PCI has been decreasing, and fewer patient require subsequent revascularization: 10% to 15% after stenting versus 25% to 35% after PCI alone. The largest decrease in luminal diameter following stent placement is evident within the first 6 to 9 months after stent placement and is the result of proliferative neointimal tissue growth in response to the associated injury and inflammation. Recently, pharmacologic agents (sirolimus, an immunosuppressant, and paclitaxel, an antineoplastic) are coupled with polymers that elute or slowly release these inhibitors from the stent surface. The DES have reduced the need for target-lesion revascularization to an even lower rate, 4% to 6%.

However, the PCI is a different therapeutic approach than CABG. PCI is targeting the area of lesion only, whereas CABG bypass targets not only the existing, but future lesion areas. This may be the reason that, at least in the intermediate term, CABG is considered to be superior for patients with multivessel disease.

Diegeler et al. showed that, for isolated high-grade lesions of the LAD, CABG through a left anterior thoracotomy is as effective as PCI with stent placement. Although stenting provided excellent short-term results with fewer periprocedural

adverse events, CABG was superior with regard to the need for repeated intervention in the target vessel and freedom from angina at 6 months of follow-up. Further, Serruys et al. compared outcomes between PCI with stent and CABG surgery and found that at 5 years, there was no difference in mortality between stenting and surgery for multivessel disease. Importantly, the incidence of stroke or MI was not significantly different between the two groups. However, overall freedom from major adverse cardiac and cerebrovascular events was higher in the stent group, driven by the increased need for repeat revascularization. A recent report on 10-year outcomes also showed that for the treatment of unprotected LMCA disease, PCI with stent implantation showed similar long-term mortality and rates of death, Q-wave MI, or stroke. However, stenting, even with DES, was associated with higher rates of repeat revascularization than was CABG. Lastly, a recent comparison between stenting and CABG in patients with previously untreated three-vessel disease or LMCA disease concluded that CABG remains the standard of care for patients with three-vessel or LMCA disease, since the use of CABG, as compared with PCI, resulted in lower rates of the combined end point of major adverse cardiac or cerebrovascular events at 1 year.

A.4. What are the results of CABG?

Kuan et al. reported a perioperative MI rate of 4% to 6%. The overall operative mortality rate of CABG at major medical centers is approximately 1%. Reoperation is associated with a higher operative mortality, approximately 2% to 3%. Rahimtoola et al. studied the status of patients who underwent CABG for unstable angina over a 10-year period. The 1-month mortality rate was 1.8%. The 5-year survival rate was 92%, and the 10-year survival rate was 83%. CABG was repeated at a rate of 1% to 2% per year; 81% of patients were angina-free or had only mild angina. Loop et al. found that the 10-year survival rate among the group receiving the internal mammary artery graft, as compared with the group receiving the vein grafts (exclusive of hospital deaths), was 93.4% versus 88% for those with one-vessel disease; 90.0% versus 79.5% for those with two-vessel disease; and 82.6% versus 71.0% for those with three-vessel disease. At the end of the first 10 postoperative years, the patency of internal mammary artery grafts is 85% to 95%, whereas the patency of saphenous vein grafts is only 38% to 45%.

A systematic overview of the seven randomized trials that compared coronary bypass surgery with medical therapy between 1972 and 1984 yielded 2,649 patients.

Patients undergoing CABG had a significantly lower mortality at 5, 7, and 10 years, but by 10 years, 41% of the patients initially randomized to medical therapy had undergone CABG. Therefore, coronary bypass surgery prolongs survival in patients with significant left main CAD (irrespective of symptoms), in patients with multivessel disease and impaired left ventricular function, and in patients with three-vessel disease that includes the proximal LAD coronary artery (irrespective of left ventricular function). Surgical therapy also has been demonstrated to prolong life in patients with two-vessel disease and left ventricular dysfunction, particularly in those with a critical stenosis of the proximal LAD coronary artery. Although no study has documented a survival benefit with surgical treatment in patients with single-vessel disease, there is some evidence that such patients who have impaired left ventricular function have a poor long-term survival rate with medical therapy alone. Such patients with angina and/or evidence of ischemia at a low or moderate level of exercise, especially those with obstruction of the proximal LAD coronary artery, may benefit from coronary revascularization by either angioplasty or bypass surgery.

Hannah et al. studied prospectively 37,212 patients who underwent CABG, and 22,102 patients who underwent stenting; CABG was associated with a significantly higher likelihood of survival (hazard ratios for death 0.75 for two- and 0.64 for three-vessel CAD, compared with stenting). The CABG patients had significantly lower median ejection fractions, were more likely than patients who received stents to have had an MI in the week before the procedure, had a significantly higher prevalence of numerous coexisting conditions, and were significantly more likely to have three-vessel disease.

More recently, use of perioperative statin therapy appears to significantly reduced mortality outcomes in patients undergoing CABG surgery. Magoven et al., reported an operative mortality of 2.4% for all patients, 1.7% for statin users and 2.8% for non-statin users ($P < .07$). According to multivariate analysis, lack of statin use was found to be an independent predictor of mortality in high-risk patients (n = 245, 12.9% vs. 5.6%, $P < .05$).

B. Preoperative Evaluation and Preparation

B.1. Which preoperative tests would you order?

In addition to the routine systemic examinations of all organ systems, special attention should be paid to the cardiovascular status.

- Renal function—urinalysis, blood urea nitrogen, creatinine
- The routine evaluation of the hepatic function is not any more the standard, unless specifically indicated, that is, previous history of hepatitis or jaundice or the patient is drug abuser.
- Pulmonary function—chest x-ray film (absolutely indicated in reoperated sternotomies to investigate the proximity of the sternum to the anterior surface of the heart), baseline arterial blood gases, and spirometry if indicated.
- Hematologic function—complete blood count, prothrombin time, partial thromboplastin time, platelets (platelet function if available and/or indicated; namely, for those patients previously receiving antiplatelet therapy)
- Metabolism—electrolytes and blood sugar
- Cardiovascular function—resting and exercise ECG (if a stress test was performed preoperatively), cardiac catheterization and coronary angiography, location and severity of coronary occlusion, echocardiography, and left ventricular function (from catheterization, magnetic resonance imaging, enhanced multidetector CT, and/or echocardiography).

B.2. How would you evaluate the patient's left ventricular function?

- Medical history—presence or absence of MI and angina
- Symptoms and clinical signs of left ventricular failure (dyspnea at rest or exercise, nocturnal orthopnea) and/or right heart failure (ascites, pitting edema, jugular vein distention)
- Cardiac catheterization, angiography, and echocardiography
- Ejection fraction (normally ~ 65%)
- Left ventricular end-diastolic pressure (LVEDP) or pulmonary artery occlusion pressure (PAOP: normal 6 to 15 mm Hg)
- Left ventricular wall motion—normal (wall thickening of >30%), hypokinesia (wall thickening of 10% to 30%), akinesia (wall thickening of <10%), or dyskinesia (outward motion during systole) (Fig. 5.2)
- Cardiac index (normal 2.2 to 3 L/min/m^2)
- Myocardial viability studies (contrast echocardiography or positron emission tomography study)
- End-systolic pressure volume relation from multiple pressure–volume loops

Abnormal regional wall motion (RWM), most commonly, is the result of CAD, which interrupts perfusion to fairly well-defined territories and hence results in abnormal motion in those segments. There is a gradation of wall motion abnormality that consists progressively of hypokinesis, akinesis, and, subsequently, dyskinesis in which a wall moves away from the center of the ventricle. Because wall thickening and endocardial motion are intrinsically tied, virtually all RWM abnormalities are expected initially to be associated with abnormalities of thickening as well as endocardial motion (see also Chapter 6, section A.3).

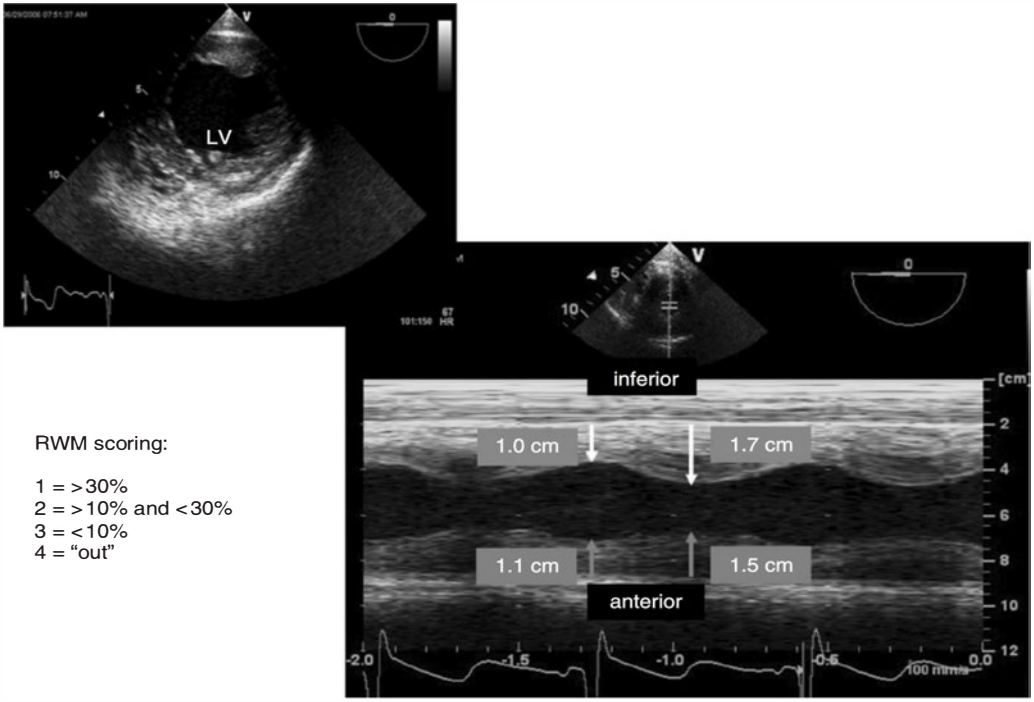

Figure 5.2 Echocardiographic evaluation of the left ventricle (LV). The transgastric mid-papillary short axis view of the left ventricle is shown in left. By placing a cursor line across the middle of the inferior (top of the image) and anterior (bottom of the image) segments of the left ventricular myocardium, the motion of the segments over time is shown in the right image. The percent wall thickening can be either visually estimated, or measured, between diastole and systole.

B.3. What are the three major determinants of myocardial oxygen consumption? How are they measured clinically?

The three major determinants of myocardial oxygen consumption are myocardial wall tension, contractility, and HR.

Myocardial wall tension is estimated by the following:

- The Laplace equation states that the wall tension (T) is analogous to the diameter of the ventricle (R, radius) and the intracavitary pressure (P) and inversely proportional to the myocardial wall thickness (Th): $T = P \times R \div 2Th$
- Preload—left ventricular end-diastolic volume (LVEDV), LVEDP, left atrial pressure, or PAOP
- Afterload—systolic ventricular pressure or systolic BP if there is no aortic stenosis

Contractility is measured by the following:

- *Invasive techniques.* Maximal velocity of contraction (Vmax), dP/dt (pressure time indices of ventricle: how fast [dt] the intraventricular pressure [dP] develops), or left ventricular end-systolic pressure/volume ratio
- *Noninvasive technique.* Preejection period/left ventricular ejection time, and global and regional ventricular wall motion by echocardiography (Fig. 5.3)

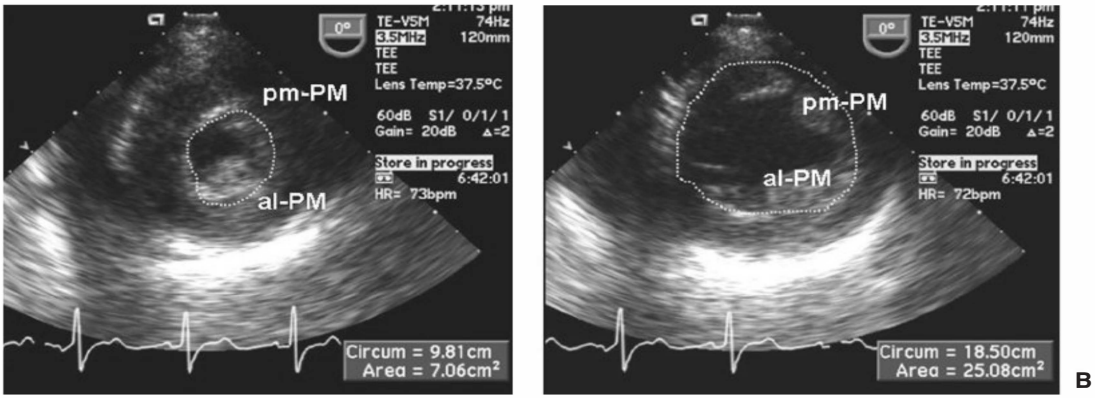

Figure 5.3 Echocardiographic evaluation of the systolic function of the left ventricle. The transgastric mid-papillary short-axis view of the left ventricle is shown in systole **(A)** and diastole **(B)**. The endocardial border is traced (without including the endocardium of the two papillary muscles), and the end-systolic (ESA) and end-diastolic (EDA) areas are calculated. The percentage area change (fractional area change [FAC]) is calculated as: FAC = (EDA − ESA)/EDA. The FAC correlates with, but does not substitute the percentage ejection fraction. al-PM, anterolateral papillary muscle; pm-PM, posteromedial papillary muscle.

B.4. Which factors determine myocardial oxygen supply?

Myocardial oxygen supply = coronary blood flow × arterial oxygen content

The coronary blood flow depends on the following:

- Aortic diastolic pressure (DAP)
- LVEDP
- Patency of coronary arteries
- Coronary vascular tone

And it can be determined by the formula:

$$\text{Coronary blood flow} = \text{coronary perfusion pressure} \div \text{myocardial vascular resistance,}$$
$$\text{Or, (DAP} - \text{LVEDP)} \div \text{myocardial vascular resistance}$$

Arterial O_2 content is determined by the following equation:

$$Cao_2 = 1.34 \times \text{hemoglobin} \times O_2 \text{ saturation} + (0.0031 \times Pao_2)$$

O'Brien ERM, Nathan HJ. Coronary physiology and atherosclerosis. In: Kaplan JA, Reich DL, Savino JS, et al., eds. *Kaplan's Cardiac Anesthesia.* 6th ed. Philadelphia: Elsevier Saunders; 2011:132–156.

B.5. Would you discontinue digoxin? Why? What is its half-life?

In order to prevent digitalis intoxication after CPB, digitalis preparations are usually discontinued one half-life (1.5 to 1.7 days for digoxin, 5 to 7 days for digitoxin) before surgery. Digitalis intoxication is quite possible, especially after CPB when acid–base and electrolytes are abnormal. If a digitalis-dependent patient is in congestive heart failure (CHF), digitalis is continued until the night before surgery. However, the predisposing factors to digitalis intoxication, especially hypopotassemia and hypercalcemia, have to be prevented.

Royster RL, Butterworth J, Groban L, et al. Cardiovascular pharmacology. In: Kaplan JA, Reich DL, Savino JS, et al., eds. *Kaplan's Cardiac Anesthesia*. 6th ed. Philadelphia: Elsevier Saunders; 2011:239–297.

B.6. Would you discontinue the β-blocker (metoprolol)? Why? What is its half-life? What is the role of the β-adrenergic blockers in treating congestive heart failure (CHF)?

The β-blocker (metoprolol) should be continued not only up until surgery, but probably throughout the perioperative period. In patients with unstable angina, sudden withdrawal of β-blocker may produce an exacerbation of symptoms and may precipitate acute MI. The dose of β-blocker does not need to be reduced before surgery for fear of bradycardia, hypotension, or difficulty in weaning from CPB. The half-life of oral propranolol is 3.4 to 6 hours and of metoprolol 3 hours. Both propranolol and metoprolol are metabolized in the liver. Propranolol disappears from the plasma and atria within 24 to 48 hours after discontinuing doses of 30 to 240 mg per day. Shand and Keats have shown that with a 0.5-mg dose of propranolol IV, blood levels as high as 50 ng per mL are obtained, but rapidly drop off to immeasurable levels within 5 to 10 minutes. No myocardial depression has been seen with these small intravenous doses. Current advanced cardiac life support guidelines suggest a 5-mg bolus of metoprolol at 5-minute intervals, and a 0.1 mg per kg bolus dose of propranolol divided into three equal doses at 2- to 3-minute intervals.

Reductions in HR with a β-blocker (propranolol or metoprolol) occur at lower serum levels than depression of myocardial contractility. Accordingly, as drug levels decrease after discontinuation of therapy, reductions in chronotropic response last longer than reductions in inotropy. This is an important concept in treating tachycardias in patients with significant ventricular dysfunction and CHF: a small dose is appropriate, and indicated, whereas a large dose may suppress even further the inotropic state.

Numerous studies have confirmed improvements in cardiac function, exercise capacity, and long-term survival in patients with heart failure resulting from MI, hypertrophic cardiomyopathy, or idiopathic dilated cardiomyopathy with β-antagonists. β-Antagonists may also be of benefit in patients with diastolic dysfunction, secondary to hypertension.

Potential benefits of β-adrenergic blockade in heart failure include decreased HR and normalization of β-receptor function. Slower HRs improve diastolic function by increasing the diastolic filling time and myocardial perfusion and by decreasing the myocardial oxygen consumption. β-Adrenergic receptors are downregulated in heart failure, but their response is normalized by long-term β-blockade. Partial β-agonists may provide baseline sympathetic drive but act as antagonists against excessive sympathetic stimulation.

B.7. If the patient who is on metoprolol develops hypotension intraoperatively, how would you manage it?

The more common causes of intraoperative hypotension, such as hypovolemia, deep anesthesia, and surgical manipulation, should be corrected first. There are no specific antagonists for metoprolol. In rare instances, it is necessary to administer atropine for bradycardia or epinephrine, isoproterenol, glucagon, calcium, or digitalis to counteract the negative inotropic state associated with β-blockade. Cardiogenic hypotension is usually associated with high PAOP and low BP.

Royster RL, Butterworth J, Groban L, et al. Cardiovascular pharmacology. In: Kaplan JA, Reich DL, Savino JS, et al., eds. *Kaplan's Cardiac Anesthesia*. 6th ed. Philadelphia: Elsevier Saunders; 2011:239–297.

B.8. What is nifedipine? How does it work?

Nifedipine is a calcium channel blocker. The commonly used calcium channel blockers in the United States are nifedipine, verapamil, and diltiazem hydrochloride. Five classes of compounds have been examined: phenylalkylamines, dihydropyridines, benzothiazepines, diphenylpiperazines, and diarylaminopropylamine. At present, verapamil (a phenylalkylamine); diltiazem (a benzothiazepine); nicardipine, nifedipine, isradipine, amlodipine, felodipine, nimodipine, clevidipine, (dihydropyridines); and bepridil (a diarylaminopropylamine ether) are approved for clinical use in the United States. They inhibit excitation—contraction coupling of myocardial and smooth muscle by blocking calcium influx at cellular membranes. This results in decreased myocardial contractility and vasodilation. Therefore, myocardial oxygen consumption is decreased. Calcium channel blockers are effective for the treatment of variant angina (Prinzmetal angina), angina pectoris, and possibly acute MI (see also Chapter 18, section A.11).

Although nitrates and β-adrenergic blockers are effective for angina, several of the calcium channel blockers are longer acting and may be used in the presence of chronic obstructive pulmonary disease and asthma. Calcium also plays a key role in cardiac electrical activity. The electrical activity of the sinoatrial (SA) and AV nodal cells are especially dependent on the calcium or "slow" current, whereas the remaining of the specialized conduction system is more dependent on the sodium or "fast" current. Verapamil has a more profound influence on the calcium current of the SA and AV nodes. This drug has been most useful in the treatment of supraventricular tachyarrhythmias, which are often caused by reentry through the AV node. In contrast, nifedipine has less influence on the SA node and no effect on AV conduction time. Therefore, nifedipine might be used when further suppression of AV conduction is undesirable. The relative cardiovascular effects of calcium channel blockers are shown in Table 5.1. Verapamil was found to profoundly depress the cardiovascular system during high concentrations of halothane, enflurane, or isoflurane anesthesia. However, because of a tendency for increased incidence of sinus arrest and bradycardia and more hemodynamic depression during enflurane anesthesia, Rogers et al. concluded that intravenous verapamil is better tolerated during low-dose isoflurane and halothane anesthesia than during comparable concentrations of enflurane anesthesia.

Table 5.1 Relative Cardiovascular Effects of Oral Calcium Channel Blockers

	VERAPAMIL	DILTIAZEM	NIFEDIPINE
Antiarrhythmic	+++	++	–
Cardiac depression	++	+	+
Vasodilation	+	++	+++
Tachycardia	–	–	++

–, No effect; +, mild effect; ++ moderate effect; +++ marked effect.

C. Intraoperative Management

C.I. *Before Cardiopulmonary Bypass*

C.I-1. How do you monitor the patient?

- ECG—simultaneous leads V_5 and II, multiple-lead ST-segment analysis
- Arterial line for BP and arterial blood gases
- Pulmonary artery (PA) catheter—pulmonary and central venous pressures (CVP), hemodynamic parameters (cardiac output, stroke volume, systemic and pulmonary vascular resistance)
- CVP line only—if the patient has good left ventricular function and no problems are expected
- Urine output
- Temperature—esophageal (or PA) and bladder (or rectal, tympanic, or nasopharyngeal)
- Laboratory—arterial blood gases, electrolytes, hematocrit, activated coagulation time (ACT), and oxygen saturation of the mixed venous blood (Svo_2)
- Airway pressures and respiratory gases analyzer
- End-tidal CO_2 analyzer
- Pulse oximeter for plethysmography (adequacy of peripheral pulse, pulse rate) and arterial oxygenation
- Transesophageal echocardiography (TEE) if not contraindicated. Absolute contraindications are esophagectomy or esophagogastrectomy, active upper gastroesophageal bleeding, or recent surgery, oropharyngeal trauma, and presence of esophageal pathology (tracheoesophageal fistula, stricture, trauma, tumor, scleroderma, Mallory-Weiss tear, and diverticulum). However, the anticipated benefits should be weighed against potential risks in every patient, prior to deciding whether to insert a TEE probe.
- Cerebral oximeter especially for patients with high risk of postoperative neurologic outcomes, such as those undergoing hypothermic circulatory arrest.
- Bispectral index to ensure adequate level of unconsciousness and eliminate the risk of intraoperative awareness.

C.I-2. What is the Allen test?

The Allen test is used to detect the presence of adequate collateral ulnar circulation. The radial and ulnar arteries are occluded by the examiner's fingers. The patient is then asked to make a tight fist repeatedly, to empty the blood from the hand (until the palmar skin is blanched). The hand is held above the heart level to help venous drainage. If the patient is under anesthesia, the blood in the hand may be drained by a third person squeezing the hand. Then, the fist is opened slowly and put down to the heart level. Only the ulnar compression is released and the flush of the palmar skin is watched.

- Normal—less than 7 seconds (presence of adequate collateral connections between the superficial [ulnar] and deep [radial] palmar arches)

- Borderline—7 to 15 seconds
- Abnormal—greater than 15 seconds

A modified Allen test may be done with a Doppler detector or a pulse oximeter. The results of Allen test are abnormal in approximately 3% of young healthy individuals. However, Slogoff et al. studied the complications following radial artery cannulation in 1,699 cardiovascular surgical patients. They concluded that in the absence of peripheral vascular disease, Allen test is not a predictor of ischemia of the hand during or after radial artery cannulation, and that radial artery cannulation is a low-risk, high-benefit monitoring technique that deserves wide clinical use. However, in the current litigious setting and in the face of some evidence to the contrary, it is probably prudent to continue to perform Allen test and document the results. Some authorities still consider the use of Allen test as the standard of care.

C.I-3. Should you monitor temperature from multiple sites?

In many cardiac surgery centers, measurement of two or more temperatures is common in order to estimate the accurate core temperature and achieve even distribution of body heat during cooling and rewarming by extracorporeal circulation (ECC), there is uneven distribution of body heat. Esophageal, nasopharyngeal, bladder, or tympanic sites measure core temperature; the axillary and rectal sites measure peripheral temperature. Urinary bladder temperature monitoring through a urinary catheter is quite convenient and popular, and reflects a body temperature between core and periphery. During cooling and rewarming by ECC, the core temperature changes rapidly, whereas the peripheral temperature changes slowly. The opposite changes are witnessed during surface cooling or warming.

Temperatures are measured during cooling on ECC to ensure that the organs most susceptible to potential hypoperfusion, such as the brain, actually receive the protective effect of the desired hypothermia. In this regard, nasopharyngeal or tympanic membrane temperatures are the monitoring sites, although they, at times, overestimate or underestimate the actual brain temperature. During rewarming, cerebral hyperthermia is often detected, should be avoided (by maintaining a gradient of 5° C between the arterial blood and brain, with the brain having the lower temperature), and should be corrected immediately because hyperthermia increases the cerebral oxygen consumption and may exacerbate postoperative neuropsychologic dysfunction.

Several modalities can be used: fluoroscopy, echocardiography (intraoperative TEE), and by pressure tracings.

C.I-4. How do you know that the tip of the pulmonary artery (PA) catheter is in the right ventricle (RV) or PA?

There are three main differences in the pressure tracings, as shown in Figure 5.4.

Diastolic pressure is higher in PA than in RV, because the closed pulmonary valve maintains a diastolic gradient between the PA and the RV

- PA pressure—20 to 25/5 to 10 mm Hg
- RV pressure—20 to 25/0 to 5 mm Hg

Pressure contour

- PA pressure tracing has a dicrotic notch, which is created by the closure of pulmonary valve, and the diastolic part is descending (decreasing).
- RV pressure tracing has a sharp drop and a plateau in early diastole, and the diastolic part is ascending (increasing).

Ventricular filling

- In the late diastolic phase, PA pressure is decreasing because of diastolic runoff in the pulmonary circulation, whereas the RV pressure is increasing because of ventricular filling.

C.I-5. What is normal pulmonary artery occlusion pressure (PAOP)?

- Normal—4 to 12 mm Hg
- Borderline—13 to 17 mm Hg
- Heart failure—over 18 mm Hg

Barash PG, Cullen BF, Stoelting RK, et al., eds. *Clinical Anesthesia.* 6th ed. Philadelphia: Lippincott Williams & Wilkins; 2009:706–707.

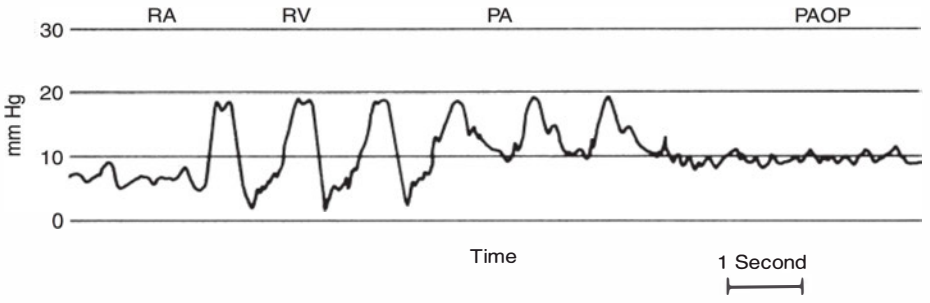

Figure 5.4 Pressure tracings of right atrium (RA), right ventricle (RV), pulmonary artery (PA), and pulmonary artery occlusion pressure (PAOP).

C.I-6. Is it necessary to monitor PA pressure for coronary artery operations?

The indication to monitor PA pressure includes the following:

Diagnostic

- Diagnosis of shock states
- Differentiation of high- versus low-pressure pulmonary edema
- Diagnosis of primary pulmonary hypertension
- Diagnosis of valvular disease, intracardiac shunts, cardiac tamponade, and pulmonary embolus
- Monitoring and management of complicated acute MI
- Assessing hemodynamic response to therapies
- Management of multiorgan system failure and/or severe burns
- Management of hemodynamic instability after cardiac surgery
- Assessment of response to treatment in patients with primary pulmonary hypertension

Therapeutic: Aspiration of air emboli

The indication to monitor PA pressure depends on the ventricular function. Patients may be divided into two categories on the basis of left ventricular function. For patients who have good left ventricular function (ejection fractions >50% and normal ventricular wall motion), the CVP is considered to correlate well with the PAOP; therefore, PA pressure monitoring may not be necessary for this group of patients. On the other hand, for patients with poor left ventricular function (ejection fractions <40% or prominent wall motion abnormalities), the CVP is not considered to correlate with the PAOP, and PA pressure monitoring is indicated. Other indications for monitoring PA pressure include the presence of pulmonary hypertension, combined coronary stenosis and valvular disease, and complex cardiac lesions.

However, results of several studies in recent past involving critically ill patients have consistently demonstrated that use of PA catheter was either associated with increased mortality and morbidity or no difference in fatal and nonfatal outcomes as compared to use of CVP alone or other noninvasive monitoring. Much debate exists regarding this topic and its unlikely that there ever will be a resolution. Nevertheless, there has been substantive reduction in the use of the PA catheter both in surgical and medical settings.

C.I-7. What are the complications of PA catheterization?

From venopuncture sites (as for central venous pressure)

Common complications:

- Infection—sepsis
- Hematoma
- Air embolism
- Thrombosis
- Catheter shearing and embolization

Subclavian approach:

- Pneumothorax
- Hemothorax
- Hydrothorax

Internal jugular approach:

- Pneumothorax
- Neck hematoma from puncture of carotid artery
- Possible vagus nerve injury and brachial plexus injury
- Thoracic duct perforation from left-side approach

The basilar or cephalic vein approach has fewer complications, but the failure rate is higher.

From pulmonary artery catheter

Arrhythmias 1.5% to 11%, complete heart block, thromboembolism, pulmonary infarction from continuous wedging, massive hemorrhage from perforation of PA or right atrium (RA), failure to wedge, hemoptysis, intracardiac knotting, balloon rupture, endocardial thrombi, and tricuspid valve injury.

C.I-8. What are the hemodynamic consequences of myocardial ischemia (MI)? How can you detect MI? Is PAOP a sensitive indicator of MI?

For four decades following Tennant and Wiggers' classic observation on the effects of coronary occlusion on myocardial contraction, it was believed that transient severe

ischemia caused either irreversible cardiac injury—that is, infarction—or prompt recovery. However, in the 1970s, it became clear that after a brief episode of severe ischemia, prolonged myocardial dysfunction with gradual return of contractile activity occurred, a condition termed *myocardial stunning*. Alternatively, severe chronic ischemia can result in diminished contractile performance manifested by chronic regional wall motion abnormalities (RWMA) (hibernation).

Acute myocardial ischemia affects systolic and diastolic pump function. Diastolic dysfunction usually manifests before systolic alterations in function. The immediate impact on ventricular compliance is related to the etiology of the ischemic event. Decreased myocardial oxygen supply is initially accompanied by an increase in compliance. In contrast, increased myocardial oxygen demand is associated with an immediate loss of ventricular compliance (e.g., the ventricle becomes stiffer). Therefore, the ventricle requires a higher filling pressure (end-diastolic pressure) to maintain a given stroke volume. A cascade of events occurs, which may include wall motion abnormalities, dysrhythmias, and conduction block. An 80% reduction of coronary blood flow causes akinesis (less than 10% of radial systolic thickening), whereas a 95% decrease causes dyskinesis (thinning, instead of thickening, during systole). If the ischemia becomes severe, the continuously elevated LVEDP will lead to pulmonary edema (Fig. 5.5).

Although a number of sensitive techniques are available for detection of ischemia, such as magnetic resonance spectroscopy, radio-labeled lactate determinations,

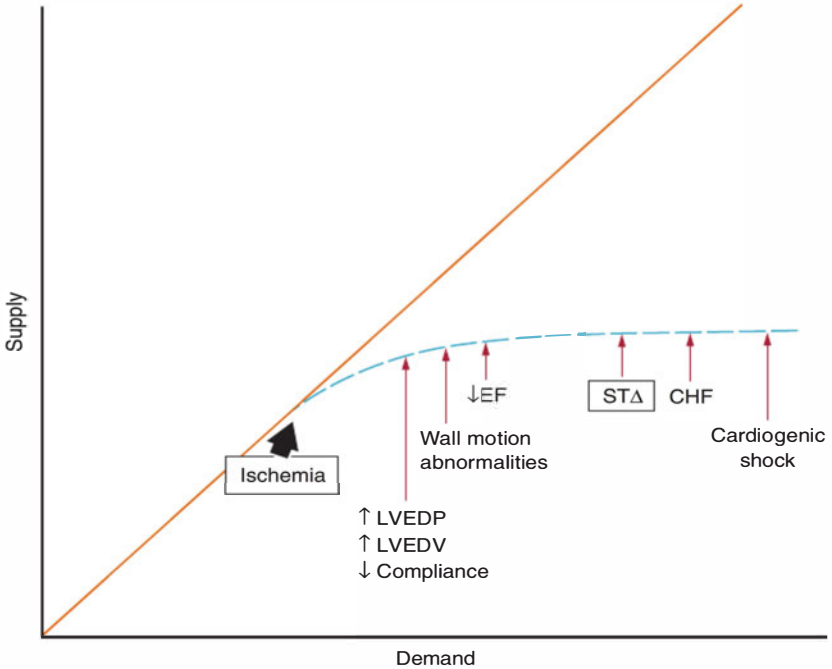

Figure 5.5 Hemodynamic consequences of myocardial ischemia. Ischemia occurs when demand exceeds supply. CHF, congestive heart failure; EF, ejection fraction; LVEDP, left ventricular end-diastolic pressure; LVEDV, left ventricular end-diastolic volume; STΔ, ST-segment changes. (From Barash PG. Monitoring myocardial oxygen balance: physiologic basis and clinical application. *ASA Refresher Courses in Anesthesiology.* 1985;13:24, with permission.)

or direct measurement of end-diastolic pressure, these are impractical. The most popular and accepted sign of ischemia is ECG ST-segment changes. The ECG criteria for ischemia are horizontal or down-sloping ST-segment depression at least 0.1 mV at 0.06 second from J-point, up-sloping ST-segment depression at least 0.2 mV at 0.08 second from J-point, and ST-segment elevation at least 0.15 mV (1 mV = 10 mm). Other ECG signs of ischemia include inverted T waves and a new onset of arrhythmias or conduction abnormalities.

RWMA, detected with two-dimensional echocardiography, have been shown to be the earliest and most sensitive sign of myocardial ischemia. RWMA are produced with just 25% decrease in coronary blood flow in the absence of ECG changes, whereas ECG signs of ischemia are apparent with a 50% decrease in coronary blood flow. During exercise, patients with CAD develop RWMA after 30 seconds, whereas ECG changes do not occur until after 90 seconds. Smith et al. found that RWMA was four times more sensitive than ECG ST-segment change in detecting intraoperative ischemia. Moreover, ST-segment changes cannot be analyzed if the patient has conduction disturbances, such as bundle-branch block or ventricular-paced rhythms. They have also found that patients experiencing persistent RWMA were more likely to have MI than those having only transient changes. No patient without a new RWMA had MI. Although TEE is the most sensitive monitor for myocardial ischemia, a recent study by Eisenberg et al. concludes that routine monitoring for myocardial ischemia with TEE or 12-lead ECG during noncardiac surgery appears to have little incremental clinical value over preoperative clinical data and two-lead ECG monitoring in identifying patients at high risk for perioperative ischemic outcome.

Measurement of PAOP has been suggested as an early and sensitive indicator of ischemia, to be used when the ECG is not diagnostic. Although acute increases in PAOP or development of V waves may reflect ischemia, the absence of a change in PAOP does not ensure the absence of ischemia. Haggmark et al. reported that the sensitivity, specificity, and predictive value (positive and negative) of PAOP abnormalities for ischemia ranged between 40% and 60%. In CABG patients, Lieberman et al. also found a low positive predictive value (24%) but a higher negative predictive value (85%); however, the PAOP was no better than CVP measurement, except in patients with moderate to severe preoperative ventricular dysfunction. Leung et al. found that 61% of TEE wall-motion abnormalities in CABG patients occurred without significant changes (>20% of control) in HR, systolic arterial pressure, or PA pressure. Only 10% of episodes were accompanied by 5 mm Hg or greater changes in PA pressure. Roizen et al. found that 11 out of 12 patients developed TEE wall-motion abnormalities when the aorta was cross-clamped above the supraceliac artery, but that PAOP remained normal (12 mm Hg) in 10 out of 12, with only 2 out of 12 having transient increases. Therefore, these studies question the value of PA catheterization and monitoring for detection of intraoperative ischemia.

C.I-9. How would you monitor electrocardiogram (ECG)? Why V_5? If you do not have precordial leads in your ECG machine, how can you monitor the left ventricle (LV)?

Multiple-lead ECG monitoring provides the best clinically available method of detecting perioperative ischemia. Based primarily on results obtained from exercise treadmill testing, combining ECG leads II and V_5, can detect 96% of ischemic events; therefore, leads II and V_5 are the optimal leads for intraoperative myocardial ischemia. However, London et al. recently found that the standard combination of leads II and V_5 was only 80% sensitive, whereas combining leads V_4 and V_5 increased sensitivity to 90% in patients with known or suspected CAD undergoing noncardiac surgery with general anesthesia. The sensitivity increased to 96% by combining leads II, V_4, and V_5. If only one lead can be displayed, V_5 should be used because lead V_5 has the greatest sensitivity: 75% intraoperatively and 89% during exercise treadmill testing. See also Chapter 13, section C.3.

C.I-10. Discuss the principles and clinical applications of intraoperative transesophageal two-dimensional echocardiography.

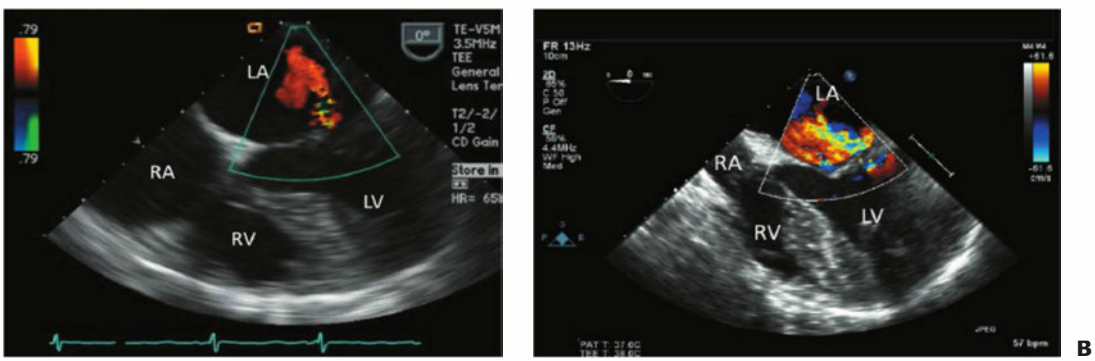
TEE is a well-established technique to visualize cardiac anatomy and function. Echocardiography is based on fundamental ultrasonic principles. Ultrasound is defined as sound above the upper threshold of human hearing (20,000 Hz). The ultrasound waves (1 to 7 MHz) are created by applying an alternating electric current of 500 to 1,500 pulses per second on a piezoelectric crystal. A short burst (pulse) of high-frequency, low-intensity sound is then emitted and directed through the human body to detect boundaries between structures of different acoustic impedance. The ultrasound wave is partially reflected at the boundary of media with different acoustic impedance, a property that is primarily determined by the slight difference in density between different tissues. The transmission of ultrasound through the heart, with detection of the returning echoes detailing the position and movement of cardiac structures, is termed *cardiac ultrasound* or *echocardiography*. Two-dimensional ultrasound reconstructs cardiac anatomy in shades of gray, from the time delay and decreased intensity of the reflected ultrasound. The ultrasound beam sweeps in an arc to give a panoramic view of the heart that results in cross-sectional images that are anatomically recognizable. M-mode ultrasound is a different technique, where the ultrasonic beam is aimed in one direction only and therefore depicts only one dimension of the target structure in an image that does not resemble cardiac structure. See also Chapter 6, section A.6.

Doppler echocardiography images blood flow by applying Doppler frequency shift analysis to echoes reflected by a moving target (red blood cells or cardiac tissue). The Doppler principle states that the frequency of the reflected ultrasound is different from the frequency of the emitted ultrasound. This shift in frequency is proportional to the speed of the moving target. Color-coded Doppler flow imaging (color flow Doppler) simultaneously presents real-time images of intracardiac blood flow and moving cardiac structures in two dimensions: continuous color maps of flow superimposed on gray-colored cross-sectional echocardiograms. Color flow Doppler permits the evaluation of valvular function and intracardiac shunts.

The clinical applications of intraoperative echocardiography are as follows:

- *Monitoring ventricular volume and function.* When left ventricular short-axis cross-section is monitored at the level of the midpapillary muscles, TEE provides the anesthesiologist with a direct, semiquantitative method to assess left ventricular preload and ejection in real time, and guide the administration of fluids and inotropes.

- *Monitoring diastolic function.* Both Doppler assessment of transmitral and transpulmonary vein flow patterns can provide important information about diastolic dysfunction that may be prevalent in as many as 50% of patients presenting for open heart surgery, namely, those with history of hypertension, aortic stenosis, and hypertrophic cardiomyopathy. It is important to note that in patients with valvular disease, a component of LV dysfunction arises from abnormal diastolic function.
- *Ischemic heart disease.* RWMA, such as hypokinesia, akinesia, and dyskinesia, are the earliest signs of myocardial ischemia (Figs. 5.2 and 5.3), as discussed in section C.I-8. Measurements of systolic wall thickening, another excellent sign of myocardial ischemia, are not reproducible because of a difficulty in delineating the epicardial border accurately in two-dimensional echocardiography. The impairment of the diastolic function can be qualitatively estimated and the filling pressures can be estimated using a combination of spectral Doppler measurements of the blood flow through the pulmonary veins and the mitral valve.
- *Valvular heart disease*
- *Air embolism.* In the left atrium, LV, and aorta, air embolism can be detected by TEE during open heart surgery. Therefore, TEE can be used to help the surgeon evacuate air bubbles from the left heart before the heart ejects blood and air into the systemic circulation.
- *Valvular regurgitation.* Valvular regurgitation can be determined intraoperatively by color Doppler echocardiography before and immediately after conservative valve repair (annuloplasty, commissurotomy) or valve replacement. The degree of valvular incompetency can be accurately measured using a combination of two-dimensional and Doppler techniques (Figs. 5.6 and 5.7), and the function of the repaired or replaced valve can be quantitatively evaluated.
- *Valvular stenosis.* Spectral Doppler echocardiography can be used intraoperatively to measure the pressure gradient across a valvular stenosis and calculate the area of the diseased valve.

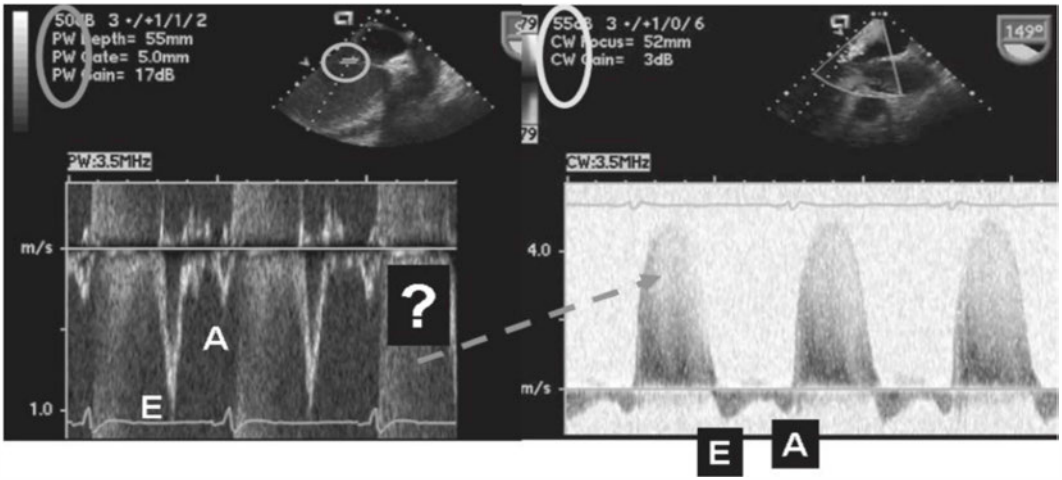


A B

Figure 5.6 Color Doppler echocardiography. **A.** Superimposed on a two-dimensional image (here, the mid-esophageal view), the relative velocities of the red blood cells from a selected area (*triangle*) are visualized. Timed to the ECG (*on the bottom of the sector image*), normal or abnormal blood flows can be viewed as they cross orifices. In this case, a small regurgitant jet originating from the mitral valve during systole is seen. The color of the jet displays velocity and direction, according to the scale, on the left side of the figure. The mitral regurgitation jet is moving upward toward the left atrium (LA), and is colored red. **B.** In this mid esophageal four chamber view of the left ventricle (LV), a systolic mitral regurgitant jet is directed inside the left atrium. RA, right atrium; RV, right ventricle.

Pulsed-wave Doppler
Site-specific (sample volume)
Aliasing limited: velocity <1.5 m/s

Continuous-wave Doppler
Cannot localize origin
Records very high velocity: 7–8 m/s



A B

Figure 5.7 Doppler mode. **A.** A typical pulsed-wave (PW) Doppler velocity consists of a spectral recording of varying intensity, depending on the acoustic density of the reflected interface (the mass of blood cells). The most dense (or brightest) portion of the spectral tracing represents the velocity of most blood cells. The velocity is recorded from a specific site (*white circle*), and the maximum velocity recorded is limited (usually <1.5 m/s). In this PW Doppler spectrum, *E* represents the diastolic early filling, and *A* the diastolic late (due to atrial contraction) velocity. During systole, there is a broad signal (*question mark*) representing systolic flow through the mitral valve (probably mitral regurgitation). However, neither the direction nor the peak velocity can be visualized. **B.** In contrast, continuous-wave (CW) Doppler records the velocities of all the red blood cells moving along the path of the sound beam. A CW Doppler recording always consists of a full spectral envelope with the outer border corresponding to the fastest moving blood cells. The site of origin of a high-velocity jet is inferred from the particular lesion that is being examined. The maximum velocity that can be recorded can be as high as 8 m/s. Here, the direction (from bottom to top, or from the left ventricle toward the left atrium) as well as the maximum systolic velocity (~ 5 m/s) can be visualized, detailing the mitral regurgitation jet.

- *Congenital heart disease*. TEE techniques allow a more aggressive approach to complex cardiac reconstructions because the surgeon has the ability to visualize the heart and evaluate adequacy of the surgical repair immediately after the operative procedure.
- *Thoracic aorta*. TEE can accurately diagnose thoracic aortic aneurysm, dissection, disruption, and atheromatosis. At the New York Presbyterian Hospital–Cornell Medical Center, we routinely use TEE for all patients to screen severe atheromatosis of the aortic arch and descending aorta. Epiaortic echocardiography is performed to examine the ascending aorta and arch if severe atheromatosis is found in the descending aorta or arch by TEE. Severe atheromatosis of thoracic aorta is an independent predictor of postoperative neurologic outcome. The atheroma is graded as follows: grade I, normal to mild intimal thickening; grade II, severe intimal thickening; grade III, atheroma protruding less than 5 mm into the lumen; grade IV, atheroma protruding greater than 5 mm; and grade V, atheroma with a mobile component (Fig. 5.8).

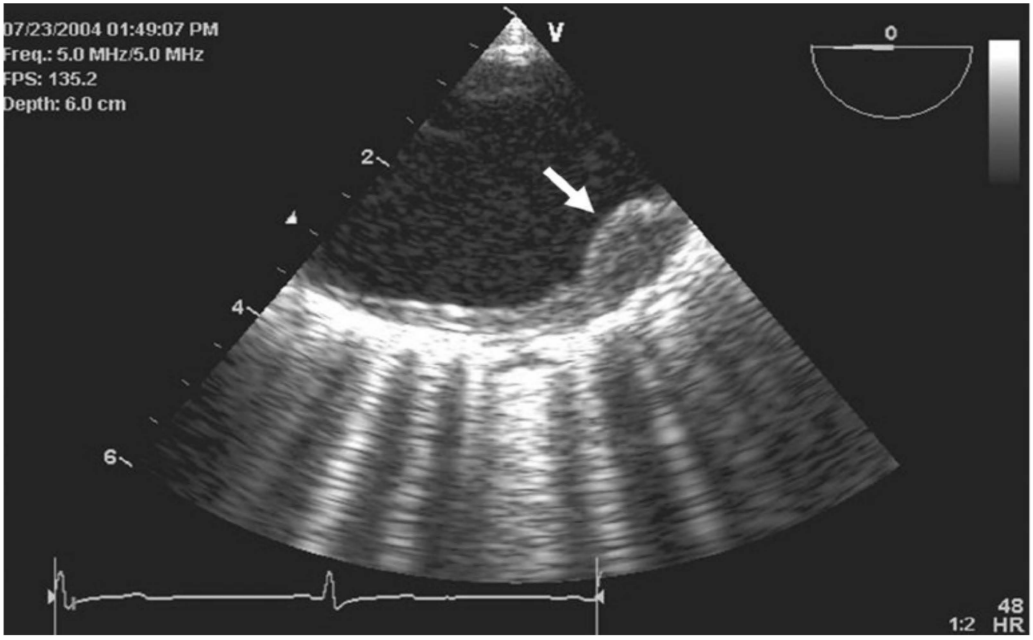


Figure 5.8 Atheromatous aortic disease. An echocardiographic picture of the short-axis view of the descending thoracic aorta is shown. The anterior aortic wall is irregularly thickened, and a large atheroma (8 mm) is present at 5 o'clock (*arrow*). This is a grade IV atheroma.

- *Cardiac tumors*. Atrial myxoma can be easily diagnosed by TEE. Preoperative and postoperative TEE with contrast can assess the presence and severity of mitral regurgitation secondary to valve damage from a ball-valve effect of the myxoma.
- *Other cardiac lesions*. Hypertrophic obstructive cardiomyopathy (HOCM) (idiopathic hypertrophic subaortic stenosis) can be identified by the combination of systolic anterior motion of the mitral valve and left ventricular outflow obstruction. Cardiac tamponade caused by a pericardial effusion or hematoma can be detected.
- *Neurosurgery*. TEE was found to be the most sensitive monitor to detect venous air embolism during neurosurgical operations in the sitting position. Patent foramen ovale and paradoxical air embolism can be detected by TEE.

C.I-11. How would you induce anesthesia?

Midazolam 1 to 2 mg is given as soon as the standard monitors are applied and prior to the arterial line is inserted (under local anesthesia). This is important in alleviating anxiety, which can exacerbate myocardial ischemia. A smooth induction is essential to prevent hypotension, hypertension, and tachycardia. Different techniques may be used to achieve a smooth induction. For patients with good left ventricular function, anesthesia is induced with fentanyl, 5 to 10 μg per kg; and thiopental (no longer available in the United States), 2 to 4 mg per kg; or propofol, 2 to 3 mg per kg. The patient is ventilated by mask with 100% oxygen. After administration of succinylcholine, 1 mg per kg, or pancuronium, 0.1 mg per kg, the trachea is intubated. The choice of non-depolarizing muscle relaxant varies extremely from center to among practitioners. Succinylcholine is used less frequently in cardiac surgery. If the patient has a history of hypertension or the initial systolic BP is over 150 mm Hg, fentanyl 10 μg per kg is usually required to blunt the intubation-associated hypertension and tachycardia. For patients with poor left ventricular function, potent inhalation agents such as isoflurane, sevoflurane, and desflurane should be used cautiously during induction of anesthesia because of their dose-dependent reduction in myocardial contractility and systemic arterial resistance. In lieu of the increasing incidence of delirium in the elderly postoperatively, benzodiazepines should be avoided in patients older than 70 years. Alternatively, etomidate 0.2 mg per kg may be administered for induction. However, it is more important to maintain stable hemodynamics than the choice of induction anesthetic agents. See also Chapter 10, section C.6 for other measures to prevent tachycardia and hypertension at the time of intubation.

C.I-12. How would you maintain anesthesia?

Again, smooth anesthesia is essential to achieve a balance between myocardial oxygen demand and supply. Different agents and techniques may be used to accomplish the same goal. A combination of fentanyl (or another synthetic opioid) and isoflurane, sevofluorane, or desflurane (or propofol) is a popular choice. After the patient is intubated, a mixture of 60% air and 40% oxygen is administered to lessen the possibility of oxygen toxicity. Clearly, this ratio is subject to underlying pulmonary disease and ongoing intraoperative clinical conditions.

The depth of anesthesia must be titrated to meet the requirements of the varying intensities of surgical stimulation. Skin incision and sternal splitting are very painful. But the strongest stimulation is usually from sternal retraction with the self-retaining retractor. Fentanyl, around 5 μg (0.1 mL) per kg (or another synthetic opioid), is given right before the skin incision, before sternotomy, and intermittently throughout sugery as needed to maintain adequate analgesia. Very high doses of fentanyl or sufentanil have been successfully used for cardiac anesthesia. There has been significant changes in practice over the past decade, whereby much lower doses of narcotic are administered to facilitate early extubation. Nowadays, maintenance of anesthetic is based on administration of volatile agents and smaller opioid dosages as was the practice in the 1980s and 1990s. Vasoactive agents are also used to regulate the hemodynamics (HR, systemic arterial pressure, and filling pressures)

C.I-13. What is the better anesthetic agent for this operation—an inhalation or intravenous agent?

Both inhalation, intravenous, and combined agents have been used successfully. Both have advantages and disadvantages. Understanding the cardiovascular effects of each anesthetic agent and careful titration of each drug will improve the balance between myocardial oxygen demand and supply. Early detection and appropriate control of the major determinants of myocardial oxygen consumption (BP, HR, PAOP) are mandatory if myocardial ischemia is to be avoided. Another consideration is the desirability of early extubation. High-dose narcotic and large doses of sedatives and muscle relaxants should be avoided if early extubation is planned.

Three large-scale outcome studies of patients undergoing CABG surgery reported that anesthetic choice did not affect incidence of perioperative morbidity and mortality. However, studies do point toward a beneficial effect of volatile agents in preconditioning the myocardium against an ischemic injury.

C.I-14. What are the cardiovascular effects of halothane, enflurane, isoflurane, desflurane, sevoflurane, morphine, and fentanyl?

In general, halothane, enflurane, isoflurane, desflurane, and sevoflurane produce a dose-related depression in ventricular function and vascular tonus. Halothane sensitizes the heart to catecholamine much more than enflurane, isoflurane, desflurane, and sevoflurane. Isoflurane and desflurane depress cardiac output to a lesser degree than does halothane or enflurane secondary to their greater vasodilating capacity. The HR changes least with halothane and increases most with desflurane. Isoflurane and desflurane may cause tachycardia if the inspiratory concentration is increased rapidly; the mechanism is due to increased sympathetic system outflow. Most studies suggest that halothane, enflurane, and isoflurane decrease coronary vascular resistance. Of these, isoflurane is the most potent coronary vasodilator.

All of the potent drugs decrease arterial pressure in a dose-related manner. The mechanism of BP decrease includes vasodilation, myocardial depression and decreased cardiac output, and decreased sympathetic nervous system tone. With halothane, decreased cardiac output is the predominant cause. Halothane also increases venous compliance, and in patients who have high sympathetic tone, such as those with heart failure, halothane decreases systemic vascular resistance. Enflurane causes both vasodilation and decreased myocardial contractility. With isoflurane and desflurane, a low peripheral resistance is the major cause of

hypotension. Evidence of the relatively greater myocardial depression with halothane and enflurane is the greater increase in right atrial pressure seen with these drugs than with isoflurane.

Narcotics such as morphine and fentanyl at their clinical dose have minimal cardiovascular effects. Both may cause bradycardia. Neither sensitizes the heart to catecholamine or depresses myocardial function. The cardiovascular effects of morphine depend on the dose used. Large doses of morphine sulfate have reportedly caused myocardial lactate production and reduction in coronary blood flow in animals. Sethna found that morphine sulfate, 0.25 mg per kg IV, did not produce a global myocardial ischemia in patients with CAD. High doses of morphine, 1 mg per kg, produce a significant decrease in arterial BP and systemic vascular resistance accompanied by an average 750% increase in plasma histamine. On the other hand, high doses of fentanyl, 50 μg per kg, do not produce any significant changes in BP, vascular resistance, and plasma histamine levels.

C.I-15. Is isoflurane dangerous for the patient with CAD?

In patients with CAD, the use of isoflurane is still controversial. Reiz et al. reported that 1% isoflurane induced coronary vasodilation that was not related to normal autoregulation and that both decreased coronary perfusion pressure (systemic hypotension), and redistribution of myocardial blood flow (coronary steal) may contribute to development of regional myocardial ischemia. Another Reiz study, using 1.5 minimum alveolar concentration (MAC) isoflurane–nitrous oxide anesthesia, concluded that isoflurane may cause coronary steal with myocardial ischemia in patients with CAD. However, Smith et al. reported that the substitution of 0.5% to 1.12% isoflurane for 85 μg per kg of fentanyl did not result in an increased incidence of myocardial ischemia, as seen by ST-segment or segmental wall-motion changes in patients with CAD. Moreover, Tarnow et al. demonstrated that 0.5% isoflurane with 50% nitrous oxide (N_2O) improved the tolerance to pacing-induced myocardial ischemia in patients with significant CAD. Two large-scale prospective outcome studies by Slogoff et al. and Tuman et al. could find no evidence that the incidence of ischemia was increased by isoflurane in patients with CAD undergoing CABG surgery. Furthermore, this finding held true even for patients with steal-prone coronary anatomy in the studies by Slogoff et al., Pulley et al., and Leung et al.

Several animal studies further confused this issue. Priebe proved that isoflurane was a myocardial depressant and a potent coronary vasodilator in the dog. Sill et al. demonstrated that high concentrations of isoflurane (1.5% and 2.5%) dilated intramyocardial arterioles rather than epicardial coronary arteries in the intact dog. Buffington et al. reported that isoflurane (1.2% to 1.5%) produced a decrease in collateral flow and a decrement in collateral zone contraction while enhancing flow in the normally perfused zone. They concluded that isoflurane was an arteriolar vasodilator and hence produced coronary steal in dogs with chronic

coronary occlusion. On the contrary, Cason et al. found that in the dog, isoflurane or halothane at 0.5% and 1.5 MAC had little effect on coronary vascular resistance, and ischemia was precipitated by tachycardia or hypotension rather than by coronary steal. Moreover, Davis and Frank demonstrated that isoflurane decreased myocardial infarct size after left anterior descending (LAD) coronary artery occlusion in dogs. In addition, Gilbert et al. reported greater coronary reserve in swine anesthetized with isoflurane versus halothane at 0.5 to 2.0 MAC. Recently, Hartman et al. demonstrated that adenosine, but not isoflurane, redistributed blood flow away from collateral-dependent myocardium in the presence of a coronary steal-prone anatomy in the chronically instrumented dog. They further found that reductions in myocardial perfusion during isoflurane anesthesia depend on systemic arterial pressure and that isoflurane did not produce coronary steal in this model of multivessel CAD. Furthermore, Cheng et al. found that neither isoflurane nor halothane as the sole anesthetic in clinical concentrations caused significant coronary vasodilation or coronary steal when the coronary perfusion pressure decreased from 55 to 30 mm Hg in a swine model of chronic coronary occlusion with collateral development.

On the basis of recent animal and recent clinical studies, we can conclude that isoflurane in clinical concentrations may be used safely in patients with CAD provided that hypotension and tachycardia are avoided.

C.I-16. What is the cardiovascular effect of nitrous oxide (N_2O)?

N_2O is a weak central nervous system depressant. It has been generally considered to have minimal effects on other organ systems. N_2O has significant cardiovascular effects that may be depressant or stimulatory, depending on the anesthetics with which it is combined. When high-dose fentanyl is used during coronary surgery, the effects of N_2O depend on the patient's cardiac function. Following the administration of 50% N_2O, there are no significant changes in any of the hemodynamic parameters in patients with normal left ventricular function (LVEDP <15 mm Hg). On the contrary, there is a significant decrease in cardiac index and stroke volume index in patients with left ventricular dysfunction (LVEDP >15 mm Hg). When added to other inhalation anesthetics, N_2O increases arterial pressure and systemic vascular resistance, suggesting that it has a vasoconstrictive action. N_2O increases pulmonary vascular resistance in patients with mitral stenosis and pulmonary hypertension.

The pulmonary vascular effects of N_2O are also variable. Patients with elevated PA pressure may have further increases when N_2O is added. Konstadt et al. did not corroborate these findings in patients with mitral valvular disease. A study in infants failed to show further increases of pulmonary vascular resistance with the addition of N_2O.

The contribution of N_2O to myocardial ischemia is controversial. Philbin et al. suggested that addition of N_2O to anesthesia with high-dose fentanyl (100 μg per kg followed by 1 μg/kg/min), or sufentanil (30 μg per kg followed by 0.3 μg/kg/min), can produce clinically imperceptible regional myocardial ischemia in the areas supplied by stenotic coronary arteries of dogs. However, monitoring with two-dimensional TEE did not reveal myocardial ischemia in patients with CAD when N_2O was added to low-dose fentanyl (15 μg per kg followed by 0.2 μg/kg/min), or high-dose sufentanil (20 μg per kg).

Clinically, N_2O may be used before CPB if high-dose narcotics are not used and hypotension does not occur. However, after CPB, N_2O should be avoided because of the possibility of expanding any air bubbles remaining in the coronary and cerebral circulation.

In the current clinical practices across the country, N_2O is probably used in very few centers, as the most common anesthetic scheme appears to be a balanced anesthetic with variable mixtures of oxygen in air, a potent volatile agent (amnesia) and low-dose fentanyl or sufentanil along with liberal use of vasoactive medications to regulate the hemodynamics.

C.I-17. What kind of muscle relaxant would you use? Why?

Previously, use of pancuronium in cardiac sugery was popular. When full paralyzing doses are given in a bolus, pancuronium generally produces tachycardia and

hypertension caused by vagolytic effect and norepinephrine released from cardiac sympathetic nerves. Pancuronium is an attractive agent to avoid hypotension and bradycardia (HR <50 beats per minute) when both the systolic BP and the HR are on the thresholds of normal. Theoretically, pancuronium may increase myocardial O_2 consumption caused by tachycardia and hypertension. In practice, most patients with CAD receive β-adrenergic blocking agents, which can counteract the vagolytic effects of pancuronium. Also, the bradycardia associated with the popular narcotic anesthetic techniques can attenuate the tachycardia induced by pancuronium. Rocuronium, vecuronium, and cisatracurium have no major cardiovascular effects, but their intermediate duration of action necessitates frequent administration of the relaxant.

Mittnacht A, Weiner M, London M, Kaplan JA. Anesthesia for myocardial revascularization. In: Kaplan JA, Reich DL, Savino JS, et al., eds. *Kaplan's Cardiac Anesthesia*. 6th ed. Philadelphia: Elsevier Saunders; 2011:522–569.

C.I-18. If ST-segment depression is seen during surgery, how would you treat it? What is the relation between perioperative myocardial ischemia and postoperative MI?

ST-segment depression may indicate myocardial ischemia, mostly from increased O_2 demand or decreased O_2 supply. The treatment includes the following:

- *Increase O_2 supply*. Correct hypotension (with IV phenylephrine), hypoxemia, anemia.
- *Decrease O_2 demand*. Correct hypertension, tachycardia, and increased PAOP or CVP by deepening anesthesia with a volatile agent or by using vasodilators (nicardipine or nitroglycerin) or β-blockers (metoprolol, esmolol, or labetalol). All the major determinants of decreased O_2 demand have to be considered and corrected to their normal levels.

Gerson et al. (in experimental dogs) found that elevation of ST segments induced by occlusion of the coronary artery was less prominent with halothane than with a combination of nitroprusside and propranolol. These can be explained the effects of halothane on coronary vascular reserve and the known effects of nitroprusside (reduction of myocardial blood flow to ischemic myocardium).

If there are no obvious changes in BP, HR, and pulmonary wedge pressure, nitroglycerin is indicated if coronary spasm is suspected. Nitroglycerin may be given by intravenous drip. Intravenous nicardipine or diltiazem may also be given to relieve coronary spasm.

Slogoff and Keats reported that perioperative myocardial ischemia occurred in 37% of all patients undergoing CABG. They proved that perioperative MI was almost three times as frequent in patients with ischemia (6.9%) compared with patients without ischemia (2.5%). Intraoperative tachycardia was associated with a higher incidence of myocardial ischemia and infarction. However, Knight et al. demonstrated that 42% of CABG patients had preoperative episodes of myocardial ischemia, 87% of which were clinically silent. They further found that anesthesia and surgery did not worsen the preoperative ischemic pattern. Furthermore, Slogoff and Keats in another study postulated that approximately 90% of new myocardial ischemia observed during anesthesia was the manifestation of silent ischemia observed in the patient before the operation, and only 10% was related to anesthetic management. Therefore, the relation between intraoperative ischemia and postoperative outcome is still unsolved.

It is important to note that ST-segment changes, suggestive of myocardial ischemia may be observed with alteration of the patients' position, particularly during retraction of the sternum for internal mammary harvesting. In addition to being

attentive to the ECG, addressing presence of ischemia by echocardiography and by changes in PA catheter is advised.

C.I-19. Would you use prophylactic nitroglycerin during CABG to prevent intraoperative myocardial ischemia or perioperative MI?

No. It has been reported that prophylactic administration of nitroglycerin, 0.5 or 1.0 μg/kg/min, during fentanyl anesthesia in patients undergoing CABG did not prevent myocardial ischemia or reduce the incidence of perioperative MI.

Royster RL, Butterworth J, Groban L, et al. Cardiovascular pharmacology. In: Kaplan JA, Reich DL, Savino JS, et al., eds. *Kaplan's Cardiac Anesthesia*. 6th ed. Philadelphia: Elsevier Saunders; 2011:239–297.

C.I-20. How would you correct hypertension?

$$\text{Blood pressure} = \text{blood flow} \times \text{resistance}$$

Hypertension is usually due to inadequate depth of anesthesia and/or activation of the sympathoadrenal pathways that occurs with stress/surgery. Rarely, it is due to fluid overloading. The treatment of hypertension includes the following:

- *Deepening the anesthesia*. Inhalation agents such as isoflurane and sevoflurane are more effective than narcotics because of their vasodilator effect.
- *Vasodilators*. When inhalation agents are not used.
  - Sodium nitroprusside produces more arteriolar dilation than venodilation. Dose: 10 to 100 μg per minute IV drip titration. More recently, nitroprusside's popularity has decreased and is infrequently used for acute management of perioperarive hypertension, whereas the second-generation (nicardipine) and third-generation (clevidipine) dihydroperidines calcium channel blockers have gained preference.
  - Nicardipine. Dose 0.5 μg/kg/min, titrate to effect.
  - Labetalol. Dose 5-mg increments, titrate to effect.
  - Nitroglycerin produces more venodilation than arteriolar dilation. Dose: 20 to 200 μg per minute IV drip titration, or bolus in 20-μg increments. It is important to note that this agent affects BP mainly via venodilation, which frequently will drop preload and may lower the cardiac output such that greater fluid intake may be required.

Also see Chapter 10, section C.10.

C.I-21. How would you treat hypotension?

Hypotension is usually caused by acute hypovolemia, deep anesthesia, bradycardia, or ventricular failure. The treatment options are as follows:

- Increase fluid infusion when CVP or PAOP is low (but beware of hemodilution in patients with anemia)
- Lighten the level of anesthesia or use a vasoconstrictor: phenylephrine, 0.1 mg IV increments, to correct vasodilation produced by anesthesia.
- For bradycardia, epicardial pacing may be used to increase the HR. Rarely, is atropine or other chronotropic agent used. These would include isoproterenol, ephedrine, dobutamine, epinephrine, and dopamine.
- Treat cardiac failure when PAOP is high and TEE shows global hypokinesis (poor diastolic and systolic function):
  - Avoid deep levels of anesthesia.
  - Restrict fluids.
  - Inotropes
    - $CaCl_2$ (0.5 to 1.0 g).
    - Epinephrine—2 to 8 μg per minute IV drip
    - Dobutamine or dopamine—5 to 20 μg/kg/min IV drip
    - Milrinone 0.025 mg per kg, then 0.2 to 0.5 μg/kg/min IV drip
    - Norepinephrine and/or vasopressin if peripheral vascular resistance is low.
    - Intra-aortic balloon pump (IABP)

C.I-22. What are the indications for intravenous metoprolol, labetalol, or esmolol during surgery? How much would you give? What are the relative contraindications?

Indications

- ST-segment depression associated with tachycardia; no response to deepening the level of anesthesia
- Supraventricular tachycardia
- Recurrent ventricular arrhythmias

Contraindications

- Asthma, reactive chronic obstructive pulmonary disease

Esmolol is cardioselective and appears to have little effect on bronchial or vascular tone at doses that decrease HR in humans. Esmolol is a short-acting β-blocker with an elimination half-life of 9 minutes and a pharmacologic half-life of 10 to 20 minutes. It has been used successfully in low doses in patients with asthma. Esmolol is metabolized rapidly in the blood by an esterase located in the erythrocyte cytoplasm.

Dosage

- Metoprolol, 1- to 2-mg increments every 1 to 2 minutes, total dose 5 to 10 mg.
- Esmolol, 10-mg increments up to 0.5 mg per kg followed by 50 to 300 μg/kg/min IV drip.
- Labetalol, 5-mg increments, titrate to effect. Not indicated if BP is decreased.

Royster RL, Butterworth J, Groban L, et al. Cardiovascular pharmacology. In: Kaplan JA, Reich DL, Savino JS, et al., eds. *Kaplan's Cardiac Anesthesia.* 6th ed. Philadelphia: Elsevier Saunders; 2011:239–297.

C.I-23. How would you correct increased PAOP?

It is important to consider all hemodynamics and not concentrate on one specific abnormal value. All monitored parameters should be taken into account. Increased PAOP during surgery is usually due to a light level of anesthesia or CHF. Combining the readings of PAOP and BP will produce a differential diagnosis. Occasionally, an increased PAOP with hypotension and low cardiac output is caused by HOCM, also known as idiopathic hypertrophic subaortic stenosis. HOCM can be diagnosed by TEE, which demonstrates systolic anterior motion of mitral valve and left ventricular outflow obstruction, mitral regurgitation, and usually good left ventricular contractility.

Inadequate anesthesia: Increased PAOP with hypertension

- Deepen the level of anesthesia with inhalation agents such as isoflurane, halothane, or enflurane, which also have a vasodilator effect.
- Give a vasodilator. Nitroglycerin is a better venodilator than nitroprusside.

Congestive heart failure: Increased PAOP with hypotension and low cardiac output

- Lighten the level of anesthesia.
- Use inotropes.
- Restrict fluids.
- Use arterial vasodilators to lower afterload in cases of very poor LV function and/or moderate to severe mitral insufficiency.
- Give diuretics. While an important agent for outpatient and for postoperative management of heart failure, they have extremely little to *no* role intraoperatively.

Hypertrophic obstructive cardiomyopathy

- β-Blocker and volatile agents to decrease HR and contractility
- Fluid loading to keep LV full and decrease LV outflow tract obstruction
- Increase afterload to keep LV full

Reich DL, Mittnacht A, London M, et al. Monitoring of the heart and vascular system. In: Kaplan JA, Reich DL, Savino JS, et al., eds. *Kaplan's Cardiac Anesthesia*. 6th ed. Philadelphia: Elsevier Saunders; 2011:416–451.

C.I-24. What should you do during sternal splitting?

For first-time sternotomy, it is recommended that ventilation be held to protect the lungs from injury from the electric saw.

C.I-25. Would you monitor PAOP continuously? Why?

No. If the Swan-Ganz catheter balloon is inflated continuously, pulmonary infarction distal to the occlusion may ensue. Usually the gradient between PA diastolic pressure and PAOP is estimated periodically intraoperatively, and PA diastolic pressure is monitored continuously instead.

Skubas N, Lichtman AD, Sharma A, et al. Anesthesia for cardiac surgery. In: Barash PG, Cullen BF, Stoelting RK, eds. *Clinical Anesthesia*. 6th ed. Philadelphia: Lippincott Williams & Wilkins; 2009:1073–1107.

C.I-26. Discuss autologous transfusion and blood conservation for cardiac surgery.

Autologous transfusion is the collection and reinfusion of the patient's own blood or blood components. The realization that homologous blood is responsible for transmission of AIDS, hepatitis, transfusion reaction, and autosensitization has led to increased interest in autologous transfusion and blood conservation. Most often, the easiest, safest, and most cost-effective approach for blood conservation is intraoperative normovolemic hemodilution, pharmacologic treatment, and perioperative blood salvage, while options such as preoperative autologous blood donation, preoperative use of erythropoietin, and intraoperative plasmapheresis are rarely used nowadays.

Preoperative autologous blood donation

Donations are appropriate for properly selected patients with stable CAD, stable valvular disease, and congenital heart disease. The risk of blood donation may be higher for patients with unstable angina or severe aortic stenosis; these patients are usually not considered good candidates for autologous blood donation. The patient should have a hemoglobin of greater than 11 g per dL to donate blood.

The optimal donation period begins 4 to 6 weeks before surgery, and the last donation is usually collected no later than 72 hours before surgery. Despite the potential benefits of the method, it is rarely used currently because of logistical reasons (multiple preoperative visits to the hospital, cost).

Preoperative use of erythropoietin

This is an established, efficacious but relatively expensive therapy to reduce blood transfusions. To optimize the hemoglobin response, oral or intravenous iron supplementation is recommended. The method is particularly indicated in anemic patients such as those with renal failure or patients of the Jehovah's Witness faith.

Intraoperative normovolemic hemodilution

This is the removal of blood through an arterial or venous catheter immediately after induction of anesthesia, before CPB or the administration of heparin. Depending on the patient's size and hematocrit, 500 to 1,000 mL of blood is collected into blood bags containing CPDA-1 anticoagulant and is kept at room temperature.

This blood is spared the rigors of CPB, including hemolysis, platelet destruction, and clotting factor degradation. The autologous blood is transfused after reversal of the heparin with protamine. It has been demonstrated that the effect of one unit of fresh whole blood on platelet aggregation after CPB is at least equal, if not superior, to the effect of 8 to 10 stored platelet units. However, if the patient's hematocrit is below 33% or the hemoglobin is below 11 g per dL, normovolemic hemodilution is not recommended because further decreasing the oxygen-carrying capacity may worsen myocardial ischemia. In addition, hemodilution during CPB will further decrease hematocrit to levels that require homologous blood transfusion. Normovolemic hemodilution should be performed cautiously in patients with critical left main coronary stenosis and aortic stenosis because sudden cardiac arrest has been observed during the procedure.

Pharmacologic treatment

The prophylactic use of ε-aminocaproic acid (EACA) and tranexamic acid reduces blood transfusions in cardiac surgery. The synthetic antifibrinolytics, EACA and tranexamic acid, bind to plasminogen and plasmin, thereby inhibiting binding of plasminogen at the lysine residues of fibrinogen. Effective antifibrinolysis requires a loading dose of 100 to 150 mg per kg for EACA or 10 mg per kg for tranexamic acid and a constant infusion for each at one-tenth the loading dose each hour.

Perioperative blood salvage

This is the collection and reinfusion of blood lost during and immediately after surgery. The posttransfusion survival of perioperatively salvaged red cells has been shown to be comparable to that of allogeneic red cells. At the conclusion of CPB, all blood remaining in the oxygenator and bypass circuits should be salvaged and, if needed, infused. Blood salvaged intraoperatively may be transfused directly (unwashed) or processed (washed) before infusion. Commercially available equipment exists for each option. Blood collected by intraoperative salvage represents an excellent source of red cell support. However, salvaged blood is deficient in coagulation factors and platelets.

Postoperative blood salvage is another technique of autologous blood transfusion utilizing blood lost following surgery. Blood salvaged following cardiac surgery generally is collected from mediastinal and chest drains and transfused without washing. Because usually it is defibrinated, it does not require anticoagulation before transfusion. Although dilute, the blood is sterile and contains viable red cells.

C.II. *During Cardiopulmonary Bypass*

C.II-1. What anticoagulant would you give before cardiopulmonary bypass (CPB)? How much would you give? What is its mechanism?

Heparin has been used conventionally in doses of 300 (200 to 400) units per kg of body weight, assuming an initial concentration of at least 2 to 4 units per mL of whole blood. Empirically, after 2 hours of the initial dose, subsequent doses of 1 mg per kg are given for each additional hour of bypass. Because there is marked individual variation, heparin doses are best monitored by the celite–activated coagulation time (ACT) test.

Heparin acts indirectly by means of a plasma cofactor. The heparin cofactor, or antithrombin III (AT III), is an α_2-globulin and a protease inhibitor that neutralizes several activated clotting factors: XIIa, kallikrein, XIa, IXa, Xa, IIa, and XIIIa. AT III forms irreversible complexes with thrombin (IIa) and, as a result, both proteins are inactivated. Inhibition of thrombin and factor Xa accounts for most of the anticoagulant effect of heparin. Heparin increases the rates of the thrombin–antithrombin reaction at least 1,000-fold by serving as a catalytic template to which both the inhibitor

and the protease bind. Heparin also binds to cofactor II, a glycoprotein of 65,000 Da that inactivates thrombin independently of AT III. This reaction occurs more slowly and requires higher heparin concentrates than does thrombin inhibition through the heparin–AT III complex.

Spiess BD, Horrow J, Kaplan JA. Transfusion medicine and coagulation disorders. In: Kaplan JA, Reich DL, Lake CL, et al., eds. *Kaplan's Cardiac Anesthesia.* 6th ed. Philadelphia: Elsevier Science, WB Saunders; 2011:949–991.

C.II-2. What is the half-life of heparin? How is it eliminated?

The biologic half-life of heparin varies with dosages and temperature. It has a remarkable individual variation. The average half-life is approximately 100 minutes in normothermic man for the initial doses of 300 units, increasing with higher doses and decreasing temperature. When 100, 400, or 800 units of heparin are given intravenously, the approximate half-life is 1, 2.5, and 5 hours, respectively. Heparin concentrations decline progressively at all temperatures, but the rate of decline is delayed in proportion to the hypothermia.

The primary mechanism for heparin elimination remains uncertain. Heparin appears to be cleared and degraded primarily by the reticuloendothelial system; a small amount of heparin also appears in the urine.

Spiess BD, Horrow J, Kaplan JA. Transfusion medicine and coagulation disorders. In: Kaplan JA, Reich DL, Lake CL, et al., eds. *Kaplan's Cardiac Anesthesia.* 6th ed. Philadelphia: Elsevier Science, WB Saunders; 2011:949–991.

C.II-3. How do you monitor heparin dosage? What is the activated coagulation time (ACT) test?

Heparin therapy can be assessed by the partial thromboplastin time, heparin assay, heparin–protamine titration, and the ACT test. The most convenient and practical method used to monitor heparin therapy in the operating room is the celite-ACT test. There is a very good correlation among the ACT, plasma heparin units, and thrombin time. After central venous injection of a heparin bolus, the onset of maximal ACT prolongation in the radial artery blood sample occurs within 1 minute. Previous work suggested that heparin action peaks 10 to 20 minutes after administration, but this finding probably represented an artifact from other factors prolonging the ACT such as hemodilution and hypothermia. Two milliliters of blood are put into a test tube containing celite to activate coagulation. Then, the tube is kept at 37° C (98.6° F) and clot formation is watched for ACT. The normal control value of ACT is 105 to 167 seconds. A baseline value is determined before the administration of heparin, and the test is repeated 3 to 5 minutes after heparin is given and at intervals of 30 to 60 minutes thereafter. With the dose of heparin in milligrams per kilogram on the vertical axis and ACT in seconds on the horizontal axis, a dose-response curve can be plotted. ACT values are maintained at least twice the control value and should never decrease less than 300 seconds during normothermia.

Precise determination of plasma heparin concentration can also be used. The patient's plasma is incubated with factor Xa in the presence of its inhibitor, Xai. Heparin accelerates factor Xa inhibition, and residual factor X remaining after 2 minutes is measured and converted to a heparin concentration, expressed in units per milliliter. This method has been shown to decrease the amount of heparin used compared to heparin-ACT dose-response curves. The major disadvantage of this technique is the time delay before results are available.

Shore-Lesserson L. Coagulation monitoring. In: Kaplan JA, Reich DL, Lake CL, et al., eds. *Kaplan's Cardiac Anesthesia*. 6th ed. Philadelphia: Elsevier Science, WB Saunders; 2011:496–521.

C.II-4. What is total CPB? What is partial bypass?

Total bypass indicates that all the venous return from superior and inferior venae cavae, and the coronary sinus is drained to the oxygenator, and no blood is pumped by the RV to the lungs. The PA and systemic pressure tracings become nonpulsatile. Partial bypass means that some of the blood return is still pumped by both RV and LV. Some venous blood is drained to the oxygenator and pumped back to the arterial side. Femoral–femoral bypass is one example of partial CPB.

Gravlee GP, Davis RF, Kurusz M, et al. *Cardiopulmonary Bypass, Principles and Practice*. 3rd ed. Philadelphia: Lippincott Williams & Wilkins; 2008:674–675.

C.II-5. What is the purpose of venting the LV? How can it be done?

Although all the venous return is bypassed from the RV, 2% to 5% of cardiac output is draining to the LV. This represents the physiologic shunt from the bronchial, thebesian, and pleural veins. Other sources of blood flow to the left heart during CPB include aortic regurgitation from aortic insufficiency and extracardiac left-to-right shunts such as patent ductus arteriosus and Blalock-Taussig, Waterston, and Potts shunts. The left ventricular sump drain prevents overdistention of the LV, which may cause postpump heart failure. A suction needle inserted proximal to the aortic cross-clamp may serve the same purpose.

Venting of the LV can be accomplished by inserting a catheter to the following sites:

- Aortic root such as cardioplegia cannula for CABG
- Junction of the right superior pulmonary vein and the left atrium and advancing through the left atrium and mitral valve into the LV
- Apex of the LV
- PA or the left atrium only

Gravlee GP, Davis RF, Kurusz M, et al. *Cardiopulmonary Bypass, Principles and Practice*. 3rd ed. Philadelphia: Lippincott Williams & Wilkins; 2008:89–92.

C.II-6. How many types of oxygenators are there? What are the advantages of each type?

There are two basic types of oxygenators in terms of their interface with blood.

Direct gas interface

- Disk
- Vertical screen
- Bubble

Without gas interface

- Membrane—solid or microporous
- Fluid—fluid using fluorocarbon liquid

The disk and screen oxygenators are not disposable and have proven to be somewhat difficult to clean, prepare, and resterilize.

The bubble oxygenator has the advantages of simplicity, disposability, and relatively low cost.

The disadvantages of gas interface oxygenators include the following:

- Protein denaturation
- Increased fragility of cells
- Susceptibility to hemolysis
- Denaturation of platelet membrane materials resulting in platelet aggregation, clumping
- Formation of air embolism
- Large priming volume
- Variable reservoir level resulting in potential shifts of blood volume between intracorporeal and extracorporeal circuit

The membrane oxygenator has become more popular, economical, efficient, and less traumatic to blood. Its advantages include the following:

- Less trauma to blood components
- No defoaming
- Decreased complement activation
- Independent control of oxygen and carbon dioxide exchange
- Use of air–oxygen mixture without the risk of gaseous microemboli

However, the advantage of a membrane oxygenator for a short perfusion (<2 hours) is unclear, although lower plasma hemoglobin levels are present using membrane oxygenators.

The disadvantages of membrane oxygenators include the following:

- Expense
- Potential difficulty in eliminating all bubbles during priming
- Moderately large priming volume

The major differences in changes of clotting factors between the bubble and membrane oxygenators become apparent after 4 to 6 hours of extracorporeal circulation.

Wagner JA. Oxygenator anatomy and function. *J Cardiothorac Vasc Anesth.* 1997;11:175–281.

C.II-7. What kind of priming solution would you use? How much priming solution would you use? When would you prime with blood? Why?

The usual priming solution for adults at the New York Presbyterian Hospital–Cornell Medical Center includes 1,400 mL of balanced salt solution (Normosol), 100 mL of 25% albumin, and 200 mL of 20% mannitol. The priming volumes vary with the size of the oxygenators used and the tubing volume; most oxygenators for adult patients have priming volumes of 500 to 1,000 mL. In general, blood is added to the oxygenator if the patient is markedly anemic (prepump hematocrit below 30%) or if the priming volume is large in relation to the patient's blood volume, such as in pediatric patients. In order to maintain oxygen carrying capacity, the hematocrit is kept at levels above 18% to 20%. Mannitol has long been used as an osmotic diuretic in situations where

hemolysis or diminished renal function is expected. Mannitol has been found to decrease the incidence of renal failure during hypotension by promoting osmotic diuresis and increasing renal blood flow by decreasing renal vascular resistance. Heparin, 3,000 to 10,000 units, is added to the prime depending on the size of the prime volume. This allows heparin to be distributed over the thrombogenic surfaces of the CPB circuit.

Gravlee GP, Davis RF, Kurusz M, et al. *Cardiopulmonary Bypass, Principles and Practice.* 3rd ed. Philadelphia: Lippincott Williams & Wilkins; 2008:417–419, 691.

C.II-8. What are the advantages and disadvantages of hemodilution?

Advantages of hemodilution

- An increase in microcirculation due to a reduction of blood viscosity
- Improved oxygen delivery to tissues
- Decreased metabolic acidosis
- Reduced risk of hypertension
- Reduced blood demands
- Reduced incidence of hepatitis, AIDS, or reactions from blood transfusions
- Reduced postoperative blood loss
- Improved blood flow at lower perfusion pressure, especially during hypothermic perfusion

Disadvantages of hemodilution

- Decreased oxygen carrying capacity
- Postoperative extracellular fluid overload
- Possible pulmonary edema
- Increased risk of postoperative renal dysfunction
- Hypotension from decreased viscosity and peripheral resistance
- Decreased concentration of calcium, magnesium, phosphate, and zinc

C.II-9. What kind of pumps do you use? Are they pulsatile or not?

There are three types of pumps available for modern CPB machines: the double-headed nonocclusive roller pump, the centrifugal blood pump, and the ventricular-type pneumatic or hydraulic pump. Only the first two types are in common use.

The roller pump is the most commonly used pump. It is driven by an afterload-independent motor. Once the pump speed is set, it will continue the forward displacement

of the same blood volume (or even air volume) even if the resistance is increased by kinking or clamping the arterial line. This will result in the rupture of connections between sections of tubing. Some centers use pressure gauges on the arterial inflow line to avoid this type of disaster.

The centrifugal pump is a kinetic pump that operates on the constrained vortex principle. Blood is driven through the pump by centrifugal forces generated by a vortex in the pump. The advantages of centrifugal pumps are as follows:

- Less trauma to blood components than the roller pump.
- Less risk of increasing arterial line pressure because blood flow decreases when line resistance is increased.
- Inflow responsiveness—if a large quantity of air is introduced into the pump, cohesive forces will no longer exist between layers of blood and pumping will stop.
- Less risk of micro-air embolism because small, low-density air bubbles are trapped in the center of the vortex.

Ventricular-type pumps, although potentially more powerful, are rather cumbersome and have not been well accepted. This type of pump is mainly used for pulsatile bypass.

The first two types of pumps are nonpulsatile. Pulsatile pumps are commercially available now. Methods available to generate pulsatile flow include an indwelling IABP, an extracorporeal balloon, ventricular-type pumps, Keele pump, Polystan pulsatile pump, modified roller pumps, and modified centrifugal pumps. Pulsatile pumps may offer advantages over continuous flow by providing diastolic runoff and stimulation of the endothelium. Improved outcomes with pulsatile pumps have been attributed to improved blood flow to vital organs and a decrease in the incidence of systemic inflammatory response syndrome. There is a decreased incidence of postoperative death in both adult and pediatric patients. Nevertheless, it has been difficult to design systems to provide sufficient pulsatility to mimic normal pulsatile circulation. In addition, the limit of pulse pressure required is also not well known. Some studies indicate that with prolonged perfusion, pulsatile flow appears to be more physiologic and superb for organ function; however, scientists are less certain that it is an important factor during short-term bypass. The differences between the two modes and a benefit for pulsatile perfusion are most clearly manifested in identifiable high-risk patient groups.

C.II-10. How do you monitor the patient during CPB?

Clinical monitoring

- Mean arterial pressure (MAP) should be kept between 50 and 100 mm Hg to maintain tissue perfusion. In hypertensive patients and in older patients, a higher MAP is frequently utilized—there is very little support for this in the literature.
- PA pressure should be low or zero to prevent overdistention of the LV.
- CVP should be low or zero to make sure there is no obstruction to venous return from the head (when monitored from a site proximal to the RA) or there is adequate drainage of blood to the CPB circuit (when monitored from inside the RA).

- Pump-flow rate should be adequate for tissue perfusion and oxygenation.
- Urine output should be maintained above 1 mL/kg/hour by adequate perfusion.
- ECG
- Electroencephalogram is used in patients in whom cerebral circulation problems may occur.
- Bladder and esophageal temperatures are recorded (tympanic also may be used).
- Anesthesia should be maintained at the appropriate level.
- Pupillary size should remain normal and equal.
- Transcranial Doppler and/or TEE may be used to detect aortic and cerebral embolism.
- Cerebral oximeter to maintain adequate brain oxygen saturation (>40%).

Laboratory monitoring at least once every hour

- Arterial blood gases are kept at normal range.
- Venous Po_2 should be 40 to 45 mm Hg.
- Hematocrit maintained between 20% and 30%.
- Electrolytes Na^+, K^+, ionized Ca^{2+}.
- ACT measured each hour and maintained above 400 to 480 seconds.
- Blood sugar probably should be kept below 250 mg per dL.

Yao FS, Tseng CC, Trifiletti RR, et al. Neurologic complications following cardiac surgery is associated with cerebral desaturation. *Anesth Analg*. 2000;90(45):76.

C.II-11. How much BP would you keep during CPB? Why?

Controversy continues over what constitutes adequate pressures while the patient is on bypass. The MAP is usually maintained at approximately 50 to 100 mm Hg to ensure adequate tissue perfusion. BP depends on cardiac output (pump flow) and total peripheral resistance (TPR). We believe that adequate cardiac output (pump flow) is more important for tissue perfusion than BP.

During hypothermic cardioplegia, higher systemic pressures (mean BP >70 mm Hg) are often avoided because of increased noncoronary collateral blood flow into the heart through the pericardium and pulmonary venous drainage. Such collateral flow of relatively warm blood tends to wash the colder cardioplegic solution out of the heart and decreases the hypothermic protection against myocardial ischemia.

The range of cerebrovascular autoregulation during hypothermia is controversial. Although pooled data from clinical studies indicate a lower autoregulatory threshold of 20 to 30 mm Hg in patients without cerebrovascular disease or pre-existing hypertension, other studies suggest a pressure-dependent cerebral circulation when MAP is less than 50 mm Hg. Until prospective studies clearly define the autoregulatory threshold under various clinical conditions, BP of less than 50 mm Hg should be regarded as potential physiologic trespass, which may compromise cerebral circulation. In patients with cerebrovascular disease or hypertension, higher perfusion

pressure is recommended. Gold et al. studied 248 patients randomized to either low MAP (50 to 70 mm Hg) or high MAP (80 to 100 mm Hg) during CPB and found a trend toward improvement in cardiac and neurologic outcome with higher MAP. However, MAP had no significant effect on neurologic outcome in those patients at low risk for cerebral embolization (normal to mild aortic atherosclerosis by TEE). Patients at high risk for adverse neurologic outcome (severe aortic atherosclerosis by TEE) had a significantly lower risk of worse neurologic outcome when randomized to higher MAP. More recently, widened pulse pressure was shown to be a better predictor of cerebral and renal ischemic outcomes over that of systolic or diastolic BP. Other recent data suggest that MAP during CPB is not a primary predictor of cognitive decline or stroke following cardiac surgery. However, there was an association among hypotension (<50 mm Hg) and age, and decline in spatial and figural memory. Therefore, we recommend maintenance of high MAP during CPB in patients with increased risk of neurologic outcome such as history of cerebrovascular accident or transient ischemic attack, hypertension, carotid stenosis, advanced age, and severe aortic atherosclerosis detected by TEE.

With the recent introduction of noninvasive cerebral oximetry, the frontal cortex oxygen saturation can be monitored by near-infrared spectroscopy. The technique measures the oxygen saturation of the mixed arterial and venous blood in the brain cortex. Because the volume of blood is predominantly venous, it reflects the balance between oxygen supply and demand in the brain. Our study showed good correlation between brain oxygen saturations and neurologic and cognitive outcomes. The MAP should be kept at levels enough to maintain adequate cerebral oxygen saturations (at least 70% of baseline values or >40% saturation). In a randomized controlled trial, Murkin et al. showed that in patients undergoing coronary artery bypass in whom cerebral regional oxygen saturation was monitored, profound cerebral desaturation was avoided. This led to significantly fewer incidences of major organ dysfunction and death.

C.II-12. How would you treat hypotension during CPB?

$$\text{Mean arterial pressure (MAP)} = \text{cardiac output (CO)} \times \text{total peripheral resistance (TPR)}$$

Hypotension may be caused by low cardiac output or low peripheral resistance. First, cardiac output should be corrected by increasing the pump-flow rate. Then, if the cardiac output is adequate, peripheral resistance can be raised by giving vasopressors. We use the primarily α-adrenergic vasopressor phenylephrine in increments of 0.5 mg to raise the MAP to 50 mm Hg. In cases of more profound vasoplegia, agents such as norepinephrine and vasopressin may be required. According to Poiseuille law, low TPR usually is due to decreased viscosity or increased vascular diameter (vasodilation). During CPB using blood-free–priming solutions, total viscosity is reduced by hemodilution, although plasma viscosity is increased by hypothermia. A short period of hypotension with a MAP of approximately 30 to 40 mm Hg usually is seen in the first 5 to 10 minutes of bypass. It is due to the following causes:

- Inadequate pump flow at the beginning of bypass
- Hypoxic vasodilation from initial perfusion with blood-free primes carrying no oxygen
- Vasodilation from vasoactive materials released because of the initial reaction of the serum proteins, blood cells, and platelets with the foreign surfaces of the heart–lung machine
- Decreased plasma levels of catecholamines by hemodilution

C.II-13. How would you treat hypertension (a mean arterial pressure [MAP] of over 100 mm Hg)?

Hypertension during bypass is usually the result of inadequate depth of anesthesia, which causes increased catecholamine output and increased vascular resistance. Pump-flow rate should not be reduced to lower the pressure. Low pump flow may cause tissue hypoxia although BP is high. The most effective treatment involves administering an inhalation agent such as through the vaporizer in the heart–lung machine. Intravenous agents such as sodium thiopental, propofol, and narcotics may be used, but they are frequently not as effective and have to be supplemented with vasodilator drugs. Previously, nitroprusside and nitroglycerin were commonly used but, more recently, the IV calcium channel blockers (nicardipine and clevidipine) and beta-blockers are frequently used.

Treatment of acute postoperative hypertension in cardiac surgery patients: an efficacy study of clevidipine assessing its postoperative antihypertensive effect in cardiac surgery-2 (ESCAPE-2), a randomized, double-blind, placebo-controlled trial. *Anesth Analg*. 2008;107(1):59–67.

C.II-14. How do you prepare an intravenous infusion of sodium nitroprusside, nicardipine, and nitroglycerin? What are the usual doses? Which do you prefer to use?

Intravenous solutions may be prepared by adding to 250 mL of 5% dextrose in water 50 mg of nitroglycerin or sodium nitroprusside, or 25 mg of nicardipine, to make a concentration of 200 μg per mL (nitroglycerin or nitroprusside) or 100 μg per mL nicardipine. The usual doses are nitroglycerin or nitroprusside 0.5 to 10 μg/kg/min, or 0.05 μg/kg/min nicardipine, determined by careful titration (Table 5.2). We prefer nitroglycerin or nicardipine infusion. Sodium nitroprusside dilates both arterial and venous smooth muscle. It is very effective in reducing both preload and afterload. It may cause cyanide and thiocyanate toxicity. Because nitroprusside dilates the intramyocardial arterioles, intracoronary steal may occur. The solution has to be covered with aluminum foil to prevent decomposition from exposure to light. Nitroglycerin primarily causes venodilation, resulting in reduction of preload and myocardial oxygen consumption. At larger doses and by the intravenous route, it has mild arteriolar dilation and reduces afterload. It has no known toxicity and does not produce intracoronary steal because it dilates epicardial arteries. It may redistribute blood flow to the subendocardium and increase collateral circulation through the myocardium. Nicardipine is a systemic and coronary arterial dilator. The afterload is decreased, while the preload is not affected. It may cause a slight increase in HR (reflex tachycardia).

C.II-15. How much pump flow would you maintain during CPB?

The pump blood flow is equivalent to cardiac output and to supply tissue oxygenation. The normal average cardiac output for adults is 70 mL/kg/min or 3.1 L/min/m^2. Because of higher metabolism, pediatric patients need higher flow rates for each unit of body weight. Usually 70% of normal cardiac output is enough to maintain tissue oxygenation. When body surface is used, both pediatric and adult patients require about the same pump flow, 2.2 to 3.1 L/min/m^2. In summary, at normothermia and normal hemoglobin levels, the pump flow is as follows:

Adults 50 to 70 mL/kg/min	or	2.2 to 3.1 L/min/m^2
Children 100 to 150 mL/kg/min	or	2.2 to 3.1 L/min/m^2

However, some perfusion teams use low-flow (40 mL/kg/min), low-pressure (approximately 40 mm Hg) bypass quite successfully. This technique has the advantages of less bleeding through intracardiac collaterals, less trauma to blood cells and platelets, and lower fluid requirements, but it also has the potential for inadequate perfusion. Clinically, low-flow and low-pressure techniques are used in conjunction with hypothermia and hemodilution. Therefore, pump blood flow should be adjusted accordingly to match the oxygen supply with demand.

Table 5.2 Cardiac Anesthesia Intravenous Medications[a]

DRUG	AMOUNT TO ADD	TOTAL VOLUME WITH D_5 W	CONCENTRATION	DOSAGE RANGE
Amicar (EACA)	15 g	150 mL	1 mL = 100 mg	Load: 10 g over 1/2 hr
			10 mL = 1 g	Maintenance: 1 g/hr × 5 hr
Amiodarone	450 mg	250 mL	1 mL = 1.8 mg	Initial: 150 mg over 10 min
				Followed by: 1 mg/min × 6 hr (360 mg). Then: 0.5 mg/min × 18 hr
Dexamedetomadine			1 mL = 4 μg	Load: 1.0 μg/kg over 10 min
				Maintenance: 0.2–0.7 μg/kg/hr
Diltiazem	25 mg	100 mL	1 mL = 0.25 mg	Load: 0.1–0.15 mg/kg
				Maintenance: 0.5–.25 μg/kg/min
Dobutamine	500 mg	250 mL	1 gt = 33.3 μg	5–20 μg/kg/min
			1 mL = 2 mg	
Dopamine	400 mg	250 mL (premixed)	1 gt = 26.6 μg	Renal: 1–5 μg/kg/min
			1 mL = 1.6 mg	β: 10 μg/kg/min
				α: 10–15 μg/kg/min
Epinephrine	2 mg	250 mL	8 gtt = 1 μg	2–8 μg/min
Esmolol	5 g	250 mL	1 gt = 333 μg	50–300 μg/kg/min
			1 mL = 20 mg	
Levophed	8 mg	250 mL	2 gtt = 1 μg	4–32 μg/min
Lidocaine	2 g	500 mL (premixed)	15 gtt = 1 mg	1–4 mg/min
			1 mL = 4 mg	
Milrinone	20 mg	100 mL	3 gtt = 1 μg	0.375–1 μg/kg/min
			1 mL = 200 μg	
Nicardipine	25 mg	250 mL	1 gt = 1.66 μg	Load: 5 mg/hr
				Maintenance: Increase by 2.5 mg/hr every 15 min
				Maximum amount: 15 mg/hr
Nitroprusside	50 mg	250 mL (premixed)	1 gt = 3.33 μg	1–10 μg/kg/min

(Continued)

Table 5.2 Cardiac Anesthesia Intravenous Medications[a] *(cont.)*

DRUG	AMOUNT TO ADD	TOTAL VOLUME WITH D_5 W	CONCENTRATION	DOSAGE RANGE
Nitroglycerin	50 mg	250 mL (premixed)	1 gt = 3.33 μg	10–80 μg/min
Phenylephrine	20 mg	250 mL	19 gtt = 25 μg	25–125 μg/min
Procainamide	2 g	500 mL (premixed)	15 gtt = 1 mg	Load: 500–1,000 mg (20 mg/min)
			1 mL = 4 mg	
				Dosage: 1–4 mg/min
Sodium bicarbonate	100 mEq	100 mL undiluted	1 mL = 1 mEq	1–3 mEq/kg/hr (titrate to pH)
Tranexamic acid			1 mL = 100 mg	Load: 10 mg/kg
				Maintenance: 1 mg/kg/h
Vasopressin	100 units	100 mL	1 mL = 1 unit	Initial dose: 0.04 U/min, 2.4 U/hr
				Titrate: 0.005–0.01 U/min
				(0.3–0.6 mL/hr) every 10 min to max of 0.1 U/min or 6 U/hr

[a] There are 60 guttae per milliliter (gtt/mL), therefore, gtt/min = mL/hr.
EACA, aminocaproic acid.

C.II-16. How would you adjust the pump flow during hypothermia?

Hypothermia decreases oxygen consumption. Therefore, the pump flow may be decreased proportionally if the blood oxygen content does not change. The oxygen consumption at different body temperatures is listed in the following text:

Temperature (° C)	37	32	30	28	25	20	10
O_2 consumption (%)	100	60	50	40	25–30	20	10

Because the O_2 consumption at 30° C (86° F) is half of that at 37° C (98.6° F), the required pump flow at 30° C (86° F) is 50% of the flow at 37° C (98.6° F) (50° to 70 mL/kg/min). Therefore, a pump flow of 25 to 35 mL/kg/min is adequate for adults at 30° C (86° F) if there is no hemodilution. During profound hypothermia (10° to 20° C [50° to 68° F]), the patients usually can tolerate total circulatory arrest without pump support for approximately 60 to 90 minutes. The decrease in metabolism during hypothermia is not a linear process. From 37° to 30° C (98.6° to 86° F), the metabolism decreases approximately 7% by each degree centigrade. Below 30° C

(86° F), the rate of metabolism decrease slows down. Usually, every 7° to 8° C (44.4° to 46.4° F) decrease in temperature reduces oxygen consumption by 50%. Clinically, it has been demonstrated that pump flows as low as 30 mL/kg/min or 1.2 L/min/m^2 will not compromise whole-body oxygen delivery when moderate systemic hypothermia is employed.

C.II-17. How would you adjust the pump flow during hemodilution?

$$\text{Oxygen delivery} = \text{cardiac output} \times \text{arterial oxygen content}$$
$$\text{Arterial oxygen content} = 1.34 \times \text{hemoglobin} \times O_2 \text{ saturation} + (0.003 \times Pao_2)$$

Hemodilution reduces hemoglobin concentration and hence decreases oxygen content. In order to deliver the same amount of oxygen, the pump flow has to be increased accordingly during hemodilution. For example, if the hematocrit is diluted from 40% to 20% during CPB, the pump flow has to be doubled (increased by a factor of 40/20 = 2). Clinically, both hypothermia and hemodilution are applied simultaneously so that the adjustment has to be done at the same time. For example, the pump flow for adults at a temperature of 30° C (86° F) and a hematocrit of 25% will be as follows:

$$50 \text{ to } 70 \text{ mL/kg/min} \times 50\% \times 40/25 = 40 \text{ to } 56 \text{ mL/kg/min}$$

C.II-18. What are the advantages of hypothermia? Does hypothermia offer neuroprotection?

Hypothermia decreases oxygen consumption and helps to preserve the function of tissues during a hypoxic or ischemic insult. Pump flow may be decreased during CPB with hypothermia.

Hypothermia has been shown to confer significant protection in the setting of transient, but not permanent, ischemia. The mechanism is unclear. The reduction in cerebral metabolic rate is believed to be less important when compared with the effect of hypothermia on the release of excitatory neurotransmitters, catecholamines, or other mediators of cellular injury. It is for this reason that mild hypothermia (33° to 35° C [91.4° to 95° F]) provides significant neuroprotection.

The effect of hypothermia during CPB on postoperative cognitive or neurologic function remains controversial. Animal models show profound reduction in infarct size and release of excitatory amino acid with minimal levels of hypothermia. However, clinical studies comparing normothermic and moderately hypothermic CPB have yielded conflicting results and did not produce evidence of protection from cognitive decline. This may relate to differences in defining normothermia. Many groups allow temperature to drift downward during normothermic CPB, with temperature decreasing to below 34° C (93.2° F). McLean, in a recent study of this type, showed no difference in cognitive or neurologic outcome between warm and moderately hypothermic groups. In actuality, this is a study of mild versus moderate hypothermia confirming the experimental animal data that as little as 2° to 3° C (35.6° to 37.4° F) of hypothermia markedly reduces excitatory amino acid release and neurologic injury compared to normothermia. The single large study comparing true normothermia with hypothermia during CPB showed a significantly greater incidence of focal neurologic injury in the warm group, supporting the beneficial role of hypothermia in neuroprotection. In addition, recent data showed that minimum CPB temperatures greater than 35° C (95° F) increased the incidence of perioperative stroke approximately fourfold (4.5% vs. 1.2%).

In this context, the avoidance of cerebral hyperthermia deserves comment. Hyperthermia as little as a 2° C (35.6° F) increase in temperature significantly worsens neurologic outcomes. It has been demonstrated in a rat model, that following

10 minutes of ischemia during which temperature was increased from 35° to 39° C (95° to 102.2° F), the percentage of damaged neurons increased from 15% to 80%. This is clinically relevant because cerebral temperatures above 39° C (102.2° F) have been documented in patients during rewarming, a period when cerebral embolic risk is greatest. Therefore, hyperthermia should be carefully monitored and avoided. Grigore et al. found greater neuropsychological dysfunction in patients randomized to a faster rather than slower rewarming rate in the setting of CABG surgery. Of note, the patients rewarmed at a faster rate were also exposed to higher peak temperatures and a higher mean temperature of greater than 37° C than patients rewarmed slower with lower peak temperatures.

C.II-19. How does blood viscosity change during hypothermia and hemodilution?

Blood viscosity varies inversely with temperature; a 2% increase occurs for every 1° C (1.8° F) decrease in temperature. At a hematocrit of 40%, a decrease in temperature from 37° to 27° C (98.6° to 80.6° F) increases viscosity by approximately 25%. Hemodilution with balanced salt solution will decrease blood viscosity. Decreasing the hematocrit from 40% to 20% at 27° C (80.6° F) decreases viscosity by approximately 40%. It has been recommended that the hematocrit be adjusted to the same numerical value as the core body temperature in degree centigrade if blood viscosity is to be kept approximately constant. For example, normal viscosity at 37° C (98.6° F) with hematocrit of 40% approximates that seen at 25° C (77° F) with hematocrit of 25%.

C.II-20. What are the main causes of death associated with accidental hypothermia?

Ventricular fibrillation and asystole are the major rhythm disturbances leading to cardiac arrest during hypothermia. In humans externally cooled for cardiac surgery, ventricular fibrillation generally occurs at 23° C (73° F) and asystole at 20° C (68° F). However, asystole and ventricular fibrillation have been reported at 21° to 28° C (69.8° to 82.4° F). Respiratory arrest usually accompanies cardiac arrest during accidental hypothermia.

C.II-21. Would you give anesthesia during CPB? Why?

Anesthesia is maintained with intermittent administration of intravenous propofol, benzodiazepines, narcotic, and/or inhalation agents through the pump oxygenator to achieve unconsciousness and analgesia, to control BP, and to prevent shivering. Intravenous agents are diluted by the priming solution during CPB. Meanwhile, hypothermia itself produces anesthesia and prolongs the action duration of intravenous agents by decreasing hepatic metabolism and urinary excretion.

C.II-22. Would you give muscle relaxants during CPB? How is the action of muscle relaxant affected during CPB?

Yes. Muscle relaxants are given to prevent diaphragmatic movement that interferes with surgery and to prevent shivering during hypothermia. Shivering may increase oxygen consumption to as high as 486% of normal. The effect of a muscle relaxant is altered by both hypothermia and hemodilution. The plasma concentration of muscle relaxants is diluted by the priming solution. Therefore, more relaxant is required to maintain the same degree of relaxation. Hypothermia was originally reported to decrease the effect of nondepolarizing relaxants, because decreased cholinesterase enzyme activity during hypothermia resulted in more acetylcholine accumulation to compete with the nondepolarizing relaxant. Contrary to the earlier reports, it is now established that atracurium, vecuronium, or pancuronium is needed to maintain muscle relaxation during hypothermia because hypothermia reduces renal and biliary excretions. Hypothermia does prolong the onset of paralysis. Moreover, hypothermic CPB per se facilitates neuromuscular transmission at the electrochemical level, yet compromises mechanical contractility. The duration of action of rocuronium is prolonged by hypothermic CPB.

Modifications of partial neuromuscular blockade by hypothermic bypass are the result of muscle relaxation enhancing or interfering with the impact of hypothermia on normal neuromuscular transmission. The best way to monitor muscle relaxation is by using a peripheral nerve stimulator.

C.II-23. How do you know the patient is well perfused during CPB?

If the perfusion pressure is maintained between 50 mm Hg and 100 mm Hg, and the pump-flow rate is adequately maintained according to the degree of hypothermia and hemodilution, there should be adequate urine output, greater than 1 mL/kg/hour, no metabolic acidosis, and normal mixed venous oxygen tension of 40 to 45 mm Hg. However, cerebral perfusion is not routinely monitored and the autoregulation range of BP may be higher than the normal range in the elder and high-risk patients. Cerebral oximetry should be used for patients with increased risk for neurologic and cognitive outcomes. It is recommended to keep cerebral oxygen saturation over 40%.

C.II-24. How much gas flow would you use for the oxygenator? What kind of gas would you use? Why?

Normal alveolar ventilation is 4 L per minute and pulmonary circulation is 5 L per minute. The $\dot{V}/\dot{Q}$ ratio is 0.8. The oxygenator is not as efficient as human lungs. We usually start with 2 L of gas for each liter of pump-flow rate, and then adjust the gas-flow rate according to blood $Paco_2$ and Pao_2. The gas flow may be decreased if the $Paco_2$ is low and the Pao_2 is too high. The ratio may be increased if the $Paco_2$ is over 40 mm Hg or the Pao_2 is under 100 mm Hg. In the past, we used a mixture of 99% oxygen and 1% carbon dioxide for the bubble oxygenator. Because of low CO_2 production during hypothermia, high CO_2 elimination from high gas flow, and high CO_2 diffusion capacity, 1% CO_2, was added to oxygen to prevent severe hypocapnia. Because the routine use of membrane oxygenators oxygen–air mixtures instead of

100% oxygen have been used. In a bubble oxygenator, bubbles containing nitrogen may be slowly absorbed into the systemic circulation, increasing the risk of gaseous microemboli. In a membrane oxygenator, this risk does not exist. Meanwhile, air–oxygen mixtures allow better control of oxygen tension during CPB. Because we use alpha-stat regulation for acid–base management, it is not necessary to add CO_2 to the ventilating gas during hypothermia to elevate $Paco_2$ and decrease the pH.

Gravlee GP, Davis RF, Kurusz M, et al. *Cardiopulmonary Bypass, Principles and Practice*. 3rd ed. Philadelphia: Lippincott Williams & Wilkins; 2008:157–164.

C.II-25. What are the disadvantages of hypocapnia during CPB?

- Cerebral blood flow decreases approximately 2% to 4% for each mm Hg decrease in $Paco_2$ when $Paco_2$ is in the range of 20 mm Hg to 60 mm Hg due to cerebral vasoconstriction. Cerebral oxygen saturation decreases approximately 1% for each mm Hg decrease in $Paco_2$.
- Respiratory alkalosis shifts the oxygen dissociation curve to the left, which increases the O_2 affinity to hemoglobin and decreases the release of O_2 to the tissues.
- Hypokalemia occurs because alkalosis shifts the potassium intracellularly.
- Alkalosis decreases ionized calcium.

C.II-26. The arterial blood gases and electrolytes during CPB are as follows: pH, 7.36; $Paco_2$, 42 mm Hg; Pao_2, 449 mm Hg; CO_2 content, 24 mEq per L; Na, 128 mEq per L; K, 5.8 mEq per L; and Hct, 20%. The patient's temperature is 27° C (80.6° F). At what temperature are blood gases measured? How would you correct the blood gases according to patient's body temperature? Would you treat the arterial blood gases at 37° C (98.6° F) or at patient's body temperature?

Blood gases are measured at a constant temperature of 37° C (98.6° F). They may be corrected according to body temperature. Each degree centigrade below 37° C (98.6° F) increases blood pH by 0.015. If pH is 7.40 at 37° C (98.6° F) in vitro, in vivo pH will be 7.55 at 27° C (80.6° F) body temperature ($7.40 + 0.015 \times [37 - 27] = 7.55$). The pH increases at lower temperatures, because of increased Pka and decreased CO_2 tension from increased CO_2 blood solubility during hypothermia. In vivo Pao_2 is decreased because of increased oxygen solubility during hypothermia. At the New York Presbyterian Hospital–Cornell Medical Center, we measure blood gases at 37° C (98.6° F) and interpret at 37° C (98.6° F) without correcting them to body temperature. The normal values of blood gases at 37° C (98.6° F) are as follows: pH, 7.40 ± 0.05; $Paco_2$, 40 ± 5; and Pao_2, 95 ± 5. During hypothermia, the normal values of blood gases are not the same as those at 37° C (98.6° F). The same blood specimen has different Po_2 values when measured at different temperatures. Yet, the oxygen content remains unchanged. It is easier to calculate the oxygen content at 37° C (98.6° F) than at other temperatures where oxygen dissociation curves are shifted.

Optimal management of pH and $Paco_2$ for patients undergoing hypothermic CPB remains controversial. The two strategies for interpreting blood gases are the pH-stat (temperature-corrected) method and the alpha-stat (temperature-uncorrected) method. The pH-stat strategy aims at keeping constant arterial pH at 7.40 and $Paco_2$ at 40 mm Hg at any given temperature. A $Paco_2$ of 60 mm Hg analyzed at 37° C (98.6° F) would be equivalent to a $Paco_2$ of 40 mm Hg if "corrected" for a body temperature of 27° C (80.6° F). The alpha-stat strategy aims at keeping a constant ratio of $[OH^-] : [H^+]$ at approximately 16 : 1. This is based on the premise that the pH of blood is regulated to keep the state of dissociation of imidazole moiety (i.e., the alpha of imidazole) constant. Histidine, which contains the imidazole moiety, is an integral part of the active site of many enzyme systems. The function of enzyme systems has been shown to be optimal when the ratio of $[OH^-] : [H^+]$ is approximately 16 : 1. This ratio represents different pH values at different temperatures.

The differences between pH-stat and alpha-stat strategies are listed in Table 5.3. With the pH-stat strategy, the blood gas values are corrected to the patient's temperature; the patient is treated as if he were a hibernating animal. With the alpha-stat strategy, the blood gas values are not corrected regardless of the patient's actual temperature; the patient is treated as if he were a poikilotherm. Studies indicate that myocardial function is better preserved when the alpha-stat strategy is employed. Moreover, maintenance of cerebral blood flow autoregulation appears to remain intact with alpha-stat management, whereas flow becomes pressure dependent with pH-stat management. Alpha-stat blood gas management preserves cerebral blood flow-metabolism coupling such that hypothermic-induced decreases in metabolic rate are accompanied by proportionate decreases in cerebral blood flow. Therefore, most medical centers use alpha-stat management of blood gases during hypothermic CPB. However, Bashein et al. found no difference in neuropsychologic outcome between patients randomized to alpha-stat and those randomized to pH-stat management.

However, more recent studies have shown less decline in cognitive performance when alpha-stat management is used, especially in cases with prolonged CPB times. These data may support an embolic threshold above which recognizable neurologic injury occurs.

During deep hypothermic circulatory arrest, both animal and clinical studies have shown that pH-stat is associated with better neurologic outcome probably because of increased cerebral blood flow, which provides better brain cooling and greater cellular oxygen availability. In summary, most recent outcome studies support the utilization of alpha-stat for adult CPB and pH-stat for children under deep hypothermic circulatory arrest.

Table 5.3 Different Hypothermic Acid–Base Regulatory Strategies

STRATEGY	AIM	TOTAL CO_2 CONTENT	pH AND $Paco_2$ MAINTENANCE	INTRACELLULAR STATE	α-IMIDAZOLE AND BUFFERING	ENZYME STRUCTURE AND FUNCTION	CEREBRAL BLOOD FLOW AND COUPLING	EFFECT ON ISCHEMIC TISSUE
pH-stat	Constant pH	Increases	Normal corrected values	Acidotic (excess H^+)	Excess (+) charge	Altered and activity decreased	Flow close to normothermic	? Lessens hypothermic protection
					Buffering decreased		? Flow and metabolism uncoupled	
Alpha-stat	Constant OH^-/H^+	Constant	Normal uncorrected values	Neutral ($H^- = OH^-$)	Constant net charge	Normal and activity maximal	Flow decreases (appropriate)	? Allows full hypothermic protection
					Buffering constant		? Flow and metabolism coupled

C.II-27. If the blood level of the venous reservoir is low, what would you replace it with? Blood or balanced salt solution?

We try to maintain a hematocrit of at least 18% to 20% during hemodilution. If the hematocrit decreases below 18% to 20%, blood is added to the CPB circuit. If the hematocrit is above 20%, a balanced salt solution (Normosol) is added to the oxygenator. However, hematocrit values in the range of 15% to 18% appear to be well tolerated clinically. When cerebral oxygen saturation (rSo_2) is less than 40%, we use packed red cells to improve oxygen-carrying capacity. When rSo_2 is over 40%, it means the patient has acceptable cerebral oxygenation although hematocrit is below 18%.

C.II-28. How do you estimate the fluid balance during CPB?

During CPB, all intravenous lines are shut off. The intake includes cardioplegic solution, fluid or blood added to the oxygenator during CPB, and the decreased blood level in the oxygenator. The output includes urine and the increased blood level in the oxygenator.

C.II-29. How would you preserve the myocardium during CPB?

The most popular and effective method of protecting the myocardium is to reduce myocardial oxygen demand by hypothermia and cardioplegia. Hypothermia is induced by a combination of systemic blood cooling by heat exchangers in the oxygenator; local application of cold saline solution or iced slush to the external surface and chambers of the heart (if the heart is open); and infusion of cold cardioplegic solution through the aortic root, venous grafts, retrograde coronary sinus, or coronary ostium to the coronary arterial tree. The myocardial temperature may be decreased to 10° to 15° C (50° to 59° F).

In addition to inducing hypothermia and cardioplegia, one may take the following measures before aortic cross-clamping:

- Avoid tachycardia or increased contractility by discontinuing pacing at rapid rate and discontinuing inotropes if they were utilized.
- Initiate rapid arrest (asystole).
- Utilize proper venting methods and ensure adequate venous drainage to the pump to avoid ventricular distention, which decreases subendocardial blood supply.
- Prevent and treat ventricular fibrillation, which increases oxygen demand in normothermic myocardium.
- Maintain adequate coronary perfusion pressure of at least 50 mm Hg and greater than 70 mm Hg in the presence of severe coronary disease or left ventricular hypertrophy.

Gravlee GP, Davis RF, Kurusz M, et al. *Cardiopulmonary Bypass, Principles and Practice.* 3rd ed. Philadelphia: Lippincott Williams & Wilkins; 2008:172–184.

C.II-30. What is the cardioplegic solution? How much would you use?

Cardioplegic solution contains mainly high concentrations of potassium (10 to 30 mEq per L) or magnesium (160 mEq per L) to relax the heart. Flaccid cardioplegia itself reduces myocardial oxygen consumption and provides optimal conditions for surgery. Bicarbonate or tris(hydroxymethyl)-aminomethane (THAM) is usually added to raise the pH to levels between 7.40 and 7.80 to increase the intracellular shift of potassium and to decrease the metabolic acidosis from ischemia. Steroids, calcium, and procaine may be added to stabilize lysosomal and cell membranes. Glucose and insulin are added to provide energy and improve the intracellular shift of potassium. Nitroglycerin is added to dilate coronary vessels, resulting in better perfusion to the myocardium, including ischemic areas. At the New York Presbyterian Hospital–Cornell Medical Center, for crystalloid cardioplegia, we add 20 mEq of potassium chloride and 10 mEq of sodium bicarbonate to 1,000 mL of 5% glucose in a 0.225% salt solution, resulting in a final pH of 7.83, potassium of 20 mEq per L, and osmolarity of 380 mOsm per L.

When blood cardioplegia is used, four parts of bypass blood are mixed with one part of cardioplegic solution. The composition of full-strength solution is as follows: 500 mL of 5% glucose in a 0.225% salt solution, 70 mEq of potassium chloride, 10 mEq of sodium bicarbonate, and 1 mg of nitroglycerin. Blood cardioplegia seems to have several advantages over crystalloid cardioplegia. The heart is arrested while being oxygenated, so that adenosine triphosphate (ATP) is not depleted before asystole. Repeated infusions provide a source of oxygen and glucose for continued metabolism and ATP repletion. Although little oxygen is released from hemoglobin during hypothermia, enough is probably dissolved in the plasma to sustain metabolism when reinfusion is performed every 30 minutes. Buffering capacity is improved because of the presence of the histidine buffering system present in red cells. Myocardial edema is reduced because of the osmolarity of blood. The risk of calcium paradox following ischemia is reduced and functional recovery is improved because of the physiologic calcium concentration provided by blood. The presence of red cell enzyme catalase may scavenge free radicals produced by ischemia. Capillary perfusion is improved and more homogeneous because of the presence of red cells. However, results of clinical studies in which blood cardioplegia was compared with crystalloid cardioplegia either detected no significant difference or showed that blood cardioplegia improved contractility late in the postoperative course. Multiple-dose cardioplegia is required for satisfactory results, whereas single-dose blood cardioplegia results in poor ventricular function.

Intermittent, continuous, or single infusions of cardioplegic solution have been used. Usually 300 to 600 mL of cold cardioplegic solution is needed to paralyze the myocardium and cool the myocardium to 10° to 20° C (50° to 68° F).

In the case of severe obstructive coronary lesions, antegrade infusion into the aortic root may cause maldistribution of the cardioplegia. Therefore, retrograde infusion through the coronary sinus into the coronary veins may be additionally employed to ensure homogeneous distribution of cardioplegia.

In the late 1980s and early 1990s, warm cardioplegia with near-systemic normothermia was popular for better myocardial protection. In a prospective randomized study by Franke et al., there was no difference in mortality, MI, IABP use, or postoperative inotropic requirements between patients receiving cold cardioplegia and those receiving warm cardioplegia. Patients receiving warm cardioplegia were less likely to require defibrillation following cross-clamp release, have less postoperative ventricular dysrhythmias, and a lower reoperation rate for bleeding. However, one study identified a threefold increase in strokes in the "warm" patients. The technique is no longer popular.

C.II-31. For how long a period can the aorta be cross-clamped?

When cardioprotective strategies including intermittent hypothermic blood cardioplegia, initiation of rapid arrest, and left ventricular venting are employed, the limits of "safe" ischemic time during aortic cross-clamping can be increased from as little as 15 to 45 minutes to as much as 240 minutes in animal models with normal ventricular function. However, many patients have preoperative ventricular dysfunction and the protection from hypothermic cardioplegia may not be optimal because of coronary artery obstruction. Clinically, the aorta may be safely cross-clamped for 60 to 120 minutes without perfusion. The shorter the cross-clamping time, the better the myocardial function will be.

C.II-32. Why would urine become pink in some cases of CPB? What is the renal threshold for plasma hemoglobin?

Pink urine is a sign of massive hemolysis. Hemolysis is mainly associated with the frothing, violent turbulence, acceleration, and shear forces of negative pressures generated by the suction apparatus and is associated to a lesser degree with the action of the pumps or with the gas–blood interface effects in the oxygenator. The renal threshold for hemoglobin is 100 to 150 mg per 100 mL. It is advisable to maintain a high output of alkaline urine to prevent possible tubular damage from acid hematin crystals, which are converted from hemoglobin.

Gravlee GP, Davis RF, Kurusz M, et al. *Cardiopulmonary Bypass, Principles and Practice*. 3rd ed. Philadelphia: Lippincott Williams & Wilkins; 2008:42,59,99.

C.II-33. At what temperature can the patient be weaned from CPB?

An esophageal or nasopharyngeal temperature of 37° C (98.6° F) and a rectal or bladder temperature at least 35° C (95° F) must be reached before the patient can come off the pump. After discontinuation of the pump, surface warming should be continued in pediatric patients to prevent hypothermia owing to redistribution of heat in the body. However, in adults, the use of warming blankets and warmed humidified airway gases has not been found beneficial in preventing the expected temperature "afterdrop." Usually, esophageal or nasopharyngeal temperature will decrease and rectal or bladder temperature will increase during heat redistribution.

Gravlee GP, Davis RF, Kurusz M, et al. *Cardiopulmonary Bypass, Principles and Practice*. 3rd ed. Philadelphia: Lippincott Williams & Wilkins; 2008:614–615.

C.II-34. Why does it take longer to rewarm than to cool the patient by the pump oxygenator?

It usually takes 5 to 10 minutes to cool the patient from 37° to 25° C (98.6° to 77° F) of average body temperature. It takes 20 to 40 minutes to rewarm the patient from 28° to 35° C (82.4° to 95° F). The speed of heat exchange by the bloodstream depends on the temperature gradient between venous blood and water in the heat exchanger, the pump blood-flow rate, and the water-flow rate of the heat exchanger. The initial venous blood temperature is 37° C (98.6° F) and the water temperature of the heat exchanger is 0° to 4° C (32° to 39.2° F) during cooling, creating a temperature gradient of 34° to 37° C (93.2° to 98.6° F). During rewarming, the water temperature is limited to 42° C (107.6° F) or less to prevent denaturation and destruction of blood proteins. The temperature gradient is limited to 10° C (18° F) or less to prevent gas embolism from a decrease of gas solubility in the blood associated with a sharp increase in temperature. The heat exchanger water flow does not differ much during cooling and rewarming. However, the pump blood flow is usually maintained to a very high level during the initial cooling because of low BP in the beginning of cooling. During rewarming, the pump blood flow is frequently maintained at a low level because the BP is usually high and the body temperature is still low. Rewarming may be accelerated by administering inhalation anesthetics, or employing vasodilators, to decrease vascular resistance and thereby increase pump flow to maintain the same BP. Because the increased vascular resistance is usually due to inadequate anesthesia during rewarming, we prefer inhalation anesthetics to vasodilators in patients with good ventricular function. In cases of poor ventricular function, inhalation agents are avoided because of the potential cardiac depression after CPB.

C.II-35. How would you defibrillate the heart internally during CPB?

The heart is defibrillated internally by a DC defibrillator, with 5 to 10 watt-seconds (joules). If the heart remains in ventricular fibrillation, blood gases, electrolytes, and temperature are rechecked and lidocaine, 1 to 2 mg per kg, is administered before repeated DC defibrillation attempts. MAP is usually increased to 80 mm Hg. Occasionally, esmolol, metoprolol, and amiodarone are added to treat intractable ventricular fibrillation or tachycardia.

C.II-36. Why is calcium chloride usually administered right before the patient comes off the pump?

With hemodilution, the ionized calcium frequently falls to approximately 1.5 to 1.8 mEq per L (normal 2.2 to 2.6 mEq per L, 1.1 to 1.3 mmol per L, or 4.5 to 5.6 mg per dL). Calcium chloride, 0.5 to 1.0 g, frequently is given to increase myocardial contractility and reverse potassium cardioplegia. Calcium increases the inotropic state of the myocardium and induces an increase in systemic vascular resistance that outlasts the inotropic effects. However, some believe that calcium administration is contraindicated at this time because of the compromised calcium hemostasis that accompanies the insult of aortic cross-clamping. Administration of calcium may exacerbate ischemic and reperfusion injury by causing accumulation of intracellular calcium. β-Blockers, on the other hand, increase intracellular calcium but also promote its reuptake into the sarcoplasmic reticulum and may be more appropriate in this setting. Therefore, use of calcium salts at the conclusion of bypass should be guided by determination of ionized calcium levels. Calcium salts should probably not be given to patients with good ventricular function in the absence of hypocalcemia or hyperkalemia because of the potential detrimental effects of iatrogenic hypercalcemia; whether this is true in patients with ventricular dysfunction is unknown.

C.II-37. If the HR is 40 beats per minute, what should you do?

A temporary atrioventricular (AV) block at the end of bypass because of potassium cardioplegia and ischemic insult during aortic cross-clamping. Although atropine may be theoretically administered to treat sinus or nodal bradycardia, more frequently, a temporary epicardial pacemaker is usually employed. Atrial pacing is preferred because of improved cardiac output when the atrial kick is preserved. Ventricular pacing is necessary if there is complete AV block. AV sequential pacing is indicated when ventricular pacing does not provide adequate cardiac output.

Shanewise JS, Hines RL, Kaplan JA. Discontinuing cardiopulmonary bypass. In: Kaplan JA, Reich DL, Lake CL, et al., eds. *Kaplan's Cardiac Anesthesia.* 6th ed. Philadelphia: Elsevier Science, WB Saunders; 2011:992–1009.

C.II-38. How does the blood sugar level change during CPB? Why? Does hyperglycemia increase neurologic complications during CPB?

Blood sugar levels are elevated during the perioperative period in patients undergoing cardiac surgery with the use of CPB. Hyperglycemia is most profound during hypothermic CPB, with approximately 100% of patients (diabetic and nondiabetic) achieving plasma glucose levels greater than 200 mg per dL. There are several reasons for this: First, the practice of making patients NPO (nothing by mouth) overnight induces a state of starvation, marked by peripheral resistance to insulin at the level of muscle and fatty tissues, therefore allowing glucose uptake by the brain; second, sympathoadrenal activation, in response to surgical stress, also tends to induce a diabetogenic state; third, active cooling the body during bypass causes a profound reduction in insulin production, induces peripheral insulin resistance, and is associated with renal tubular impairment in glucose regulation; lastly, use of dextrose-containing cardioplegia is a major contributor to intraoperative hyperglycemia. Of interest, postoperative hyperglycemia continues despite insulin administration and has been shown to remain above normal up to several weeks postoperatively. At the cellular level, the alterations in insulin receptor/resistance are very similar to that of type 2 diabetes. It is controversial whether hyperglycemia increases neurologic complications during CPB. Under conditions of limited cerebral oxygen delivery, anaerobic glucose oxidation becomes the primary method of ATP production, resulting in intracellular lactic acidosis. Hyperglycemia, by providing more glucose for anaerobic oxidation, increases the degree of intracellular acidosis, which, in numerous animal studies, correlates with the severity of subsequent injury. Although the deleterious effect of hyperglycemia in the face of both global and focal cerebral ischemia is generally accepted, a recent human study challenges these conclusions. Metz and Keats reported zero neurologic injury in a group of 54 patients undergoing CABG managed with glucose-containing fluids (glucose during bypass—approximately 700 ± 100 mg per dL) versus one stroke and one case of encephalopathy in 53 patients in whom glucose was avoided during CABG (glucose during bypass—approximately 200 ± 100 mg per dL). The authors contend that glucose does not affect neurologic outcome in the presence of a permanent focal lesion. Although provocative, this study can be faulted for (1) its lack of sensitive monitors of neurologic outcome, and (2) its small sample size in relation to the occurrence rate of the event of interest. More recently, there are a number of reports that show a strong association between plasma glucose levels and postoperative morbidity and mortality. In an observational study of 200 consecutive diabetic patients undergoing cardiac surgery, Ouattara demonstrated that poor intraoperative control of blood glucose concentrations was associated with an increased incidence of in-hospital morbidity, including neurologic, cardiovascular, infectious, respiratory, and renal. Based on these findings, "tight" glucose control is being recommended for all patients undergoing CPB. Murkin suggests avoidance of glucose containing intravenous, cardioplegic, and pump-priming solutions as well as aggressive insulin dosing strategies. Recent evidence suggests that this is best achieved with continous insulin infusion or hyperinsulinemic normoglycemic clamp technique. Regarding the optimal range of glucose control, there continues to be some debate about maintaining plasma glucose below the threshold of 110 mg per dL. Hypoglycemia remains a safety issue. Many authors suggest that a target glucose range of less than 150 mg per dL is favorable for maintaining euglycemia.

C.II-39. What are the effects of CPB on platelet and coagulation factors?

Platelet dysfunction and thrombocytopenia are found on and after CPB. Platelet dysfunction is the most common cause of a bleeding problem following CPB after heparin is reversed and surgical bleeding is controlled. Transient defects in platelet plug formation and aggregation are seen in all patients put on CPB. Generally, platelet function returns to near normal status 2 to 4 hours following CPB. The defects are exacerbated and prolonged by drugs such as aspirin and platelet glycoprotein GPIIb/IIIa inhibitors (clopidogrel, tirofiban), which inhibit platelet function.

Platelet counts fall more with the bubble-type oxygenator than with the membrane-type oxygenator, but rarely below the levels clinically required for hemostasis. Thrombocytopenia is mainly caused by hemodilution, aggregation, adhesion, and the adenosine diphosphate–release reaction induced by the foreign surfaces and the blood–gas interface. Heparin may potentiate platelet aggregation and adhesions.

The level of coagulation factors decreases at the beginning of bypass because of hemodilution; surface absorption by the plastic, glass, and metal; and protein denaturation induced by the blood–gas interface. At the same time, the synthesis of clotting factors by the liver increases so that the concentration of clotting factors returns to normal within a period of hours. Membrane oxygenators cause few changes in clotting factors.

Gravlee GP, Davis RF, Kurusz M, et al. *Cardiopulmonary Bypass, Principles and Practice.* Philadelphia: Lippincott Williams & Wilkins; 2008:325–326, 427–428, 450–453.

C.II-40. How would you prepare for termination of CPB?

Before termination of CPB, cardiac and pulmonary function must be optimized. To ensure that all-important steps are not inadvertently omitted, the patient and all monitors should be carefully checked. The mnemonic LAMPS for Laboratory data, Anesthesia machine, Monitors, Patient (Pump), and Support is one useful approach.

Laboratory data

- Arterial pH, Pco_2, Po_2 within normal limits
- Hematocrit—20% to 25%
- K^+ —4.0 to 5.5 mEq per L
- Ionized calcium 1.1 to 1.2 mmol per L
- Pump mixed venous O_2 saturation greater than 70%

Anesthesia/Machine

- Adequate anesthesia
- Anesthesia machine functional

Monitors

- ECG—stable rate and rhythm (use pacing if necessary)
- Systemic BP restored to normothermic levels
- PA catheter functional
- Transducers rezeroed and calibrated
- TEE out of freeze mode
- Nasopharyngeal/PA catheter temperature 36° to 37° C (96.8° to 98.6° F)
- Bladder/rectal temperature greater than 35° C (95° F)

Patient/Pump

- The heart—contractility, size, rhythm, and air removed
- The lungs—atelectasis reexpanded, fluid in thoracic cavities drained, ventilation reinstituted

Support

- Inotropes/vasopressors/vasodilators
- IABP if needed

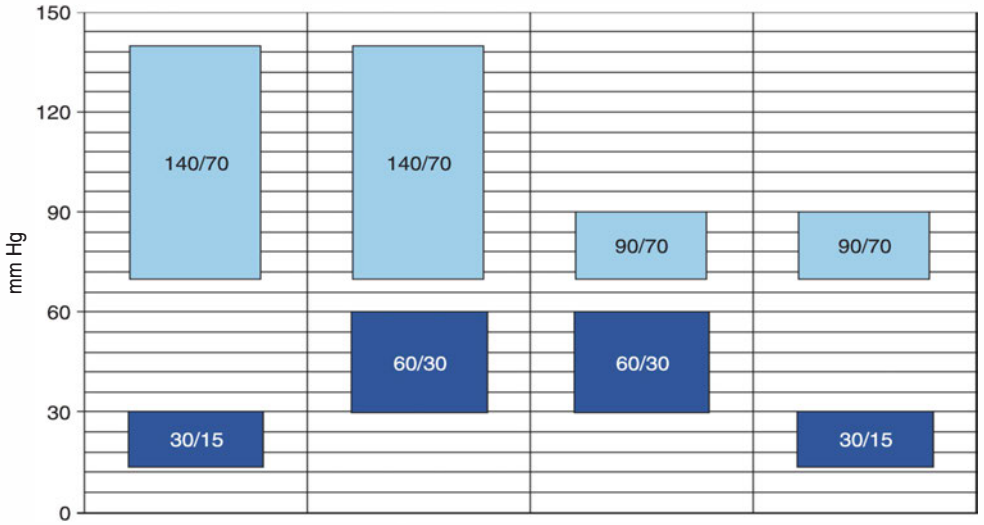
C.II-41. How would you decide the need for inotropic support?

The need for inotropic support after CPB is usually assessed by the following (Fig. 5.9):

- Preoperative ventricular function (ejection fraction)
- Effectiveness of intraoperative myocardial protection
- Adequacy of surgical repair
- Duration of aortic cross-clamping and CPB
- Patient's age



A		B		C		D

Figure 5.9 Hemodynamic management during weaning from cardiopulmonary bypass. The hemodynamic evaluation is performed by combining information from the systemic (light shade boxes) and pulmonary (black boxes) arterial pressures. **A.** A combination of elevated systemic arterial and low pulmonary arterial pressure suggests either a hyperdynamic cardiac function (if cardiac output is high) or a vasoconstrictive state (if the peripheral vascular resistance is high). **B.** If systemic hypertension is accompanied by pulmonary hypertension, then either the volume status is elevated (if cardiac output is high), or there is generalized vasoconstriction (if cardiac output is decreased). **C.** In case of systemic hypotension and pulmonary hypertension, the cardiac output may be high (systemic vasodilation) or low (depressed contractility, requiring immediate intervention). **D.** When both systemic and pulmonary pressures are decreased, there is either vasodilation (if the cardiac output is high) or hypovolemia or depressed contractility or right-sided failure are suspected (if cardiac output is decreased). The relative treatment for each hemodynamic derangement is shown in the table. CO, cardiac output; CVP, central venous pressure; IABP, intra-aortic balloon pump; LVAD, left ventricular assist device; NO, nitric oxide; PGI_2, prostacyclin; RV, right ventricle; SVR, systemic vascular resistance; ↑, increase; ↑↑, marked increase; ?, questionable.

If LV ejection fraction is predicted to be 25% to 35%, milrinone infusion may be added. Norepinephrine infusion is usually needed during milrinone therapy. Generally, IABP is also employed when LV ejection fraction is predicted to be below 25%. The choice of vasoactive and cardioactive agents used is frequently center and/or physician specific and, in most cases, initiated as prophylaxis. Recent data suggest that this practice should be avoided because inotropic and vasopressors can have negative effects, which can result in both morbid and fatal events.

C.III. *After Cardiopulmonary Bypass*

C.III-1. How would you reverse heparin? How much protamine would you use? What are the other drugs used to neutralize heparin?

It has been recommended that 1.1 to 1.3 mg of protamine sulfate is needed to reverse each 100 units of remaining heparin calculated by ACT dose-response curve or protamine titration test. At the New York Presbyterian Hospital–Cornell Medical Center, we give 1.0 mg of protamine to reverse each 100 units or 1 mg of heparin initially administered. Only the initial dose of heparin is counted. The subsequently added dose of heparin, to keep the ACT level above 480 seconds, is not considered because of its metabolism and elimination. The ACT test is repeated 10 minutes after the administration of protamine. ACT usually returns to its control level. If the ACT is still prolonged, additional protamine is given according to the ACT dose-response curve. However, the ACT is affected by dilution and by hypothermia; dose-response curves utilizing data obtained during hypothermia may be misleading. In addition, severe thrombocytopenia also prolongs the ACT because clot formation using the ACT depends on platelet phospholipid surface. Furthermore, because heparin rebound is possible, it may be optimal to administer protamine at two times following CPB: once after bypass and again 1 or 2 hours later to counteract heparin rebound. Of note, recent work by Bollinger and colleagues suggests that increase in bleeding may occur paradoxically from "extra" protamine administration.

Other drugs that have been used to neutralize heparin include platelet factor 4 (PF4), heparinase, protamine variants, polybrene, and toluidine blue. Human or recombinant PF4 has been used in animals and humans to reverse heparin and does not cause systemic arterial hypotension, or pulmonary hypertension, or changes in white blood cell count, platelet count, or complement levels. Heparinase neutralizes heparin by enzymatic cleavage of α-glycoside linkages at AT III binding site. Heparinase is an effective antagonist of heparin and has minimal effects on platelets, whereas protamine markedly inhibits platelet responsiveness. It appears to be a potential alternative to protamine.

Two protamine variants, so-called designer protamines, are currently under investigation. The side effects of protamine such as hypotension and low cardiac output were significantly reduced by the protamine variants. Polybrene, also known as hexadimethrine bromide, at one time was commonly used, but it was withdrawn from clinical use because of suspected nephrotoxicity and production of pulmonary hypertension. Toluidine blue has also been used for heparin reversal, but it is less effective than protamine and is associated with methemoglobinemia.

Lastly, reversal for low molecular weight heparin compounds does not exist, but recently a recombinant antithrombin variant was shown to be a potent antidote to fondaparinux and other heparin derivatives.

C.III-2. What is the action mechanism of protamine?

Heparin is a strong organic acid (polyanion). Protamine is a strong organic base (polycation). They combine ionically to form a stable salt and lose their own anticoagulant activity. Protamine contains two active sites, one that neutralizes heparin and another that exerts a mild anticoagulant effect independent of heparin.

Spiess BD, Horrow J, Kaplan JA. Transfusion medicine and coagulation disorders. In: Kaplan JA, Reich DL, Lake CL, et al., eds. *Kaplan's Cardiac Anesthesia*. 6th ed. Philadelphia: Elsevier Science, WB Saunders; 2006:959.

C.III-3. What are the complications of too much protamine?

Protamine itself is an anticoagulant. Protamine administered intravenously in the absence of heparin interacts with platelets and with many clotting proteins. Protamine induces transient thrombocytopenia in humans. Platelet aggregation is impaired by the protamine–heparin complex, but protamine alone has no deleterious effects. Protamine may bind to thrombin and inhibit thrombin's ability to convert fibrinogen to fibrin.

C.III-4. Why did the patient develop hypotension after protamine was administered? How do you treat and prevent this condition?

Three different types of circulatory reactions to protamine reversal of heparin have been proposed by Horrow:

Type I: Systemic Hypotension from Rapid Injection: A Predictable Pharmacologic Reaction

Type II: Anaphylactic or Anaphylactoid Reaction

- Antibody-medicated
- Immediate anaphylactoid response without antibody involvement
- Delayed anaphylactoid response (noncardiac pulmonary edema)

Type III: Catastrophic Pulmonary Vasoconstriction with Systemic Hypotension

However, etiologically, there are only two types of reaction: (1) pharmacologic side-effect reactions, and (2) idiosyncratic reactions. Therefore, an alternative classification was proposed by Moorman, Zapl, and Lowenstein as follows:

- Pharmacologic histamine release
- True anaphylaxis (immunoglobulin E–mediated)
- Anaphylactoid reactions
- Pulmonary vasoconstriction
- Noncardiogenic pulmonary edema

Mild to moderate systemic hypotension from pharmacologic side effects is almost always the reaction seen when protamine is given rapidly or is given to patients who are relatively hypovolemic and vasoconstricted. Because it can be elicited in most patients, it is classified as a pharmacologic side effect, not an idiosyncratic reaction. This side effect is possibly mediated by histamine and is characterized by venodilation, reduced cardiac filling pressures, and decreased vascular resistance. Mild cardiac depression by protamine is suggested but probably does not occur. This type of hypotension can be corrected by rapid volume administration from the CPB pump while the arterial cannula is in place and by administration of phenylephrine in 0.1-mg increments. There have been many attempts to modify the hypotensive response (e.g., intra-aortic or left atrial administration, protamine pretreatment), with little evidence of predictable success. Only slower rates of intravenous infusion over 5 to 10 minutes and simultaneous maintenance of an adequate blood volume have been shown to decrease the incidence of hypotension.

Anaphylactic or anaphylactoid reaction is uncommon and rarely seen in infants and children. The reaction varies from mild skin flushing and urticaria to severe vascular collapse. Systemic hypotension is usually accompanied by low pulmonary arterial pressure and low right-sided and left-sided filling pressures. This type of hypotension may be treated and prevented with rapid volume infusion and administration of vasoconstrictors. The use of antihistamines and steroids is commonly employed by many cardiovascular anesthesiologists with few, if any, existing data supporting this practice. There are several unanswered questions such as: When should these angents be given? What dose to give? Which agent? and so forth. Diabetic patients taking neutral protamine Hagedorn (NPH) insulin may develop antibodies to protamine and would appear to be at increased risk. However, clinical reactions do not predictably occur in these patients. Suspected cross-sensitivity in cases of fish allergy or autosensitization in men after vasectomy do not seem to put most patients at increased risk.

Catastrophic pulmonary hypertension occurs in approximately 0.2% to 4.0% of patients. There are severalfold increases in PA pressure leading to right ventricular failure, elevated CVP, low flow across the pulmonary circuit, and low left atrial pressure. Elevated plasma levels of C5a anaphylatoxins and thromboxane are responsible for pulmonary vasoconstriction and accompanied bronchoconstriction. Treatment with isoproterenol, milrinone, or amrinone is reasonable; epinephrine in 0.1-mg increments has been successfully used. If severe hypotension persists, the patient should be heparinized again and return to bypass to maintain circulation. A recent study has shown that left ventricular infusion of protamine provides no protection from pulmonary hypertension and that histamine and platelet-activating factors are not involved in acute pulmonary vasoconstriction. Therefore, antihistamines and steroids may not be effective in preventing this reaction. However, it has been shown that the rate of intravenous protamine infusion in sheep is an important factor in the generation of sufficient mediators required to initiate a characteristic physiologic response, including pulmonary vasoconstriction and thromboxane B_2 generation. Slowing the

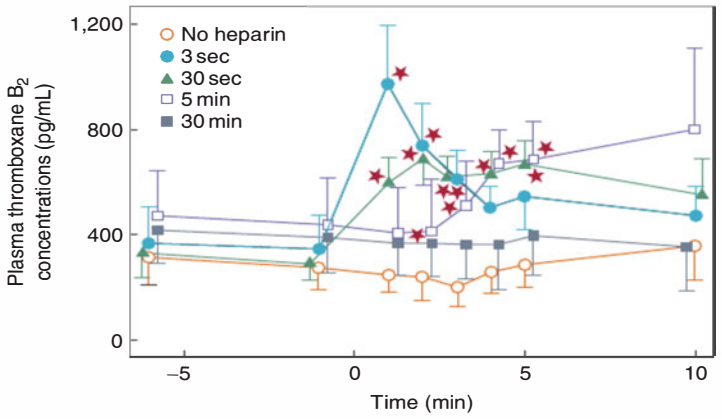

Figure 5.10 Plasma thromboxane B_2 concentrations before and after administration of protamine infused over 3 seconds, 30 seconds, 300 seconds, and 30 minutes. Heparin is injected at 5 minutes; protamine infusion is started at 0 minutes. Data points represent mean ± SE values; n = 6 in each group ($P < .05$ from unheparinized group). (From Morel DR, Costabella PM, Pittet JF. Adverse cardiopulmonary effects and increased plasma thromboxane concentrations following the neutralization of heparin with protamine in awake sheep are infusion rate-dependent. *Anesthesiology*. 1990;73:415–424, with permission.)

rate of protamine infusion results in a proportional attenuation of the response (Figs. 5.10 and 5.11).

In conclusion, the treatment of hypotension after protamine administration depends on pulmonary arterial pressure. Hypotension with low pulmonary arterial pressure may be corrected with rapid volume infusion and vasoconstrictors, and hypotension with high pulmonary arterial pressure should be treated with inotropes that have a vasodilating effect. The only effective prevention is a slow infusion of diluted protamine solution.

Recently, Yang developed a reactor device containing immobilized protamine (defined as a protamine bioreactor) that can be placed on the distal end of the extracorporeal CPB circuit. The protamine bioreactor binds and selectively removes heparin in the extracorporeal device before it is returned to the patient. The device successfully prevents protamine-induced complications in dogs. It is hoped that in the near future, the device can be used clinically to remove heparin without administration of protamine to the patients.

C.III-5. What are the indications for intra-aortic balloon pump (IABP)?

IABP is primarily used for pump failure and myocardial ischemia that are not responsive to maximal pharmacologic support. The indications include the following:

Ischemic heart disease

- Cardiogenic shock
- Acute MI complicated by
  - Mechanical defects: ventricular or septal rupture, acute mitral insufficiency, or ventricular aneurysm
  - Continued ischemic pain and extension of infarction
  - Refractory ventricular arrhythmias
- During cardiac catheterization

- Undergoing noncardiac surgery
- Failed PCI and awaiting CABG
- Acute mitral insufficiency with CHF

Cardiac surgery

- Before CPB and postoperatively
- After CPB: low output syndrome

Pulsatile CPB. Rare
Pediatric congenital heart disease. Rare
Neurosurgery. Temporarily increases total cerebral blood flow in specific circumstances.

C.III-6. What are the principles of IABP?

IABP counterpulsation is designed to increase the myocardial oxygen supply during diastole and to decrease myocardial oxygen demand during systole (Fig. 5.12). The balloon is inflated during diastole to increase the diastolic aortic pressure, resulting in increased coronary blood flow. The balloon should be inflated immediately following the closure of the aortic valve at the dicrotic notch of arterial tracing. The balloon is deflated just before the next systole to decrease the intra-aortic pressure and afterload, resulting in decreased myocardial oxygen consumption. The cardiac output is increased because of increased coronary perfusion (diastolic augmentation) and decreased resistance (systolic unloading).

C.III-7. What are the complications of IABP?

- Ischemia of the leg
- Dissection of the aorta
- Thrombus formation and embolization
- Renal artery occlusion
- Splenic, mesenteric, and spinal cord infarction
- Internal mammary occlusion
- Thrombocytopenia
- Infection
- Gas embolization

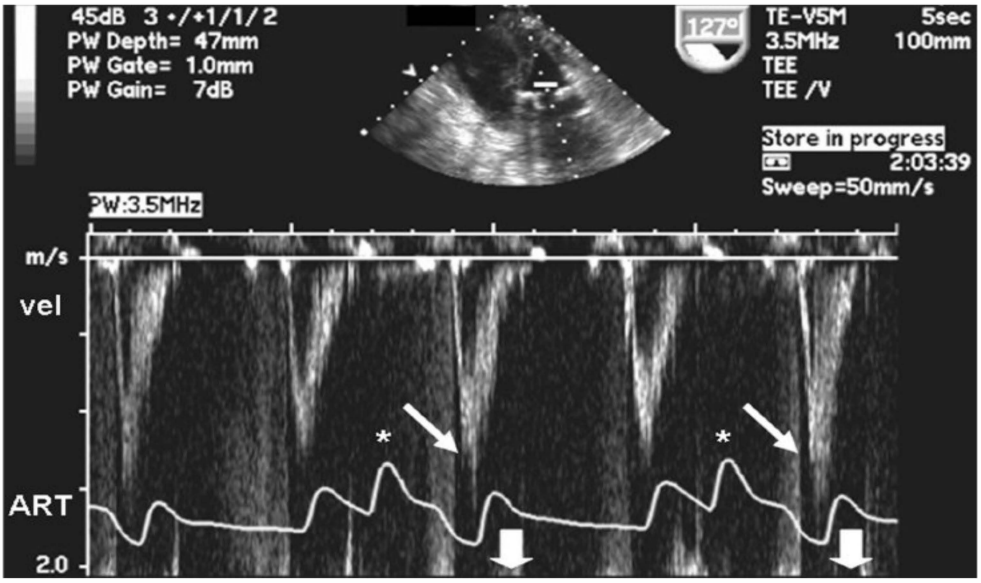

Figure 5.12 The function of the intra-aortic balloon pump (IABP). In this patient with an IABP in place, the velocity (vel) of the blood flow, as it exits the left ventricle (LV), is recorded. The arterial waveform is shown in the following text. The IABP is set on a 1:2 ratio; that is, it inflates every other beat, in diastole (*asterisks*). The velocity (and the amount) of blood exiting the LV is increased (*arrows*) after the diastolic inflation of the IABP because the LV is ejecting against lower systemic resistance. This is the reason that the systolic arterial pressure following IABP inflation is lower (*down arrows*).

- Inability to place the IABP
- Retroperitoneal bleeding
- Arterial–venous fistula

C.III-8. Can PAOP represent left ventricular end-diastolic volume (LVEDV) after CABG?

It has been demonstrated that in nonsurgical patients, there was a significant correlation between changes in PAOP and LVEDV. However, in patients during the first few hours after CABG, there was a poor correlation between changes in PAOP and LVEDV. The poor correlation was not explained by changes in systemic or pulmonary vascular resistance. The altered ventricular pressure–volume relation may reflect acute changes in ventricular compliance. Although measurement

of PAOP remains valuable in clinical management to avoid pulmonary edema, it cannot reliably be used as an index of left ventricular preload while attempting to optimize stroke volume. TEE can accurately assess LVEDV and cardiac contractility.

Harsen RM, Viquerat CE, Matthay MA, et al. Poor correlation between pulmonary arterial wedge pressure and left ventricular end-diastolic volume after coronary artery bypass graft surgery. *Anesthesiology*. 1986;64:764–770.

Reich DL, Mittnacht A, London M, et al. Monitoring of the heart and vascular system. In: Kaplan JA, Reich DL, Savino JS, et al., eds. *Kaplan's Cardiac Anesthesia*. 6th ed. Philadelphia: Elsevier Saunders; 2011:416–451.

D. Postoperative Management

D.1. What are the postoperative complications?

Cardiovascular. CHF, arrhythmias, low output syndrome, myocardial ischemia or infarction due to surgical manipulation, prolonged CPB and aortic cross-clamp (coronary ischemia), use of cardioplegic solution, and occlusion or kinking of grafts.

Pulmonary. Acute lung injury or adult respiratory distress syndrome due to the following:

- Decreased blood flow to the lung during total CPB
- Collapsed alveoli during CPB, resulting in decreased surfactant and decreased distensibility
- Fluid overloading
- Hyperoxia during CPB
- Left ventricular failure
- Microemboli
- Reperfusion injury
- Inflammatory response
- Infections
- Transfusion-related lung dysfunction

Renal

- Polyuria from hemodilution and diuretics
- Oliguria from hypoperfusion
- Acute kidney injury
  - Hypoperfusion
  - Ischemia
  - Inflammatory response
  - Neprotoxins (preoperative contrast dyes, antibiotics)
- Acute tubular necrosis
- Acute or chronic renal insufficiency

Hemorrhage

- Too much or too little protamine to reverse heparin
- Thrombocytopenia and decreased coagulation factors
- Qualitative and quantitative platelet defect
- Disseminated intravascular coagulopathy
- Fibrinolysis with low levels of fibrinogen
- Poor surgical hemostasis

Embolism. Due to air, destroyed or aggregated formed blood elements, fat, endogenous and exogenous debris.
Neurologic. Stroke and neurocognitive dysfunction marked by functional changes in behavior, personality, or other brain functions; cerebral embolism; and seizures.
Hyperglycemia. Hypothermia, dextrose-containing cardioplegia, increased catecholamine levels, and diabetogenic state associated with sugery and CPB.
Hypopotassemia. Due to hemodilution, alkalosis, and diuretics.

Gravlee GP, Davis RF, Kurusz M, et al. *Cardiopulmonary Bypass, Principles and Practice*. 3rd ed. Philadelphia: Lippincott Williams & Wilkins; 2008:382, 403, 506, 628–629.

Levy JH, Tanaka K, Bailey JM, et al. Postoperative cardiovascular management. In: Kaplan JA, Reich DL, Lake CL, et al., eds. *Kaplan's Cardiac Anesthesia*. 6th ed. Philadelphia: Elsevier Science, WB Saunders; 2011:98-131.

D.2. Would you reverse the muscle relaxants? Why?

Yes and no. If early extubation (fast-track) is planned, short- or intermediate-acting muscle relaxants should be used after CPB and the neuromuscular function should be monitored. At the end of the procedure, reversal agent can be given to ensure that the patient does not experience paralysis while awake. It may be advisable to continue a short-acting sedative/hypnotic agent such as propofol or midazolam during transport to the ICU and for the immediate period required to establish criteria for extubation. In patients that are hemodynamically unstable, with profound hypoxemia (acute respiratory distress syndrome), and/or "open" chest, paralysis should be continued postoperatively until the clinical state has improved. However, it is important to recognize that prolonged paralysis can lead to marked skeletal myopathy.

D.3. When will you wean the patient from the respirator?

Ventilator mangement, weaning strategy, and extubation time vary significantly among centers practicing cardiac surgery. Historically, patients were weaned from the respirator the following morning after surgery. More recently, if the operative course is smooth and if the patient is hemodynamically stable, weaning and extubation can be performed early (usually 2 to 6 hours after surgery).

Early tracheal extubation (fast-track) after CABG surgery may have cost-benefits and improvement in resource use when compared with late tracheal extubation. In one report, early tracheal extubation 1 to 6 hours after surgery reduced total cost per CABG surgery by 25% without increasing the rate or costs of complications in patients younger than 75 years.

Cheng DC, Havski J, Peniston C, et al. Early tracheal extubation after coronary artery graft surgery reduces costs and improves resource use. *Anesthesiology*. 1996;85:1300–1310.

Higgins TL, Yared J-P. Postoperative respiratory care. In: Kaplan JA, Reich DL, Lake CL, et al., eds. *Kaplan's Cardiac Anesthesia*. 6th ed. Philadelphia: Elsevier Science, WB Saunders; 2011:1046–1060.

D.4. What criteria would you use in deciding when to wean the patient from the respirator?

- Consciousness—awake and alert
- Stable vital signs
- Acceptable arterial blood gases—pH, 7.35 to 7.45; Pao_2, over 80 mm Hg with FIo_2,0.4; $Paco_2$, 35 to 45 mm Hg

- Acceptable respiratory mechanics
- Vital capacity greater than 10 to 15 mL per kg
- Maximal inspiratory force—greater than 20 to 25 cm H_2O
- Hemostasis—less than 100 mL per hour of chest tube drainage
- Stable metabolic state—normal temperature and electrolytes

The patient should tolerate being on continuous positive airway pressure of 5 cm H_2O and pressure support of 5 cm H_2O with 40% oxygen. If the patient tolerates the continuous positive airway pressure well for 30 minutes and arterial blood gases are acceptable, the patient may be extubated.

Higgins TL, Yared J-P. Postoperative respiratory care. In: Kaplan JA, Reich DL, Lake CL, et al., eds. *Kaplan's Cardiac Anesthesia*. 6th ed. Philadelphia: Elsevier Science, WB Saunders; 2011:1046–1060.

CHAPTER 6

Valvular Heart Disease

Natalia S. Ivascu and Gregg S. Hartman

A 78–YEAR-OLD MAN

was admitted with increasing shortness of breath. He had chest pain in the past but was able to continue with normal activities. He had passed out twice in the past year. On physical examination, a loud systolic murmur could be heard at the left sternal border radiating to the neck. His vital signs were: blood pressure 150/90 mm Hg, heart rate 88 beats per minute and irregular. The electrocardiogram showed sinus rhythm with atrial premature contractions and left ventricular hypertrophy (LVH) with strain. A transthoracic echocardiogram (TTE) showed a hypertrophied left ventricle, and Doppler examination demonstrated severe aortic stenosis with a gradient of 64 mm Hg, mild aortic insufficiency, and moderate mitral regurgitation. He was scheduled for aortic valve replacement and possible mitral valve repair or replacement.

A. Medical Disease and Differential Diagnosis

1. What are the major etiologies of aortic stenosis, aortic insufficiency, mitral stenosis, and mitral regurgitation?
2. What are the major changes in the loading conditions of the left ventricle that result from the four different lesions? Why do they occur? What changes result from them?
3. What are pressure–volume (P–V) loops? What do the different inflection points represent?
4. What are representative P–V loops for the four valvular lesions?
5. Draw the pressure/time curves for the left ventricle, left atrium, pulmonary artery, and aorta for a normal patient and for patients with each of the four valvular lesions.
6. What are the basic principles of echocardiography? What are M-mode, B-mode, and Doppler color modalities? How do TTE and transesophageal echocardiography (TEE) differ?
7. What are the three TEE vantage points for the comprehensive imaging of the left ventricle? How are pressure gradients measured by echocardiography?

How do the pressure gradients derived from Doppler echocardiography differ from those obtained in the catheterization laboratory by direct pressure measurement?

8. What is the role for three-dimensional (3D) echocardiography in the operating room?
9. What are the echocardiographic and cardiac catheterization criteria for the four valvular lesions?

B. Preoperative Evaluation and Preparation

1. What are the presenting signs and symptoms of the four valvular lesions listed previously?
2. What is the New York Heart Association classification of heart failure?
3. Discuss the role of premedication for patients with the four different valvular lesions.
4. How would you premedicate the patient with severe atrial stenosis and mitral regurgitation?

C. Intraoperative Management

1. Outline the hemodynamic management goals for each of the four valvular lesions. What are the anesthetic goals with respect to heart rate and rhythm, preload, afterload, and contractility?
2. What are the hemodynamic goals for this patient with the combination of severe aortic stenosis and mitral regurgitation?
3. How would you monitor this patient with severe atrial stenosis and mitral regurgitation?
4. Should the patient have a pulmonary artery catheter placed before induction?
5. Is a pulmonary artery catheter with pacing capabilities indicated?
6. What anesthetic technique would you employ? Why?
7. What muscle relaxant would you use for this patient?
8. What are the usual TEE findings in a patient with aortic stenosis, aortic insufficiency, or mitral regurgitation? How do you grade the severity of aortic stenosis by TEE? How do you quantify the severity of mitral regurgitation? What is the impact of aortic stenosis on the severity of mitral regurgitation?
9. What special considerations particular to cardiopulmonary bypass (CPB) operations do you have for each of the four lesions? Focus on these concerns with respect to the induction and prebypass, bypass, and postbypass periods.
10. The patient cannot be weaned from CPB following an aortic valve replacement and mitral valve replacement. What are the possible causes?
11. How would you diagnose right heart failure and pulmonary hypertension? How would you treat it?
12. How does an intra-aortic balloon pump (IABP) work to benefit the failing heart?
13. What role does the IABP have in this setting?
14. What role does TEE play in the placement, timing, and demonstration of efficacy of an IABP?
15. How would you properly time the IABP cycle?
16. What are the contraindications to the use of an IABP?
17. What is the role for ventricular assist devices?

D. Postoperative Management

1. In the intensive care unit (ICU) 4 hours later, the patient became hypotensive with a low cardiac output. How could you distinguish between cardiac tamponade and pump failure? How would the TEE images differ?

2. Would you extubate this patient early in the ICU? Why?
3. What are the advantages and disadvantages of early extubation?

E. Alternative treatments

1. What are the percutaneous options for mitral valve repair?
2. How is percutaneous mitral valve repair performed?
3. What are the percutaneous options for aortic valve repair and replacement?
4. How is percutaneous aortic valve replacement performed?
5. What anesthetic techniques and monitors are used?
6. What is minimally invasive cardiac valve surgery?

A. Medical Disease and Differential Diagnosis

A.1. What are the major etiologies of aortic stenosis, aortic insufficiency, mitral stenosis, and mitral regurgitation?

Aortic stenosis occurs as a congenital lesion but more commonly as an acquired disease. Stenosis may develop on a previously normal valve following rheumatic fever or from progressive calcification. Congenitally bicuspid valves are also prone to calcification with eventual stenosis. Calcification of the leaflets can result in incomplete closure of the valve with associated insufficiency.

Aortic insufficiency is usually an acquired disease. The most common causes include bacterial endocarditis and rheumatic heart disease. Annular dilation may result from diseases such as cystic medial necrosis and collagen disorders or following aortic dissections with resultant insufficiency. When occurring as a congenital lesion, aortic insufficiency rarely occurs in the absence of other cardiac abnormalities.

Mitral stenosis is almost always caused by rheumatic fever, although only half of patients will have a history of an acute febrile illness. The inflammatory process of rheumatic fever results in thickening of the leaflets and fusion of the commissures. Other rare causes include congenital stenosis and other systemic diseases, including systemic lupus erythematosus and carcinoid. Pathophysiology similar to that seen with valvular mitral stenosis can occur with obstructing left atrial tumors and cor triatriatum. Mitral stenosis commonly occurs in conjunction with other valvular heart disease; only 25% of patients present with isolated mitral stenosis, and approximately 40% have combined mitral stenosis and mitral regurgitation.

Mitral regurgitation can result from defects in the leaflets, the annular ring or the supporting chordae, the papillary muscles, or any combination of these. Primary leaflet dysfunction occurs with rheumatic fever but can also follow bacterial endocarditis, connective tissue disorders, and congenital malformations. Annular dilation can follow ventricular dysfunction and left ventricular dilation. Mitral valve prolapse and rupture of papillary muscles result in incomplete leaflet closure or coaptation with resultant mitral regurgitation. Left ventricular ischemia can affect papillary muscle contraction and is the cause of postischemic or postinfarction mitral regurgitation.

A.2. What are the major changes in the loading conditions of the left ventricle that result from the four different lesions? Why do they occur? What changes result from them?

Aortic stenosis represents a chronic systolic pressure load on the left ventricle. This elevation increases wall tension in accordance with Laplace's law.

$$\text{Wall tension} = \frac{(\text{Pressure} \times \text{Radius})}{(2 \times \text{Wall thickness})}$$

The ventricle undergoes parallel duplication of muscle fibers in an attempt to compensate for the increase in tension. This results in increased wall thickness or concentric (common center) hypertrophy and some decrease in radius, thereby normalizing wall stress. If the mitral valve remains competent, the major pressure overload occurs in the left ventricle and little change in the other cardiac chambers results.

Aortic insufficiency causes left ventricular diastolic volume overload, resulting in eccentric (away from the center) hypertrophy and left ventricular dilation. Compliance, the relation between volume and pressure, is altered only slightly because both end-systolic and end-diastolic volumes increase. Some concentric hypertrophy occurs as well secondary to the increase in wall stress resulting from an increase in left ventricular radius. The aortic diastolic pressure is lower with aortic insufficiency. Remember, the diastolic pressure is the pressure that must be exceeded by the work of the left ventricle to open the aortic valve and result in ventricular ejection. Therefore, the increased volume work required to eject the additional blood (which flowed into the left ventricle across the incompetent aortic valve during diastole) is reduced because the work can be performed against a lower outflow impedance (lower diastolic pressure). Stroke volume and ejection fraction, therefore, may be preserved until late in the disease process. As with aortic stenosis, the presence of a competent mitral valve confines the changes to the left ventricle. However, the left ventricular dilation that follows chronic aortic insufficiency may result in mitral annular dilation or alteration in chordae tendineae geometry with resultant mitral regurgitation. Left atrial enlargement secondary to mitral regurgitation can therefore occur. It may also occur because of left atrial pressure overload as left ventricular end-diastolic pressures (LVEDPs) rise in the course of aortic insufficiency.

Mitral stenosis results in a chronically underfilled left ventricle because of progressive obstruction to left atrial emptying. This chronic underloading condition can result in decreased left ventricular thickness and diminished contractile function (a "disuse atrophy" of sort). In addition, if the cause of the mitral stenosis is rheumatic, myofibril damage may have occurred. Although the left ventricle is pressure and volume *under*loaded, the left atrium is both pressure and volume *over*loaded. To maintain flow across the progressively narrowing mitral orifice, the pressure in the left atrium must be correspondingly increasing. Gorlin's equation for pressure gradient follows.

$$\text{Pressure gradient} = \left\{\frac{\text{Flow rate}}{(\text{K} \times \text{valve area})}\right\}^2$$

It would predict that the pressure gradient increases by the square of any increase in flow rate or decrease in valve area. The elevations in left atrial pressure leads to hypertrophy and eventually dilation that predisposes to premature atrial contractions and subsequently atrial fibrillation. The loss of atrial contraction further diminishes forward flow across the stenotic mitral valve. The elevations in left atrial pressure limit pulmonary venous flow with consequent pulmonary engorgement. The pulmonary vasculature undergoes reactive changes, including intimal fibroelastosis inducing irreversible elevations in pulmonary vascular resistance. Right ventricular failure may develop because this chamber is poorly equipped to deal with the elevations in afterload (e.g., pulmonary hypertension).

Right ventricular dilation combined with increased right ventricular systolic pressures leads to tricuspid regurgitation.

Mitral regurgitation results in volume overload of the left ventricle. The outflow of the left ventricle is divided between the high-pressure/low-compliance outflow tract of the arterial tree and the low-pressure/high-compliance outflow route across the incompetent mitral valve into the left atrium. Although the volume work of the left ventricle is increased, the high-compliance outflow route permits a large portion of this work to be performed at a low pressure; therefore, left ventricular wall tension is minimally increased, if increased at all. As with aortic insufficiency, the volume overload results in marked left ventricular dilation and eccentric hypertrophy. In contrast, however, the left atrium is also volume overloaded and undergoes dilation. When the volume overload occurs slowly, the left atrium enlarges and minimal rises in pulmonary pressures result despite large regurgitant volumes. In contrast, the occurrence of acute mitral regurgitation, for example, an acute myocardial infarction with papillary muscle rupture, presents the left atrium with a sudden volume overload. Without the time to dilate, the left atrial pressure rapidly rises, limiting pulmonary drainage with resultant pulmonary engorgement.

A.3. What are pressure–volume (P–V) loops? What do the different inflection points represent?

The P–V loop analysis (Fig. 6.1) depicts the relation between left ventricular volume and left ventricular pressure during a single cardiac cycle. Opening and closing of the mitral and aortic valves are represented by the inflection points A, B, C, and D, respectively (Fig. 6.1). Moving from points A through D, AB depicts left ventricular filling, BC depicts isovolumetric contraction, CD shows left ventricular ejection, and DA shows isovolumetric relaxation. Point A coincides with opening of the mitral valve and represents left ventricular end-systolic volume and early diastolic pressure. Point B is closure of the mitral valve and the end of diastolic pressure (LVEDP) and volume (left ventricular end-diastolic volume [LVEDV]). Point C represents the opening of the aortic valve and coincides with systemic, aortic diastolic pressure. Finally, point D is the closure of the aortic valve and represents left ventricular end-systolic pressure and volume, coinciding with the dicrotic notch in the aortic pressure tracing (Fig. 6.1). Left ventricular compliance is the relation between the change in pressure and change in volume of the chamber and is defined by the slope of the filling phase or segment AB. Preload is the P–V relation before the onset of contraction (LVEDP). Contractility may be illustrated by the slope of a line termed the *end-systolic pressure–volume relation* (ESPVR). The ESPVR slope is created by connecting multiple points (D) from multiple P–V loops generated by changing the filling volume to the left ventricle (LV) (Fig. 6.2). Increased contractility results in a steeper line, whereas diminished contractility results in a flatter relation. The P–V loop analysis permits illustration of stroke volume and ejection fraction. Stroke

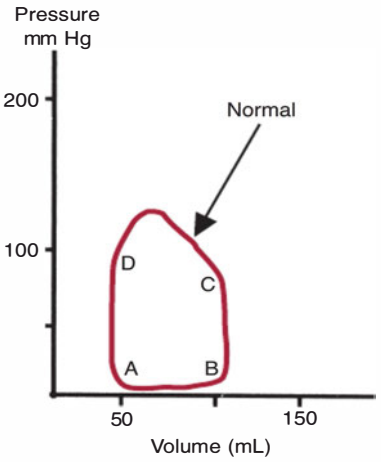

Figure 6.1 Normal pressure–volume loop and valve positions. *A.* Mitral valve (MV) opening. *B.* MV closure. *C.* Aortic valve (AV) opening. *D.* AV closure. *AB.* Left ventricular filling. *BC.* Isovolumetric contraction. *CD,* Ejection. *DA,* Isovolumetric relaxation.

volume is defined as difference in volume from the end of filling to the end of ejection (EDV–ESV), whereas the ejection fraction is the ratio of stroke volume to total volume in the heart at peak filling (SV/EDV). Therefore, the P–V loop analysis permits illustration of the volume–pressure relations and their changes with each of the four valvular lesions.

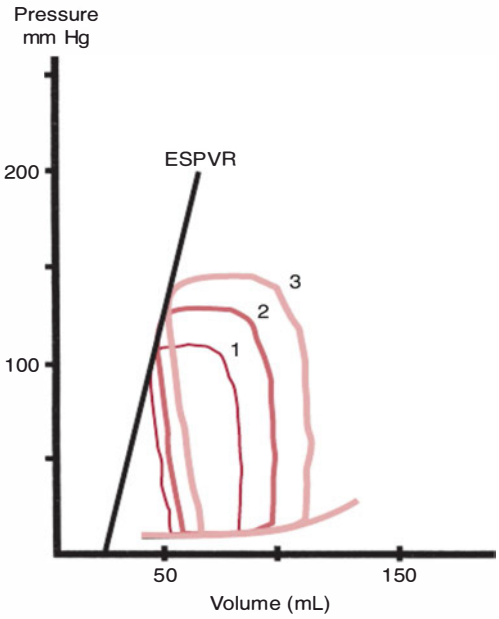

Figure 6.2 Contractility. ESPVR, end-systolic pressure–volume relations.

A.4. What are representative P–V loops for the four valvular lesions?

The hallmarks of aortic stenosis illustrated by the P–V loop analysis framework are a high left-ventricular systolic pressure and an upward and counterclockwise rotation in the end-diastolic P–V relation (AB) indicative of decreased chamber compliance (Fig. 6.3). Stroke volume and ejection fraction are well preserved, but the ejection phase of the loop occurs at much higher pressures. This is permitted by an increase in contractility of a counterclockwise rotation of the ESPVR line.

The schematic P–V loop for aortic insufficiency depicts the enlarged left ventricle of chronic aortic insufficiency. The minimal change in LVEDP despite the large volume overload is seen by the shift in the diastolic P–V curve to the right (A′B′) (Fig. 6.4). Low systemic diastolic pressures result in a brief isovolumetric phase (B′C′) and early complete ejection. The isovolumetric relaxation phase is absent because the incompetent valve permits regurgitant filling of the left ventricle from the aorta during diastole even before opening of the mitral valve. In contrast, when acute aortic insufficiency occurs, the left ventricular compliance is unchanged. Rapid increases in LVEDP from volume overload along the unshifted left ventricular diastolic P–V curve (AB) rapidly lead to increased left atrial pressure and pulmonary congestion.

The P–V loop of mitral stenosis illustrates hypovolemia, the cause of which cannot be determined from the loop alone (Fig. 6.5). Because the predominant impact of mitral stenosis occurs proximal to the left ventricle, the P–V analysis format is less useful.

In mitral regurgitation, the diastolic P–V relation (line AB) is shifted to the right, as it is in chronic aortic insufficiency, consistent with a marked increase in

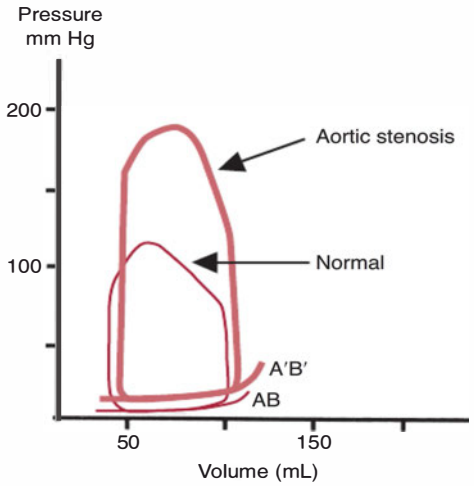

Figure 6.3 Pressure–volume loop of aortic stenosis.

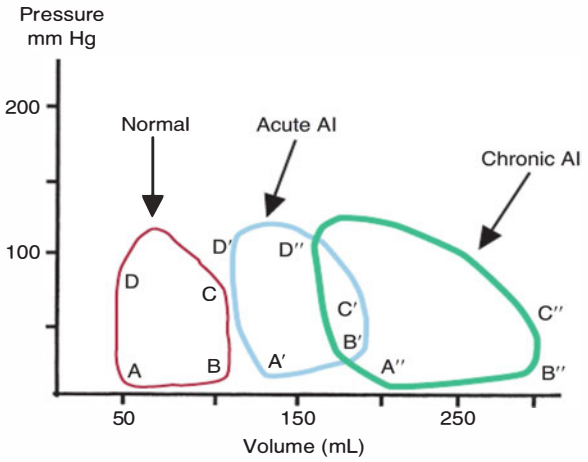

Figure 6.4 Pressure–volume loops of acute and chronic aortic insufficiency.

compliance (Fig. 6.6). The isovolumetric phase (BC) is nearly absent because the left atrium generally serves as a low-pressure/high-compliance route for ejection because of the incompetent mitral valve. Decreases in contractility are depicted by a decrease in the slope of the end-systolic-PV line (line through D). Nevertheless stroke volume and ejection fraction are maintained because of this low-pressure left atrial vent.

A.5. Draw the pressure/time curves for the left ventricle, left atrium, pulmonary artery, and aorta for a normal patient and for patients with each of the four valvular lesions.

Normal curves are shown in Fig. 6.7. The points A, B, C, and D correspond to the same points in the P–V loops.

Aortic Stenosis

The additional systolic pressure work of aortic stenosis can be seen in the left ventricular pressure tracing (Fig. 6.8). Elevations in LVEDP (point B) can be seen to diminish the perfusion gradient for coronary flow to the left ventricle. The augmentation in left ventricular filling late in diastole secondary to atrial contraction (left atrial "kick" from sinus rhythm) is highlighted in the inset. Rising left ventricular diastolic pressures secondary to decreased compliance necessitate elevations in left atrial pressures to permit complete left ventricular volume loading. Atrial systole provides this elevation in left atrial pressure synchronous with elevations in LVEDP while keeping left atrial pressures relatively low during the remaining cardiac cycle facilitating pulmonary venous drainage.

Aortic Insufficiency

The rapid upstroke and rapid decline of arterial pressure indicate absence of aortic valve closure and low end-diastolic aortic pressure (Fig. 6.9). Elevations in LVEDV and LVEDP are typical of aortic insufficiency. The early increase in LVEDP can result in left ventricular pressures exceeding those of the left atrium during diastole, with resultant premature closure of the mitral valve.

Mitral Stenosis

Elevations in pressure are seen in both the left atrial and pulmonary artery tracing with mitral stenosis (Fig. 6.10). The large gradient between left atrial and left ventricular pressures is highlighted in the inset. Chronic elevation in pulmonary volume induces changes in the luminary vascular bed and leads to pulmonary hypertension.

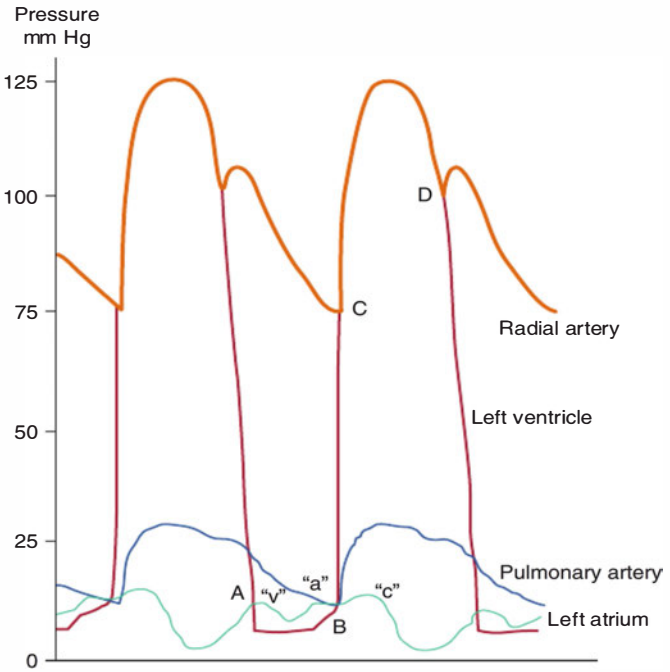

Figure 6.7. Pressure curves for the left ventricle, left atrium, pulmonary artery, and aorta in a healthy individual.

Mitral Regurgitation

The hallmark of mitral regurgitation is the marked elevations of left atrial pressure during systole and the occurrence of a giant "cv" wave and elevated pulmonary artery pressures (Fig. 6.11).

A.6. What are the basic principles of echocardiography? What are M-mode, B-mode, and Doppler color modalities? How do TTE and transesophageal echocardiography (TEE) differ?

Echocardiography is the use of sound waves to image structures and blood flow within the heart and great vessels. To image tissue, sound waves are emitted from a transducer at known speeds and constant intervals. The sound packets bounce off structures in their path, and the reflected sound waves are received at the point of origin, either by a separate receiving crystal or by the same emitting transducer, which spends a portion of its time in this "listening" mode. The time it takes for the reflected waves to return to the crystal is measured, and because the velocity of sound in tissues is relatively constant, solving for distance can be easily accomplished.

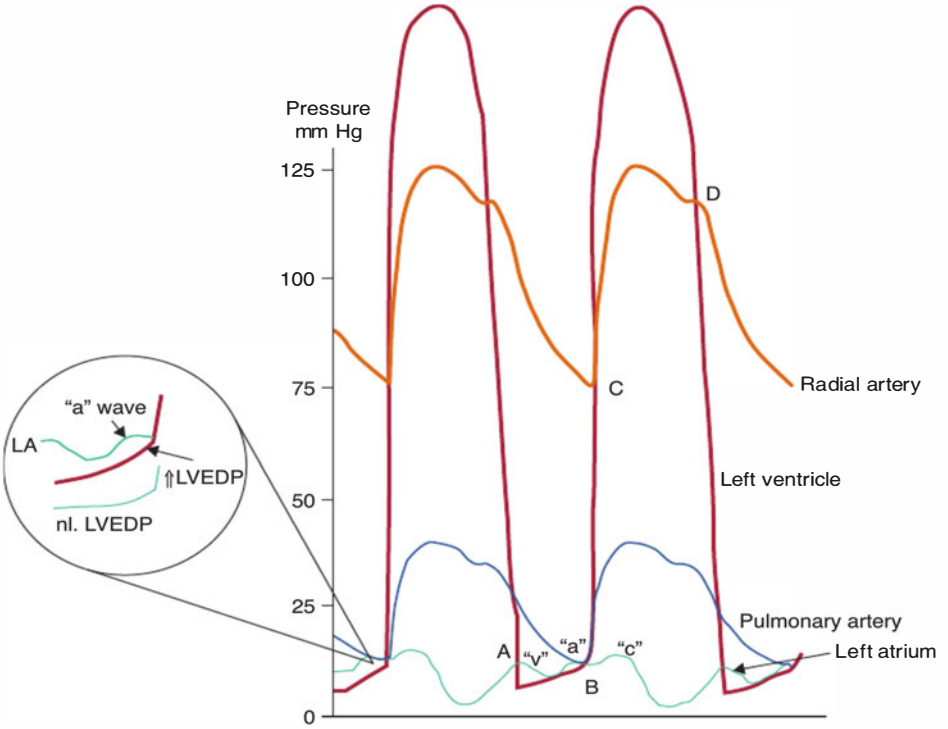

Figure 6.8 Pressure curves for the left ventricle, left atrium (LA), pulmonary artery, and aorta in patients with aortic stenosis. LVEDP, left ventricular end-diastolic pressure.

$$\text{Distance} = \tfrac{1}{2}\,(\text{velocity} \times \text{time})$$

(½ because the distance is traversed twice, once to the object and again on returning.)

In this manner, the spatial orientation of cardiac structures can be determined. The strength of the returning signal can be quantified as an amplitude, therefore "A" or amplitude mode (Fig. 6.12B). The echo machine codes this amplitude on a black and white scale, thereby converting the amplitude to brightness or B-mode scanning (Fig. 6.12C). Fig. 6.12D shows this "ice-pick" view through the left ventricle of the heart. Each change in tissue density results in some sound waves being reflected and hence an interface. In this example, bold lines are seen at the epicardial, the endocardial-chamber, the chamber-endocardial, and the epicardial borders. If these amplitude bars are displayed in real time, a motion or M-mode display results (Fig. 6.12E). These images were difficult to reliably obtain and interpret because the views represent a linear slice without surrounding structural images for referencing. If the probe is rocked back and forth repetitively, multiple M-mode images can be obtained in a given instant and a 2D image formed. This rapid rocking back and forth of the ultrasound beam is performed electronically in a phased-array transducer. The images derived in this manner appear as a cine-radiographic display of myocardial movement. Therefore, echocardiography can provide information about the size, shape, location, and movement of myocardial structures.

In addition to determining how long it takes for a given sound wave to return and thereby deriving the distance from the transducer, contact of the sound wave packet with the reflecting object (tissue, blood cells, air) will alter the wavelength of the sound packet according to the Doppler principle. When the object coming in contact with the sound wave is moving toward the source of the ultrasound, the reflected ultrasound wavelengths are compressed (shorter) or of higher pitch. The opposite occurs when the contacted object is moving away from the sound source. These shifts in frequency are proportional to the velocity of the contacted structure and, thereby, the speed and direction of the encountered object (usually of blood flow) can be calculated. This velocity information can be displayed on a color map (Doppler color flow) or on a time/velocity scale (spectral Doppler display). Doppler-derived blood flow velocity information can determine laminar and turbulent flow patterns, regurgitant or stenotic lesions, and congenital anomalies and can permit quantification of pressure gradients. Using the modified Bernoulli equation ($\delta P = 4\ v^2$), determination of a blood flow velocity permits the estimation of pressure gradients.

Simply, the greater the velocity of blood flow, the higher is the pressure gradient. Only the component of blood flow parallel to the Doppler beam will be analyzed. The Doppler equation: $V = c\ (F_S - F_T)/2\ F_T\ (\cos\ \theta)$, contains the cosine of the angle of incidence between the ultrasound beam and the moving object. Because the cosine of 90 degrees is zero, blood flow that is perpendicular to the ultrasound beam will not have any Doppler shift and, therefore, will not be represented in the color display. For this reason, it is important to choose an ultrasound "window" in which the expected blood flow direction is most parallel to the ultrasound.

TTE uses imaging points or "acoustic windows" obtained with the transducer handheld on the chest wall. It is simple and noninvasive. Most standard echocardiograms are obtained from this position. During cardiac surgery, the chest wall is in the sterile field and therefore unavailable. The esophagus lies immediately adjacent

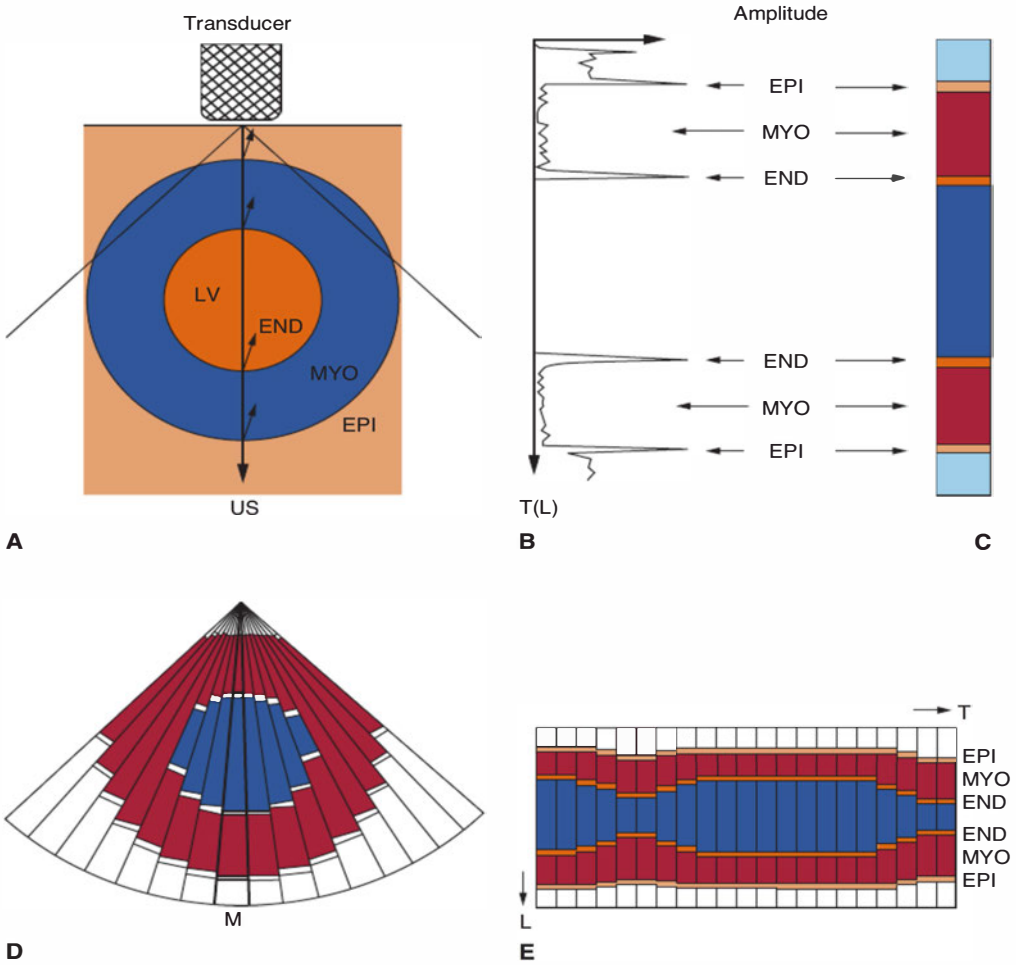

Figure 6.12 The process of producing the B-mode and M-mode images. **A.** A pulse of ultrasound is emitted into the object, and the backscattered echo is received by the same transducer. **B.** The received acoustic signal is converted to the electric signal (A-mode). **C.** The amplitude is modulated into brightness (B-mode). **D.** As subsequent pulses of ultrasound are emitted with the sequentially changing angles and the obtained one-dimensional (1D) B-mode images are compounded according to the direction of each ultrasound emission, the first frame of the sector-shaped image is formed. **E.** When the ultrasound is repeatedly transmitted in one direction, a series of 1D B-mode images is obtained. As these are arranged against time, an M-mode image is obtained. (From Okay Y, Goldiner PL, eds. *Transesophageal Echocardiography*. Philadelphia: JB Lippincott, 1992:12, with permission.) to the heart outside of the operative field and affords an excellent imaging vantage point. In 1976, Yasu Oka from the Albert Einstein College of Medicine developed a practical method of intraoperative imaging. He mounted an ultrasound crystal on the end of a gastroscope and, thereby, obtained images of the heart during surgery. This has been refined considerably since. TEE has become the standard of care for heart surgery at many institutions. The close proximity of the probe to the heart affords

excellent resolution. The probe is not in the operative field, so surgery is unhindered and sterility is not an issue. Although mildly invasive, the risk for esophageal injury in the anesthetized state is very low.

Intraoperative TEE is beneficial for quantification of cardiac contractility, for determination of the severity of regurgitant and stenotic valvular disease, for detection of intracardiac shunts and the occurrence of dissections, and as a guide for catheter placement.

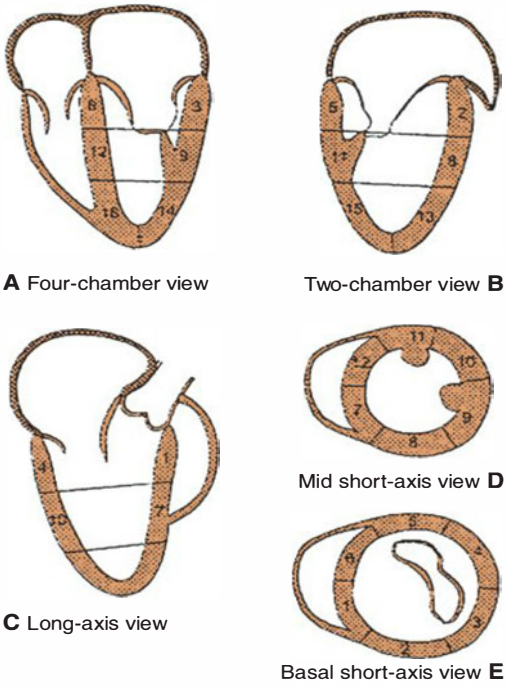
A.7. What are the three TEE vantage points for the comprehensive imaging of the left ventricle? How are pressure gradients measured by echocardiography? How do the pressure gradients derived from Doppler echocardiography differ from those obtained in the catheterization laboratory by direct pressure measurement?

The heart has two main axes: the longitudinal axis running from the base to the apex and the short axis perpendicular to that. Because the ultrasound beam can be thought of as a 2D structure, multiple scan planes are required to completely image a 3D structure. The left ventricle may be divided into 16 segments: 6 at the basal level, 6 at the midpapillary level, and 4 at the apical level (Fig. 6.13). By moving the transesophageal echocardiography probe in the esophagus and rotation of the crystal within the transducer tip, the left ventricle can be imaged from three acoustic windows. These are the midesophageal four-chamber, the transgastric short axis, and the transgastric two-chamber view. Normal ventricular motion requires that the wall segment move centrally with systole and similarly undergo thickening along this axis during contraction. Function is usually quantified as normal; mild, moderate, and severe hypokinesis; akinesis; and dyskinesis.

In addition to function, TEE permits the determination of wall thickness and chamber size—important parameters in understanding the pathophysiology of valvular heart disease.

As mentioned previously, pressure gradients are derived through analysis of the Doppler profiles of blood flow. A commonly determined echocardiography gradient is that which is present from the left ventricle to the aorta in the setting of aortic stenosis. To obtain the change in blood flow velocity across the aortic valve with TEE, the probe is advanced far into the stomach and sharply anteflexed and left deflected to obtain the window from the apex of the heart (deep transgastric long axis) and align the ultrasound beam most parallel to the path of blood flow. From this window, the continuous-wave Doppler cursor is directed across the left ventricular outflow tract and aortic valve. An example of such a spectral Doppler display is seen in Figure 6.14. The large increase in blood flow velocity in this display occurs at the narrowest point along its path, which, in this case, is the aortic valve. Using the modified Bernoulli equation mentioned previously, a gradient is calculated (100 mm Hg in the example). This represents the maximum instantaneous pressure difference between the left ventricle and the aorta. Aortic stenosis is also quantified at the time of catheterization by measuring the pressures from within the left ventricle and the aorta as a rapid response pressure transducer catheter is withdrawn from the left ventricle back to the aorta across the stenotic valve. The standard reported gradient is the difference between the maximum left ventricular and aorta pressures. Figure 6.15 illustrates that these peaks are not simultaneous events. Therefore, Doppler-derived aortic stenosis gradients are usually higher than those derived at the time of left heart catheterization.



Basal segments	Mid segments	Apical segments
1 = Basal anteroseptal	7 = Mid anteroseptal	13 = Apical anterior
2 = Basal anterior	8 = Mid anterior	14 = Apical lateral

A.8 What is the role for three-dimensional (3D) echocardiography in the operating room?

Modern TEE technology has progressed from 2D multiplane images to real-time 3D displays of the heart. The 3D probes are equipped with 20 to 40 times more piezoelectric crystals on the same size probe surface. This allows for a pyramidal scanning volume.

The orientation of the mitral valve is such that perpendicular alignment of the TEE probe is achieved. All of the 3D imaging modalities can be used to assess valvular pathology (live, zoom, and full-volume). The MV 3D images can be further modified by cropping in any plane to investigate leaflet morphology. Studies have shown that intraoperative assessment of the mitral valve with 3D TEE examinations have decreased interobserver variability and provided better correlation with surgical findings.

The atrial valve is more difficult to image in 3D. A normal atrial valve with thin cusps are not well visualized. Stenotic valves encounter echo dropout secondary to calcifications.

Left ventricular assessments including volume and wall motion can easily be done in the operating room. After identification of the left ventricle walls and apex from two orthogonal 2D views, a 3D model of the heart is created using endocardial border tracking. Stroke volume and ejection fraction are automatically calculated.

A.9. What are the echocardiographic and cardiac catheterization criteria for the four valvular lesions?

The TEE severity scales of the various valvular lesions are summarized in Table 6.1.

Aortic Stenosis

Echocardiographic criteria for aortic stenosis include 2D images demonstrating limited aortic valve opening and motion and left ventricular concentric hypertrophy. Doppler examination will reveal a turbulent, high-velocity jet across the aortic valve, and color-flow Doppler will demonstrate a turbulent, mosaic-appearing color map. The gradient across the aortic valve measured at cardiac catheterization is different from that measured by echocardiography as mentioned previously. Quantification of this Doppler-derived pressure gradient again relies on the modified Bernoulli equation.

$$\text{Pressure gradient} = 4\ v^2$$

where v = velocity (m/second), pressure (mm Hg)

Because flow is an important determinant of pressure gradients, both the catheterization and Doppler-derived values are interpreted along with cardiac output. Calculations permit the determination of a valve area. Severe aortic stenosis is present when the gradient exceeds 75 mm Hg or the valve area is less than 0.8 cm^2.

Aortic Insufficiency

Catheterization criteria for aortic insufficiency rely on the qualitative estimation of the regurgitation volume and an estimation of left ventricular size and ejection fraction. Similar quantification can be made from Doppler color echocardiography-derived data. A commonly used echocardiographic criteria compares the width of the regurgitant jet at the level of the valve to the width of the left ventricular outflow tract. A ratio of greater than 0.66 corresponds with severe aortic insufficiency. Another sign

of severe aortic insufficiency can be observed in the spectral Doppler display of blood velocity in the descending thoracic aorta. The TEE probe is advanced to the level of the descending thoracic aorta and rotated to 90 degrees to obtain a long axis view. Under normal conditions, flow remains forward (to distal beds) during diastole. In severe aortic insufficiency, regurgitation of blood back into the ventricle decreases proximal pressure in the aorta and thus the spectral display of blood velocities will demonstrate a reversal of blood flow during diastole back toward the aortic root.

Mitral Stenosis

The severity of mitral stenosis can be obtained by the direct measurement of a diastolic gradient between the left atrium and ventricle at the time of cardiac catheterization. This requires a transatrial puncture, a procedure largely replaced by echocardiographic techniques. Echocardiographic diagnosis is based on gradient estimation by Doppler and by measuring the rate of decay in the pressure with the time spent in diastole (pressure halftime). The mitral area in square centimeters can be derived from an empirical formula wherein the mitral valve area equals 220 divided by this pressure halftime (Hatle constant). Severe mitral stenosis is present when the end-diastolic gradient exceeds 12 mm Hg, corresponding to a valve area of less than 1.0 cm^2.

Mitral Regurgitation

In the presence of mitral regurgitation, ventriculography will demonstrate the reflux of dye from the left ventricle into the left atrium. Severe mitral regurgitation is diagnosed when dye refluxes into the pulmonary veins. Color Doppler echocardiography permits similar quantification. Estimation relies on an estimation of regurgitant jet volume as compared with the left atrium and through analysis of pulmonary venous flow profiles.

In every case, color Doppler echocardiography is often useful in identifying the cause of the valvular lesion, its extent of involvement within and around the valve, and the associated hemodynamic changes. Therefore, for many valvular lesions, it may be sufficient for the diagnosis. Catheterization, however, is often performed to assess the presence of concomitant coronary artery disease, especially in patients of advanced age.

B. Preoperative Evaluation and Preparation

B.1. What are the presenting signs and symptoms of the four valvular lesions listed previously?

See Table 6.2.

Aortic Stenosis

The triad of angina, syncope, and congestive heart failure represent the progression of symptoms associated with atrial stenosis. These symptoms correlate directly with mortality; the 50% survival data for these symptoms are 5, 3, and 2 years from the

Table 6.2 The Signs and Symptoms for the Various Valvular Lesions

LESION	SIGNS AND SYMPTOMS
AS	Angina, syncope, dyspnea/CHF
AI	
Chronic	Fatigability, dyspnea
Acute	Severe pulmonary edema, CHF
MS	Pulmonary congestion, AFib
MR	
Chronic	DOE, PND, AFib
Acute	Severe pulmonary edema, CHF

AFib, atrial fibrillation; AI, aortic insufficiency; AS, aortic stenosis; CHF, congestive heart failure; DOE, dyspnea on exertion; MR, mitral regurgitation; MS, mitral stenosis; PND, paroxysmal nocturnal dyspnea.

onset of these symptoms, respectively. Angina results from both increased demand for and a decrease in supply of coronary blood flow. Increased muscle mass from LVH and the high energy requirements to generate increased (high) systolic pressure combine to increase demands for coronary blood flow. In addition, insufficient supply secondary to decreased perfusion gradients and a decrease in coronary vasculature relative to the large amount of myocardium sum to diminish relative myocardial blood supply. Therefore, up to one-third of patients with aortic stenosis can have angina in the absence of significant coronary artery disease.

Aortic Insufficiency

Patients with aortic insufficiency have variable clinical presentations, primarily depending on the rapidity with which the left ventricular volume overload develops. When the volume increase occurs gradually as in chronic aortic insufficiency, there is usually a long asymptomatic period. The onset of the symptoms of fatigability and dyspnea signals either reduced cardiac output or increased LVEDP, indicative of impairment of left ventricular contractile function. When aortic insufficiency occurs acutely, the ventricular compliance is unchanged; increased left ventricular diastolic volumes from regurgitant flow, therefore, lead to rapid rises in LVEDP and the clinical picture of congestive failure.

Mitral Stenosis

Mitral stenosis is a slowly progressive obstruction to flow across the mitral valve with gradual increase in left atrial pressure and volume. Symptoms of pulmonary congestion result from elevations in left atrial pressures and *not* from poor left ventricular systolic function. Atrial fibrillation develops secondary to atrial dilation.

Mitral Regurgitation

The time course for the development of mitral regurgitation determines the severity of the symptoms. When the volume of regurgitant flow from the left ventricle to the left atrium increases gradually, the left atrium compensates by gradual dilatation. In contrast, the onset of acute mitral regurgitation can lead to rapid increases in left atrial pressures, severe pulmonary congestion, and congestive heart failure.

B.2. What is the New York Heart Association classification of heart failure?

The New York Heart Association heart failure classification is based on the amount of symptoms, specifically dyspnea and fatigue. The various classes are listed in the following:

Class I. No symptoms
Class II. Symptoms with ordinary activity
Class III. Symptoms with less than ordinary activity
Class IV. Symptoms at rest

Criteria Committee of the New York Heart Association. *Diseases of the Heart and Blood Vessels (Nomenclature and Criteria for Diagnosis)*. 6th ed. Boston: Little, Brown and Company, 1964.

B.3. Discuss the role of premedication for patients with the four different valvular lesions.

The role of premedication is to allay the anxiety of the impending surgical procedure, thereby controlling the sympathetic outflow that may accompany the stress response. Acute changes in heart rate, venous return, and systemic resistance can have particularly profound effects on patients with valvular heart disease.

Patients with aortic stenosis may benefit from premedication by preventing unnecessary increases in heart rate. Concern must be taken to ensure adequate venous return and preservation of sinus mechanism (see later discussion).

Patients with aortic insufficiency can similarly benefit from premedication because any increases in afterload, which may accompany sympathetic stimulation, can increase regurgitant volume. Drug doses should be adjusted based on the severity of debilitation and degree of systemic hypoperfusion.

Patients with mitral stenosis should be premedicated with caution. Elevations in carbon dioxide resulting from narcotic-induced hypoventilation can dramatically elevate pulmonary pressures further compromising right ventricle output. Conversely, venodilation may excessively diminish filling pressures.

Patients with mitral regurgitation can respond similarly to those with mitral stenosis, particularly when pulmonary hypertension is present. However, elevations in systemic pressure from stress can also compromise forward left ventricular output. Proper premedication can be delivered by careful dose selection and the provision of supplemental oxygen.

Hartman GS. *Management of Patients with Valvular Heart Disease.* Cleveland: International Anesthesia Research Society; 1994:141–151. 1994 IARS Review Course Lectures.

Thomas SJ, Kramer JL, eds. *Manual of Cardiac Anesthesia.* 2nd ed. New York: Churchill-Livingstone; 1993:81–127.

B.4. How would you premedicate the patient with severe atrial stenosis and mitral regurgitation?

Premedication of a patient with severe atrial stenosis and mitral regurgitation must be approached with caution. The patient should receive supplemental oxygen. A light premedication could be provided with small doses of benzodiazepines by mouth. However, I would prefer to titrate in small intravenous doses of sedation while the patient was under the closely monitored situation of the operating room or holding area and with inspired oxygen supplementation. In this setting, incremental doses of midazolam 0.5 mg intravenously would be administered. It is important to remember that there may be significant delay in the onset of effect of intravenous medications secondary to pooling in the pulmonary and left atrial systems. Adequate waiting periods must be observed between each aliquot to avoid inadvertent overdose with ensuing respiratory depression, pulmonary hypertension, systemic hypotension, and right heart failure. In the elderly, use of benzodiazepines has been linked to postoperative delirium, which can be quite severe and difficult to treat as well as increase length of stay and resource utilization.

C. Intraoperative Management

C.1. Outline the hemodynamic management goals for each of the four valvular lesions. What are the anesthetic goals with respect to heart rate and rhythm, preload, afterload, and contractility?

Table 6.3 summarizes the hemodynamic goals with respect to heart rate and rhythm, preload, afterload, and contractility.

Table 6.3 Hemodynamic Goals for the Various Valvular Lesions

		HEMODYNAMIC GOALS		
LESIONS	HR AND RHYTHM	PRELOAD	AFTERLOAD	CONTRACTILITY
AS	60–70, sinus	Full	Maintain	—
AI	80–90	Maintain	Lower	May need support
MS	60–70	Full	—	—
MR	80–90, sinus if possible	Maintain	Lower	May need support

AI, aortic insufficiency; AS, aortic stenosis; HR, heart rate (beats/min); MR, mitral regurgitation; MS, mitral stenosis.

Aortic Stenosis

Patients with aortic stenosis need the left ventricular filling obtained through a well-timed atrial contraction. Similarly, LVH renders the ventricle stiff and adequate preload is required. Reducing vascular tone will do little to relieve the fixed afterload increases from a stenotic valve but rather lower diastolic coronary perfusion gradients and should be avoided. Patients with aortic stenosis experiencing angina may require the administration of an α-agonist such as phenylephrine rather than nitroglycerin to increase coronary perfusion pressure.

Aortic Insufficiency

The severity of aortic insufficiency is determined by the size of the regurgitant orifice, the pressure gradient between the aorta and left ventricle during diastole, and the time spent in that phase of the cardiac cycle. Elevated heart rates decrease the time spent in diastole and can lead to a decrease in heart size. Afterload reduction can lessen the regurgitant driving forces, but therapeutic maneuvers to accomplish this may be limited by resulting systemic hypotension.

Mitral Stenosis

Patients with mitral stenosis can swiftly deteriorate in the setting of rapid heart rates. The decreased filling time necessitates the marked elevation of left atrial pressures, and pulmonary edema can rapidly ensue. Whereas left ventricle contractility is generally preserve in mitral stenosis, use of β-blockade does result in decreased right ventricular contractility, which in the setting of pulmonary hypertension can further compromise the cardiac output and systemic blood pressure. However, the loss in right ventricle contractility is more than offset by the beneficial effects of the reduction of heart rate. Slower heart rates permit adequate time for transfer of blood from the left atrium to the left ventricle across the stenotic mitral valve to occur. In addition, the pressure gradient across the mitral valve is also reduced; thereby lowering left atrial pressure and diminishing pulmonary congestion. Because there is some variability in the individual response, the use of short-acting β-blockers such as esmolol is prudent because an adverse response should be evanescent.

Mitral Regurgitation

Patients with mitral regurgitation can rapidly deteriorate with marked increases in systemic blood pressure and afterload. As with other volume overload lesions such as aortic insufficiency, slightly rapid heart rates (80 to 90 beats per minute) should result in smaller left ventricular volumes. This may lessen any component of mitral regurgitation secondary to annular dilation or chordal malalignment. Importantly, tachycardia should be avoided in patients with ischemic mitral regurgitation.

C.2. What are the hemodynamic goals for this patient with the combination of severe aortic stenosis and mitral regurgitation?

In the patient with combined aortic stenosis and mitral regurgitation, the situation is more complex than when only a singular valvular lesion is present. Careful examination of the hemodynamic goals for each of the two lesions will reveal that therapy beneficial to patients with atrial stenosis may exacerbate the severity of the mitral regurgitation. Early aggressive intervention is the key to these combined lesions. A lower margin for error usually exists because minor hemodynamic aberrations can rapidly lead to cardiac collapse. A good rule of thumb is to prioritize the management based on the character of the present symptoms. Patients with aortic stenosis and mitral regurgitation who present with syncope or angina are best managed for their atrial stenosis, whereas patients with dyspnea and pulmonary edema are best managed for their congestive symptoms. It is prudent to maintain the patient's own usual hemodynamics and avoid physiologic trespass. TEE evaluation of left ventricular performance can be helpful in separating pulmonary congestion secondary to left heart failure from that secondary to poor diastolic left ventricular compliance.

Thomas SJ, Kramer JL, eds. *Manual of Cardiac Anesthesia.* 2nd ed. New York: Churchill Livingstone; 1993:81–127.

C.3. How would you monitor this patient with severe atrial stenosis and mitral regurgitation?

In addition to the standard American Society of Anesthesiologists recommended monitors, the patient would have a radial artery and a pulmonary artery catheter. Following induction of anesthesia and endotracheal intubation, a TEE probe would be inserted to confirm the valvular pathology and to assess ventricular function. Following valve replacement, the TEE probe would be used to check for adequacy of valvular function and the absence of paravalvular leaks and to assess postbypass ventricular function.

Practice guidelines for perioperative transesophageal echocardiography. A report by the American Society of Anesthesiologists and the Society of Cardiovascular Anesthesiologist Task Force on transesophageal echocardiography. *Anesthesiology.* 1996;84:986–1006.

C.4. Should the patient have a pulmonary artery catheter placed before induction?

Volume status may be particularly difficult to assess in patients with valvular heart disease yet of critical importance in the management of these patients. Patients with stenotic lesions depend on adequate filling pressures for diastolic filling of the ventricle. Patients with the volume overload lesions of aortic insufficiency and mitral regurgitation can benefit from the careful reductions in pulmonary pressure guided by the simultaneous assessment of cardiac performance. In these capacities, the pulmonary artery catheter is useful. Patients with current hemodynamic stability, without severe respiratory distress, can be safely anesthetized before placement of the pulmonary artery catheter. In all, there is no evidence that use of the pulmonary artery catheter improves outcome in the setting of surgery.

Practice guidelines for pulmonary artery catheterization: an updated report by the American Society of Anesthesiologists task force on pulmonary artery catheterization. *Anesthesiology*. 2003;99:4.

C.5. Is a pulmonary artery catheter with pacing capabilities indicated?

Patients with aortic stenosis can become severely compromised with the loss of atrial kick or the presence of slow junctional rhythms. Patients with aortic insufficiency or mitral regurgitation can experience left ventricular dilation in the setting of slow heart rates. In such cases, a pulmonary artery catheter with atrial and ventricular pacing capacity can be useful in this setting. In patients with intact conduction systems, rate manipulation can often be achieved pharmacologically. Transesophageal atrial pacing is another option; transthoracic pacing elicits a ventricular response only and does not permit atrial stimulation. Transthoracic pacing is indicated when the ability to rapidly open the pericardium and obtain epicardial pacing is limited. This occurs in the setting of reoperations or with patients having a history of inflammatory pericardial disease. Pacing will be limited to capture of the ventricle alone. The loss of atrial contraction can lead to underfilling and hemodynamic compromise in patients dependent on the added volume from atrial systole. One of the other pacing modalities is best in this setting.

C.6. What anesthetic technique would you employ? Why?

For the patient undergoing CPB and aortic valve replacement, general anesthesia with endotracheal intubation is the obvious choice. Both narcotics and inhalation anesthetics can be safely administered. When prolonged postoperative ventilation is anticipated, a high-dose narcotic anesthetic has numerous advantages. Recent anesthetic technique for cardiac surgery has focused on the use of techniques permitting earlier extubation, so-called fast tracking. Anesthetic combinations using smaller total narcotic doses, inhalation anesthetics, and short-acting intravenous sedatives such as propofol are gaining popularity. For uncomplicated valve replacements with good ventricular function, the advantages of early extubation can be safely achieved. In complicated cases with longer bypass periods, poor ventricular function, or postbypass bleeding, the hemodynamic stability of a high-dose narcotic technique may be advantageous.

Tuman KJ, McCarthy RJ, Spiess BD, et al. Comparison of anesthetic techniques in patients undergoing heart valve replacement. *J Cardiothorac Anesth*. 1990;4:159–167.

C.7. What muscle relaxant would you use for this patient?

Muscle relaxants can alter hemodynamics both from the effects of histamine release, including vasodilatation and bronchospasm, and through effects on rhythm. Although slowing of heart rates usually benefits the patient with angina, it may have

severe consequences in patients with valvular heart disease. The typical high-dose narcotic anesthesia usually results in bradycardia secondary to the vagotonic actions. Pancuronium-mediated increases in heart rate usually offset these actions and result in a stable heart rate.

Hemodynamically "neutral" relaxants such as vecuronium, rocuronium, or cisatracurium could be used, but their intermediate duration of action offers little, if any, advantage in this setting.

Therefore, it is important to choose that combination of agents that will promote hemodynamic stability in a particular patient with his or her unique hemodynamic presentation. In this patient, I would use pancuronium in conjunction with the high-dose narcotic anesthetic.

C.8. What are the usual TEE findings in a patient with aortic stenosis, aortic insufficiency, or mitral regurgitation? How do you grade the severity of aortic stenosis by TEE? How do you quantify the severity of mitral regurgitation? What is the impact of aortic stenosis on the severity of mitral regurgitation?

The severity of aortic stenosis is usually stated in terms of aortic valve area. Normal aortic valve area is 2.5 to 3.5 cm^2. Moderate stenosis is when the aortic valve area is within the range of 0.8 to 1.2 cm^2 and severe stenosis when the aortic valve area is less than 0.8 cm^2. A patient with a large peak pressure gradient (usually more than 75 mm Hg) in the absence of excessively high cardiac output is usually considered to have severe aortic stenosis as well. In the setting of low cardiac outputs, the pressure gradient may not be that great (20 to 30 mm Hg), and determination of aortic valve area is required. This can be accomplished with echocardiography.

Mitral regurgitation is graded by the amount of blood regurgitated backward into the left atrium during systole. Doppler color flow permits quantification of this flow. Common methods for mitral regurgitation quantification include the depth of mitral regurgitation jet extent into the left atrium (25% mild mitral regurgitation, 25% to 75% moderate mitral regurgitation, and more than 75% severe mitral regurgitation). Other methods of quantification include calculation of the area of the regurgitant jet by planimetry, by comparison of the mitral regurgitation jet area to the area of the left atrium, and by analysis of pulmonary vein flow profiles. It is important to remember that the amount of regurgitant blood flow in the setting of mitral regurgitation is determined by the amount of time spent in systole, the size of the defect in the mitral valve, and the pressure gradient across the defect. Therefore, mitral regurgitation severity by Doppler color flow is load dependent. The lower pressure of the anesthetic state can often mask more severe degrees of mitral regurgitation seen when the patient is under his or her usual hemodynamic conditions.

The left ventricular pressures are increased in the setting of aortic stenosis. Therefore, the gradient across the mitral valve is increased often leading to more severe mitral regurgitation. Following replacement of the stenotic aortic valve and elimination of the outflow tract obstruction, left ventricular pressures are markedly reduced. Moderate levels of mitral regurgitation without major structural defects in the mitral valve apparatus usually revert to minimal or certainly less severe levels following reduction in the left ventricular outflow obstruction.

Spain MG, Smith MD, Grayburn PA, et al. Quantitative assessment of mitral regurgitation by Doppler color flow imaging: angiographic and hemodynamic correlations. *J Am Coll Cardiol.* 1989;13:585–590.

C.9. What special considerations particular to cardiopulmonary bypass (CPB) operations do you have for each of the four lesions? Focus on these concerns with respect to the induction and prebypass, bypass, and postbypass periods.

Aortic Stenosis

Critical to the management of a patient with aortic stenosis is the avoidance of hypotension. Low blood pressure can initiate a cascade of events leading to cardiac arrest. Hypotension decreases the gradient for coronary perfusion with resultant ischemia. Ischemia leads to diminished cardiac output and decreased blood pressure further compromising coronary perfusion. The occurrence of cardiac arrest in a patient with aortic stenosis is particularly catastrophic because closed-chest cardiac massage will provide little gradient for blood flow across a stenotic aortic valve.

Patients with aortic stenosis are particularly dependent on their atrial kick for adequate ventricular filling volume and can rapidly become hypotensive and ischemic following the onset of supraventricular tachycardia or atrial fibrillation. These rhythms are not uncommon during atrial cannulation. Therefore, it is of particular importance that every preparation for the initiation of CPB be made before atrial manipulation. Increased muscle mass of ventricular hypertrophy can be more difficult to adequately protect with cardioplegia. Careful attention to surface cooling, myocardial temperature measurement, and the use of retrograde cardioplegia can be helpful. Following aortic valve replacement, hypertension from left ventricular output now unopposed by any valvular lesion can result in stress on suture lines and excessive bleeding. It is important to remember that the compliance of the left ventricle is unchanged by surgery and still critically dependent on adequate preload and sinus rhythm.

Aortic Insufficiency

Patients undergoing aortic valve replacement for aortic insufficiency can often present difficult management decisions. The usual treatment measures for hypotension (α-agonist) may have deleterious effects by increasing regurgitant volume. The use of combined α- and β-agonists (ephedrine, epinephrine, or infusions of dopamine or dobutamine) may be required. Although it would serve to lessen regurgitant volume, afterload reduction is beneficial in only a subset of patients with aortic insufficiency. Those patients with elevated LVEDP, reduced ejection fraction, diminished cardiac output, and systemic hypertension usually benefit from afterload reduction. In contrast, those patients without the previously mentioned constellation may experience a decrease in forward cardiac output secondary to diminished preload from reduced venous return. Systemic hypotension usually limits the utility in the acute setting. The presence of aortic insufficiency makes initiation of CPB a critical period. Periods of bradycardia or ventricular fibrillation can lead to rapid volume overload of the left ventricle through the incompetent aortic valve. Pacing, electrical defibrillation, and/or cross-clamping should be performed to prevent ventricular distention. Similarly, myocardial protection is compromised by aortic insufficiency. Generation of adequate root pressures is usually not obtainable; hence, delivery of cardioplegia requires aortotomy and cannulation of the coronary ostia. Use of retrograde cardioplegia is advantageous. Following aortic valve replacement, the ventricle no longer has the lower pressure/impedance outflow afforded by the low aortic diastolic pressure. Inotropic support is often required. As

with aortic stenosis, the presence of an aortic suture line necessitates rapid response to hypertension to avoid bleeding and dissection.

Mitral Stenosis

Patients undergoing mitral valve replacement for mitral stenosis are particularly challenging. Marked elevations in pulmonary vascular resistance can be present with associated right heart failure. Stasis in the left atrium necessitates careful echocardiographic examination for the presence of atrial thrombi. Manipulation of the heart before cross-clamping should be avoided. Following replacement, the chronically underfilled, underworked left ventricle may be unable to handle the new volume load. Inotropic support is often required for right ventricular failure and occasionally to improve left ventricular function. Afterload reduction and improved systemic perfusion through an IABP may be beneficial.

Mitral Regurgitation

Similarly, patients with mitral regurgitation may have pulmonary hypertension and right heart failure. In contrast to aortic insufficiency, almost all patients with mitral regurgitation can be greatly benefited by afterload reduction, both pharmacologically and through an IABP. Diminution of left ventricular systolic pressure through afterload reduction decreases the pressure gradient from the left ventricle to the left atrium during systole, with resultant decreased regurgitant volume.

Prebypass assessment can be misleading. Preserved ejection fractions and elevated stroke volumes may mask marked left ventricular systolic dysfunction. It should be remembered that much of the left ventricular volume is ejected into the low-pressure/impedance outflow path of the left atrium. This route is no longer available after valve replacement. Following mitral valve replacement, dysfunctional ventricles may be unable to provide adequate forward flow into the systemic circuit with its elevated vascular resistance and usually necessitate the use of inotropic support.

Patients previously in atrial fibrillation without marked atrial enlargement often revert to or can be converted to sinus rhythm following valve replacement. The capacity of maintaining a person in sinus rhythm dramatically decreases when the diameter of the atrium is more than 5 cm.

Thys DM, Hillel Z, Schwartz AJ, eds. *Textbook of Cardiothoracic Anesthesiology*. New York: McGraw-Hill; 2001:589–629.

C.10. The patient cannot be weaned from CPB following an aortic valve replacement and mitral valve replacement. What are the possible causes?

The adequacy of myocardial preservation should be considered. LVH without or with accompanying coronary artery disease increases myocardial oxygen demands. Prolonged cross-clamp time necessitated by dual valve replacement can lead to inadequate and/or nonhomogeneous myocardial protection. In addition, there may be residual cardioplegia present within the myocardium. Therefore, some degree of postbypass left ventricular dysfunction can be anticipated. Inotropic support may be required. It is important to remember that although the obstruction to left ventricular ejection is acutely relieved by replacement of the stenotic valve, left ventricular compliance is largely unchanged. Adequate preload still depends on sinus rhythm and sufficient left ventricular filling pressures (pulmonary artery occlusion pressure [PAOP] or LVEDP).

Elevations in pulmonary vascular resistance may render estimation of left atrial pressure through the pulmonary artery catheter inaccurate. In this setting, placement of an left atrial catheter is indicated. TEE may prove invaluable in identifying surgically correctable causes for inability to wean from CPB. Evaluation of left ventricular filling and contractility can help resolve the situation of low cardiac output and high filling pressures. A small underfilled left ventricle with hyperdynamic contractility and a dilated, overfilled, hypokinetic left ventricle can both give the same hemodynamic parameters but obviously require different pharmacologic interventions. Abnormal valve seating may compromise flow into the coronary ostia and return to bypass with valve repositioning or coronary artery bypass grafting may be indicated. Similarly, perivalvular leaks or aortic dissections can be readily identified. Iatrogenic injury to the circumflex artery, although rare, can occur during mitral valve annuloplasty or replacement. The course of the circumflex artery along the posterior path of the mitral valve annulus makes it a potential target for errant valve stitches. New regional wall motion abnormalities in the inferior-lateral territory may help to make this unusual diagnosis or influence the decision to pursue diagnostic testing, such as emergent cardiac catheterization. The coronary sinus can also be damaged during mitral valve repair and replacement as the suture line is placed in the lateral mitral annulus. TEE may demonstrate abnormal echodensities in the area of the atrioventricular groove, and color flow Doppler can demonstrate high-velocity flow jets from the chambers to the sinus.

C.11. How would you diagnose right heart failure and pulmonary hypertension? How would you treat it?

Right heart failure is diagnosed by the elevations in right-sided filling pressures, specifically central venous pressure. Careful examination is required to rule out tricuspid insufficiency as the cause of the central venous pressure elevation. A high central venous pressure indicates the inability of the right heart to adequately propel the venous return volume into the pulmonary circulation. Elevation in pulmonary artery pressures is indicative of pulmonary hypertension. The combination of high central venous pressure and high pulmonary artery pressures indicates severe right heart failure. This scenario can be difficult to manage. Attempts to elevate systemic perfusion pressure with α-agonists can worsen pulmonary hypertension. Administration of vasodilators to lower pulmonary pressures results in systemic hypotension. In this setting, it is often prudent to return to CPB, relieve ventricular distention, and improve myocardial perfusion. During this "rest period," adjustments in inotropic therapy, ventilation, and cardiac rhythm can be instituted. Optimization of acid–base status and hemoglobin concentration should also be performed. Separation from bypass can then be reattempted.

Typical inotropic agents effective in this setting are those with high degrees of β-adrenergic potency and potent vasodilation in the pulmonary vasculature. Commonly employed agents include dobutamine, epinephrine, prostaglandin E_1 and the phosphodiesterase-III (PDE-III) inhibitors amrinone and milrinone. It is not uncommon to require the administration of α-agonists to counteract the systemic vasodilating effects of prostaglandin E_1 and the PDE-III agents. Some selective pulmonary vasodilating action and systemic vasoconstricting effects can often be achieved by administration of pulmonary vasodilating agents such as prostaglandin E_1 through the right-sided access (central venous pressure or pulmonary artery catheter) and

infusion of the α-agonists through the left arterial line, thereby minimizing vasoconstriction of the pulmonary arterial bed.

Nitric oxide is a potent, inhaled pulmonary vasodilator. Its half-life in the systemic circulation is extremely short, permitting its administration to the pulmonary vasculature with minimal systemic hypotensive effects. Nitric oxide can selectively and effectively dilate the pulmonary vasculature. The exact method of delivery, scavenging of waste gases, and high cost remain as obstacles to its clinical application.

C.12. How does an intra-aortic balloon pump (IABP) work to benefit the failing heart?

An IABP is a catheter with a large balloon (40 to 60 mL) at its tip. It is positioned in the thoracic aorta distal to the left subclavian artery origin and proximal to the take-off of the renal vessels. It is timed to inflate during diastole to increase diastolic perfusion pressure to the coronary arteries, great vessels, and major abdominal organs and to deflate just before systole, creating a void in volume within the aorta and thus a low pressure with resultant decrease in afterload. The decreased afterload increases stroke volume and hence forward cardiac output. It is a unique modality that can improve coronary perfusion pressures while reducing myocardial oxygen demand.

Baskett RJ, Ghali WA, Maitland A, et al. The intraaortic balloon pump in cardiac surgery. *Ann Thorac Surg.* 2002;74:1276–1287.

Cheung AT, Savino JS, Weiss SJ. Beat-to-beat augmentation of left ventricular function by intraaortic counterpulsation. *Anesthesiology*. 1996;84:545–554.

C.13. What role does the IABP have in this setting?

An IABP may be useful because unlike any pharmacologic maneuver it is capable of increasing mean pressure during diastole critical for coronary perfusion while lowering afterload to systolic left ventricular ejection. Myocardial dysfunction secondary to inadequate protection during bypass can be reduced by decreased afterload and augmentation of diastolic pressures through IABP counterpulsation. Studies have shown superior survival among patients with isolated cardiac artery bypass graft (CABG) treated with IABP's compared with patients undergoing non-CABG cardiac surgeries. The IABP can only aid patients in whom ventricular function can recover in a relatively short time. Outside of this population, ventricular assist devices may be more appropriate.

Baskett RJF, Ghali WA, Maitland A, Hirsch G. The intraaortic balloon pump in cardiac surgery. *Ann Thorac Surg.* 2002;74:1276–1287.

Cheung AT, Savino JS, Weiss SJ. Beat-to-beat augmentation of left ventricular function by intraaortic counterpulsation. *Anesthesiology.* 1996;84:545–554.

C.14. What role does TEE play in the placement, timing, and demonstration of efficacy of an IABP?

The thoracic aorta and aortic arch can be clearly imaged by TEE. Imaging of the take-off of the left subclavian artery facilitates optimal positioning of the IABP. In addition, before insertion the aorta can be evaluated for dissection or the presence of severe atheromatous disease, both contraindications to IABP insertion. TEE can demonstrate the efficacy of an IABP by showing enhanced ventricular emptying during systole and filling during diastole.

C.15. How would you properly time the IABP cycle?

Inflation should occur just following the dicrotic notch and deflation before the upstroke in the aortic pressure curve. Augmentation in pressures during diastole and mean pressures should occur. Diastolic pressure (the lowest pressure in the cardiac cycle) should in fact fall. Peak pressure generated by the left ventricle or systolic pressure should fall while the balloon generated pressure during ventricular diastole (augmented pressure) should increase.

C.16. What are the contraindications to the use of an IABP?

The most common contraindications are severe aortic insufficiency and severe aortic disease, atheromatous, aneurysmal, or a dissection. Although often listed as absolute contraindications, there are reports of the effective use of IABP in these settings. TEE can be helpful in evaluating the effect of an IABP on overall ventricular function. End-systolic areas should decrease, and end-diastolic areas should at least not increase but may decrease as well.

Sanfelippo PM, Baker NH, Ewy HG, et al. Experience with intraaortic balloon counterpulsation. *Ann Thorac Surg.* 1986;41:36–41.

C.17. What is the role for ventricular assist devices?

Ventricular assist devices are used in the management of chronic heart failure after exhausting medical therapy. These devices can be used as a bridge to transplantation or as a destination therapy in those who do not qualify for transplantation. The short-term use of ventricular assist devices includes patients with refractory heart failure in the immediate postoperative setting. Historically, the operative mortality associated with postcardiotomy assist devices was very high. Newer machines utilize smaller cannulas and have smaller, more efficient pumps. The magnetically suspended centrifugal pumps are associated with minimal trauma to red blood cells or pump failures. The use of these devices is rapidly expanding, and early indications are improved mortality for patients experiencing postcardiotomy shock with recoverable myocardium. Ventricular assist devices are used for right, left, and biventricular support.

D. Postoperative Management

D.1. In the intensive care unit (ICU) 4 hours later, the patient became hypotensive with a low cardiac output. How could you distinguish between cardiac tamponade and pump failure? How would the TEE images differ?

The differentiation between cardiac tamponade and primary pump failure in the immediate postbypass-ICU setting can be difficult. Elevations in filling pressures, systemic hypotension, and low cardiac output are consistent with both diagnoses. The classic teaching of equalization of cardiac pressures seen in a "fluid" tamponade may not be present because areas of focal compression from clot can markedly reduce filling of only one chamber in the absence of an intact pericardium. Echocardiography can be beneficial in this setting by permitting visualization of chamber volume and function. The transesophageal approach has particular advantage over TTE in the postoperative setting in which the usual transthoracic window may be obscured by dressings and drainage tubing. Focal compression of the cardiac chambers from a clot or pericardial effusion can readily be distinguished from a volume-overloaded, failing heart with poor myocardial contractility. When the diagnosis is not clear, however, surgical re-exploration may be indicated. (See Chapter 11, Cardiac Tamponade.)

Price S, Prout J, Jaggar SI, et al. 'Tamponade' following cardiac surgery terminology and echocardiography may both mislead. *Eur J Cardio Surg*. 2004:1156:1160.

D.2. Would you extubate this patient early in the ICU? Why?

No. This patient has undergone a double valve replacement. In this more complex procedure, coagulopathy and postoperative bleeding, hypothermia from incomplete and nonuniform rewarming, and pulmonary hypertension are not uncommon occurrences in the immediate postoperative period. Sedation, paralysis, and mechanical ventilation can reduce the oxygen requirements during this early phase of recovery, minimize pulmonary hypertension secondary to hypercarbia, and permit reestablishment of core temperatures.

Cheng DCH. Pro: early extubation after cardiac surgery decreases intensive care unit stay and cost. *J Cardiothorac Vasc Anesth*. 1995;9:460–464.

Guenther CR. Con: early extubation after cardiac surgery decreases intensive care unit stay and cost. *J Cardiothorac Vasc Anesth*. 1995;9:465–467.

D.3. What are the advantages and disadvantages of early extubation?

The advantages of early extubation are both medical and financial. Early extubation can lessen the adverse sequelae from prolonged endotracheal intubation, including epithelial damage, decreased ciliary motility, and diminished mobilization of secretions. Positive pressure ventilation can have adverse effects on venous return. Nevertheless, the overwhelming drive toward early extubation is cost and patient comfort. Early extubation can decrease cost by decreasing ICU staff requirements, decreasing the cost of sedatives, lessening the duration of ICU stays, and improving operating room use by lessening cancellation of cases secondary to blocked ICU beds.

The potential advantages of early extubation, both financial and physiologic, must be weighed against the potential disadvantages of early extubation. The potential for respiratory compromise leading to hypoxemia, hypercarbia, ischemia, and the potential for infarction and neurologic injury is real. Any savings realized from early extubation can be rapidly lost by one adverse event. Success relies on careful integration of all players in the care of the patient undergoing cardiac surgery, from the management of intraoperative anesthetic techniques to the organization of the ICU and staff and the provision of postoperative analgesia. Equally important to the success of an early extubation program is appropriate patient selection.

E. Alternative Treatments

E.1. What are the percutaneous options for mitral valve repair?

In 1991, Otavio Alfieri described a surgical correction of mitral regurgitation using a technique of suturing the middle portions of the two mitral leaflets together. The resultant double orifice valve is an adequate solution for many mitral valve lesions. Based on this principle, a percutaneous treatment for mitral regurgitation has emerged.

E.2. How is percutaneous mitral valve repair performed?

The MitraClip is a small, polyester fabric-covered cobalt-chromium clip that is applied to the mitral leaflets, to mimic the surgical procedure described above. The device is delivered percutaneously via a femoral venous, transseptal approach. Although this device is still in trials, the initial results are favorable to reduce mitral regurgitation to less than 2+. General anesthesia is typically used.

Hussaini A, Kar S. Percutaneous mitral valve repair: potential in heart failure management. *Curr Heart Fail Rep*. 2010;7:22–26.

E.3. What are the percutaneous options for aortic valve repair and replacement?

Surgical valve replacement is the treatment of choice for severe aortic stenosis. For those patients at very high risk for surgery, alternative treatments may be preferable. Aortic balloon valvuloplasty has been a nonsurgical option since the 1980s. Although it is far less invasive than surgery, high complication rates and in-hospital mortality have reserved this treatment for a select population. In addition, high restenosis rates make this a short-lived solution. Percutaneous aortic valve replacement is emerging as another alternative to surgery in the high-risk population.

Billings FT, Kodali SK, Shanewise JS. Transcatheter aortic valve implantation: anesthetic considerations. *Anesth Analg*. 2009;108:1453–1462.

Hara H, Pedersen WR, Ladich E, et al. Percutaneous balloon aortic valvuloplasty revisited: time for a renaissance? *Circulation*. 2007;115:e34–e338.

E.4. How is percutaneous aortic valve replacement performed?

Currently, two devices are in human trials. The percutaneous devices are bioprosthetic valves mounted in self-expanding nitinol stents. The valves may be delivered by femoral artery retrograde or transapical antegrade approaches. After balloon valvuloplasty, the valve-stent is deployed. Rapid ventricular pacing is used to decrease cardiac translation and minimize ejection pressure during deployment. Transesophageal and fluoroscopic guidance are used. Complications of these procedures include iliac artery avulsion, aortic dissection, atherosclerotic embolic events, and renal injury secondary to radiocontrast exposure.

E.5. What anesthetic techniques and monitors are used?

General anesthesia is mostly used to allow for simultaneous TEE examination and in the case of thoracotomy for the transapical approach. Large-bore central venous access is necessary in the event of vascular injury or to administer vasoactive medications. Pulmonary artery catheters are frequently used in percutaneous atrial valve replacement procedures. Alternatively, local infiltration and intravenous sedation may be used for these procedures. In these cases, TTE examination is performed for evaluation at the conclusion of the procedure. Radial artery catheters are placed before induction for continuous monitoring and for arterial blood gases analysis.

Covello RD, Maj G, Landoni G, et al. Anesthetic management of percutaneous aortic valve implantation: focus on challenges encountered and proposed solutions. *J Cardiothorac Vasc Anesth*. 2009;23:280–285.

E.6. What is minimally invasive cardiac valve surgery?

The Society of Thoracic Surgeons database considers "any procedure not performed with a full sternotomy and cardiopulmonary bypass support" a minimally invasive procedure. The practical applications of "mini-valve surgery" include partial sternotomy, thoracotomy, and video-assisted and robot-assisted procedures. The downside to minimally invasive approaches include difficulty converting to a sternotomy in the case of cannula displacement or aortic dissection and complications of femoral artery cannulation (including arterial dissection, infection, and hematoma). The anesthetic management varies from standard sternotomy cases, including single-lung ventilation for thoracotomy approaches and transjugular coronary sinus catheters, to provide retrograde cardioplegia. Intraoperative TEE is especially critical in these cases to monitor for cardiac distention, removal of air, and cannula placement. There is clearly a significant learning curve to provide an equivalent surgical outcome with a "mini" versus traditional strategy. In successful procedures, patients enjoy improved cosmesis and decreased bleeding, wound infection, pain, and hospital length of stay. Unfortunately, in high-risk patients, the increased time of aortic cross-clamping and CPB may be deleterious. Also, complications are extremely morbid, including aortic dissection and death. Mini-valve surgery is limited to patients with an isolated valve disease.

CHAPTER 7

Pacemakers, Implantable Cardioverter-Defibrillators, and Cardiac Resynchronization Therapy Devices

Alan Cheng and Fun-Sun F. Yao

A 63-YEAR-OLD WOMAN

was scheduled for urgent open cholecystectomy. She underwent a dual-chamber permanent pacemaker (PPM) implantation 10 years ago for sick sinus syndrome and intermittent heart block. The pacemaker was upgraded to an implantable cardioverter-defibrillator (ICD) with cardiac resynchronization therapy (CRT) 9 months ago because of ischemic cardiomyopathy and worsening heart failure symptoms in the setting of a left bundle branch block. Her blood pressure was 110/68 mm Hg, and her heart rate was regular at 60 beats per minute. An electrocardiogram (ECG) obtained on admission demonstrated atrioventricular (AV) sequential pacing.

A. Medical Disease and Differential Diagnosis

1. What are the indications for PPMs?
2. What is sick sinus syndrome?
3. How would you diagnose first-, second-, and third-degree AV block, right bundle branch block (RBBB) with left anterior fascicular hemiblock, and left posterior fascicular hemiblock?
4. Is it necessary to insert a temporary pacemaker before general anesthesia for an asymptomatic patient with bifascicular or trifascicular block?
5. What are the three-letter and five-letter identification codes of the North American Society of Pacing and Electrophysiology (NASPE) and British Pacing and Electrophysiology Group (BPEG) generic (NBG) code for pacemaker classification?
6. How many modes of pacing are available in modern-day PPMs? How do they work? What is the difference between DDD pacing and DDI pacing?
7. The patient was mechanically hyperventilated during surgery and her pacemaker gradually increased her heart rate. What feature of the PPM is accounting for this?

8. What are the advantages and disadvantages of atrial pacing only? What are the disadvantages of ventricular pacing?
9. What are the indications for and complications associated with AV sequential PPMs?
10. How would you know if the patient's PPM was atrially, ventricularly, or atrioventricularly sequentially pacing?
11. What is the maximum amount of energy that a modern PPM can provide in terms of pulse amplitude and pulse width?
12. During a PPM implantation, what are the acceptable values for modern pacemaker leads in terms of pacing thresholds, amplitude of sensed intrinsic activity and impedance?
13. What is a biventricular PPM or CRT device? What are the indications for such a device?
14. What are the usual life spans of PPMs and ICDs?
15. What is an ICD? How does it work?
16. What are the indications for ICDs?
17. What is the NASPE and BPEG generic defibrillator (NBD) code?

B. Preoperative Evaluation and Preparation

1. How would you preoperatively evaluate the patient described earlier?
2. How do you determine whether the patient has a cardiac implantable electronic device (CIED) and define what type of CIED?
3. How do you determine whether the patient is dependent on the pacing function of the CIED?
4. How do you know if the implanted PPM or ICD is working?
5. What information would you like to obtain from interrogating this device?
6. How do you preoperatively prepare the patient for surgery and anesthesia?
7. Would you recommend reprogramming this device to asynchronously pace before surgery? What would you recommend regarding the ICD functions of the device?

C. Intraoperative Management

1. How would you monitor this patient?
2. What drugs and equipment would you like to have on hand in the operating room?
3. How would you set up the transcutaneous external pacer and defibrillator?
4. Had this patient's ICD been implanted the day before surgery, would you consider avoiding certain inhalational gases for anesthesia?
5. Electromagnetic interference (EMI) from electrocautery during the case results in significant noise on your cardiac monitor. You recall that EMI can also inhibit pacing function from the pacemaker. In this pacemaker-dependent patient, how can you determine whether inappropriate inhibition of the pacemaker is occurring?
6. What are the potential responses of pacemakers and ICDs to electrocautery?
7. How would you prevent the effects of EMI on the pacemaker or ICD from the electrocautery?
8. What are the effects of a magnet over pacemakers and ICDs?
9. In the middle of surgery, the patient developed ventricular tachycardia. What would you do?
10. What precautions should be taken when a patient with a CIED is undergoing extracorporeal shock wave lithotripsy (ESWL)?

11. Is electroconvulsive therapy (ECT) contraindicated in patients with pacemakers or ICDs?
12. Is magnetic resonance imaging (MRI) contraindicated in patients with a CIED?
13. What are the precautions during radiofrequency ablation for a patient with a CIED?

D. Postoperative Management

1. How would you monitor this patient in the postanesthesia care unit?
2. How would you confirm that the CIED is functioning properly after surgery?

A. Medical Disease and Differential Diagnosis

A.1. What are the indications for PPMs?

Artificial pacing is generally indicated for the treatment of symptomatic bradycardia of any origin. The two major indications for permanent pacing are failure of impulse formation and failure of cardiac conduction. Clinically, sick sinus syndrome and complete heart block are the most common indications for pacemakers. The following conditions are class I and IIA indications for a PPM:

- Sinus node dysfunction with documented symptomatic bradycardia, chronotropic incompetence, or symptomatic sinus bradycardia secondary to required drug therapy for medical conditions
- Sinus node dysfunction for heart rates less than 40 beats per minute when a clear association between symptoms consistent with bradycardia and the actual presence of bradycardia is absent
- Recurrent syncope caused by spontaneous carotid sinus hypersensitivity or greater than 3-second episode of ventricular asystole induced with carotid sinus pressure
- Third-degree or advanced second-degree AV block associated with bradycardia with symptoms or ventricular arrhythmias presumed secondary to AV block
- Asymptomatic third-degree or advanced second-degree AV block in patients with sinus rhythm and documented periods of asystole greater than 3 seconds, escape rate less than 40 beats per minute, or an escape rhythm that is below the AV node (as suggested by a wide QRS complex)
- Ventricular pauses of greater than 5 seconds in patients with atrial fibrillation with bradycardia
- Third-degree or advanced second-degree AV block resulting from catheter ablation or cardiac surgery
- First- or second-degree AV block associated with symptoms similar to those of pacemaker syndrome or hemodynamic compromise
- Chronic bifascicular block with advanced second-degree AV block or intermittent third-degree AV block
- Chronic bifascicular block with alternating left bundle branch block (LBBB) and RBBB conduction
- High-risk patients with congenital long QT syndrome or those with documented sustained pause-dependent ventricular tachycardia
- New York Heart Association class III or class IV heart failure symptoms despite optimal medical therapy in patients with dilated cardiomyopathy (ejection fraction less than 35%), QRS duration greater than 120 milliseconds and sinus rhythm (e.g., biventricular pacing)

A.2. What is sick sinus syndrome?

Sick sinus syndrome describes an array of clinical disorders resulting from irreversible sinus node dysfunction. This may be manifested by episodes of sinus arrest, sinus pause, or bradycardia secondary to inadequate sinus node automaticity. As a result, episodes of tachyarrhythmias from ectopic atrial foci can occur as well. Extended cardiac telemetry such as 24-hour Holter monitoring is helpful to make a diagnosis. When episodes of tachycardia and bradycardia coexist, it is often referred to as *tachy-brady* syndrome. This is one of the most common indications for pacemakers and is characterized by the following:

- Unexpected persistent severe sinus bradycardia
- Episodes of sinus arrest or exit block
- Paroxysmal or chronic atrial fibrillation or atrial flutter
- Alteration of paroxysms of rapid regular or irregular atrial tachyarrhythmias and periods of slow atrial and ventricular rates (tachy-brady syndrome)
- Slow return to sinus rhythm following cardioversion
- Lack of increase in sinus rate above 90 beats per minute following intravenous administration of 1.5 to 2 mg atropine

A.3. How would you diagnose first-, second-, and third-degree AV block, right bundle branch block (RBBB) with left anterior fascicular hemiblock, and left posterior fascicular hemiblock?

First-degree AV block is characterized by a PR interval of greater than 0.20 seconds during normal sinus rhythm (Fig. 7.1). Second-degree AV block is subdivided into two types. Mobitz type I, or Wenckebach block, is characterized by a progressively lengthening PR interval, which occurs until a P wave is not conducted down the AV node and a QRS complex is dropped. The site of block is typically in the AV node. Mobitz type II block is characterized by a loss of AV conduction with no progressive lengthening of the PR interval before the sudden dropping of one or more QRS complexes. The site of block is typically below the AV node and within the His-Purkinje system. Third-degree AV block, also called complete heart block, occurs when all electrical activity from the atrium fails to progress into the Purkinje system. The site of block can lie in either the AV node or the His-Purkinje system. The atrial and ventricular contractions have no relation with each other. As a result, the QRS complexes seen result from an ectopic focus either from the ventricular myocardium or in an area of

First-degree heart block. Sustained prolongation of the PR interval with no dropped QRS complexes.

Second-degree heart block, type I. Also referred to as Wenckebach block or Mobitz I, there is progressive prolongation of the PR interval before the dropped QRS complex. The PR interval of the first return QRS complex has normalized compared to the PR interval of the QRS complex of the last beat before dropping. This behavior suggests that the location of block occurs in the AV node.

Second-degree heart block, type II. Also referred to as Mobitz II, there is no progressive increase in the PR interval before the dropped QRS complex. This suggests that the location of the block occurs below the AV node. Note also the QRS morphology during conducted beats. The wide QRS complex suggests the presence of infranodal disease, which is often seen in the presence of Mobitz II heart block.

Third-degree heart block. The P waves mark through with no communication with the ventricular beats.

Figure 7.1 Atrioventricular heart block.

the AV node/His-Purkinje system below the site of block. Therefore, the QRS complex may appear wide or narrow, respectively, and typically occur with a rate of 40 to 60 beats per minute.

RBBB with left anterior hemiblock is present when the ECG shows an RBBB with a left axis deviation (usually greater than −60 degrees) in the absence of an inferior myocardial infarction. Complete RBBB with right axis deviation (greater than

90 degrees) is indicative of RBBB and left posterior hemiblock in the absence of a lateral myocardial infarction or evidence of right-sided heart failure.

Libby P, Bonow RO, Mann DL, et al., eds. *Braunwald's Heart Disease: A Textbook of Cardiovascular Medicine*. 8th ed. Philadelphia: Saunders; 2008:167–172, 913–921.

A.4. Is it necessary to insert a temporary pacemaker before general anesthesia for an asymptomatic patient with bifascicular or trifascicular block?

The risk for progression to complete heart block in asymptomatic patients with bifascicular block is low. Further, no clinical characteristics have been identified that accurately predict the risk of development of complete heart block. Therefore, routine pacemaker (PPM) implantation in patients with asymptomatic bifascicular block is not recommended. Observations made in the perioperative period have suggested that development of complete heart block during general anesthesia is also rare; therefore, it is generally not recommended that patients undergo temporary pacemaker insertion before general anesthesia. However, it is advisable to have an external pacemaker available in the operating room. Trifascicular heart block describes patients with a bifascicular block and prolongation of the PR interval. This term is somewhat of a misnomer because, in truth, if all three fascicles (i.e., right bundle, left anterior bundle, left posterior bundle) were blocked, the patient would be in complete heart block. Although it is generally agreed that individuals with trifascicular block have a higher risk for sudden death, there is no single clinical variable that predicts a higher risk for complete heart block during surgery. Small case series have shown that the development of intraoperative complete heart block in asymptomatic patients with trifascicular block is uncommon. Therefore, routine temporary pacemaker insertion before general anesthesia in these patients is not recommended.

A.5. What are the three-letter and five-letter identification codes of the North American Society of Pacing and Electrophysiology (NASPE) and British Pacing and Electrophysiology Group (BPEG) generic (NBG) code for pacemaker classification?

Given the complexity of current pacemaker systems, the Intersociety Commission for Heart Disease Resources established a classification code in the 1970s that is now widely accepted. The original nomenclature involved a three-letter identification code, as shown in the first three columns of Table 7.1. In 1980, this code was extended to five letters; the last two letters can be deleted when not applicable. In 1987, this five-letter coding system become known as the NBG pacemaker code after being adopted by both the NASPE (now known as the *Heart Rhythm Society*) and BPEG. The first letter describes the chamber(s) that the pacemaker can pace, the second letter describes the chamber(s) that it senses, and the third letter describes the response

Table 7.1 NASPE/BPEG Generic (NBG) Pacemaker Identification Code[a]

LETTER I CHAMBER(S) PACED	LETTER II CHAMBER(S) SENSED	LETTER III MODE OF RESPONSE	LETTER IV PROGRAMMABILITY RATE MODULATION	LETTER V ANTITACHYARRHYTHMIA FUNCTION(S)
O = None	O = None	O = None	O = None	O = None
A = Atrium	A = Atrium	T = Triggered	P = Single programmable	P = Pacing
V = Ventricle	V = Ventricle	I = Inhibited	M = Multiprogrammable	S = Shock
D = Dual (A + V)	D = Dual (A + V)	D = Dual (T + I)	C = Communicating	D = Dual (P + S)
			R = Rate modulation	

[a]Although the pacemaker identification coding involved the use of five letters, few modern pacemakers have antitachyarrhythmia functions. Therefore, most pacemakers are currently described by the first four letters of the coding system.
BPEG, British Pacing and Electrophysiology Group; NASPE, North American Society of Pacing and Electrophysiology; NBG, NASPE and BPEG Generic.

of the pacemaker to sensed intrinsic activity. The last two letters describe additional features such as rate responsiveness that are commonly omitted when not used. For example, a VVI pacing mode paces in the ventricle, can sense intrinsic activity in the ventricle, and inhibits pacing when it senses intrinsic activity. A VOO pacing mode paces in the ventricle but does not sense intrinsic activity; nor does it inhibit pacing—it simply paces regardless of the heart's electrical activity.

Libby P, Bonow RO, Mann DL, et al., eds. *Braunwald's Heart Disease: A Textbook of Cardiovascular Medicine*. 8th ed. Philadelphia: Saunders; 2008:831–832.

Practice advisory for the perioperative management of patients with cardiac implantable electronic devices: pacemakers and implantable cardioverter-defibrillators. An updated report by the American Society of Anesthesiologists Task Force on Perioperative Management of Patients with Cardiac Implantable Electronic Devices. *Anesthesiology*. 2011;114:247–261.

A.6. How many modes of pacing are available in modern PPMs? How do they work? What is the difference between DDD pacing and DDI pacing?

Modern pacemakers are programmable into one of three modes of pacing: asynchronous pacing, single-chamber demand pacing, and dual-chamber AV sequential demand pacing. Asynchronous or fixed-rate (e.g., AOO, VOO, DOO [see section A.5 for details]) modes pace at a programmable preset rate that is independent of the inherent heart rate. They can be atrial, ventricular, or dual chamber. Competition and rarely induction of ventricular arrhythmias are the potential complications when pacing occurs in the presence of intrinsic myocardial electrical activity. Ventricular tachyarrhythmias can theoretically occur because the pacing spike can potentially be delivered during the vulnerable period of ventricular repolarization, resulting in an R on T phenomenon, but this is extremely rare.

Single-chamber demand pacing (e.g., AAI, VVI) paces at a preset rate only when the spontaneous heart rate drops below the programmed preset rate. For example, if this patient's device was programmed to VVI 70, the device would pace in the ventricle only when the native ventricular rate fell below 70 beats per minute. Once the native ventricular rate resumed above 70 beats per minute, the device would sense this activity and inhibit further pacing. Single-chamber demand pacing in the atrium functions in a similar way but is rarely used alone in the United States.

Dual-chamber AV sequential pacing requires two pacemaker leads, one in the right atrium and one in the right ventricle. The atrium is stimulated to contract first; then, after an adjustable PR interval (also referred to as the AV interval), the ventricle is stimulated to contract if no intrinsic ventricular activity is sensed by the ventricular pacing lead. For example, if this patient's device was programmed to DDD 70 with an AV interval of 200 milliseconds, the device would begin pacing the atrium first if the intrinsic sinus rate fell below 70 beats per minute. After the atrium has been paced, the device will wait for 200 milliseconds to sense intrinsic ventricular activity. If it does not see intrinsic activity within 200 milliseconds, it will then pace in the ventricle as well. DDD pacemakers can also pace in the ventricle in response to intrinsic atrial activity. For example, if the intrinsic atrial rate was 80 beats per minute, the device would inhibit pacing in the atrium because the base rate was set to 70 beats per minute. But because it is a dual-chamber device programmed to inhibit and trigger pacing in both chambers (i.e., the third "D" in the coding sequence), it will wait 200 milliseconds from the time of the intrinsic atrial activity and watch for intrinsic ventricular activity as well. If it sees intrinsic ventricular activity (i.e., the atrial signal conducted down the AV node and to the ventricle), it will inhibit ventricular pacing. If it does not see intrinsic ventricular activity occurring within 200 milliseconds from the intrinsic atrial activity, the pacemaker will then "trigger" the ventricular pacing lead to pace the ventricle. Dual-chamber pacemakers programmed to DDI differ slightly from devices programmed to DDD. In many ways, DDI programming is analogous to having a pacemaker with both AAI and VVI programming mode occurring simultaneously. AV sequential pacing occurs only when atrial pacing is present. This is in contrast to DDD pacing in which AV sequential pacing is preserved regardless of whether atrial pacing or atrial sensing is occurring. Similar to DDD programming, if the sinus rate fell below 70 beats per minute (as in this example), the atrial pacing lead would pace the atrium. After a 200-millisecond interval, if intrinsic ventricular activity was seen by the ventricular lead, then the ventricular lead would be inhibited from pacing the ventricle. If ventricular activity was not seen after 200 milliseconds, the ventricular lead would pace the ventricle. In contrast to DDD programming, if the sinus rate was above the preset rate and no atrial pacing was occurring, ventricular pacing would not be "triggered" after 200 milliseconds by these atrial sensed events and only occur if the *ventricular* rate fell below the preset rate of 70.

Libby P, Bonow RO, Mann DL, et al., eds. *Braunwald's Heart Disease: A Textbook of Cardiovascular Medicine*. 8th ed. Philadelphia: Saunders; 2008:837–840.

A.7. The patient was mechanically hyperventilated during surgery and her pacemaker gradually increased her heart rate. What feature of the PPM is accounting for this?

All modern pacemakers have the ability to adjust the pacing rate according to the patient's level of activity in an effort to obtain a more physiologic response to exercise. This is known as *rate-response* (adaptive) pacing and is denoted by an "R" in the fourth position of the NBG coding schema. Various activity-detecting systems have been developed to create a reliable rate-responsive pacemaker. They included muscle movement, respiratory rate, minute ventilation, central venous temperature, QT interval, myocardial contractility (dp/dt), oxygen saturation and pH in mixed venous blood, and ventricular depolarization gradient. Currently, PPMs used in the United States rely on sensors of motion or changes in minute ventilation. Because of the latter phenomenon, patients undergoing general anesthesia who are subjected to mechanical hyperventilation (e.g., neurosurgery) can experience an increase in the rate of pacing. Although it is generally not required to disable rate-responsive features before surgery, pacemaker-induced changes in heart rate resulting from intraoperative hyperventilation or significant motion may sometimes be mistaken for inadequate anesthesia. Hence, it is important that the anesthesia team be aware of the programmed settings

of the pacemaker. If reprogramming the device to disable rate-responsive features is not readily available, a magnet may be placed over the pacemaker site to temporarily convert it to asynchronous pacing. Although the response to a magnet may be programmed off in some pacemakers, all properly functioning pacemakers within the United States have magnet-responsive features activated as a default.

Ellenbogen KA, Kay GN, Lau CP, et al., eds. *Clinical Cardiac Pacing, Defibrillation and Resynchronization Therapy*. 3rd ed. Philadelphia: Elsevier; 2007:201–233.

A.8. What are the advantages and disadvantages of atrial pacing only? What are the disadvantages of ventricular pacing?

Atrial pacing only increases cardiac output by 26% over the cardiac output of ventricular pacing only because atrial contraction contributes to approximately 15% to 25% of the diastolic filling of the ventricle. It has been shown that coronary blood flow increases and coronary resistance decreases during atrial pacing only. Atrial pacing has also been shown to reduce the incidence of atrial fibrillation. Atrial pacing only is seldomly used in the United States and often is implanted with the addition of a ventricular pacing lead in the event of AV block.

Ventricular pacing, occurring individually or sequentially with atrial pacing, has been shown to result in dyssynchronous left ventricular electrical activation and mechanical contraction. Under normal circumstances, electrical activation along the His-Purkinje system results in a near simultaneous activation of the entire left ventricle. This allows for efficient contraction and is said to be synchronous. When ventricular pacing is introduced, this results in activation of the right ventricle first, followed by passive activation of the left ventricular free wall. This form of contraction is said to be dyssynchronous and has been shown to potentially worsen congestive heart failure and left ventricular ejection fraction. Prior studies have shown that individuals at greatest risk for developing reductions in ejection fraction from right ventricular pacing are those who exhibit ventricular pacing greater than 40% of the time. Further, individuals at greatest risk for worsening congestive heart failure are those who not only have a pacing greater than 40% of the time, but also have an ejection fraction less than 40% at the time of pacemaker implantation.

A.9. What are the indications for and complications associated with AV sequential PPMs?

When ventricular pacing alone cannot maintain adequate cardiac output and atrial pacing alone is not justified, as in complete AV block, AV sequential pacing is indicated. Because of the success of transvenous leads, bioengineering advances such as thinner polyurethane insulation and improved device programmability, the indications for dual-chamber pacing, have broadened. It can be used for sick sinus syndrome and all degrees of heart block. PPMs programmed to DDD pacing are the ultimate form of physiologic pacing. Programmable features include the mode of pacing, the AV delay, the maximum atrial rate that the ventricle will follow (atrial tracking), and the minimum atrial rate for sensing at which atrial pacing commences. The major advantage of such pacing

is the ability to significantly increase the cardiac output under extreme stress and a reduced incidence of atrial fibrillation development. Historically, the major disadvantage of DDD pacing has been the possibility of pacemaker-mediated tachycardia. More recently, another disadvantage recognized has been the development of ventricular dyssynchrony (see section A.8) as a result of ventricular pacing. Long-term follow-up of patients with dual-chamber pacemakers demonstrated reductions in left ventricular ejection fractions when compared to atrial pacing alone, especially in the setting of preexisting left ventricular dysfunction.

A.10. How would you know if the patient's PPM was atrially, ventricularly, or atrioventricularly sequentially pacing?

In atrial pacing, an electrical spike often appears before the P wave and the QRS complex is usually normal, provided there is normal intrinsic AV conduction. One may need to adjust the monitor so that pacing spikes are accentuated and can readily be seen. In ventricular pacing, the electrical spike is followed immediately by a widened left bundle branch block–like QRS complex. In AV sequential pacing, there are two spikes, one before the P wave and another preceding the QRS complex.

Libby P, Bonow RO, Mann DL, et al., eds. *Braunwald's Heart Disease: A Textbook of Cardiovascular Medicine*. 8th ed. Philadelphia: Saunders; 2008:837–846.

A.11. What is the maximum amount of energy that a modern PPM can provide in terms of pulse amplitude and pulse width?

In order to successfully pace the heart, the PPM must provide enough energy to allow for cardiac depolarization. Energy is a direct function of the amount of voltage produced (pulse amplitude) and the duration of time the voltage is delivered (pulse width). Although small variations exist among all modern PPMs, the maximum pulse amplitude or output of stimulation usually is 7.5 volts (V). The maximum pulse width or the duration of stimulation is usually 1.5 msec.

Libby P, Bonow RO, Mann DL, et al., eds. *Braunwald's Heart Disease: A Textbook of Cardiovascular Medicine*. 8th ed. Philadelphia: Saunders; 2008:841–842.

A.12. During a new PPM implantation, what are the acceptable values for modern pacemaker leads in terms of pacing thresholds, amplitude of sensed intrinsic activity and impedance?

Because current PPMs have a maximal pacing output of 7.5 V at 1.5 msec, the pacing threshold cannot exceed the previously mentioned values. In fact, fluctuations in the pacing threshold can occur during the first few weeks after a pacing lead has

been implanted. There is an initial sharp rise in the pacing threshold during the first 2 weeks because of tissue reaction around the tip of the electrode despite the presence of steroid embedded at the tip. The threshold then returns to levels similar to what were seen at the time of implant. As a result, all device manufacturers recommend that the pacing output be at least two times the voltage of the threshold value or three times the pulse width of the threshold value. In the chronic state, pacing thresholds remain essentially at the same level in 80% of patients. For the ventricular lead, the intrinsic R waves should be at least 5 to 6 mV in amplitude. For the atrial lead, the intrinsic P waves should be at least 1mV in amplitude. Impedances for atrial or ventricular leads should be between 250 and 1300 ohms, depending on the type of lead implanted. Acceptable threshold values for the atrial or ventricular lead are typically those below 2V at 0.4msec.

A.13. What is a biventricular PPM or CRT device? What are the indications for such a device?

It has long been recognized that individuals with interventricular conduction abnormalities have a predilection toward impaired left ventricular systolic function. In fact, one of the more common interventricular conduction delays seen in patients with congestive heart failure is left bundle branch block (LBBB). On a mechanistic level, individuals with LBBB demonstrate ventricular dyssynchrony, a phenomenon whereby the left ventricle contracts in a stepwise process. Unlike normal individuals where the left ventricular septum and the left ventricular lateral free wall contract nearly simultaneously, patients with LBBB have a delay in the activation of the left lateral free wall. As a result, there is marked impairment in left ventricular systolic function and increased myocardial work and oxygen consumption. One approach to correct this dyssynchrony is to "resynchronize" the heart through the use of a biventricular pacemaker/ICD. These devices are capable of pacing both the left ventricular septum (through a pacemaker lead in the right ventricle) and the left ventricular lateral free wall simultaneously (through a pacemaker lead in the coronary sinus), thereby allowing for activation of the entire left ventricle at the same time. Candidates for implantation of a biventricular device include individuals with severe cardiomyopathy (ejection fraction 35% or less), wide QRS complex greater than 120 milliseconds with moderate to severe heart failure symptoms despite optimal medical therapy.

Jarcho JA. Biventricular pacing. *N Engl J Med.* 2006;355:288–294.

A.14. What are the usual life spans of PPMs and ICDs?

Lithium-powered pacemakers can last 5 to 10 years for dual-chamber pacing and 7 to 12 years for single-chamber pacing. The silver-vanadium oxide batteries used in ICDs typically last for 5 to 8 years.

Atlee JL, Bernstein AD. Cardiac rhythm management devices (part I). *Anesthesiology.* 2001;95:1265–1280.

Ellenbogen KA, Kay GN, Lau CP, et al., eds. *Clinical Cardiac Pacing, Defibrillation and Resynchronization Therapy*. 3rd ed. Philadelphia: Elsevier; 2007:235–259.

A.15. What is an ICD? How does it work?

An ICD system consists of a pulse generator and leads for tachyarrhythmia detection and therapy. ICDs provide antitachycardia and antibradycardia pacing; synchronized (cardioversion) or nonsynchronized (defibrillation) shocks; telemetry;

and diagnostics including stored event electrograms and history logs. Essentially, the pulse generator is a self-powered computer within a hermetically sealed titanium casing (can). A battery with high power density is used to power the pulse generator, circuitry, and aluminum electrolytic storage capacitors. Most ICD designs use two capacitors in series to achieve a maximum voltage for defibrillation. A major challenge in ICD design is the large range of voltages that must be controlled in a very small package. Modern devices can charge up to 41 joules of energy.

Modern ICDs use transvenous lead systems for sensing, pacing, and shocks. Epicardial leads are still used in infants and small children. Ventricular demand pacing for bradycardia is a standard feature of all ICDs. Modern day ICDs have all the capabilities of modern day pacemakers, including rate-adaptive pacing and automatic mode switching. The response of ICDs to magnets differs from that of a pacemaker (see section C.8).

Current ICDs have many programmable features, but essentially they measure each cardiac R-R interval and categorize the rate as normal, too fast (short R-R interval), or too slow. When the device detects a sufficient number of short R-R intervals within a period of time (all programmable), it will declare a tachycardia episode. The internal computer will decide between antitachycardia pacing (less energy use, better tolerated by patient) and shock based on its programmed algorithm. If shock is chosen, an internal capacitor is charged that takes approximately 5 to 13 seconds depending on the amount of energy to be delivered and age of the device. Most devices are programmed to reconfirm ventricular tachycardia or ventricular fibrillation after charging to prevent inappropriate shock therapy. Typically, ICDs deliver no more than six shocks per episode. Once therapy is delivered, the ICD will redetect to determine whether or not the therapy successfully terminated the arrhythmia. A tachycardia episode is considered terminated when sinus rhythm has been restored for a certain period (varies by manufacturer).

Atlee JL, Bernstein AD. Cardiac rhythm management devices (part I). *Anesthesiology*. 2001;95:1265–1280.

Libby P, Bonow RO, Mann DL, et al., eds. *Braunwald's Heart Disease: A Textbook of Cardiovascular Medicine*. 8th ed. Philadelphia: Saunders; 2008:847–852.

A.16. What are the indications for ICDs?

Initially, ICDs were indicated for hemodynamically significant ventricular tachycardia or ventricular fibrillation. Newer indications include the following and continue to evolve:

- Survivors of cardiac arrest because of ventricular tachycardia/ventricular fibrillation not resulting from a transient or reversible cause
- Spontaneous or induced at electrophysiology study sustained ventricular tachycardia in the presence of structural heart disease
- Syncope of undetermined origin with clinically relevant, hemodynamically significant sustained ventricular tachycardia or ventricular fibrillation-induced at electrophysiology study
- Ischemic cardiomyopathy (ejection fraction ≤30%) without a recent myocardial infarction (within the last 40 days) or revascularization in the past 3 months
- Ischemic or nonischemic dilated cardiomyopathy (ejection fraction ≤35%) with NYHA class II or III heart failure symptoms
- Brugada syndrome—RBBB and ST segment elevation leads V_1 to V_3
- Arrhythmogenic right ventricular dysplasia
- Long and short QT syndromes
- Hypertrophic obstructive cardiomyopathy

A.17. What is the NASPE and BPEG generic defibrillator (NBD) code?

Like pacemakers, ICDs have a generic code to indicate lead placement and function. The NBD code is shown in Table 7.2. The most robust form of identification, referred to as the "label form," replaces the fourth letter of the NBD with the appropriate generic pacemaker code.

Practice advisory for the perioperative management of patients with cardiac implantable electronic devices: pacemakers and implantable cardioverter-defibrillators: an updated report by the American Society of Anesthesiologists Task Force on Perioperative Management of Patients with Cardiac Implantable Electronic Devices. *Anesthesiology.* 2011;114:247–261.

B. Preoperative Evaluation and Preparation

B.1. How would you preoperatively evaluate the patient described earlier?

Preoperative evaluation should include the routine systemic workup, paying particular attention to cardiovascular disorders. The comprehensive evaluation includes complete blood count, urinalysis, coagulation screening with prothrombin time and partial thromboplastin time, serum electrolytes, blood urea nitrogen, blood sugar, chest radiograph, and ECG. Special attention should be paid to the history, symptoms, and signs of myocardial infarction, congestive heart failure, and arrhythmia. Serum electrolytes, especially potassium level, must be in the normal range. For the patient with a CIED, recent guidelines have recommended that all CIEDs be properly interrogated within 3 to 6 months before surgery. This evaluation should include the following:

- Establish whether a patient has a CIED
- Define the type of CIED
- Determine dependency on pacing function of the CIED
- Determine CIED function and programming details

- Determine magnet behavior and whether CIED requires reprogramming on the day of surgery to avoid inappropriate device behavior from EMI.

Practice advisory for the perioperative management of patients with cardiac implantable electronic devices: pacemakers and implantable cardioverter-defibrillators: an updated report by the American Society of Anesthesiologists task force on perioperative management of patients with cardiac implantable electronic devices. *Anesthesiology*. 2011;114:247–261.

The Heart Rhythm Society Expert Consensus Statement on the perioperative management of patients with implantable defibrillators, pacemakers and arrhythmia monitors: Facilities and patient management. Crossley GH, Poole JE, Rozner MA, et al. Heart Rhythm 2011; in press.

B.2. How do you determine whether the patient has a cardiac implantable electronic device (CIED) and define what type of CIED?

Determining whether a patient has a CIED should be based on (1) a focused history including but not limited to the patient interview, medical records review, review of available chest radiograph, ECG, or any available monitor or rhythm strip information, and (2) a focused physical examination (e.g., checking for scars, palpating for device).

Defining the type of device is accomplished by (1) obtaining the manufacturer's identification card from the patient or other source, (2) ordering chest radiography studies if no other data are available, or (3) referring to supplemental resources (e.g., manufacturers' databases, pacemaker clinic records, consultation with a cardiologist).

Practice advisory for the perioperative management of patients with cardiac implantable electronic devices: pacemakers and implantable cardioverter-defibrillators: an updated report by the American Society of Anesthesiologists task force on perioperative management of patients with cardiac implantable electronic devices. *Anesthesiology*. 2011;114:247–261.

B.3. How do you determine whether the patient is dependent on pacing function of the CIED?

CIED dependency for pacemaking function may be determined by one or more of the following: (1) a verbal history or an indication in the medical record that the patient has experienced a bradyarrhythmia that has caused syncope or other symptoms requiring CIED implantation, (2) a history of successful AV nodal ablation that resulted in CIED placement, or (3) a CIED evaluation that shows clinically evidenced hemodynamic compromise when the pacemaking function of the CIED is temporarily programmed to VVI pacing mode at the lowest programmable rate.

Practice advisory for the perioperative management of patients with cardiac implantable electronic devices: pacemakers and implantable cardioverter-defibrillators: an update report by the American Society of Anesthesiologists task force on perioperative management of patients with cardiac implantable electronic devices. *Anesthesiology*. 2011;114:247–261.

B.4. How do you know if the implanted PPM or ICD is working?

The CIED function is ideally assessed by interrogating the device. If interrogating the device is not an option, one can slow the intrinsic heart rate to a rate below that

of the pacemaker by carotid massage or the Valsalva maneuver. Carotid massage to slow the heart rate should be used cautiously because it could result in an arteriosclerotic plaque embolizing to the cerebral circulation. If the rate does not slow down enough for the pacemaker to take over the ventricle, the device can be tested by placing a magnet over it that will temporarily program it to a fixed-rate pacing mode. In this mode, pacing spikes march through the rhythm strip with no regard for the intrinsic electrical activity of the heart. The rate at which the pacemaker will pace in the presence of a magnet varies among device manufacturers and is dependent on the battery life. Once the magnet is removed, the device returns to its normal programming.

Practice advisory for the perioperative management of patients with cardiac implantable electronic devices: pacemakers and implantable cardioverter-defibrillators: an updated report by the American Society of Anesthesiologists task force on perioperative management of patients with cardiac implantable electronic devices. *Anesthesiology*. 2011;114:247–261.

B.5. What information would you like to obtain from interrogating this device?

Device interrogations provide information on the status and current programmed settings of a PPM or ICD. The important primary information for anesthesiologists include (1) battery life, (2) programmed pacing mode such as VVIR, DDDR, (3) pacemaker dependency, (4) intrinsic rhythm, (5) behavior to a magnet, (6) prior recorded arrhythmic events, and (7) pacemaker lead parameters (including pacing threshold, ability to sense intrinsic activity, and lead impedance).

Practice advisory for the perioperative management of patients with cardiac implantable electronic devices: pacemakers and implantable cardioverter-defibrillators: an updated report by the American Society of Anesthesiologists task force on perioperative management of patients with cardiac implantable electronic devices. *Anesthesiology*. 2011;114:247–261.

B.6. How do you preoperatively prepare the patient for surgery and anesthesia?

Preparation for patient safety and proper maintenance of the device during a procedure includes the following:

- Determining whether EMI is likely to occur during the planned procedure, as well as the location of the EMI
- Properly positioning the electrocautery grounding pad so the path of conduction across the device is minimized to the fullest extent
- Determining whether reprogramming the CIED pacemaking function to an asynchronous pacing mode or disabling any special algorithms, including rate-adaptive functions, is needed
- Suspending antitachyarrhythmia functions if present
- Advising the surgeon performing the procedure to minimize prolonged bursts or monopolar cautery or use other less interfering sources of energy including bipolar electrocautery or ultrasonic (harmonic) scalpel
- Ensuring the availability of temporary pacing and defibrillation equipment
- Evaluating the possible effects of anesthetic techniques and of the procedure on CIED function and patient–CIED interactions.

Practice advisory for the perioperative management of patients with cardiac implantable electronic devices: pacemakers and implantable cardioverter-defibrillators: an updated report by the American Society of Anesthesiologists task force on perioperative management of patients with cardiac implantable electronic devices. *Anesthesiology*. 2011;114:247–261.

B.7. Would you recommend reprogramming this device to asynchronously pace before surgery? What would you recommend regarding the ICD functions of the device?

Given the number of patients with CIEDs, recommending that all patients undergo reprogramming immediately before surgery is untenable and would significantly compromise perisurgical throughput. Moreover, reports have described individuals with ICDs or PPMs who later expired because the device was not reactivated before discharge after surgery. These issues raise the need for proper triaging of patients who truly need their devices reprogrammed before surgery. The patient in this example has a CRT-implantable cardioverter defibrillator because of sick sinus syndrome, intermittent heart block, and ventricular tachycardia. It is likely that the patient is functionally dependent on the CIED. Furthermore, the location of the EMI delivered in this case is close to the device system and therefore would likely result in inappropriate inhibition of pacing or sensing of EMI that the device would inappropriately mark as ventricular fibrillation. Given functional dependency on the device and the location of the EMI delivered, reprogramming the device would be recommended to deactivate the ICD and pace asynchronously before surgery for the following reasons:

- Electrocautery during surgery may inhibit pacing function.
- A magnet cannot convert the pacemaker in an ICD system to asynchronous mode pacing. A magnet placed over an ICD only disables tachycardia detection and therapy of the ICD. This is true of all devices used in the United States. One notable exception are ICDs manufactured by ELA Medical (Cedex, France), which, in the presence of a magnet, will not only disable tachycardia detection therapy but also convert pacing to a fixed rate at 96 beats per minute.

Practice advisory for the perioperative management of patients with cardiac implantable electronic devices: pacemakers and implantable cardioverter-defibrillators: an updated report by the American Society of Anesthesiologists task force on perioperative management of patients with cardiac implantable electronic devices. *Anesthesiology*. 2011;114:247–261.

C. Intraoperative Management

C.1. How would you monitor this patient?

Intraoperative monitoring should include both continuous ECG and continuous peripheral pulse monitoring. Peripheral pulse can be monitored by palpation of the pulse, auscultation of heart sounds, pulse plethysmography or oximetry, a tracing of arterial wave form, or ultrasound peripheral pulse monitoring.

Arterial line and central venous pressure or pulmonary artery pressure monitoring may be used only if the patient has poor ventricular function. The artifact filter on the ECG monitor should be disabled to detect the pacing spikes. The ECG monitor should be set in diagnostic mode instead of monitoring mode.

Practice advisory for the perioperative management of patients with cardiac implantable electronic devices: pacemakers and implantable cardioverter-defibrillators: an updated report by the American Society of Anesthesiologists task force on perioperative management of patients with cardiac implantable electronic devices. *Anesthesiology*. 2011;114:247–261.

The Heart Rhythm Society Expert Consensus Statement on the perioperative management of patients with implantable defibrillators, pacemakers and arrhythmia monitors: Facilities and patient management. Crossley GH, Poole JE, Rozner MA, et al. Heart Rhythm 2011; in press.

C.2. What drugs and equipment would you like to have on hand in the operating room?

A complete array of drugs and equipment must be immediately available for cardiopulmonary resuscitation. The minimal requirements include ECG monitor, a transcutaneous external pacing and direct current (DC) defibrillator, and the usual drugs for resuscitation.

Atlee JL, Bernstein AD. Cardiac rhythm management devices (part I). *Anesthesiology*. 2001;95:1265–1280.

Ellenbogen KA, Kay GN, Lau CP, et al., eds. *Clinical Cardiac Pacing, Defibrillation and Resynchronization Therapy*. 3rd ed. Philadelphia: Elsevier; 2007:561–651.

C.3. How would you set up the transcutaneous external pacer and defibrillator?

We prefer applying defibrillating electrodes such as Zoll® Pads to paddles because the electrodes can be placed before surgery at the desirable positions and connected to a defibrillator/pacemaker for pacing and defibrillation. The electrodes should be placed as far (more than 6 in. or 15 cm) from a CIED as possible. The three recommended electrode placements are as follows:

- *Anteroposterior placement*. The right arm (RA) electrode placed under the left scapula and the left leg (LL) electrode at apex of the heart (as shown in Fig. 7.2).
- *Apex-anterior placement*. The RA electrode placed under the right clavicle and the LL electrode at the apex of the heart (Fig. 7.3A).
- *Apex-posterior placement*. The RA electrode placed over the right scapula and the LL electrode at the apex of the heart (Fig. 7.3B).

It is important to remember that the presence of a CIED should not deter standard resuscitation efforts.

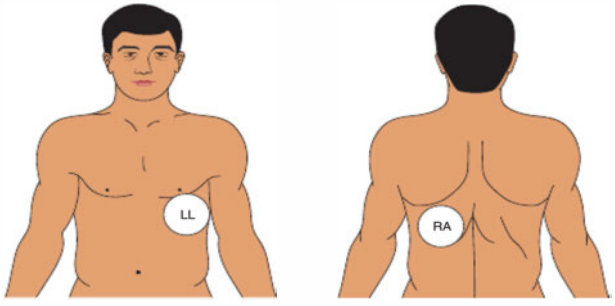

Figure 7.2 Anterior–posterior placement of defibrillating electrodes. The right arm (RA) electrode is placed under the left scapula, and the left leg (LL) electrode is placed at the apex of the heart.

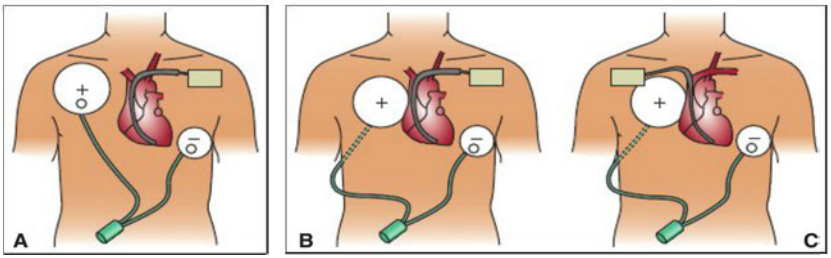

Figure 7.3 Placement of defibrillating electrodes. **A.** Apex–anterior placement with both pads placed anteriorly. **B** and **C.** Apex–posterior placement shown with the device in the left prepectoral region **(B)** and the right pectoral region **(C)**. (Adapted from Ellenbogen KA, Kay GN, Wilkoff BL, eds. *Clinical Cardiac Pacing and Defibrillation*. 2nd ed. Philadelphia: Saunders; 2000:944.)

Stone KR, McPherson CA. Assessment and management of patients with pacemakers and implantable cardioverter defibrillator. *Crit Care Med*. 2004;32(suppl):S155–S165.

C.4. Had this patient's ICD been implanted the day before surgery, would you consider avoiding certain inhalational gases for anesthesia?

It has been reported that nitrous oxide could cause pacemaker malfunction by increasing gas in the prepectoral pacemaker pocket. Despite air evacuation with antibiotic solution before closure of the prepectoral pocket, a small amount of air remains entrapped in the pocket. In general, this small amount of air should have no clinical significance. Nitrous oxide is 35 times more soluble in blood than nitrogen. When nitrous oxide is used for anesthesia, the amount of nitrous oxide diffused from blood to the air pocket is much more than the amount of nitrogen diffused from the air pocket to blood. Therefore, this causes an expansion of the gas in the pocket that leads to loss of anodal contact and pacing system malfunction. It is advisable not to use nitrous oxide in a patient with a newly implanted pacemaker.

Lamas GA, Rebecca GS, Braunwald NS, et al. Pacemaker malfunction after nitrous oxide anesthesia. *Am J Cardiol*. 1985;56:995.

C.5. Electromagnetic interference (EMI) from electrocautery results in significant noise on your cardiac monitor. You recall that EMI also can inhibit pacing function from the PPM. In this pacemaker-dependent patient, how can you determine whether inappropriate inhibition of the PPM is occurring?

During electrocautery, the ECG is frequently useless because of interference. The best monitor available to determine if inhibition is taking place is a hand on the pulse. The precordial or esophageal stethoscope, pulse oximeter, or blood pressure is also acceptable.

Practice advisory for the perioperative management of patients with cardiac implantable electronic devices: pacemakers and implantable cardioverter-defibrillators: an updated report by the American Society of Anesthesiologists task force on perioperative management of patients with cardiac implantable electronic devices. *Anesthesiology*. 2011;114:247–261.

C.6. What are the potential responses of pacemakers and ICDs to electrocautery?

The responses of pacemakers to electrocautery or other EMI include the following:

- Inhibition of pacing
- Asynchronous pacing
- Reset to backup mode
- Myocardial burns, rare
- Ventricular fibrillation, rare

The responses of ICDs include the following:

- Inhibition of pacing
- Asynchronous pacing
- Inappropriate tachy therapy
- Inhibition of tachy therapy

Salukhe TV, Dob D. Pacemakers and defibrillators: anesthetic implications. *Br J Anesth.* 2004;93:95–104.

Stone KR, McPherson CA. Assessment and management of patients with pacemakers and implantable cardioverter defibrillator. *Crit Care Med.* 2004;32(suppl):S155–S165.

C.7. How would you prevent the effects of EMI on the pacemaker or ICD from the electrocautery?

The safest way to prevent intraoperative EMI response is appropriate reprogramming. The following precautions should be taken to minimize the effects of electrocautery:

- Place the cautery grounding plate as close to the operative site and as far from the CIED as possible to make sure that the current pathway does not pass through or near the CIED system. For some cases, the grounding plate might need to be placed on a site different from the thigh (e.g., the superior posterior aspect of the shoulder contralateral to the CIED generator position for a head and neck case).
- Do not use cautery within 15 cm of the pacemaker because it may interfere with the battery circuitry. If in contact with a break in the insulation of the electrode, it may cauterize the myocardium at the electrode tip, rendering it insensitive to pacing impulses.
- Limit cautery use to 1-second bursts every 10 seconds to prevent repetitive asystolic periods (if possible).
- If the pacemaker is inhibited by the cautery, place a high-powered magnet over the demand nonprogrammable pacemaker to convert it to fixed-rate mode.
- Using bipolar electrocautery forceps or ultrasonic (harmonic) scalpel reduces EMI.

Practice advisory for the perioperative management of patients with cardiac implantable electronic devices: pacemakers and implantable cardioverter-defibrillators: an updated report by the American Society of Anesthesiologists Task Force on Perioperative Management of Patients with Cardiac Implantable Electronic Devices. *Anesthesiology.* 2011;114:247–261.

Stone KR, McPherson CA. Assessment and management of patients with pacemakers and implantable cardioverter defibrillator. *Crit Care Med.* 2004;32(suppl):S155–S165.

C.8. What are the effects of a magnet over pacemakers and ICDs?

The effect of placing a magnet over a pacemaker or ICD can vary quite considerably depending on the device manufacturer, model, and individual programmed modes. This information may be obtained by consulting the device manufacturer's representative. Most pacemakers will switch to a fixed-rate pacing mode when a magnet is placed. However, the response of a pacemaker to a magnet placement may also include the following:

- Asynchronous pacing without rate responsiveness
- No response
- Brief (10 to 100 beats) asynchronous pacing
- Continuous or transient loss of pacing

The response of an ICD to magnet placement is different from the response of a pacemaker. Magnets will disable tachyarrhythmia detection and therapy that, except in some Guidant-Boston Scientific devices, are reenabled when the magnet is removed. Magnets generally will, with a few exceptions, not affect the pacing mode or rate of ICDs. Therefore, the pacemaker in an ICD can be inappropriately inhibited by electrocautery even when a magnet is placed.

It is important to remember that some early generation Guidant-Boston Scientific ICDs are permanently disabled when a magnet is placed for more than 30 seconds. The ICD will not be reactivated when the magnet is removed. To reactivate the Guidant-Boston Scientific ICDs, the magnet has to be reapplied over the ICD for more than 30 seconds and then removed. If a magnet is to be used during surgery, the magnet effects should be tested in the operating room before surgery to ensure that the desired effects will occur during surgery.

Salukhe TV, Dob D. Pacemakers and defibrillators: anesthetic implications. *Br J Anesth.* 2004;93:95–104.

Stone KR, McPherson CA. Assessment and management of patients with pacemakers and implantable cardioverter defibrillator. *Crit Care Med.* 2004;32(suppl):S155–S165.

C.9. In the middle of surgery, the patient developed ventricular tachycardia. What would you do?

For a patient with an ICD and magnet-disabled therapies:

- Advise the surgeon performing the procedure to terminate all sources of EMI.
- Remove the magnet to reenable antitachycardia therapies.
- Observe the patient and the monitors for appropriate CIED therapy. This can be delayed for as long as 10 to 12 seconds as the ICD is charging.
- If the activities mentioned in the preceding text do not restore ICD function, proceed with emergency external defibrillation.

For a patient with an ICD and programming-disabled therapies:

- Advise individual performing the procedure to terminate all sources of EMI while magnet is removed.
- Reenable therapies through programming if the programmer is immediately available and ready to be used.
- Observe the patient and the monitors for appropriate CIED therapy.
- If the activities mentioned in the preceding text do not restore ICD function, proceed with emergency external defibrillation.

For external defibrillation (see also section C.3):

- Position defibrillation/cardioversion pads or paddles as far as possible from the CIED generator.

- If it is technically impossible to place the pads or paddles in locations that help to protect the CIED, defibrillate/cardiovert the patient in the quickest possible way and be prepared to provide pacing through other routes.
- Use a clinically appropriate energy output.

Practice advisory for the perioperative management of patients with cardiac implantable electronic devices: pacemakers and implantable cardioverter-defibrillators: an updated report by the American Society of Anesthesiologists task force on perioperative management of patients with cardiac implantable electronic devices. *Anesthesiology.* 2011;114:247–261.

C.10. What precautions should be taken when a patient with a CIED is undergoing extracorporeal shock wave lithotripsy (ESWL)?

ESWL is no longer contraindicated for patients with pacemakers. The only exception to this general statement is the abdominally placed pacemaker generators. Because these generators are in the blast path of the shock wave, such patients should not be treated with ESWL. Nevertheless, most transvenous pacemaker generators are placed in a pectoral location that is at a safe distance from the blast path. Consider preoperative disabling of atrial pacing if the lithotripsy system triggers on the R wave. Avoid focusing the lithotripsy beam near the pulse generator.

Although most pacemakers are not affected by ESWL, sometimes it may cause pacemaker malfunctions that include the following:

- Switching to magnet mode
- Reaching upper rate limit
- Pacing irregularity
- Oversensing of asynchronous shocks
- Damage to rate-sensing piezoelectric crystal
- Intermittent inhibition of ventricular output in dual-chamber pacemaker
- EMI

There may be a rate increase in a rate-response (adaptive) pacemaker after ESWL shocks. Therefore, special precautions should be taken preoperatively. The type of pacemaker, indications for its placement, degree of patient dependence, and pacemaker programmability must be determined before lithotripsy. A dedicated pacemaker programmer should be available in the lithotripsy suite should pacemaker malfunction be caused by the shock waves. In addition, an alternative means of pacing, such as transcutaneous pacing, should also be available in case the pacemaker becomes permanently damaged. Low-energy shock waves (less than 16 kV) should be used initially; then the energy level is gradually increased while pacemaker function is monitored carefully. It is best to disable tachycardia detection of an ICD during ESWL and to thoroughly test the ICD following the procedure.

Practice advisory for the perioperative management of patients with cardiac implantable electronic devices: pacemakers and implantable cardioverter-defibrillators: an updated report by the American Society of Anesthesiologists task force on perioperative management of patients with cardiac implantable electronic devices. *Anesthesiology.* 2011;114:247–261.

C.11. Is electroconvulsive therapy (ECT) contraindicated in patients with pacemakers or ICDs?

It is advisable to consult with the ordering physician, the patient's cardiologist, a cardiac rhythm management device (CIED) service, or the device manufacturer. ECT appears safe for patients with pacemakers or ICDs because little current flows within the heart due to the high impedance of body tissues. Nevertheless, the seizure and

succinylcholine fasciculations may generate sufficient myopotentials for pacemaker inhibition (unipolar devices) or ventricular tracking (adaptive-rate devices). Therefore, it is advisable to program the pacemaker to a nonsensing (asynchronous) mode for pacemaker-dependent patients either by reprogramming prior to the procedure or using a magnet during the case. It is also important to keep in mind that a magnet placed over an ICD will only disable tachytherapies and will not cause the ICD to pace asynchronously. An external pacemaker should also be available. Current guidelines also suggest that all ICDs should be programmed so that tachycardia detection is disabled before ECT and reprogrammed to its original programmed parameters prior to discharge.

Practice advisory for the perioperative management of patients with cardiac implantable electronic devices: pacemakers and implantable cardioverter-defibrillators: an updated report by the American Society of Anesthesiologists task force on perioperative management of patients with cardiac implantable electronic devices. *Anesthesiology*. 2011;114:247–261.

Stone KR, McPherson CA. Assessment and management of patients with pacemakers and implantable cardioverter defibrillator. *Crit Care Med*. 2004;32(suppl):S155–S165.

C.12. Is magnetic resonance imaging (MRI) contraindicated in patients with a CIED?

MRI is generally contraindicated in patients with a CIED. If MRI must be performed, consult with the ordering physician, the patient's cardiologist, the diagnostic radiologist, and the CIED manufacturer. MRI can cause rapid pacing, inhibition, resetting of DDD pacemakers, and transient reed switch malfunction with asynchronous pacing. Serious malfunction with no output or rapid pacing may occur because pulsed energy from MRI can enter the lead by capacitive coupling and cause rapid ventricular pacing. Recent studies suggest that MRI may be safe, at least with some models of pacemakers or ICDs, provided the CIED generator and leads are not inside the magnet bore. When MRI is considered absolutely essential, it is reasonable to program the pacemaker to its lowest voltage and pulse width or to OOO mode, provided the patient has an adequate underlying rhythm. The pulse waveform should be closely monitored in pacemaker-dependent patients, and an external pacemaker and defibrillator should be available. Device function must be checked after MRI.

Atlee JL, Berstein AD. Cardiac rhythm management devices (part I). *Anesthesiology*. 2001;95:1265–1280.

Practice advisory for the perioperative management of patients with cardiac implantable electronic devices: pacemakers and implantable cardioverter-defibrillators: an updated report by the American Society of Anesthesiologists task force on perioperative management of patients with cardiac implantable electronic devices. *Anesthesiology*. 2011;114:247–261.

Roguin A, Schwitter J, Vahlhaus C, et al. Magnetic resonance imaging in individuals with cardiovascular implantable electronic devices. *Europace*. 2008;10:336–346.

C.13. What are the precautions during radiofrequency ablation for a patient with a CIED?

- Avoid contact of radiofrequency catheter with the CIED generator and leads
- Radiofrequency current path as far away from the CIED generator and leads as possible
- Discuss these concerns with the operator

Practice advisory for the perioperative management of patients with CIEDs: pacemakers and implantable cardioverter-defibrillators: an updated report by the American Society of Anesthesiologists task force on perioperative management of patients with cardiac implantable electronic devices. *Anesthesiology*. 2011;114:247–261.

D. Postoperative Management

D.1. How would you monitor this patient in the postanesthesia care unit?

Cardiac rate and rhythm should be continuously monitored throughout the immediate postoperative period. Backup pacing capability and cardioversion-defibrillation equipment should be immediately available at all times.

Practice advisory for the perioperative management of patients with cardiac implantable electronic devices: pacemakers and implantable cardioverter-defibrillators: an updated report by the American Society of Anesthesiologists task force on perioperative management of patients with cardiac implantable electronic devices. *Anesthesiology*. 2011;114:247–261.

The Heart Rhythm Society Expert Consensus Statement on the perioperative management of patients with implantable defibrillators, pacemakers and arrhythmia monitors: Facilities and patient management. Crossley GH, Poole JE, Rozner MA, et al. Heart Rhythm 2011; in press.

D.2. How would you confirm that the CIED is functioning properly after surgery?

Postoperative interrogation and restoration of CIED function are basic elements of postoperative management. But given the robustness of modern devices, not all CIEDs require postoperative interrogation before discharge, especially in cases in which the EMI is remote from the device system. CIEDs that should be interrogated postoperatively before discharge include:

- CIEDs that were reprogrammed or deactivated before surgery so that baseline settings can be restored
- Patients who underwent hemodynamically embarrassing surgeries such as cardiac surgery or significant vascular surgery
- Patients who experienced significant intraoperative events, including cardiac arrest, requiring temporary pacing or cardiopulmonary resuscitation and/or tachyarrhythmias requiring external electrical cardioversion during surgery

All other individuals should have their devices evaluated as an outpatient within the next 3 months.

CHAPTER 8

Thoracoabdominal Aortic Aneurysms

J. Mauricio Del Rio, Jeffrey G. Gaca, Mani A. Daneshmand, and Madhav Swaminathan

A 67-YEAR-OLD WOMAN

presents for evaluation and surgical treatment of a thoracoabdominal aortic aneurysm (TAAA). The patient's past medical history is significant for a type III aortic dissection 8 years ago, hypertension, chronic obstructive pulmonary disease (COPD), smoking (50-pack years), and stage III chronic kidney disease. The patient currently complains of intermittent back pain. Computed tomography (CT) reveals a 9-cm TAAA originating just distal to the left subclavian artery that extends to the iliac bifurcation. Chest radiograph shows thoracic aortic aneurysmal dilation, with displacement of the left bronchial mainstem. Echocardiogram shows concentric left ventricular hypertrophy and a normal ejection fraction. Laboratory studies indicate hemoglobin, 9.3 g/dL; hematocrit, 37%; blood urea nitrogen, 22 mg/dL; and creatinine, 1.9 mg/dL.

A. Medical Disease and Differential Diagnosis

1. What are the different types of aortic pathologies?
2. What is the pathogenesis of aortic aneurysms?
3. How are thoracic aortic dissections classified?
4. How are TAAAs classified?
5. Describe the natural history and clinical presentation of TAAAs.
6. What are the indications for and timing of surgical intervention for TAAAs? Describe the medical management.

B. Preoperative Evaluation and Preparation

1. How should TAAAs be surgically evaluated?
2. Describe the preoperative evaluation and risk assessment of the patient scheduled for TAAA repair.
3. Describe the spinal cord blood supply.

C. Intraoperative Management

1. What hemodynamic monitors should be used for the patient undergoing TAAA repair?
2. What are the possible blood conservation techniques and blood product requirements for TAAA repair?
3. Describe the surgical approach to TAAA repair.
4. What are the specific considerations for anesthetic management of the patient for TAAA repair?
5. What major organ systems are threatened during TAAA repair?
6. What strategies are used for spinal cord protection?
7. How do you detect spinal cord ischemia?
8. What strategies are used for mesenteric and renal preservation?
9. Describe the pathophysiology of aortic clamping and unclamping.

D. Postoperative Management

1. What are the potential complications of TAAA repair?

E. Anesthesia for Endovascular TAAA Repair

1. Which patients are candidates for endovascular TAAA repair?
2. What are the surgical steps for endovascular TAAA repair?
3. What are the specific anesthetic considerations for endovascular TAAA repair?
4. What are the potential complications of endovascular TAAA repair?

A. Medical Disease and Differential Diagnosis

A.1. What are the different types of aortic pathologies?

The major disease processes affecting the aorta are aneurysms and dissections. An aneurysm is a localized abnormal dilation of a blood vessel. A true aortic aneurysm is defined as a localized dilation of the aorta, 1.5 times the normal diameter (for anatomic segment, age, gender, and body size), which includes an intact attenuation of all three-vessel layers (i.e., the intima, media, and adventitia). In contrast, a pseudoaneurysm is a defect in the vascular wall leading to an extravascular hematoma that freely communicates with the intravascular space. Aneurysms can also be classified according to morphology and location.

The morphologic classification distinguishes true aneurysms into *fusiform* and *saccular*. Fusiform aneurysms involve diffuse, circumferential dilation of a long vascular segment. Saccular aneurysms are spherical outpouchings that involve only a portion of the vessel wall (Fig. 8.1). Fusiform aneurysms are much more common than saccular ones, and both of these types are not specific for any disease or clinical manifestation.

Apart from shape, aortic aneurysms may also be classified according to the segment involved as thoracic aneurysms (which include the ascending or descending aorta in the thoracic cavity), and thoracoabdominal or abdominal (involving the infrarenal abdominal aorta). Ascending aortic aneurysms are typically fusiform and may extend into the aortic arch. Descending aortic aneurysms start below the ligamentum arteriosum and often begin distal to the origin of the left subclavian artery. These aneurysms are typically fusiform and can extend to the level of the abdominal aorta. Chronic aneurysms tend to be larger, which, over time, develop sluggish flow, leading to intraluminal thrombus formation (Fig. 8.2). The location of the aneurysm has clinical and therapeutic implications because the pathogenesis and natural history of ascending and descending aortic aneurysms are different.

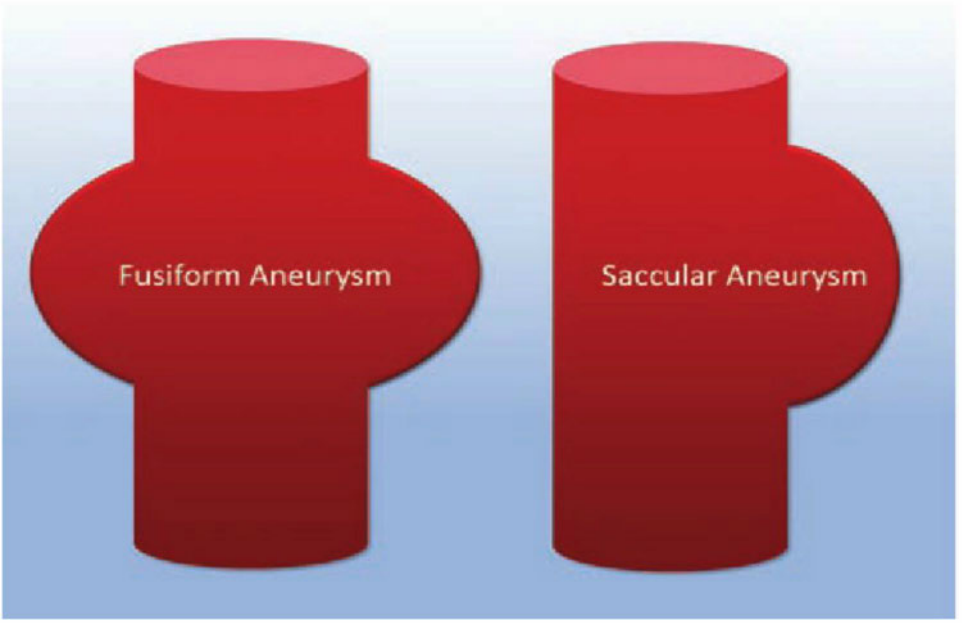

Figure 8.1 Illustration of two different morphologic forms of aortic aneurysms. The figure on the left shows a circumferential dilation of the aortic wall and represents a *fusiform* aneurysm, while the figure on the right shows a localized dilation, termed a *saccular* aneurysm.

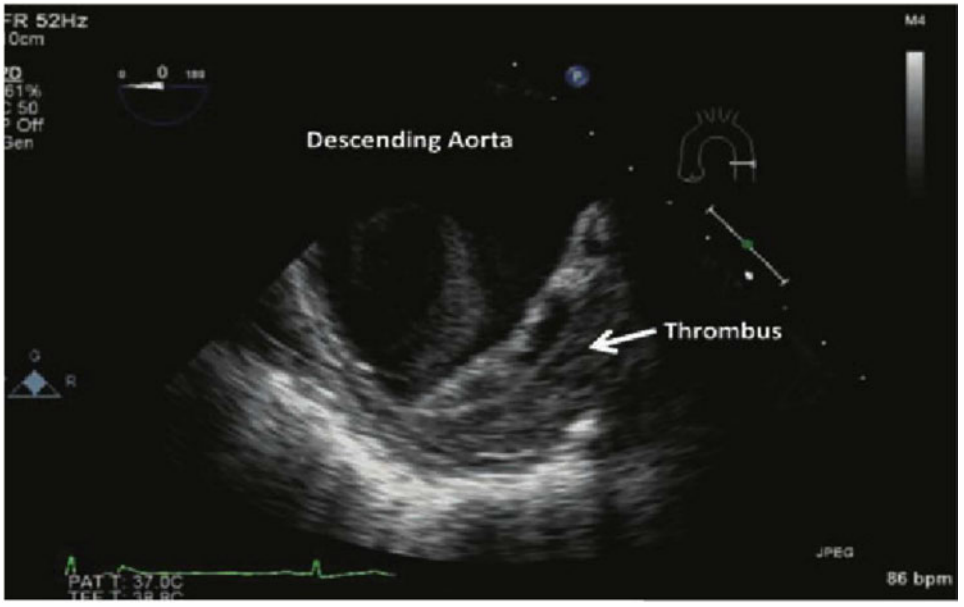

Figure 8.2 Transesophageal echocardiographic image of the descending thoracic aorta demonstrating a large aneurysm with an intraluminal thrombus.

TAAAs have features of both thoracic and abdominal aneurysms and constitute only about 3% of all aortic aneurysms. TAAAs are considered separately because of extensive aortic involvement and special considerations required for surgical repair.

An aortic dissection presents when blood enters the arterial wall through an intimal tear, causing a hematoma that propagates longitudinally between the laminar planes of the media forming a blood-filled channel within the aortic wall. Aortic dissections can rupture through the adventitia causing massive hemorrhage, or they could reenter the lumen through a second intimal tear. It is noteworthy that while aortic aneurysms are predisposed to dissection, aortic dissections may or may not be associated with a pre-existing aortic aneurysm. Consequently, the term "dissecting aneurysm" should be avoided. There are two separate variants of aortic dissection: *intramural hematoma* and *penetrating aortic ulcer*. The intramural hematoma differs from a typical dissection in that it is located circumferentially around the aortic lumen rather than obliquely across it, and there is no flap defining a true and a false lumen. It is not clear if intramural hematomas arise from a small nondissected intimal tear or from a rupture of vasa vasorum within the aortic wall. Penetrating aortic ulcers (Fig. 8.3) are erosions that enter the aortic wall, disrupting the internal elastic lamina and extend into the media, which can lead to rupture, intramural hematoma, or pseudoaneurysm formation. In some cases, these ulcers can mimic true dissections or initiate them. In general, *hypertension* is the major risk factor for aortic dissection. Although medial degeneration is a common finding, it is not essential for a dissection to occur.

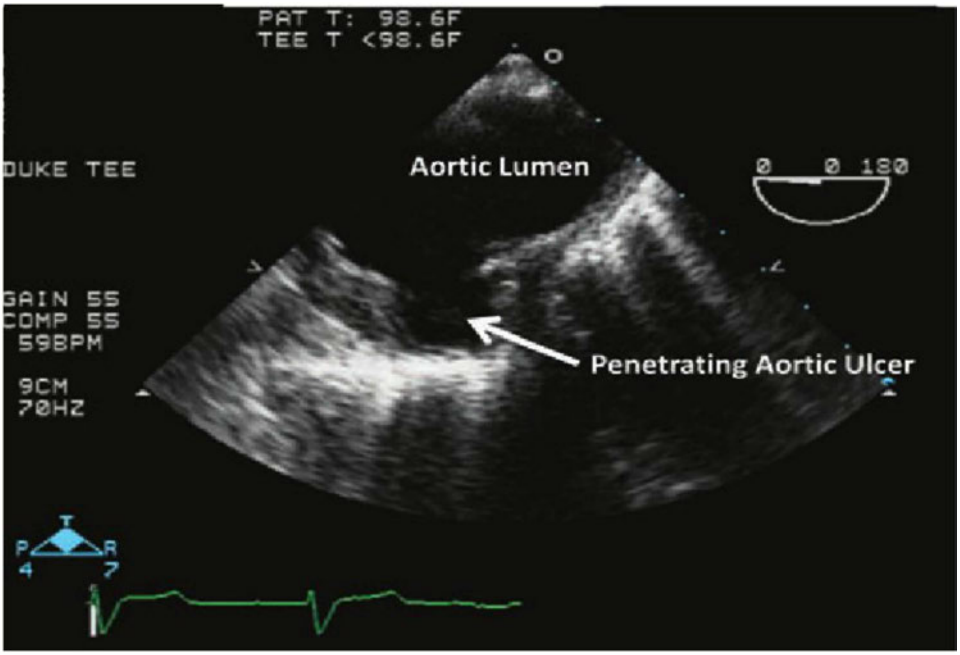

Figure 8.3 Transesophageal echocardiographic image of the descending thoracic aorta demonstrating a penetrating aortic ulcer. Note the overhanging margins of the ulcer, which are characteristic of this condition.

A.2. What is the pathogenesis of aortic aneurysms?

In general, arteries are dynamically remodeling tissues that maintain their structural and functional integrity by constantly synthesizing, degrading, and repairing their extracellular matrix (ECM). Any alteration in the integrity of the connective tissue can cause weakness of the aortic wall by the following mechanisms:

- *Poor intrinsic quality of vascular wall connective tissue:*
  - In *Marfan syndrome,* the defective synthesis of *fibrillin-1* leads to altered transforming growth factor-beta (TGF-β) activity and weakening of elastic tissue. The aorta progressively dilates as a consequence of remodeling of the media. There are more than 125 identified mutations on the *human fibrillin-1 gene (FBN1).*
  - In *Loeys-Dietz syndrome,* mutations in TGF-β (1 or 2) receptors lead to abnormalities in elastin and collagen II and I. Aneurysms in these patients tend to rupture at smaller sizes. Like Marfan syndrome, it is an autosomal dominant disorder and is subdivided into type 1A, 1B, 2A, and 2B depending on the receptor affected and the location of the mutation. Type 1A is also known as *Furlong disease,* and type 2B was previously known as Marfan syndrome type 2. Clinically, these patients have widely spaced eyes, cleft palate or bifid uvula, and tortuous aneurysmal aortas that are prone to dissection. Many patients with *Loeys-Dietz syndrome* also have bicuspid aortic valves.
  - In *Ehlers-Danlos syndrome,* there is defective type III collagen synthesis.
  - In *severe vitamin C deficiency,* there is altered cross-linking of type III collagen.
- *Imbalance of collagen synthesis and degradation:*
  - The presence of *local inflammatory mediators* in *atherosclerosis* and *vasculitis* promotes an increased production of matrix metalloproteinases by macrophages. These enzymes can degrade all the components of the ECM in the aortic wall. A simultaneous decrease in tissue inhibitor of metalloproteinase expression contributes to ECM degradation.
- *Loss of smooth muscle cells and inappropriate synthesis of noncollagen/nonelastic ECM in the vascular wall:*
  - *Ischemia* of the aortic wall causes degenerative changes, characterized by scarring, loss of smooth muscle cells and elastic fibers, and abnormal deposition of glycosaminoglycans. Ischemia can occur at two levels; when there is atherosclerotic thickening of the intima, there is an increased distance for oxygen and nutrients to diffuse to the inner media. Otherwise, significant narrowing of the vasa vasorum induced by hypertension causes outer media ischemia.
  - The histopathologic changes described above are termed *cystic medial degeneration.* These changes are not specific to any pathology and can be seen in the other entities previously discussed.
- *Polymorphisms of matrix metalloproteinases and/or tissue inhibitor of metalloproteinase genes cause genetic predisposition to aneurysm formation:*
  - There are familial clusters of TAAA and dissection referred as *familial thoracic aortic aneurysm syndrome*. Some mutations in genes encoding for TGF-β receptors 1 and 2 have been identified. Similarly, mutations in the human *myosin heavy chain 11 gene* are responsible for a familial association between thoracoabdominal dissection and patent ductus arteriosus.

- Many ascending thoracic aortic aneurysms are associated with *congenital bicuspid aortic valve*. In the past, it was thought that those aneurysms were caused by "post-stenotic dilatation." In fact, congenital bicuspid aortic valve is associated with a dilated aorta regardless of the presence of hemodynamically significant aortic valve dysfunction. As many as 30% of patients with bicuspid aortic valves will develop aortic dilation. There are inadequate levels of fibrillin-1 during embryogenesis in these patients.
- In *Turner syndrome,* there is association with bicuspid aortic valve (30% of patients) and aortic coarctation. There are other multiple cardiovascular anomalies, including thoracic aortic aneurysms, which typically involve the ascending aorta.

Many diverse noninfectious and infectious inflammatory aortitis can cause thoracic aortic aneurysms. These conditions include *giant cell arteritis, syphilitic aortitis, mycotic aneurysm (often caused by bacterial endocarditis), Takayasu arteritis, rheumatoid arthritis, psoriatic arthritis, ankylosing spondylitis, reactive arthritis, Wegener granulomatosis, and Reiter syndrome.* Otherwise, infectious aortitis can occur from a primary bacterial infection of the aortic wall leading to an aneurysm formation. In particular, mycotic aneurysm arise from secondary infections of pre-existing aneurysm, which can result (1) from septic embolization; (2) as a consequence of extension of an adjacent process; or (3) due to circulating microorganisms seeding the damaged aortic wall. Tertiary syphilis is now a rare cause of aortic aneurysms. The bacteria that are most commonly associated with aneurysm formation are *Salmonella* spp., *Staphyllococcus* spp., and *Mycobacterium* spp. HIV is also an infectious agent that can cause aortic aneurysms.

In general, the two most prevalent disorders that predispose to aortic aneurysms are *atherosclerosis* and *hypertension.* Atherosclerosis is the predominant factor in abdominal aortic aneurysms and a significant one for descending thoracic aortic aneurysms, emphasizing the inflammatory nature of aortic aneurysm formation. Hypertension is the most common condition associated with ascending aortic aneurysms. Trauma can also lead to aneurysm formation but, more importantly, it can lead to acute aortic transection and rupture of a pre-existing aortic aneurysm.

A.3. How are thoracic aortic dissections classified?

Aortic dissections are commonly classified using either the DeBakey or Stanford systems (Fig. 8.4). The DeBakey system classifies aortic dissections by both their site of origin and their distal extension, providing four different categories with potentially distinct clinical implications:

- Type I dissection begins in the ascending aorta and extends throughout the aorta down to the common iliac arteries.
- Type II dissection is limited to the ascending aorta only.

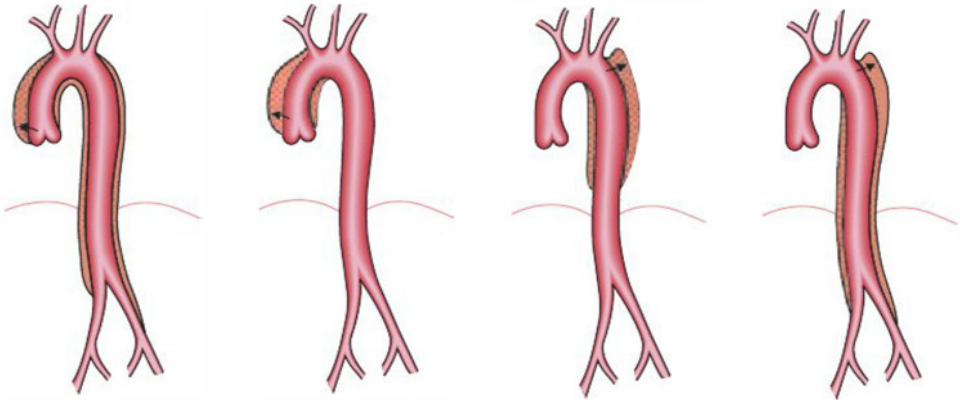

Figure 8.4 Schematic illustration of the Debakey and Stanford systems of classification of aortic dissection. (From Reece T, Green G, Kron I. Aortic dissection. In: Cohn LH, ed. *Cardiac Surgery in the Adult.* New York: McGraw-Hill; 2008:1195–1222, with permission.)

- Type III dissections begin distal to the left subclavian artery and they are subdivided into subtypes a and b depending upon abdominal aortic involvement.
  - Type IIIa dissections end in the descending thoracic aorta.
  - Type IIIb dissections extend into the abdominal aorta.

The Stanford system classifies aortic dissections into types A and B based on the involvement of the ascending aorta only. The Stanford system is a more simple and functional classification based on the premise that the clinical course and surgical significance of aortic dissection is determined by the involvement of the ascending aorta. Some experts argue that patients with type A dissection have different clinical behavior depending on the distal extension.

- Type A dissections affect the ascending aorta regardless of the extension or where the primary tear occurs (Fig. 8.5). This type includes DeBakey's type I and type II dissections.
- Type B dissections originate in the descending aorta and are equivalent to DeBakey's type III dissection (Fig. 8.6A,B).

Reece TB, Green GR, Kron IL. Aortic dissection. In: Cohn LH, ed. *Cardiac Surgery in the Adult*. New York: McGraw-Hill; 2008:1195–1222.

A.4. How are TAAAs classified?

TAAAs compromise the aorta from the origin of the left subclavian artery and can involve variable portions, including extension into the aortic bifurcation. The

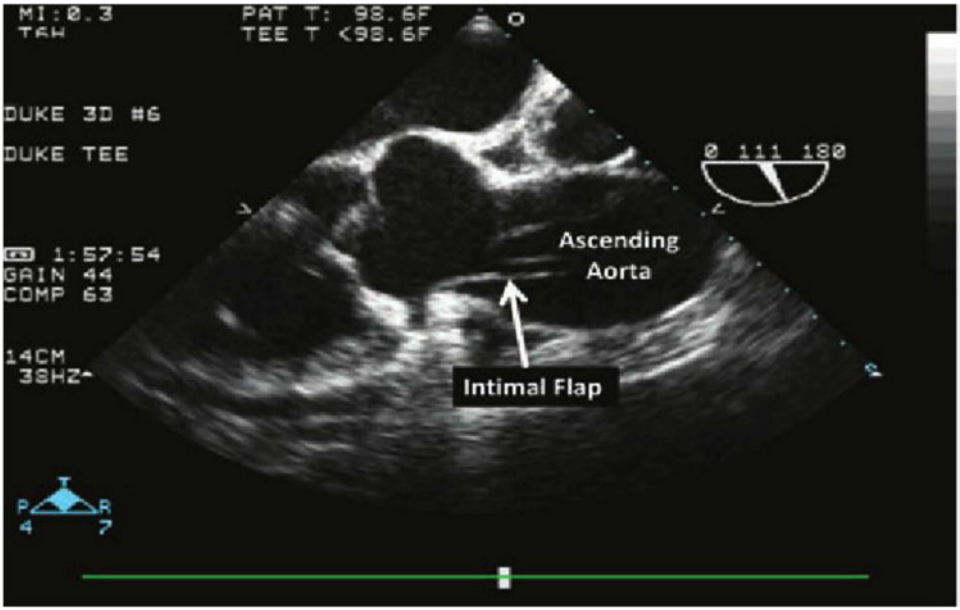

Figure 8.5 Transesophageal echocardiographic image of the ascending aorta demonstrating an intimal flap in the aortic lumen in a patient with a Stanford type A aortic dissection.

Crawford classification system takes into account the extent of aortic involvement, which has significant implications in the selection of treatment and determination of morbidity and mortality associated with surgical repair; but, most importantly, in the assessment of neurologic risk.

There are four Crawford categories (Fig. 8.7) described as follows:

- Type I TAAA originates below the left subclavian artery and extends into the abdominal aorta, including the celiac axis and mesenteric arteries.
- Type II TAAA involves the same areas as type I, but extends caudally to include the infrarenal abdominal aorta.
- Type III TAAA begins in the lower descending thoracic aorta and involves the remainder of the aorta.
- Type IV TAAA begins at the diaphragm and involves the abdominal aorta only.

Crawford ES, Crawford JL, Safi HJ, et al. Thoracoabdominal aneurysms: preoperative and intraoperative factors determining immediate and long-term results in 605 patients. *J Vasc Surg*. 1986;3:389–404.

A.5. Describe the natural history and clinical presentation of TAAAs.

Thoracic aortic aneurysms grow at a very slow rate (average 0.12 cm per year). The rate of growth is greater for descending (0.3 cm per year) versus ascending aorta aneurysms (0.1 cm per year). Aortic aneurysms grow at a faster rate when there has been a chronic dissection of a pre-existing aneurysm or in patients with Marfan

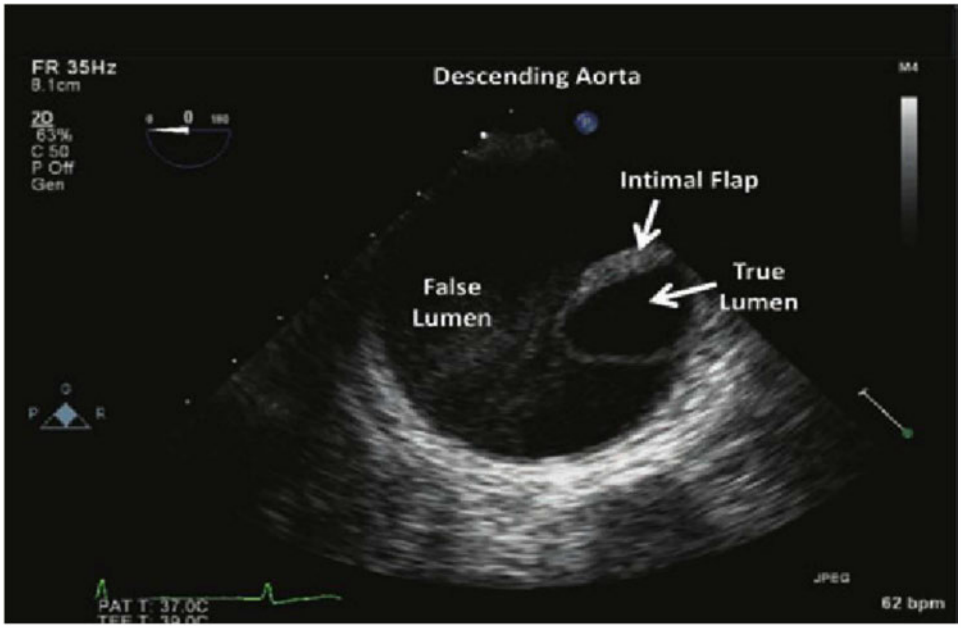

Figure 8.6 Transesophageal echocardiographic image of the descending thoracic aorta in a patient with a Stanford type B aortic dissection demonstrating the true and false lumens separated by an intimal flap. Panel **A** shows the aorta in short axis, while panel **B** shows a long axis view in the same patient.

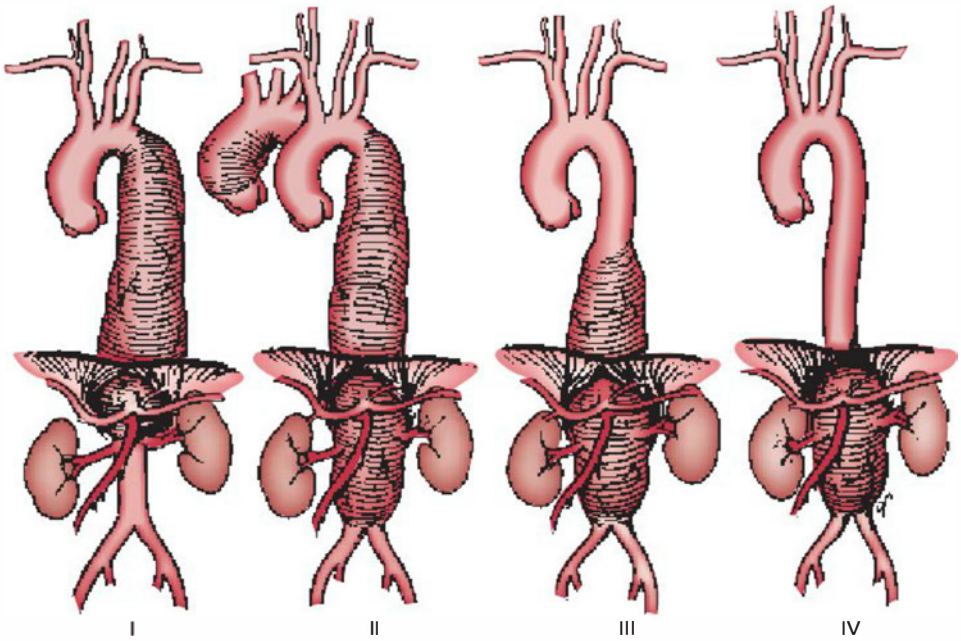

Figure 8.7 Schematic illustration of the Crawford system of classification of thoracoabdominal aortic aneurysms. (From Coselli J, LeMaire S. Descending and thoracoabdominal aortic aneurysms. In: Cohn LH, ed. *Cardiac Surgery in the Adult*. New York: McGraw-Hill; 2008:1277–1298, with permission.)

syndrome. Most commonly, TAAAs grow in an asymptomatic fashion (~43% of patients) until diagnosis is made incidentally when an imaging study is obtained for an unrelated reason. Only 5% to 10% of patients present with symptoms. Aneurysms can produce pain from aortic wall stretching or extrinsic compression of contiguous structures depending upon their location. Ascending aortic aneurysms can produce retrosternal pain, whereas descending ones can cause interscapular pain. Chest wall or posterior chest pain may arise from compression or erosion of ribs and vertebral bodies, respectively. Associated symptoms such as cough and dyspnea, caused by tracheal or airway impingement, are more common in ascending and arch aneurysms. Hemoptysis can occur from erosion of TAAAs into bronchi or lung parenchyma. There may be hoarseness or dysphagia from compression of the recurrent laryngeal nerve or the esophagus, respectively. TAAAs can be a source of atheroembolism to peripheral tissues due to mural thrombosis. Otherwise, in many instances, the presenting feature is rupture or dissection, leading to death. It is critical to have a high index of suspicion whenever a patient has chest pain of unknown cause.

The incidence of TAAAs is 10 per 100,000 patient-years, and is similar among women and men. The fact that the mid- to long-term survival of patients with aneurysms is poor (5-year survival rate of 19.2%), and the main cause of death in these patients is aneurysm rupture (51%) emphasizes the importance of early diagnosis and management. The major complications of thoracic aneurysms are rupture and dissection, which occur at a rate of 7% per year. The incidence of rupture, dissection, or death increases in a linear fashion as the aorta grows, reaching maximal levels at an aortic diameter of 6 cm, beyond which the aorta reaches the limits of its mechanical

properties and distensibility, and the rate of complications increases exponentially. Indeed, the lifetime risk of rupture or dissection above this point is 34%. Therefore, the diagnosis before this "hinge-point" at which the rate of rupture, dissection, and death increases at an unacceptable level is crucial. In general, it is accepted that intervention should occur when the annual risk of rupture and/or dissection exceeds the risk for surgical repair. Other factors, such as patient age, comorbidities, aneurysm morphology and extent, as well as surgical expertise, are important considerations for decision-making purposes.

There are certain patient-related predictors of rupture. Advanced age increases the relative risk of thoracic aortic disruption by a factor of 2.6 for every decade of life. The presence of chronic obstructive pulmonary disease (COPD) is another significant predictor of rupture. Patients with TAAAs and chest or back pain are also at increased risk of aneurysm rupture. In several studies, women have had both faster rates of aneurysm expansion and higher rate of aneurysm rupture (approximately 79% of ruptures occur in women). Hypertension and obstructive sleep apnea, although correlating with aneurysm development, have not conclusively shown to increase the risk of rupture.

A.6. What are the indications for and timing of surgical intervention for TAAAs? Describe the medical management.

Both the etiology and location of an aneurysm may affect its growth rate and propensity for dissection or rupture. The main determinants of the risk of rupture or dissection for TAAAs are size and rate of expansion. As such, surgical intervention is performed when the aneurysm is large enough to be considered at significant risk for rupture. The initial size is an important predictor of the rate of aneurysm growth. In this regard, the annual rate of rupture or dissection is 2% for aneurysms less than 5 cm, 3% for aneurysms 5 to 5.9 cm, and 7% for aneurysms 6 cm or more in diameter.

Medical therapy to slow aneurysm growth or to reduce the risk of dissection or rupture has met with limited success. Long-term β-blocker therapy has been shown to significantly slow the rate of aortic dilatation and to lower mortality. Recently,

oral losartan has shown promise in decreasing aneurysmal degeneration rate in murine models of Marfan syndrome. This data is the precedent for the ongoing COMARE study (COzaar in Marfan pAtients Reduces aortic Enlargement). The goal of antihypertensive therapy is to maintain systolic blood pressure (BP) between 105 and 120 mm Hg. Patients should be followed with serial imaging studies for surveillance. A second imaging study should be obtained 6 months after initial diagnosis. If the aneurysm is unchanged in size, it is then reasonable to obtain an imaging study annually in most cases, except patients with Marfan syndrome or acute aortitis. Should there be a significant increase in aneurysm size between studies, the study interval should be decreased to 3 or 6 months. The optimal timing of surgical repair of thoracic aortic aneurysms depends both on the aneurysm size, patient size, degree of aortic valvular pathology, rate of aneurysm growth, and the patient's associated comorbidities. As previously mentioned, the goal of aortic aneurysm surgery is to prevent aortic rupture or dissection. Therefore, for ascending thoracic aortic aneurysms in patients without significant comorbidities, surgery is indicated at an aortic diameter of 5.5 cm or greater. The threshold for surgery is raised to 6 cm or more for patients with an increased operative risk (e.g., the elderly or those with comorbidities). The threshold is lowered to 5 cm if a patient has a bicuspid aortic valve as those patients are at risk for aortic rupture or dissection at a smaller aortic diameter. In patients with collagen vascular diseases such as Marfan syndrome or Loeys-Dietz, aortic repair is recommended at 4 cm. Indeed, when patients with a bicuspid aortic valve require valve replacement surgery, the recommendation is for prophylactic replacement of the ascending aorta if its diameter is 4.5 cm or more. Patient size can also play a role in the decision to operate on an aortic aneurysm. It is appropriate to use an aortic size index, especially in very small or very large individuals. Rate of growth of an aortic aneurysm can also be an indication for aortic repair. Although this is usually caused by inaccurate imaging measurements, a rate of growth greater than 1.0 cm per year can be an indication for surgery. This scenario is usually seen in patients with prior aortic dissection. Given the increased operative risk in descending thoracic aneurysms, surgery is recommended at an aortic diameter of 6 cm or more.

B. Preoperative Evaluation and Preparation

B.1. How should TAAAs be surgically evaluated?

Preoperative assessment of the patient for elective TAAA repair requires a delicate balance between the risks of aneurysm rupture versus surgical morbidity. The mortality of TAAA repair may range from 3% to 23%. Particularly, the incidence of spinal cord injury is 3% to 18%, with long-term survival being shorter in patients who suffer postoperative paraplegia or paraparesis. Indeed, the 5-year survival rate for patients with spinal cord injury was 44%, whereas it was 62% for those without spinal cord injury. Therefore, the determination of neurologic risk and anatomic planning of the procedure is crucial to minimize complications. Moreover, the incidence of spinal cord injury is related with the complexity of the repair and the possible need and duration of aortic cross-clamping.

Once the decision has been made to proceed with surgical repair, a comprehensive radiographic evaluation of the aorta is necessary for operative planning. Due to the advanced capabilities of modern helical computed tomography (CT), a high-quality CT angiogram is usually sufficient (Fig. 8.8). Contrast arteriography or magnetic resonance angiography is rarely required. All iodinated contrast studies should be performed well in advance of the planned procedure to avoid contrast-related acute kidney injury (AKI). Patients with baseline renal insufficiency may receive *N*-acetylcysteine and intravenous hydration to reduce the risk of contrast-induced nephropathy and postoperative AKI. Preoperative assessment of the aneurysm anatomy and of the major branches is critical to surgical planning. Open TAAA repair can be performed with or without distal aortic perfusion as well as with cardiopulmonary bypass (CPB) with or without deep hypothermic circulatory arrest (DHCA). Determinants of this decision include aneurysm and aortic anatomy, patient body habitus, the expected difficulty of aortic exposure, and the expected risk of postoperative end-organ dysfunction. Recent studies have demonstrated preserved end-organ function and decreased paraplegia utilizing CPB with DHCA. Endovascular repair of

Figure 8.8 Three-dimensional reconstruction CT angiogram of a large transverse arch aneurysm extending to within a centimeter of the left common carotid artery, but with ≥ 2 cm of proximal landing zone distal to the innominate artery. (From Hughes GC, Sulzer CF, McCann RL, Swaminathan M. Endovascular approaches to complex thoracic aortic disease. *Semin Cardiothorac Vasc Anesth.* 2008;12:298–319, with permission.)

TAAAs does not require CPB or distal aortic perfusion, as the duration of aortic flow disruption is quite limited.

Unfortunately, the studies used to assess the aneurysm vasculature are imperfect with respect to delineating the spinal cord blood supply. CT angiography and magnetic resonance angiography detect the artery of Adamkiewicz in only 50% to 80% of patients. This is significant as the risk of postoperative paraplegia is 5% if the artery of Adamkiewicz is identified preoperatively and reimplanted, whereas it is as high as 50% if the artery is not identified and reattached.

B.2. Describe the preoperative evaluation and risk assessment of the patient scheduled for TAAA repair.

The preoperative evaluation of a patient undergoing TAAA repair requires a thorough multisystem assessment. The goal is to diagnose comorbidities, assess the risk of adverse outcomes, optimize medical status, and plan an anesthetic technique that reduces the risk of complications. Cardiovascular diseases, including hypertension (70% to 90% of patients) and coronary artery disease (CAD) (50% of patients), are common. Accurate assessment of baseline cardiac function is mandatory for perioperative decision making. All patients should undergo pharmacologic stress/nuclear perfusion tests to evaluate myocardial ischemic risk and, if there is evidence of heart failure, there should be a complete assessment of valvular and ventricular function. Angioplasty or coronary artery bypass graft surgery should be considered in patients with significant CAD. Cerebrovascular disease and symptomatic lower extremity arterial occlusive disease occur in 15% of patients. The risk of perioperative cardiac morbidity and mortality is approximately 12% to 15%.

History of smoking and significant COPD is common in this population. About 25% of patients have significant COPD as manifested by a forced expiratory volume in 1 second below 50%. Although impairment in pulmonary function can be detected on a clinical basis, pulmonary function tests add useful prognostic information, as COPD is a significant risk factor. In fact, postoperative respiratory failure is a major complication (25% to 45% of cases) and a leading cause of mortality in patients undergoing TAAA repair. Moreover, pulmonary function tests are instrumental for planning purposes as one-lung ventilation is essential for surgical repair of type I, II, and III aneurysms. Patients with poor diffusing capacity or severe COPD may require the use of CPB for TAAA repair, as they may not be able to tolerate one-lung ventilation. As a

large aneurysm can distort the left mainstem bronchus, CT scan may give vital information relevant to double lumen endotracheal tube placement.

Associated visceral and renovascular disease is reported in about 30% of patients. Among surgical candidates for TAAA repair, 13% to 24% have baseline chronic kidney disease (CKD) (serum creatinine >1.5 mg per dL). A significantly increased creatinine level (>1.8 mg per dL) is present in 15% of patients. In cases with extensive visceral compromise and aneurysmal occlusion of more than one visceral/renal artery, a creatinine level >2.5 mg per dL is a relative contraindication to elective surgery unless there is evidence of potential renal function preservation or recovery with renal artery reconstruction. Preoperative CKD is associated with an increased risk of postoperative AKI and up to an eightfold increase in perioperative mortality.

The contemporary operative mortality for TAAA repair ranges from 7% to 10%, with higher volume surgeons having the best results in centers of reference. Of special note, surgical treatment in nonelective situations doubles both perioperative mortality and the incidence of complications. Another predictor of poor outcome is advanced age or, more importantly, decreased overall functional status. In general, the presence of more comorbidities increases the perioperative risk. Otherwise, as mentioned above, patients who sustain major neurologic deficits have a significantly increased risk of operative mortality. Paraplegia and stroke rates range from 1.5% to 5% and 1.3% to 7.5%, respectively. Five-year survival rates are about 65% with mid- and long-term mortality usually unrelated to the surgical intervention.

B.3. Describe the spinal cord blood supply.

The spinal cord has a system of longitudinal and transverse arteries. The most important longitudinal arteries are a single anterior spinal artery supplying 75% of the cord and a pair of posterior spinal arteries supplying the remaining 25%. The anterior spinal artery is unique, because it is a single long vessel supplying the anterior portion of the spinal cord that principally controls motor function. Also, the anterior spinal artery receives minimal contribution from transverse radicular arteries, which result in little blood flow reserve to the anterior spinal cord. The territory supplied by the anterior spinal artery is divided into three functionally distinct levels: cervicodorsal, midthoracic, and thoracolumbar. The cervicodorsal region receives its blood supply from the vertebral, subclavian, thyrocervical, and costocervical arteries. The

midthoracic region is supplied only by a left or right intercostal artery arising between the fourth and the ninth thoracic vertebrae. The thoracolumbar region of the anterior spinal artery receives its blood supply mainly from one of the intercostal arteries called the *arteria radicularis magna* (ARM) or the artery of Adamkiewicz. It arises at the level of T5–T8 in 15%, T9–T12 in 60%, L1 in 14%, and L2 in 10% of patients. If the aortic cross-clamp is applied distal to the ARM, there is low probability of spinal cord ischemic injury. Otherwise, if this artery is patent and arises from the aneurysm wall or distal to the level of the cross-clamp, a significant risk of spinal cord injury is incurred. The anterior spinal artery is smaller above than below the entry of the ARM. Resistance to blood flow is 51 times greater going "up" the anterior spinal artery. Therefore, distal aortic perfusion during thoracic aortic cross-clamping protects the spinal cord below the ARM, but has minimal impact above it. The distal spinal cord and cauda equina are supplied by the hypogastric arteries in the pelvis.

Recently, multiple anastomotic pathways outside the spinal canal, in the perivertebral tissues and in the paraspinous muscles that connect to each other and to the spinal cord arteries, have been described. According to this "collateral network" concept, there can be increased blood flow from any one of these sources if the flow to another is reduced. In a similar fashion, a steal phenomenon can occur if an alternate pathway of low resistance is available. Evidence of this phenomenon comes from the clinical observation of back bleeding from intercostal arteries into an open aortic segment after exclusion by cross-clamping during surgical repair.

C. Intraoperative Management

C.1. What hemodynamic monitors should be used for the patient undergoing TAAA repair?

Initially, all patients should have standard American Society of Anesthesiologists monitors applied. Particularly, multilead ECG with ST-segment analysis is essential as the incidence of intraoperative myocardial ischemia and arrhythmias is significant. Given the extensive and anticipated hemodynamic changes, a direct continuous invasive monitoring of arterial BP is mandatory. In this regard, right radial artery is the preferred site because it reflects pressure in the carotid arteries. If the aneurysm extends proximally, requiring surgical manipulation close to the aortic arch, monitoring of the left radial pressure can be helpful for assessment of left subclavian artery patency. In this situation, the proximal application of the aortic cross-clamp may disrupt left subclavian arterial blood flow, rendering left radial monitoring useless. Otherwise, monitoring of

femoral arterial pressure allows assessment of perfusion distal to the aortic cross-clamp during partial left heart bypass. It is also instrumental in evaluating the adequacy of surgical repair by documenting the simultaneous pressure gradient between upper and lower body (across the repair). The femoral vessels should be accessed in consultation with the surgeon given the possibility of extracorporeal circulation or placement of an intra-aortic balloon pump. Placement of a pulmonary artery catheter should be strongly considered in order to assess preload and afterload as well as to monitor for perioperative left ventricular dysfunction and ischemia.

The use of transesophageal echocardiography (TEE) during TAAA repair allows confirmation of the extent and severity of the aortic disease. It also gives real-time functional and hemodynamic information regarding biventricular and valvular compromise. Ventricular dysfunction and regional wall motion abnormalities can be readily diagnosed. TEE can also assist during the placement of perfusion cannulae and offers valuable information at a low risk of complications. Of note, because of the lateral positioning of the patient, presence of the TEE probe may cause "pressure" injury of both tissues and neurovascular structures in the posterior larynx (recurrent laryngeal nerve, vocal cords, etc.). Thus, the risk and benefit of TEE monitoring must be weighed carefully. Theoretically, a pediatric probe may lessen the aforementioned complications.

Large-bore intravenous access is essential for TAAA repair, as the potential for rapid intraoperative blood loss is significant. One or two large-bore peripheral intravenous catheters are recommended along with a large-bore central venous introducer. Left upper extremity peripheral intravenous catheters should be avoided during aortic arch surgery, because the left innominate vein may be injured or intentionally ligated during the procedure. Central venous access allows monitoring of cardiac filling pressures, and also permits infusion of medications, intravenous fluids, and blood products. The femoral vein can be accessed with a large-bore introducer to permit rapid infusion of fluids or blood products to the lower body, which can be useful during distal perfusion or partial left-heart bypass (LHB). Once again, a preoperative discussion with the surgical team is highly desirable for formulating a coherent strategy. The use of rapid infusing systems with a heat exchanger for delivery of high volume of intravenous fluids and blood products is considered standard. Besides invasive direct hemodynamic monitoring, placement of a urinary catheter is mandatory in order to assess fluid balance/urinary output and renal perfusion.

C.2. What are the possible blood conservation techniques and blood product requirements for TAAA repair?

TAAA repair is associated with the potential for massive blood loss. The anticipated requirements for blood products may exceed several blood volumes in extreme circumstances. As such, intraoperative and postoperative coagulopathy are common. The causes of coagulopathy are hemodilution and massive transfusion, platelet dysfunction, heparin effects, and fibrinolysis. The most common defects include quantitative and qualitative platelet dysfunction attributable to hypothermia and the use of extracorporeal circulation. Apparently, the event that initiates fibrinolysis is visceral ischemia due to supraceliac aortic cross-clamping. Acute peripheral ischemia (other than mesenteric) also enhances the fibrinolytic state by promoting activity of tissue-type plasminogen activator and a decrease in plasminogen activator inhibitor.

Although the use of antifibrinolytic agents should be considered during the perioperative period in order to minimize blood loss, several studies have suggested that antifibrinolytic therapy is of limited efficacy in the setting of TAAA repair. Therefore, blood salvaging techniques for autotransfusion are essential. The use of a device for centrifugation after collection and washout out of red cells ("cell saver") is the most commonly used technique. Unfortunately, the use of "cell saver" induces loss of platelets, plasma proteins, and coagulation factors. There is also a time delay associated with processing of the shed blood. Otherwise, in heparinized patients, the use of a cardiotomy suction/reservoir permits the autotransfusion of filtered unwashed whole blood, which has significant advantages due to the preservation of platelets and coagulation factors. Some institutions advocate collection of autologous blood by acute normovolemic hemodilution performed in selected patients usually before or soon after anesthetic induction. Early communication with the blood bank is imperative to ensure that adequate quantities of packed red blood cells (pRBCs), fresh frozen plasma, platelets, and, possibly, cryoprecipitates are available. Five to ten units of pRBCs should be immediately available in the operating room, with a similar number of units available in the blood bank. A similar amount of fresh frozen plasmas, typically in a ratio of one per two or three pRBCs transfused should be readily available in order to avoid further dilution of clotting factors.

The use of moderate heparinization before aortic cross-clamping prevents the initiation of the clotting cascade and reduces the incidence of disseminated intravascular coagulation. Unlike full CPB, a reduced dose of heparin may be used for partial bypass. The potential complications of this approach are bleeding and coagulopathy. Additionally, if heparin is used as an anticoagulant in the cell saver, additional protamine sulfate may need to be administered.

C.3. Describe the surgical approach to TAAA repair.

- *Position*. The surgical approach is typically through the left chest, with the patient in a partial right lateral decubitus position and the hips almost supine to allow femoral cannulation, if necessary.
- *Incision*. The incision is tailored to complement the extent of the aneurysm. For Crawford types II, III, or IV aneurysms, a thoracoabdominal incision is made from the symphysis pubis, extending midline to the umbilicus, curving straight into the costal cartilage and into a posterolateral thoracotomy incision. For types I and IV, a modified thoracoabdominal incision is used, where the incision extends from the umbilicus to the chest and exposes the upper abdominal aorta. In this manner, an aortic cross-clamp can be applied either above or below the renal arteries. In either case, the intra-abdominal portion of the dissection is performed in the retroperitoneal space after the diaphragm is divided.
- *Cannulation for left-heart bypass (LHB)*. Left atrial-to-femoral artery bypass is often used in patients with significant myocardial dysfunction or other systemic disease and in patients with extensive aneurysms that would require prolonged

aortic cross-clamping. Typically, an outflow cannula is placed in the left atrium, and blood is routed through a centrifugal pump to an inflow cannula in the right femoral artery. Unlike CPB, the use of LHB requires reduced heparinization (100 U per kg of heparin approximately 5 minutes before cannulation). The potential advantage of LHB includes improved perfusion of the lower extremities and possibly of the anterior spinal artery through collateral vessels, while the proximal aorta is cross-clamped. The use of LHB therefore minimizes the development of acidosis in the lower extremities, which, in turn, improves hemodynamic stability upon release of the aortic cross-clamp. LHB is typically initiated at a rate of 500 mL per minute, and once the proximal aortic clamp is placed, the flows are adjusted to maintain the proximal aortic pressure above 90 mm Hg or distal mean arterial pressure of approximately 70 mm Hg.

- *Cannulation for CPB with DHCA*. The use of CPB with DHCA obviates the need for proximal aortic cross-clamping and potential spinal cord injury. In some institutions, this is the preferred method for all open repairs. Studies have shown preserved end-organ function (especially renal) as well as decreased paraplegia when a DHCA strategy is utilized. A thorough TEE evaluation is necessary prior to surgery, as this approach is contraindicated in patients with more than mild aortic valve insufficiency as the heart can significantly distend when fibrillation occurs with cooling. Typically, a right femoral venous cannula is placed via either an open approach, or percutaneously using the Seldinger technique prior to positioning the patient in the partial right lateral decubitus position. The venous cannula is advanced into the right atrium using TEE or fluoroscopy for guidance. Arterial cannulation can be obtained at the distal arch, proximal descending aorta, axillary artery, or femoral artery depending on the anatomy of the aneurysm and the planned repair. The pericardium is opened and a left ventricular vent is placed via the left ventricular apex or the left inferior pulmonary vein. During the circulatory arrest, some strategies utilize antegrade cerebral perfusion, direct cannulation and antegrade perfusion of visceral segments, or a combination of the two.
- *Proximal aortic anastomosis*. In type I and II repairs, the proximal thoracic aorta distal to the left subclavian is dissected away from the esophagus in order to prevent a possible esophageal–aortic fistula. Following circulatory arrest (or the placement of proximal aortic cross-clamp if LHB is utilized), an appropriately sized Dacron graft is then sutured proximally to the descending thoracic aorta and checked for hemostasis. Once the proximal anastomosis is completed, the descending aortic graft is cannulated and CPB reinitiated. With each subsequent anastomosis, the clamp can be moved further distally on the graft, sequentially reperfusing visceral segments.

When utilizing the LHB strategy, the aneurysm is opened. The celiac axis, superior mesenteric artery (SMA), and renal arteries are then identified and perfused with special catheters in order to protect the mesentery. The catheters perfusing the kidneys are typically passed through an ice-bath, maintaining the renal artery temperature below 15°C (59°F). Where feasible, reattachment of patent segmental intercostal and lumbar arteries in the T8 to L1 region is then performed. Intercostal arteries in the T4–T8 region are usually ligated if they exhibit excessive retrograde bleeding, indicating good collateral circulation. If the intercostal arteries between T8 and L1 are occluded by intimal atherosclerosis, patent intercostal arteries in the T4–T8 region may be reattached to preserve circulation.

- *Visceral aortic anastomoses*. The visceral aortic anastomoses are evaluated intraoperatively. It is important to avoid a single patch technique to re-implant visceral artery segments, especially in patients with collagen vascular diseases. Therefore, one may employ a specially manufactured multiple branch Dacron graft to anastomose each visceral artery segment individually in an end-to-end manner. This avoids the long-term complications of visceral patch aneurysms seen in many patients with prior TAAA repair. Once the anastomoses are complete, visceral

perfusion is stopped and the cannulas removed. The patient is then placed in a head-down position, the aortic graft flushed proximally, and then the aortic cross-clamp slowly released. The clamp is then moved to the abdominal aortic graft from distal to visceral anastomoses.

- *Distal aortic anastomosis*. The graft is now cut to the appropriate length and is sutured to the infrarenal aorta. Before the completion of the distal anastomosis, the graft is flushed proximally and the aorta distally. The lower clamp is slowly released to restore the pulsatile flow to the viscera. Large patent lumbar arteries can be re-implanted on the graft and smaller lumbar arteries can be ligated.
- *Other techniques*. The "clamp and sew" technique involves clamping the proximal descending thoracic aorta and replacing the aneurysm with a graft. The distal anastomosis to the lower abdominal aorta is then performed without a clamp, allowing the distal aorta to decompress. Although this technique avoids the need for full heparinization, it imposes a time limit on the surgeon as there is no pump to support distal or collateral perfusion.

C.4. What are the specific considerations for anesthetic management of the patient for TAAA repair?

In general, patients with TAAAs have multisystem organ involvement due to the presence of generalized atherosclerosis and other coexisting medical conditions. Initially, the objective is to perform a pre-anesthetic evaluation that detects such comorbidities and assesses the perioperative risks while optimizing the patient's medical status. A careful anesthetic plan should devise a technique that minimizes complications. There should be a clear understanding that this patient population remains at high-risk even with optimal preoperative management given the nature of TAAAs and the surgical procedure (intrathoracic, aortic, and major vascular). Moreover, many patients present on an emergent basis, which precludes ideal preoperative evaluation and optimization, and, in turn, increases the risks for complications.

All antihypertensive and antianginal medications should be continued during the preoperative period to decrease the possibility of myocardial ischemia and aneurysm leakage. Judicious sedation and pain control will offer a similar benefit but clinical signs of complications or neurologic deterioration and organ ischemia (e.g., abdominal pain) can be missed if there is obtundation. Other conditions such as airway protection and risk of aspiration should also be taken into consideration. Importantly, patients can present with established hemodynamic instability and organ malperfusion due to hemorrhage, pericardial tamponade, myocardial ischemia, congestive heart failure, and renal failure.

In addition to extensive hemodynamic monitoring (already discussed) and placement of a urinary catheter, monitoring of differential temperature between central (bladder or rectal) and core (blood or esophageal) compartments is essential. A tympanic or nasopharyngeal probe will approximate brain temperature. A double-lumen endotracheal tube for one-lung ventilation provides optimal surgical exposure,

potentially decreases the injury to the lung by avoiding additional manipulation, and protects the contralateral lung from contamination by blood or other secretions. The method for one-lung isolation varies from one practitioner to another, each providing strong support for his or her preference. Critically important is the ability to provide single-lung ventilation and preparedness to troubleshoot problems as they arise. If placement of a double-lumen tube poses significant risk of aneurysm injury or if there is evident left main bronchus distortion, lung isolation with a bronchial blocker may be a safer alternative. At the end of the surgical procedure, significant airway edema may preclude the exchange of a double-lumen for a single-lumen endotracheal tube.

The main goal of the anesthetic management is to avoid hemodynamic changes that will increase the risk of aneurysm rupture while maintaining adequate end-organ perfusion. In general, the systolic BP should be kept between 105 and 115 mm Hg, the heart rate between 60 and 80 beats per minute, and the cardiac index between 2 and 2.5 L/min/m^2. Short-acting agents such as nitroglycerin, nicardipine, labetalol, or esmolol are ideal for hemodynamic control. Use of nitroprusside is discouraged because it has been associated with a higher risk of neurologic complications. For anesthetic induction, a slow technique with strict hemodynamic control is preferred. Otherwise, a "modified" rapid sequence induction can provide expeditious airway control while keeping stable hemodynamics in indicated cases. In the latter situation, acute hemodynamic changes are more prevalent and rapid titration of medications may be needed. If motor evoked potentials (MEPs) are being monitored, either succinylcholine or a short-acting nondepolarizing agent may be used to facilitate tracheal intubation. Anesthetic maintenance may be achieved using a low concentration of an inhalation agent, combined with an infusion of propofol or short-acting narcotic (e.g., sufentanil, remifentanil). If MEPs are not being monitored, the patient may be fully paralyzed, and inhalation agents with narcotics used.

C.5. What major organ systems are threatened during TAAA repair?

The repair of TAAA is a complex surgical procedure associated with significant multiorgan dysfunction. The main source of morbidity is end-organ ischemia. The most significant determinant of the extent and severity of organ ischemia is the aortic cross-clamp duration, and, to a lesser degree, the extension of aneurysm, which determines the anatomic placement of the aortic clamp. The aortic cross-clamp time is related to aneurysm type, complexity of the repair and surgical technique, and the surgeon's experience.

The main organ systems at risk during TAAA repair are:

- *Spinal cord*. Spinal cord injury is the most feared complication of TAAA repair. Prolonged spinal cord ischemia is the main cause of spinal cord injury, which can result in paraplegia or paraparesis. Factors contributing to spinal cord ischemia include the duration and site of placement of the aortic cross-clamp, presence of pre-existing cord ischemia, prior descending aortic aneurysm surgery, and variability in the spinal arterial supply. There are other associated factors such as reperfusion injury, local metabolic rate, and oxygen supply and demand balance.
- *Kidneys*. Risk factors associated with postoperative AKI in patients with TAAA include: age greater than 50 years, pre-existing renal insufficiency, hemodynamic instability, diffuse atherosclerosis, duration of renal ischemia (>40 minutes), and

massive transfusion. In particular, preoperative CKD or AKI present the greatest morbidity and mortality risk. The principal mechanism of kidney injury is ischemia due to aortic cross-clamping. Other forms of injury include perioperative embolic events due to aortic manipulation and the use of nephrotoxic agents (e.g., intravenous contrast dye or antibiotics).

- *Lungs*. Postoperative respiratory failure is the single most common complication of TAAA repair, occurring in 25% to 45% of patients. One of the main determinants of postoperative respiratory dysfunction is the division of the left hemidiaphragm. Even with proper isolation, the left lung parenchyma is exposed to retraction and compression during surgical dissection. Much of this manipulation occurs after the patient is anticoagulated. Tracheobronchial bleeding can significantly complicate perioperative ventilation. Other significant contributors are phrenic nerve and recurrent laryngeal nerve injuries. Excessive retraction of the lung during dissection of the aortic arch may also lead to disruption of the left main pulmonary artery and is an important cause of acute lung injury. Importantly, a significant number of patients presenting for TAAA surgery have a strong history of tobacco abuse and abnormal pulmonary function studies.
- *Mesenteric organs*. Visceral ischemia occurs with supraceliac aortic cross-clamping. An early effect is triggering of fibrinolysis. Bowel ischemia can also lead to an increase in intestinal permeability with subsequent bacterial translocation, endotoxemia, and sepsis.
- *Heart*. The presence of CAD in patients with TAAA in addition to the abrupt intraoperative changes in preload, afterload, and oxygen carrying capacity subject the heart to profound alterations in myocardial oxygen delivery and consumption. These factors, along with intraoperative acidosis, hypocalcemia, and hypokalemia, can all negatively affect myocardial contractility and conduction—increasing the incidence of perioperative myocardial ischemia or infarction and significant arrhythmias. Aortic aneurysm as well as aortic dissection are both markers of arterial stiffening and commonly associated with both isolated systolic hypertension and increased pulse pressure. Consequently, these patients may be at risk for perioperative major vascular complication due to both long-standing effects of pulsatile injury and inadequate perfusion from "diastolic hypotension." This is particularly true preoperatively where "classic" practice is to lower the systolic component to just above 100 mm Hg without any attention to the diastolic component, which can be critically low (i.e., less than 40 mm Hg).

C.6. What strategies are used for spinal cord protection?

Neurologic deficits can be seen with all types of TAAAs. More specifically, type I and II aneurysms carry the greatest risk of spinal cord injury. The incidence of paraplegia

and paraparesis is secondary to the interruption of blood supply to the spinal cord. As such, spinal cord injury is linearly proportional to aortic cross-clamp time. The risk of spinal cord injury is minimal if the aortic cross-clamp time is less than 15 minutes. In their experience with 1,509 patients, Svensson et al. reported a 20% risk of neurologic injury if aortic cross-clamp time was greater than 60 minutes and less than 10% if the surgical repair was performed in less than 20 minutes. Recent reports have identified increased risk of spinal cord injury when more than eight segmental arteries are sacrificed during TAAA repair. Other associated risk factors for perioperative spinal cord injury are emergency surgery, presence of dissection or aortic rupture, level of aortic cross-clamping, extensive disease, advanced age, and history of renal dysfunction.

The spinal cord perfusion pressure (SCPP) may be estimated as the difference between distal mean aortic pressure and cerebrospinal fluid (CSF) pressure (SCPP = MAP-CSF) (Fig. 8.9). Thus, spinal cord ischemia may be induced by perioperative hypotension, distal aortic hypotension during aortic cross-clamping, injury to the anterior spinal artery, significant increases of CSF pressure, and perioperative hypoxemia. In general, there are several different strategies for spinal cord protection: (1) maintenance of spinal cord perfusion pressure or blood flow; (2) minimization of CSF pressure; (3) attenuation of secondary spinal cord injury after primary ischemic lesion caused by interruption of blood flow; and (4) lowering of body temperature (usually accomplished by allowing "drifting" of body temperature to 34°C).

There are several techniques that can contribute to preservation of spinal cord blood flow such as proximal hypertension to increase the contribution of vertebral artery and collateral flow, reattachment of critical segmental arteries, distal aortic perfusion or LHB, and intrathecal papaverine for spinal cord arterial dilation. Otherwise, sequential aortic clamping with minimal aortic segment exclusion is effective in reducing ischemic time by moving the aortic clamp distally along the graft to restore flow to the recently attached arterial branches, and by placing the aortic clamps relatively close to each other.

The development of strategies to reduce CSF pressure was prompted by the evidence that CSF pressure rises during aortic cross-clamping. This acute increase is attributable to changes in the capacitance veins in the epidural space. The spinal veins collapse when CSF pressure exceeds spinal venous pressure. Thus, CSF drainage is used intraoperatively and postoperatively to minimize resistance to blood flow into

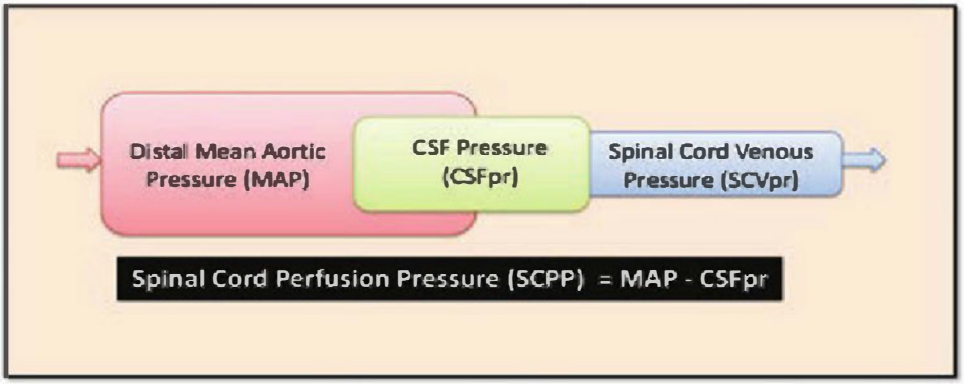

Figure 8.9 Schematic illustration of the hemodynamics governing spinal cord perfusion pressure (SCPP). The distal mean aortic pressure (MAP) must be maintained higher than the cerebrospinal fluid (CSF) pressure for adequate spinal cord perfusion. Elevation of the spinal cord venous pressure above the CSF pressure can also compromise SCPP.

the intrathecal space. In any case, oxygen delivery should be maximized with maintenance of normal hematocrit levels and Pao_2. It has also been reported that surgical retraction of the aortic arch may result in an important increase in CSF pressure.

There are various measures that increase the tolerance of the spinal cord to ischemia such as hypothermia, regional epidural cooling, and pharmacologic adjuncts including barbiturates, high-dose steroids, mannitol, and naloxone. Notably, the recently published 2010 guidelines for the diagnosis and management of patients with thoracic aortic disease recommended CSF drainage as a class I intervention for spinal cord protection in both open and endovascular TAAA repair for patients at high risk of spinal cord ischemic injury. Spinal cord pressure optimization techniques and moderate systemic hypothermia were given a level IIa recommendation. The other above-mentioned adjunctive techniques are class IIb recommendations.

- *Placement of a CSF drain*. Evidence from clinical studies supports the use of CSF drainage. One study concluded that CSF drainage resulted in an 80% reduction in the relative risk of postoperative deficits. An 18-gauge intrathecal catheter is inserted preoperatively via the L2–L3 or L3–L4 interspace. Passive continuous drainage is allowed to a CSF pressure of 8 to 10 mm Hg during the intraoperative and early postoperative period. The target pressure is raised progressively to 10 to 12 mm Hg within the first 48 hours and to 12 to 15 mm Hg once there is confirmation of preserved motor function. Complications include headache, spinal or epidural hematoma, intracranial bleeding, meningitis, and persistent CSF leaks. In this regard, excessive CSF drainage could cause cerebral hemorrhage consequent to massive intracranial fluid shifts or from tearing of cerebral bridging vessels. The rate and amount of volume removed had been found to be an independent predictor of subdural hemorrhage, which has a 50% surgical mortality. Other means of decreasing CSF pressure involve lowering the preload (by increasing drainage or pump blood flow during LHB), use of hyperosmotic agents, and hyperventilation. The potential for complications from CSF drainage limits this technique to patients at the highest risk for paraplegia (Crawford type I and II TAAAs).
- *Distal aortic perfusionc or partial LHB*. The use of LHB reduces spinal cord and mesenteric ischemic time by maintaining distal aortic perfusion. This procedure also serves to unload the left heart and control proximal hypertension during aortic cross-clamping, and enables rapid infusion of intravascular volume. Thus, it minimizes myocardial hemodynamic stress by reducing preload (potentially reducing myocardial ischemic complications) and reducing pressure on the surgeon to complete the proximal anastomosis in a short time. Patients with the most complex repairs benefit the most from LHB. In fact, a retrospective review by Coselli et al. found a reduced incidence of spinal injury only in patients with Crawford type II aneurysm. The incidence of paraplegia or paraparesis was reported as 3.9% with LHB. There are other specific circumstances in which the use of LHB offers clear benefit; anticipated technical complexity of the proximal anastomosis (such as in chronic dissection), anticipated extensive intercostal reconstruction, and involvement of a significant descending thoracic or abdominal aortic segment with possibility of performing distal aortic perfusion.
- *Hypothermia*. Moderate passive hypothermia (core body temperature 32° C to 34° C) is routinely used to limit ischemic damage mainly to the spinal cord and kidneys. This decrease of only 5° C increases the tolerable ischemic interval for the spinal cord 2.5-fold. The benefits of hypothermia are well established and are derived from a complex interaction between decreasing both the spinal cord metabolic rate and its oxygen demand, neuronal membrane stabilization, reduced excitatory neurotransmission, and optimization of microvascular flow. Longer ischemic intervals can be tolerated at lower temperatures as is evident by the use of DHCA for TAAA repair. However, lower levels of hypothermia are associated with the risk of atrial and ventricular fibrillation and other postoperative complications such as shivering, myocardial depression, and coagulopathy. Moderate hypothermia is

achieved easily by passive cooling of the patient in a cold operating room with a major incision. The use of an extracorporeal circuit allows temperature regulation in either direction. Otherwise, selective regional hypothermia can be employed inducing epidural cooling by continuous infusion of cold (at 2° C to 4° C) normal saline (via low thoracic epidural catheter) with significant reduction in the rate of postoperative neurologic deficits.

- *Reattachment of segmental arteries*. Reattachment of patent segmental intercostal and lumbar arteries in the T8 to L1 region is performed whenever feasible. This may require local endarterectomy of the artery's origin. Intercostals in the T4–T8 zone are typically oversewn, unless situated so as to be easily preserved in a beveled proximal aortic anastomosis in Crawford type I, II, or III TAAAs. More extensive reconstructions should be performed in patients with compromised collateral flow (i.e., previous history of abdominal aortic surgery or concomitant iliac aneurysm repair). Some believe that implantation of segmental vessels complicates the surgical procedure and increases the ischemic time without providing clear benefit. More importantly, the prevention of steal from the collateral network that supplies the spinal cord is achieved by temporary occlusion of segmental vessels within the open aorta.
- *Pharmacologic agents*. Several neuroprotective agents have been evaluated. Thiopental can decrease the risk of spinal cord injury by increasing the tolerance to ischemia and permitting longer periods of electrophysiologic silence. However, the use of barbiturates is limited by the high incidence of side effects from myocardial depression and vasodilation at clinically used doses. Recently, manufacturing of thiopental was discontinued and it is no longer available in the United States. A dose of methylprednisolone (30 mg/kg) before and after aortic occlusion may offer spinal protection by decreasing edema and promoting free radical scavenging. Mannitol can also decrease ischemic spinal cord injury by similar mechanisms. Naloxone is used with the purpose of decreasing the metabolic rate (inhibited neuroexcitatory state) of the spinal cord. Other substances being actively studied include memantine, allopurinol, desferrioxamine, activated protein C, insulin-like growth factor 1, riluzole, hydroxyethyl starch, adenosine, prostaglandins, and ziconotide. Of note, there is very little data in humans demonstrating efficacy of the aforementioned strategies.
- *Postoperative management*. Although a majority of spinal cord injuries occur during the procedure, up to 50% of paraplegic events may occur within the first 48 hours postoperatively in patients who had preserved somatosensory evoked potentials (SSEPs) and MEPs levels intraoperatively. In their retrospective review, Etz et al. identified both elevated central venous pressure and hypotension (relative to preoperative BP) during the first 5 postoperative hours to be statistically associated with new onset of paraplegia. Therefore, careful hemodynamic and clinical monitoring immediately after surgery may prevent some spinal cord deficits.

In summary, a multimodal approach for spinal cord protection during TAAA repair is currently the most widely recommended approach (e.g., DHCA, LHB, CSF drainage, aggressive intercostal artery reconstruction, pharmacologic adjuncts, and continuous neurophysiologic monitoring).

C.7. How do you detect spinal cord ischemia?

Evoked potentials may be used to continuously monitor spinal cord perfusion and detect spinal cord ischemia. These modalities of neurophysiologic monitoring are based on the detection of periodic changes of latency and amplitude as a result of a given stimulus. The signals monitored are generated by synaptic transmission of stimulus. In general, a decrease in amplitude or an increase in signal latency is an indicator of synaptic pathway disruption. In addition to ischemia, evoked potentials may also be altered by changes in temperature, anesthetic depth, and blood flow. Two varieties of evoked potentials are commonly used. *SSEPs* are recorded at the scalp as cortical signals that are stimulated at the posterior tibial or peroneal nerves. The potentials travel through the dorsal root ganglia to the posterior columns of the spinal cord and continue along the lemniscal pathways to the thalamus and the cortex. Comparison of the latency and amplitude of the potentials, tested minutes apart, define the degree of change in the SSEP. As changes in blood flow through the anterior spinal artery are not reflected in the posterior columns, it is possible to develop postoperative paralysis despite normal intraoperative SSEPs. Monitoring of SSEPs can be done until the patient is fully awake. In contrast, *MEPs* monitor the function of the corticospinal tract and anterior horn motor neurons, both areas supplied by the anterior spinal artery. The motor cortex is stimulated and the anterior tibial muscle response recorded. MEPs also have the advantage that they respond more rapidly to ischemia than SSEPs. Although injury to the motor pathways is unlikely to occur in the absence of detected changes in SSEPs, the use of only SSEPs has not improved outcomes. Most anesthetic medications decrease the amplitude of evoked potentials and increase their latency. As a general rule, potent volatile anesthetics, nitrous oxide, benzodiazepines, and barbiturates all have major effects in neurophysiologic monitoring. Conversely, opioids only

have mild inhibitory effects on SSEPs and MEPs. Obviously, muscle relaxants have severe effects on MEPs. Propofol has advantages over other anesthetic agents because, in comparison to volatile anesthetics and nitrous oxide, it produces less attenuation of SSEPs at clinical anesthetic levels. Other advantage of propofol is that it does not have a dose-dependent effect on SSEPs or MEPs. As a useful generalization, MEPs are extremely sensitive to most anesthetic agents, whereas SSEPs are only intermediately sensitive. Detection of ischemia by SSEPs, MEPs, or both during TAAA repair should prompt aggressive improvement in hemodynamics by increasing MAP (by proximal hypertension and increasing distal aortic perfusion), decreasing CSF pressure, or increasing oxygen delivery. Otherwise, it should require a modification of the surgical technique. In fact, some surgeons utilize a combination of MEPs and/or SSEPs with provocative maneuvers to induce reversible spinal cord ischemia to identify critical segmental vessels and collaterals that require re-implantation.

C.8. What strategies are used for mesenteric and renal preservation?

A major source of morbidity related with TAAA repair is multiorgan ischemia. Specific techniques used for spinal cord protection have already been previously discussed. Several modalities provide different degrees of ischemic protection ranging from systemic protection from DHCA to other more selective approaches including the use of moderate systemic heparinization, and moderate permissive hypothermia. At an organ specific level, there are a few techniques that benefit the renal and mesenteric circulations: LHB, sequential aortic clamping, cold crystalloid renal perfusion, and selective visceral perfusion.

- *Moderate heparinization*. The administration of heparin (100 IU per kg) before aortic clamping helps prevent e3mbolization, decreases the incidence of disseminated intravascular coagulation and ultimately improves microcirculation. The use of heparin could potentially prevent thrombosis of segmental intercostal arteries, decreasing the incidence of spinal cord infarction. However, increased bleeding and coagulopathy are major disadvantages.
- *Selective visceral perfusion*. Several strategies exist for mesenteric protection. Initially, distal aortic perfusion provides blood flow to renal and mesenteric circulation during the proximal aortic anastomosis. Once the proximal anastomosis is complete, the aortic clamp is moved distally to the infrarenal aorta. Thereafter, the aneurysm is opened while the intercostals, celiac axis, and SMA are reconstructed. In order to reduce the risk of liver dysfunction, pancreatic and bowel ischemia when the aneurysm is open, separate balloon perfusion

catheters may be directly placed into each visceral artery. In the meantime, distal aortic perfusion below the level of the repair is continued. The catheters placed at the origin of the celiac axis and SMA are connected to the LHB circuit by a Y-tubing from the arterial perfusion line. These vessels are then perfused with oxygenated blood from the centrifugal pump while the proximal intercostals and visceral branches are attached to the graft, thereby reducing the mesentery ischemic time. An alternative approach is the use of right atrial–femoral arterial bypass, which has been used with or without oxygenator—like partial LHB. When this approach is selected and no oxygenator is used, blood is returned with a Pao_2 ~ 40 mm Hg (saturation 45% to 65%) and can successfully provide lower body tissue perfusion provided hemoglobin levels are maintained above 10 g/dL.

- *Renal protection*. Renal perfusion may be maintained through the use of distal aortic perfusion during the proximal aortic anastomosis. Selective renal artery perfusion improves outcomes by decreasing the incidence of postoperative AKI. This is achieved by continuous or intermittent infusion of cold (4° C) lactated Ringer's solution into the renal artery ostia when the aneurysm is open, rapidly achieving renal core hypothermia. Some institutions add 25 g of mannitol per liter and 1 g of methylprednisolone per liter to the infusion fluid, which may provide extra protection, as mannitol decreases oxygen renal demand and steroids stabilize cell membranes during the ischemic period. This technique also provides uninterrupted urine output during the procedure. Other pharmacologic adjuncts had been used for renal protection. Patients who received intravenous mannitol before and during aortic cross-clamping had better postoperative diuresis and less glomerular and renal tubular damage. In contrast, there is little evidence to support the use of furosemide as a renal protective agent during TAAA repair. Traditionally, low-dose dopamine (1 to 3 μg/kg/min) had been used due to its potential effects on renal blood flow from dilation of the renal afferent arterioles. These effects are correlated with increased urine output and creatinine clearance, but randomized clinical trials had shown that dopamine does not improve outcomes and provides no more benefit than maintenance of euvolemia during major vascular surgery. Continuous infusion of fenoldopam, a selective dopaminergic agonist, had some promising results in patients undergoing TAAA repair by promoting a more rapid return of renal blood flow and other renal performance parameters postoperatively. Finally, the traditional "clamp-and-sew" technique has been shown to be effective, in selected cases, to shorten aortic clamp times when used by experienced surgeons in referral centers.

In general, the central goal during TAAA repair is to minimize the ischemic time by performing an effective repair which can be better accomplished in a high-volume, tertiary center with availability of an experienced and dedicated operating team.

C.9. Describe the pathophysiology of aortic clamping and unclamping.

Response to aortic cross-clamping

The main consequences of aortic occlusion are profound hemodynamic changes. Proximal arterial hypertension is the most dramatic and consistent component of the hemodynamic response to aortic cross-clamping and is attributed to a sudden increase in afterload. During supraceliac aortic cross-clamping, venous capacitance below the clamp decreases, causing redistribution of venous blood from vascular beds below the level of the clamp. Therefore, preload acutely increases, as manifested by increases in central filling pressures. There is also an increase in contractility secondary to augmented release of catecholamines. Otherwise, there could be a decrease in heart rate. Initially, these increases in afterload, preload, and contractility result in a significant increase in myocardial oxygen consumption that can potentiate myocardial ischemia. Over time, with increasing duration of aortic cross-clamp, systemic vascular resistance increases, and cardiac output decreases. In contrast, infraceliac aortic cross-clamping has a smaller impact on arterial and myocardial filling pressures. Due to the expected sudden increase in preload upon aortic cross-clamping, the preload at time of aortic occlusion should be kept low. It is also important to attenuate the increase in proximal aortic pressure caused by the aortic clamp while considering that SCPP should not be compromised. The use of nitroglycerine for preload control and of sodium nitroprusside (SNP) for proximal arterial pressure control have been well studied. Unfortunately, there is evidence that the use of nitroglycerine alone (with no CSF drainage) and/or SNP (even with CSF drainage) may result in adverse neurologic outcome by compromising SCPP. The use of esmolol is more effective in controlling proximal arterial pressure, with greater SCPP, than the use of SNP. Another method of controlling the sudden increase in afterload is to augment the depth of anesthesia. In this setting, the use of isoflurane results in higher SCPP when compared with SNP, and is associated with a lower incidence of neurologic injury. Probably, the best results in terms of control of preload and proximal hypertension can be accomplished by the use of an extracorporeal circuit where loading conditions of the heart can be controlled by intermittent or continuous drainage into a cardiotomy reservoir. In this regard, the partial LHB circuit can provide reliable modification of these hemodynamic parameters by control of pump flow.

There are associated changes with aortic cross-clamping that occur at multiple levels.

- *SCPP or CSF pressure*. As explained previously, aortic occlusion causes an acute increase in CSF pressure, which combined with a distal decrease in MAP causes a significant decrease in SCPP. The use of vasodilators can further compromise SCPP by causing proximal and distal hypotension and also by a spinal cord blood flow steal phenomenon from the collateral network. In particular, SNP increases CSF pressure and spinal blood flow steal with potentially higher risk of adverse neurologic outcome.
- *Oxygen consumption and tissue perfusion*. Aortic pressure below the cross-clamp is directly dependent on proximal aortic pressure. Blood flow distal to the cross-clamp does not increase when preload and cardiac output are increased. Oxygen consumption below the aortic cross-clamp decreases, while oxygen uptake in tissues above the clamp increases. The subsequent imbalance between oxygen delivery and consumption and lower body hypoperfusion cause a progressive metabolic acidemia caused by increased lactate production.

Response to aortic unclamping

- *Hemodynamics*. The primary hemodynamic response to aortic cross-clamp removal is hypotension, which is attributable to: (1) central hypovolemia caused by blood volume redistribution and pooling into the reperfused tissues; (2) hypoxia-mediated

vasodilation with increased venous capacitance; and (3) release of vasoactive and myocardial-depressant metabolites from ischemic tissues, mainly lactic acid.

- *Hypoxemia*. Following cross-clamp release, a large volume of desaturated blood returns to the heart from hypoperfused tissues below the cross-clamp. However, the transit time through the pulmonary circulation may be inadequate for hemoglobin to fully saturate. The result is temporary systemic hypoxemia.
- *Metabolic*. The physiologic perturbation associated with TAAA surgery can be exaggerated as a result of tissue hypoperfusion, acid-base disturbances, hypothermia, CPB-related effects, pre-existing comorbidities, etc. As such, there should be vigilant monitoring of hemodynamics and inspection of laboratory tests to mitigate the severity of the metabolic disturbances. Severe hyperglycemia can be expected as a manifestation of significant surgical stress response. This fact could make perioperative blood glucose control difficult, more importantly in diabetic patients. Massive transfusions are accompanied by hyperkalemia, hypocalcemia, and if significant perioperative liver dysfunction is present, citrate toxicity.
- *Acidosis*. Removal of the aortic cross-clamp may therefore result in acute metabolic acidosis that may increase ventricular irritability, decrease myocardial contractility, and cause profound vasodilation. The hemodynamic changes resulting from aortic unclamping may be minimized by gradual release of the aortic cross clamp, administration of fluid and vasoactive drugs before unclamping, reducing the depth of anesthesia, and by minimizing the cross-clamp time. The goal is an expedited correction of the hypovolemia, vasodilation, and acidemia. If there is severe and persistent hemodynamic instability, the aorta can be partially or totally re-clamped while further interventions are taken and a delayed, slower clamp release can be performed.

D. Postoperative Management

D.1. What are the potential complications of TAAA repair?

Morbidity and mortality are significantly higher in the elderly and in patients undergoing TAAA reoperation. Postoperative complications may include the following:

- *Myocardial infarction*. The incidence of perioperative myocardial infarction is 7% to 13%, and can result from a continued imbalance between myocardial oxygen supply and demand, especially in patients with known CAD. Pain and tachycardia can increase oxygen demands while hypoxia from respiratory dysfunction, anemia from excessive bleeding, and tachycardia can result in reduced oxygen supply to the myocardium.
- *Respiratory failure*. The likelihood of respiratory complications is increased in surgeries with thoracic and abdominal incisions. Respiratory failure occurs in up to 20% of patients following TAAA repair. Many of these patients have pre-existing pulmonary disease, which may be worsened by the sequelae of one-lung ventilation. The release of vasoactive substances from the ischemic lower extremities and lung hypoperfusion may also lead to interstitial edema. The risk of respiratory failure is increased in the elderly and in patients with a history of COPD, smoking, and cardiac or renal failure.
- *Acute kidney injury*. The incidence of AKI is 3% to 14% after TAAA repair. A cross-clamp duration greater than 30 minutes is the major determinant of postoperative

AKI. Other risk factors include age more than 50 years, CAD, diabetes, an elevated preoperative creatinine, and massive transfusion.

- *Bleeding*. The incidence of reoperation for bleeding is 3% to 5%. Causes of bleeding include heparinization, thrombocytopenia, hypothermia, acidosis, factor deficiency, disseminated intravascular coagulation, chronic hepatic or kidney disease, and coagulopathy from visceral ischemia.
- *Spinal cord injury*. The incidence of paraplegia following TAAA repair is 2% to 40%, and depends on the aneurysm type, surgical technique, and ischemia duration. Paraplegia is increased significantly with emergency surgery and cross-clamp times greater than 30 minutes. Spinal cord injury presents as loss of motor function and sensation.
- *Stroke*. The incidence of stroke following TAAA repair is reported in one series to be as high as 9.6%. However, in centers having high volume of TAAA surgery, stroke outcomes are fewer than 3%.

E. Anesthesia for Endovascular TAAA Repair

E.1. Which patients are candidates for endovascular TAAA repair?

Endovascular TAAA repair is an alternative to conventional open surgical repair. Advantages of endovascular repair include the following: (1) it is less invasive; (2) local or regional anesthesia may be used; (3) the aorta is only briefly occluded; (4) there is minimal hemodynamic and metabolic stress; (5) the patient can ambulate and be discharged earlier; and (6) reduced hospital costs. However, not all patients are candidates for endovascular repair. Patient selection must take into account the surgical risk of "open repair" in patients with significant comorbidity. Furthermore, the proximal aneurysm neck must be at least 15 to 20 mm in length depending on the endovascular device utilized, and the maximum aneurysm diameter should be no larger than the largest available endograft. Often, to achieve sufficient proximal neck length, the left subclavian artery needs to be covered by the endograft. The distal attachment site must also be non-aneurysmal and of sufficient length to accommodate the graft. Finally, there must be at least one large, acceptable iliac artery that can be used as a conduit for graft delivery. Many patients who historically were not candidates for endovascular repair due to visceral segment involvement and/or lack of appropriate iliac artery conduit can undergo "hybrid" procedures with abdominal aortic debranching and/or surgical iliac replacement followed by endovascular repair of their TAAA. However, few long-term outcome data actually compare endovascular repair to other medical and surgical options.

Bergeron P, De Chaumaray T, Gay J, et al. Endovascular treatment of thoracic aortic aneurysms. *J Cardiovasc Surg*. 2003;44:349–361.

Kahn RA, Moskowitz DM, Marin M, et al. Anesthetic considerations for endovascular aortic repair. *Mt Sinai J Med.* 2002;69:57–67.

E.2. What are the surgical steps for endovascular TAAA repair?

The most common point of access is the femoral artery. A small horizontal incision is made in the inguinal fold and the common femoral artery is exposed. Alternatively, an open approach to the iliac arteries or a percutaneous approach from the left or right brachial artery may be used. Brachial artery access is used particularly when the supra-aortic vessels need to be imaged. A puncture is made in the femoral artery and a guidewire inserted and advanced into the thoracic aorta. A 7-French diameter introducer is then placed over the guidewire. A similar introducer may also be optionally placed through the contralateral femoral artery to permit arteriography of the TAAA. The ascension of the delivery system follows removal of the 7F introducer. Once the stent-graft is properly positioned, it is then deployed. If graft extension is needed, one or more complementary stent-grafts may be deployed, with overlap of at least 2 cm between grafts. Finally, there is a global angiographic assessment for any endoleaks, with additional balloon inflation or cuff extension being performed as necessary to complete sealing. The delivery system is then removed and the arteriotomy site closed. For aortic dissections, the endoluminal graft is deployed in the true channel, covering the proximal dissection entry site. Intraoperative TEE and intravascular ultrasound are extremely helpful in confirming exclusion of the false channel.

If the aneurysm extent involves the visceral segments, abdominal debranching allows for improved aortic coverage (Fig. 8.10). In a two-stage procedure utilizing a custom Dacron graft, the visceral vessels are bypassed individually and attached to the iliac artery. This custom graft has a side port for easy inline access for endograft deployment. Typically, abdominal debranching is performed first and then endovascular repair of the aorta is performed later in a staged fashion. The technique for endovascular repair utilizing this strategy is the same as described above with the sole exception that the side port of the debranching graft may be utilized for arterial access in place of the femoral or iliac arteries (Fig. 8.11). This technique increases the availability of endovascular aneurysm repair to those who previously may have required LHB or DHCA to repair their aneurysms.

Hughes GC, Sulzer CF, McCann RL, Swaminathan M. Endovascular approaches to complex thoracic aortic disease. *Semin Cardiothorac Vasc Anesth.* 2008;12:298–319.

E.3. What are the specific anesthetic considerations for endovascular TAAA repair?

The anesthetic approach for endovascular TAAA repair offers similar challenges to the traditional open procedure. In fact, candidates for endovascular repair often have more complex medical conditions and a higher perioperative risk that precludes an open surgical procedure. Although endovascular approaches are less invasive, the above-mentioned issues and the potential need to convert to open surgery warrant additional precautions. The preoperative workup of the patient scheduled for endovascular TAAA repair does not differ from that of the patient scheduled for open surgery. The main goals for intraoperative anesthetic management are to provide

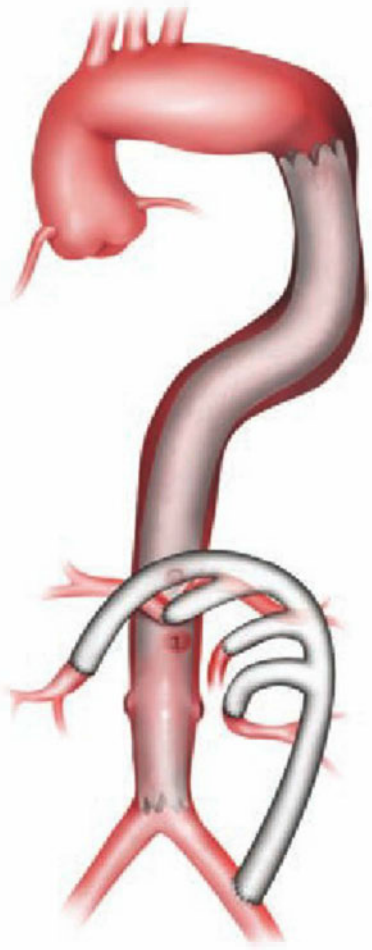

Figure 8.10 Illustration of the "hybrid" thoracoabdominal aneurysm repair with open visceral debranching and concomitant endograft-enabled aneurysm exclusion. (From Hughes GC, Sulzer CF, McCann RL, et al. Endovascular approaches to complex thoracic aortic disease. *Semin Cardiothorac Vasc Anesth*. 2008;12:298–319, with permission.)

hemodynamic stability while preserving cardiac, spinal, renal and mesenteric flow, and to maintain intravascular volume, adequate oxygenation, and normothermia. Large-bore central venous access and a right radial arterial line are recommended. Available locations for vascular access are usually limited as both groins and the left upper extremity are part of the surgical field. The femoral arteries are used for access with large-bore sheaths for both, guidewires/fluoroscopy, and the stent-graft delivery system. If required, the left arm allows proximal access via the brachial artery. Both general and regional anesthesia techniques are suitable for this procedure. General anesthesia with tracheal intubation offers the advantage of airway control in the event of emergent situations. Most commonly, general anesthetic techniques are chosen due to the increasing use of TEE and neurophysiologic monitoring during endovascular

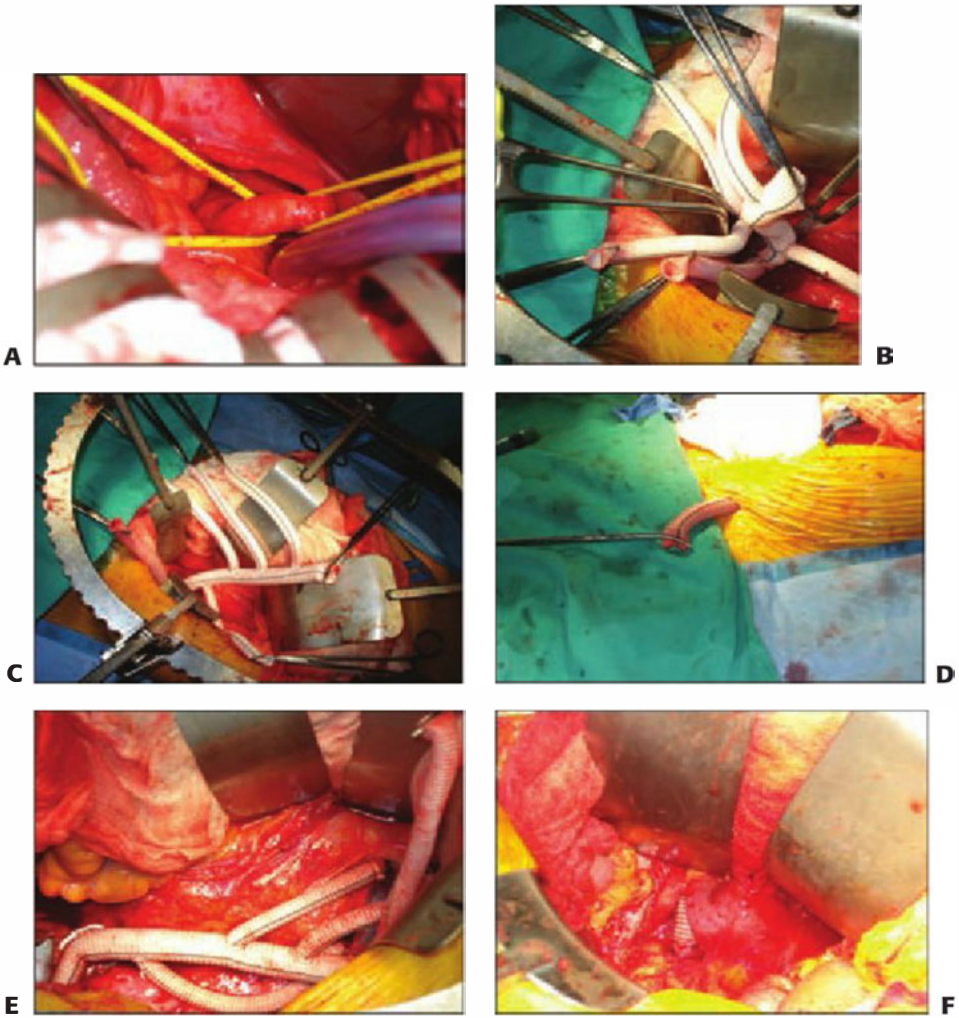

Figure 8.11 Intraoperative photographs of "hybrid" TAAA repair. **A.** The left common iliac artery has been isolated in the pelvis. **B.** The proximal anastomosis of the visceral debranching graft to the left common iliac is completed. **C.** The integral limb for the left renal artery (*bottom of photo*) is shown being put on stretch to evaluate proper length and to avoid kinking. **D.** The antegrade limb of the debranching graft for introduction of the endograft is brought out through a separate stab incision in the left lower quadrant to allow a straighter angle of entry for the endograft into the aorta. This limb will be clipped and oversewn in the abdomen at the completion of the endograft portion of the procedure. **E.** The three left-sided end-to-end anastomoses to the left renal artery, celiac axis, and superior mesenteric artery have been completed. The integral limb for the right renal artery (seen at *right of photograph*) will be tunneled through the lesser sac over to the right renal artery where it emerges beneath the inferior vena cava. **F.** View of completed right renal artery debranching in right upper quadrant of abdomen. (From Hughes GC, Sulzer CF, McCann RL, et al. Endovascular approaches to complex thoracic aortic disease. *Semin Cardiothorac Vasc Anesth.* 2008;12:298–319, with permission.)

procedures. However, regional anesthesia offers an attractive alternative in patients with reduced baseline pulmonary function.

Open and endovascular TAAA repair have comparable rates of spinal cord injury. With endovascular repair, injury is most likely the result of permanent coverage of important intercostal arteries or collaterals supplying the spinal cord. The longer the length of aorta to be covered by the stent, the higher the risk of spinal cord ischemia. According to the 2010 guidelines for the diagnosis and management of patients with thoracic aortic disease, the considerations for CSF drainage during endovascular procedures should be similar to the open approach. CSF drainage is recommended as a class I intervention for spinal cord protection in patients at high risk of spinal cord ischemic injury, regardless of type of surgical procedure.

The most critical phase of the surgical procedure is device deployment. In particular, tachycardia and hypertension should be avoided. Older-generation devices are balloon-based with a large cross-sectional area. As such, these devices are predisposed to distal migration as a result of forward aortic blood flow. Device malposition secondary to inadvertent migration may result either in occlusion of major arterial branches or incomplete aneurysm exclusion. Induced hypotension may be needed to reduce device migration. Other methods include the administration of high-dose adenosine or the induction of ventricular fibrillation to temporarily induce asystole and hence a "still" field. Newer-generation endografts are either thermally or mechanically activated ("self-deploying" stents), which do not require those maneuvers. After stent deployment, position is confirmed, and the proximal and distal ends of the graft are sealed to the aortic wall by a non-occluding endoluminal balloon. During this brief period of aortic occlusion, the patient may experience significant hemodynamic stress, especially if baseline cardiac function is poor. There are other issues specific to endovascular TAAA repair. Importantly, if there is injury of the iliac or femoral vessels, blood loss is difficult to quantify and there may be concealed retroperitoneal bleeding. Endovascular TAAA repair requires the use of substantial amounts of radiographic contrast to assist during deployment of the stent, to assess for proper positioning, to evaluate for full exclusion of the aneurysmal sac, and to exclude the presence of endoleaks. Consequently, contrast-induced nephropathy remains a significant cause of perioperative AKI, which can potentially affect long-term outcome.

TEE is an important diagnostic imaging modality during endovascular procedures for confirming aortic pathology, guiding placement of the endograft, monitoring cardiac performance, and detecting endoleaks after endograft deployment. There is some evidence suggesting that TEE is more sensitive and specific than angiography in detecting endoleaks.

"Hybrid" procedures (combined open and endovascular repairs) provide the benefits of durable repairs in patients with complex anatomy (not suitable for endovascular approach) or previous open surgery. They also reduce physiologic stress when the open approach is contraindicated due to severe comorbidities. However, hybrid procedures pose additional challenges given significant blood, fluid, and heat losses as well as increased risks of embolism, particularly when aortic arch debranching is required (Fig. 8.12). Additionally, "visceral debranching" can result in hypotension due to reperfusion with a consequently higher risk of AKI and mesenteric ischemia due to temporary ischemia and embolism.

Hiratzka LF, Bakris GL, Beckman JA, et al. 2010 ACCF/AHA/AATS/ACR/ASA/SCA/SCAI/SIR/STS/SVM guidelines for the diagnosis and management of patients with thoracic aortic disease: executive summary: a report of the American College of Cardiology Foundation/American Heart Association Task Force on Practice Guidelines, American Association for Thoracic Surgery, American College of Radiology, American Stroke Association, Society of Cardiovascular Anesthesiologists, Society for Cardiovascular Angiography and Interventions, Society of Interventional Radiology, Society of Thoracic Surgeons, and Society for Vascular Medicine. *Anesthesia & Analgesia.* 2010;111:279–315.

E.4. What are the potential complications of endovascular TAAA repair?

- *Hypotension*. The differential diagnosis of acute hypotension after stent deployment includes aortic rupture, allergic reaction to contrast dye, adenosine side effects, or sympathetic nerve blockade, if regional anesthesia is being used. The possibility of acute intraoperative aneurysm rupture is always a real risk, and the anesthesiologist must be prepared for rapid volume resuscitation, including large-bore peripheral and central venous access, arterial line, rapid infusing systems, and vasoactive agents.
- *Spinal cord ischemia*. As mentioned previously, the incidence of postoperative neurologic injury after endovascular TAAA repair is similar to that of open repair. The specific risk factors for spinal cord injury include the length of the deployed endograft and a history of previous repair. CSF drainage, avoidance of hypotension, and steroid administration are recommended in these patients. Intraoperative monitoring of SSEPs and MEPs may provide early clues of spinal cord ischemia. In these cases, pharmacologic augmentation of mean arterial pressure may improve spinal cord perfusion through collateral circulation and decrease the risk of permanent spinal cord damage.
- *Postimplantation syndrome*. This commonly observed postoperative syndrome is characterized by fever, elevated C-reactive protein levels, and leukocytosis. It is usually mild and self-limiting, lasting from 2 to 10 days. Treatment is with nonsteroidal anti-inflammatory agents.

CHAPTER 9

Abdominal Aortic Aneurysm Repair

Anup Pamnani and Lori A. Rubin

THE PATIENT IS A 76-YEAR-OLD MAN

with a 6-cm infrarenal aortic aneurysm discovered on routine physical examination and confirmed by abdominal computed tomography (CT) scan. He is a former smoker and complains of dyspnea on exertion and claudication. His electrocardiogram (ECG) shows Q waves in leads II, III, and avF; chest x-ray film displays mild hyperinflation of the lung fields; and his hematocrit is 46%. His baseline serum creatinine is 1.9.

A. Medical Disease and Differential Diagnosis

1. What are the major causes of morbidity and mortality in the patient with an abdominal aortic aneurysm (AAA)?
2. What other diseases are commonly found in patients with aortic aneurysms?
3. What is the incidence of morbidity and mortality in these patients if they undergo elective open surgical repair? What is the natural history of the disease without surgical repair?
4. What should be done for smaller aortic aneurysms that are found in patients?
5. What is the risk of perioperative myocardial infarction (MI) in patients with ischemic heart disease? What can be done to reduce the risk of ischemic events in these patients?
6. Does the morbidity and mortality of elective repair of an aortic aneurysm differ significantly from that of an emergency repair?

B. Preoperative Evaluation and Preparation

1. Which preoperative laboratory tests would you require for this patient?
2. What is the significance of the preoperative ECG? Would you wish to pursue a preoperative cardiac workup? What tests would you request, and what would they tell you?
3. Is it necessary to evaluate this patient's pulmonary status?

4. Preoperative arterial blood gas (ABG) measurement shows pH, 7.35; $Paco_2$, 47 mm Hg; and Pao_2, 68 mm Hg on room air. What is the significance of this result?
5. How would you measure creatinine clearance in this patient, and what is its value in this case?
6. Describe the blood flow to the spinal cord. What is its relevance to surgery involving the abdominal aorta?
7. How do you detect spinal cord ischemia?
8. What are the various surgical approaches to repair an AAA?
9. How does the choice of surgical technique affect the anesthetic management?
10. How would you premedicate this patient?

C. Intraoperative Management

1. Would you use an arterial line? What are the complications of arterial line placement?
2. What various monitors are available for myocardial ischemia? Is a pulmonary artery catheter (PAC) helpful in determining the occurrence of ischemia?
3. What additional monitors would you employ?
4. Is there a role for somatosensory evoked potential (SSEP) monitoring during aortic clamping?
5. How would you anesthetize this patient for an open repair of the aorta? What techniques could be used for an endovascular aortic aneurysm repair? Discuss the various anesthetic techniques that can be employed for this surgery.
6. This patient is to be heparinized intraoperatively, and anticoagulation may be continued postoperatively. Is this a contraindication to the preoperative placement of either an epidural or intraspinal catheter? What if the patient is receiving anticoagulants in the preoperative period?
7. What are your plans for fluid and blood replacement during surgery?
8. What are the hemodynamic changes of aortic cross-clamp placement? What efforts can be made to minimize these changes both before and during cross-clamping? If the patient develops ST-segment depressions with a rising pulmonary capillary wedge pressure (PCWP) during cross-clamp, what maneuvers should be taken?
9. Because this case involves an infrarenal aneurysm, is renal blood flow affected with the placement of the cross-clamp? If an endovascular repair is chosen, what are the risks to the kidneys? Are there any treatment maneuvers that can be taken to minimize these risks in either repair?
10. What are the hemodynamic consequences of aortic cross-clamp removal? What can be done to minimize the effects of removing the aortic cross-clamp? If the systemic blood pressure remains depressed after removal of the cross-clamp, what is the differential diagnosis? How would you diagnose and correct the problem?

D. Postoperative Management

1. What are the parameters used to extubate this patient?
2. What are the anticipated changes in postoperative pulmonary function in these patients? How does the surgical technique affect postoperative pulmonary function? Are there any postoperative maneuvers that can improve respiratory parameters?
3. How would you control postoperative pain? What are the alternatives in the management of this patient's postoperative pain?

A. Medical Disease and Differential Diagnosis

A.1. What are the major causes of morbidity and mortality in the patient with an abdominal aortic aneurysm (AAA)?

MI is the single most common cause of early morbidity in patients presenting for AAA resection, accounting for approximately 55% of perioperative deaths. Of all patients who suffer a perioperative MI, 70% will not survive. Other postoperative complications include bleeding, renal insufficiency, pulmonary infections and insufficiency, cerebrovascular accidents, hepatic failure, and paraplegia resulting from spinal cord ischemia. However, these events account for less than 1% of the total number of deaths from this operation. Risk factors affecting postoperative mortality are the presence of coronary artery disease (CAD), serum creatinine of greater than 1.2 mg per dL, blood urea nitrogen (BUN) greater than 40 mg per dL, age older than 60 years, emergency surgery, and indicators of poor liver function. Postoperative complications also increase with increasing transfusion requirements and emergency surgery on the abdominal aorta.

Barash PG, Cullen BF, Stoelting RK, eds. *Clinical Anesthesia*. 6th ed. Philadelphia: Lippincott Williams & Wilkins; 2009:1122–1132.

A.2. What other diseases are commonly found in patients with aortic aneurysms?

The major pathologic cause of aneurysmal disease is atherosclerosis. In addition, hypertension (55%), heart disease (73.5%), peripheral vascular disease (21%), stroke and transient ischemic attacks (22%), diabetes mellitus (7%), and renal insufficiency (10%) are the most common comorbid illnesses. It is worth noting that in some studies, smoking history has been reported in as many as 80% of patients presenting for AAA repair. These risk factors, combined with advanced age (greater than 60), are exacerbated by the extreme physiologic changes that occur during aneurysmal surgery.

Cruz CP, Drouilhet JC, Southern FN, et al. Abdominal aortic aneurysm repair. *Vasc Surg*. 2001;35(5):335–344.

Ellis JE, Roizen MF, Youngberg JA. Anesthesia for abdominal aortic revascularization. In: Youngberg JA, Lake CL, Roizen MF, et al., eds. *Cardiac, Vascular and Thoracic Anesthesia*. 1st ed. Philadelphia: Churchill Livingstone; 2000:538–566.

A.3. What is the incidence of morbidity and mortality in these patients if they undergo elective open surgical repair? What is the natural history of the disease without surgical repair?

Morbidity in this patient group is most commonly due to cardiovascular, pulmonary, and renal complications. Perioperative mortality for elective open AAA repair is 2% to 5%. Increased postoperative mortality was associated with older age, elevated serum creatinine, and a lower forced expiratory volume in 1 second (FEV_1). The major cause of death in the nonsurgically treated patient is rupture with a mortality of up to 80%. Ruptured AAAs account for approximately 9,000 deaths per year in the United States. In one study, resection of AAAs doubled life expectancy. The incidence of rupture within 5 years of diagnosis of an AAA is 80%. The incidence of rupture increases with aneurysmal size: 25% for lesions of 4 to 7 cm in diameter, 45% for lesions 7 to 10 cm, and 60% for lesions larger than 10 cm. Repairing aneurysms smaller than 5.5 cm has not been shown to improve survival. Thus, only patients with aneurysms larger than 5.5 cm should be considered for surgical intervention.

After 10 years, graft patency is worse for patients with disease in distal vessels. Mortality is also increased for patients with diseased distal vessels. Survival rate is 28% in patients with isolated aortoiliac disease and increases to 41% in patients with femoral popliteal or tibial disease.

Lederle FA, Kane RL, Macdonald R, et al. Systematic review: repair of unruptured abdominal aortic aneurysm. *Ann Intern Med.* 2007;146:735–741.

A.4. What should be done for smaller aortic aneurysms that are found in patients?

Physical examination and screening, either by abdominal ultrasound or CT scan, uncover many patients with aortic aneurysms less than 5.5 cm in diameter. One study compared patients with smaller aneurysms that were followed until the aneurysm reached 5.5 cm, enlarged by more than 0.7 cm in 6 months, 1.0 cm in 1 year, or were symptomatic from their aneurysm. Mortality was the same in patients randomized to immediate repair or followed closely with no intervention. Aneurysm repair was delayed 4 years in patients who received close monitoring instead of surgical intervention. Therefore, watchful waiting is suggested for aneurysms that are smaller than 5.5 cm.

Lederle FA, Kane RL, MacDonald R, et al. Systematic review: repair of unruptured abdominal aortic aneurysm. *Ann Intern Med.* 2007;146(10):735–741.

A.5. What is the risk of perioperative myocardial infarction (MI) in patients with ischemic heart disease? What can be done to reduce the risk of ischemic events in these patients?

A retrospective analysis confirmed that cardiac mortality is high for patients who undergo vascular surgery and experience postoperative myocardial ischemia. Key factors that determine perioperative morbidity and mortality rates include the stress of surgery (aortic, peripheral vascular, emergency surgery), increased blood loss, poor preoperative cardiac functional status, history of congestive heart failure (CHF), a low ejection fraction, known CAD, and preoperative history of coronary artery bypass grafting.

The occurrence of a recent MI is an important independent predictor of perioperative morbidity and mortality. In a group of patients studied prospectively for perioperative reinfarction by Rao et al., the statistical rate of reinfarction was related to the length of time since the initial MI, decreasing to less than 2% if the infarction occurred more than 6 months earlier. Patients were monitored with PACs and arterial lines and were aggressively treated and monitored in an intensive care unit setting for 3 to 4 days postoperatively. Currently, the acute care for MI has improved and subsequent risk stratification with noninvasive testing allows for a more tailored approach to the timing of surgery in these patients.

Special consideration needs to be given to patients who have recently undergone percutaneous coronary intervention procedures for revascularization of stenotic lesions

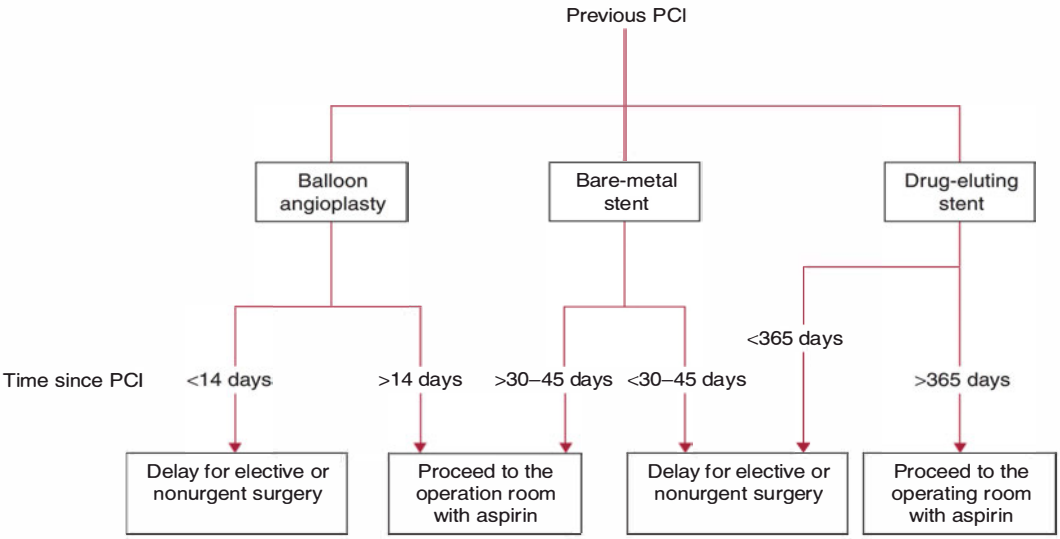

Figure 9.1 Algorithm for patients with previous percutaneous coronary interventions (PCI) for noncardiac surgery. (Adapted from Fleisher LA, Beckman JA, Brown KA, et al. 2009 ACCF/AHA focused update on perioperative beta blockade incorporated into the ACC/AHA 2007 guidelines on perioperative cardiovascular evaluation and care for noncardiac surgery: a report of the American College of Cardiology Foundation/American Heart Association Task Force on Practice Guidelines. *Circulation.* 2009;120:e169–e276.)

and are being treated with platelet inhibitors (Fig. 9.1). Depending on the type of intervention undertaken, balloon angioplasty, bare metal or drug-eluting stent placement, surgery may need to be delayed for a period of 2 weeks to 1 year. This is due to the significant risk of acute stent restenosis or thrombosis in these patients if antiplatelet therapy is terminated prematurely. Caring for patients with coronary stents in the perioperative period requires input from a team consisting of anesthesiologists, surgeons, and cardiologists. The management of the dual antiplatelet therapy regimen should be customized to each patient depending on the type and urgency of surgery, type of coronary stent, time since the coronary intervention, and complexity of the coronary intervention. The current recommendations for perioperative management of patients with DES are shown in Fig. 9.2. For patients identified at high risk for stent thrombosis, surgery should be planned in a hospital with cardiac catheterization facilities. Postoperatively, these patients require a monitored setting and their antiplatelet agents restarted immediately. Signs and symptoms of stent thrombosis should be promptly recognized and aggressively treated with percutaneous coronary intervention.

In most studies, the morbidity following a perioperative MI approaches 50%. The risk after a MI may be best linked to the ongoing risk of ischemia. Patients who have survived a non-Q wave infarction are potentially at great risk for further ischemia. Badner et al. reported a 17% post-myocardial infarction mortality rate after noncardiac surgery. The mortality rate was higher if the ST segment and T-wave changes occurred during the intraoperative period. These patients should be evaluated by symptom-limited exercise testing and/or cardiac catheterization. The prevention of perioperative myocardial ischemia is the goal of the anesthesiologist regardless of the technique chosen. The basic goal is to reduce myocardial oxygen demand by avoiding tachycardia and hypertension, while increasing oxygen supply by preventing hypotension and anemia. Oxygen demand on the left ventricle is dependent on heart

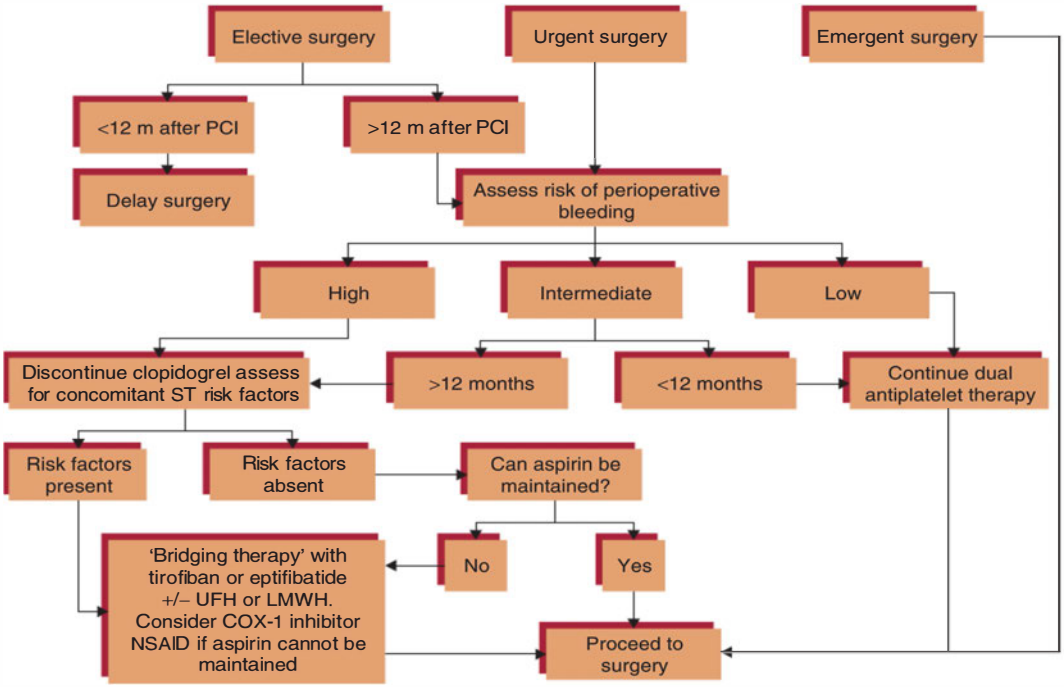

Figure 9.2 Algorithm of perioperative management of patients with DES. COX, cyclooxygenase; DES, drug-eluting stent(s); LMWH, low molecular weight heparin; NSAID, nonsteroidal anti-inflammatory drug; PCI, percutaneous coronary intervention; ST, stent thrombosis; UFH, unfractionated heparin. (From Abualsaud AO, Eisenberg MJ. Perioperative management of patients with drug-eluting stents. *J Am Coll Cardiol Intv*. 2010;3:131–142.)

rate, contractility, and the ventricular loading conditions. Of the three, the increase in heart rate imposes the greatest demand and should be readily controlled by the anesthesiologist. Left ventricular preload and afterload also affect oxygen demand by end-diastolic and systolic wall tension. Other factors, such as coronary collateral blood flow, hematocrit, and blood rheology also may influence myocardial ischemia.

β-Adrenergic antagonists are a well-established class of drugs effective in reducing myocardial oxygen consumption. Some studies suggest that β-blockers reduce perioperative ischemia and may reduce the risk of MI and cardiovascular death in patients undergoing high-risk procedures such as vascular surgery. The mechanism of reduction of myocardial oxygen consumption with β-antagonism is related to decreases in heart rate and myocardial contractility, counteracting the deleterious effects of sympathetic stimulation. In addition, this class of drugs has antiarrhythmic qualities. However, results of recent trials have not shown efficacy of high-dose, acutely administered, perioperative β-blockers to reduce overall mortality in patients undergoing noncardiac surgery. The largest of these trials, the POISE study, did show better perioperative *cardiac* outcomes with β-blocker use, however, *increased mortality* and stroke rate was also noted in the β-blocker group. Interestingly, the sub-analysis of vascular surgery patients in the study, demonstrated efficacy of perioperative β-blockers. Currently, the only class I recommendation for perioperative β-blockers use by the American Heart Association (AHA) is to continue their use in the patients who are already on β-blockers. Patients undergoing vascular surgery

who have multiple risk factors or have reversible ischemia on preoperative testing may benefit from perioperative β-blockers (class IIa). Although there are some differences between the European Society of Cardiology and the AHA guidelines, they both agree that if β-blockers are used for prophylactic purposes, they should be slowly titrated (at least a week prior to elective surgery) and acute administration of high-dose β-blockers in high-risk population is not recommended.

Nitrates also can reduce myocardial oxygen demand by decreasing preload and by dilating large epicardial coronary arteries and collateral conduit vessels. However, the benefit of perioperative nitroglycerin prophylaxis has not been proven.

The use of statins in patients with cardiovascular disease is increasingly supported by multiple studies that display a reduction in the risk of MI, stroke, and mortality. Further, accumulating data suggests that continuation of statin therapy in the preoperative period reduces the risk of postoperative death and acute coronary syndromes. The mechanisms by which statin medications attenuate cardiovascular disease extend beyond their lipid-lowering properties. In addition to anti-inflammatory and antioxidant actions, they also improve endothelial function and stabilize plaques. Thus, current American College of Cardiology (ACC)/AHA guidelines recommend continuation of statin therapy in the perioperative period.

A.6. Does the morbidity and mortality of elective repair of an aortic aneurysm differ significantly from that of an emergency repair?

Overall mortality for a ruptured aortic aneurysm is greater than 50%. One study showed an overall survival rate of 19.8% as compared with an elective surgical survival rate of

95%. The worst prognosis occurred in patients older than 80 years; a systolic blood pressure of less than 80 mm Hg on admission; a prior history of hypertension, angina, or previous MI; and an operating time of greater than 4 hours. Other risk factors include a systolic blood pressure less than 100 mm Hg at the end of surgery and blood loss greater than 11,000 mL. Retroperitoneal rupture was more likely to be associated with a higher rate of survival. Elective surgical intervention should be considered if the size of the aneurysm changes rapidly or if its diameter is greater than 5.5 cm.

B. Preoperative Evaluation and Preparation

B.1. Which preoperative laboratory tests would you require for this patient?

The patient should have the following laboratory tests as part of the preoperative evaluation: complete blood count and platelet count, serum electrolytes, BUN, creatinine, coagulation profile. ABG analysis may be useful, but pulse oximetry can give similar information and $Paco_2$ may be inaccurate if the patient is hyperventilating or sedated prior to obtaining the test. Clues to the degree of chronic hypercarbia may, however, be gleaned from the serum bicarbonate value. A chest radiograph will help ascertain whether signs of heart failure or pulmonary disease are present. Further, it will help assess the degree of pulmonary dysfunction. When significant signs and symptoms of chronic obstructive pulmonary disease (COPD) are present on history and physical examination, a radiograph can help detect underlying pneumonia. In addition, a preoperative chest radiograph can help establish a baseline for comparison should pulmonary complications occur in the perioperative period. Spirometry should be considered in the patient with severe disease and those in whom an adequate medical history is not available. In addition, spirometric data may be useful in assessing the effects of inhaler therapy.

An ECG should be obtained because this patient displays multiple risk factors for ischemic disease. The ECG is a sensitive and simple screening test for active cardiac conditions, such as unstable coronary syndromes and significant arrhythmias, which necessitate further management prior to proceeding to surgery. Additionally, preoperative laboratory tests should be defined by positive findings on history and physical exam.

Roizen MF, Cohn S. Preoperative evaluation for elective surgery: what laboratory tests are needed? In: *Advances in Anesthesia*. St. Louis: Mosby-YearBook; 1993:25–48.

B.2. What is the significance of the preoperative ECG? Would you wish to pursue a preoperative cardiac workup? What tests would you request, and what would they tell you?

The patient's preoperative ECG is consistent with a prior inferior wall MI. Patients with a history of a prior MI or angina in conjunction with an abnormal ECG have a fivefold increase in postoperative mortality when compared with those with no clinical indication of CAD. His history of claudication suggests peripheral vascular disease. Patients with peripheral artery disease have a fourfold increase in risk for MI and a

twofold to threefold increase in risk of stroke than those without peripheral artery disease. If this patient's dyspnea on exertion is a symptom of CHF, this could significantly increase perioperative morbidity. In selected patients with severe or unstable cardiac ischemia, evaluation may be needed to assess if prior myocardial revascularization is indicated.

When coronary angiography was performed on 1,000 patients undergoing elective peripheral vascular surgery, it was revealed that more than half of the patients had significant CAD (greater than 50% stenosis), and 33% had severe stenosis (greater than 70%). Of the asymptomatic patients with no history or electrocardiographic evidence of ischemic heart disease, 15% had severe CAD and 22% of these seemingly normal patients had impaired left ventricular function. Hertzer et al. found that only 8% of patients undergoing elective vascular surgery had normal coronary arteries.

A comparison of this patient's current ECG with a prior ECG may aid in assessing the timing of the previous infarction if the history alone is not helpful. The 2007 update to the joint AHA/ACC guidelines concerning perioperative cardiovascular assessment suggest incorporating clinical risk factors, exercise tolerance, and surgical risk when determining whether further testing is necessary. Vascular surgeries, such as AAA repair, are categorized as high-risk procedures. In addition, clinical risk factors include a history of ischemic disease, compensated or prior heart failure, cerebrovascular disease, diabetes mellitus, and renal insufficiency. The algorithm for the cardiac assessment of patients undergoing surgical procedures associated with a high perioperative cardiac risk is shown in Figure 9.3.

Many vascular surgery patients are unable to undergo exercise stress testing because of limitations presented by their cardiac, pulmonary, or peripheral vascular disease. A dipyridamole-thallium stress test or a dobutamine stress echocardiogram is a pharmacologic test to assess ischemic potential. Dipyridamole causes vasodilation of normal coronary arteries. This results in a "steal" of blood flow from the area beyond a coronary stenosis. Blood flow redistributes as the drug dissipates.

Positive results on preoperative stress testing may not always necessitate revascularization. There is evidence to suggest that vascular patients who undergo coronary revascularization have an increased risk of periprocedural and long-term complications. The decision to perform coronary revascularization procedures, rather than employ medical management, should be undertaken in close consultation with a cardiologist and a cardiac surgeon. Recent evidence also suggests that patients at significant risk for ischemic heart disease may benefit from an endovascular approach, if anatomically feasible.

B.3. Is it necessary to evaluate this patient's pulmonary status?

The patient's smoking history and the chronic changes present on his chest radiograph are evidence of COPD. Provided the patient is minimally symptomatic and has good functional status, a detailed history and thorough physical exam can provide significant information regarding pulmonary status. A chest radiograph can be particularly useful at detecting underlying lung infection. If the radiograph displays the absence of acute pulmonary processes, as in this patient, further pulmonary testing may not be indicated. In the patient with severe signs and symptoms of COPD, an ABG analysis can be particularly helpful. ABG analysis can evaluate the patient's ability to oxygenate and ventilate. Patients with severe COPD tend may be chronically hypercarbic and hypoxic. A preoperative ABG is particularly helpful at guiding perioperative ventilatory management and predicting the likelihood of postoperative mechanical ventilation in these patients.

In those patients with severe disease, particularly those with poor functional status and significant findings on physical exam and chest radiograph, pulmonary function testing may be indicated. Preoperative pulmonary function testing evalu-

ates baseline forced vital capacity (VC) and FEV_1. Maximum midexpiratory flow rate (MMEFR) is an effort-independent value that is a sensitive index of small airway obstruction. Peak expiratory flow rate is related to the FEV_1 and MMEFR, although often it is less reproducible. These tests should be performed before and after bronchodilator therapy to assess reversibility of airway obstruction. A 15% improvement is considered a positive response.

This patient is a 2-pack-per-day smoker with dyspnea on exertion and the anticipated surgery required an upper abdominal incision. These factors likely affect his baseline pulmonary function and presage postoperative ventilatory problems. A VC less than 50% of predicted, or less than 2 L total, is an indicator of increased risk of pulmonary complications as a VC at least three times the tidal volume is necessary for an effective cough. FEV_1 less than 2 L, maximum breathing capacity less than 50% of predicted, and MMEFR less than 50% of predicted are also values associated with increased risk of postoperative mechanical ventilation.

Discontinuation of smoking for 48 hours preoperatively increases oxygen tissue availability and, if stopped 4 to 6 weeks before surgery, may decrease postoperative complications. Pulmonary function tests should be viewed as a management tool to optimize preoperative pulmonary function should not be the sole means of assessing risk. Functional status, severity of illness, and comorbid medical conditions also have significant predictive value.

B.4. Preoperative arterial blood gas (ABG) measurement shows pH, 7.35; $Paco_2$, 47 mm Hg; and Pao_2, 68 mm Hg on room air. What is the significance of this result?

The normal value for Pao_2 in young adults ranges from 85 to 100 mm Hg with an average of about 95 mm Hg. This value falls steadily with aging to an average Pao_2 of 80 mm Hg at age 60. One formula for estimating Pao_2 is $Pao_2 = 100 - (\text{age in years}/3)$. The normal range for $Paco_2$ is 37 to 43 mm Hg and is unaffected by aging. For every 10 mm Hg increase in $Paco_2$, pH decreases by 0.05. For every 10 mm Hg decrease in $Paco_2$, pH increases by 0.1.

The main causes of arterial hypoxemia are hypoventilation, diffusion impairment, shunting, and ventilation/perfusion ($\dot{V}/\dot{Q}$) mismatch. The major causes of hypercarbia or carbon dioxide retention are hypoventilation and $\dot{V}/\dot{Q}$ mismatch. Mild $\dot{V}/\dot{Q}$ mismatch does not necessarily cause an increase in arterial CO_2. This is due to the fact that CO_2 is a highly diffusible gas and central chemoreceptors compensate for increasing CO_2 tension by causing an increase in ventilation. The same is not true of arterial oxygenation, however, as even mild degrees of $\dot{V}/\dot{Q}$ mismatch can lead to hypoxemia.

The assessment of this patient's blood gas analysis reveals moderate hypoxemia with a mildly elevated CO_2 tension. The pH is consistent with a mild respiratory acidosis. The most likely reason for this patient's blood gas abnormality is $\dot{V}/\dot{Q}$ mismatch, secondary to COPD, which is likely the result of his extensive smoking history.

West JB. *Respiratory Physiology*. 8th ed. Baltimore: Lippincott Williams & Wilkins; 2008:55–74.

B.5. How would you measure creatinine clearance in this patient, and what is its value in this case?

Preoperative renal dysfunction indicates potential postoperative impairment. Despite maximal medical management, including hemodialysis, acute renal failure (ARF) after aortic reconstruction carries a mortality of greater than 30% postoperatively. Maintenance of intravascular volume and adequate blood pressure are the best means of avoiding postoperative renal failure. This complication is more likely in patients requiring a suprarenal cross-clamp, but also occurs with infrarenal clamping.

Operative mortality is 19% when aortic reconstruction is performed on patients with a creatinine greater than 2 mg per dL, but mortality is only 4.6% if the levels are lower. Therefore, if the creatinine is greater than 2 mg per dL, reversible factors, such as renal stenosis, should be investigated. The most direct measurement of glomerular filtration rate (GFR) is the measurement of creatinine clearance. Although BUN and serum creatinine are related to renal function, they are altered by such nonrenal factors as protein metabolism, diet, liver dysfunction, or skeletal muscle mass. A 24-hour collection of urine is measured, and the following equation is used to calculate GFR: $GFR = U \times V/P$. U, urine concentration of creatinine (mg per dL); V, volume of urine measured (mL per minute); P, plasma concentration of creatinine (mg per dL). A 2-hour sample collected through a Foley catheter has been shown to correlate well with a 24-hour sample collection.

In spite of the widespread use of creatinine clearance to detect renal impairment, it should be noted that as much as 50% of functional nephron mass may be lost before changes in creatinine concentration become apparent. As a result, patients with lower baseline creatinine concentration can have acute kidney injury (AKI) despite normal creatinine clearance. Several novel biomarkers are being studied now that may be able to detect AKI earlier than traditional markers such as urinary output and serum creatinine. Neutrophil gelatinase associated lipocalin (NGAL) is a protein found in excess in urine and plasma in patients with AKI as many as 48 hours prior to increase in serum concentration. Serum cystatin C, a protease inhibitor that is less affected by sex, age, muscle mass, and diet than creatinine, also allows earlier detection of AKI.

B.6. Describe the blood flow to the spinal cord. What is its relevance to surgery involving the abdominal aorta?

The spinal cord has a system of longitudinal arteries and a system of transverse arteries as shown in Figure 9.4. Anatomic studies have shown that the most important longitudinal arteries are a single anterior spinal artery supplying 75% of the cord and a pair of posterior spinal arteries supplying 25% of the cord. Although in humans the anterior spinal artery is a continuous vessel, modern anatomy has emphasized the importance of the reinforcing transverse arteries rather than the meager longitudinal vessels. The territory supplied by the anterior spinal artery is divided into three functionally distinct levels: cervicodorsal, intermediate or midthoracic, and thoracolumbar. The cervicodorsal region receives its blood supply from the vertebral, subclavian, thyrocervical, and costocervical arteries. The midthoracic region is supplied

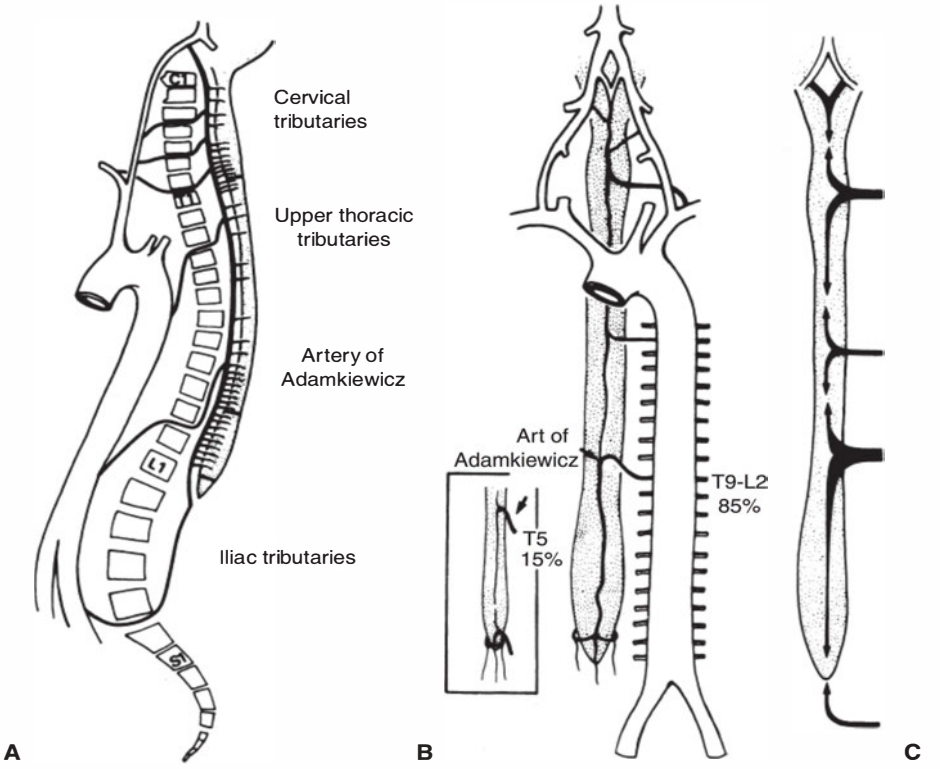

Figure 9.4 Diagram to show components of the anterior spinal artery. **A.** lateral view. **B.** Anteroposterior view showing origins of artery of Adamkiewicz. **C.** Schematic representation of direction and volume of flow from nutrient vessels supplying the anterior spinal artery. Size of arrows is proportional to flow contribution. (Adapted from Bromage PR. *Epidural Anesthesia*. Philadelphia: WB Saunders; 1978:50–54.)

by a meager left or right intercostal artery arising between the fourth and the ninth thoracic vertebrae. The thoracolumbar region of the anterior spinal artery receives its blood supply mainly from one of the intercostal arteries called the arteria radicularis magna or the artery of Adamkiewicz. It arises at the level of T5–T8 in 15%, T9–T12 in 60%, L1 in 14%, and L2 in 10% of patients. The arteria radicularis magna often is involved in the surgical repair.

The anterior spinal artery is smaller above than below the entry of the arteria radicularis magna. Resistance to blood flow is 51.7 times greater going up the anterior spinal artery as compared with coming down the artery. Therefore, distal aortic perfusion during thoracic aortic cross-clamping protects the spinal cord below the arteria radicularis magna but not above it. This is why paraplegia still occurs in approximately 2% to 15% of patients having thoracic aortic surgery with distal aortic perfusion. However, reimplantation of intercostal arteries during surgery has been shown to reduce the incidence of neurologic injury.

Spinal cord ischemia can develop during aortic cross-clamping as a result of one of two mechanisms: decreased blood flow through critical intercostal arteries (important in infrarenal cross-clamping) and hypotension in the aorta distal to the cross-clamp, leading to a "steal" phenomenon through the collateral circulation to

the distal aorta (important in thoracic cross-clamping). There are many strategies to prevent spinal cord ischemia: moderate hypothermia (local and systemic), cerebrospinal fluid drainage, and femoral–femoral bypass. The only definitive methods of preservation are fast surgery and maintenance of cardiac output.

Richenbacher J, Landolt AM, Theiler K. *Applied Anatomy of the Back*. Berlin: Springer-Verlag; 1985:268–280.

B.7. How do you detect spinal cord ischemia?

Evoked potential is used in thoracoabdominal surgery to detect spinal cord ischemia. Two varieties of evoked potential are used in thoracoabdominal aortic aneurysm repair. Somatosensory evoked potentials (SSEPs) travel through the dorsal root ganglia to the posterior columns of the spinal cord. The potentials continue along the lemniscal pathways on to the thalamus and the cortex. Comparison of the latency and amplitude of the potentials, tested minutes apart, define the degree of change in the SSEP. Temperature, anesthetic depth, and changes in blood flow can alter the evoked potentials. Changes in blood flow through the anterior spinal artery are not reflected in the posterior columns. It is possible, therefore, to have paralysis with normal SSEPs.

Ischemia of the spinal cord is indicated by increases in latency and/or decreases in amplitude of evoked potential tracing. The typical SSEP trace is shown in Figure 9.5, and its response to aortic cross-clamping is shown in Figure 9.6. The latency increases as early as 4 minutes following aortic cross-clamping, with progress to cessation of spinal cord conduction within 7 minutes of cross-clamping. Return of spinal cord conduction occurs 47 minutes following distal aortic reperfusion, with return to normal spinal cord conduction within 24 hours after operation. It has been shown that the loss of SSEP signals for longer than 14 to 30 minutes was associated with postoperative neurologic deficit.

Motor evoked potentials (MEPs) do monitor areas of the cord supplied by the anterior spinal artery. To assess motor evoked potential, patients require partial paralysis and light plane of anesthesia. Both of these requirements are suboptimal anesthetic options for a thoracoabdominal aortic aneurysm repair.

Finally, the signal-to-noise ratio of evoked potentials make interpretation of the data in the operating room more difficult and less reliable.

B.8. What are the various surgical approaches to repair an AAA?

The classic approach to the abdominal aorta is through a vertical anterior midline incision with a transperitoneal approach to the retroperitoneal space. This gives access to all major arteries in the abdomen and pelvis. A transverse abdominal incision (supraumbilical) is also adequate for a transperitoneal approach. Although the entry is slower, there is less pain and pulmonary impairment postoperatively. The transperitoneal approach, with the necessary exposure of the abdominal organs, causes major heat and fluid loss and prolonged postoperative ileus.

The retroperitoneal approach is performed through a left flank incision with the patient in the right lateral decubitus position. In some studies, this approach has been shown to have less respiratory and wound complications, less postoperative ileus,

less blood loss, lower fluid requirements, and earlier discharge from the hospital. Monitoring and line placement must take the lateral position into consideration.

A less invasive approach to aortic aneurysm repair is endovascular aortic repair (EVAR) surgery. As stent graft technology improves, this technique is being employed in an increasing number of patients. The EVAR technique has the advantage of a shorter length of stay relative to open repair and a shortened recovery period. Due to the cost of the stents and imaging equipment, this does not necessarily translate to overall cost reduction. Anatomic issues can significantly complicate stent placement. A common problem is iliac and common femoral arteries that are of insufficient caliber. Successful aneurysm exclusion has been achieved in 50% to 90% of selected cases. Problems of the procedure include vessel perforation, inability to seal the aneurysm (endoleaks), and inability to advance the device past the iliac artery, ultimately necessitating the conversion to an open repair.

In the EVAR-1 and DREAM randomized clinical trials, reinterventions were required in two to three times as many patients in the endovascular group as in those who had open repair. Endovascular leaks are one of the leading causes of postoperative complications necessitating reintervention in up to 15% of patients. The various types of endovascular leaks are shown in Figure 9.7. In the EVAR-1 trial, postoperative complications were five times more frequent with endovascular repair when

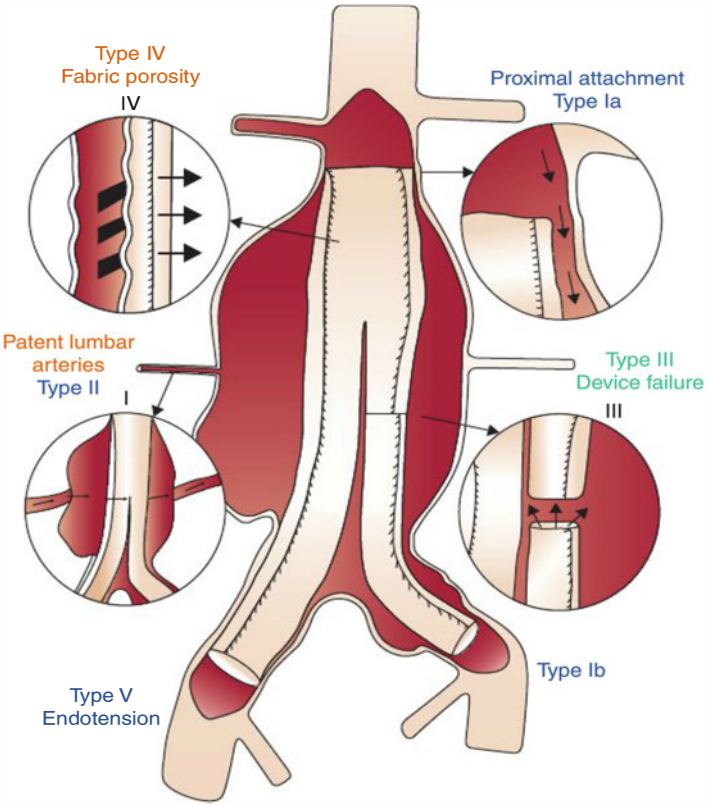

Figure 9.7 Types of endovascular leaks. (Adapted from http://www.vascular.co.nz/abdominal_aortic_aneurysms.htm. Updated July 13, 2009. Accessed June 2, 2010.)

compared to the open repair group. This highlights the importance of close follow-up in these patients and necessitates periodic reimaging for the remainder of these patients' lives. It is also worthy to note that endovascular repair has not been shown to improve survival in patients who have medical contraindication to open repair.

In contrast, when compared with open abdominal repair in the perioperative period, endovascular surgery is associated with 60% less blood loss, sooner extubation, and fewer days spent in the intensive care unit and the hospital in total. Currently, overall mortality of the procedures appears similar, and when using the Eagle criteria as a predictor of adverse cardiac events for patients undergoing major vascular surgery, it appears that a history of CHF and Q waves on ECG are predictive of cardiac events (6% in the open repair group vs. 4.8% in the endovascular group).

B.9. How does the choice of surgical technique affect the anesthetic management?

Debate exists over the advantages of general anesthesia compared with regional anesthesia or combined approaches to the management of patients with CAD. Meticulous control of heart rate and blood pressure should be the goals of any method chosen. Regional anesthesia has the potential to decrease coronary perfusion pressure as sympathetic tone is diminished and general anesthesia risks increases in sympathetic stimulation with intubation and emergence. Regional anesthesia may decrease hypercoagulability and thrombotic events in patients undergoing vascular surgery. In addition, the epidural may be used to prevent the sympathetic stimulation caused by postoperative pain.

The goals for the management of patients with CAD should include prevention and control of the effects of sympathetic nervous system stimulation. This can be achieved by using β-antagonists, narcotics, or volatile anesthetics during the perioperative period. Coronary perfusion pressure, defined as aortic diastolic pressure minus left ventricular end diastolic pressure, should be meticulously maintained. Myocardial contractility and heart rate should not be increased as this will increase oxygen demand.

B.10. How would you premedicate this patient?

The most common problem a patients faces when presenting to the operating room is anxiety. Methods to relieve anxiety need to be individualized for each patient and may vary based on the preference of the anesthesiologist. Any drugs that are given should be titrated to the goals of the induction and surgery and minimize deleterious side effects. Typically, a low-dose anxiolytic is likely to be sufficient premedication for most patients. Any other preoperative medications can be given intravenously upon arrival to the operating room. If oral medications are indicated, they may be taken with a sip of water 1 hour prior to the procedure. In addition, psychological preparation for surgery is an effective technique for reducing preoperative anxiety and should be undertaken by the anesthesiologist.

Additional specific pharmacologic regimens should be tailored to individual patient needs. Various medications and combinations have been used, including narcotics, anticholinergics, barbiturates, and benzodiazepines. No single agent or combination has been demonstrated to be superior to others. Certainly, respiratory depressants should be avoided in patients who are at risk for hypoventilation (e.g., chronic CO_2 retention).

C. Intraoperative Management

C.1. Would you use an arterial line? What are the complications of arterial line placement?

Arterial pressure monitoring is exceedingly important in this case, from induction of anesthesia through emergence. In this patient with a history of CAD, an arterial line is particularly important for blood pressure management during induction and should be placed prior to the institution of anesthesia.

Vascular insufficiency and infection are the two major complications of arterial line placement. Catheter size and duration of cannulation are implicated in vascular occlusion. The causes of most vascular injuries are embolic. Radial artery cannulation is a low-risk, high-benefit method that can be used to closely monitor blood pressure in this patient. Open AAA repair is frequently associated with blood pressure lability, particularly on clamping and unclamping, and arterial blood pressure monitoring is particularly helpful in this situation. In addition, frequent sampling of arterial blood gases to assess hematocrit, ventilation, perfusion, electrolyte levels, glucose, and level of anticoagulation may be necessary. If a radial artery catheter cannot be placed, cannulation attempts can be made at the brachial and axillary arteries. Concerns have been raised that brachial artery cannulation might be inadvisable given the lack of adequate collateral supply to the forearm and hand. In practice, however, complications from brachial artery cannulation have been reported rarely and the risk of vascular insufficiency

appears to be no different from that of radial cannulation. Axillary artery cannulation, however, may carry an added risk of vascular insufficiency and nerve injury from thrombosis and hematoma formation. This added risk is likely due to the fact that the axillary neurovascular bundle travels in the confined space of the axillary sheath.

C.2. What various monitors are available for myocardial ischemia? Is a pulmonary artery catheter (PAC) helpful in determining the occurrence of ischemia?

Monitoring of the patient undergoing aortic reconstruction surgery should be aimed at preserving myocardial, pulmonary, and renal function as well as maintaining intravascular volume. Therefore, it is mandatory, particularly in the patient with known CAD, to monitor for myocardial ischemia and maintain volume status in the face of fluid shifts. Monitoring of the ST segments of the V_5 and II leads of the ECG is the most common method used to assess for intraoperative myocardial ischemia. However, in some studies, this alone was insufficient to recognize from 40% to 75% of intraoperative ischemic events detected by wall-motion abnormalities seen with a two-dimensional transesophageal echocardiogram.

Monitoring the PA pressure tracing for the appearance of V waves and increasing pulmonary capillary wedge pressure (PCWP) with decreasing cardiac output are other methods of detecting intraoperative myocardial ischemia. Unfortunately, the PAC is not a particularly sensitive technique for detecting ischemic events. Wall-motion abnormalities, detected by transesophageal echocardiography (TEE), are highly sensitive markers of myocardial ischemia and appear earlier than either ST segment or PAC waveform changes.

A microcomputer-based ECG reader (ST-segment trend monitor) also has been advocated as a monitor of myocardial ischemia. These systems can pick up more subtle changes in ST segments than by simple observation. Multilead ECG systems are most helpful. The most sensitive means for monitoring patients to determine the development of myocardial ischemia at its earliest presentation is, in fact, wall-motion abnormalities demonstrated by two-dimensional TEE. As yet, no improvement in outcome has been demonstrated by the use of any of these monitors.

C.3. What additional monitors would you employ?

An invasive monitor of volume status is recommended in patients undergoing open AAA repair. The choice of invasive monitoring, central venous pressure (CVP) or PAC can be based on the level of aortic cross-clamping and the severity of the patient's underlying cardiac disease. The CVP is informative only if it is very low or very high. As the right side of the heart is usually a compliant system, large changes in intravascular volume can occur without significant changes in the CVP. The PCWP, as obtained by a PAC, may be more accurate in determining intravascular volume status. In addition, the PAC allows for measurement of cardiac output, which may be helpful during aortic cross-clamp in the patient with left ventricular dysfunction. In this situation particularly, CVP may not accurately reflect left-sided pressures reflected by the PCWP. This is also true of the patient with significant pulmonary disease. The decision regarding placement of a PAC can also be influenced by the level at which the cross-clamp is applied. Suprarenal and supraceliac cross-clamping are associated with greater hemodynamic lability than infrarenal clamp application. Thus, PAC insertion may be of greater value during these procedures, particularly if cardiac dysfunction is also present.

In spite of all the conceptual benefits attributed to the use of PAC, evidence is lacking to recommend a reduction in morbidity and mortality associated with the use of this modality. In addition, the risk of multiple associated morbidities, including pulmonary artery rupture, arrhythmias, and complications associated with introducer placement, should be considered prior to placement of a PAC. The most recent revision of the ASA practice guidelines suggests, however, that the use of PAC may be helpful in carefully selected situations. The guidelines suggest that such monitoring may be beneficial when employed in high-risk procedures (cardiac, aortic reconstruction, anticipated hemodynamic instability, and large-volume fluid shifts), in patients with an acceptable risk for complications from catheter placement and when appropriate staff, familiar with the use and maintenance of such devices, are available. Further, when such monitoring is employed, it should only be utilized by those who are trained to interpret and intervene appropriately based on the data generated.

TEE is another monitoring modality that is being increasingly utilized in aortic reconstruction procedures. TEE has several potential benefits over other invasive monitors such as the PAC and the CVP. Currently, TEE is the most sensitive modality for detecting myocardial ischemia. It is able to detect regional wall motion abnormalities well before changes appear on other heart monitors such as the ECG or PAC. In addition, TEE allows for detailed analysis of valvular dysfunction which may significantly alter perioperative anesthetic management. In fact, certain conditions which can confound PAC data, such as systolic anterior motion of the mitral valve, severe aortic insufficiency, mitral stenosis, and severe left ventricular dysfunction, can be detected easily and quantified by TEE. The ASA practice guidelines for perioperative TEE make specific recommendations guiding the appropriate use of TEE in noncardiac surgery. According to the guidelines, the use of TEE may be appropriate when the nature of the planned surgery or the patient's known or suspected cardiovascular pathology might result in severe hemodynamic, pulmonary, or neurologic compromise. In addition, provided equipment and expertise are available, TEE should be used when unexplained life-threatening circulatory instability persists despite corrective therapy.

Another useful measure of intravascular volume status, as well as renal blood flow, is the collection of urine through a Foley catheter. Urine output will diminish with decreasing glomerular filtration caused by decreased renal blood flow. Assessment of urine output, provided kidney function is unimpaired, can be an accurate and cost-effective measure of volume status.

Temperature monitoring should also be employed as with any case under general anesthesia. Body temperature should be closely monitored and aggressively maintained. These patients can undergo tremendous heat and insensible fluid loss as a result of the enormous surface area of the bowel exposed to room air. If forced hot air thermal blankets are used, they are contraindicated on the lower extremities when an aortic cross-clamp is applied. They may, however, be used on the upper body throughout the procedure, along with fluid warmers, to maintain temperature.

Finally, pulse oximetry, capnography, and mass spectral analysis of inhaled agents also should be employed. This data combined with ABG analysis, derived from the arterial catheter, can allow for efficient ventilatory management and accurate delivery of anesthetic gases.

C.4. Is there a role for somatosensory evoked potential (SSEP) monitoring during aortic clamping?

SSEPs can be used during aortic reconstruction surgery to monitor spinal cord function. For thoracic aortic surgery, SSEPs remain stable if the distal aortic pressure is maintained above 60 mm Hg. At lower pressures, SSEPs disappear gradually. In one study, paraplegia occurred in five of six patients whose SSEPs remained absent for more than 30 minutes. Patients should be monitored for SSEP changes if they are at higher risk of spinal cord ischemia. SSEPs are changed or lost with aortic cross-clamp most commonly in those patients who are already at increased risk for neurologic complications. Higher (especially thoracic) or prolonged cross-clamp placement also places the patient at increased risk for development of spinal cord ischemia. With a conduction block in place, such as epidural or spinal anesthesia, SSEPs will be ablated.

C.5. How would you anesthetize this patient for an open repair of the aorta? What techniques could be used for an endovascular aortic aneurysm repair? Discuss the various anesthetic techniques that can be employed for this surgery.

All anesthetic techniques have been used and advocated for abdominal aortic surgery. Pure general anesthesia, combined general and regional techniques, and pure regional anesthesia all have been described. Outcome studies seem to indicate no particular difference between the techniques or agents used. Benefits and disadvantages can be argued regardless of technique, thus, allowing the anesthesiologist some flexibility in the anesthetic approach to these patients. Tailoring the anesthetic approach to the individual patient's medical condition, however, is the most effective strategy. The primary goals in the anesthetic management of patients undergoing aortic reconstruction include protection of myocardial, neurologic, and renal function. In patients with ischemic heart disease, a slow heart rate is exceedingly beneficial. Thus, anesthetic techniques in these patients should be constructed with this goal in mind.

When combined regional (epidural) and general anesthesia techniques are employed, fluid requirements may be increased in order to maintain hemodynamic stability. Typically, this additional fluid requirement can be up to 2 L per case. In addition, the sympatholysis induced by the epidural anesthetic can predispose to hypotension on clamp removal. The use of an α-agonist to provide vasoconstriction, however, can be particularly effective at counteracting the vasodilatory effects of epidural anesthesia and may reduce fluid requirements as well as episodes of intraoperative hypotension. In addition, the placement of an epidural catheter may also be of benefit for postoperative pain management of the patient.

Anesthesia for endoluminal repair has ranged from general, general combined with epidural anesthesia, lumbar epidural with sedation, or sedation with local anesthesia. Considerations for choice of anesthesia include the need to have the patient remain perfectly still for an extended period, the need for intravenous anticoagulation (heparin), the possibility of massive blood loss, and prevention of heat loss. It is important to keep blood pressure controlled during the time of balloon occlusion of the aorta to prevent distal migration of the stent. If neuraxial techniques are used, coagulation status must be carefully monitored in the perioperative period.

C.6. This patient is to be heparinized intraoperatively, and anticoagulation may be continued postoperatively. Is this a contraindication to the preoperative placement of either an epidural or intraspinal catheter? What if the patient is receiving anticoagulants in the preoperative period?

There is concern that placement of an epidural catheter in a patient to be anticoagulated increases the risk of an epidural hematoma and subsequent neurologic

deficit. For those cases in which there is significant risk of spinal cord ischemia, the diagnostic confusion of epidural hematoma versus cord ischemia may preclude the placement of an epidural catheter. However, an epidural catheter can be placed with a relative degree of confidence in patients who are not anticoagulated at the time of the puncture but who will receive anticoagulation later. Current guidelines suggest administration of intravenous heparin at least 1 hour after neuraxial catheter placement. Further, in patients who have undergone systemic heparinization, heparin should be discontinued for at least 2 to 4 hours prior to neuraxial catheter removal, coagulation status assessed before catheter manipulation, and careful assessment of the presence of sensory and motor function in the lower extremities for at least 12 hours after catheter removal.

Low molecular weight heparins (LMWHs), which are increasingly being employed for thromboprophylaxis, pose a significant potential for increased risk of neuraxial hematoma. In patients receiving these drugs, needle placement should occur at least 12 hours after the last dose of LMWH. If higher doses have been used (e.g., enoxaparin 1 mg/kg twice daily), needle placement should be delayed at least 24 hours. It is currently recommended that indwelling catheters be removed prior to initiation of LMWH thromboprophylaxis. In addition, the first dose should be administered at least 2 hours after catheter removal.

In those patients who are on chronic anticoagulation with oral warfarin, several recommendations are applicable with regard to perioperative management of neuraxial anesthesia. Oral warfarin should be discontinued at least 4 to 5 days prior to surgery. International normalized ratio (INR) should be measured at least 24 hours prior to the procedure. Neuraxial placement should only occur if INR has normalized. Neurologic testing of sensory and motor function should be performed routinely during epidural analgesia for patients on warfarin therapy. The type of analgesic solution should also be tailored to minimize the degree of sensory and motor blockade so as to allow frequent neurologic monitoring. As thromboprophylaxis with warfarin is reinitiated in the postsurgical period, neuraxial catheters should be removed while the INR is less than 1.5.

Fibrinolytic and thrombolytic drugs predispose to a high risk of hematoma formation when neuraxial anesthesia is employed. Previous guidelines based on the original contraindications for thrombolytic drugs suggested avoidance of these drugs for 10 days after puncture of noncompressible vessels. However, the third edition of ASRA practice guidelines, addressing regional anesthesia in the anticoagulated patient, recommends avoidance of all neuraxial techniques in patients who have received thrombolytic or fibrinolytic therapy. There appears to be no clear data detailing the length of time neuraxial puncture should be avoided after discontinuation of these drugs.

While the use of antiplatelet agents such as aspirin and NSAIDs do not contraindicate the use of neuraxial techniques, care should be exercised when combinations of anticoagulants and antiplatelet drugs are used. Such combinations increase the risk of hemorrhagic complications in the perioperative period and may necessitate longer waiting periods during which neuraxial puncture should be avoided after discontinuation of medications. Neurologic testing of sensory and motor function should be routinely performed on patients with indwelling catheters undergoing simultaneous anticoagulation. Again, analgesic solutions should be tailored to minimize sensory and motor changes to allow for close neurologic monitoring.

C.7. What are your plans for fluid and blood replacement during surgery?

Fluid replacement should be aimed at maintaining the patient's intravascular filling pressures. The use of an invasive hemodynamic monitoring may simplify this matter greatly. In most patients, isotonic crystalloids should be used. There is little evidence to suggest that colloid administration poses any advantage over crystalloid administration.

There has been much controversy in recent literature regarding the use of "liberal" versus "restrictive" fluid protocols during open abdominal procedures. Most of this data has been gathered on patients undergoing bowel procedures, nevertheless, these models are likely applicable to the patient undergoing open AAA repair. Much of the controversy has centered on a lack of consensus regarding a predefined optimal fluid management protocol. What has emerged from this data, however, is the notion of using fluid therapy to optimize tissue perfusion rather than predefined volume replacement models.

Current paradigms for fluid management for open abdominal procedures suggest a shift away from the classic model of preoperative fluid deficit and routine replacement of high insensible losses and third space losses. Increasingly, most clinicians are employing "demand-related" regimens with the goal of maximizing tissue blood flow yet minimizing interstitial edema. Intravascular losses are replaced by timely fluid and blood product administration as measured by visual blood loss, vital signs, urinary output, hematocrit and acid–base status, and invasive hemodynamic monitoring (as available). Insensible losses are replaced at a significantly lower rate, typically 0.5 to 1 mL/kg/hr, than the traditionally higher estimates previously used. Further, the traditional concept of a third-space compartment is increasingly being abandoned. Instead, it is now being recognized that fluid shift into the interstitium is primarily related to crystalloid overload and deterioration of vascular permeability. Thus, fluid regimens should be tailored toward judiciously maintaining intravascular volume while minimizing edema rather than filling a theoretical compartment that does not appear to exist.

The concurrent use of an autotransfuser (e.g., Cell Saver) decreases the need for homologous blood transfusions. Overtransfusion of blood products should be avoided because multiple long-term complications, such as delayed hemolytic transfusion reaction, immune suppression, transmission of infectious organisms and lung injury, have been associated with blood product administration. With the hemodynamic changes associated with aortic cross-clamping, it is vital to maintain adequate intravascular volume to ensure adequate renal perfusion and normotension after removal of the cross-clamp.

C.8. What are the hemodynamic changes of aortic cross-clamp placement? What efforts can be made to minimize these changes both before and during cross-clamping? If the patient develops ST-segment depressions with a rising pulmonary capillary wedge pressure (PCWP) during cross-clamp, what maneuvers should be taken?

The systemic hemodynamic response to aortic cross-clamping is shown in Figure 9.8.

Arterial hypertension is the most dramatic and consistent result of the application of an aortic cross-clamp. This is easily envisioned as a result of a sudden increase

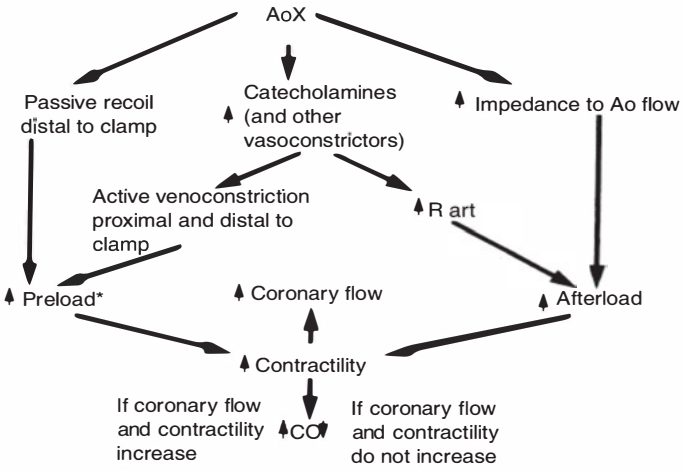

Figure 9.8 Systemic hemodynamic response to aortic cross-clamping. Ao, aortic; AoX, aortic cross-clamping; R art, arterial resistance; ↑ and ↓ , increase and decrease, respectively. *Different patterns are possible. (From Gelman S. The pathophysiology of aortic cross-clamping, and unclamping. *Anesthesiology*. 1995;82:1026-1060, with permission.)

in afterload resulting in increased left ventricular end-diastolic wall stress and systemic arterial pressure. Usually these changes are accompanied by decreased cardiac output. Some of these changes may also be due to redistribution of blood volume from the venous vasculature to the upper part of the body. All of the previously stated factors are more profound in the case of supraceliac or thoracic cross-clamp placement. Variations in blood volume status or splanchnic vascular tone are affected by the depth of anesthesia, type of anesthestic, and intravascular volume status. These factors all help determine the pattern of blood volume redistribution.

A sudden increase in afterload can lead to left ventricular failure, particularly in the patient with a noncompliant left ventricle. Ideally, the patient should have lower filling pressures for the half hour prior to cross-clamp placement. This helps to minimize the adverse response to the sudden increase in afterload. The PAC is helpful in accurately assessing and maintaining preclamp values for the left side of the heart. A potent anesthetic agent and/or a vasodilator such as nicardipine is used to return afterload to near normal. This also helps increase the cardiac output and decrease stress on the left ventricle. If this is insufficient to reverse left ventricular failure, the addition of an inotrope may be necessary.

The increase in afterload, following cross-clamp placement, may also result in myocardial ischemia. Ischemia, reflected as a rising PCWP and ST-segment depressions, can be managed with intravenous nitroglycerin, a potent dilator of the capacitance vessels. This drug is used to decrease left ventricular end-diastolic volume and left ventricular end-diastolic pressure. Decreasing left ventricular end-diastolic pressure also decreases the transluminal pressure across the coronary vasculature. This increases blood flow to the myocardium.

Ellis JE, Roizen MF, Youngberg JA. Anesthesia for abdominal aortic revascularization. In: Youngberg JA, Lake CL, Roizen MF, et al., eds. *Cardiac, Vascular and Thoracic Anesthesia*. 1st ed. Philadelphia: Churchill Livingstone; 2000:538–566.

C.9. Because this case involves an infrarenal aneurysm, is renal blood flow affected with the placement of the cross-clamp? If an endovascular repair is chosen, what are the risks to the kidneys? Are there any treatment maneuvers that can be taken to minimize these risks in either repair?

ARF after aortic aneurysm repair is associated with a mortality of greater than 30%. Decreased renal function is observed in many patients after aortic cross-clamping, even when the clamp is placed distal to the renal arteries. Although it is clear that a suprarenal cross-clamp will decrease renal blood flow up to 80%, an infrarenal cross-clamp also causes a decrease in renal cortical blood flow with an associated decrease in GFR. The degree of decrease in urine output does not correlate with the decrease in GFR nor does it predict postoperative renal failure. The most dangerous complication of alteration in renal blood flow is acute tubular necrosis and ARF.

The maintenance of cardiac output and adequate circulating blood volume is of prime importance in sustaining renal blood flow and in the prevention of renal failure. Low-dose dopamine (2–3 μg/kg/min) increases renal blood flow and may improve urine output, although decreased incidence of postoperative renal failure has not been proven. Renal protection may, however, be provided by the administration of mannitol (0.25 g/kg). The use of mannitol attenuates the reduction of renal cortical blood flow before, during, and after renal ischemia, causes a concurrent increase in glomerular ultrafiltration pressure, which increases the GFR, and is a hydroxyl free radical scavenger. Drugs such as fenoldopam and furosemide are also occasionally used during aortic reconstruction procedures with the hope of preventing renal injury. Unfortunately, strong clinical evidence is currently lacking for any of these measures.

During endovascular repair, the use of radiocontrast material may cause further insult to the kidneys. There is some suggestion that the use of a bicarbonate infusion or pretreatment with N-acetyl cysteine maybe protective. It is prudent to minimize the use of nonionic contrast or to use gadolinium dimeglumine if possible for imaging.

C.10. What are the hemodynamic consequences of aortic cross-clamp removal? What can be done to minimize the effects of removing the aortic cross-clamp? If the systemic blood pressure remains depressed after removal of the cross-clamp, what is the differential diagnosis? How would you diagnose and correct the problem?

The hemodynamic response to aortic unclamping is shown in Figure 9.9.

During cross-clamping, blood flow to the lower extremities is grossly decreased. Metabolism switches from aerobic to anaerobic as ischemia develops. This results in maximal vasodilation and lactic acid production. When the cross-clamp is released,

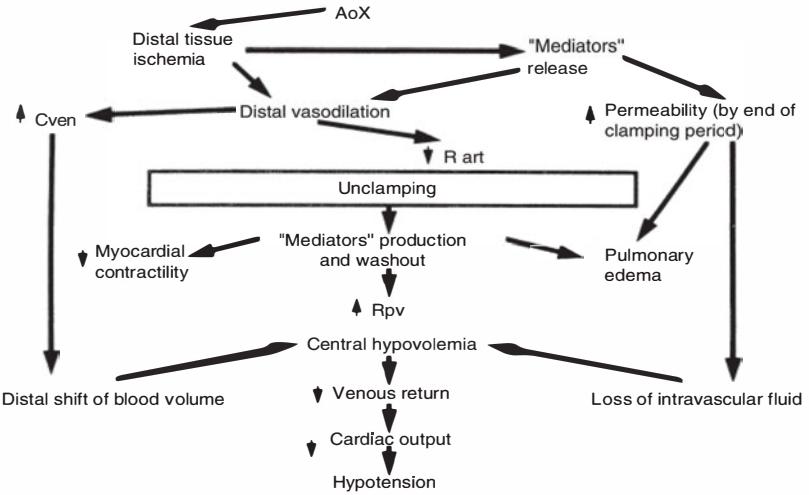

Figure 9.9 Systemic hemodynamic response to aortic unclamping. AoX, aortic cross-clamping; Cven, venous capacitance; R art, arterial resistance; Rpv, pulmonary vascular resistance; ↑ and ↓, increase and decrease, respectively. (From Gelman S. The pathophysiology of aortic cross-clamping and unclamping. *Anesthesiology.* 1995;82:1026–1060, with permission.)

systemic vascular resistance and arterial blood pressure decreases dramatically. Reactive hyperemia is a consequence of unclamping. This may be the result of arterial relaxation (myogenic mechanism), an accumulation of vasodilating substances below the occlusion, or anoxic relaxation of smooth muscles. Peripheral vasodilation can result in relative volume depletion and hypotension. Vasodilation may become systemic as the lactic acid is washed out of the extremities into the central circulation. This condition is sometimes known as "declamping shock."

To minimize the hypotensive response, volume loading in the period prior to cross-clamp release is suggested to raise filling pressures to slightly above normal. Vasodilators such as nitroprusside and/or nitroglycerin during this period allow additional volume loading with maintenance of filling pressures. In addition, gradual release of the clamp allows time for adjustments in volume, pressors, and correction of acidosis.

Sometimes, even in the face of adequate volume loading, the blood pressure remains low following cross-clamp removal. The more cephalad the cross-clamp is placed, the greater the incidence of this problem. In this situation, it is advisable to ask the surgeon to reapply the aortic cross-clamp to varying degree depending on the severity of hypotension. Such maneuvers allow more time for correction of blood volume or acidosis.

Other causes of sustained hypotension in the face of adequate management include a continued site of hemorrhage and myocardial ischemia and/or failure. Measurement of filling pressures or use of TEE can particularly help in the differentiation of the etiology of sustained hypotension. Ischemia or failure can be detected by wall motion abnormalities or elevated filling pressures accompanying systemic hypotension. In contrast, hemorrhage is diagnosed by low filling pressures and increased systemic vascular resistance (due to reflex vasoconstriction).

D. Postoperative Management

D.1. What are the parameters used to extubate this patient?

Once the patient is awake and alert, has an adequate gag reflex and displays signs of adequate reversal of neuromuscular blockade, the following ventilatory criteria can be used to assess suitability for extubation: The patient is suitable for extubation once he is awake and alert, has an adequate gag reflex, displays signs of adequate reversal of neuromuscular blockade, and meets minimum respiratory parameters for extubation. The typical respiratory parameters used to assess suitability for extubation are shown in Table 9.1.

It is important to recognize that such parameters should serve merely as a guide in the clinical assessment of suitability for extubation. The decision to extubate ultimately should be guided by assessment of the patient's overall status and clinical judgment. Extubation may need to be delayed in those patients who display labored breathing on physical exam, inadequate pain control, or hemodynamic instability.

Perioperative fluid management also should be carefully considered when assessing a patient's suitability for extubation. For shorter cases with minimal anticipated fluid shifts, the patient can be extubated in the immediate postoperative period. For longer cases, instances of large volumes of fluid replacement and significant blood product administration, extubation should be delayed until the hemodynamics are stabilized and temperature is normalized. In these cases, airway swelling also can be a significant concern and may lead to ventilatory failure in the postoperative period. A "cuff leak" test may be somewhat indicative of the degree of airway edema. It is performed by occluding the endotracheal tube of a spontaneously breathing patient and auscultating for breath sounds with the cuff deflated.

Kurup V. In: Hines RL, Marschall KE, eds. *Stoelting's Anesthesia and Coexisting Disease*. 5th ed. Philadelphia: Churchill Livingstone; 2008:184–191.

Table 9.1 Typical Respiratory Parameters Used to Determine Suitability for Extubation

Vital capacity greater than 15 mL/kg
pH greater than 7.30
Pa_{O_2} greater than 60 mm Hg at F_{IO_2} less than 50%
Pa_{CO_2} less than 50 mm Hg
Maximal negative inspiratory force greater than −20 cm H_2O
Stable hemodynamic status
Respiratory rate less than 30 breaths per minute

D.2. What are the anticipated changes in postoperative pulmonary function in these patients? How does the surgical technique affect postoperative pulmonary function? Are there any postoperative maneuvers that can improve respiratory parameters?

The transabdominal approach to the aorta involves an upper abdominal incision. Total lung capacity and its subdivisions decrease after upper abdominal surgery. VC decreases 25% to 50% and returns to normal in 1 to 2 weeks, and residual volume increases 13%. Functional residual capacity declines 30% and recovers over 3 to 4 days. Expiratory reserve volume declines 20% after lower abdominal surgery and up to 60% after upper abdominal and thoracic incisions. Tidal volume decreases 20% on the first postoperative day and gradually returns to normal. The retroperitoneal approach to the aorta involves a flank incision, which leads to far less respiratory compromise.

In a series of adult men undergoing abdominal surgery, postoperative pulmonary complications occurred more frequently than cardiac complications (9.6% vs. 5.7%) and were associated with significantly greater length of hospitalization. Many of these complications are related to disruption of the normal activity of the respiratory muscles, from the beginning of the anesthetic to the postoperative period. In addition, the effects of surgical trauma are most pronounced after upper abdominal surgery. Lower abdominal and thoracic incisions impact the respiratory muscles to a lesser degree. This occurs through surgical disruption of the respiratory muscles, postoperative pain, and abdominal contents, preventing normal movement of the diaphragm. The resulting respiratory pattern is that of shallow rapid breaths without sighs.

Although regional anesthetic techniques have the potential to improve pain and reflex inhibition of respiratory muscles, they also may significantly alter postoperative respiratory muscle function. The overall effect of postoperative regional analgesia on the pattern of breathing may be complex, but it is thought that epidural analgesia may decrease the risk for postoperative pulmonary complications. Ambulation and control of postoperative pain diminish splinting and help maximize respiratory parameters. Maneuvers to encourage deep breathing are of proven benefit.

Warner DO. Preventing postoperative pulmonary complications. The role of the anesthesiologist. *Anesthesiology*. 2000;92:1467–1472.

D.3. How would you control postoperative pain? What are the alternatives in the management of this patient's postoperative pain?

The goal of effective postoperative pain relief is to produce a high quality of pain control with the fewest number of side effects and complications. Neuraxial analgesia in the immediate postoperative period is the preferred method of pain management in this high-risk patient population. The ideal opiate, its concentration, and combination with local anesthetic have yet to be defined. (For suggested protocols, see Table 9.2.)

Complications of the epidural route of analgesia include dural puncture, epidural hematoma, and epidural abscess. The risk of epidural hematoma is small in patients receiving appropriate doses of anticoagulation postoperatively but is prohibitively high in patients receiving thrombolytic treatment or LMWHs. Careful consideration should be given to the timing of insertion and removal of the catheter. The risk of complications is similar whether the catheter is placed at the thoracic or lumbar level. Other complications include pruritus, nausea, urinary retention, and delayed respiratory depression. The latter is less than 1% when epidural morphine is used, similar to

Table 9.2 Epidural Opioid/Bupivacaine Combinations Administered by Continuous Infusion[a]

DRUG COMBINATIONS	SOLUTION[b]	BOLUS DOSE OF BUPIVACAINE	BASAL INFUSION[c]	BREAKTHROUGH DOSES	INCREMENTS IN BREAKTHROUGH[d]
Morphine	0.01%		6–8 mL/h	1–2 mL every 10–15 min	1 mL of the solution
Bupivacaine[e]	0.05%–0.1%	0.5%–0.25%			
Hydromorphone	0.0025%–0.005%		6–8 mL/h	1–3 mL every 10–15 min	1 mL of the solution
Bupivacaine[f]	0.05%–0.1%	0.5%–0.25%			
Fentanyl	0.001%		0.1–0.15 mL/kg/h	1–1.5 mL every 10–15 min	1 mL of the solution
Bupivacaine[g]	0.05%–0.1%	0.5%–0.25%			
Sufentanil	0.0001%		0.1–0.2 mL/kg/h	1–1.5 mL every 10–15 min	1 mL of the solution
Bupivacaine[h]	0.05%–0.1%	0.5%–0.25%			

[a] Catheter insertion site is the dermatome corresponding to the middle of the surgical incision. Administer a bolus dose of 0.5% bupivacaine or 2% lidocaine to establish surgical anesthesia, or 0.25% bupivacaine to induce postoperative analgesia in 5-mL aliquots.
[b] Due to infectious control, a total volume of 150 mL is recommended.
[c] Initial basal infusion rates will depend on the age, general condition, and weight of the patient.
[d] If analgesia is inadequate after 1 hour, increase the breakthrough dose by the recommended amount. If analgesia is inadequate after one additional hour, decrease the lockout interval by 5 minute.
[e] Prepare this solution by mixing 75–150 mg of bupivacaine with 15 mg of preservative-free morphine in a total volume of 150 mL of preservative-free normal saline.
[f] Prepare this solution by mixing 75–150 mg of bupivacaine with 3.75–7.5 mg of hydromorphone in a total volume of 150 mL of preservative-free normal saline.
[g] Prepare this solution by mixing 75–150 mg of bupivacaine with 1,500 μg of fentanyl in a total volume of 150 mL of preservative-free normal saline.
[h] Prepare this solution by mixing 75–150 mg of bupivacaine with 150–300 μg of sufentanil in a total volume of 150 mL of preservative-free normal saline.
From deLeon-Cosa Sola OA, Lema MJ: Postoperative epidural opioid analgesia: What are the choices? *Anesth Analg.* 1996;83:867–875, with permission.

the oral and parenteral route. Difficulty ambulating and orthostatic hypotension are minimized when catheters are placed in the thoracic region with low infusion rates and bupivacaine concentrations used are less than 0.08%.

Systemic narcotic analgesia can be used to provide effective postoperative pain control. Intravenous narcotics are commonly administered by a patient-controlled analgesia (PCA) pump after this type of procedure, allowing the patient to titrate the dose of narcotic to achieve adequate pain control. These modified infusion pumps are able to administer infusions of narcotics, small preprogrammed bolus doses on patient demand, and larger bolus doses by prescription. The PCA technique allows the patients to self-titrate narcotic doses to achieve optimal analgesic doses while avoiding the toxic side effects that result from high peak serum levels.

CHAPTER 10

Hypertension

Manuel L. Fontes and Fun-Sun F. Yao

A 70-YEAR-OLD MAN

with cholelithiasis was scheduled for a cholecystectomy. His blood pressure (BP) was 230/120 mm Hg; pulse, 60 beats per minute. Hematocrit was 38%; serum sodium, 140 mEq per L; and serum potassium, 2.7 mEq per L. His medications included metoprolol, aspirin, atorvastatin (Lipitor), and hydrochlorothiazide.

A. Medical Disease and Differential Diagnosis

1. Define hypertension and classify its severity.
2. What is the prevalence of hypertension?
3. What is the general classification of hypertension? Enumerate the causes of each type of hypertension.
4. What are the clinical patterns of hypertension encountered?
5. What is the pathophysiology of essential hypertension?
6. What is the pathophysiology of isolated systolic hypertension (ISH) and of pulse pressure hypertension (PPH)?
7. What are the end-organ damages caused by long-standing hypertension?
8. Are hypertensive patients at an increased risk for perioperative cardiac morbidity?
9. Perioperative cerebral and renal complications are mostly associated with which subtype of hypertension?
10. Would you employ a controlled hypotensive technique for hypertensive patients? How much would you safely lower the BP?
11. What is the mechanism of action of antihypertensive drugs?
12. Does the choice of antihypertensive therapy influence hemodynamic responses to induction, laryngoscopy, and intubation?
13. Does chronic angiotensin-converting enzyme (ACE) inhibition influence anesthetic induction?

B. Preoperative Evaluation and Preparation

1. How would you evaluate this patient preoperatively?
2. Would you postpone the surgery? Why? What BP would you like the patient to achieve before surgery?
3. Should all or any of the chronic medications be discontinued before the operation?
4. Should hypokalemia be treated before anesthesia? Why?
5. Should hypomagnesemia be treated before anesthesia? Why?
6. Does an asymptomatic carotid bruit increase the risk in these patients?
7. The surgery was postponed for 6 weeks. The patient was on metoprolol, aspirin, atorvastatin, captopril, hydrochlorothiazide, and potassium chloride. His BP was 160/60 mm Hg and potassium 4.0 mEq per L. How would you premedicate this patient?
8. If the patient is an untreated hypertensive patient with BP 170/70 mm Hg, would you treat the patient preoperatively with an antihypertensive agent?

C. Intraoperative Management

1. How would you monitor this patient?
2. What are the anesthetic goals for hypertensive patients?
3. How would you induce anesthesia for the hypertensive patient?
4. How does tracheal intubation produce hypertension?
5. What happens to the left ventricular ejection fraction during and immediately following intubation?
6. What other measures can prevent hypertension and tachycardia at the time of intubation?
7. After induction and intubation, the BP decreased to 70/40 mm Hg. What would you do?
8. What is your choice of agents for maintenance of anesthesia? Why?
9. How would you manage fluid therapy for hypertensive patients?
10. During the surgery, BP increased to 220/120 mm Hg. How would you treat the hypertension?
11. What could you do to prevent hypertension during extubation and emergence?
12. Would you consider regional anesthesia for this patient?

D. Postoperative Management

1. The patient developed hypertension BP 210/110 mm Hg in the postanesthesia care unit. What would you do?

A. Medical Disease and Differential Diagnosis

A.1. Define hypertension and classify its severity.

True systemic hypertension can be diagnosed when there is an increase in arterial pressure above accepted normal pressure for age, sex, and race. According to the latest classification and characterization of BP by the Joint National Committee on Evaluation, Detection, and Prevention of High Blood Pressure, an optimal BP for adults is less than 120 mm Hg systolic with a diastolic of less than 80 mm Hg. Table 10.1 shows the categories of BP for optimal, normal, and high

Table 10.1 Categories of Blood Pressure and Subtypes of Hypertension

JNC 6 CATEGORY	SBP/DBP	JNC 7 CATEGORY
Optimal	<120/<80	Normal
Normal	120–129/80–84	Prehypertension
Borderline	130–139/85–89	
Hypertension	≥140/≥90	Hypertension
Stage 1	140–159/90–99	Stage 1
Stage 2	160–179/100–109	Stage 2
Stage 3	≥180/≥110	

DBP, diastolic blood pressure; JNC, Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure; SBP, systolic blood pressure

Sources: The Sixth Report of the Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure. *Arch Intern Med.* 1997;157:2413–2446.

The Seventh Report of the Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure. *JAMA.* 2003;289:2560–2571.

normal as well as the two stages of hypertension. The accepted upper limits of normal BP in pediatric are as follows:

Adolescent	100/75 mm Hg
Early childhood	85/55 mm Hg
Infant	70/45 mm Hg

It is important to note that newer classification of hypertension define and specify hypertension according to systolic and to diastolic hypertension, each representing different pathophysiologic processes. Systolic hypertension is a marker of macrovascular disease and large arterial stiffening (atherosclerosis) and diastolic hypertension is a consequence of microvascular disease involving typically vessels less than 1 mm in size.

Hypertension is also categorized as urgent and emergent. According to the JNC VII Report, hypertensive emergency is defined as BP >180/120 mm Hg complicated by evidence of impending or progressive end-organ damage, whereas hypertensive urgency is severe elevation of BP without progressive end-organ damage.

Libby P, Bonow RO, Mann DL, et al., eds. *Braunwald's Heart Disease.* 8th ed. Philadelphia: WB Saunders; 2008:1027–1046.

A.2. What is the prevalence of hypertension?

The prevalence of hypertension depends on both the racial composition of the population and the criteria used to define hypertension. In a white suburban population like that in the Framingham study, nearly one-fifth have BP greater than 160/95 mm Hg,

and almost one-half have BP greater than 140/90 mm Hg. A higher prevalence has been found in the non-white population. The frequency increases with the age of the population with nearly two-thirds of hypertensive patients being older than 50 years. The subtype of hypertension is also influenced by age. Younger individuals suffer from diastolic hypertension and combined systolic and diastolic hypertension whereas older persons predominantly experience systolic hypertension. The number of hypertensive persons in the United States in 1983 was estimated to be 57.7 million—more than double the estimate made in 1960 to 1962. Currently, approximately 70 million Americans suffer from hypertension.

A.3. What is the general classification of hypertension? Enumerate the causes of each type of hypertension.

Hypertension is classified according to its subtypes: systolic, diastolic, and pulse pressure (Table 10.2). Historically, only diastolic hypertension—essential hypertension—was recognized, but more recently, there has been increasing emphasis and recognition of systolic hypertension, namely, *isolated systolic hypertension* (ISH). ISH is the most common subtype of hypertension affecting predominantly individuals older than 60 years of age. In fact, approximately 70% of hypertensive patients have ISH with approximately half of these individuals having very wide pulse pressure (>65 mm Hg) or *pulse pressure hypertension* (PPH). Isolated diastolic hypertension is most prevalent in individuals younger than 50 years and is an important marker of coronary heart disease and mortality in this age group. Some

Table 10.2 Classification of Hypertension

Systolic and diastolic hypertension
• Essential
• Renal
• Endocrine
• Neurogenic
• Miscellaneous
Systolic hypertension with wide pulse pressure
• Increased cardiac output
• Rigidity of aorta

hypertensive patients have both systolic and diastolic hypertension categorized as *combined systolic and diastolic hypertension*. The ranges of systolic, diastolic, and pulse pressure that define each subtype of hypertension are presented in Table 10.1.

Etiology of hypertension

- *Essential hypertension*. Unknown etiology
- *Renal*. Acute and chronic glomerulonephritis, chronic pyelonephritis, polycystic kidney, diabetic nephropathy, hydronephrosis, renovascular stenosis, renin-producing tumors, primary sodium retention
- *Endocrine*. Adrenal—Cushing syndrome, primary aldosteronism, congenital adrenal hyperplasia, pheochromocytoma, acromegaly, hypothyroidism, carcinoid, hyperthyroidism, oral contraceptives, corticosteroids
- *Neurogenic*. Psychogenic, increased intracranial pressure, spinal cord section, familial dysautonomia, lead poisoning, Guillain-Barré syndrome, sleep apnea
- *Miscellaneous*. Coarctation of aorta, increased intravascular volume, pregnancy-induced hypertension, polyarteritis nodosa, acute porphyria, hypercalcemia, alcohol and drug use, acute stress including surgery

A.4. What are the clinical patterns of hypertension encountered?

- "Vasoconstricted" hypertension—in medical patient with chronic renovascular hypertension, characterized by diastolic hypertension and systemic vascular resistant with normal or even decreased cardiac output and heart rate.
- "Hyperdynamic" hypertension—in postoperative surgical patient, characterized by acute systolic hypertension; widened pulse pressure; and increased cardiac output, heart rate, and systemic vascular resistant.

A.5. What is the pathophysiology of essential hypertension?

The underlying mechanism of essential hypertension is unknown. A variety of abnormalities, including heredity, fetal undernutrition, abnormal sympathetic nervous system activity, cell membrane defects, renal retention of excess salt, microcirculatory alterations, endothelial cell dysfunction, hyperinsulinemia secondary to insulin resistance, vascular hypertrophy, and altered renin–angiotensin system regulation are implicated. There is increasing evidence that "local renin–angiotensin" paracrine factors may be involved in the development of hypertension. However, characteristic hemodynamic changes are present as follows:

- Increased systemic vascular resistance with normal cardiac output
- Markedly increased sympathetic response to stress such as endotracheal intubation
- A greater increase in BP with vasoconstriction and a greater decrease in BP with vasodilation because of the increased thickening of arterial wall and high ratio of wall thickness to internal diameter

The higher the level of BP, the more likely that various cardiovascular diseases will develop prematurely through acceleration of arteriosclerosis. If untreated, approximately 50% of hypertensive patients die of coronary heart disease or congestive heart failure (CHF), approximately 33% of stroke, and 10% to 15% of renal failure.

Libby P, Bonow RO, Mann DL, et al., eds. *Braunwald's Heart Disease*. 8th ed. Philadelphia: WB Saunders; 2008:1027–1046.

A.6. What is the pathophysiology of isolated systolic hypertension (ISH) and of pulse pressure hypertension (PPH)?

ISH is a manifestation of atherosclerotic disease involving predominantly the aorta and its major branches. Both ISH and PPH reflect arterial stiffening and represent the pulsatile component of BP, whereas the mean arterial pressure (MAP) represent the static state. Systole, then, is directly influenced by the ventricular contractile state, the ejected volume, heart rate, and, importantly, compliance of the aorta and pulse wave velocity. With increasing age and factors such as diabetes, smoking, increased cholesterol as well as some genetic factors, compliance of the aorta diminishes markedly (Fig. 10.1). The net result is stiffening of the arterial tree and inability to absorb the pulsatile load, causing the systolic pressure to rise sharply. Pulse wave velocity has gained much attention lately because it may be a richer substrate for characterizing the physiology of blood flow and pressure. Under normal physiologic conditions, the ejected blood volume is transmitted peripherally as a propagated wave. After reaching the periphery, in particular, at the bifurcation sites, a reflected wave or a retrograde wave is generated from the encountered impedance. Under normal conditions, wave reflection arrival coincides with the beginning of diastole, thereby augmenting the diastolic pressure. However, with stiffening of the aorta as occurs with aging, both the propagated and the reflected waves travel much more rapidly, and early return of the reflected arterial wave during late systole augments the systolic component, effectively increasing afterload. The ensuing loss of diastolic augmentation results in a disproportionate increase in the systolic blood pressure and lower diastolic blood pressure—a hallmark of ISH and of PPH.

Mechanistically, pulse pressure is also an index of the stiffness of conduit vessels and the rate of pressure wave propagation and reflection within the arterial tree. Approximately half of patients with ISH also have wide pulse pressure; however, both individuals who are normotensive (systolic, <140 mm Hg) with a low diastolic pressure

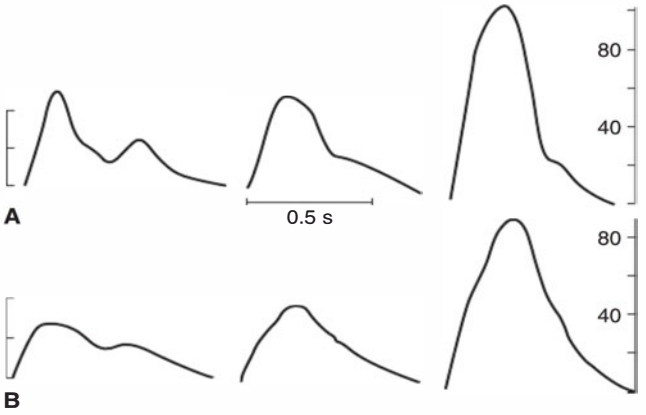

Figure 10.1 Change in amplitude and contour of the upper limb **(A)** and ascending aortic **(B)** pressure wave with age, as recorded in three female members of a family: at age 18 **(left)**, at age 48 **(center)**, and 97 years **(right)**. Upper limb pulse pressure was just more than twice as high in the old compared with the young subject (102 vs. 46 mm Hg), whereas aortic pulse pressure was more than three times higher (104 vs. 27 mm Hg). (From O'Rourke MF, Nichols WW. Aortic diameter, aortic stiffness, and wave reflection increase with age and isolated systolic hypertension. *Hypertension.* 2005;45(4):652–628, with permission.)

or persons with combined systolic and diastolic hypertension (systolic >140 mm Hg and diastolic >90 mm Hg) can have wide pulse pressure (normal values being ≤40 mm Hg).

A.7. What are the end-organ damages caused by long-standing hypertension?

The end-organ damages caused by long-standing hypertension are as follows:

Cardiac involvement:
Left ventricular hypertrophy (LVH)
Angina or myocardial infarction (MI)

Arrhythmias
Congestive failure

Eye involvement:
Vascular changes in the fundus reflect hypertensive retinopathy and arteriosclerotic retinopathy

Renal involvement:
Nephropathy

Cerebral involvement:
Stroke or transient ischemic attack

Complications of hypertension to vascular disease probably involve three interrelated processes: pulsatile flow, endothelial cell dysfunction, and smooth muscle cell hypertrophy. These three interrelated processes are probably responsible for the arteriolar and arterial sclerosis that is the usual consequence of long-standing hypertension. Large vessels such as the aorta may be directly affected and be at risk for aneurysms and dissection. As discussed previously, the consequences of long-standing hypertension need be addressed according to the subtypes of hypertension; for the associated risks for cerebral, cardiac, and renal vascular complications differ according to systolic, diastolic, and PPH. For example, diastolic hypertension being a better predictor of coronary heart disease in younger patients, whereas systolic and pulse pressure being associated with greater risk of stroke, coronary heart disease and mortality in persons older than 60 years.

A.8. Are hypertensive patients at an increased risk for perioperative cardiac morbidity?

Hypertensive patients are at increased risk for coronary artery disease, silent myocardial ischemia, CHF, and stroke. However, whether preoperative hypertension is predictive of perioperative major cardiac morbidity remains controversial. Some investigators have shown that patients with untreated, poorly controlled, or labile preoperative hypertension are at increased risk for perioperative BP lability, dysrhythmias, myocardial ischemia, and transient neurologic complications. Some suggested that preoperative hypertension predicted perioperative MI. However, Goldman and Caldera demonstrated that mild-to-moderate hypertension did not increase the risk of major morbid events. Instead, preoperative hypertension may predict several intermediates of outcome, such as BP lability and myocardial ischemia. The controversy may be due to the wide variability in the hypertensive population. Hypertension may affect perioperative morbidity through the extent of end-organ damage and not the manifestation of the disease itself. LVH, which signifies long-standing poorly controlled hypertension, can increase the risk of myocardial ischemia from imbalances of myocardial oxygen supply and demand regardless of the presence or absence of coronary artery disease.

ISH (systolic BP >140 mm Hg and diastolic BP <90 mm Hg) has been identified as a risk factor for cardiovascular complications in the general population and treatment reduces the future risk of stroke. More recently, Aronson and Fontes found that amongst the various component of BP, preoperative pulse pressure was independently and significantly associated with postoperative stroke, renal failure, and mortality in patients undergoing coronary artery bypass. Neither ISH nor isolated diastolic hypertension were predictive of vascular complications. This finding is consistent with results of longitudinal studies finding that increase in pulse pressure is a better predictor of major vascular complications than either systolic or diastolic BP. Interestingly, rises in pulse pressure as few as 10 mm Hg in both normotensive and hypertensive individuals is associated with 20% or more increase risk of renal, coronary, and cerebral events.

A.9. Perioperative cerebral and renal complications are mostly associated with which subtype of hypertension?

Both systolic hypertension and high pulse pressure are strongly associated with risk for perioperative cerebrovascular accidents and acute renal failure. The brain and the kidneys as well as the heart differ from most organs in that they receive large amount of blood flow and have very low resistance. As such, the pulsatile load (pulse pressure) tends to be very high. Over a period of many years of poorly or untreated hypertension, endothelial injury and vascular remodeling changes can promote both arteriosclerosis and atherosclerosis, which are known risk factors for cerebral and renal vascular complications. The pulsatile stress also can cause dislodgment of plaques from the aorta and its major branches, resulting in embolic stroke.

In hypertensive patients, autoregulation of cerebral blood flow is reset to a higher range than normal, and although it protects the brain against sudden increases in

pressure, it makes it more vulnerable to hypotension. Therefore, when BP is lowered acutely, hypertensive patients will show signs of cerebral ischemia at a higher level of BP than normotensive patients.

Hypertension may accelerate cognitive decline with age. Hypertension, particularly systolic, is a major risk factor for initial and recurrent stroke and for transient ischemia attacks caused by extracranial atherosclerosis.

Chronic renal insufficiency is a common sequela of hypertension. Patients with hypertension should have a measurement of baseline serum creatinine. In the original Cardiac Risk Index, an elevated serum creatinine level (>3.0 mg per dL [>265.2 mmol per L]) was one of the independent risk factors for perioperative cardiovascular morbidity and mortality. This has been confirmed in the revised Cardiac Risk Index in which a preoperative serum creatinine level greater than 2.0 mg per dL (176.8 mmol per L) was one of six independent factors that predicted increased cardiovascular risk.

A.10. Would you employ a controlled hypotensive technique for hypertensive patients? How much would you safely lower the BP?

Uncontrolled or untreated severe hypertension is a contraindication to controlled hypotension. However, controlled hypotension may be used with caution in treated hypertensive patients. Because cerebral autoregulation is shifted to the right with chronic hypertension, the lower limit of controlled hypotension should be higher for hypertensive patients. However, with long-term treatment, the autoregulation curve shifts leftward to approach that in normals. Strangaard found that the lower limit of autoregulation was 113 mm Hg in severe untreated or uncontrolled hypertensives; 96 mm Hg in formerly severe, now-treated hypertensives; and 73 mm Hg in normotensive patients. The lowest level of mean BP tolerated without symptoms of hypoperfusion was 65 mm Hg in severe hypertensives, 53 mm Hg in treated hypertensives, and 43 mm Hg in normal patients. However, although the autoregulation may shift toward normal with treatment, in many patients the autoregulation did not shift toward normal even after 12 months of treatment. Because one cannot measure patients' autoregulation, a useful clinical guide is that a 25% decrease in MAP reaches the lower limit of autoregulation and a 55% decrease in MAP reaches symptomatic cerebral hypoperfusion. Another suggested rule is that the systolic pressure of controlled hypotension should not be lower than the diastolic pressure of the patient's usual pressure. It is important to note that peripherally measured blood pressure do

not match central aorta blood pressure, which is more reflective of actual cerebral blood pressure.

Recently, noninvasive cerebral oximeter using near-infrared spectroscopy may be used to monitor the oxygen saturations of cerebral cortex. The values of cerebral oxygen saturations correspond with those of a mixture of 85% jugular venous O_2 saturation and 15% of arterial O_2 saturation. It reflects the balance between cerebral O_2 delivery and O_2 demand. In a steady state of anesthesia, the cerebral O_2 demand does not change significantly. Therefore, cerebral O_2 saturations will not decrease until the BP falls below its autoregulation range. Therefore, the cerebral oximeter may be employed to determine the lower limit of autoregulation and to ensure adequate cerebral oxygenation. Unfortunately, there is wide variability in measured cerebral saturations with some individual's baseline oximetric saturation values being near 50% at baseline. Further, the measured value is reflective of regional saturation such that distant areas that may be ischemic are not detected.

It should be mentioned that neither the threshold for upper nor lower limits of systolic and diastolic BP have been established. Frequently, these limits have been chosen arbitrarily and the relation of perioperative hypertension to outcomes has been inconsistent among the studies that have addressed this question. In part, the limitation comes from grouping all types of hypertension together. Moreover, available vasoactive agents are not selective in lowering or raising systolic BP and diastolic BP without a concomitant increase or fall in the other component. Undermining the broad-based reliance on systolic BP and diastolic BP are a number of studies in humans over the past several decades that clearly show that both morbidity and mortality do not always linearly correlate with rises or fall in BP. In individuals with demonstrable coronary disease, namely, those with previous infarcts, coronary mortality was significantly related to diastolic pressure in a U-shape configuration—occurring more frequently in those with very high or very low diastolic BP. Unfortunately, the emphasis on BP management perioperatively has been to control the systolic component with no attention paid to the diastolic component. This is particularly concerning in patients with ISH and with very wide pulse pressure where the diastolic BP is already critically low. By reducing the systolic component, further lowering of the diastolic BP can result in ischemic complications in most sensitive vascular beds such as the brain, the heart, and the kidneys. Lastly, it is critical to recognize that peripheral arterial pressures do not necessarily reflect central pressures with exception of the MAP. In a subset of hypertensive individuals, both the systolic and the pulse pressures are grossly higher peripherally as compared to central aortic pressures, such that lowering of the peripheral BP may result in critical reduction in perfusion pressure.

A.11. What is the mechanism of action of antihypertensive drugs?

Antihypertensive drugs are categorized by their mechanism of action as follows.

Diuretics

They include thiazides (e.g., hydrochlorothiazide), loop diuretics (e.g., furosemide, ethacrynic acid), and potassium-sparing agents (e.g., spironolactone, triamterene). All diuretics initially lower the BP by increasing urinary sodium excretion and by reducing plasma volume, extracellular fluid volume, and cardiac output. Within 6 to 8 weeks, the cardiac output returned to normal. The lowered BP is related to a fall in peripheral resistance. Diuretics may cause hypokalemia, hypomagnesemia, hyperuricemia, hyperlipidemia, hypercalcemia, and hyperglycemia. For patients with ST-segment changes and evidence of pulmonary edema and hypertension or with increased intracranial cerebral pressure and hypertension, intravenous furosemide may be appropriate.

Antiadrenergic agents

- *Centrally acting drugs*. Clonidine, dexmedetomidine, and mivazerol. These drugs and their metabolites are primarily α_2-receptor agonists. Stimulation of α_2 receptors in the vasomotor centers of the brain reduces sympathetic outflow.
- *Peripherally acting drugs*
  - α-Receptor blockers
    α_1 and α_2 Receptors—phenoxybenzamine (Dibenzyline), phentolamine (Regitine)
    α_1 Receptor—prazosin (Minipress), doxazosin (Cardura)
    By blocking α-mediated vasoconstriction, these drugs induce a fall in peripheral resistance with both arteriolar and venous dilation.
  - β-Receptor blockers—atenolol (Tenormin), metoprolol (Lopressor), nadol (Corgard), pindolol (Visken), propranolol (Inderal), esmolol (Brevibloc). These drugs lower the BP by decreasing heart rate, contractility, cardiac output, and renin levels. BP is decreased without reflex tachycardia or widening of the pulse pressure. They also have antiarrhythmic activity and suppress both ventricular and supraventricular ectopic rhythms.
  - α- and β-Receptor blockers—labetalol (Trandate)
  - Endothelin receptor antagonist—act on endothelin A and B receptors to block the effect of endothelin-1, which is the most potent vasoconstrictor that is secreted primarily from vascular smooth muscle and endothelial cells. Bosentan (receptor A and B antagonist) and sitaxsentan (receptor A antagonist) are examples of a few of this class of agents used in the management of pulmonary hypertension and less so for hypertension-related heart failure

Direct vasodilators

They include hydralazine, nitroprusside, nitroglycerin, and calcium channel blockers. These drugs directly relax the smooth muscle of resistance and capacitance vessels to different degrees.

Dopaminergic agonists

Dopaminergic agonists (DAs) are classified into DA_1 and DA_2 subtypes.

Stimulation of DA_1 receptors causes vasodilation, and inhibition of active sodium transport in the proximal tubule, leading to natriuresis.

Stimulation of DA_2 receptors inhibits norepinephrine release and promotes peripheral vasodilation.

Fenoldopam, a dopamine receptor (DA_1 selective) agonist and a systemic and renal vasodilator, offers significant advantages as a parenterally administered agent for the management of BP in hypertensive emergencies and in the periop-

Table 10.3 Cardiovascular Effects of Calcium Channel Blockers

erative setting. Parenteral fenoldopam has a rapid onset and offset of effect, with an elimination half-time of approximately 10 minutes. Prepared in concentration of 10 mg in 250 mL (40 μg/mL), the recommended starting dose is 0.05 μg/kg/minute. This should be titrated to effect by 0.025 μg/kg/minute every 10 to 15 minutes, to a maximum dose of 0.5 to 0.8 μg/kg/minute. The drug should not be administered in boluses; the incidence of reflex tachycardia is related to rapidity of upward titration. Unlike dopamine, it has no β- or α-adrenergic activity and increasing doses result in increasing vasodilation without tachycardia or tachyarrhythmias.

Calcium channel blockers

The cardiovascular effects of calcium antagonists are listed in Table 10.3. These drugs decrease BP mainly by peripheral vasodilation. Renin and aldosterone secretion may be reduced as well.

Angiotensin-converting enzyme inhibitors

They include captopril, enalapril, lisinopril, quinapril, and ramipril. The renin–angiotensin system may be inhibited in four ways as shown in Figure 10.2. These drugs inhibit the conversion of the inactive decapeptide angiotensin I to the active octapeptide angiotensin II. Lower levels of angiotensin II may decrease BP by

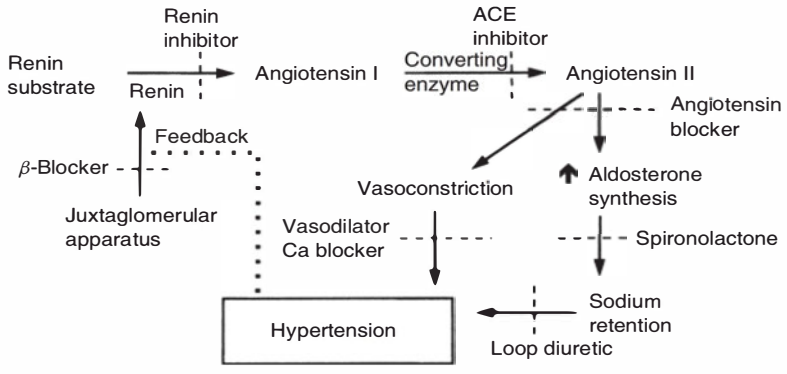

Figure 10.2 The renin–angiotensin system and the mechanism of action of antihypertensive drugs. ACE, angiotensin-converting enzyme.

reducing angiotensin II–induced vasoconstriction and by decreasing aldosterone synthesis. Angiotensin-converting enzyme (ACE) inhibitors also retard the degradation of a potent vasodilator (bradykinin), alter prostaglandin production (most notably with captopril), and can modify the activity of the adrenergic nervous system.

ACE inhibitors provide predominantly arterial vasodilation and have become primary therapy for the treatment of CHF by afterload reduction. Cardiac output is increased without excessive decrease in preload, with a favorable effect on survival.

Angiotensin II receptor blockers

Angiotensin II receptor antagonists or blockers (ARBs), represent the third class that antagonizes the renin–angiotensin–aldosterone system. Blockade of the action of angiotensin II leads to elevations in plasma levels of renin, angiotensin I, and angiotensin II. However, this build-up of precursors does not overwhelm the receptor blockade, as evidenced by a persistent fall in both BP and plasma aldosterone levels. There are several possible differences between ACE inhibitors and angiotensin II receptor antagonists. These include the following:

- ACE is a kininase. Therefore, inhibiting this enzyme, which normally degrades bradykinin, with an ACE inhibitor leads to increased kinin levels, an effect not seen with an angiotensin II receptor antagonist. High bradykinin levels may also provide additional vasodilation and other benefits not observed with angiotensin II receptor antagonists.
- ACE inhibitors, by decreasing angiotensin II production, reduce the effect of both AT_1 and AT_2 receptors; only the former are inhibited by the angiotensin II receptor blockers. Chronic stimulation of the AT_2 receptor may be beneficial.
- In the heart, kidney, and perhaps the blood vessels, the production of angiotensin II may be catalyzed by enzymes other than ACE, such as chymase. The effect of the angiotensin II produced by this reaction can be inhibited by the angiotensin II receptor antagonists but not by ACE inhibitors.

There is evidence that ARBs are more effective in treating ISH and PPH particularly in combination with ACE inhibitors and with endothelin receptor blockers.

Other vasodilators

They include brain natriuretic peptides such as nesiritide that is primarily used in acute exacerbation of heart failure to improve forward flow and reduce symptoms and signs of heart failure. There has been recent controversy about the clinical efficacy of these agents. Importantly, there have been several reports suggesting that the renal outcome is worsened in patients receiving nisiritide.

A.12. Does the choice of antihypertensive therapy influence hemodynamic responses to induction, laryngoscopy, and intubation?

The pressor responses to induction, laryngoscopy, and intubation differ little whether patients with mild-to-moderate hypertension receive a β-blocker, a calcium channel blocker, an ACE inhibitor, or a diuretic. Even changes of a similar magnitude are also observed in untreated hypertensive patients. On the other hand, hypotensive responses may be magnified in those patients with poorly controlled hypertension following induction—generally due to a reduced intravascular volume in the face of increased vascular sympathetic tone. As mentioned previously, attention should be directed not only to the systolic but also to pulse and diastolic pressures.

Sear JW, Jewkes C, Teller JC, et al. Does the choice of antihypertensive therapy influence haemodynamic responses to induction, laryngoscopy and intubation? *Br J Anaesth*. 1994;73:303–308.

A.13. Does chronic angiotensin-converting enzyme (ACE) inhibition influence anesthetic induction?

Coriat et al. reported that, in hypertensive patients chronically treated with ACE inhibitors, therapy until the day of surgery is a major factor influencing BP responsiveness to anesthetic induction for vascular surgery. If enalapril (a long-acting ACE inhibitor) treatment is continued, a very low plasma-converting enzyme activity will be observed and an exaggerated hypotensive response may occur at induction. If captopril (a short-acting ACE inhibitor) treatment is continued, the magnitude of the decrease in BP in response to induction, although lower than with enalapril, is enhanced compared with that noted in patients in whom captopril had been stopped. All of the hypotensive episodes in patients who received ACE inhibitors until the day of surgery were easily corrected by administration of an α-agonist. The temporary withdrawal of these two ACE inhibitors attenuated the hypotensive response to induction but did not lead to an abnormal BP response to induction and intubation. However, recently, Ryckwaert and Colson reported that ACE inhibitor treatment in patients with infarction-induced myocardial dysfunction does not increase the incidence of severe hypotension after induction of anesthesia. In all, the overwhelming opinion is to continue all antihypertensive medication including the day of surgery and resumption of such therapy postoperatively. A number of studies have shown an improvement in outcome when therapy is continued versus a worsening in outcome when either ACE inhibitors or β-blockers have been withdrawn.

B. Preoperative Evaluation and Preparation

B.1. How would you evaluate this patient preoperatively?

In addition to the routine systemic preoperative physical and history, special attention should be paid to the following: etiology and severity of hypertension, the subtype of hypertension, current therapy, and the end-organ damage from chronic hypertension.

The underlying cause of hypertension should be clear. Surgical mortality is relatively high in patients with renovascular hypertension. Moreover, failure to diagnose a pheochromocytoma preoperatively, albeit a rare finding, may prove fatal, because anesthetic agents are well known to precipitate a crisis in such patients. Meanwhile, the severity of hypertension alters anesthetic risk.

Antihypertensive drugs have different anesthetic implications. Diuretics frequently cause chronic hypokalemia and hypomagnesemia, which may increase the risk of arrhythmia. Therefore, serum electrolytes should be checked preoperatively.

The presence of target-organ damage in the brain, heart, and kidney signifies long-standing, poorly controlled hypertension. Unfortunately, markers of organ damage become demonstrable only after significant end-organ damage has occurred.

For cardiac evaluation, electrocardiogram and chest x-ray film serve as minimal tests. The echocardiogram will be helpful. LVH can increase the risk of perioperative myocardial ischemia from imbalances of myocardial oxygen supply and demand regardless of the presence or absence of coronary artery disease. There is a very high correlation between LVH, ISH and PPH—it is uncertain which comes first. Some authorities believe that hypertensive patients without evidence of LVH or other risk factors are at a lower perioperative cardiac risk and do not require further evaluation for most operations. Patients with severe hypertension are also at an increased risk for diastolic dysfunction causing CHF.

For renal evaluation, urinalysis, serum creatinine, and blood urea nitrogen should be measured to define the presence and extent of renal parenchymal disease. If chronic renal failure exists, hyperkalemia and elevated plasma volume may be of concern. Normal saline crystalloid intravenous solution is recommended for such cases.

For cerebrovascular evaluation, a history of cerebrovascular accidents and transient ischemic attacks and the presence of hypertensive retinopathy should be looked for.

B.2. Would you postpone the surgery? Why? What BP would you like the patient to achieve before surgery?

It is prudent to postpone elective surgery with a BP of 230/120 mm Hg. This patient should be considered to have hypertensive emergency if additional end-organ sequelae are present, in which case he needs to be admitted for intravenous control of BP. Otherwise, for hypertensive urgency, it is recommended that the patent be placed in a quiet environment and managed with rest and oral antihypertensives. The patient should be discharged and instructed to follow-up with his/her internist for management and control of hypertension. Prior to rescheduling for surgery., if time permits, the BP should be gradually lowered over 6 to 8 weeks to less than 140/90 mm Hg. Acute control within several hours is inadvisable before elective surgery because this practice may put the cerebral or other circulations at risk for ischemia.

In moderate hypertensive patients with severe end-organ involvement, preoperative BP should be normalized as much as possible, although in asymptomatic patients with mild-to-moderate hypertension (diastolic BP $<$110 mm Hg), elective surgery may proceed without increased cardiovascular risks. Goldman et al. found that patients with mild and moderate hypertension were not at increased risk of vascular complications unless they had other risks of coronary heart disease. In all, the thresholds being recommended apply only in part to today's surgical population. Most hypertensive patients presenting for surgery are elderly patients who suffer almost exclusively from ISH and PPH. It is uncertain what acute changes in BP preoperatively will have on outcome giving that the pathologic changes are chronic and unlikely to normalize with treatment. In patients with medically refractory coronary disease requiring coronary artery bypass grafting (CABG) surgery, PPH was associated with an increased risk of major vascular complication.

Nikolov N, Fontes M, White WD, et al. Is increased pulse pressure associated with a reduction in long-term survival after CABG surgery? *Anesth Analg*. 2010;110:335–40.

B.3. Should all or any of the chronic medications be discontinued before the operation?

Current opinion generally favors continuation of antihypertensive medications, especially β-blockers, up to the time of surgery. There is concern that acute withdrawal of these medications may precipitate ischemic myocardial events. Because β-blockade does not impair the hemodynamic response to hemorrhage and does not adversely affect responses to hypoxia, the medications should be continued. The withdrawal syndrome is characterized by an enhanced sensitivity to sympathetic stimulation and has been attributed to various factors, including sympathetic overactivity and increased triiodothyronine levels, but most probably it is a result of increased β-receptor density.

The safety of β-blockers and their benefits (prevention of hypertensive responses, dysrhythmias, and myocardial ischemia) have been long established. Similarly, treatment with calcium channel blockers, ACE inhibitors, statins, and diuretics can be maintained. Indeed, the responses to induction of anesthesia, laryngoscopy, and intubation differ little whether patients receive a β-blocker, a calcium channel blocker, an ACE inhibitor, or a diuretic. Withdrawal of clonidine has been associated with rebound hypertension.

B.4. Should hypokalemia be treated before anesthesia? Why?

Hypokalemia is a frequent finding in hypertensive patients treated with the diuretic thiazides. It is important to maintain normal electrolyte balance in patients with heart or coronary artery disease. A low value of potassium (3.0 to 3.5 mEq per L) in these patients may cause arrhythmias, increase sensitivity to digitalis, and depress neuromuscular function. In patients without risk of cardiac complications of surgery and anesthesia, this modest reduction (3.0 to 3.5 mEq per L) should not prompt postponement of surgery or immediate potassium replacement. Patients with more severe potassium depletion (≤2.9 mEq per L) should be treated and/or undergo work-up for such profound hypokalemia. For those patients, at least 1 week before surgery supplemental potassium should be given if renal function is not impaired. In surgical emergencies, potassium may be given at a rate not to exceed 0.5 mEq per kg of body weight per hour. Administration should be stopped during surgery and restarted postoperatively, depending on serial potassium determinations. Vitez et al. concluded that chronic hypokalemia per se is not associated with a higher incidence of intraoperative arrhythmia.

B.5. Should hypomagnesemia be treated before anesthesia? Why?

The normal level of magnesium is between 1.5 and 2.5 mEq per L. Magnesium ion is essential for the proper function of most enzyme systems. Depletion is characterized by neuromuscular and central nervous system hyperexcitability. These signs are similar to those of calcium deficiency. Cardiovascular abnormalities include coronary artery spasm, cardiac failure, and dysrhythmias. When severe, hypomagnesemia may induce seizures, confusion, and coma. Replacement should be done only in cases of severe depletion. Magnesium should not be given to the oliguric patient and should be given very carefully to patients with renal insufficiency. Small intravenous doses should be used, with careful observation for toxicity (lethargy, weakness, and loss of deep tendon reflexes).

Barash PG, Cullen BF, Stoelting RK, eds. *Clinical Anesthesia*. 6th ed. Philadelphia: Lippincott Williams & Wilkins; 2009:321–322.

B.6. Does an asymptomatic carotid bruit increase the risk in these patients?

Yes. The incidence of stroke is increased in such patients, although the stroke may not be thrombotic or related to the carotid artery in which the bruit was heard. Bruits are general predictors of vascular disease and may be predictors of perioperative strokes. It is important to note that in patients who are asymptomatic from their carotid stenosis, endarterectomy is no longer recommended. Nevertheless, there continues to be much debate on this topic.

B.7. The surgery was postponed for 6 weeks. The patient was on metoprolol, aspirin, atorvastatin, captopril, hydrochlorothiazide, and potassium chloride. His BP was 160/60 mm Hg and potassium 4.0 mEq per L. How would you premedicate this patient?

Because half or more of hypertensive patients still have elevated BP despite treatment, the anesthesiologist should determine the anxiety level of the patient. With this knowledge, the premedication with diazepam, lorazepam, or midazolam can be regulated to have the patient arrive in the operating room sedated. However, due to a high occurrence of delirium in the elderly receiving benzodiazepines, premedication with such agents is being discouraged. This will help to prevent a starting BP well above the optimal level. All the antihypertensive medications are continued up to the day of surgery.

B.8. If the patient is an untreated hypertensive patient with BP 170/70 mm Hg, would you treat the patient preoperatively with an antihypertensive agent?

Yes. The preoperative administration of clonidine, β-blockers, or angiotensin-converting enzyme (ACE) inhibitors has been advocated to reduce the intraoperative hemodynamic lability and myocardial ischemia in hypertensive patients. Clonidine, a central α_2 agonist, decreases sympathetic outflow and reduces plasma catecholamines, aldosterone levels, and renin activity. A single dose of clonidine, 5 μg per kg orally, 2 hours before surgery significantly decreases anesthetic requirements and hemodynamic lability in patients with mild-to-moderate hypertension. However, preoperative clonidine did not decrease BP lability during aortic operation. Perioperative use of clonidine also has been shown to have short and long-term benefits related to cardiac morbidity and survival.

The best treatment may be cardioselective β-blocker therapy. A single small oral dose of a β-adrenergic blocking agent such as labetalol, atenolol, or lopressor given preoperatively to untreated, asymptomatic, mildly hypertensive patients effectively attenuated tachycardia with tracheal intubation and emergence. The incidence of myocardial ischemia was reduced from 28% in the control group to 2% in the β-blocker groups. An oral-dose ACE inhibitor such as enalapril given preoperatively also attenuates the hemodynamic responses to intubation and surgical stimulation.

C. Intraoperative Management

C.1. How would you monitor this patient?

- *Electrocardiogram*. Simultaneous leads V_5 and II, multiple lead ST analysis, if possible, are essential because hypertensive patients are at increased risk for myocardial ischemia regardless of the presence or absence of coronary disease.

- *BP*. A continuous monitoring of BP is essential because of lability of BP in these patients. Direct intra-arterial measurement of BP permits beat-to-beat observation. However, noninvasive automatic oscillometric techniques usually are sufficient.
- *Pulmonary artery catheter (PAC)*. Only for those hypertensive patients with a history of CHF or a recent MI, a PAC may be helpful in managing fluid replacement and monitoring ventricular function. Of note, there is a strong correlation between hypertension and LVH, which results in poor ventricular compliance reflected by elevated pulmonary artery occlusion pressure in the face of low or normal ventricular volumes and normal contractility. Presence of CHF in hypertensive patients is frequently a marker of diastolic dysfunction and NOT systolic dysfunction.
- *Pulse oximeter*. This should be used to monitor peripheral blood flow and oxygenation.
- *End-tidal CO_2 analyzer*. This monitor will help maintain normocarbia.

C.2. What are the anesthetic goals for hypertensive patients?

The anesthetic goal is to minimize wide lability of BP in response to anesthetic and surgical stimuli to prevent the following:

- Myocardial ischemia from tachycardia or less common from either hypertension or hypotension
- Cerebral hypoperfusion from hypotension
- Cerebral hemorrhage and hypertensive encephalopathy resulting from hypertension or embolic stroke from rupture of plagues either locally or from the aorta and the neck vessels.
- Renal failure from renal hypoperfusion

Particular attention to diastolic BP is strongly recommended while attempting to reduce systolic BP. It is unfortunate that clinical practice perioperatively hinges on manipulation of the systolic BP without attention to the diastolic component. This is particularly troublesome in most elderly patients who suffer from ISH and/or wide pulse pressure. In both subtypes of hypertension, the already lower diastolic pressure can easily be reduced further—predisposing to myocardial hypoperfusion and ischemia.

Recently, Lee et al. showed that patients with wide pulse pressure have an increased risk for thrombogenesis marked by elevated levels of D-dimers, von Willebrand factor, and platelet activation. This along with extensive atherosclerotic disease of the aorta, carotid, and renal arteries, which is also common in patients with ISH, provides a pathophysiologic basis for the increase incidence of perioperative stroke, MI, and renal dysfunction observed in hypertensive patients.

Lastly, careful control of the hemodynamic responses to noxious stimuli such as endotracheal intubation, surgical incision and manipulation, and emergence from anesthesia is essential in the hypertensive patient.

C.3. How would you induce anesthesia for the hypertensive patient?

While the patient is being preoxygenated, fentanyl, 7 to 8 μg per kg, is given slowly to achieve drowsiness. Then, either thiopental in 50-mg increments or propofol in 30 to 50 mg increments is titrated to produce unconsciousness, followed by succinylcholine, 1 mg per kg, or nondepolarizing muscle relaxants to facilitate tracheal intubation.

All anesthetic agents are acceptable with the possible exception of ketamine, which may produce significant hypertension and tachycardia. However, deeper anesthesia with potent inhalation agents to attenuate tachycardia and hypertension should be done with caution because of higher incidence of hypotension arising from both vasodilation and cardiac depression.

Hines RL, Marschall KE, eds. *Stoelting's Anesthesia and Co-existing Disease.* 5th ed. Philadelphia: Churchill Livingstone; 2008:96.

Martin DE, Rosenberg H, Aukburg SJ, et al. Low-dose fentanyl blunts circulatory responses to tracheal intubation. *Anesth Analg.* 1982;61:680.

C.4. How does tracheal intubation produce hypertension?

Translaryngeal intubation of the trachea stimulates laryngeal and tracheal receptors, resulting in marked increase in the elaboration of sympathomimetic amines. This sympathetic stimulation results in tachycardia and a rise in BP. In normotensive patients, this rise is approximately 20 to 25 mm Hg; it is much greater in hypertensive patients. This increase in BP results from vasoconstriction, because of unopposed α stimulation in hypertensive patients taking β-blocking drugs.

Prys-Roberts C, Greene LT, Meloche R, et al. Studies of anaesthesia in relation to hypertension. II: haemodynamic consequences of induction and endotracheal intubation. *Br J Anaesth.* 1971;43:531.

C.5. What happens to the left ventricular ejection fraction during and immediately following intubation?

During and immediately following intubation associated with tachycardia and hypertension, there is a decrease in the left ventricular ejection fraction. This is particularly marked in patients with coronary artery disease. Nevertheless, such hemodynamic perturbations can be anticipated and treated accordingly with β-blockade, narcotic, and titration of hypnotic and/or inhalation agents.

Giles RW, Berger JH, Barash PG, et al. Continuous monitoring of left ventricular performance with the computerized nuclear probe during laryngoscopy and intubation before coronary artery bypass surgery. *Am J Cardiol.* 1982;50:735.

C.6. What other measures can prevent hypertension and tachycardia at the time of intubation?

The rise in BP and heart rate occurs approximately 14 seconds after the start of laryngoscopy and becomes maximal after 30 to 45 seconds of direct laryngoscopy. If possible, laryngoscopy time should be 15 seconds or less to minimize BP elevation. Simultaneous administration of fentanyl, 7 to 8 μg per kg with the induction dose of

thiopental or propofol, can blunt the cardiovascular response to tracheal intubation. Other measures are described as follows:

- Lidocaine, 1.5 mg per kg is given 2 minutes before intubation.
- Esmolol, up to 2 mg per kg, appears to be especially effective in providing consistent and reliable protection against hypertension and tachycardia with intubation. It is easy to titrate and does not exacerbate postintubation hypotension because of its short duration of action.
- Labetalol, 0.15 to 0.45 mg per kg is comparable to esmolol 1.5 to 4.5 mg per kg in attenuating hemodynamic effects. However, the half-lives of intravenous esmolol and labetalol are 9 minutes and 5 hours, respectively. Additionally, labetalol has minimal effects on heart rate and through its action on α receptors, it acts similar to a vasodilator, particularly with chronic use.
- Nicardipine, 1 mg intravenously 2 minutes before tracheal intubation maintained hemodynamic stability during the intraoperative period. Both doses of 0.015 and 0.03 mg per kg attenuated BP but not heart rate responses during emergence and extubation. Greater BP control occurred with the larger nicardipine dose of 0.03 mg per kg.

It is important to remember that all the previously mentioned doses are used with a single agent only. If a combination of different agents or anesthetics is used, doses should be decreased accordingly. Otherwise, severe hypotension may ensue.

C.7. After induction and intubation, the BP decreased to 70/40 mm Hg. What would you do?

Hypotension after induction of anesthesia is usually due to combination of vasodilation, hypovolemia, and cardiac depression. Vasodilation can be caused by inducing

agents such as thiopental, propofol, diazepam, or midazolam; moderate-to-high doses of narcotics; and potent inhalation agents. Hypertensive patients are in relative hypovolemia because of chronic vasoconstriction and/or diuretic therapy. Preoperative bowel preparation and nothing by mouth further contribute to hypovolemia. Barbiturates, benzodiazepines, and inhalation agents can cause a mild-to-moderate degree of cardiac depression.

Hypotension after induction of anesthesia usually can be easily corrected by volume replacement and simultaneous titration of vasopressors such as ephedrine 5 to 10 mg or phenylephrine in 0.1-mg increments.

Coriat P, Richters C, Douraki T, et al. Influence of chronic angiotensin-converting enzyme inhibition on anesthetic induction. *Anesthesiology*. 1994;81:299–307.

C.8. What is your choice of agents for maintenance of anesthesia? Why?

No particular anesthetic technique or specific drug combinations have been demonstrated to be superior to others in hypertensive patients. Potent inhalation anesthetics or narcotics should be titrated to the desired level of central nervous system depression while the BP is monitored continuously.

Narcotics and nitrous oxide provide an anesthetic with less overall lability of BP, but commonly intraoperative hypertension is difficult to control by moderate doses of narcotics. High doses of narcotics are not suitable for early extubation. Likewise, use of nitrous oxide is debatable in open cholecystectomy given its propensity to increase bowel distention—the severity being related to higher concentration of nitrous oxide and to longer duration of use. This concern is less pertinent for laparoscopic cholecystectomy whereby insufflation of gas to pressurize the abdomen should counteract the distensible property of nitrous oxide (also see Chapter 26, section C.8).

Potent inhalation agents provide greater control of hypertension but seem to produce less stability. Isoflurane, desflurane, and sevoflurane possess the advantage of more peripheral vasodilation and less cardiac depression.

Akca O, Lenhardt R, Fleischmann E, et al. Nitrous oxide increases the incidence of bowel distension in patients undergoing elective colon resection. *Acta Anaesthesiol Scand*. 2004;48(7):894–898.

Taylor E, Feinstein R, White PF. Anesthesia for laparoscopic cholecystectomy. Is nitrous oxide contraindicated? *Anesthesiology*. 1992;76(4):541–543.

C.9. How would you manage fluid therapy for hypertensive patients?

Patients with essential hypertension are usually hypovolemic because of vasoconstriction and diuretic therapy. Hydration of the hypertensive patient should be started before induction of anesthesia to minimize the "roller-coaster" often seen with hypertension. However, overhydration should be avoided because it may contribute to postoperative hypertension when the vasodilating effects of anesthetics are gone. Therefore, careful estimation of fluid intake and output is essential. Foley catheter and central venous pressure monitor are indicated for major surgery with extensive fluid exchange.

As discussed previously, presence of LVH in hypertensive patients shifts the left ventricular compliance curve upward and leftward such that for the same ventricular volume, a higher left ventricular diastolic pressure is attained as compared to a nonhypertrophied ventricle. When managing these patients with a PAC, higher pulmonary

artery occlusion pressure (sometimes >20 mm Hg) is necessary to achieve normovolemia. Cardiac output also must be checked frequently during volume challenges.

C.10. During the surgery, BP increased to 220/120 mm Hg. How would you treat the hypertension?

Intraoperative control of hypertension is outlined in Table 10.4. Severe hypertension that occurs during a surgical procedure is most frequently due to inadequate anesthesia. Inadequate blockade of sensory input from the surgical procedure stimulates the elaboration of sympathomimetic amines, resulting in hypertension and tachycardia. If a potent inhalation anesthetic is being used, the level of anesthesia should be deepened by increasing the inspired concentration of the anesthetic. A narcotic may not control the rise in BP, and it may be necessary to switch to a potent inhalation anesthetic.

Hydralazine, 5-mg increments, may be titrated to decrease BP safely with little chance of excessive reduction. The onset of action is in 10 to 15 minutes with 1 to 2 hours duration.

Labetalol, 5- to 10-mg increments, is very useful in controlling hypertension and tachycardia. It makes the most sense to use β-blockers after a significant rise in BP

Table 10.4 Intraoperative Control of Hypertension

Anesthetics
Narcotics, inhalation agents, butorphanol, lidocaine
Antihypertensives
Adrenergic blockers
α-Blocker: phentolamine
β-Blocker: propranolol, metoprolol
α- and β-blocker: labetalol
Calcium channel blockers
Diltiazem, nicardipine, verapamil
ACE inhibitors
Enalapril
Direct vasodilators
Hydralazine, nitroglycerin, nitroprusside
Dopaminergic agonists
Fenoldopam

ACE, angiotensin-converting enzyme.

because these agents act directly to antagonize the effects of the catecholamines. Although other agents may lower the BP, it is highly possible that the excessive availability of both norepinephrine and epinephrine will continue to exert their effects at the receptor site—compromising tissue perfusion from microcirculatory vasoconstriction. This view may explain the broad anti-ischemic effects of perioperative β-blockers on the brain, the heart, and the kidneys.

Rarely, continuous infusion of nicardipine, nitroglycerin, or nitroprusside, direct arteriolar vasodilators, is needed to control hypertension during anesthesia.

Sladen RN. Perioperative hypertension. *IARS review course lectures*. Cleveland, OH: International Anesthesia Research Society; 2002:100–114.

C.11. What could you do to prevent hypertension during extubation and emergence?

It is logical to use to use antihypertensive agents during extubation and emergence, as the patient is awakened at the end of surgery. Many drugs or combinations are effective, including intravenous lidocaine, esmolol, labetalol, verapamil, or diltiazem 2 minutes before extubation. If BP goes over desired levels after extubation, additional doses may be titrated to control BP.

Mikawa K, Nishina K, Maekawa N, et al. Attenuation of cardiovascular responses to tracheal extubation: verapamil versus diltiazem. *Anesth Analg*. 1996;82:1205–1210.

Nishina K, Mikawa K, Maekawa N, et al. Attenuation of cardiovascular responses to tracheal extubation with diltiazem. *Anesth Analg*.1995;80:1217–1222.

C.12. Would you consider regional anesthesia for this patient?

Certainly, regional anesthesia can avoid marked increases in sympathetic tone and hemodynamic changes that occur with intubation and extubation. Spinal or epidural anesthesia may be used for lower abdominal surgery. For cholecystectomy, higher levels of regional anesthesia are needed and may compromise respiratory function. Meanwhile, prolonged surgery can cause anxiety and irritability that may induce hypertension and tachycardia.

Hines RL, Marschall KE, eds. *Stoelting's Anesthesia and Co-existing Disease*. 5th ed. Philadelphia: Churchill Livingstone; 2008:94–97.

D. Postoperative Management

D.1. The patient developed hypertension, BP 210/110 mm Hg in the post-anesthesia care unit. What would you do?

The management of postoperative hypertension depends on the etiology of the hypertension, the clinical scenario, and the level of hypertension. First, the cause

of hypertension should be determined and treated accordingly. Hypertension per se should also be treated by an antihypertensive agent. The causes of postoperative hypertension include pain, emergence excitement, hypoxemia, hypercarbia, reaction to endotracheal tube, full bladder, hypothermia, relative hypervolemia from intraoperative administration of excess fluid, and chronic medication and withdrawal. The most common cause of postoperative hypertension is incisional pain. As the patient awakens, pain triggers an outpouring of catecholamines. The extreme lability of BP in many hypertensive patients makes this rapid increase critical to control. Depending on the cause of hypertension, intravenous analgesics, and antihypertensives or diuretics should be titrated to control hypertension. If both tachycardia and hypertension occurred postoperatively, calcium channel blockers such as verapamil, diltiazem, or nicardipine and β-blocking agents such as propranolol, esmolol, labetalol, or metoprolol are preferred agents. Hypertension resulting from pain can be preventable or attenuated by asking the surgeon to inject a long-lasting local anesthetic along the incision or to perform a local nerve block.

CHAPTER 11

Cardiac Tamponade

MANUEL L. FONTES, NIKOLAOS SKUBAS, AND JAMES OSORIO

A 69-YEAR-OLD WOMAN

was presented with shortness of breath, inability to lie supine, oliguria, and overt weakness, 4 days after two-vessel coronary artery bypass graft procedure and replacement of a mitral valve. On examination, she appeared anxious and diaphoretic with the following vital signs: respiratory rate, 38 breaths per minute; heart rate (HR), 120 beats per minute (normal sinus rhythm); and systemic blood pressure, 115/66 mm Hg. A pulmonary artery catheter (PAC) was placed and revealed: pulmonary artery (PA) pressures, 55/15 mm Hg; pulmonary artery occlusion pressure (PAOP), 14 mm Hg; central venous pressure (CVP), 23 mm Hg; and cardiac output (CO), 2.7 L per minute. Both the prothrombin and the partial thromboplastin times (PTTs) were elevated.

A. Medical Disease and Differential Diagnosis

1. What is the differential diagnosis of low CO postoperatively?
2. What is cardiac tamponade? Enumerate the common etiologies.
3. What is the difference between acute and delayed cardiac tamponade?
4. How is postcardiotomy cardiac tamponade diagnosed?
5. What is regional cardiac tamponade?
6. What is pulsus paradoxus? What is Kussmaul sign?
7. Describe ventricular interaction in cardiac tamponade.
8. How is coronary blood flow affected in cardiac tamponade?
9. What are the electrocardiographic abnormalities associated with cardiac tamponade?
10. What radiographic and echocardiogram findings are noted in cardiac tamponade?
11. What is in the differential diagnosis of postcardiopulmonary bypass (post-CPB) bleeding?

12. What is the mechanism of action of low molecular weight heparin (LMWH)?
13. Describe the advantages of LMWH therapy over standard heparin therapy.
14. What is heparin-induced thrombocytopenia (HIT)? How is the diagnosis made?
15. What is the therapy for HIT?
16. Can HIT be caused by LMWH?
17. What is the mechanism of heparin antagonism by protamine?
18. What is "heparin rebound"?
19. How does warfarin affect the coagulation system? What is the therapy for reversing its effect?
20. What do the following measure: prothrombin time (PT), activated partial thromboplastin time (aPTT), thrombin time, activated clotting time (ACT)?
21. How is the anticoagulant effect of LMWH monitored?
22. What is point-of-care testing (POCT) and what are the commonly used point-of-care devices?
23. How does desmopressin aid hemostasis?
24. What is fibrinolysis?
25. What is aminocaproic acid? What is tranexamic acid?

B. Preoperative Evaluation and Preparation

1. Interpret the hemodynamic findings of this patient.
2. How would you treat the low output status of this patient?
3. How would you evaluate this patient's coagulation status?
4. What do fresh frozen plasma (FFP) and cryoprecipitate contain?
5. What are the indications for transfusing FFP, platelet concentrate, and cryoprecipitate?
6. What are the complications associated with blood component transfusions?
7. What is the risk of acquiring human HIV from blood exposure?
8. Assuming that the patient has cardiac tamponade, how would you prepare this patient for surgery?

C. Intraoperative Management

1. How would you monitor this patient during transport to the operating room? What emergency drugs would you bring with you?
2. In this patient, what hemodynamic effects would occur from intravenous induction with ketamine, thiopental, fentanyl, propofol, etomidate, or midazolam?
3. Describe the induction process for cardiac tamponade.
4. Following induction and intubation, the systemic blood pressure decreased to 55/30 mm Hg. Describe the clinical events accounting for this perturbation and the management steps required for resuscitation.
5. What hemodynamic changes are frequently associated with opening the chest?
6. What is myocardial stunning? What is myocardial hibernation?

D. Postoperative Management

1. How would you manage hypertension in the intensive care unit (ICU)?
2. When would it be appropriate to extubate this patient?

A. Medical Disease and Differential Diagnosis

A.1. What is the differential diagnosis of low CO postoperatively?

CO is the product of stroke volume (SV) and HR (CO = HR × SV). Therefore, a low output state can occur when SV and/or HR decrease. Fast HRs, of either ventricular or atrial origin (i.e., atrial fibrillation) can also cause a low output state because the diastolic filling time is decreased or the atrial contribution to the ventricular filling is reduced or abolished. Because SV is the difference between left ventricular end-diastolic volume and left ventricular end-systolic volume, the etiology of a reduced SV can be more accurately determined by exploring whether there has been a change in the preload (left ventricular end-diastolic volume), the afterload, and/or the contractile state of the left ventricle. Either too much preload (that may cause ventricular over-distention and systolic dysfunction) or too little preload can lower the CO. Myocardial contractility can be compromised by either direct causes (myocardial ischemia, myocardial infarction, myocardial stunning, or myocardial hibernation) or indirect causes (mechanical factors as in cardiac tamponade, pulmonary embolism; pharmacologic agents; and by toxins, namely, inflammatory cytokines and bacterial endotoxins). A combination of different hemodynamic disturbances can coexist in the same patient. For example, a patient can have both a decrease in contractility and a reduced preload to account for the low output state. Therefore, correcting one problem alone may not produce the optimal hemodynamic condition.

A.2. What is cardiac tamponade? Enumerate the common etiologies.

Cardiac tamponade is defined as significant extrinsic compression of the heart by accumulating intrapericardial blood and clots (postcardiotomy, chamber perforation, dissecting aortic aneurysm, trauma, anticoagulant therapy), exudative effusions (malignant states, infective pericarditis, idiopathic pericarditis), nonexudative effusions (uremia, systemic lupus erythematosus, rheumatoid arthritis, idiopathic, radiation), and air. Irrespective of the actual volume, if the intrapericardial pressure is increased enough, globally or regionally, the risk for cardiac tamponade exists. The level of significance of cardiac tamponade depends on whether the definition is clinical or physiologic. Cardiac tamponade is a pathophysiologic continuum that on one extreme may be clinically insignificant and on the other extreme presents as a life-threatening condition requiring emergent surgical attention. Clinical tamponade is frequently associated with marked increase in pericardial pressure relative to atrial and ventricular intracardiac pressures such that SV progressively declines, resulting in systemic hypotension and cardiogenic shock.

A.3. What is the difference between acute and delayed cardiac tamponade?

In the setting of cardiac surgery, acute cardiac tamponade can occur over minutes, hours, or after a few days postoperatively. The reported incidence of acute cardiac tamponade is 0.5% to 5.8%. In the typical patient, a significant chest tube output (greater than 200 mL per hour) in the immediate postoperative period, with or without hemodynamic signs of inadequate CO, is a sign of an increased amount of blood around the heart. Alternatively, the chest tubes may become clogged by blood clots impeding mediastinal drainage and the clinical picture of cardiac tamponade develops sooner. Delayed tamponade has been arbitrarily defined as cardiac tamponade occurring 5 to 7 days after pericardiotomy. The incidence is 0.3% to 2.6%. It is often misdiagnosed because of a low index of suspicion and because the clinical signs and symptoms can be comparable to those of congestive heart failure, pulmonary embolism, and generalized fatigue (i.e., failure to thrive postoperatively). The most common culprit in delayed cardiac tamponade is anticoagulant therapy with warfarin (Coumadin), heparin, or platelet-inhibiting agents. However, a pericardial effusion (PE) after cardiac surgery is common. Using echocardiography, Weitzman et al. evaluated 122 consecutive patients postoperatively and demonstrated that most of them (103/122, 84%) had PEs. Generally, effusions reach their maximum size by the 10th postoperative day and regress spontaneously thereafter.

A.4. How is postcardiotomy cardiac tamponade diagnosed?

The diagnosis of cardiac tamponade following cardiac surgery is often difficult to make and requires a high degree of clinical suspicion, physical examination, proficient knowledge of PAC-derived measurements, and diagnostic tools such as echocardiography and chest radiography. Often, the diagnosis is made in the operating room, whereby evacuation of clot and blood from the mediastinum is associated with a drastic improvement in hemodynamics (Fig. 11.1). Relying on one modality alone for diagnosis can lead to inaccurate management decisions and increase patient morbidity. For example, the PAC is an important device for monitoring cardiac function; however, its measures can be misleading postcardiotomy unless the clinician is aware of its limitations. The classical teaching of equalization of diastolic blood pressures in cardiac tamponade (CVP = pulmonary artery diastolic pressure [PAD] = PAOP) is infrequently observed postoperatively because the previously transected pericardium is left open. Thus, blood or clot or both do not distribute homogeneously around the heart to produce equalization of pericardial diastolic pressures. Generally, the CVP is elevated but the PAD and the PAOP can be normal, elevated, or, in some cases, reduced. With significant compression of the right heart, reduced blood flow to the PA and to the left heart can yield low left-sided heart pressures that would be inconsistent with "classical" tamponade physiology. Russo et al. found that only 33% of patients with the diagnosis of postoperative cardiac tamponade had right heart catheterization findings that reflected equalization of diastolic blood pressures. Overall, 90% of patients with postcardiotomy cardiac tamponade had atypical clinical, hemodynamic, and/or echocardiographic findings. Therefore,

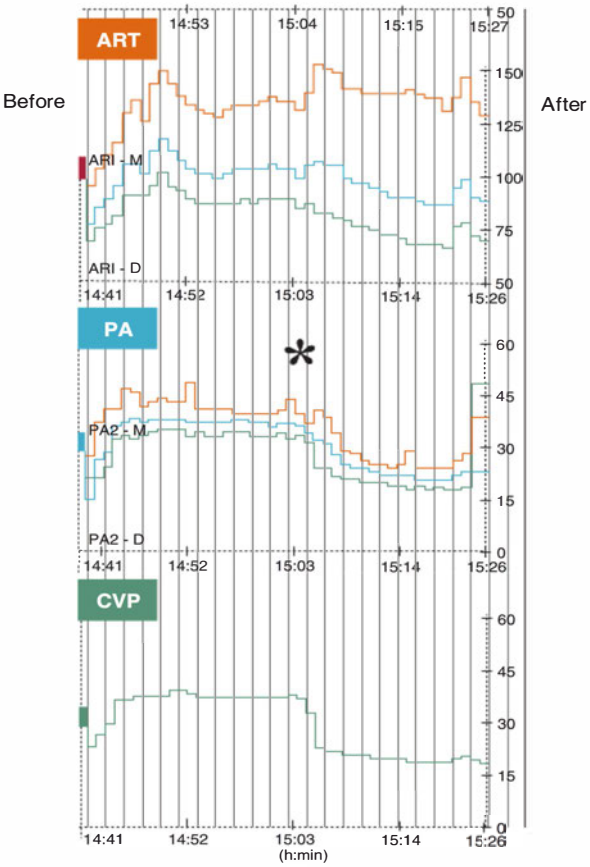

Figure 11.1 Intraoperative hemodynamics before and after evacuation of pericardial fluid. Arterial blood pressure (ART), pulmonary artery pressure (PA), and central venous pressure (CVP) are shown during chest exploration for cardiac tamponade. Note the elevated diastolic PA and CVP at the beginning of the anesthetic (left hand of the pressure trends). There is equalization of CVP and diastolic PA pressure, suggesting global pericardial effusion. As soon as the chest was opened and the pericardial collection was evacuated (*asterisk*), the ART increased abruptly and the pulse pressure widened, although both PA and CVP immediately decreased to normal levels. Taking into consideration that ART increased whereas CVP decreased after evacuation of the pericardial collection; one can assume that the cardiac output has increased.

the diagnosis of postoperative cardiac tamponade should be considered every time hemodynamic deterioration is encountered, particularly when reduction in CO or blood pressure or both are not readily responsive to conventional management. Furthermore, in delayed tamponade, the complaints tend to be vague and invasive hemodynamic data (i.e., PAC) is usually not available to allow prompt diagnosis of tamponade. Whenever the patient is not progressing as expected postoperatively and signs of end-organ dysfunction (fall in urine output or increase blood urea nitrogen and creatinine) are present, an echocardiogram should be obtained to rule out cardiac tamponade.

Spodick D. Pathophysiology of cardiac tamponade. *Chest*. 1998;113:1372–1378.

A.5. What is regional cardiac tamponade?

Regional cardiac tamponade occurs when one or more cardiac chambers (and not necessary the entire heart) become compressed by blood or blood clot or both, thereby compromising heart function (Figs. 11.2 and 11.3). Postcardiotomy, the diastolic regional collapse of the right atrium or the right ventricle is the most common echocardiographic finding in "early" cardiac tamponade. Postoperatively, a right atrial hematoma often becomes localized around the anterior and lateral walls. Clots can also be found behind the left atrium where they become encysted in the oblique sinus. Selective compression of the right heart by hematoma becomes less prominent in "delayed" tamponade, as the right heart becomes adherent or tethered to the anterior chest wall. As discussed in the previous answer, the diagnosis of tamponade is often misdiagnosed because the classical features of tamponade are often absent and blood and blood clots are unevenly distributed around the heart. The clinical presentation may be mistaken for congestive heart failure, acute left or right ventricular dysfunction, septic shock, or pulmonary embolism.

A.6. What is pulsus paradoxus? What is Kussmaul sign?

Normally, during spontaneous inspiration, the extrathoracic to intrathoracic pressure gradient is increased and the filling of the right heart is slightly larger than the filling of the left heart. In the latter, the decreased intrapulmonary pressure during inspiration will cause a relative "pooling" of the blood in the lungs and decreases the filling gradient. That causes an inspiratory fall of less than 10 mm Hg in the arterial systolic pressure along with an accompanying inspiratory fall in the venous pressure. A paradoxical pulse differs from the normal situation in two aspects: the inspiratory fall of the arterial pressure exceeds 10 mm Hg and the inspiratory venous pressure remains steady or increases (Kussmaul sign), instead of decreasing. Echocardiographic studies of patients with cardiac tamponade by D'Cruz et al. described phasic respiratory changes whereby both left ventricular dimensions and mitral valve excursion decreased during inspiration. In contrast, right ventricular dimensions increased in association with a shifting of the interventricular septum toward the left ventricle. That is, the right heart filling is done at the expense of the left. Of importance, pulsus paradoxus is not unique to cardiac tamponade. The phasic respiratory changes in ventricular dimensions with exaggerated decrease in systemic systolic arterial pressure during inspiration can be present in a variety of clinical conditions such as respiratory distress, airway obstruction, chronic obstructive pulmonary disease, and pulmonary embolism. A prominent feature of cardiac tamponade, pulsus paradoxus, may not be present at all in patients with chest wall trauma, neuromuscular disease, and pneumothorax because these patients cannot generate sufficient negative intrapleural pressure during inspiration to produce the typical changes in chamber dimension and the fall in left ventricular SV. Similarly, those who are receiving positive pressure mechanical ventilation (early postoperative period) and patients with severe aortic regurgitation do not exhibit pulsus paradoxus.

A.7. Describe the ventricular interaction in cardiac tamponade.

Ventricular interaction is extremely important for the maintenance of adequate cardiac performance. Under normal conditions, the average SV of the right ventricle equals the SV of the left ventricle; however, cyclical respiratory differences in left and right ventricular SV do occur. During inspiration, the generated negative intrapleural pressure facilitates blood return to the right heart, whereas blood return to the left heart is diminished for the following reasons: (1) lung expansion increases its reservoir for blood and (2) the increase in right ventricular filling causes the interventricular septum to "bulge" leftward, thereby reducing left ventricular dimensions and altering its compliance and filling (ventricular interaction). During exhalation, the reverse process occurs. In the case of cardiac tamponade, the ventricular interaction is augmented and involves not only the interventricular septum but also other chambers depending on the etiology of the tamponade (fluid versus clot, regional versus global tamponade). Fundamentally, as intrapericardial content increases, it will reach a point whereby the parietal pericardium cannot stretch to accommodate the rising pressure. Because of the fixed space within the pericardium, the cardiac chamber dimensions become smaller as the pericardial contents increase. First, the thin-walled and more compliant atria progressively gets compressed, followed by the right ventricle, and finally by the left ventricle. Overall, the physiology of ventricular interaction in clinical cardiac tamponade becomes complex as the pressure–volume relation of mediastinal and chest structure alters with each heartbeat and from respiratory and neuroendocrine influences.

Spodick DH. Pathophysiology of cardiac tamponade. *Chest*. 1998;113:1372–1378.

A.8. How is coronary blood flow affected in cardiac tamponade?

In the absence of coronary artery disease, coronary blood flow is reduced in cardiac tamponade, but this reduction is not sufficient to add an ischemic insult to the heart, because there is a proportionate decrease in ventricular preload (underfilled heart) and ventricular afterload. Consequently, both myocardial work and oxygen consumption are reduced. In contrast, patients with coronary artery disease may be at increased risk for myocardial ischemia and infarction.

Reddy PS, Curtiss EL, O'toole JD, et al. Cardiac tamponade: hemodynamic observations in man. *Circulation*. 1978;58:265–272.

A.9. What are the electrocardiographic abnormalities associated with cardiac tamponade?

Electrocardiographic changes may occur in the setting of cardiac tamponade. These include nonspecific ST-T wave abnormalities, low-voltage QRS complex, signs of myocardial ischemia and pericarditis, and electrical alternans (Fig. 11.4). The latter is seen in patients with large effusions and is characterized by beat-to-beat shifts in electrical axis. This beat-to-beat alteration may be due to increased distance between the heart and the chest wall resulting in a "pendulum" like motion of the heart. However, it has been shown that with minimal amount of pericardial fluid removal, the presence of electrical alternans can be abolished while the pericardial space remains enlarged. Therefore, the electrocardiographic change of electrical alternans may reflect a

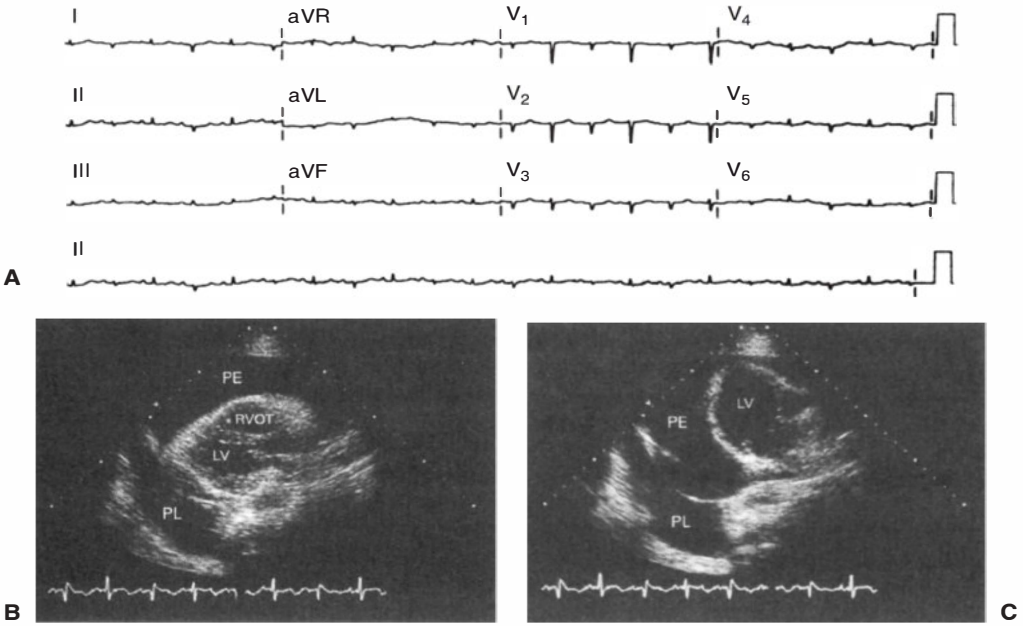

Figure 11.4 Depiction of electrical alternans in a patient with cardiac tamponade **(A)**. The images demonstrate significant pericardial effusions (PE) obtained during transthoracic echocardiography. Note the image of the left ventricle (LV) during systole **(B)** and diastole **(C)**. PL, pleural effusion; RVOT, right ventricular outflow tract. (From Longo MJ, Jaffe CC. Images in clinical medicine: electrical alternans. *N Engl J Med*. 1999;341:2060, with permission)

hemodynamic pathology rather than an anatomic abnormality. This finding, although sensitive for cardiac tamponade, is not very specific (very few patients with tamponade present with electrical alternans).

A.10. What radiographic and echocardiographic findings are noted in cardiac tamponade?

On standard anterior-posterior chest radiography, the cardiac silhouette may appear normal in size or extremely enlarged, depending on the acuity and chronicity of the tamponade process. Normally, the pericardial fluid amounts to 15 to 25 mL. Acute tamponade physiology can arise with as little as 150 mL of effusion, whereas chronic effusions may exceed 1,000 mL before clinical signs and symptoms of cardiac tamponade become evident. In the latter case, on chest radiography film, the cardiac silhouette will appear "widened" with or without features such as obscuring of the pulmonary vessels at the hilum and a globular or "water bottle" configuration of the heart.

Transthoracic or transesophageal echocardiography can differentiate between cardiac dysfunction arising from direct myocardial injury and cardiac dysfunction associated with mechanical processes. Pericardial effusions can be readily seen and semi quantitated. Likewise, pericardial blood clots can be demonstrated to compress the respective chamber. Additional echocardiographic signs observed in tamponade include (1) diminished left ventricular dimension and mitral valve excursion during inspiration, (2) shifting of the interventricular septum toward the left ventricle, (3) transvalvular (mitral and aortic) flow characteristics seen by Doppler techniques, (4) diastolic posterior motion of the right ventricular wall, and (5) in some cases, a systolic notch on the right ventricular epicardium (Figs. 11.2 and 11.3). Although many of the findings of both radiographic film and echocardiogram can be suggestive of cardiac tamponade, not a single sign is 100% sensitive and specific.

A.11. What is in the differential diagnosis of postcardiopulmonary bypass (post-CPB) bleeding?

Significant bleeding following cardiac surgery requiring surgical exploration "bring-back" occurs in approximately 3% of cases. Often, the source of bleeding cannot be ascertained and its etiology is ascribed to a coagulation defect. Procedures that require cardiopulmonary bypass (CPB) are known to adversely affect the hemostatic mechanisms, including vascular endothelium, fibrinolytic and coagulation factors, platelet, plasminogen, and inflammatory pathways (Fig. 11.5). Under normal settings, these systems (and others yet unknown) act in concert and in opposition with one another to prevent bleeding by promoting clot formation at the site of endothelial injury (procoagulant effects) and prevent or destroy clot formation (anticoagulant effects—either directly or indirectly through inhibitory mediators). Once blood elements come in contact with a nonendothelialized surface (bypass circuit), the procoagulant system becomes activated, resulting in consumption of platelets, coagulation factors, and fibrinogen (tissue factor pathway). The potential for postoperative bleeding will depend on the degree of activation and pre-existing levels of the procoagulants as well as other factors such as the duration of CPB, systemic hypothermia, comorbid states (renal and liver insufficiency), type of surgery (reoperation, circulatory arrest, combined procedures), and prior or current treatment with anticoagulant (platelet inhibitors, warfarin process). Once activated, they secrete several types of granules. Granules, containing peptides such as fibrinogen, thrombospondin, factors V and VIII, and β-thromboglobulin, are reduced in both number and content during CPB. Of greater importance is the loss of several membrane glycoproteins (IIb-IIIa) that interact with fibrinogen and other cellular elements, allowing for platelet conjugation and propagation of clot formation. Overall, postcardiotomy bleeding is due to (1) a qualitative and a quantitative platelet defect, (2) deficiency, and (3) surgical bleeding. The latter can arise from either venous or arterial sources that were undetected before closure of the chest. Attentive and meticulous effort to surgical hemostasis can significantly reduce the incidence of bring backs.

A.12. What is the mechanism of action of low molecular weight heparin (LMWH)?

Unfractionated heparin exerts its anticoagulant activity through antithrombin III (ATIII). ATIII inhibits thrombin (factor IIa) and factors IXa, Xa, and XIa. Unfractionated heparin accelerates the formation of ATIII-IIa complex by 2,000 folds (and that requires the simultaneous binding of unfractionated heparin of at least 18 saccharide units–length to both ATIII and IIa), and the formation of ATIII-Xa by 1,200 folds. LMWHs are fragments of unfractionated heparin produced by controlled enzymatic or chemical depolymerization processes yielding chains having molecular weight of 6,000 to 7,000 daltons. LMWHs consist of 8 to 16 saccharide units and inhibits factor Xa preferentially. This inhibition requires only that LMWH binds to ATIII and the latter interacts with factor Xa, without the interaction between LMWH and factor Xa being necessary. LMWH has greater inhibitory effect on factor Xa, whereas unfractionated heparin exerts an equipotent effect against both thrombin and factor Xa. The aPTT monitors the anti-IIa activity more closely than the anti-Xa activity. Finally, both LMWH and unfractionated heparin cause release of tissue factor pathway inhibitor from vascular endothelium, which then forms a complex with and inhibits factor Xa. This complex in turn inactivates factor VIIa.

A.13. Describe the advantages of LMWH over standard heparin therapy.

There are several clinical and pharmacologic advantages of LMWH over unfractionated heparin. The plasma half-life of LMWH is two to four times longer than unfractionated heparin, which undergoes a dose-dependent elimination by the liver and the kidneys. A significant amount of unfractionated heparin is bound to plasma proteins, vascular endothelium, and macrophages, resulting in less bioavailability and an unpredictable anticoagulant effect. Consequently, careful laboratory monitoring is required. Additional benefits of LMWH over unfractionated heparin include less bleeding (less platelet inhibition and decreased propensity for increased microvascular permeability). Several clinical trials have improved the efficacy and safety of LMWH over unfractionated heparin. Of note, LMWH is not recommended in the setting of renal failure. The anticoagulant activity of LMWH may be measured by assaying factor Xa levels. Many different types of LMWH are available, each having slightly different pharmacologic effects (bioavailability, anticoagulant effect). Our understanding of the anticoagulant mechanism of LMWH continues to evolve and, although its indications continue to broaden, there may be safety concerns that ought not to be dismissed.

A.14. What is heparin-induced thrombocytopenia (HIT)? How is the diagnosis made?

Heparin normally binds to platelet membranes at GPIb and other receptor sites and aggregates normal platelets by releasing adenosine diphosphate. HIT is a serious complication of heparin therapy that is predominantly immune-mediated by a binary complex formed between heparin and platelet factor 4. The reaction is commonly caused by an immunoglobulinG antibody that binds and activates platelets in the presence of heparin. Other immunoglobulins may also potentiate HIT.

HIT exists in two forms. A benign form of HIT, type I, is observed in approximately 10% to 20% of patients receiving unfractionated heparin. This mild form of thrombocytopenia (rarely less than 100,000 per μL) occurs after 1 to 4 days of therapy with heparin. It is due to proaggregatory effects of heparin on platelets and generally improves despite continuing heparin administration. In contrast, HIT type II is a life-threatening condition that develops 5 to 10 days after initiating heparin therapy

and is associated with devastating thromboembolic processes (most commonly arterial thrombosis resulting in limb ischemia, cerebrovascular events, and myocardial infarction), from activated platelets that adhere, aggregate, and form platelet ("white") clots. The platelet count falls to less than 50,000 per μL and in severe cases to less than 5,000 per μL. The incidence of HIT in patients receiving full-dose heparin ranges between 0% and 30%. Although there is no randomized prospective study looking at the true incidence of HIT, the expected incidence is estimated to be less than 5%. Those patients who have had a previous exposure to heparin (recent and in some cases remote history) *may* develop HIT earlier after institution of heparin therapy compared with those with no previous exposure. The frequency of HIT is also higher in patients receiving porcine mucosal heparin compared with bovine lung heparin.

The diagnosis of HIT should be entertained in any patient with a significant fall in platelet count while on heparin therapy (less than 150,000 per μL or a 50% or greater decrease in platelet count after 5 days of heparin therapy). The definitive diagnosis requires the following steps: (1) thrombocytopenia while on heparin, (2) exclusion of other etiology of thrombocytopenia, (3) improvement in platelet count following cessation of heparin therapy, and (4) presence of heparin-dependent platelet antibody by an in vitro test. In most cases, the diagnosis is made on clinical findings.

A.15. What is the therapy for HIT?

Because HIT type II is a potentially lethal condition, the most effective therapy is discontinuation of heparin. The thrombocytopenia should improve progressively. Although tempting, the need for platelet transfusion is discouraged because bleeding occurs infrequently and vascular thrombosis may be potentiated. Several anticoagulants have been recommended for use in HIT, as heparin replacement. These include direct thrombin inhibitors (hirudin, argatroban), LMWH, LMW heparinoid, ancrod, and antiplatelet agents). Most of these agents are not available in the United States; others are under clinical investigation. Hirudin has been extensively used in Europe with demonstrable benefit and safety. LMWH has been shown to have cross reactivity with unfractionated heparin approaching 100% (by C-serotonin release or heparin-induced platelet aggregation assays) and should not be used in the setting of HIT unless there are demonstrable negative cross reactivity assays with standard heparin. Ancrod is a defibrinogenating agent (not available in the United States) extracted from the Malayan pit viper and is immunologically distinct from heparin. It acts by cleaving fibrinopeptide A from fibrinogen, and its activity can be measured by assaying for plasma fibrinogen concentration. Finally, in the setting of HIT, a synthetic analogue of prostacyclin (iloprost—a potent inhibitor of platelet activation) has been used successfully during cardiac surgery to inactivate platelets and prevent further reduction of platelet count.

A.16. Can HIT be caused by LMWH?

Based on confirmed laboratory tests, the prevalence of HIT is 2% for patients receiving unfractionated heparin. Although LMWHs can also induce thrombocytopenia, they may be acceptable alternatives for patients who develop HIT from unfractionated heparin, but reactivity of the particular LMWH with the patient's platelets should be confirmed in vitro.

A.17. What is the mechanism of heparin antagonism by protamine?

Heparin is a large molecule consisting of chains of alternating residues of D-glucosamine and uronic acid. It is highly negatively charged, whereas protamine is mostly positively charged. The two combine irreversibly to form a heparin–protamine complex that does not have the ability to bind to thrombin or factor Xa. Once neutralized, the complex of heparin and protamine is eliminated.

A.18. What is "heparin rebound"?

The ACT is used to confirm the adequacy of heparin neutralization by protamine. The reappearance of circulating heparin several hours after its neutralization by protamine is called heparin rebound and is usually incriminated for clinical bleeding occurring after

cardiac surgery. The concept of heparin rebound following protamine reversal may be explained by sequestration of heparin in tissues that are poorly perfused (i.e., fat), late release of heparin by endothelial cells, and more rapid clearance of protamine in relation to heparin (because heparin is mobilized back into the circulation, it can inhibit thrombin formation and predispose to post-CPB bleeding). Studies in which 1 mg of protamine is given per 100 units of heparin (total dose) found no evidence of heparin rebound.

A.19. How does warfarin affect the coagulation system? What is the therapy for reversing its effect?

Warfarin (Coumadin) remains the most commonly used anticoagulant agent in the outpatient setting (atrial fibrillation, prosthetic valves, and devices). Its predominant pharmacodynamic effect is inhibition of synthesis of vitamin K–dependent factors (II, VII, IX, and X) in the liver and its clinical efficacy is monitored by measuring the PT or more specifically, the international normalized ratio (INR). The safe or efficacy levels of either INR or PT is variable because of multiple factors, including hepatic, nutritional, drug interaction, age, and presence of other comorbid conditions. On average, it takes several days of therapy to achieve the desired INR (2 to 4); consequently, administration of LMWH or unfractionated heparin may be necessary for initiating anticoagulation. Complications occur because of inadequate anticoagulation (thrombosis) or because of excessive anticoagulation (bleeding and hemorrhage). To reverse its effect, warfarin should be discontinued several days (more than 3 days) to allow levels of the aforementioned factors to normalize. Acute reversal is achieved with FFP. Administration of vitamin K is often necessary to accelerate the synthetic process.

A.20. What do the following measure: prothrombin time (PT), activated partial thromboplastin time (aPTT), thrombin time, activated clotting time (ACT)?

Prothrombin time

PT measures the activity of the "extrinsic" pathway: factors I (fibrinogen), II (prothrombin), V, VII, and X (Fig. 11.5). Deficiencies of factors V, VII, and X (50% of normal) significantly prolong the PT. The concentrations of fibrinogen and prothrombin required to prolong the PT are much lower. The activity of three of the four vitamin K–dependent factors (II, VII, IX, and X) are measured by the PT. Normal values are less than 12 seconds.

Activated partial thromboplastin time

aPTT measures the activity of the "intrinsic" pathway: factors XII, XI, IX, VIII, V, X, prothrombin, and fibrinogen (Fig. 11.5). The aPTT is prolonged when the concentration of these factors is less than 20% to 30%. Normal values are 25 to 40 seconds.

Thrombin time

Thrombin time measures the conversion of fibrinogen to fibrin by thrombin—the final step in the coagulation cascade (Fig. 11.5). The thrombin time is decreased in the presence of low concentrations of fibrinogen and thrombin. Heparin prolongs the thrombin time, whereas warfarin has little effect. Normal values are less than 10 seconds.

Activated clotting time

ACT measures the overall function of the coagulation system. It is used primarily to measure the adequacy of heparinization during CPB and protamine reversal of heparin following CPB. Prolonged ACTs may be due to heparin, low levels of coagulation factors, or thrombocytopenia. It is not particularly specific for platelet or factor deficiencies. Normal values are 110 to 140 seconds.

Sconce EA, Kamali F. Appraisal of current vitamin K dosing algorithms for the reversal of over-anticoagulation with warfarin: the need for a more tailored dosing regimen. *Eur J Haematol.* 2006;77:457–462.

A.21. How is the anticoagulant effect of LMWH monitored?

There is no evidence that monitoring of LMWH dosage improves the clinical efficacy. In contrast, any overdose increases the risk for hemorrhage. Because the kidneys play a significant role in the elimination of LMWH, therapeutic use of these agents should be monitored with an antifactor Xa assay, especially in patients who have renal insufficiency, are elderly, and have clinical conditions that increase the risk for bleeding.

Boneu B, de Moerloose P. How and when to monitor a patient treated with low molecular weight heparin? *Semin Thromb Hemost.* 2001;27:519–522.

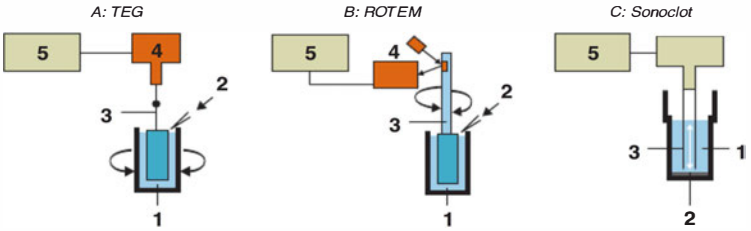
A.22. What is point-of-care testing (POCT) and what are the commonly used point-of-care devices?

The need for POCT has developed as a result of limitations of central laboratories to timely and completely provide results to clinicians for the diagnosis and management of coagulopathic bleeding associated with cardiac surgery, liver transplantation, and trauma beyond standard coagulation tests (PT/aPTT, platelet count, and fibrinogen level). Specific defects in hemostasis (coagulation, analysis of platelet function, as well as abnormal fibrinolysis) can be identified and guided component transfusion practices accomplished. POCT can be performed on-site, in the operating room, and in the ICU. Decrease in the need for blood and blood components (Packed red blood cells, platelets, FFP, cryoprecipitate) has been shown with use of POCT in guiding transfusion practice.

The three devices used in clinical practice are thromboelastography (TEG), rotation thromboelastometry (ROTEM) and Sonoclot analysis.

Thromboelastography (TEG)

The Thromboelastograph (TEG) (Hemoscope Corporation, Niles, IL) measures physical properties of a clot using a stationary cylindrical cup that holds the blood sample and oscillates at an angle. A pin is suspended in the blood by a torsion wire. Motion of the torsion wire is monitored in different phases of in vitro platelet and clot interaction, fibrin formation, and lysis (Fig.11.6A). The analysis performed provides a



A. Thrombelastograph (TEG): Rotating cup with blood sample (1), coagulation activator (2), pin and torsion wire (3), electromechanical transducer (4), data processing (5).

B. Rotation thrombelastography (ROTEM): Cuvette with blood (1), activator added by pipetting (2), pin and rotating axis (3), electromechanical signal detection via light source and mirror mounted on axis (4), data processing (5).

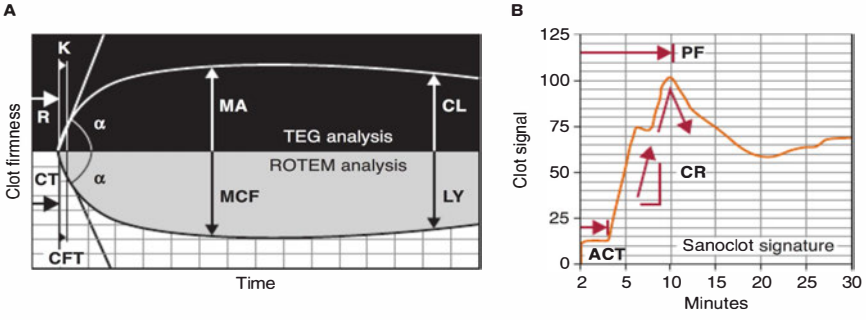
C. Sonoclot: Blood sample in cuvette (1), containing activator (2), disposable plastic probe (3), oscillating in blood sample mounted on electromechanical transducer head (4), data processing (5).

Figure 11.6 Working principles of viscoelastic point-of-care coagulation devices.

graphic and numerical display (Fig.11.7A, upper side). The etiology of a coagulopathy may be obtained by analyzing characteristic TEG signatures (Fig.11.8).

Thromboelastometry

Thromboelastometry also measures viscoelastic properties of a blood sample. ROTEM-rotation thromboelastometry (Pentapharm GmbH, Munich, Germany) is the commercially available device. The principle of the ROTEM is based on the use of a moving pin suspended in a cup of blood sample. The signal is transmitted by an optical detector



A. Upper side:

Figure 11.7 Typical tracings of viscoelastic point-of-care coagulation devices.

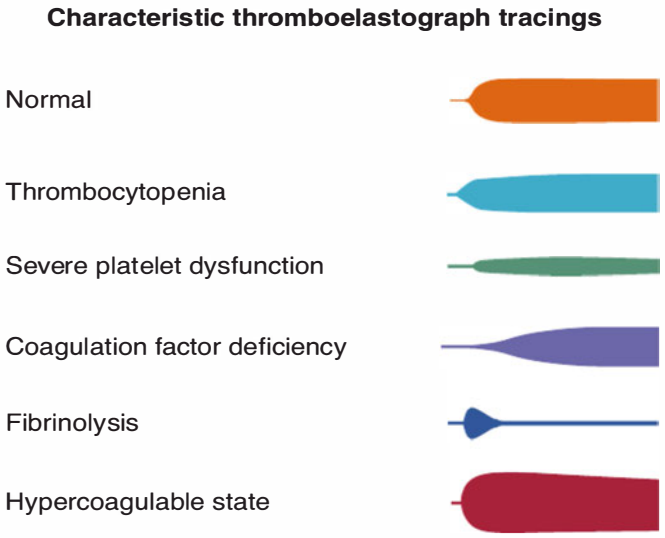

Figure 11.8 Qualitative analysis of thromboelastogram.

system from the moving pin (Fig. 11.6B). The ROTEM provides a measure and graphical display of the changes in viscoelasticity recorded at all stages of the developing clot and characteristic tracings of abnormal findings (Fig. 11.7A lower side and Fig.11.9). Although the basic principles of function as well as the TEG and ROTEM tracings are very similar, the nomenclature and reference ranges are different (Table 11.1).

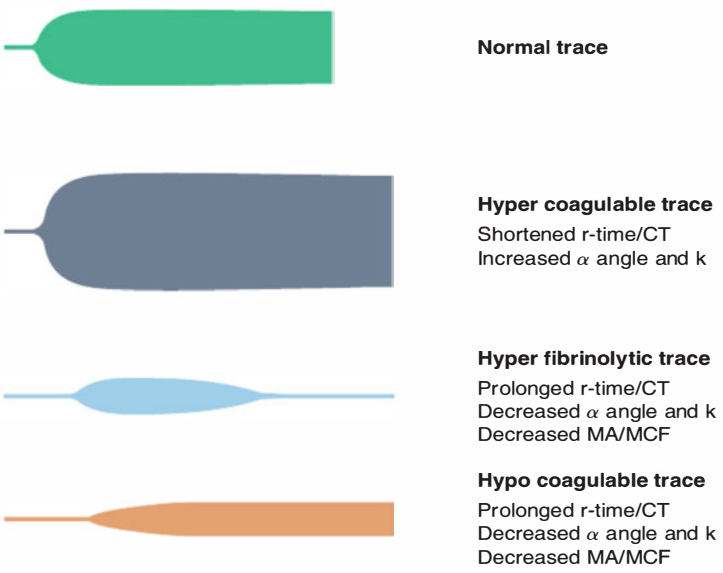

Figure 11.9 Examples of abnormal ROTEM traces.

Table 11.1 Nomenclature and Reference Values of Thrombelastography (TEG) Thrombelastometry (ROTEM)

	TEG	ROTEM®
Clotting time (period to 2 mm amplitude)	*R* (reaction time)	*CT* (clotting time)
	N (WB) 4–8 min	*N* (Cit, in-TEM) 137–246 s
	N (Cit, kaolin) 3–8 min	*N* (Cit, ex-TEM) 42–74 s
Clot kinetics (period from 2 to 20 mm amplitude)	*K* (kinetics)	*CFT* (clot formation time)
	N (WB) 1–4 min	*N* (Cit, in-TEM) 40–100 s
	N (Cit, kaolin) 1–3 min	*N* (Cit, ex-TEM) 46–148 s
Clot strengthening (alpha angle)	α (slope between r and k)	α (slope of tangent at 2 mm amplitude)
	N (WB) 47°–74°	*N* (Cit, in-TEM) 71°–82°
	N (Cit, kaolin) 55°–78°	*N* (Cit, ex-TEM) 63°–81°
Amplitude (at set time)	*A*	*A*
Maximum strength	*MA* (maximum amplitude)	*MCF* (maximum clot firmness)
	N (WB) 55–73 mm	*N* (Cit, in-TEM) 52–72
	N (Cit, kaolin) 51–69 mm	*N* (Cit, ex-TEM) 49–71 mm
		N (Cit, fib-TEM) 9–25 mm
Lysis (at fixed time)	CL30, CL60	LY30, LY60

TEG: *N* = normal values for kaolin activated TEG in native whole blood (WB) or citrated and recalcified blood samples (Cit) (Haemoscope Corp.). ROTEM: *N* = normal values for contact (partial thromboplastin phospholipids, in-TEM), tissue factor (ex-TEM), and tissue factor plus platelet inhibitor cytochalasin D (fib-TEM) activated, citrated, and recalcified blood samples.[6] Reference values depend on reference population, blood sampling technique, other preanalytical factors, and coagulation activator.

Abnormal ROTEM tracing's reflective of specific defects of hemostasis are illustrated in Fig. 11.9

Sonoclot analyzer

The Sonoclot similarly measures the development of clot viscoelastic strength. The principle of function is based on a vertically moving piston (Fig. 11.6C). The device measures the impedance to vibration at the tip of the probe. Information provided includes function of coagulation, fibrin gel formation, clot retraction (platelet function) and fibrinolysis. The Sonoclot analyzer generates both a qualitative graph (Sonoclot signature) and quantitative results on the clot formation time (ACT—onset) and rate of fibrin polymerization (clot rate) (Fig. 11.7B).

A.23. How does desmopressin aid hemostasis?

Desmopressin (1-deamino-8-D-arginine vasopressin [DDAVP]) is a vasopressin analog with more potency, longer lasting antidiuretic activity, and much less vasoconstriction than the parent compound. Desmopressin increases von Willebrand's factor and factor VII activity in plasma. von Willebrand's factor is found in subendothelial tissue, is released from platelets, and is in part responsible for platelet adhesion to damaged blood vessels. DDAVP was initially shown to significantly decrease postoperative bleeding. Although its routine use is not recommended, DDAVP may be beneficial in patients with end-stage renal disease to increase von Willebrand's factor that is decreased in those patients. The optimal dose of DDAVP is 0.3 μg per kg.

A.24. What is fibrinolysis?

Fibrinolysis is fibrin breakdown in thrombi. Plasmin, derived from plasminogen, is the enzyme involved in this process. Physiologic fibrinolysis involves clot remodeling and removal during the healing process. Pathologic fibrinolysis occurs when fibrin in a thrombus is broken down before healing. Although elevated concentrations of plasminogen activators are found during CPB, their half-lives are very short after bypass.

Spiess BD, Horrow J, Kaplan JA. Transfusion medicine and coagulation disorders. In: Kaplan JA, Reich DL, Savino JS, et al., eds. *Kaplan's Cardiac Anesthesia*. 6th ed. Philadelphia: WB Saunders; 2011:949–984.

A.25. What is aminocaproic acid? What is tranexamic acid?

ϵ-Aminocaproic acid (Amicar) and tranexamic acid are analogues of lysine. Their primary mechanism of action is inhibition of plasminogen and plasmin, resulting in less breakdown of fibrinogen, fibrin (fibrinolysis), and other clotting components. These antifibrinolytic agents have been effective in treating coagulopathy in the setting of heart surgery, portocaval shunts, hematologic disorders such as aplastic anemia, abruptio placentae, hepatic cirrhosis, and neoplastic diseases.

Compared with placebo, use of tranexamic acid or aminocaproic acid in cardiac surgery has been shown to reduce blood loss by 30% to 49% as well as reduce homologous blood transfusion. Considering the low cost associated with aminocaproic acid therapy (less than $12), many cardiac surgical centers use this agent routinely for uncomplicated open-heart procedures.

The standard intravenous preparation and dosage for cardiac surgery include 5 to 10 g of aminocaproic acid diluted and infused over 1 hour, followed by a continuous infusion at a rate of 1 g per hour. Higher infusion rates may be used. There are several adverse events that include thrombosis (early graft closure, myocardial ischemia, and infarction), agranulocytosis, leukopenia, and thrombocytopenia. Although rare, bradycardia and mild reduction in blood pressure have also been reported.

B. Preoperative Evaluation and Preparation

B.1. Interpret the hemodynamic findings of this patient.

The patient has an adequate blood pressure; however, this appears to be maintained through compensatory mechanisms, including an increase in both arterial resistance (systemic vascular resistance) and HR. The PA systolic pressure is consistent with pulmonary hypertension arising most likely from either chronic mitral valvular disease (stenosis or insufficiency) or decreased compliance of the left ventricle (because it may occur in ischemia). Both the PAD and the PAOP suggest that the left ventricular end-diastolic pressure—a correlate of left ventricular preload—is within the normal limits. Keep in mind that pressure measurements do not correlate with volume status unless the compliance of the chamber (the relation between pressure and volume in diastole) is constant. Therefore, a PAOP of 14 mm Hg could represent hypovolemia, normovolemia, or hypervolemia depending on the compliance of the left ventricle. A CVP of 23 mm Hg is suggestive of right ventricular or biventricular dysfunction, tricuspid stenosis or insufficiency, or obstruction and compression of the right atrium. The CO is inadequate. The derived SV of 22 mL (CO/HR) combined with the other derangements (elevated CVP strongly reflects right heart dysfunction). Taking into consideration the patient's overall presentation (physical examination and laboratory findings), the differential diagnosis includes right ventricular ischemia and/or infarction, pulmonary embolism, atrial or ventricular septal defect causing volume overload of the right ventricle, and cardiac tamponade. An echocardiogram should be performed to assist in the diagnostic process and clinical management.

Fontes ML, Bellows W, Ngo L, et al. McSPI Research Group. Assessment of ventricular function in critically ill patients: limitations of pulmonary artery catheterization. Institutions of the McSPI Research Group. *J Cardiothorac Vasc Anesth*. 1999;13: 521–527

Kern MJ, Lim MJ, Goldstein JA. Hemodynamic rounds: interpretation of cardiac physiology from pressure wave analysis. 3rd ed. Hoboken: Wiley-Blackwell; 2009:269.

B.2. How would you treat the low output status of this patient?

Although the HR is increased, it may be unwise to attempt to normalize it before correcting the SV. The latter is a function of the preload, the afterload, and the contractile status of the myocardium. Whereas the preload of the right heart may be excessive (CVP = 23 mm Hg), the preload of the left heart may not be adequate despite a PAOP of 14 mm Hg. While waiting for the echocardiogram to be performed, a fluid bolus can be attempted. If there is a positive response (i.e., the blood pressure and/or the CO increase), additional fluid bolus can be administered until the limit of the preload reserve has been reached (operating on the flat end portion of the Frank-Starling curve). In the setting of right ventricular failure, it is customary to fluid load the patient. It is important to note that fluid challenge alone will not improve cardiac performance without addressing the contractility and the afterload that, in this patient, appear to be deranged. Because there is no knowledge of the exact etiology of the low output state, it would be rational to institute inotropic support. With regard to the afterload, both systemic and pulmonary afterload are elevated. On the

right side, PA hypertension can be improved with nitroglycerin or nitroprusside but the associated systemic hypotension would prohibit their use. In fact, most vasodilators with the exception of nitric oxide would compromise the systemic pressures. At the same time, if the compliance of the right ventricle is presumed to be decreased, then the increased CVP does not necessarily correlate with adequate preload of the right ventricle. Alternatively, an inotrope that has vasodilatory properties, such as milrinone or dobutamine, would be a better choice. In summary, a rational management of the hemodynamic findings presented would include administering fluid (crystalloid or blood products as indicated), prescribing inotropic support, obtaining an echocardiogram, and addressing the other systemic complications (pulmonary, renal, and coagulation).

Ghobashy A, Fontes ML, Hines RL. Cardiogenic shock. In: Murray MJ, Coursin DB, Pearl RG, et al., eds. *Critical Care Medicine: Perioperative Management*. 2nd ed. Philadelphia: Lippincott Williams & Wilkins; 2002:287.

B.3. How would you evaluate this patient's coagulation status?

A complete blood cell count and a complete coagulation panel should be performed. Assuming that both the hematocrit and the platelet function are adequate, attention should be directed to the elevated PT and the aPTT. The patient has a prosthetic valve and it would be appropriate to surmise that she has been taking anticoagulants. The most common agent to be used 4 days after surgery is warfarin (Coumadin). Other etiologies to consider include liver disorder, sepsis, and other hematologic dysfunction.

Keller C, Matzdorff AC, Kemkes-Matthes B. Pharmacology of warfarin and clinical implication. *Semin Thromb Hemost*. 1999;25:13–16.

Spiess BD, Horrow J, Kaplan JA. Transfusion medicine and coagulation disorders. In: Kaplan JA, Reich DL, Savino JS, et al., eds. *Kaplan's Cardiac Anesthesia*. 6th ed. Philadelphia: WB Saunders; 2011:949–984.

B.4. What do fresh frozen plasma (FFP) and cryoprecipitate contain?

FFP contains the labile factors V and VIII as well as the stable coagulation factors (II, VII, IX, X, XI). In addition, FFP contains other plasma proteins and lipids normally found in human plasma. Cryoprecipitate is derived by thawing FFP at 4° C (39.2° F). It contains factors VIII and XIII, von Willebrand's factor, and fibrinogen.

Drummond JC, Petrovich CT. Hemotherapy and hemostasis. In: Barash PG, Cullen BF, Stoelting RK, eds. *Clinical Anesthesia*. 5th ed. Philadelphia: Lippincott Williams & Wilkins; 2006:221.

B.5. What are the indications for transfusing FFP, platelet concentrate, and cryoprecipitate?

Blood usually coagulates appropriately when coagulation factor concentrations are at least 20% to 30% of normal and when fibrinogen levels are greater than 75 mg per dL. Although laboratory values such as PT and PTT may be abnormal, the American Society of Anesthesiologist Task Force on Blood Component Therapy

discourages conventional use of FFP for perioperative treatment of bleeding because there are few clinical circumstances whereby coagulopathy arises from factor deficiency. Although massive blood replacement can produce prolongation of PT and/or PTT, the task force states that a true dilutional coagulopathy does not ordinarily occur until more than 100% of the patient's blood volume has been replaced. It supports the use of FFP in patients having vascular bleeding with PT and PTT values greater than 1.5 times the laboratory's normal value. FFP should be administrated in doses calculated to achieve a minimum of 30% of plasma factor concentration (i.e., 10 to 15 mL per kg of FFP).

Recommended indications for FFP:

- Replacement of factor deficiencies
- Reversal of warfarin effect
- Massive blood transfusions
- Treatment of antithrombin III deficiency in patients who are heparin resistant requiring systemic anticoagulation with heparin

In 1994, the College of American Pathologists recommended platelet transfusions after CPB in patients with normal coagulation values and platelet count below 100,000 per μL when major unexplained bleeding occurs. Transfusion of one platelet concentrate will increase the platelet count by approximately 5,000 to 10,000 per μL in the average adult. The usual therapeutic dose is one platelet concentrate per 10-kg body weight.

Platelet concentrate is indicated in the following:

- Active bleeding associated with thrombocytopenia
- Massive blood transfusions

The American Society of Anesthesiologist's Task Force on Blood Component Therapy recommends the administration of cryoprecipitate for:

- Prophylaxis in nonbleeding perioperative or peripartum patients with congenital fibrinogen deficiencies or von Willebrand disease unresponsive to DDAVP (whenever possible, these decisions should be made in consultation with the patient's hematologist)
- Bleeding patients with von Willebrand disease
- Correction of microvascular bleeding in massively transfused patients with fibrinogen concentrations less than 80 to 100 mg per dL

One unit of cryoprecipitate per 10-kg body weight raises plasma fibrinogen concentration approximately 50 mg per dL in the absence of continued consumption or massive bleeding. Bleeding following cardiac surgery without demonstrable abnormalities of coagulation is not considered to be an indication for transfusion of FFP, platelets, or cryoprecipitate. Recent report suggests that postoperative bleeding after CPB may be secondary to excessive fibrinolysis that is responsive to cryoprecipitate. Importantly, the smaller volume of cryoprecipitate compared to FFP makes it a more desirable choice when there is concern of either hemodilution or volume overload.

B.6. What are the complications associated with blood component transfusions?

Complications associated with transfusions of blood elements include transmission of infectious agents (e.g., hepatitis, HIV infection), hemolytic and nonhemolytic transfusion reactions, immunosuppression, anaphylactic or anaphylactoid reactions, and alloimmunization to platelet-specific antigens and the Rh antigen (resulting from erythrocyte contamination because they are stored at room temperature). Platelets in particular may contain proliferating bacteria. Finally, in the immunosuppressed, graft-versus-host effects may occur following platelet transfusion.

Nightingale SD. Department of Health and Human Services Advisory Committee on Blood Safety and Availability. Universal WBC reduction. *Transfusion*. 2001;41:1306–1309.

B.7. What is the risk for acquiring HIV from blood exposure?

The risk for HIV infection in the United States is 1/1,500,000 to 1/2,000,000 per unit transfused. However, with the implementation of donor screening tests for HIV-1 antigen, there is an expectation of preventing up to 25% of the window period cases (the period between viral infection and its detection by tests for the presence of antibodies). Perhaps the immunoviral agent most transmitted by blood transfusion is cytomegalovirus.

B.8. Assuming that the patient has cardiac tamponade, how would you prepare this patient for surgery?

As with any patient undergoing surgery, the following steps should be taken: first, a complete review of the patient's history, physical examination, and laboratory findings are mandated; second, key areas of concern should be identified and appropriate steps taken to address them; third, an anesthetic plan that is tailored to cardiac tamponade is devised; last, communication with the respective medical (surgeons, nurses, perfusionist, blood bank) and paramedical staff to ensure readiness and teamwork. The patient's presentation suggests that she is in some degree of respiratory distress. Initially, management should consist of supplemental oxygen, review of

chest radiograph, and assessment of arterial blood gasses. Shortness of breath and the inability to lie supine are frequent symptoms in patients having cardiac tamponade physiology, and every effort should be made to provide comfort and lessen the associated emotional stress. Positive pressure ventilation should be avoided at all cost unless the clinical picture indicates that the patient will have a cardiac arrest. The persistent oliguria most likely reflects prerenal or renal (acute tubular necrosis) process secondary to reduced CO and the associated vasoconstrictive state. As described in the previous answer, optimization of hemodynamics should also improve the renal function. Whereas some may administer diuretics in this setting, such management is strongly discouraged. The most effective management is surgical evacuation of the PE or clot. The hematologic issues include elevated PT and aPTT, blood loss, and the potential for further blood loss perioperatively. The coagulopathy should be corrected appropriately, the patient's hematocrit and platelets should be checked and treated accordingly, and sufficient blood (4 to 6 units) will be required in the operating room before commencing surgery.

Ghobashy A, Fontes ML, Hines RL. Cardiogenic shock. In: Murray MJ, Coursin DB, Pearl RG, et al., eds. *Critical Care Medicine: Perioperative Management*. 2nd ed. Philadelphia: Lippincott Williams & Wilkins; 2002:287.

C. Intraoperative Management

C.1. How would you monitor this patient during transport to the operating room? What emergency drugs would you bring with you?

The patient must be under astute observation, and the vital signs must be continuously assessed, including invasive monitoring of systemic blood pressure, electrocardiogram, and oxygen saturation. In addition, emergency cardioactive and vasoactive drugs should be available during transport:

- Oxygen: Increase the F_{IO_2} as needed. All necessary equipment for intubation should be present (laryngoscope and several blades, bag-mask units, and adult-size endotracheal tubes)
- DC cardioversion unit: in case of tachyarrhythmias
- Phenylephrine: dose: bolus, 0.1 to 0.5 mg; infusion, 25 to 125 μg per minute
- Epinephrine: dose: 0.01 to 0.1 μg/kg/minute
- Calcium chloride: dose: 2 to 4 mg per kg
- Lidocaine: 1 to 2 mg per kg
- Atropine: 0.01 mg per kg

C.2. In this patient, what hemodynamic effects would occur from intravenous induction with ketamine, thiopental, fentanyl, propofol, etomidate, or midazolam?

Ketamine

After intravenous administration, ketamine (1 mg per kg) has a rapid onset of action and achieves a peak plasma concentration in less than 1 minute. It also possesses a short duration of action. After the initial dose, patients may remain unconscious for 10 to 15 minutes, but the analgesic effect (somatic greater than visceral) persists for an additional 30 minutes or longer. Some of the hemodynamic effects of ketamine may

include small increases in blood pressure, HR, CO, and myocardial oxygen demand. This response is mediated by a direct central sympathetic stimulation and by inhibition of norepinephrine uptake into the postganglionic sympathetic nerve endings. Ketamine has also been shown to have intrinsic depressant properties on the myocardium. In clinical conditions in which norepinephrine stores are reduced, and in the presence of pre-existing cardiac dysfunction (mechanical or myocardial), administration of ketamine can produce hemodynamic depression.

Fentanyl

Fentanyl does not possess any depressant effects on myocardial contractility but because of its vagotonic effect (decreases in HR) and mild sympatholytic effect (central sympathetic outflow), blood pressure may decrease. This response may be more profound in shock or preshock states, and when fentanyl is used concomitantly with other induction agents (benzodiazepines, thiopental, propofol).

Propofol

Propofol produces effects very similar to those of thiopental. It can cause significant reduction in systemic pressures (greater than 30%), and there have been several reports of cardiovascular arrest in both adults and children following inductions with propofol. Propofol also has some antiarrhythmic effect on the atrioventricular node, as well as on other conduction pathways. It should be used with caution when other agents that slow down atrioventricular nodal conduction are present (calcium channel blockers, β-blockers, digoxin). As with thiopental, the use of propofol for induction in cardiac tamponade is strongly disfavored.

Etomidate

Etomidate has a very favorable hemodynamic profile and is the preferred agent to be used during induction when cardiovascular collapse is anticipated. With an induction dose (0.2 to 0.3 mg per kg), etomidate may cause a slight decrease in mean arterial pressure but such changes are not attributable to myocardial depression, as is typical of propofol and sodium thiopental. Pain at the injection site and involuntary muscle movements are the most common adverse events noted with etomidate. It also appears to reduce seizure threshold and enhance its duration when used during electroconvulsion therapy.

Midazolam

Midazolam may cause mild to moderate systemic vasodilation, particularly when used in combination with opioids.

Overall, of the agents discussed, etomidate would be the preferred agent for induction, followed by ketamine, and/or fentanyl; thiopental and propofol would be the least desired.

White PF, Romero G. Nonopioid intravenous anesthesia. In: Barash PG, Cullen BF, Stoelting RK, eds. *Clinical Anesthesia*. 6th ed. Philadelphia: Lippincott Williams & Wilkins; 2009:450–455.

C.3. Describe the induction process for cardiac tamponade.

The patient should have standard monitors placed, as well as invasive monitors, including indwelling arterial access for beat-to-beat monitoring of systemic arterial pressures and for obtaining blood gases. This patient has a PAC in situ; however, its usefulness in this setting remains debatable. The actual induction should proceed ONLY in the presence of a surgical team that is ready and gowned and after the patient has been completely prepared and draped. The choice of induction agents is limited to opioids,

muscle relaxant (depolarizing or nondepolarizing), and either etomidate or ketamine. Regardless of the induction technique, the anesthesiologist should expect, and be prepared to manage, ensuing circulatory collapse.

Levy JH, Tanaka K, Bailey JM, et al. Postoperative cardiovascular management. In: Kaplan JA, Reich DL, Savino JS, et al., eds. *Kaplan's Cardiac Anesthesia*. 6th ed. Philadelphia: WB Saunders; 2011:1025–1045.

C.4. Following induction and intubation, the systemic blood pressure decreased to 55/30 mm Hg. Describe the clinical events accounting for this perturbation and the management steps required for resuscitation.

Cardiac tamponade is caused by significant pericardial pressure from accumulating pericardial contents (fluid, blood, and blood clots) that impede chamber filing resulting in a low CO state. The precipitous fall in blood pressure observed with induction can be accounted for by the following: first, most induction agents will have negative hemodynamic effects that are either direct or indirect; second, sympatholysis reduces arterial resistance as well as chronotropy and inotropy of the heart; third, the physiologic consequences of switching from negative pressure ventilation to positive pressure ventilation will further reduce cardiac filling by increasing intrathoracic pressure and afterload; and finally, placing the patient in a supine position will also compromise atrial and ventricular preload (i.e., hydrostatic effects, loss of diaphragmatic motion, and mediastinal structures weighing on the heart).

The management of hypotension will require use of vasoactive drugs, cardioactive drugs, and/or fluid challenge. Reducing inspiratory positive pressure (i.e., lowering tidal volume or switching from ventilator-delivered breaths to hand ventilation) may also improve the hemodynamic status by facilitating filling. These would be merely temporizing measures; surgical relief of tamponade would be the definitive treatment of this problem.

Levy JH, Tanaka K, Bailey JM, et al. Postoperative cardiovascular management. In: Kaplan JA, Reich DL, Savino JS, et al., eds. *Kaplan's Cardiac Anesthesia*. 6th ed. Philadelphia: WB Saunders; 2011:1025–1045.

C.5. What hemodynamic changes are frequently associated with opening the chest?

Chest opening normalizes the pressure relation between the pericardium and the heart chambers, thereby relieving the tamponade and its hemodynamic effects. Unless the myocardium has suffered injury or is stunned, the expected hemodynamic changes include drastic improvement in both blood pressure and SV. Most of the vasoactive and cardioactive agents being administered can be quickly weaned. In addition, oxygenation, acid–base status, and renal function (urine output) tend to improve significantly.

C.6. What is myocardial stunning? What is myocardial hibernation?

The myocardium can exhibit segmental dysfunction or a generalized decrease in function related to injury (i.e., ischemia and infarction). It has also been noted that myocardial function can be coupled or uncoupled with tissue perfusion. For example, following a period of oxygen deprivation and restoration of flow, the affected myocardium can resume normal function, or have diminished function or no function

(dysfunction). The term *myocardial stunning* represents a state of uncoupling between function and flow in which myocardial flow is normal but function is diminished or absent. In the setting of cardiac surgery, myocardial stunning can be a cause of ventricular dysfunction that generally resolves within the first 6 to 8 hours post-CPB. During this period, inotropic support has been shown to be effective. Myocardial hibernation, on the other hand, is a myocardial process that manifests after weeks or months and denotes a condition in which both myocardial function and flow are reduced (perfusion and function are coupled). Perhaps this is an adaptive process that allows the myocytes to lower their metabolic activity and oxygen consumption to survive during states of oxygen deprivation. The definitive diagnosis of stunning and hibernation may be difficult to make because regional myocardial blood flow is difficult to assess or quantify clinically. Therefore, most cases of stunning and hibernation require a retrospective analysis. First, segmental myocardial dysfunction must be established; second, myocardial blood flow should be restored by revascularization (surgical, pharmacologic, or angioplasty/stenting); and third, improvement of regional function should follow revascularization.

D. Postoperative Management

D.1. How would you manage hypertension in the intensive care unit (ICU)?

The management of hypertension depends on its etiology. Rather than administering antihypertensive agents indiscriminately, the clinician should exclude the following conditions as causality of hypertension: hypoxemia, hypercarbia, acid–base derangements, and pain. The occurrence of hypertension is a common phenomenon during the first several hours in the ICU. In most cases, the etiology is uncertain and probably represents a state of marked sympathoadrenal activation. Once correctable causes of hypertension have been addressed, antihypertensive therapy can be achieved with a variety of agents. Because the underlying mechanism of the hypertension involves endogenous release of norepinephrine (with minimal epinephrine), the most rational agents to use are the β-blockers. Labetalol antagonizes both α- and β-adrenergic receptors and is an effective antihypertensive agent. Alternatively, metoprolol, atenolol, esmolol, or propranolol can be used, particularly if the hypertension is associated with tachycardia. Unfortunately, these agents are used infrequently because of theoretical concerns of myocardial depression and bradycardia. Current cardiology practice strongly endorses the use of β-blockers in the setting of moderate and severe ventricular dysfunction. In addition, the cardioprotective effects of β-blockers have been shown in several perioperative trials whereby the incidence of myocardial injury and mortality (up to 2 years postoperatively) are significantly reduced in patients treated perioperatively with β-blockers.

Varon J, Marik PE. Perioperative hypertension management. *Vasc Health Risk Manag*. 2008;4:615–627.

D.2. When would it be appropriate to extubate this patient?

The timing of extubation depends on the following:

- Clinical stability (stable hemodynamics without need for significant inotropic or vasoactive support)
- Intact neurologic function (alertness and ability to comprehend and execute simple verbal commands)
- Adequate pulmonary function (acceptable arterial blood gases and acid–base status and adequate weaning parameters—tidal volume, respiratory rate, vital capacity, and inspiratory effort)
- Normal body temperature and neuromuscular function (reverse paralysis if necessary)
- Normal coagulation (bleeding less than 60 mL per hour and normalization of coagulation parameters)

Following relief of tamponade, most patients can be extubated as early as possible assuming that the previously listed criteria have been met.

CHAPTER 12

Heart Transplantation and Subsequent Noncardiac Surgery

Jeff T. Granton and Davy C. H. Cheng

A 41-YEAR-OLD MAN

with a history of idiopathic dilated cardiomyopathy is admitted to the cardiac care unit in a quaternary cardiac center for potential heart transplantation assessment. He has known systolic dysfunction, with an ejection fraction of <25% on transthoracic echocardiogram. Recurrent ventricular arrhythmias necessitated insertion of an implantable cardioverter defibrillator (ICD). Right heart catheterization revealed a pulmonary vascular resistance (PVR) of 4 Woods units. Recently, his symptoms have worsened and have progressed to New York Heart Association class IV. During this hospital admission, his clinical status continued to deteriorate, necessitating the initiation of inotropic support and the insertion of an intra-aortic balloon pump (IABP). He is subsequently placed on the transplant list with high priority. However, due to further deterioration, consideration is being given to the insertion of a left ventricular assist device (VAD) to maintain adequate end-organ perfusion while waiting for a donor heart to become available.

A. Medical Disease and Differential Diagnosis

1. What are the common diagnoses requiring adult heart transplantation?
2. What are the indications and relative contraindications for recipient selection?
3. What are the criteria for donor heart selection?
4. What are the principles of perioperative donor management?
5. What are the risk factors associated with posttransplant mortality?
6. What is the difference between the biatrial and bicaval surgical techniques of heart transplant?
7. When is combined heart/lung transplant indicated? What are the important differences?
8. What are the medical and surgical alternatives to cardiac transplantation?
9. What is the role for VADs in these patients?

10. What are the considerations in anesthetizing patients for left ventricular assist device (LVAD) insertion?

B. Preoperative Management

Three weeks after insertion of an LVAD, a donor heart becomes available.

1. How would you assess this patient preoperatively?
2. How would you premedicate this patient? Why?

C. Intraoperative Management

1. What anesthetic equipment and monitors would you set up? Why?
2. What is the role of transesophageal echocardiography (TEE)?
3. Describe the induction and maintenance of anesthesia.
4. How would you manage this patient during cardiopulmonary bypass (CPB)?

D. Postoperative Management

1. What are the early postoperative complications?
2. What are the mechanisms of early right heart failure?
3. How would you treat right heart failure following heart transplantation?
4. How does inhaled nitric oxide (NO) work as a selective pulmonary vasodilator?
5. What is the pathophysiology of the denervated heart?
6. What are the common cardiac dysrhythmias following heart transplant?
7. What are the causes of posttransplant bleeding?
8. How would you treat posttransplant bleeding?
9. What are the causes of early graft failure?
10. How would you manage this patient in the intensive care unit?

E. Subsequent Noncardiac Surgery

The patient recovers successfully following heart transplant. However, 2 years postoperatively, he fractures his left radius after a fall. He then presents for open reduction and internal fixation of the fracture.

1. How would you monitor this patient?
2. What type of anesthetic is best for the heart-transplanted patient?
3. Which anesthetic technique would you give this patient?
4. Do you need to use a muscarinic antagonist with cholinesterase inhibitors to reverse the muscle relaxant in heart-transplanted patients?
5. What are the anesthetic implications for heart-transplanted patients?
6. What is the significant implication of the denervated heart?
7. What is the significance of allograft rejection?
8. What is the significance of infection in these patients?
9. What are the significant implications of drug interactions?
10. What is cardiac allograft vasculopathy (CAV)? Why is this important?
11. What is the significant implication of posttransplant hypertension?
12. What is the significant implication of renal dysfunction?
13. Is ambulatory surgery appropriate for heart transplant recipients?

A. Medical Disease and Differential Diagnosis

A.1. What are the common diagnoses requiring adult heart transplantation?

Heart transplantation is now considered to be a viable treatment option for selected patients with end-stage heart disease. At present, more than 4,000 heart transplants

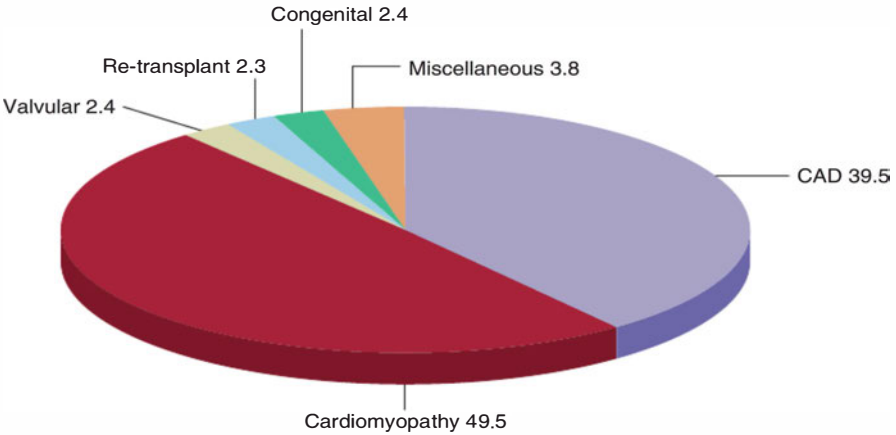

Figure 12.1 Indications for adult heart transplant (%). CAD, coronary artery disease.

are done annually worldwide. The indications for adult heart transplant, as reported to the Registry of the International Society for Heart and Lung Transplantation from 2002 to 2008, are shown in Figure 12.1. Ischemic coronary artery disease (39.5%) and nonischemic cardiomyopathy (49.5%) represent the most frequent causes for transplantation.

Taylor DO, Oz M, Mancini D, et al. Registry of the International Society for Heart and Lung Transplantation: twenty-sixth official adult heart transplant report-2009. *J Heart Lung Transplant*. 2009;28(10):1007–1022.

A.2. What are the indications and relative contraindications for recipient selection?

It should be noted that indications/contraindications can be flexible and can vary from center to center.

Criteria for selection include the following:

- End-stage heart disease
- Physiologic age less than 65. However, over the last 10 years, greater than 20% of heart recipients were ≥60 years of age. There are even rare cases of patients greater than 70 years old receiving a heart transplant.
- Maximal oxygen uptake ($\dot{V}O_{2max}$) during cardiopulmonary exercise testing is considered. Although the cut-offs are highly variable and have many caveats, generally, patients with a peak $\dot{V}O_{2max}$ <10 mL/kg/min have an indication for transplantation.

Contraindications (not necessarily absolute)

- Neoplasm with significant chance of recurrence
- Obesity (BMI >30 kg/m^2)
- Fixed pulmonary hypertension: PVR greater than 5 Woods units
- Nonreversible renal dysfunction
- Age over 70
- Peripheral vascular disease, carotid stenosis (depending on severity)

- Diabetes with end-organ damage neuropathy, nephropathy, retinopathy
- Psychosocial impairments
- Drug or alcohol addiction, smoking, mental defect that will limit compliance, history of noncompliance
- Other diseases that may limit survival (human immunodeficiency virus [HIV], pulmonary disease, hepatitis, etc.)

Merha MR, Kobashigawa J, Starling R, et al. Listin criteria for heart transplantation: International Society for Heart and Lung Transplantation guidelines for the care of cardiac transplant candidates-2006. *J Heart Lung Transplant*. 2006;25(9):1024–1042.

Taylor DO, Oz M, Mancini D, et al. Registry of the International Society for Heart and Lung Transplantation: twenty-sixth official adult heart transplant report-2009. *J Heart Lung Transplant*. 2009;28(10):1007–1022.

A.3. What are the criteria for donor heart selection?

The limiting factor in heart transplantation is the shortage of donor organs. In Canada, 162 heart transplants were performed in 2008, with 131 people on the waiting list at the end of that year. In the United States, 2,163 heart transplants were performed in 2008, with 2,791 patients on the waiting list as of June 2009. Following establishment of brain death, organ harvest may be considered for the purpose of donation. Preferably, the donor should not have sustained prolonged cardiac arrest, severe chest trauma, intracardiac injections, septicemia, excessive inotropic support, and be less than 55 years of age. In all cases, a careful clinical examination of the potential donor is undertaken to rule out coronary artery atherosclerosis and contractile dysfunction; investigations may include angiography and echocardiography. The use of coronary angiography would be dictated by patient age, sex, and risk factors. In general, a contrast ventriculogram is avoided to reduce the risk of nephrotoxicity.

Poor ejection fraction (<40%), despite optimization of physiologic variables, would exclude a potential donation. Transplantation can proceed with mild left ventricular hypertrophy, however, wall thickness >13 mm or electrocardiogram (ECG) criteria for left ventricular hypertrophy would make transplantation unadvisable. In general, severe congenital or valvular abnormalities would preclude donation, with the exception of abnormalities in which "bench" repair can be undertaken before transplant.

ABO compatibility is important, as mismatch may result in hyperacute rejection. The donor body weight should be within 20% of that of the recipient. However, in the case of a small donor matching, using BMI or height is more accurate than using weight. Preferably donor heart ischemic time should be less than 4 hours. Prolonged ischemic time may contribute to early allograft failure; however, techniques to allow improved tolerance of ischemia may be on the horizon.

The use of non–heart-beating donors is now used in multiple jurisdictions for kidney, liver, and lung transplantation. There have been cases of heart transplantation from non–heart-beating donors. However, the ethical and legal issues surrounding the technique for this form of heart donation are controversial.

Zaroff JG, Rosengard BR, Armstrong WR, et al. Consensus conference report. Maximizing use of organs recovered from the cadaver donor: cardiac recommendations. *Circulation*. 2002;106:836–841.

A.4. What are the principles of perioperative donor management?

The goals of management are to maintain euvolemia, achieve relatively normal afterload, and optimize cardiac output (CO) without excessive use of inotropic medications, in particular β-agonists. Unfortunately, the brain-dead patient often can become extraordinarily unstable, and achieving hemodynamic stability can be a challenge. In addition, the treatment modalities to support certain end organs for harvest are often at odds with each other. The onset of diabetes insipidus needs to be considered when excessive urine output (greater than 300 mL/hour) is observed and must be treated promptly with desmopressin (1-deamino-8-D-arginine vusopressin [DDAVP]). As a result of dysfunction of the hypothalamic-pituitary system, it is suggested that hormonal replacement therapy be undertaken in patients with ejection fractions less than 40% or with hemodynamic instability. This includes the use of intravenous (IV) exogenous thyroid therapy, arginine vasopressin, and methylprednisolone. In addition, adequate glycemic control should be achieved.

Shemie SD, Ross H, Pagilarello J, et al. Organ donor management in Canada, recommendations of the forum on medical management to optimize donor organ potential. *CMAJ*. 2006;174(4):S13–S30.

Zaroff JG, Rosengard BR, Armstrong WR, et al. Consensus conference report. Maximizing use of organs recovered from the cadaver donor: cardiac recommendations. *Circulation*. 2002;106:836–841.

A.5. What are the risk factors associated with posttransplant mortality?

Overall survival at 1 year is 86%. Having congenital heart disease as the indication for transplant is a powerful predictor of postoperative 1-year mortality. In addition, the requirement of extracorporeal circulatory support, dialysis, female gender, preoperative mechanical ventilation, nonidentical ABO matching, previous blood transfusions, coronary artery disease as the indication for transplant, and being hospitalized immediately before transplant all are risk factors for 1-year mortality. Mortality during the first year is greater than the next 4 years combined, so risk factors associated with 1-year mortality are powerful predictors of 5-year mortality. For those that have survived after 1 year, allograft vasculopathy during the first year posttransplant, diabetes, treatment for rejection in year 1, recipient age, donor age, recipient weight, and transplant center volume are risk factors for 5-year mortality.

The most common causes of death are the following:
Within 30 days posttransplant
- Graft failure, multi-organ failure, non-cytomegalovirus infection (CMV)
From 31 to 365 days posttransplant
- Non-CMV infection, graft failure, acute rejection
After 5 years
- Allograft vasculopathy, late graft failures, malignancies, non-CMV infections

Taylor DO, Oz M, Mancini D, et al. Registry of the International Society for Heart and Lung Transplantation: twenty-sixth official adult heart transplant report-2009. *J Heart Lung Transplant*. 2009;28(10):1007–1022.

A.6. What is the difference between the biatrial and bicaval surgical techniques of heart transplant?

The older biatrial technique involves anastomoses of the recipient and donor atrial cuffs. The bicaval technique maintains the above-left atrial anastomoses, and attempts to maintain cardiac anatomy with separate bicaval anastomoses to the right atrium.

Morgan JA, Edwards NM. Orthotopic cardiac transplantation: comparison of outcome using biatrial, bicaval and total techniques. *J Card Surg*. 2005;20:102–106.

A.7. When is combined heart/lung transplant indicated? What are the important differences?

Congenital cardiac disease is the most common indication for combined heart/lung transplant. Other indications include idiopathic pulmonary hypertension, cystic fibrosis, α1-antitrypsin deficiency and other forms of lung disease, such as emphysema and idiopathic pulmonary fibrosis. The procedure is performed through a transverse thoracotomy incision and the donor heart/lungs are transplanted *en-bloc*. Important postoperative problems include bleeding and reperfusion lung injury, which may require NO or occasionally extracorporeal membrane oxygenation (ECMO). Survival following heart/lung transplant is 64%, 43%, and 28% at 1, 5, and 10 years respectively.

Christie JD, Edwards LB, Aurora P, et al. The Registry of the International Society for Heart and Lung Transplantation: twenty-sixth official adult lung and lung–heart transplantation report-2009. *J Heart Lung Transplant*. 2009;28(10):1031–1049.

A.8. What are the medical and surgical alternatives to cardiac transplantation?

An ongoing worldwide shortage of donor hearts has meant ongoing pressure to manage medically patients with end-stage cardiac failure. Patients need to adhere to strict lifestyle modifications and diet, otherwise any other therapy will have limited usefulness. As heart failure progresses, patients may respond to a variety of medications. Angiotensin-converting enzyme (ACE) inhibitors have been shown to improve symptoms and decrease mortality in patients with heart failure. Angiotensin II receptor blockers also can be considered for patients intolerant of ACE inhibitors. Patients with severe forms of heart failure also may benefit from a low-dose aldosterone antagonist (spironolactone), with attention paid to potential hyperkalemia. Tailored doses of diuretic therapy may offer some symptomatic relief. Beta-blockade with carvedilol, sustained-release metoprolol, or bisoprolol has been shown to reduce the risk of death. In addition, patients with advanced heart failure may reduce their risk of sudden cardiac

death by the insertion of an ICD. Furthermore, ICD implantation can be combined with cardiac resynchronization therapy, which has been shown to improve functional class and survival in advanced heart failure, once patients also have achieved optimal medical management. IABP and, increasingly, VAD implantation or semi-implantable pericorporeal devices also are finding a role in the management of patients as a bridge to transplant, particularly for those presenting in acute decompensated heart failure.

Hunt SA, Antman EM, Smith SC, et al. ACC/AHA 2005 guideline update for the diagnosis and management of chronic heart failure in the adult-Summary article. *Circulation*. 2005;112:1825–1852.

Ramani GV, Uber PA, Mehra MP. Chronic heart failure: contemporary diagnosis and management. *Mayo Clinic Proceedings*. 2010;85:180–195.

A.9. What is the role for VADs in these patients?

In the United States, over 1,000 LVADs were placed from 2006 to 2009. Far fewer right ventricular (RVAD) and biventricular assist devices were inserted. Indications for LVAD insertion included cardiogenic shock (30%), progressive decline (40%), and inotrope dependence (15%). Of those that received an LVAD, 87.3% were listed or were being considered for heart transplant. In general, three major categories of patients considered for VAD have emerged. These include (1) temporary insertion while cardiac function recovers from insult (bridge to recovery); (2) insertion while awaiting transplant or transplant assessment (bridge to transplant); and (3) patients who need long-term support, but are not transplant candidates (destination therapy). Interestingly, for almost 10% of patients, LVAD insertion was considered a destination therapy.

A variety of composite risk scores have been developed to help guide patient selection and predict survival after LVAD implantation. Issues such as aortic valve incompetence and the presence of intracardiac shunts need to be investigated, as these may make LVAD insertion unadvisable. It also would seem that there has been a move toward continuous flow pump technology since 2008 versus the pulsatile pump.

Kirklin JK, Naftel DC, Kormos RL, et al. Second INTERMACS annual report: more than 1000 primary left ventricular assist device implants. *J Heart Lung Transplant*. 2010;29(1):1–10.

Wilson SR, Mudge GH, Stewart GC, et al. Evaluation for a ventricular assist device, selecting the appropriate candidate. *Circulation*. 2009;119:2225–2232.

A.10. What are the considerations in anesthetizing patients for left ventricular assist device (LVAD) insertion?

Significant cardiac abnormalities (e.g., aortic insufficiency, patent foramen ovale) should be identified preoperatively and, if possible, addressed at the time of surgery. These patients may have an ICD in place and if deactivated, placement of external defibrillator pads is advisable. LVADs can be inserted with a sternotomy or a left thoracotomy. Patients are at high risk for significant perioperative blood loss and large-bore IV access is essential and antifibrinolytics often are administered. TEE is mandatory for LVAD insertion to assess for patent foramen ovale, ensure aortic valve competence, confirm proper position of device, assess amount of air in cardiac chambers, guide fluid management, and monitor right ventricular (RV) function. Inadequate right heart function is a potential complication after LVAD insertion and can be treated with phosphodiesterase inhibitors and inhaled NO. Vasopressin and/or norepinephrine may be required to maintain adequate systemic vascular resistance post-CPB. However, caution needs to be exercised with vasoconstrictors, as excessive afterload can impair device function.

Williams M, Oz M, Mancini D. Cardiac assist devices for end-stage heart failure. *Heart Disease*. 2001;3:109–115.

B. Preoperative Management

Three weeks after insertion of an LVAD, a donor heart becomes available.

B.1. How would you assess this patient preoperatively?

Prospective transplant candidates usually have been fully preoperatively evaluated by a multidisciplinary team, including cardiology, respirology, and surgery, as well as anesthesia. In case of subsequent deterioration, however, the anesthesiologist should review the recipient's current cardiac status, including medications and level of mechanical support, with particular attention to hemodynamic parameters and reversibility of elevated PVR. Pertinent anesthetic history, concomitant diseases, and fasting status also must be ascertained. Baseline electrolytes, urea, creatinine, blood glucose, international normalized ratio (INR)/prothrombin time (PTT), and complete blood count should be obtained. In addition, specific preoperative investigations need to be reviewed, such as echocardiogram, pulmonary function tests, ECG, and chest radiograph.

There are typically two types of patients presenting for heart transplantation. The first type of patient is relatively compensated, requiring possible IV inotropic support or may even be ambulatory in a nonhospital setting. The second type is moribund and decompensated, requiring mechanical ventilation and/or mechanical circulatory support. At the time of transplant, 44.8% of patients are on IV inotropes, 19% have an LVAD, 6.9% have an IABP, and 2.9% are mechanically ventilated. Only 0.7% require ECMO before transplant. Recipients who have undergone prior cardiac surgery need to be identified, as this will increase the surgical time to achieve CPB due to adhesions and bleeding. Large-bore IV access must be secured and cross-matched blood should be readily available in the operating room before surgery commences. The use of antifibrinolytics is routine for these cases.

Taylor DO, Oz M, Mancini D, et al. Registry of the International Society for Heart and Lung Transplantation: twenty-sixth official adult heart transplant report-2009. *J Heart Lung Transplant*. 2009;28(10):1007–1022.

B.2. How would you premedicate this patient? Why?

Patients should be transported to the operating room with oxygen supplementation. Caution should be exercised with sedative or narcotic premedication. With minimal cardiac reserve, sedation may blunt the patient's respiratory and sympathetic drive and can lead to hypoxemia, hypercapnia, and even hypotension. Antibiotic prophylaxis often is achieved with 1 to 2 g of cephazolin or vancomycin.

Jhaveri R, Tardiff B, Stanley TE III. Anesthesia for heart and heart–lung transplantation. *Anesthesiol Clin N Am*. 1994;12:729–747.

C. Intraoperative Management

C.1. What anesthetic equipment and monitors would you set up? Why?

Anesthetic equipment includes a ventilator with air mixture capability, airway and intubation set-up, fluid/blood warmer, extracorporeal bypass machine with membrane oxygenator, and NO delivery and monitoring system. The patient is taken to the operating room breathing supplemental oxygen. Monitors include a 5-lead ECG, digital pulse oximeter, noninvasive blood pressure cuff, capnography, urinary catheter, temperature probe(s), and peripheral nerve stimulator. All invasive lines are placed with meticulous attention to aseptic technique and titrated sedation. A no.14 g IV line and a no. 20 g radial arterial catheter for continuous blood pressure monitoring are inserted. Routinely, a pulmonary arterial (PA) catheter is inserted via the right internal jugular vein for pre-CPB, post-CPB, and postoperative measurement of PA pressure, PVR, and CO. The PA catheter is withdrawn back to about a 20-cm position in an 80-cm sterile sleeve before cardiectomy. TEE also is very useful in the intraoperative management of the pretransplant and posttransplant periods. A bispectral index monitor may be applied before induction. In some centers, cerebral oximetry also would be used as a monitor of cerebral oxygen delivery.

C.2. What is the role of transesophageal echocardiography (TEE)?

The echocardiographer can provide feedback to the surgeon and anesthesiologist regarding overall function of the transplanted heart. In particular, wall motion abnormalities, end-diastolic volume, and valvular function can be assessed. Of particular interest is RV function and an assessment of PA pressures. TEE also may be useful in the assessment of surgical anastomosis, performed by an echocardiographer with advanced training. Specifically, the main PA anastomosis should be evaluated for stenosis. The long-axis view of the left atrium is composed of recipient and donor tissue and may appear large. If excessive tissue is present, acquired cor triatriatum may develop due to an unfolding of redundant tissue.

Suriani RJ. Transesophageal echocardiography during organ transplantation. *J Cardiothorac Vasc Anesth.* 1998;12:686–694.

C.3. Describe the induction and maintenance of anesthesia.

It is important to time the anesthesia induction and surgery carefully to achieve CPB at the time of donor heart arrival in order to minimize ischemia time, particularly for a re-sternotomy patient. Prompt securing of the airway may be required as the recipient is not always properly fasted for transplantation surgery; however, a rapid induction needs to be balanced against the risk of hemodynamic compromise. The patient is anesthetized with midazolam and fentanyl or sufentanil titrated based on hemodynamic status and level of consciousness. Muscle relaxation may be achieved with pancuronium, rocuronium, cisatracurium, or vecuronium. Succinylcholine usually is not used because of concern of bradycardia during induction, as blood pressure in pre–heart transplant recipients often is heart rate dependent. Maintenance phase is achieved through the use of a balance anesthetic technique. Volatile agents (sevoflurane or isoflurane) are combined with fentanyl or sufentanil, midazolam, and muscle relaxation as required. Nitrous oxide generally is avoided, due to its effect on PVR.

Previously, many centers would have used aprotinin as an antifibrinolytic therapy. However, Bayer, the manufacturer of aprotinin, removed it from the market after concerns of increased mortality surfaced in clinical trials. Tranexamic acid and epsilon-aminocaproic acid have taken this role now in many cardiac transplant centers.

Fergusson DA, Hebert PC, Mazer CD, et al. A comparison of aprotinin and lysine analogues in high-risk cardiac surgery. *NEJM*. 2008;358:2319–2331.

Mangano DT, Tudor IC, Dietzel C. The risk associated with aprotinin in cardiac surgery. *NEJM*. 2006;354:353–365.

C.4. How would you manage this patient during cardiopulmonary bypass (CPB)?

The anesthetic management of CPB in these patients is not different from that in nontransplant patients, except that rewarming usually is prolonged because of the profound cooling of the donor heart and the prolonged ischemic time. Early in the perfusion, mixed venous oxygen desaturation and metabolic acidosis must be corrected. The fluid balance, hematocrit, electrolyte composition, and serum glucose must be monitored closely. During CPB, anesthesia maintenance is achieved by narcotic supplementation, an inhalational agent, and/or benzodiazepine. Once cardiac rhythm has been established and anastomosis of the pulmonary artery is completed, the patient is placed in a head-down position for air evacuation from the left side of the heart. An isoproterenol infusion (1 to 5 μg/min) may be considered to improve contractility and to increase heart rate to about 90 to 110 beats per minute. If necessary, the heart may be externally paced via epicardial leads.

D. Postoperative Management

D.1. What are the early postoperative complications?

The early postoperative complications include:

- Right heart failure/Pulmonary hypertension
- Denervated heart
- Bleeding
- Early graft failure

D.2. What are the mechanisms of early right heart failure?

Right-sided heart failure is an important cause of posttransplant morbidity and mortality. It has a diverse number of causes related to both increases in flow and resistance across the pulmonary vascular bed. One prime cause is long-standing elevation in left ventricular pressure, leading to an increase in pulmonary pressure and vasoconstriction. This pulmonary vasoconstriction may become fixed over time, compromising RV function after transplant. However, a normal preoperative PVR does not rule out the potential for RV failure posttransplant. Poor organ preservation and CPB also can have deleterious effects on graft ventricular function.

Stobierska-Dzierzek B, Awad H, Michler RE. The evolving management of acute right-sided heart failure in cardiac transplant recipients. *J Am Coll Cardiol*. 2001;38:923–931.

D.3. How would you treat right heart failure following heart transplantation?

RV failure is associated with dilation, ischemia, and poor contractility. This can result in a shift of the ventricular septum to the left, with a reduction in left ventricular filling and reduced CO. Basic therapeutic goals are to maintain adequate coronary perfusion, optimize oxygen delivery, prevent further distention of the RV by judicious use of fluids, minimize myocardial oxygen consumption, and reduce PVR to decrease RV afterload.

Phosphodiesterase inhibitors, such as milrinone, which have systemic and pulmonary vasodilatory effects in addition to positive inotropy, are particularly useful. Prostacyclin (PGI_2), prostaglandin E(1), isoproterenol (1 to 5 μg/min), dobutamine, and nitrates also have been used with success to treat RV failure. However, vasodilator use often can be accompanied by arterial hypotension, requiring the administration of vasopressors to maintain adequate coronary perfusion. Inhaled NO also is widely used as a selective pulmonary vasodilator in severe pulmonary hypertension and RV failure. Sildenafil also can be considered when trying to reduce PVR. It should be remembered that simple management goals of avoiding hypoxia, hypercarbia, and excessive positive end-expiratory pressure (PEEP) will help avoid elevated PVR.

In severe cases of refractory RV failure, posttransplant mechanical support should be considered, including IABP, RVAD, or ECMO.

Costanzo MR, Task Force. The International Society of Heart and Lung Transplantation guidelines for the care of heart transplant recipients. *J Heart Lung Transplant.* 2010;29:914–956.

Stobierska-Dzierzek B, Awad H, Michler RE. The evolving management of acute right-sided heart failure in cardiac transplant recipients. *J Am Coll Cardiol.* 2001;38:923–931.

D.4. How does inhaled nitric oxide (NO) work as a selective pulmonary vasodilator?

The advantage of inhaled NO as a pulmonary vasodilator lies mainly in the fact that its smooth muscle relaxant effect is limited to the pulmonary vasculature—the half-life in vivo of inhaled NO is only a few seconds. Therefore, it has little effect on the systemic circulation, unlike IV vasodilators, such as nitroprusside, nitroglycerin, prostaglandins, and calcium channel blockers. Furthermore, inhaled NO selectively causes vasodilation in ventilated lung units, thus decreasing $\dot{V}/\dot{Q}$ mismatch and shunt. Inhaled NO (1 to 20 ppm) can result in significant decreases in pulmonary artery pressure, PVR, and central venous pressure (CVP), while increasing mean arterial pressure, CO, and arterial oxygenation. In addition, a TEE documented alteration of the ventricular septal shift with a significant reduction in RV chamber and tricuspid valvular annulus size can be seen.

Konstadt S. Nitric oxide: has it progressed from molecule of the year to wonder drug of the decade? *J Cardiothorac Vasc Anesth.* 1995;9:625–626.

D.5. What is the pathophysiology of the denervated heart?

Following cardiac transplantation, the cardiac plexus is interrupted and the heart is denervated. The recipient atrium remains innervated but hemodynamically

unimportant, while the donor atrium is denervated and is responsible for the electrophysiologic responses of the transplanted heart. The ECG often contains two P waves. The denervated heart retains its intrinsic control mechanisms, which include the Frank-Starling mechanism and intact alpha- and beta-adrenoreceptor responses to circulating catecholamines. This denervated heart lacks the ability to respond acutely to hypovolemia or hypotension with reflex tachycardia, but responds to stress primarily by an increase in stroke volume. This reflects dependence of the sinus node on direct stimulation by endogenously released catecholamines and the absence of control via neural mechanisms. This is why heart-transplanted patients are said to be "preload dependent." Interestingly, however, some studies have demonstrated reinnervation within a year after transplantation. This has led to symptoms of angina pectoris when ischemia develops in the transplanted heart.

Kobashigawa JA. Postoperative management following heart transplantation. *Transplantation Proceedings*. 1999;31:2038–2046.

D.6. What are the common cardiac dysrhythmias following heart transplant?

A wide variety of arrhythmias can occur in the heart transplant recipient. Early on, the course of recovery from heart transplant bradyarrhythmias is common and often is self-limited. However, this underscores the utility of epicardial pacemaker placement at the time of surgery. The spectrum of other arrhythmias include premature ventricular complexes, atrioventricular (AV) blockade, and supraventricular tachycardia. In fact, 5% to 24% of heart transplant recipients suffer from atrial fibrillation. The causes of arrhythmia include surgical disruption of normal conduction pathways and the sinus node, denervation, rejection, and coronary allograft vasculopathy.

Stecker EC, Sterlich KR, Chugh SS, et al. Arrhythmias after orthotopic heart transplantation. *J Cardiac Failure*. 2005;11(6):464–472.

D.7. What are the causes of posttransplant bleeding?

Perioperative bleeding is a significant cause of mortality following heart transplantation. The causes of posttransplant bleeding are anastomosis leaks and coagulopathy. Immediately before weaning from bypass, with the heart filled, the posterior anastomosis is carefully checked again by the surgeon for "water-tightness," because leaks in this area are more difficult and riskier to repair later. Coagulopathy, or what some term "medical bleeding," often results from a combination of mechanisms, including inadequate heparin reversal, dilution of platelets and coagulation factors, hypothermia, and CPB effects on fibrinolysis, platelet function, and factor activation. In addition, those patients with a ventricular assist device in place before transplant are at particular risk for perioperative hemorrhage.

Bourge RC, Naftel DC, Costanzo-Nordin MR, et al. Pre-transplantation risk factors for death after heart transplantation: a multi-institutional study. *J Heart Lung Transplant*. 1993;12:549–562.

Wegner JA, DiNardo JA, Arabia FA, et al. Blood loss and transfusion requirements in patients implanted with a mechanical circulatory support device undergoing cardiac transplantation. *J Heart Lung Transplant*. 2000;19:504–506.

D.8. How would you treat posttransplant bleeding?

Prevention of potential causes of bleeding is key. The use of antifibrinolytics is strongly encouraged, in particular if re-do sternotomy is to be undertaken. Avoidance of excessive crystalloid in the prebypass period may reduce the dilutional component of coagulopathy. Maintaining normothermia with forced air warming devices and fluid warmers also is imperative. When bleeding is evident in the postoperative period, the judicious use of packed red blood cells, fresh frozen plasma, and platelets is a starting point. If hemorrhage is not responsive to conservative measures, disseminated intravascular coagulopathy must be ruled out. If serum fibrinogen is low (less than 0.8 to 1.0 g/L), then the use of cryoprecipitate should be entertained. Although not routine, desmopressin (0.3 μg/kg) also may have a role in refractory cases. Finally, recombinant factor VIIa has been used successfully to treat hemorrhage in cardiac transplant patients. However, the risk of thrombosis needs to be weighed against the risk of ongoing bleeding, and consultation with a hematologist would be advisable before administration. It always should be remembered that bleeding that is excessive and not clearly secondary to coagulopathy warrants surgical re-exploration.

Costanzo MR, Task Force. The International Society of Heart and Lung Transplantation guidelines for the care of heart transplant recipients. *J Heart Lung Transplant*. 2010;29:914–956.

Kogan A, Berman M, Kassif Y, et al. Use of recombinant factor VII to control bleeding in a patient supported by right ventricular assist device after heart transplantation. *J Heart Lung Transplant*. 2005;24:347–349.

D.9. What are the causes of early graft failure?

Graft failure (primary and nonspecific) is the most common cause of death in the first 30 days after heart transplant. Etiologies include biventricular failure, RV failure (often due to high PVR), flow-limiting coronary stenosis, and hyperacute rejection.

Luckraz H, Goddard M, Charman SC, et al. Early mortality after cardiac transplantation: should we do better? *J Heart Lung Transplant*. 2005;24:401–405.

D.10. How would you manage this patient in the intensive care unit?

Within the first 30 days, posttransplant graft failure (primary and nonspecific), multiorgan failure, and non-CMV infection are the most common causes of death at 41%, 13%, and 13%, respectively. Early management goals include prevention of infection and rejection, treatment of bleeding and dysrhythmias, cardiovascular support, and avoidance of elevated pulmonary artery pressures. If possible, one should aim to wean the patient from the ventilator and extubate within 24 hours. In order to facilitate oxygenation and weaning, strict supervision of fluid balance and body weight is required. Immunosuppression often is achieved with a cocktail of medications, including steroids (methylprednisolone then prednisone); calcineurin inhibitors (tacrolimus, cyclosporine); and antiproliferative agents (mycophenolate mofetil). Leucodepleting agents may be used perioperatively, such as antithymocyte globulin or OKT3. Secondary to immunosuppression, patients often are covered prophylactically with ganciclovir (CMV prophylaxis) and trimethoprim/sulfamethoxazole (*Toxoplasma* and *Pneumocystis carinii* prophylaxis).

Blasco LM, Parameshwar J, Vuylsteke A. Anaesthesia for noncardiac surgery in the heart transplant recipient. *Curr Opin Anaesthesiol*. 2009;22:109–113.

Costanzo MR, Task Force. The International Society of Heart and Lung Transplantation guidelines for the care of heart transplant recipients. *J Heart Lung Transplant*. 2010;29:914–956.

Taylor DO. Cardiac transplantation: drug regimens for the 21st century. *Ann Thorac Surg*. 2003;75:S72–S78.

E. Subsequent Noncardiac Surgery

The patient recovers successfully following heart transplant. However, 2 years postoperatively, he fractures his left radius after a fall. He then presents for open reduction and internal fixation of the fracture.

E.1. How would you monitor this patient?

This patient should have similar monitoring requirements for nontransplant patients undergoing similar procedures. Smooth and safe anesthesia is contingent upon careful preoperative assessment, which may reduce the need for invasive monitoring with all its attendant risks. Adequate preload must be attained preoperatively and intravascular volume status maintained intraoperatively, because these patients are "preload dependent." Monitors in the above case would include an ECG, noninvasive blood pressure cuff, capnometer, oxygen saturation probe, and, if general anesthetic was delivered, a temperature probe, agent-specific gas monitor, and a neuromuscular stimulator would be applied. However, for cases with potential for blood loss and fluid shifts, consideration should be given to additional intraoperative monitors, including an arterial line, central venous line, pulmonary artery catheter, and TEE.

Cheng DCH, Ong DD. Anaesthesia for non-cardiac surgery in heart-transplanted patients. *Can J Anaesth*. 1993;40:981–986.

E.2. What type of anesthetic is best for the heart-transplanted patient?

In a series of 86 heart-transplanted recipients, 18 returned for 32 noncardiac surgical procedures. The breakdown included 18 neurolept-anesthesia cases, 12 general anesthesia cases with a combination of N_2O/O_2/narcotic/relaxant and low doses of volatile agents, and 2 spinal cases. The patients had normal requirements of IV and inhalational agents, muscle relaxants, and local anesthetics. There was no prolonged action of any anesthetic agents. This indicates that the choice of general, neuroleptic, or spinal anesthesia does not affect postoperative outcome in heart-transplanted recipients undergoing subsequent noncardiac surgery.

Blasco LM, Parameshwar J, Vuylsteke A. Anaesthesia for noncardiac surgery in the heart transplant recipient. *Curr Opin Anaesthesiol*. 2009;22:109–113.

Cheng DCH, Ong DD. Anaesthesia for non-cardiac surgery in heart-transplanted patients. *Can J Anaesth*. 1993;40:981–986.

E.3. Which anesthetic technique would you give this patient?

This patient could safely receive general anesthesia or regional blockade of his brachial plexus for the upcoming surgery.

E.4. Do you need to use a muscarinic antagonist with cholinesterase inhibitors to reverse the muscle relaxant in heart-transplanted patients?

Although it does not compromise other hemodynamic parameters, neostigmine has been shown to produce a dose-dependent decrease in heart rate in heart-transplanted patients. In remote transplanted patients (>6 months), a muscarinic antagonist should be administered simultaneously with cholinesterase inhibitors to block the cardiac and muscarinic side effects, as slow development of cardiac reinnervation may be possible.

Ashary N, Kaye AD, Hegazi AR, et al. Anesthetic considerations in the patient with a heart transplant. *Heart Disease.* 2002;4:191–198.

Backman SB, Fox GS, Stein RD, et al. Neostigmine decreases heart rate in heart transplant patients. *Can J Anaesth.* 1996;43:373–378.

E.5. What are the anesthetic implications for heart-transplanted patients?

The anesthetic implications for heart-transplanted patients include:

- Denervated heart
- Allograft rejection
- Infection due to immunosuppression
- Drug interaction
- Allograft coronary artery disease
- Hypertension
- Renal dysfunction

Ashary N, Kaye AD, Hegazi AR, et al. Anesthetic considerations in the patient with a heart transplant. *Heart Disease.* 2002;4:191–198.

Cheng DCH, Ong DD. Anaesthesia for non-cardiac surgery in heart-transplanted patients. *Can J Anaesth.* 1993;40:981–986.

E.6. What is the significant implication of the denervated heart?

The denervated heart retains its intrinsic control mechanisms, which include Frank-Starling mechanism, impulse formation and conductivity, and responsiveness to circulating catecholamines in the form of increased heart rate and contractility. But the normal respiratory variations or response to carotid sinus massage and Valsalva maneuvers are absent. At rest, the heart rate reflects the intrinsic rate of depolarization at the donor sinoatrial node, and in the absence of any vagal tone, is faster than normal at about 90 to 100 beats per minute. The heart rate shows minimal response to drugs, such as muscle relaxants (pancuronium); anticholinergics (atropine, glycopyrrolate, and scopolamine); cholinesterase inhibitors (neostigmine, edrophonium, pyridostigmine, physostigmine); digoxin, nifedipine, phenylephrine, or nitroprusside, but will respond to isoproterenol, ephedrine, dopamine, and epinephrine.

Cardiac dysrhythmias may occur in heart-transplanted patients. First-degree AV block is common. Dual AV nodal pathways frequently are observed, but re-entry dysrhythmias are rare. Bradyarrhythmic therapy in these patients should be treated with a direct beta-adrenergic stimulating agent (epinephrine, isoproterenol). Medications used to treat tachyarrhythmias (calcium channel blockers, beta-blockers) need to be used with caution due to their negative inotropic effects.

Ashary N, Kaye AD, Hegazi AR, et al. Anesthetic considerations in the patient with a heart transplant. *Heart Disease*. 2002;4:191–198.

Stein KL, Darby JM, Grenvik A. Intensive care of the cardiac transplant recipient. *J Cardiothorac Anesth*. 1988;2:543–553.

E.7. What is the significance of allograft rejection?

The majority of rejection episodes occur in the first 6 months posttransplant. These patients can present with fever, malaise, arrhythmias, and shortness of breath. Hemodynamic compromise is considered a late sign of rejection. The gold standard for diagnosis is endomyocardial biopsy. Rejection episodes are treated primarily with steroids; however, more severe forms may require more aggressive immunosuppression with IV immunoglobulin or plasmapheresis.

Costanzo MR, Task Force. The International Society of Heart and Lung Transplantation guidelines for the care of heart transplant recipients. *J Heart Lung Transplant*. 2010;29:914–956.

Kobashigawa JA. Postoperative management following heart transplantation. *Transplantation Proceedings*. 1999;31:2038–2046.

E.8. What is the significance of infection in these patients?

Immunosuppressive drugs are continued indefinitely in heart-transplanted patients and infection remains a major cause of death, with 10% of mortality 5 years posttransplant secondary to non-cytomegalovirus (CMV) infections. Early postoperative bacterial infections (e.g., mediastinitis) and opportunistic infections (e.g., CMV, *P. carinii*, *Toxoplasma*) are of great concern. Invasive monitoring techniques and all forms of instrumentation should be kept to the minimum consistent with safe anesthesia. Attention to sterile technique should be paramount. Intubation via the orotracheal route is preferable to the nasotracheal route as the latter is associated with infection by diphtheroids and staphylococcal organisms from the nasopharynx and skin.

Blasco LM, Parameshwar J, Vuylsteke A. Anaesthesia for noncardiac surgery in the heart transplant recipient. *Curr Opin Anaesthesiol*. 2009;22:109–113.

E.9. What are the significant implications of drug interactions?

Chronic steroid treatment may result in an abnormal stress response, so patients should receive perioperative steroid coverage. Azathioprine has been reported to antagonize the competitive neuromuscular-blocking drugs by its phosphodiesterase-inhibiting properties, therefore larger doses of relaxants may be required. In experimental animals, cyclosporine infusions have been shown to potentiate the neuromuscular-blocking effects of atracurium and vecuronium, and single doses of cyclosporine may result in increased duration of action of both barbiturates and narcotics.

Ashary N, Kaye AD, Hegazi AR, et al. Anesthetic considerations in the patient with a heart transplant. *Heart Disease*. 2002;4:191–198.

Cirella VN, Pantuck CB, Lee YJ, et al. Effects of cyclosporine on anesthetic action. *Anesth Analg*. 1987;66:703–706.

E.10. What is cardiac allograft vasculopathy (CAV)? Why is this important?

The transplanted heart is vulnerable to an accelerated process of coronary atherosclerosis called cardiac allograft vasculopathy (CAV). Between the 1st and 10th year posttransplant, 44% of patients develop CAV. It is characterized by concentric intimal proliferation and diffuse narrowing along the coronary vessel. Diagnosis is accomplished by coronary angiography or intravascular ultrasound. The etiology is likely multifactorial, with both immunologic and nonimmunologic factors. Risk factors for CAV development within 8 years posttransplant include donor hypertension, induction therapy with IL-2 antagonists or OKT3, pretransplant coronary disease, clinical infection in donor, older donor age, and decreasing recipient age.

E.11. What is the significant implication of posttransplant hypertension?

After 10 years, 97% of surviving patients have developed hypertension. Cyclosporine often is cited as a causative factor. Current therapy may consist of a calcium channel blocker such as diltiazem. However, care must be taken, as diltiazem may increase cyclosporine serum levels. Nifedipine has a tendency to cause significant vasodilatation and may be tolerated poorly in these patients. When necessary, an ACE inhibitor may be added. Because cardiac responsiveness during exercise is dependent on circulating catecholamines, beta-blockers often are avoided after heart transplantation.

E.12. What is the significant implication of renal dysfunction?

Renal dysfunction is found in 31% of recipients at 5 years. Due to the nephrotoxic effects of cyclosporine, serum creatinine concentrations gradually increase after

cardiac transplantation, but generally plateau around 170 to 180 mmol/L^{-1}. Anesthetic drugs that are excreted mainly by renal clearance should be avoided if renal function is compromised. Also, one needs to be mindful of medications that may compromise further renal function, such as nonsteroidal anti-inflammatory drugs (NSAIDs).

E.13. Is ambulatory surgery appropriate for heart transplant recipients?

Unfortunately, there is a paucity of evidence supporting either the safety or harm of ambulatory surgery in heart transplant recipients. In addition, the choice of anesthetic technique seems to have no influence on outcome. Regardless, these patients should be seen in preadmission clinics before the day of surgery and have appropriate screening tests done preoperatively, including, but not limited to, an assessment of complete blood count, electrolytes, renal function, ECG, and an accurate blood pressure measurement. They also should be evaluated by the cardiology transplant service and if any concern is raised, further testing should be undertaken, such as echocardiography, coronary angiography, or endomyocardial biopsy. Recommendations also should be obtained from the cardiac transplant service regarding perioperative antibiotic prophylaxis and immunosuppression.

CHAPTER 13

Ischemic Heart Disease and Noncardiac Surgery

SHAMSUDDIN AKHTAR, MARBELIA GONZALEZ, J. PATRICIO ESCANDON, AND PAUL G. BARASH

A 72-YEAR-OLD MAN

is scheduled for right hemicolectomy for colon cancer. Past history reveals a myocardial infarction (MI) 5 months ago and placement of a right coronary artery stent. He also has diabetes mellitus type 2. He is treated with atenolol, diltiazem, glyburide, losartan, and an occasional sublingual nitroglycerin (NTG).

A. Medical Disease and Differential Diagnosis

1. What are the preoperative predictors for major adverse cardiac events (MACE) perioperatively?
2. What are the determinants of myocardial oxygen demand? How are they measured clinically?
3. What factors determine myocardial oxygen supply?
4. What is the mechanism of perioperative myocardial ischemia and infarction?
5. What is the incidence of perioperative reinfarction for noncardiac surgery?
6. Based on his history of MI, would you recommend that the surgery be postponed for a certain period of time? If so, why?
7. State the perioperative medical therapy you would employ to reduce the incidence of myocardial ischemia.
8. Would the patient have increased risk for perioperative major cardiac complications if the patient's preoperative electrocardiogram (ECG) shows right bundle branch block (RBBB)/left bundle branch block (LBBB)?
9. Would you recommend that this elective colectomy be postponed, if the patient underwent placement of a coronary artery bare metal stent 3 weeks ago or a drug-eluting stent (DES) and is taking aspirin and clopidogrel (Plavix)?

B. Preoperative Evaluation and Preparation

1. How would you evaluate the patient's cardiac condition? What laboratory tests would you like to order?
2. Would you recommend further cardiac testing or coronary revascularization before surgery?

3. How would you classify the cardiac risk according to the type of surgery?
4. Are patients with a Q-wave infarction at greater risk for perioperative reinfarction than those with a non–Q-wave infarction?
5. What is the role of exercise or pharmacologic stress test for this patient?
6. Would you discontinue any medication before surgery?
7. How would you premedicate this patient?
8. Is there a role for α_2-agonists in premedication?

C. Intraoperative Management

1. What are the intraoperative predictors for perioperative cardiac morbidity (PCM)?
2. How would you monitor the patient in the operating room?
3. What ECG leads would you monitor? Why V_5?
4. Would you use a pulmonary artery catheter (PAC)?
5. Would you use transesophageal echocardiography (TEE) as a monitor?
6. Is regional anesthesia better than general anesthesia for patients with cardiac disease?
7. How would you induce general anesthesia?
8. Would you induce anesthesia with etomidate? Why?
9. What is the best choice of anesthetic agents for maintenance of anesthesia? Why?
10. What muscle relaxant would you choose? Why?
11. You notice a new 3-mm ST-segment depression in lead V_5. How would you treat it?
12. Would you give prophylactic intravenous NTG to prevent myocardial ischemia?
13. What is the significance of tight control of the heart rate intraoperatively?
14. When would you extubate the trachea in this patient? What could you do to prevent hypertension and tachycardia during extubation and emergence?

D. Postoperative Management

1. What are the postoperative predictors of PCM?
2. How would you control postoperative pain?
3. Is postoperative anemia associated with adverse cardiac outcome?
4. Is postoperative hypothermia associated with postoperative myocardial ischemia?
5. How would you make a diagnosis of perioperative myocardial infarction (PMI)?
6. How would you manage the patient with a suspected PMI?

A. Medical Disease and Differential Diagnosis

A.1. What are the preoperative predictors for major adverse cardiac events (MACE) perioperatively?

PMI is one of the most important predictors of short- and long-term mortality and morbidity associated with noncardiac surgery. Therefore, the prevention of PMI relates to improvement in postoperative outcomes. Numerous risk indices and predictors for perioperative cardiac morbidity (PCM) have been published over the last 30 years.

In 1999, Lee et al. revised the Goldman Cardiac Risk Index, utilizing six independent predictors of cardiac risk:

- High-risk type of surgery
- History of ischemic heart disease (IHD)
- History of congestive heart failure (CHF)
- History of cerebrovascular disease
- Preoperative treatment of diabetes mellitus with insulin
- Preoperative serum creatinine greater than 2.0 mg per dL

They concluded that the rate of major cardiac complications (MI, pulmonary edema, ventricular fibrillation, and primary cardiac arrest) with 0, 1, 2, and more than or equal to 3 predictors, were 0.5%, 1.3%, 4%, and 9%, respectively.

According to the 2009 American College of Cardiology (ACC) and American Heart Association (AHA) guideline update on perioperative cardiovascular evaluation (ACC/AHA guidelines), clinical predictors of MACE are categorized into major, intermediate, and minor factors as follows:

Major predictors

- Unstable coronary syndromes
  - Acute (MI ≤7 days before examination) or recent MI (>7 days but ≤1 month) with evidence of important ischemic risk by clinical symptoms or noninvasive study. Notice that the traditional 3 and 6 months interval had been avoided.
- Unstable or severe angina (Canadian class III: marked limitation of ordinary physical activity; walking one to two blocks on the level and climbing one flight of stairs in normal conditions at normal pace; and Canadian class IV: inability to carry on any physical activity without discomfort—anginal syndrome may be present at rest.)
- Decompensated heart failure
- Significant arrhythmias
  - High-grade atrioventricular block, Mobitz type II atrioventricular block, third degree heart block
  - Symptomatic ventricular arrhythmias
  - Supraventricular arrhythmias (including atrial fibrillation) with uncontrolled ventricular rate (heart rate greater than 100 beats per minute at rest)
  - Symptomatic bradycardia
- Severe valvular disease (severe aortic stenosis valve area <1 cm^2 or symptomatic) or symptomatic mitral stenosis

Intermediate predictors

- History of IHD, including stable angina pectoris (Canadian class I: ordinary physical activity, such as walking and climbing stairs, does not cause angina; angina is with strenuous or rapid or prolonged exertion at work or recreation. Canadian class II: slight limitations to ordinary activity. Walking or climbing stairs rapidly; walking uphill; walking or stair climbing after meals, or in cold, or in wind, or under emotional stress, or only during the few hours after awakening. Walking more than two blocks on the level and climbing more than one flight of ordinary stairs at a normal pace and in normal conditions.)
- History of compensated or prior heart failure
- History of cerebrovascular disease
- Diabetes mellitus
- Renal insufficiency

Minor predictors

- Advanced age (>70 years)
- Abnormal ECG (left ventricular [LV] hypertrophy, LBBB, ST-T abnormalities)
- Rhythm other than sinus (e.g., atrial fibrillation)

- Low functional capacity (e.g., inability to climb one flight of stairs while carrying a bag of groceries)
- Uncontrolled systemic hypertension

Fleisher LA, Beckman JA, Brown KA, et al. 2009 ACCF/AHA focused update on perioperative beta blockade incorporated into the ACC/AHA 2007 guidelines on perioperative cardiovascular evaluation and care for noncardiac surgery: a report of the American College of Cardiology Foundation/American Heart Association Task Force on Practice Guidelines. *Circulation.* 2009;120:e169–e276.

A.2. What are the determinants of myocardial oxygen demand? How are they measured clinically?

The three major determinants of myocardial oxygen demand are (1) myocardial LV wall tension (LV preload and afterload), (2) cardiac contractility, and (3) heart rate.

A.3. What factors determine myocardial oxygen supply?

The factors determining myocardial oxygen supply include cardiac output, arterial oxygen content, heart rate, aortic diastolic pressure, LV end-diastolic pressure, patency of coronary arteries, and coronary vascular tone.

A.4. What is the mechanism of perioperative myocardial ischemia and infarction?

Myocardial ischemia occurs whenever myocardial oxygen supply does not match myocardial oxygen demand. Intraoperative ischemia can be precipitated by increases in myocardial oxygen demand caused by tachycardia, hypertension, anemia, stress, sympathomimetic drugs, or discontinuation of β-blockers. However, as many as 50% or more of the ischemic episodes may be unrelated to the indices of oxygen demand, suggesting decreased oxygen supply as the primary cause. Potential etiologies for decreased supply include external factors, such as hypotension, tachycardia, increased filling pressures, anemia, hypoxemia, and decreased cardiac output. In addition, internal factors such as acute coronary artery thrombosis and spasm also may play a role, although no data are available for determining their importance in the perioperative setting.

PMI is one of the most important predictors of short- and long-term morbidity and mortality associated with noncardiac surgery. Unfortunately, the exact nature of PMI remains uncertain and a subject of debate and controversy. The interaction between morphologic and functional factors is unpredictable. There is some pathologic and angiographic evidence that the etiology of PMI resembles that in the nonsurgical setting. In PMI, acute plaque disruption and hemorrhage in the infarct-related coronary artery seems to be common, but the severity of underlying coronary artery stenosis does not necessarily predict the infarct territory. The high incidence of histologically confirmed transmural infarctions seems to be contradictory to the ECG finding of almost exclusively non–Q-wave PMIs. On the other hand, the presence of subendocardial PMIs is consistent with a myocardial oxygen supply/demand mismatch

being the main trigger of myocardial injury. However, myocardial oxygen supply/demand mismatch and plaque rupture are not mutually exclusive mechanisms, and MIs may develop by different mechanisms at different locations in the same patient.

Most PMIs (>80%) occur early after surgery (0 to 72 hours), are asymptomatic, of the non– Q-wave type (60% to 100%), and are commonly preceded by ST-segment depression rather than ST-segment elevation. Long duration (single duration >20 to 30 minutes or cumulative duration >1 to 2 hours intraoperatively or postoperatively) rather than just the presence of postoperative ST-segment depression, seems to be the important factor associated with adverse cardiac outcome.

Landesberg's review of PMIs summarizes pathophysiology as follows:

- Ischemia occurs (67%) at the end of anesthesia or immediately after surgery, during a period characterized by high sympathetic output, hypercoagulability, hypertension, and tachycardia. Ischemia in this period is usually silent, with only ST-segment depression as a marker. And in at least one-third of the patients, this ST depression goes unnoticed.
- Patients with prolonged ST depression may present with troponin elevation, half of them asymptomatic. In this population, the diagnosis of PMI will be missed if troponins were not requested. The elevation may start within the first 8 hours postsurgery.
- Because the increase in troponin occurs during or shortly after prolonged ST-depression–type ischemia, without sudden conversion to ST elevation, it is assumed that PMI is most likely the consequence of stress-induced ischemia and not because of plaque rupture, however, the two mechanisms are not mutually exclusive.
- In approximately 50% of the patients who die secondary due to a PMI, no plaque rupture or thrombosis was found in their coronary arteries at autopsy, despite their extensive coronary artery disease (CAD). The peak incidence of cardiac death in these patients is within the first 3 postoperative days, corresponding to the peak incidence of prolonged, stress-induced, ST-depression–type PMI. The other 50% of patients with PMI, in whom plaque rupture or coronary thrombosis is detected, the timing of death is evenly distributed in the postoperative period, with no special correlation to the end of surgery (Fig. 13.1).

A.5. What is the incidence of perioperative reinfarction for noncardiac surgery?

Previously, risk assessment for noncardiac surgery of patients with CAD was based upon the time interval between the MI and surgery. However, with improvements in perioperative care, this difference has become blurred. The importance of the timing of the MI in relation to the proposed surgical procedure may no longer be valid in the era of thrombolytics, angioplasty, and risk stratification. Although many patients with a history of an MI may continue to have myocardium at risk, others may not. If a stress test does not indicate residual myocardium at risk, the likelihood of reinfarction is low. There is no data available to quote a perioperative reinfarction rate related to the age of the MI; despite this, statements contained in the current AHA/ACC guidelines for perioperative cardiovascular evaluation confers a higher risk if the MI is at least 1 month old.

Landesberg states that early mortality after PMI ranges from 3.5% to 25% and is higher among patients with marked troponin elevation compared with patients with minor troponin elevation (0% to 7%). This is in contrast to older data that reported a very high incidence of mortality.

Fleisher LA, Beckman JA, Brown KA, et al. 2009 ACCF/AHA focused update on perioperative beta blockade incorporated into the ACC/AHA 2007 guidelines on perioperative cardiovascular evaluation and care for non-cardiac surgery: a report of the American College of Cardiology Foundation/American Heart Association Task Force on Practice Guidelines. *Circulation*. 2009;120:e169–e276.

A.6. Based on his MI, would you recommend that the surgery be postponed for a certain period of time? If so, why?

The arbitrary delaying of a surgical procedure is not supported by the ACC/AHA guidelines. According to these guidelines, an acute MI (≤7 days before the preoperative evaluation) or recent MI (>7 days but ≤1 month) with evidence of important ischemic risk by clinical symptoms or noninvasive study is a major predictor of PCM. Therefore, the separation of the interval of MI to operation into the traditional 3- and 6-month intervals is no longer recommended. Current management of MI provides for risk stratification during convalescence period. If a recent stress test does not indicate residual myocardium at risk, the likelihood of reinfarction after noncardiac

surgery is low. Although there are no adequate clinical trials on which to base firm recommendations, it appears reasonable to wait 4 to 6 weeks after MI to perform elective surgery due to the decrease in incidence of fatal arrhythmias and ventricular rupture after this period of time.

Fleisher LA, Beckman JA, Brown KA, et al. 2009 ACCF/AHA focused update on perioperative beta blockade incorporated into the ACC/AHA 2007 guidelines on perioperative cardiovascular evaluation and care for noncardiac surgery: a report of the American College of Cardiology Foundation/American Heart Association Task Force on Practice Guidelines. *Circulation.* 2009;120:e169–e276.

Poldermans D, Bax JJ, Boersma E, et al. Guidelines for pre-operative cardiac risk assessment and perioperative cardiac management in non-cardiac surgery: the Task Force for Preoperative Cardiac Risk Assessment and Perioperative Cardiac Management in Non-cardiac Surgery of the European Society of Cardiology (ESC) and endorsed by the European Society of Anaesthesiology (ESA). *Eur Heart J.* 2009;30:2769–2812.

A.7. State the perioperative medical therapy you would employ to reduce the incidence of myocardial ischemia.

β-Adrenergic antagonists (esmolol, atenolol, metoprolol, bisoprolol)

This drug class:

- Reduces myocardial oxygen consumption
- Improves coronary blood flow
  - Prolonged diastolic perfusion period
  - Improved collateral flow
  - Increased flow to ischemic areas
- Improves supply/demand ratio
- Stabilizes cellular membranes
- Improves oxygen dissociation from hemoglobin (Hgb)
- Inhibits platelet aggregation

β-Blockers suppress perioperative tachycardia and appear most efficacious in preventing perioperative myocardial ischemia. They are well tolerated by most surgical patients and may reduce long-term cardiac events.

Since the 1980s, evidence suggests tachycardia as a major determinant of perioperative ischemia and its relation with the occurrence of MI in the postoperative period.

Slogoff et al. found that PMI presented more frequently in patients that sustained ischemia independent of the time of occurrence. Ischemia was significantly related to tachycardia but not hypertension or hypotension and was frequently seen in the absence of any hemodynamic abnormalities. Also, they advocated the perioperative use of β-blockers to prevent ischemia.

Mangano et al. reported a beneficial effect of atenolol in a randomized double-blind, placebo-controlled trial on overall survival and cardiovascular morbidity in noncardiac surgery patients with or at risk for CAD. Poldermans et al. reported that the β-blocker, bisoprolol, reduced the perioperative incidence of death from cardiac causes and nonfatal MI in vascular surgical patients with known CAD. Bisoprolol, started before noncardiac surgery (30 days), can substantially reduce perioperative cardiac complications in all but the highest-risk patients. However, results of recent trials have not shown efficacy of high-dose, acutely administered, perioperative β-blockers to reduce overall mortality in patients undergoing noncardiac surgery. The largest of these trials, the POISE study, did show better perioperative *cardiac* outcomes with β-blocker use, however, *increased mortality* and stroke rate also was noted in the β-blocker group. Interestingly, the sub-analysis of vascular surgery patients

in the study, demonstrated efficacy of perioperative β-blockers. Currently, the only class I recommendation for perioperative β-blockers use by the AHA is to continue their use in the patients who are already on β-blockers. Patients undergoing vascular surgery who have multiple risk factors or have reversible ischemia on preoperative testing may benefit from perioperative β-blockers (class IIa). Although there are some differences between the European Society of Cardiology (ESC) and the AHA guidelines, they both agree that if β-blockers are used for prophylactic purposes, they should be slowly titrated (at least a week prior to elective surgery) and acute administration of high-dose β-blockers in high-risk population is not recommended.

α_2-Adrenergic agonist (clonidine)

The ACC/AHA guidelines mention the potential benefits on PMI reduction with the use of this drug class (class IIb recommendation). Their benefits had been reviewed by two meta-analysis and two randomized trials. The meta-analysis has shown the reduction of MI/ischemia in vascular patients, but not in all patient groups. A recent randomized trial suggests that using perioperative transdermal/oral clonidine reduced perioperative ischemia and mortality by 31%. There are no prospective trials comparing the two forms of adrenergic modulators (β-blockers vs. α_2 agonists).

Nitrovasodilators (nitroglycerin, isosorbide dinitrate)

Nitrates are associated with the following:

- Decreased LV preload (low dose)
  - Systemic venous dilation
  - Pulmonary arterial bed dilation
  - Pulmonary vein dilation
  - Decreased LV filling pressure
  - Decrease in LV diastolic compressive forces
  - Decreased LV diastolic chamber size
- Decreased LV afterload (high dose)
  - Decreased systolic pressure
  - Decreased systemic vascular resistance
  - Decreased aortic impedance
- Coronary circulation
  - Coronary artery and arteriolar dilation (high dose)
  - Spasm reversal or prevention
  - Stenosis dilation
  - Increased collateral flow
  - Improvement of regional subendocardial ischemia

NTG, one of the oldest antianginal therapies, has had very few trials in noncardiac surgery to evaluate its role in perioperative ischemia reduction. One meta-analysis suggests that nitrates do not reduce perioperative cardiac events. However, a recent meta-analysis published in the Cochrane database has suggested that nitrates show an improvement in perioperative ischemia over placebo. Auerbach and Goldman recommend continuing antianginal medications during the perioperative period. However, the use of prophylactic intravenous NTG is not recommended.

Calcium channel blockers (verapamil, diltiazem, nifedipine, nicardipine)

Calcium channel blockers reduce myocardial oxygen demand by depression of myocardial contractility and dilation of coronary and collateral vessels, which improves blood flow. However, its most important effects may be the prevention of sympathetically mediated coronary vasoconstriction.

Calcium channel blockers interact with the L-type calcium channel and are composed of drugs from five classes: (1) the 1,4-dihydropyridine (DHP) derivatives, rep-

resented by nifedipine, nicardipine, nimodipine, clevidipine and nitrendipine; (2) the phenylalkylamines, represented by verapamil; (3) the benzodiazepines, represented by diltiazem; (4) the diarylaminopropylamine ester, represented by bepridil; and (5) diphenylpiperazine.

Due to the initial experience with nifedipine, increase incidence of MI, there has been reluctance to use this drug class. A meta-analysis of perioperative calcium channel blockers in noncardiac surgery (11 studies involving 1,007 patients) showed significantly reduced ischemia and postoperative supraventricular tachycardia. The beneficial effects were mostly due to the use of diltiazem, and the use of DHP was associated with ischemia. Another study in 1,000 patients having acute or elective aortic aneurysm surgery showed that DHP calcium channel blocker use was independently associated with an increased incidence of perioperative mortality. The use of short-acting DHP, in particular nifedipine capsules, should be avoided. Though the AHA makes no specific recommendations for the prophylactic use of calcium channels blockers, ESC recommends their continued use in patients with Prinzmetal angina pectoris (class I) and for heart rate control in patients with who have contraindications to β-blocker use (class IIb). Routine use of calcium channel blockers to reduce the risk of perioperative cardiovascular complications is not recommended (class III).

Aspirin

Aspirin (acetylsalicylic acid) inhibits platelet aggregation by blocking the production of thromboxane A_2 through a covalent acetylation of a serine residue near the active site of cyclooxygenase. This enzyme produces the cyclic endoperoxide precursor of thromboxane A_2. Acute withdrawal of aspirin may increase the risk of acute coronary syndrome at 8 to 10 days after discontinuation. However, if continued during the perioperative period, aspirin may increase the risk of bleeding. A large meta-analysis, including 41 studies in 49,590 patients, which compared perioprocedural withdrawal versus bleeding risks of aspirin, concluded that the risk of bleeding complications was increased by 1.5 but that aspirin did not lead to higher severity levels of bleeding complications. A systematic review in subjects at risk for, or with IHD, demonstrated that aspirin non-adherence/withdrawal was associated with a threefold higher risk of MACE. Aspirin should only be discontinued if the bleeding risk outweighs the potential cardiac benefit.

Statins

Statins are primarily used for their lipid lowering effects and are widely prescribed in patients with or at risk for IHD. Statins also induce coronary plaque stabilization by decreasing lipid oxidation, inflammation, matrix metalloproteinase, and cell death. These so-called non-lipid or pleiotropic effects may prevent plaque rupture and subsequent MI in the perioperative period. Many trials and observational studies have demonstrated a beneficial effect of perioperative statin use. A meta-analysis of 223,010 patients from 12 retrospective and three prospective trials showed that statins reduced mortality significantly by 44% in noncardiac surgery and by 59% in vascular surgery. The most recent randomized controlled trial was the DECREASE III study. A total of 497 vascular surgery patients were allocated to either fluvastatin (extended release 80 mg once daily) or placebo, starting 37 days prior to surgery. The incidence of myocardial ischemia and cardiac death was almost decreased by 50% in patients allocated to fluvastatin. Both the AHA and ESC guidelines recommend continuing statin therapy for patients currently taking statins and scheduled for noncardiac surgery (class I). ESC also recommends that statins be started in high-risk surgery patients, optimally between 30 days and at least 1 week before surgery (class I B).

A.8. Would the patient have increased risk for perioperative major cardiac complications if the patient's preoperative electrocardiogram (ECG) shows right bundle branch block (RBBB)/left bundle branch block (LBBB)?

A retrospective, cohort-controlled study of all noncardiac, nonophthalmologic, adult patients showed that the presence of RBBB or LBBB was not associated with a higher incidence of postoperative cardiac complications. Nevertheless, the patients with LBBB may not tolerate certain stress of perioperative noncardiac complications, such as severe sepsis. The presence of LBBB or RBBB may alert the clinician to the possibility of occult CAD or impaired LV function.

Alternatively, in men, but not in women, LBBB was associated with a significantly greater prevalence of cardiac enlargement and CHF than RBBB. The Framingham Study concluded that in an ambulatory population, men with LBBB were more likely to have or subsequently develop advanced cardiovascular abnormalities than were men with RBBB. In women, however, the clinical scenarios that correlate with the two conduction abnormalities are similar.

The ACC/AHA recommends careful evaluation for underlying cardiopulmonary disease, drug toxicity, or metabolic abnormality. Frequent premature ventricular complexes or nonsustained ventricular tachycardia have not been associated with increased risk of MI or cardiac death.

A.9. Would you recommend that this elective colectomy be postponed, if the patient underwent placement of a coronary artery bare metal stent 3 weeks ago or a drug-eluting stent (DES) and is taking aspirin and clopidogrel (Plavix)?

Extremely high mortality rates (up to 20%) have been reported secondary to acute stent thrombosis, if surgery is performed within weeks after coronary stenting, with discontinuation of antiplatelet therapy. When surgery was performed within this period, discontinuation of dual antiplatelet therapy was associated with an increased incidence of stent thrombosis. After 3 months, patients can be sent for noncardiac surgery, with continuation of at least aspirin therapy.

Current recommendations for the antiplatelet therapy after percutaneous coronary intervention (PCI) with stenting (bare metal stents) is that patients should take aspirin and other platelet inhibitor (ticlopidine, clopidogrel) for at least a full 30 to 45 days to prevent restenosis and allow reendothelialization of the stent to be completed. Therefore, it is prudent to postpone the elective surgery for a minimum of 30 to 45 days (minimum of 6 weeks by ESC recommendations). Also see Chapter 9, section A.5, Figure 9.1.

Though DES delay in-stent thrombosis, their major drawback is the need for prolonged dual antiplatelet therapy by aspirin and clopidogrel for at least 12 months. Retrospective and case series have shown that when surgery was performed within this period, discontinuation of dual antiplatelet therapy was associated with an increased incidence of stent thrombosis. It is now recommended that after DES implantation, elective surgery should not take place until after at least 12 months of continuous dual antiplatelet therapy. Even after 12 months, patients should be sent for noncardiac surgery, with continuation of at least aspirin therapy. The need and timing for surgery should be based on the specific pathology (e.g. malignant tumor, vascular aneurysm repair) and should be balanced against the excessive risk of stent thrombosis and fatal perioperative event during the first year following DES implantation. A careful "case-by-case" consideration is advisable. Discussion between the anesthesiologist, the surgeon, and the treating cardiologist is recommended. Also see Chapter 9, section A.5, Figure 9.2.

The role of preoperative coronary revascularization has been controversial for many years. Few randomized clinical trials and many small size studies have reported conflicting results. Some literature supports revascularization arguing that high-risk cardiac patients who have had PCI performed up to 18 months preoperatively have a lower incidence of perioperative MACE following vascular surgery. However, McFalls et al. published a randomized study where they concluded that coronary revascularization before vascular surgery does not significantly alter the long-term cardiovascular outcome in patients with stable cardiac symptoms. A recent meta-analysis and subsequent publication of the second prospective randomized trial, the Dutch Echocardiographic Cardiac Risk Evaluation Applying Stress Echo–V (DECREASE-V) pilot study, all failed to show survival benefit associated with preoperative revascularization.

The AHA and ESC guidelines state that the indications for coronary artery bypass grafting (CABG) and PCI should be the same as in the nonsurgical settings. These interventions are rarely indicated to "get a patient through" noncardiac surgery.

B. Preoperative Evaluation and Preparation

B.1. How would you evaluate the patient's cardiac condition? What laboratory tests would you like to order?

The initial history, physical examination, and electrocardiographic assessment should focus on identification of potentially serious cardiac disorders, including CAD (e.g., prior MI, angina pectoris), CHF, and electrical instability (e.g., symptomatic arrhythmias).

In addition to identifying the presence of pre-existing manifested heart disease, it is essential to define disease severity, stability, and prior treatment. Other factors that help determine cardiac risk include functional capacity, age, comorbid conditions (e.g., diabetes mellitus, peripheral vascular disease, renal dysfunction, chronic pulmonary disease), and type of surgery (vascular procedures and prolonged, complicated thoracic, abdominal, and head and neck procedures are considered higher risk).

This patient is an insulin-dependent diabetic. Diabetes is associated with a twofold to fourfold increase in the risk of developing CAD. The risk of a MI in patients with diabetes and no evidence of CAD match that of patients without diabetes who have had a previous MI. In patients with CAD and diabetes, the mortality rate can be up to 70% in 10 years. In addition, patients will have a worse outcome for any CAD manifestation.

The preoperative workup varies according to the presence or absence of clinical indicators of underlying CAD:

- Exercise tolerance—poor exercise tolerance has been associated by some with twofold higher odds for postoperative complications. Lee, however, did not find an independent association of functional status with increased risk.
- Evaluation of the presence or absence of any coronary syndrome/symptoms after coronary revascularization.
- Determination of stress test results post-MI/revascularization and establishment of new symptoms since coronary revascularization.

For this patient, the preoperative laboratory workup should include a Hgb/hematocrit (Hct), prothrombin time, partial thromboplastin time, electrolytes, creatinine, and blood urea nitrogen.

B.2. Would you recommend further cardiac testing or coronary revascularization before surgery?

Successful perioperative evaluation and treatment of cardiac patients undergoing noncardiac surgery requires careful teamwork and communication between patient, primary care physician, anesthesiologist, and surgeon. In general, indications for further cardiac testing and treatment are the same as those in the nonoperative setting, but their timing is dependent on factors such as the urgency of noncardiac surgery, the patient's risk factors, and specific surgical considerations. Preoperative testing should be limited to circumstances in which the results will affect patient treatment and outcomes. A conservative approach to the use of expensive tests and treatments is recommended. Coronary revascularization before noncardiac surgery to enable the patient to "get through" the noncardiac procedure is inappropriate. However, in a high-risk subset of patients, left main disease, severe multivessel disease, severe aortic stenosis, and ejection fraction of less than 20% revascularization/valve replacement may be indicated. Currently, there is overwhelming agreement that aggressive medical management to provide myocardial protection during the perioperative period is a very important element in the reduction of perioperative cardiovascular complications.

Several studies have suggested that a stepwise approach to the assessment of CAD is both efficacious and cost effective. The patient sustained a MI 5 months ago managed with a bare metal stent and was scheduled for an intermediate-risk procedure, hemicolectomy. If the patient has more than 4 METs of physical activity, without chest pain or shortness of breath, if no new cardiac symptoms are present since the revascularization, and the resting ECG showed no new changes compared to 5 months ago, the patient can undergo anesthesia and surgery without further testing. If any of these factors are positive, then exercise thallium imaging or dipyridamole-thallium (DTS) imaging (if unable to exercise) or stress dobutamine echo is recommended. If the ischemic area is small, surgery is permissible with recommended aggressive medical therapy management. If the ischemic area is moderate to large, with a suspicion of new or severe coronary stenosis, cardiac catheterization is recommended before the planned surgery. Also see Chapter 9, Section B.2, Figure 9.3.

An alternative view: McFalls et al. demonstrated the lack of benefit of perioperative revascularization of patients with significant but stable CAD; this will render the stress test and its low positive predictive value not useful in this patient. Considering the patient as high risk given all his comorbidities, adopting an aggressive perioperative medical treatment with β-blockers or α_2-blockers, statins and angiotensin inhibitors would be the alternative plan recommended.

Slogoff S, Keats A. Myocardial ischemia revisited. *Anesthesiology.* 2006;105:214–216.

B.3. How would you classify the cardiac risk according to the type of surgery?

Surgery-specific cardiac risk of noncardiac surgery is related to two important factors: the type of surgery and the degree of hemodynamic stress associated with the procedure(s). The duration and intensity of coronary and myocardial stressors can be helpful in estimating the likelihood of perioperative cardiac events, particularly for emergency surgery. Surgery-specific risk for noncardiac surgery can be stratified as high, intermediate, and low.

- *High-risk* surgery (cardiac risk often >5%) includes major emergency surgery, particularly in the elderly; aortic and other major vascular surgery; peripheral vascular surgery; and anticipated prolonged procedures associated with large fluid shifts and/or blood loss.
- *Intermediate-risk* (cardiac risk generally <5%) procedures include carotid endarterectomy, head and neck surgery, intraperitoneal and intrathoracic, orthopedic, and prostate surgery. Endovascularly performed aortic stent procedures also are included in this category.
- *Low-risk* (cardiac risk generally <1%) procedures include endoscopic and superficial procedures, cataract surgery, and breast surgery.

Fleisher LA, Beckman JA, Brown KA, et al. 2009 ACCF/AHA focused update on perioperative beta blockade incorporated into the ACC/AHA 2007 guidelines on perioperative cardiovascular evaluation and care for noncardiac surgery: a report of the American College of Cardiology Foundation/American Heart Association Task Force on Practice Guidelines. *Circulation.* 2009;120:e169–e276.

B.4. Are patients with a Q-wave infarction at greater risk for perioperative reinfarction than those with a non–Q-wave infarction?

Studies indicate that individuals who survive a non–Q-wave infarction are at greater risk for reinfarction than those who survive a Q-wave infarction. Patients who have not had a transmural wall infarction have a less extensive infarction and lower in-hospital mortality; however, they have a larger degree of jeopardized or at risk myocardium leading to a higher incidence of reinfarction or recurrent angina. This is in distinction to patients with complicated Q-wave infarctions who frequently do not survive the immediate postinfarction period but have a lower rate of reinfarction than non–Q-wave MI after this period. Theoretically, patients who have had a solitary coronary artery lesion and sustained a transmural infarction may be considered at a significantly lower risk for reinfarction as the area that was

at risk for ischemia is already necrotic. Although their risk of reinfarction may be low, there may be an increased risk of dysrhythmias because of the necrotic myocardium. It is important to remember (1) that the distinction between the Q- and non–Q-wave MI is an electrocardiographic classification and does not necessarily correlate with the pathologic findings of transmural and subendocardial infarctions; and (2) that there is overlap especially with the use of thrombolytic therapy.

B.5. What is the role of exercise or pharmacologic stress test for this patient?

The aim of functional cardiovascular testing is to elicit evidence and severity of CAD by subjecting the heart to physiologic stress. Noninvasive diagnostic testing must be used judiciously. Ideally, testing should be accurate, add useful information to the overall risk assessment, and avoid unnecessary delays in surgery. Noninvasive tests of myocardial perfusion are classified by the type of stress applied to elicit transient and reversible ischemia or by the mode of detecting the ischemic area. Myocardial stress can be induced by exercise (e.g., treadmill, sitting or supine bicycle, or handgrip), by a pharmacologic agent that increases heart rate and myocardial contraction (e.g., dobutamine, atropine), or by a pharmacologic agent that can cause redistribution of coronary blood flow (e.g., dipyridamole, adenosine). Physiologic exercise provides an estimate of functional capacity, provides blood pressure and heart rate response, and detects myocardial ischemia through ST-segment changes. The accuracy of exercise ECG varies significantly among studies. Meta-analysis of the reported studies using treadmill testing in vascular surgery patients showed a rather low sensitivity (74%) and specificity (69%), comparable with daily clinical practice. The positive predictive value was as low as 10%, but the negative predictive value was very high (98%).

A significant fraction of the high-risk population cannot exercise to an adequate level and will require pharmacologic stress testing. During a stress test, an ischemic event might be suggested or detected by the patient's reporting of symptoms, appropriate ECG changes (horizontal or down-sloping ST-segment depression of 0.1 mV or ST elevation of 0.15 mV in two contiguous leads, reversible wall motion abnormalities on echocardiography, or reversible perfusion defects on radionuclide imaging with thallium or technetium.

The DTS and dobutamine stress echocardiography (DSE) before vascular surgery predict PMI or death, with a positive predictive value of only 12% to 14% and a negative predictive value of 88% and 94%, respectively. In one meta-analysis DSE tends to perform better than DTS. However, the large majority of the cited DTS involved older planar imaging technology that is no longer used. The low positive predictive value is expected because stress tests are designed to discover fixed coronary artery stenosis that exceed 70%. However, at least 50% of PMIs are due to plaque rupture, and it is often the noncritical, nonischemia-producing lesions that rupture.

Selection of the noninvasive stress test should be based primarily on patient characteristics, local availability, and expertise in interpretation. Because of simplicity, lower cost, and widespread familiarity with performance and interpretation, the standard low-level exercise ECG stress test remains the most reasonable test in patients who are able to exercise and have a resting ECG that is interpretable for ST-segment shifts. Patients with an ECG pattern that would interfere with interpretation of the ST segment (LBBB, pre-existing ST-segment abnormality in the precordial leads V_5 and V_6) should have an exercise test with imaging. Patients who are unable to exercise should have a pharmacologic stress test with imaging.

Dobutamine stress echocardiography is the preferred test if there is an additional question regarding valvular function or LV dysfunction.

Lustik S, Eichelberger J, Chhibber K. Preoperative stress testing: new guidelines. *J Clin Anesth.* 2004;14:375–380.

B.6. Would you discontinue any medication before surgery?

Patients with CAD are usually on a variety of medications. All antianginal drugs, especially β-blockers and statins, should be continued up to the time of surgery. Sudden withdrawal of antianginal drugs may produce rebound tachycardia and hypertension that may precipitate acute myocardial ischemia or infarction.

Current management of hypertensive patients suggests the continuation of antihypertensive therapy up to the day of surgery. In particular, β-blockers, calcium channel blocker, and nitrates should be continued. There is continued controversy about withholding angiotensin-converting enzyme inhibitors (ACE inhibitors) and angiotensin-2 receptor antagonist 24 hours prior to surgery. Prolonged hypotension has been observed in patients who are undergoing general anesthesia and who have chronically been treated with ACE inhibitors. Some recommend withholding ACE inhibitors for 24 hours prior to surgical procedures involving major body fluid shifts on significant blood loss. Hypotension attributed to ACE inhibitors is frequently responsive to fluid and/or administration or sympathomimetic drugs, such as phenylephrine and ephedrine. If hypotension is refractory to these measures, treatment with vasopressin or its long-acting analogue, terlipressin, may be effective.

Tuman KJ, McCarthy RJ, O'Connor CJ, et al. Angiotensin-converting enzyme inhibitors increase vasoconstrictor requirements after cardiopulmonary bypass. *Anesth Analg*. 1995;88:7–17.

B.7. How would you premedicate this patient?

The patient with IHD should be adequately sedated before surgery to avoid anxiety-induced tachycardia and hypertension that may cause adverse myocardial ischemic events. Appropriate doses of a benzodiazepine may be given with the antianginal medications.

B.8. Is there a role for α_2-agonist in premedication?

α_2-agonists stimulate prejunctional alpha receptors and decrease norepinephrine release from prejunctional terminals, thereby decreasing noradrenergic central nervous system transmission, producing sedation, anxiolysis, and analgesia. Studies have shown that clonidine as a premedication reduces hypertension, tachycardia, and norepinephrine levels in patients undergoing aortic reconstruction. Clonidine also suppresses the normal postoperative increase in fibrinogen levels and antagonizes epinephrine-induced platelet aggregation. It has also been shown to decrease intraoperative myocardial ischemia. The more selective α_2-agonists, dexmedetomidine and mivazerol (IV form only available in Europe), also may reduce postoperative myocardial ischemia events in high-risk patients.

C. Intraoperative Management

C.1. What are the intraoperative predictors for perioperative cardiac morbidity (PCM)?

Intraoperative predictors

Classic intraoperative predictors for perioperative MACE include emergency surgery, major vascular surgery, and prolonged (more than 3 hours) thoracic or upper abdominal surgery. Among the dynamic predictors, both hypotension and tachycardia predict PCM. Preoperative hypertension remains a controversial predictor. Most MIs occur early after surgery and are commonly associated with ST-segment depression. Prolonged duration of myocardial ischemia (>20 to 30 minutes or cumulative duration of >1 to 2 hours) seems to be the important factor associated with adverse cardiac outcome. Although LV end-diastolic pressure

is a sensitive measure of ischemia, studies report that pulmonary capillary wedge pressure is an insensitive indicator. Other factors associated with poor outcome are increased intraoperative bleeding/large quantity of blood transfusions and poor preoperative cardiac functional status.

Bui H, Haukoos J, Donayre C, et al. Predictors of cardiac morbidity and mortality in patients undergoing endovascular repair of the thoracic aorta. *Ann Vasc Surg.* 2004;18(1):22–25.

Sprung J, Abdelmalak B, Gottlieb A, et al. Analysis of risk factors for myocardial infarction and cardiac mortality after major vascular surgery. *Anesthesiology.* 2000;93(1):129–140.

C.2. How would you monitor the patient in the operating room?

The patient should be monitored using the following American Society of Anesthesiologist standard guidelines:

- *ECG*—simultaneous leads V_5 and II
- *Blood pressure*—noninvasive automatic Doppler sphygmomanometer and an invasive arterial catheter
- *Capnography*—to determine continuous end-tidal CO_2 analysis.
- *Pulse oximetry*—to assess arterial oxygenation
- *Oxygen analyzer*—to determine inspired fraction of oxygen.
- *Availability of esophageal/bladder temperature probe*—to determine temperature changes.

In addition to these monitors, this patient will also required the monitoring of urine output with a Foley catheter.

American Society of Anesthesiologists. ASA standards for basic anesthetic monitoring. ASA House of Delegates, Oct. 2005.

C.3. What ECG leads would you monitor? Why V_5?

ECG ST-segment changes are most commonly used for detection of intraoperative myocardial ischemia. Multiple-lead ECG monitoring provides the best clinically available method of detecting perioperative ischemia, primarily by combining leads II, V_3, V_4, and V_5 (II/V_5 detection of 80%, II/V_4, V_5 detection of 96%).

Landesberg et al. were able to correlate the duration of ischemia observed in the ST-segment analysis of a continuously monitoring 12-lead ECG throughout the perioperative period with the incidence of PMI. He also found that ischemia is transient even in patients who will develop an infarct.

Certain prerequisites must be met to use the ECG effectively:

- The diagnostic mode allows detection of ST-segment changes that are filtered out by the monitoring mode.
- The number of ECG leads and their location affects detection of ischemic events.
- Immediate availability of a hard copy of the ECG leads for more detailed analysis.
- Studies have reported that even trained observers recognize only 15% to 40% of electrocardiographic ischemic events displayed on oscilloscope.
- The introduction of ST-segment trending helps as an early warning detection system but should not replace examination of the ECG printout.

C.4. Would you use a pulmonary artery catheter (PAC)?

Right heart catheterization is not recommended for monitoring patients with intraoperative ischemia. Large observational study and a randomized multicenter trial did not show benefit associated with the use of right heart catheterization after major noncardiac surgery. A meta-analysis of randomized controlled trials showed that the use of PAC neither increased mortality or conferred any benefits to critically ill patients. A number of studies report that PAC is an insensitive monitor for myocardial ischemia and should not be inserted with this as a primary indication.

Fleisher LA, Beckman JA, Brown KA, et al. 2009 ACCF/AHA focused update on perioperative beta blockade incorporated into the ACC/AHA 2007 guidelines on perioperative cardiovascular evaluation and care for noncardiac surgery: a report of the American College of Cardiology Foundation/American Heart Association Task Force on Practice Guidelines. *Circulation.* 2009;120:e169–e276.

C.5. Would you use transesophageal echocardiography (TEE) as a monitor?

TEE is a very sensitive diagnostic method of new onset myocardial ischemia. The echocardiographic diagnosis of myocardial ischemia is based on the development of new regional wall motion abnormalities, decreased systolic wall thickening, and ventricular dilation. Usually, a cross-sectional view (deep transgastric short axis), of the LV is imaged because this view displays the myocardial perfusion territories of the three major coronary arteries. TEE was found to be twice as predictive as ECG in identifying CABG patients who have an MI. In CABG patients, postbypass regional wall motion abnormalities were related to adverse clinical outcome.

However, practitioners should realize certain limitations of TEE. One, preintubation events are missed, as are the ischemic events that can occur frequently at the end of the surgery, when tachycardia and hypertension appear as part of the emergence from general anesthesia. Real-time intraoperative analysis of the TEE image is associated with a decreased accuracy of interpretation. The examination could divert the anesthesiologist's attention from more important clinical details. Despite numerous reports extolling the virtues of TEE as an ischemia monitor, Hollenberg et al. demonstrated little incremental value over the 12-lead ECG. Furthermore, wall motion abnormalities may be difficult to interpret in the presence of LBBB, ventricular pacing, atrial fibrillation, or right ventricular overload.

Notwithstanding TEE's limitations, ESC and the AHA guidelines recommend the use of TEE intraoperatively or perioperatively to determine the cause of an acute, persistent, and life-threatening hemodynamic abnormality (class IIa recommendation).

However, its use as an ischemia monitor in noncardiac surgery is less validated and may only be considered in patients at high risk for developing myocardial ischemia who undergo major noncardiac surgery (class IIb recommendation by ESC).

C.6. Is regional anesthesia better than general anesthesia for patients with cardiac disease?

A number of studies in patients with cardiac disease have compared the effects of regional versus general anesthetics on the incidence of perioperative infarction, dysrhythmias, and CHF. No distinct advantage is apparent between them when considering PCM and mortality in patients undergoing peripheral vascular surgery. There is some evidence to support regional anesthesia over general anesthesia in an effort to optimize graft patency if the regional technique is extended into the postoperative period to provide neuraxial analgesia. The choice of technique does not appear to affect mortality in patients requiring hip fracture surgery, although Urwin et al. reported, in a meta-analysis, decreased 1-month mortality and incidence of thromboembolic complications in patients receiving regional anesthesia for hip fracture repair. Epidural anesthesia also has been shown to promote quicker return of bowel function postoperatively when the catheter has been placed at T12 level or higher. Anastomotic (colon/bowel) breakdown in patients with epidural anesthesia/analgesia (secondary to hyperperistaltism) has rarely been reported. Most studies tend to show quicker return of bowel function when local anesthetics alone are administered epidurally. In summary, no one technique demonstrates a consistent advantage. The MASTER (Multicenter Australian Study of Epidural Anesthesia)

trial randomized 915 patients undergoing major abdominal surgery to receive either combined general and epidural anesthesia/epidural analgesia or general anesthesia with opioid analgesia. Epidural anesthesia/analgesia did not decrease death or cardiovascular outcomes, but modestly improved pulmonary outcomes compared with the general anesthesia group.

Randomized studies and a meta-analysis of several randomized clinical trials in noncardiac surgery patients, comparing outcome with regional and general anesthetic techniques have shown little consistent evidence of improved outcome and reduced postoperative morbidity and mortality. Thus, the current guidelines recommends that the choice of anesthesia is best left to the discretion of the anesthesia care team, which will consider the need for postoperative ventilation; pulmonary/neuromuscular comorbidities; cardiovascular effects, including myocardial depression; sympathetic blockade consequences; and dermatomal level of the procedure.

C.7. How would you induce general anesthesia?

It is essential to prevent hypotension, hypertension, and tachycardia, which can precipitate myocardial ischemia. Different induction techniques may be employed to achieve this goal. For example, while the patient is being preoxygenated, fentanyl (up to 5 μg per kg) is given slowly to achieve drowsiness and to attenuate the sympathetic response to direct laryngoscopy and intubation of the trachea. Then, using lower doses of thiopental, propofol, or etomidate, unconsciousness is achieved. Succinylcholine or an intermediate duration nondepolarizing relaxant is administered to facilitate tracheal intubation. A few minutes before intubation the use of a short-acting β-blocker (esmolol) could help to further attenuate the sympathetic response to intubation if necessary. High-dose opioid-based anesthesia was previously popularized because of cardiovascular stability; however, because of the need for prolonged postoperative mechanical ventilation and ICU stay, this technique is no longer considered the technique of choice. On the other hand, in patients undergoing cardiac surgery, volatile anesthetics have been shown to decrease troponin release, enhance LV function compared with propofol, midazolam, or balanced anesthesia technique with opioids. The AHA guidelines extrapolate that data and recommend that it can be beneficial to use volatile anesthetic agents during noncardiac surgery for the maintenance of general anesthesia in hemodynamically stable patients at risk for myocardial ischemia.

Fleisher LA, Beckman JA, Brown KA, et al. 2009 ACCF/AHA focused update on perioperative beta blockade incorporated into the ACC/AHA 2007 guidelines on perioperative cardiovascular evaluation and care for noncardiac surgery: a report of the American College of Cardiology Foundation/American Heart Association Task Force on Practice Guidelines. *Circulation.* 2009;120:e169–e276.

C.8. Would you induce anesthesia with etomidate? Why?

Although etomidate has a negative inotropic effect on failing and nonfailing human heart muscle in doses that exceed the clinical dose, it appears to have a better hemodynamic profile than other commonly used induction agents, especially in the setting of coronary heart disease; with an induction dose of 0.2 to 0.3 mg per kg, there are minimal changes in heart rate, stroke volume, or cardiac output, and the blood pressure may decrease up to 15% because of decrease of systemic vascular resistance. Etomidate does suppress adrenocortical function, cause myoclonus, and prolong duration of seizure when used for electroconvulsive therapy.

C.9. What is the best choice of anesthetic agents for maintenance of anesthesia? Why?

There appears to be no one best myocardial protective agent or technique. The knowledge of physiologic and pharmacologic effects of anesthetic agents in patients with cardiac disease will allow flexibility in their selection. The use of inhalation versus narcotic anesthesia in patients with cardiac disease is still debated, although the cardiovascular effects of both techniques and the physiologic differences between them are well documented. However, most outcome studies have not demonstrated a difference between the techniques. Studies of more than 3,000 noncardiac surgical patients with CAD have concluded that anesthetic type does not affect outcome.

Inhalation anesthetics are thought to possess ischemic preconditioning properties. Most investigations of anesthetic ischemic preconditioning have been done in patients undergoing cardiac surgery, but maybe there are potential beneficial effects in the high-risk cardiac patients undergoing noncardiac surgery. However, none of the trials to date were powered to evaluate MI or death as an outcome. The AHA guidelines extrapolate that data and recommend that it can be beneficial to use volatile anesthetic agents during noncardiac surgery for the maintenance of general anesthesia in hemodynamically stable patients at risk for myocardial ischemia (class IIa).

The use of nitrous oxide in patients with history of CAD has been questioned since the early 1990s, when animal and human studies showed the increase in peripheral vascular resistance, diastolic dysfunction, and subsequently myocardial

ischemia. Batner et al. demonstrated the increase on homocysteine plasma levels of patients during carotid endarterectomy when nitrous oxide was administered and the correlation of those levels with increase incidence of myocardial ischemia. A large multicenter study is currently under way to better define the harmful effects of nitrous oxide.

The objectives during maintenance are not dissimilar to any other patient: amnesia, unconsciousness, and analgesia. These goals are constrained by the hemodynamic effect of each agent in order to provide heart rate control, coronary pressure perfusion, and effects on LV function. The preferred anesthetic technique will be a balanced anesthetic approach: opioids, with low/moderate doses of volatile anesthetics and benzodiazepines. If the plan is to extubate the trachea at the end of surgery a high-dose/longer-acting narcotics should be avoided.

Badner NH, Beattie WS, Freeman D, et al. Nitrous oxide-induced increased homocysteine concentrations are associated with increased postoperative myocardial ischemia in patients undergoing carotid endarterectomy. *Anesth Analg.* 2000;91(5):1073–1079.

C.10. What muscle relaxant would you choose? Why?

The hemodynamic goals are to avoid hypotension, tachycardia, and hypertension. Intermediate-acting neuromuscular blocking agents such as vecuronium, cisatracurium, and rocuronium can be used safely because they produce minimally significant cardiovascular changes. A peripheral nerve stimulator should be used to monitor the degree of blockade.

Fleming N. Con: the choice of muscle relaxants is not important in cardiac surgery. *J Cardiothorac Vasc Anesth.* 1995;9:772–774.

Hudson RJ, Thomson IR. Pro: the choice of muscle relaxants is important in cardiac surgery. *J Cardiothorac Vasc Anesth.* 1995;9:768–771.

C.11. You notice a new 3-mm ST-segment depression in lead V_5. How would you treat it?

ST-segment depression can be an indicator of myocardial ischemia. Initial efforts should be focused on determining its etiology. Management of ischemia should include pharmacologic manipulation of the determinants of myocardial oxygen supply and demand.

The crucial aspect of such management includes the following:

- Heart rate control and adequate coronary perfusion pressure. If ST depression is associated with tachycardia and hypertension, the most common cause during surgery is inadequate anesthesia. Therefore, adequate levels of anesthesia should be achieved first. Heart rate control can also be achieved by the use of β-blockers. Caution should be exerted in patients with known contraindications and hemody-

namic instability. Calcium channel blockers (verapamil) can be used if β-blockers are contraindicated. The calcium channel blockers are considered the drug of choice if coronary spasm is suspected.

- Avoidance of hypotension and use of vasopressors to sustain coronary perfusion pressure.
- The use of nitrates is advocated as long as it does not compromise coronary perfusion pressure. Nitrates decrease myocardial oxygen demand by decreasing preload, intracavitary pressure, and myocardial tension. In addition, NTG increases the ratio of endocardial to epicardial blood flow.
- Oxygen delivery should be increased by correcting anemia and increasing the fraction of inspired oxygen.
- Oxygen demand also could be reduced by correction of hypothermia and/or shivering, if present.
- Secondary therapies should consider the use, if feasible, of antiplatelet therapy such as aspirin. If necessary, even intraoperative use of heparin can be considered, as long as it is not surgically contraindicated.

Fleisher LA, Beckman JA, Brown KA, et al. 2009 ACCF/AHA focused update on perioperative beta blockade incorporated into the ACC/AHA 2007 guidelines on perioperative cardiovascular evaluation and care for noncardiac surgery: a report of the American College of Cardiology Foundation/American Heart Association Task Force on Practice Guidelines. *Circulation.* 2009;120:e169–276.

Priebe HJ. Perioperative myocardial infarction—aetiology and prevention. *Br J Anaesth.* 2005;95:3–19.

C.12. Would you give prophylactic intravenous NTG to prevent myocardial ischemia?

There are no randomized data that support the use of prophylactic intraoperative intravenous NTG in patients at high risk. NTG should be used only when ischemia is detected and the hemodynamic effects of other agents in use are considered.

Beattie WS. Evidence-based perioperative risk reduction. *Can J Anaesth.* 2005;52(suppl 1):R3.

Fleisher LA, Beckman JA, Brown KA, et al. 2009 ACCF/AHA focused update on perioperative beta blockade incorporated into the ACC/AHA 2007 guidelines on perioperative cardiovascular evaluation and care for noncardiac surgery: a report of the American College of Cardiology Foundation/American Heart Association Task Force on Practice Guidelines. *Circulation.* 2009;120:e169–e276.

C.13. What is the significance of tight control of the heart rate intraoperatively?

Numerous studies have shown that intraoperative tachycardia and the duration of tachycardia could cause myocardial ischemia. Therefore, control of heart rate intraoperatively could significantly reduce the risk of perioperative myocardial events. It is clear that heart rate should be maintained to less than 100 beats per minute, however, the optimal heart rate for all patients has not be determined. Some recommend maintaining the heart rate between 60 to 70 beats per minute in high-risk patients.

Slogoff et al. in the 1980s were able to correlate tachycardia with the occurrence of intraoperative myocardial ischemia.

Raby et al. demonstrated that by identifying the high-risk patients, whose preoperative Holter tracing showed signs of ischemia, and controlling the heart

rate 20% below the ischemia threshold or approximately 60 beats per minute with esmolol, during vascular surgeries could reduce the risk of perioperative myocardial ischemia.

Feringa et al. demonstrated that tight heart rate control instead of just the use of β-blockers reduced perioperative myocardial ischemia and improved long-term outcome in vascular surgery patients.

C.14. When would you extubate the trachea in this patient? What could you do to prevent hypertension and tachycardia during extubation and emergence?

At the end of surgery, assuming no intraoperative complications, the trachea would be extubated when the patient is fully awake, breathing adequately, and neuromuscular blockade is fully reversed. To prevent tachycardia and hypertension associated with extubation and emergence, low doses of medications such as 1 mg per kg of lidocaine or esmolol, or 0.015 to 0.03 mg per kg of nicardipine, or 0.1 mg per kg of labetalol, diltiazem, or verapamil before emergence in order to reduce sympathetic response of emergence and extubation can be administered.

D. Postoperative Management

D.1. What are the postoperative predictors of PCM?

In noncardiac surgical patient, the highest risk of cardiac morbidity is in the postoperative period. It is during this period where up to 67% of the ischemic events occur. This period is characterized by increase in heart rate, blood pressure, sympathetic discharge, and hypercoagulability. Heart rate commonly increases postoperatively by 25% to 50% over intraoperative values, and tachycardia occurs in 10% to 25% of patients. Postoperative myocardial ischemia occurs in 27% to 41% of high-risk patients. Most of these events (50% or higher) are silent (without angina). Postoperative MI is usually preceded by prolonged ST-segment depression. This change on ECG is easily missed if not continuously monitored because most of the changes will revert completely to baseline in almost all cases. In patients with high or intermediate clinical risk, who have known or suspected CAD and who are undergoing high- or intermediate-risk surgical procedures, the procurement of ECGs at baseline, immediately after the surgical procedure, and daily on the first 2 days after surgery appears to be the most cost-effective strategy. PMI may be associated with tachycardia and pain. Studies involving large numbers of patients suggest that postoperative ischemia is the most important marker of immediate and long-term adverse cardiovascular events. It is associated with a 2.8-fold increase in the odds of all adverse cardiac outcomes.

The highest incidence of troponins elevation, a biochemical marker of ischemia, frequently occurs 8 to 24 hours after the surgical procedure; even mild elevations are associated with postoperative cardiac ischemia and they could help to categorize the short- and long-term risk of the surgical patient as they are independent predictors of mortality. Postoperative MI has also been associated with other clinical conditions as postoperative hypothermia, hypercoagulability, postoperative pain, and anemia.

Priebe HJ. Perioperative myocardial infarction—aetiology and prevention. *Br J Anaesth.* 2005;95:3–19.

D.2. How would you control postoperative pain?

The postoperative period can be stressful due to the onset of pain during emergence from anesthesia, fluid shifts, temperature changes, and alteration of respiratory function. Marked changes occur in plasma catecholamine concentration, hemodynamics, ventricular function, and coagulation following noncardiac surgery, particularly in patients with pre-existing cardiac disease. These stressors place the patient at increased risk for development of adverse cardiac outcome. Effective pain management is essential to prevent adverse outcome. Intravenous patient-controlled analgesia and/or patient-controlled epidural analgesia are popular methods for reducing postoperative pain. Several studies suggest that effective pain management leads to a reduction in postoperative catecholamine surges and hypercoagulability. Norris et al. found that

using patient-controlled intravenous analgesia or patient-controlled epidural analgesia, the incidence of myocardial ischemia/infarction were comparable in patients undergoing abdominal aneurysm repair as long as the pain control and hemodynamics of the patients were similar.

Fleisher LA, Beckman JA, Brown KA, et al. 2009 ACCF/AHA focused update on perioperative beta blockade incorporated into the ACC/AHA 2007 guidelines on perioperative cardiovascular evaluation and care for noncardiac surgery: a report of the American College of Cardiology Foundation/American Heart Association Task Force on Practice Guidelines. *Circulation.* 2009;120:e169–e276.

D.3. Is postoperative anemia associated with adverse cardiac outcome?

Patients with IHD may be adversely affected by anemia. Based on existing literature, the evidence is sufficient to state that transfusions are rarely beneficial if the Hgb level exceeds 10 g per dL (Hct >30%) in the absence of acute blood loss. It is also reasonable to state that the patient may benefit from a transfusion if the Hgb level falls below 7 g per dL. The controversy remains between Hgb concentrations of 8.0 to 10.0 g per dL.

Adverse clinical consequences of acute, iatrogenic, postoperative anemia has been demonstrated. Nelson et al. have identified a Hct of 28% as being the threshold associated with increased incidence of morbid cardiac events in postoperative vascular surgical patients. Wu et al. also demonstrated the benefit of higher Hgb levels in patients with acute myocardial infarction (MI). However, the TRICC trial (Transfusion Requirement in Critical Care) was not able to demonstrate a significant difference in 30-day mortality between patients who were "liberally" transfused (average Hgb, 10.7 g per dL) versus the restrictive group (no transfusion unless Hgb <7 g per dL). Rao et al. published the data from the combination of three large randomized trial stating the risk of death is 3.9 times greater in patients who were transfused compared with those who did not. The controversy remains, however, when confronted with high-risk patients or those who demonstrate myocardial ischemia, we are more likely to transfuse packed cells to raise the Hct to 30%.

D.4. Is postoperative hypothermia associated with postoperative myocardial ischemia?

Hypothermia is common during anesthesia and surgery owing to anesthetic-induced inhibition of thermoregulatory control. The principal initial cause of hypothermia is core-to-peripheral redistribution of body heat.

Perioperative hypothermia is associated with numerous complications; it triples the incidence of adverse myocardial outcomes in high-risk patients, increases blood loss. Even mild hypothermia has been associated with an increased incidence of wound infection following colon resection. Also, it adversely affects oxygen availability in tissues, changes the kinetics and action of some anesthetic agents and muscle relaxants, and is associated with delayed postanesthetic recovery.

Core hypothermia may increase circulating catecholamines levels, leading to tachycardia, hypertension, systemic vasoconstriction, and an imbalance between oxygen demand and supply. Frank et al. studied 100 patients undergoing lower extremity vascular surgery. They found that unintentional hypothermia (sublingual temperature less than 35°C [95° F]) on arrival to postoperative intensive care unit (ICU) is associated with a significantly higher incidence of myocardial ischemia (36% vs. 13%), angina (18% vs. 15%), and Pao_2 less than 80 mm Hg (52% vs. 30%) during the early postoperative period. Therefore, aggressive warming and heat conservation are mandatory during and after surgery. It is recommended to continue forced-air warming for the first several hours after surgery in hypothermic patients.

D.5. How would you make a diagnosis of perioperative myocardial infarction (PMI)?

The definition of MI, according to the World Health Organization, is based on elevation of biomarkers, in conjunction with cardiac symptoms, ECG changes, or echocardiographic changes.

Most ischemic episodes occur after and not during the operation: This is probably because of the high postoperative stresses related to anesthesia and surgery. Several studies have examined the optimal method for diagnosing a PMI. Clinical symptoms (mostly asymptomatic), postoperative ECG changes (even analysis of serial basal ECGs is limited in its sensitivity to new PMI, because most infarctions are non–Q wave in nature), and elevation of the MB fraction of creatine kinase (CK-MB) have been most extensively studied. Cardiac-specific enzyme elevations such as troponin I (cTn I), troponin T (cTn T) are currently the standard of care for biochemical diagnosis of a PMI because they demonstrate sensitivity and tissue specificity superior to other available biomarkers.

In the purest physiologic sense, any detectable necrosis is an acute myocardial infarction; however, troponin elevation can be observed in many other conditions in which the heart is stressed. Even small elevations of specific markers of myocardial damage, such as cardiac troponins, should be acknowledged as indicative of myocardial injury. From a clinical perspective, there is clear evidence that any amount of detectable cardiac troponin release is associated with an increased risk of new adverse cardiac events.

The increased sensitivity of troponins to myocardial injury that is not normally sufficient to cause CK-MB elevation, chest pain, or electrocardiographic abnormalities has been shown. Landesberg et al. reported a good correlation between duration of ischemia and the rise in cardiac-specific troponin I and is an area of active research. Many investigators would agree that the increase in cardiac troponins postoperatively, even if no cardiovascular signs and symptoms are present, carries poor long-term outcome.

Clinicians need to be sensitive to redundancy in testing. Some authors have demonstrated that routine cardiac troponin monitoring is an easy, effective, and inexpensive way to detect postoperative myocardial injury. However, the ACC/AHA guidelines reserves the use of this biomarkers for patients at high risk and those with clinical, ECG, or hemodynamic evidence of cardiovascular dysfunction. At best, there is still lack of agreement regarding who should be tested. Routine measurement of postoperative troponins in asymptomatic or low-risk patients undergoing low risk procedure is not warranted.

D.6. How would you manage the patient with a suspected PMI?

There is lack of control-evidence regarding management of PMI in the postsurgical patient. PMI could include three different clinical scenarios/diagnosis: unstable angina (UA), non–ST-elevation myocardial infarction (NSTEMI), and ST-elevation myocardial infarction (STEMI).

The initial management should focus on the following diagnosis:

- Evaluation of chest pain if present.
- 12-Lead ECG and determination of changes, if present.
- Measurement of biomarkers of cardiac injury. A cardiac-specific troponin is the preferred marker.
- Immediate consultation of a cardiologist and risk stratification to determine high-risk patients.

It is important to consider the recent surgical procedure and consultation with the surgical team regarding impact of aspirin and antithrombin therapy.

Unless a contraindication exists, patients with an acute coronary syndrome of the type UA or NSTEMI should be treated with oxygen, aspirin (acetylene salicylic acid), sublingual/intravenous NTG for chest pain relief, as long as blood pressure is adequate, a β-blocker, antithrombin therapy (unfractionated heparin or low molecular weight heparin), and/or a GP IIb/IIIa inhibitor.

The cardiology consultant should guide further management:

- Option one is a routine angiographic approach, in which coronary angiography and revascularization are performed unless a contraindication exists. Within this approach, the most common strategy advocates for a period of medical stabilization. A more aggressive approach calls for coronary angiography and revascularization performed within 24 hours of the onset of symptoms or diagnosis; the rationale for the more aggressive approach is the protective effect of carefully administered antithrombin and antiplatelet therapy on reperfusion procedures outcome.
- The alternative approach, commonly referred to as the initially conservative strategy, is guided by ischemia, with angiography reserved for patients with recurrent ischemia or a "high-risk" stress test despite medical therapy.

Regardless of the angiographic strategy, an assessment of LV function (echocardiography, ventriculogram, or nuclear ventriculography) should be strongly considered because of the importance of treating patients who have impaired LV function with ACE inhibitors, β-blockers and, surgical revascularization (CABG) when appropriate (e.g., three-vessel disease).

If the patient presents with a STEMI, recognized on the basis of the 12-lead ECG, the management will be initially similar to UA/NSTEMI (oxygen, acetylene salicylic acid, NTG, β-blockers), then one should attempt to complete restoration of flow in the infarct artery by pharmacologic means (fibrinolysis: usually contraindicated after a surgical procedure due to the increased risk of bleeding), PCI (balloon angioplasty with or without deployment of an intracoronary stent under the support of pharmacologic measures to prevent thrombosis), or surgical measures (CABG).

Evidence supports expeditious restoration of flow in the obstructed infarct artery after the onset of symptoms in patients with STEMI as a key determinant of short- and long-term outcomes regardless of whether reperfusion is accomplished by fibrinolysis or PCI. Early reperfusion of ischemic myocardium within the risk region of an occluded infarct-related artery interrupts the occurring necrosis, reduces ultimate infarct size, preserves regional and global ventricular function, and improves survival. A subset of patients will have severe three-vessel or left main disease or anatomic features unfavorable for PCI and may be candidates for urgent or emergency CABG.

SECTION III

The Gastrointestinal System

CHAPTER 14

Intestinal Obstruction

Joseph Tjan

A 73-YEAR-OLD WOMAN

with an acute abdomen was scheduled to undergo an emergency exploratory laparotomy. She complained of severe abdominal pain with periodic bouts of bilious vomiting. Past surgical history included a right hemicolectomy for colon cancer. Blood pressure 85/60 mm Hg, pulse of 115 beats per minute, and hematocrit of 45%.

A. Medical Disease and Differential Diagnosis

1. What is the differential diagnosis of the acute abdomen?
2. What are the causes of intestinal obstruction of the small bowel and of the large bowel?
3. Differentiate between simple and strangulated bowel obstruction.
4. Is it important to differentiate whether the bowel obstruction is located in the small bowel or large bowel? Why?
5. What are the signs and symptoms of intestinal obstruction?
6. What are the causes and effects of bowel distention?
7. Describe the fluid shifts during small bowel intestinal obstruction.
8. Discuss the systemic derangements that occur with intestinal obstruction.
9. Can there be actual losses of red cell mass?
10. What is an ileus? Discuss its causes and treatment.
11. What are the systemic effects from the absorption of bacteria and bacterial products?

B. Preoperative Evaluation and Preparation

1. Is it important to decompress the abdomen before surgical intervention? Why?
2. Describe the respiratory implications.
3. What are the implications of the tense abdominal wall?
4. Outline the methods of abdominal decompression.
5. Discuss the goals of fluid management.
6. What would you use as a guide to fluid volume replacement?

C. Intraoperative Management

1. What dangers are present during induction? How are they planned for?
2. Does the administration of antacids and/or histamine-2 (H_2) blockers before the induction of anesthesia have a significant value in patients with small bowel obstruction?
3. In what position would you intubate this patient? Would you use Sellick maneuver?
4. Is succinylcholine the best muscle relaxant to use for the rapid-sequence induction?
5. Would you remove or leave the nasogastric tube (NGT) in place before inducing anesthesia?
6. Would you use nitrous oxide in this patient?
7. Are there any benefits to using a high concentration of inspired oxygen?

D. Postoperative Management

1. What are the principles of postoperative care in this patient?
2. Are there any postoperative respiratory problems associated with factors other than aspiration?
3. If the patient did aspirate gastric contents, what are the possible sequelae of this event? What is the treatment?
4. What is gram-negative sepsis? Describe the clinical picture and treatment.

A. Medical Disease and Differential Diagnosis

A.1. What is the differential diagnosis of the acute abdomen?

Intestinal obstruction accounts for approximately 15% to 20% of hospitalized patients with an acute abdomen. Abdominal pain can be divided into three categories: visceral, somatic, and referred. Visceral pain is transmitted through the autonomic nervous system through C fibers located intramurally in hollow viscera and in the capsule of abdominal organs. Visceral pain is dull, crampy, or aching in nature, and the factors that produce it include stretching and distention that result in increased wall tension, inflammation, ischemia, torsion, compression, and certain chemicals. Transmission of somatic pain occurs through A-δ fibers of spinal nerves to produce pain that is characteristically sharp, severe, and persistent. Somatic pain is caused by irritation of the parietal peritoneum and arises as a response to acute changes in pH or temperature, as seen with bacterial or chemical inflammation. Referred pain is that which is felt in a region of the body different from the point of its origin because of the sharing of common pathways for afferent neurons arising from different sites. A proper history and physical examination with early diagnosis is of utmost importance in the management of the patient with an acute abdomen. In a recent review of over 1,100 patients with abdominal pain who presented to the emergency room, the most common diagnosis overall was nonspecific abdominal pain. Appendicitis, intestinal obstruction, urologic disorders, and gallstones were the most common surgical causes in order of decreasing

frequency. In 47% of the patients, surgical intervention was required. The gastrointestinal and intraperitoneal causes of abdominal pain are listed in Table 14.1. There are many extraperitoneal causes of abdominal pain, and these include pulmonary, cardiac, neurologic, metabolic, toxic, infectious, vascular, and hematologic conditions.

Brunicardi FC, ed. *Schwartz's Principles of Surgery*. 9th ed. New York: McGraw-Hill; 2010: 980–1001.

Table 14.1 Gastrointestinal and Intraperitoneal Causes of Abdominal Pain

I. Inflammation/infection
- A. Peritoneum
  - 1. Chemical and nonbacterial peritonitis–perforated peptic ulcer, gallbladder, ruptured ovarian cyst, mittelschmerz
  - 2. Bacterial peritonitis
    - a. Primary peritonitis–pneumococcal, streptococcal tuberculous
    - b. Perforated hollow viscus–stomach, intestine, biliary tract
- B. Hollow intestinal organs
  - 1. Appendicitis
  - 2. Cholecystitis
  - 3. Peptic ulceration
  - 4. Gastroenteritis
  - 5. Regional enteritis
  - 6. Meckel's diverticulitis
  - 7. Colitis–ulcerative, bacterial, amebic
  - 8. Diverticulitis
- C. Solid viscera
  - 1. Pancreatitis
  - 2. Hepatitis
  - 3. Hepatic abscess
  - 4. Splenic abscess
- D. Mesentery
  - 1. Lymphadenitis
- E. Pelvic organs
  - 1. Pelvic inflammatory disease
  - 2. Tuboovarian abscess
  - 3. Endometritis

II. Mechanical (obstruction, acute distention)
- A. Hollow intestinal organs
  - 1. Intestinal obstruction–adhesions, hernia, tumor, volvulus, intussusception
  - 2. Biliary obstruction–calculi, tumor, choledochal cyst, hematobilia
- B. Solid viscera
  - 1. Acute splenomegaly
  - 2. Acute hepatomegaly–cardiac failure, Budd-Chiari syndrome
- C. Mesentery
  - 1. Omental torsion
- D. Pelvic organs
  - 1. Ovarian cyst
  - 2. Torsion or degeneration of fibroid
  - 3. Ectopic pregnancy

III. Vascular
- A. Intraperitoneal bleeding
  - 1. Ruptured liver
  - 2. Ruptured spleen
  - 3. Ruptured mesentery
  - 4. Ruptured ectopic pregnancy
  - 5. Ruptured aortic, splenic, or hepatic aneurysm
- B. Ischemia
  - 1. Mesenteric thrombosis
  - 2. Hepatic infarction–toxemia, purpura
  - 3. Splenic infarction
  - 4. Omental ischemia

IV. Miscellaneous
- A. Endometriosis

From Schwartz SI, Shires GT, Spencer FC, et al., eds. *Principles of Surgery.* 7th ed. New York: McGraw-Hill;1999:1036, with permission.

A.2. What are the causes of intestinal obstruction of the small bowel and of the large bowel?

Intestinal obstruction can be of extraluminal (e.g., adhesions, hernias, or carcinomatosis); intraluminal (e.g., gallstones or foreign bodies); or intramural (e.g., Crohn disease or tumors) origin. The term *mechanical bowel obstruction* denotes an actual physical barrier that interferes with the normal progression of intestinal contents. The most common cause of small bowel obstruction is postoperative adhesions, followed by incarcerated hernias and malignant tumors. Postoperative adhesions make up approximately 75% of cases of small bowel obstruction. Alternatively, neoplasms account for most large bowel obstruction. Other causes of large bowel obstruction include diverticulitis and volvulus.

Brunicardi FC, ed. *Schwartz's Principles of Surgery*. 9th ed. New York: McGraw-Hill; 2010:980–1001, 1015–1057.

A.3. Differentiate between simple and strangulated bowel obstruction.

Simple obstruction occurs when the lumen is obstructed and the blood supply remains normal. Occlusion of the blood supply to the obstructed bowel results in a strangulated obstruction. Toxic fluid is discharged into the bowel lumen, bowel wall, and peritoneal cavity when venous outflow obstruction occurs. It is important to recognize strangulation preoperatively because the implications are more serious and the mortality rate is high at between 8% and 25%. Conversely, the mortality rate for nonstrangulating bowel obstruction is under 5%. A closed-loop obstruction is present when both limbs of the loop are obstructed. This leads rapidly to strangulation, occasionally even before clinical evidence of intestinal obstruction appears.

Brunicardi FC, ed. *Schwartz's Principles of Surgery*. 9th ed. New York: McGraw-Hill; 2010:980–1001.

A.4. Is it important to differentiate whether the bowel obstruction is located in the small bowel or large bowel? Why?

Yes. Simple mechanical obstruction of the small bowel results in altered bowel motility, bowel distention with progressive accumulation of fluid and gas, and systemic derangements. If the obstruction is not relieved promptly, strangulation ensues, leading to bowel necrosis and the leakage of blood, fluid, and toxic substances into the bowel and peritoneal cavity. Approximately 60% to 80% of intestinal obstructions occur in the small bowel.

Although the signs and symptoms may be similar, large bowel obstruction is usually more insidious than small bowel obstruction. Except for a volvulus, large bowel obstruction has less of a propensity to strangulate. The colon is essentially a storage organ and has little secretory and absorptive functions. Therefore, systemic derangements are less severe with large bowel obstruction. The most important complication is progressive distention and rupture of the colon, especially in the presence of a competent ileocecal valve. The cecum is the usual site of rupture.

Brunicardi FC, ed. *Schwartz's Principles of Surgery*. 9th ed. New York: McGraw-Hill; 2010:980–1001, 1015–1057.

A.5. What are the signs and symptoms of intestinal obstruction?

The four cardinal signs and symptoms of intestinal obstruction are crampy abdominal pain, nausea and vomiting, obstipation, and abdominal distention. Intestinal activity initially increases in an effort to overcome the obstruction, leading to colicky pain and diarrhea. The colicky pain often is diffuse and alternates with quiescent periods. The duration of the quiescent period depends on the site of intestinal obstruction. With a high obstruction, the duration is approximately 4 to 5 minutes, and with lower ileal obstruction, the duration is 15 to 20 minutes. Steady, severe abdominal pain usually indicates strangulation.

Vomiting commonly occurs immediately after the onset of bowel obstruction, followed by a variable quiescent period before recurrence. Vomiting becomes more frequent and bilious the higher the level of obstruction, and, with the exception of a volvulus, it is uncommon in colonic obstruction. Abdominal distention is a late finding that may be absent in high small bowel obstruction that is associated with frequent bouts of emesis. Other signs of intestinal obstruction include localized tenderness, fever, tachycardia, and leukocytosis. White blood cell counts of 15,000 to 25,000 per μL is strongly suggestive of strangulation, but this is not a sensitive test because 40% of patients with strangulation have normal white blood cell counts. The presence of acidosis also will increase the likelihood of strangulation. With the development of dehydration, serum chemistries will change, hemoconcentration occurs, and urine output will diminish and become concentrated.

A partial bowel obstruction is more likely to be present if the patient is able to pass stool and/or gas 6 to 12 hours after the onset of symptoms.

The most important initial diagnostic procedures are plain x-ray films of the abdomen in the supine and upright positions with upright and lateral chest x-ray films. In intestinal obstruction, gas–fluid levels are seen on the radiographs. Although normal within the stomach and colon, intestinal gas is usually minimal and infrequent in the small bowel. Therefore, gas–fluid levels are indicative of obstruction but also may be seen in gastroenteritis, severe constipation, sprue, and severe aerophagia. The radiologic findings and those features that differentiate simple mechanical obstruction from an ileus are summarized in Table 14.2.

Brunicardi FC, ed. *Schwartz's Principles of Surgery*. 9th ed. New York: McGraw-Hill; 2010:980–1001.

Table 14.2 Radiologic Signs in Intestinal Obstruction

SIGN	SIMPLE MECHANICAL OBSTRUCTION	ADYNAMIC ILEUS
Gas in intestine	Large bow-shaped loops in ladder pattern	Copious gas diffusely through intestine
Gas in colon	Less than normal	Increased, scattered through colon
Fluid levels in intestine	Definite	Often very large throughout
Tumor	None	None
Peritoneal exudate	None	Present with peritonitis; otherwise absent
Diaphragm	Somewhat elevated; free motion	Elevated: diminished motion

From Schwartz SI, Shires GT, Spencer FC, et al., eds. *Principles of Surgery*. 7th ed. New York: McGraw-Hill;1999:1061, with permission.

A.6. What are the causes and effects of bowel distention?

Intestinal obstruction results in the sequestration of fluid and gas within the bowel lumen proximal to the site of obstruction. Accumulation of fluid accounts for most of the bowel distention. As intraluminal pressure increases, the secretory function of the bowel increases progressively. Prostaglandin release seems to mediate this hypersecretion of fluid. In addition, reabsorption is impaired once intraluminal pressure exceeds 20 cm H_2O. The basic composition of the intestinal gas is that of swallowed air. As bowel distention continues from the ongoing gas and fluid accumulation, intraluminal and intramural pressures rise. The increased intramural pressures lead to progressive interference with the mesenteric blood supply, resulting in a strangulated obstruction with its associated morbidity and mortality.

Brunicardi FC, ed. *Schwartz's Principles of Surgery*. 9th ed. New York: McGraw-Hill; 2010:980–1001.

A.7. Describe the fluid shifts during small bowel intestinal obstruction.

Normally, approximately 7 to 9 L of fluid are secreted daily into the upper gastrointestinal tract. The secretions include saliva (500 to 2,000 mL); gastric juice (1,000 to 2,000 mL);, bile (300 to 600 mL); pancreatic juice (300 to 800 mL); and succus entericus (2,000 to 4,000 mL) (Table 14.3). Because of small intestinal reabsorption, only 400 mL passes the ileocecal valve.

In small bowel obstruction, several mechanisms contribute to fluid and electrolyte loss. The most important is the accumulation of fluid in the bowel lumen because the obstructed bowel becomes overly secretory instead of absorptive. Sequestration of fluid within the bowel wall accounts for the edematous appearance of the bowel. This, in turn, results in free peritoneal fluid because of transudation of fluid across the serosal surface of the bowel. Fluid accumulation above the obstruction can be remarkable. In early small bowel obstruction, 1,500 mL of fluid accumulates in the bowel. Once intestinal obstruction is well established and vomiting occurs, 3,000 mL of fluid may be present. When the patient exhibits hypotension and tachycardia, indicating circulatory instability, as much as 6,000 mL of fluid is in the abdomen. Lastly, vomiting and/or nasogastric suctioning further increase fluid losses.

Table 14.3 Volume and Composition of Gastrointestinal Fluids

	24-HOUR VOLUME (mL)	NA^+ (mEq/L)	K^+ (mEq/L)	CL^- (mEq/L)	HCO_3^- (mEq/L)
Saliva	500–2,000	2–10	20–30	8–18	30
Stomach	1,000–2,000	60–100	10–20	100–130	0
Pancreas	300–800	135–145	5–10	70–90	95–120
Bile	300–600	135–145	5–10	90–130	30–40
Jejunum	2,000–4,000	120–140	5–10	90–140	30–40
Ileum	1,000–2,000	80–150	2–8	45–140	30
Colon	—	60	30	40	—

From Miller RD, ed. *Miller's Anesthesia*. 6th ed. New York: Churchill Livingstone;2005:1788, with permission.

Brunicardi FC, ed. *Schwartz's Principles of Surgery*. 9th ed. New York: McGraw-Hill; 2010: 980–1001.

Miller RD, ed. *Miller's Anesthesia*. 7th ed. Philadelphia: Churchill Livingstone; 2010: 1723–1735.

A.8. Discuss the systemic derangements that occur with intestinal obstruction.

The systemic derangements that occur can be categorized as follows: hemodynamic changes, electrolyte abnormalities, and disturbances in acid–base balance.

Hemodynamically, if fluid and electrolyte losses are not corrected, central venous pressure will fall. Hypotension and tachycardia will follow as the vascular volume decreases in relation to the size of the vascular bed. The shock state develops as the body calls forth sympathomimetic amines to increase cardiac output and decrease the size of the vascular bed.

Small bowel obstruction results in the loss of vast quantities of isotonic extracellular fluid. The extent of extracellular fluid loss may be monitored by serial hematocrit determinations. A rise in the hematocrit is proportionate to the amount of fluid loss. For example, if the hematocrit has risen to 55%, approximately 40% of plasma and extracellular fluid volume has been lost.

As the obstruction continues, there is a gradual decrease in the plasma sodium and chloride concentrations. Hyponatremia will aggravate hypovolemic hypotension, and confusion and somnolence will ensue. Hypokalemia will be manifested in delayed ventricular conduction, ST-T segment changes, and ventricular arrhythmias. With respect to acid–base balance, the most common occurrence is metabolic acidosis because of the effects of dehydration, starvation, ketosis, and loss of alkaline secretions. Metabolic alkalosis is rare and is the result of marked loss of acidic gastric fluid. Monitoring includes serial determinations of sodium, potassium, chloride, and carbon dioxide.

Brunicardi FC, ed. *Schwartz's Principles of Surgery*. 9th ed. New York: McGraw-Hill; 2010:980–1001.

Miller RD, ed. *Miller's Anesthesia*. 7th ed. New York: Churchill Livingstone; 2010:1723–1735.

A.9. Can there be actual losses of red cell mass?

Yes. In long-standing intestinal obstruction, especially when it is associated with strangulation, increased permeability of the bowel wall occurs with loss of red cells into the bowel and peritoneal cavity. Whole blood or packed cells may be needed to restore circulating red blood cells.

Brunicardi FC, ed. *Schwartz's Principles of Surgery*. 9th ed. New York: McGraw-Hill; 2010:980–1001.

A.10. What is an ileus? Discuss its causes and treatment.

An ileus is a functional failure of normal aboral intestinal transit. Except for the discomfort of abdominal distention, it is usually not painful. The pathogenesis of ileus is poorly understood, but stimulation of the inhibitory adrenergic neurons may play an important role. Classification of ileus is as follows:

- *Adynamic or inhibition ileus*—diminished or absent motility from neuromuscular inhibition

- *Spastic ileus*—contracted bowel musculature with resultant uncoordinated motility
- *Ileus of vascular occlusion*—disordered motility secondary to ischemia

Adynamic ileus is the most common form because it is present following every intra-abdominal operation. Postoperative ileus affects different parts of the gastrointestinal tract differently. Small bowel function recovers within 24 hours, whereas gastric motility may take 24 to 48 hours to return. The colon is the most severely affected, where an ileus may persist for as long as 3 to 5 days.

If postoperative ileus is prolonged, other contributing causes should be sought that include:

- *Metabolic*—hypokalemia, hyponatremia, hypomagnesemia
- *Drugs*—narcotics, antacids, anticoagulants, phenothiazines, ganglionic blockers
- *Other*—intraperitoneal inflammation (e.g., acute appendicitis or acute pancreatitis), sepsis, hematoma, wound infection, ureteral colic, spine or rib fractures, basal pneumonia

Spastic ileus is rare and occurs with heavy metal poisoning, porphyria, and uremia. Management of ileus involves treatment of the underlying cause, nasogastric decompression, intravenous hydration, correction of metabolic abnormalities, and nutritional support if needed. No specific drug therapy has been shown to be effective.

Brunicardi FC, ed. *Schwartz's Principles of Surgery*. 9th ed. New York: McGraw-Hill; 2010:980–1001.

A.11. What are the systemic effects from the absorption of bacteria and bacterial products?

The normal mucosa is impermeable to bacteria and toxins produced by bacterial degradation, but permeability is affected when there is impairment of the blood supply in a strangulated segment of bowel. Intestinal obstruction also can lead to a change in the bacterial flora within the bowel. Subsequent transperitoneal absorption of bacteria and toxins can result in bacteremia and septic shock.

Brunicardi FC, ed. *Schwartz's Principles of Surgery*. 9th ed. New York: McGraw-Hill; 2010:980–1001.

B. Preoperative Evaluation and Preparation

B.1. Is it important to decompress the abdomen before surgical intervention? Why?

Yes, because of the respiratory and circulatory complications that ensue.

Brunicardi FC, ed. *Schwartz's Principles of Surgery*. 9th ed. New York: McGraw-Hill; 2010:980–1001.

B.2. Describe the respiratory implications.

The distended bowel produces pressure on the diaphragm, limiting its downward movement, and resulting in inadequate ventilation and an increased work of breathing in a patient who already may be malnourished. The decrease in tidal volume and the

reduction in functional residual capacity (FRC) result in a low Pao_2 and an elevated $Paco_2$. It is especially true if the stomach also is distended. An additional reason for gastric decompression is to remove fluid and air from the stomach to lessen the likelihood of aspiration of gastric contents into the tracheobronchial tree during the induction of anesthesia. A long-standing obstruction and its associated respiratory compromise will result in a gasping, dusky, cyanotic, semicomatose patient.

Brunicardi FC, ed. *Schwartz's Principles of Surgery*. 9th ed. New York: McGraw-Hill; 2010:980–1001.

B.3. What are the implications of the tense abdominal wall?

The first is related to the higher incidence of reverse peristalsis. Second, the stretched abdominal wall requires deeper anesthesia and more muscle relaxant to provide adequate operating conditions. These implications may increase morbidity. The distended abdomen significantly affects venous return by two mechanisms. First, distention decreases negative intrathoracic pressure and thereby decreases venous return. The second is due to direct vena caval compression from intraperitoneal tension. In long-standing intestinal obstruction, a large volume of intraperitoneal fluid may be present in the abdominal cavity. At the time of surgical incision, care must be taken to prevent the fluid from escaping rapidly from the abdomen to minimize severe hypotension. As fluid is slowly released from the abdominal cavity, the blood pressure should be checked frequently and the rate of fluid release adjusted to minimize a fall in blood pressure.

Brunicardi FC, ed. *Schwartz's Principles of Surgery*. 9th ed. New York: McGraw-Hill; 2010:980–1001.

B.4. Outline the methods of abdominal decompression.

There are two types of tubes available for abdominal decompression: short tubes placed in the stomach and long tubes placed in the small intestine. To reduce the likelihood of regurgitation of gastric contents, it is important that the stomach be empty before induction of anesthesia. This is best done by the sump tube, which is more efficient than the simple Levin tube. The sump tube is composed of a double lumen, one for aspiration and the other to allow air into the stomach. The Miller-Abbott tube is a long intestinal tube that is initially passed into the stomach, and an incorporated balloon containing mercury at its tip aids in its passage through the pylorus into the small bowel.

Although gastric and intestinal tubes are employed to relieve abdominal distention, they do not function solely as definitive therapy for bowel obstruction except in postoperative ileus, partial small bowel obstruction, and intestinal obstruction resulting from inflammation that is expected to subside with conservative therapy. For all other bowel obstructions, the mainstay of therapy remains surgical intervention.

Brunicardi FC, ed. *Schwartz's Principles of Surgery*. 9th ed. New York: McGraw-Hill; 2010:980–1001.

B.5. Discuss the goals of fluid management.

Estimating the degree of fluid deficit in intestinal obstruction is extremely difficult and often underestimated. There is significant sequestration of fluid within the bowel

lumen, bowel wall, and transudation into the peritoneal cavity. Poor preoperative nutrition and protein loss into the bowel may lead to hypoalbuminemia and further fluid losses. The primary goal of fluid management is the initial restoration of intravascular volume to a state of normovolemia. This will lead to the optimization of oxygen delivery to the tissues and organs. The second goal is the correction of electrolyte disturbances, including acid–base derangements, which may exist. Because the fluid lost to an obstructed segment of bowel is similar to plasma in composition, a balanced salt solution such as lactated Ringer's solution is appropriate to use for fluid resuscitation.

Brunicardi FC, ed. *Schwartz's Principles of Surgery*. 9th ed. New York: McGraw-Hill; 2010:980–1001.

Miller RD, ed. *Miller's Anesthesia*. 7th ed. New York: Churchill Livingstone; 2010:1723–1735.

B.6. What would you use as a guide to fluid volume replacement?

Fluid losses can be calculated knowing that the body turns over 17 to 18 L of fluid a day, made up of intestinal secretions, urine excreted by the kidneys, fluid loss through the feces, and insensible losses from the lungs and skin. As mentioned previously, there is tremendous fluid loss into the gut, which may amount to 4,500 to 9,000 mL of functional fluid loss, including loss resulting from vomiting and nasogastric suctioning. If there is significant bowel wall edema and leakage of fluid into the peritoneal cavity because of peritonitis, an additional 7 L of fluid may be sequestered in the peritoneal space. Measurement of central venous pressure, hourly urine output, arterial blood pressure, heart rate, and skin turgor can be used to guide fluid replacement. In addition, there must be ongoing modifications in the management of fluid and electrolytes to achieve the desired physiologic goals.

Brunicardi FC, ed. *Schwartz's Principles of Surgery*. 9th ed. New York: McGraw-Hill; 2010:980–1001.

Miller RD, ed. *Miller's Anesthesia*. 7th ed. New York: Churchill Livingstone; 2010:1723–1735.

C. Intraoperative Management

C.1. What dangers are present during induction? How are they planned for?

Regurgitation of stomach contents and subsequent aspiration into the tracheobronchial tree is the principal danger during induction of anesthesia for the patient with intestinal obstruction.

Mortality associated with aspiration of gastric contents ranges widely from 3% to 70%. Abdominal surgery in particular has been associated with up to 75% of the perioperative mortality resulting from aspiration pneumonitis. The incidence of aspiration for all anesthetics is almost 5 per 10,000 anesthetics. A rapid sequence induction intubation (RSI) has been traditionally recommended. An awake intubation might be preferred if a difficult intubation is anticipated.

For awake intubation, the patient's lips, tongue, and pharynx should be sprayed with a topical anesthetic. Care must be taken to avoid anesthetizing the larynx because the defense mechanism for laryngeal closure will be lost in the event that regurgitation or vomiting should occur. Therefore, a superior laryngeal nerve block or a transtracheal injection is not warranted in these patients. Sedation should be limited or avoided altogether.

RSI assumes the completion of tracheal intubation with a cuffed endotracheal tube to occur in the shortest possible time from the period of loss of consciousness. Intuitively, this should decrease the risk of aspiration. Scientific evidence fails to support it. A meta-analysis of 184 clinical trials failed to show a decrease in pulmonary aspiration of gastric contents following RSI. According to Sellick, cricoid pressure if applied, should not be released until the cuff is inflated and correct placement of the endotracheal tube has been verified by measures including auscultation and capnometry. There is growing controversy on usefulness of cricoid pressure itself. Cricoid pressure is associated with an increased rate of failed intubation. Radiologic studies have shown that the esophagus is displaced laterally rather than occluded in over 50% of cases and reflex relaxation of the lower esophageal sphincter (LES) in response to cricoid pressure may provoke regurgitation. Observational studies have shown that cricoid pressure is frequently applied incorrectly and it is difficult to clinically teach application of 40 N of pressure. Should the patient remain hemodynamically unstable following fluid and electrolyte resuscitation, ketamine or etomidate is preferable for induction of anesthesia.

Smith KJ, Dobranowski J, Yip G, et al. Cricoid pressure displaces the esophagus; An observational study using magnetic resonance imaging. *Anesthesiology.* 2003;99:60–64.

C.2. Does the administration of antacids and/or histamine-2 (H_2) blockers before the induction of anesthesia have a significant value in patients with small bowel obstruction?

The volume and pH of gastric contents and the presence or absence of particulate matter appear to be the three most important factors for determining the degree of pulmonary injury following aspiration. The classical term *at risk* is thought to imply a gastric volume greater than 25 mL with a pH less than 2.5. Approximately 40% of emergency surgical patients have a gastric pH below 2.5. The more critical factor involved in determining the degree of lung injury appears to be the pH of gastric contents. Therefore, outcomes are better with aspirations of large volumes of nonacidic material compared with that of small volumes of acidic material. Normally, clear, nonparticulate antacids (0.3 M sodium citrate) are effective in raising gastric pH and, likewise, H_2 blocking agents are effective in reducing gastric volume and acidity. However, because of the large volumes of fluid sequestered in the bowel, antacids and/or H_2 blockers have little or no value in high mechanical intestinal obstruction. When there is time to prepare the patient, these agents may be of some value in partial small bowel obstruction to reduce both gastric volume and acidity.

Miller RD, ed. *Miller's Anesthesia.* 7th ed. New York: Churchill Livingstone; 2010:1605–1606.

C.3. In what position would you intubate this patient? Would you use Sellick maneuver?

Because gravity will aid in keeping gastrointestinal contents within the stomach, the head-up position is likely to decrease the incidence of regurgitation and thereby lessen the risk of pulmonary aspiration. Some clinicians advise that the patient be intubated in the supine position for fear that if the patient did vomit and was in the sitting or semisitting position, there would be a greater tendency to aspirate. However, we believe the head-up position is preferable. Should massive reverse peristalsis and regurgitation occur, vigorous suctioning and the head-down position are the best methods of preventing soilage of the tracheobronchial tree. The head-down position must be at least 10 degrees to prevent aspiration into the lungs.

Miller RD, ed. *Miller's Anesthesia*. 7th ed. New York: Churchill Livingstone; 2010:1605–1606.

C.4. Is succinylcholine the best muscle relaxant to use for the rapid-sequence induction?

Succinylcholine is still the only ultrarapid onset/ultrashort duration muscle relaxant for use in the rapid-sequence induction technique despite the known complications associated with the use of this drug. Several studies have appeared advocating the use of large doses of nondepolarizing muscle relaxants for rapid-sequence induction of anesthesia using the priming principle. The technique recommends the use of a small dose of a nondepolarizing muscle relaxant (usually about 20% of the ED95), followed 2 to 4 minutes later by a second intubating dose. These authors claim that patients can be intubated significantly earlier, by approximately 30 to 60 seconds, than if they are given a single intubating dose of a nondepolarizing muscle relaxant. With use of the priming principle, tracheal intubation can be achieved approximately 90 seconds following the second intubating dose of muscle relaxant. However, some argue that 90 seconds is not fast enough for a rapid-sequence induction technique, and furthermore, intubating conditions at 90 seconds may not be as ideal as that achieved at 60 seconds following succinylcholine administration. In addition, one should keep in mind that large doses of nondepolarizing muscle relaxants will result in a longer duration of neuromuscular blockade and may increase the potential for side effects. Another consideration of the priming technique that is especially relevant to the bowel-obstructed patient is the risk of aspiration due to the variable degree of neuromuscular blockade produced by the priming dose. See Table 14.4 for the priming dose and intubating dose of various muscle relaxants.

Miller RD, ed. *Miller's Anesthesia*. 7th ed. New York: Churchill Livingstone; 2010:862–884.

C.5. Would you remove or leave the nasogastric tube (NGT) in place before inducing anesthesia?

The decision whether to remove or leave the NGT in place before induction of general anesthesia is somewhat controversial. The case for leaving the NGT in is that it allows gastric decompression, reduces intragastric pressure, and thereby reduces the chances of regurgitation. However, the presence of NGT during induction does not reliably ensure an empty stomach but renders the LES incompetent by preventing complete closure of the LES. The LES usually is 2 to 3 cm long and functions as the major impediment to reflux of gastric contents into the esophagus. An incompetent LES will increase the likelihood of regurgitation and aspiration of gastric contents into the tra-

Table 14.4 Rapid Tracheal Intubation[a] with Succinylcholine or Nondepolarizing Relaxants[b]

DRUG	PRIMING DOSE[c] (mg/kg)	INTUBATING DOSE[d] (mg/kg)	CLINICAL DURATION[e]	FULL RECOVERY[f]

Barash PG, Cullen BF, Stoelting RK, eds. *Clinical Anesthesia.* 6th ed. Philadelphia: Lippincott Williams & Wilkins; 2009:1221–1224.

C.6. Would you use nitrous oxide in this patient?

Nitrous oxide should be avoided because its administration is associated with an undesirable increase in intraluminal gas volume and pressure that may lead to detrimental consequences. The blood-to-gas partition coefficient of nitrous oxide is 34 times that of nitrogen. Therefore, nitrous oxide in the blood can enter gas-filled cavities 34 times more rapidly than nitrogen can leave those cavities to enter the blood. When this happens during abdominal surgery, bowel distention will occur. The amount of distention will depend on the amount of gas already within the bowel and the duration of nitrous oxide administration. Normally, the bowel contains approximately 100 mL of gas that is mostly swallowed air, and nitrous oxide use results in a slow increase in bowel distention and intraluminal pressure. However, with bowel obstruction, the volume of gas within the bowel is greatly increased. Under these conditions, the increased intraluminal pressure associated with nitrous oxide administration may lead to bowel ischemia and necrosis. More commonly, it will cause difficulties with abdominal closure at the conclusion of surgery. Therefore, anesthesia should be maintained with oxygen, air and a volatile agent, and increments of opioids and muscle relaxants as needed.

Barash PG, Cullen BF, Stoelting RK, eds. *Clinical Anesthesia*. 6th ed. Philadelphia: Lippincott Williams & Wilkins; 2009:1226–1227.

C.7. Are there any benefits to using a high concentration of inspired oxygen?

It has been suggested that administration of a high concentration of inspired oxygen may lead to a reduction in the incidence of surgical wound infections. Wound infections are serious complications of surgery that can prolong hospitalization, thereby increasing morbidity and medical costs. The factors that may play a role in producing surgical wound infections include the site and complexity of surgery, the tissue oxygen tension, the presence of any underlying illness, prophylactic antibiotic use, the intravascular volume status, the patient's body temperature, and postoperative pain control. Compared with the administration of 30% inspired oxygen, those patients receiving 80% inspired oxygen had approximately half the number of postoperative surgical wound infections in one study, however others have failed to reproduce these results. Timely use of prophylactic antibiotics and maintainence of normothermia in the perioperative period probably are more effective in decreasing surgical site infections.

Greif R, Akca O, Horn EP, et al. Supplemental perioperative oxygen to reduce the incidence of surgical wound infection. *N Engl J Med*. 2000;342:161–167.

D. Postoperative Management

D.1. What are the principles of postoperative care in this patient?

The principles of postoperative management are the same as those in the preoperative care of the patient, namely fluids and electrolytes, antibiotics, and gastrointestinal decompression. In the immediate postoperative period, there continues to be significant ongoing fluid loss, mostly secondary to "third spacing." However, this fluid loss gradually diminishes over time and usually by about the third postoperative day reverses in direction as fluid is transferred back into the vascular compartment. The significant autoinfusion that ensues must, therefore, be accounted for in the computations of the daily fluid requirements of the patient. Otherwise, congestive failure may follow, especially because patients with intestinal obstruction are often older adults with limited reserves in several organ systems. As electrolyte loss continues postoperatively, serial determinations of serum sodium and potassium levels may be necessary. Hyponatremia and hypokalemia are factors that contribute to prolonged postoperative ileus. Because return of normal intestinal motility usually is prolonged after surgical relief of bowel obstruction, abdominal decompression often must be continued for 5 or 6 days postoperatively, whereas bowel function returns on about the third postoperative day after a routine abdominal operation. Finally, postoperative management also may include frequent monitoring of hemodynamic parameters, hemoglobin concentration, and urine output.

Brunicardi FC, ed. *Schwartz's Principles of Surgery*. 9th ed. New York: McGraw-Hill; 2010:980–1001.

Miller RD, ed. *Miller's Anesthesia*. 7th ed. New York: Churchill Livingstone; 2010:2783–2802.

D.2. Are there any postoperative respiratory problems associated with factors other than aspiration?

The postoperative respiratory problems are those related to hypoventilation. Although the intestinal obstruction has been relieved, there still may be significant abdominal distention that will inhibit diaphragmatic motion, and the patient may develop hypoxia and hypercarbia. In addition, abdominal pain and the residual effects of inhaled anesthetics, intravenous anesthetics, and neuromuscular blockers may contribute to respiratory inadequacy. The 15% to 20% reduction in FRC associated with general anesthesia continues into the postoperative period and following upper abdominal surgery; vital capacity remains abnormal for more than a week. In summary, several pulmonary changes occur, including reductions in the following parameters: tidal volume, vital capacity, FRC, residual volume, and forced expiratory volume in 1 second (FEV_1). For these reasons, the endotracheal tube may be left in place to decrease anatomic dead space and make it possible to ventilate the patient during the immediate postanesthesia period. Leaving the endotracheal tube in place also is desirable for those patients with previous respiratory disease or in the morbidly obese individual. In both of these situations, the respiratory support will decrease residual atelectasis in the basilar portions of the lung. This will decrease any pulmonary shunt and lessen the need for a high inspired oxygen concentration (FIO_2). For those patients not requiring ventilatory support, a T-piece attached to the endotracheal tube will increase the FIO_2 to maintain the PaO_2 at an acceptable level. As the patient gradually regains respiratory adequacy (as shown by measuring inspiratory force and vital capacity), ventilation returns to normal and the patient can be safely extubated.

Miller RD, ed. *Miller's Anesthesia*. 7th ed. New York: Churchill Livingstone, 2010:2879–2897.

D.3. If the patient did aspirate gastric contents, what are the possible sequelae of this event? What is the treatment?

Aspiration of gastric contents produces a chemical pneumonitis characterized initially by hypoxemia, bronchospasm, and atelectasis. In addition, the patient may exhibit signs of tachypnea, tachycardia, coughing, cyanosis, and shock. Arterial hypoxemia is the earliest and most reliable sign of aspiration. Even saline, when aspirated, causes significant hypoxemia.

Destruction of pneumocytes, lung parenchyma, and pulmonary microvasculature ensues, resulting in decreased surfactant activity, interstitial and alveolar edema, alveolar hemorrhage, and pulmonary hypertension (which results from hypoxic pulmonary vasoconstriction). The clinical picture may resemble that of adult respiratory distress syndrome. Radiographic findings are variable and may not appear for several hours. In at least 10% of cases, the radiographic films are normal. Positive findings usually consist of diffuse infiltrates bilaterally located in either the perihilar or basal regions.

Once vomiting or regurgitation occurs, immediate lateral head positioning, vigorous suctioning, and the head-down position should be instituted. To avoid disseminating the aspirated material further distally, the trachea is suctioned before beginning positive pressure ventilation. Bronchoscopy is indicated only for those patients who have aspirated solid material resulting in significant airway obstruction. Use of bronchial irrigation with saline or sodium bicarbonate solution is of little value and may actually be more detrimental than beneficial. Management includes keeping the patient intubated and well ventilated, following arterial blood gases, and obtaining serial chest x-ray films. Depending on the arterial blood gases, regulation of the inspired oxygen concentration and the amount of ventilation to maintain PaO_2 and

$Paco_2$ within normal limits will be necessary. If the fraction of inspired oxygen (Fio_2) has to be maintained above 60%, the use of positive end-expiratory pressure may be necessary to recruit additional alveoli and improve oxygenation. The best positive end-expiratory pressure will have the least effect on venous return and at the same time allow Fio_2 to be reduced to a safe level (40% or lower), thereby decreasing the likelihood of oxygen toxicity. It is important to realize that, although a patient may look well and have a clear chest without rhonchi or wheezes in the immediate postanesthetic period following aspiration, respiratory distress still may develop. It may take as long as 6 to 12 hours before the syndrome becomes manifest. The patient should be observed closely over 24 to 48 hours for the development of aspiration pneumonitis. Corticosteroid therapy remains controversial and the routine use of prophylactic antibiotics is not recommended because it may alter the normal flora of the respiratory tract and promote colonization by resistant organisms. However, antibiotics should be administered to those patients who show clinical signs of a secondary bacterial pulmonary infection with positive Gram stain and cultures or to those patients known to have aspirated gross fecal material, as with lower intestinal obstruction.

Barash PG, Cullen BF, Stoelting RK, eds. *Clinical Anesthesia*. 6th ed. Philadelphia: Lippincott Williams & Wilkins; 2009:1433–1434.

D.4. What is gram-negative sepsis? Describe the clinical picture and treatment.

Gram-negative sepsis frequently leads to a shock state caused by endotoxins from the cell walls of gram-negative bacteria circulating in the blood. The earliest signs of a gram-negative infection include an elevated temperature above 101° F (38.33° C), the development of shaking chills, mild hyperventilation, respiratory alkalosis, and an altered sensorium. The hemodynamic abnormalities of gram-negative sepsis are not understood clearly but seem to follow two distinct hemodynamic patterns, depending on the patient's volume status.

The first is a hyperdynamic circulatory pattern associated with early septic shock that occurs in patients who are normovolemic before the onset of sepsis. These patients present with hypotension, high cardiac output, normal or increased blood volume, normal or high central venous pressure, decreased peripheral resistance, warm and dry extremities, hyperventilation, and respiratory alkalosis. However, in a patient who is hypovolemic before the onset of sepsis as with a strangulated obstruction of the small bowel, a hypodynamic pattern is seen characterized by hypotension; low cardiac output; high peripheral resistance; low central venous pressure; and cold, clammy extremities. Both types of patterns will have a better outcome if early treatment is begun, but if therapy is delayed or unsuccessful, cardiac and circulatory failure ensues associated with a low, fixed cardiac output and a resistant metabolic acidosis.

Definitive therapy of gram-negative sepsis includes the administration of appropriate antibiotics and early surgical debridement or drainage of the source of infection when indicated. Supportive measures are provided by fluid replacement and the use of vasoactive drugs. Corticosteroid administration as part of the treatment regimen for sepsis is still a controversial issue. Direct arterial blood pressure monitoring and insertion of a pulmonary artery catheter may be necessary for proper management.

CHAPTER 15

Liver Transplantation

VIVEK K. MOITRA

A 66-YEAR-OLD WOMAN

with a history of alcoholic cirrhosis and portal hypertension is admitted to the intensive care unit with altered mental status and low urine output. She has ascites and encephalopathy. Her kidney injury is acute with a creatinine clearance of 30 mL per minute. Her international normalized ratio (INR) is 3.0. Her hemoglobin level is 10.2 g per dL. She has a model for end-stage liver disease (MELD) score of 28 points. Her respiratory rate is 30 breaths per minute. She is scheduled for orthotopic liver transplantation.

A. Medical Disease and Differential Diagnosis

1. What are the potential graft options for liver transplantation?
2. What are the indications and contraindications for liver transplantation?
3. What is acute liver failure (ALF)?
4. What is the MELD score and how is it used in liver transplantation evaluation?
5. Describe the cardiovascular system of patients with end-stage liver disease (ESLD).
6. What causes acute kidney injury (AKI) in patients with cirrhosis?
7. What causes hyponatremia in patients with cirrhosis?
8. Discuss the neurologic manifestations of acute and chronic liver disease.
9. Why do patients with ESLD have abnormalities of hemostasis?
10. What is the differential diagnosis for hypoxemia in patients with cirrhosis?
11. What is portal hypertension? What are the sequelae of portal hypertension?

B. Preoperative Evaluation and Preparation

1. What preoperative workup is desirable?
2. How is ascites managed preoperatively?
3. How is hyponatremia managed preoperatively?
4. What is a transjugular intrahepatic portosystemic shunt (TIPS) procedure? What is the role of TIPS in the management of patients with ESLD?

5. How are hepatic encephalopathy and elevated intracranial pressure (ICP) treated?
6. Should this patient be transfused with fresh frozen plasma prior to surgery?

C. Intraoperative Management

1. What monitors would you use? Why?
2. What are the considerations for the induction of anesthesia?
3. How does liver disease affect intraoperative medication management?
4. What happens during the first stage (preanhepatic phase) of the liver transplant operation?
5. What happens during the second stage (anhepatic phase) of the liver transplant operation?
6. What physiologic disturbances should be anticipated during the second stage (anhepatic phase) of the liver transplant operation?
7. What is venovenous bypass? What are potential advantages and disadvantages of this procedure?
8. What surgical techniques are used to anastomose the donor and recipient inferior vena cava?
9. What are the potential advantages of the "piggyback" (vena cava preservation) technique?
10. What hemodynamic changes are expected after removal of vascular clamps? What is postreperfusion syndrome?
11. How would you treat hyperkalemia?
12. Why should you anticipate hypocalcemia?
13. What happens during the third stage of the liver transplant operation?
14. What causes intraoperative bleeding during each phase of liver transplantation? How is coagulopathy monitored and treated? What is thromboelastography (TEG)?
15. What are the complications of massive transfusion?
16. How are the complications of massive transfusion prevented?
17. How is hyperfibrinolysis managed?
18. When is intraoperative renal replacement therapy indicated?
19. What intraoperative signs suggest that the hepatic graft is working?

D. Postoperative Management

1. What are the goals of immediate postoperative care of the liver transplant patient?
2. What postoperative findings suggest that the hepatic graft is functioning?
3. What coagulation disturbances should be anticipated in the postoperative period?
4. Can renal function change after liver transplantation?
5. What vascular and biliary complications occur after liver transplantation?
6. What immunosuppressive agents will be given after liver transplantation? What are the major side effects?

A. Medical Disease and Differential Diagnosis

A.1. What are the potential graft options for liver transplantation?

Liver grafts are harvested from deceased or living donors. Cadaveric livers are procured after brain or cardiac death. Because of an increasing number of patients who

die waiting for a transplant, efforts to expand the donor pool include donation after cardiac death (DCD); harvesting marginal organs from cadavers with extended donor criteria; and procuring partial livers from living donors. DCD is the fastest growing source of transplant organs in the United States. Upon cardiac death (defined as the irreversible cessation of circulatory and respiratory function), the liver is harvested after a mandatory waiting period of 1 to 5 minutes. Warm ischemic time begins when the waiting period starts and ends when the liver is flushed with cold preservative solution. Transplantation of a DCD-donor liver that has been exposed to a longer warm ischemic time than a graft from a brain-dead donor may be associated with perioperative complications because of the organ's functional quality. Ideal organs have shorter warm and cold ischemic times and are harvested from hemodynamically stable donors younger than 50 years of age who are free of hepatobiliary or renal disease, infection, and cancer.

Extending donor criteria (age greater than 65 years; DCD; positive viral serology; split-liver; hypernatremia; or prior carcinoma, steatosis, or high-risk behaviors) to harvest organs with initial poor function or primary nonfunction expands the donor pool.

A related or unrelated healthy individual may donate a portion of the liver for transplantation. Usually, the right hepatic lobe is removed from a healthy individual and transplanted into an adult recipient. Transplantation of the smaller left hepatic lobe into pediatric or very small adults may decrease the incidence of complications in the donor. This chapter focuses on cadaveric liver transplantation into adult recipients.

Renz JF, Kin C, Kinkhabwala MD, et al. Utilization of extended donor criteria liver allografts maximizes donor use and patient access to liver transplantation. *Ann Surg*. 2005;242:556–565.

A.2. What are the indications and contraindications for liver transplantation?

Patients with acute liver failure (ALF), decompensated cirrhosis, or hepatocellular carcinoma are candidates for liver transplantation. In the United States, alcoholic liver disease is the most common cause of end-stage liver disease (ESLD), but cirrhosis from hepatitis C is the most common indication for orthotopic liver transplant. Specific indications for transplantation include recurrent cholangitis in patients with primary sclerosing cholangitis or intractable pruritus in patients with primary biliary cirrhosis. Uncommon indications for liver transplantation include hepatic tumors such as carcinoid tumors and hepatic adenoma; metabolic disorders such as alpha-1-antitrypsin deficiency; vascular disorders such as Budd-Chiari syndrome; cystic fibrosis; hemochromatosis; amyloidosis; sarcoidosis; and adult polycystic liver disease. Biliary atresia is the most common indication for pediatric liver transplantation.

Most surgeons will not offer transplantation to patients with severe cardiopulmonary or neurologic disease, significant hemodynamic instability, sepsis, extrahepatic malignancy, active alcohol or drug use, or unfavorable psychosocial circumstances. The decision to offer transplantation considers age and infection with human immunodeficiency virus.

Murray KF, Carithers RL Jr. American Association for the Study of Liver Diseases (AASLD) practice guidelines: evaluation of the patient for liver transplantation. *Hepatology*. 2005;41:1407–1432.

A.3. What is acute liver failure (ALF)?

In the absence of transplantation, ALF leads to death. ALF is defined by the absence of chronic liver disease, acute hepatitis (elevation in transaminases with an elevation in INR), encephalopathy, and illness less than 26 weeks. The most common causes of ALF are acetaminophen toxicity (39%), indeterminate (17%), idiosyncratic (13%), and acute viral hepatitis (12%, usually hepatitis B). Other etiologies include drugs (phenytoin and halothane), autoimmune disease, Wilson disease, Budd-Chiari syndrome, HELLP syndrome (hemolysis, elevated liver enzymes, low platelet count), acute fatty liver of pregnancy, toxins (i.e., trichloroethylene and tetrachloroethane in cleaning solvents and sniffed glue), and *Amanita phalloides*, the "death-cap" mushroom that grows wild in parts of the United States.

A.4. What is the MELD score and how is it used in liver transplantation evaluation?

Grafts from deceased donors are offered to patients with the highest risk of death. Since 2002, the Model for End-stage Liver Disease (MELD), a validated and widely used prognostic tool that estimates disease severity and 3-month survival in patients with chronic liver disease, prioritizes organ allocation (Fig. 15.1). The MELD score ranges from 6 to 40 points and is calculated from the patient's serum bilirubin, serum creatinine, and INR.

Formula 15.1

MELD Score = 11.2 × ln (INR) + 9.57 × ln (creatinine, milligrams per deciliter) + 3.78 × ln (bilirubin, milligrams per deciliter) + 6.43 (an intercept). The score is rounded to the nearest whole number.

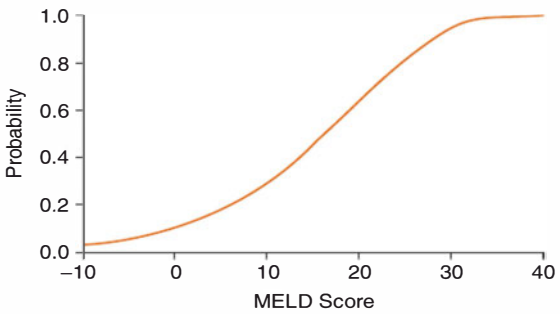

Figure 15.1 Relation between MELD score and 3-month mortality in patients with cirrhotic liver disease. MELD, model for end-stage liver disease. (From Wiesner RH, McDiarmid SV, Kamath PS, et al. MELD and PELD: application of survival models to liver allocation. *Liver Transplant*. 2001;7:567–580.)

There is a lower limit of 1 for all variables.

The maximum creatinine value is 4 mg per dL. For patients who receive dialysis, creatinine is set to 4 mg per dL.

Patients with a high score rank high on the transplant list and have a greater short-term risk of dying from liver disease than patients with lower scores. The incorporation of hyponatremia, an important prognostic factor in patient with cirrhosis, into the MELD score may provide better calibration and discrimination of the risk of death among patients awaiting liver transplantation.

Exceptions to the MELD classification exist for patients with fulminant hepatic failure and life expectancy of less than 7 days without a liver transplant. These patients are classified as *status 1* and rank highest on the waiting list. This group includes patients who develop ALF without a history of liver disease, suffer from primary graft nonfunction or hepatic artery thrombosis within 7 days of a liver transplant, or have acutely decompensated Wilson disease. Special case exceptions also exist for patients with diagnoses such as hepatocellular carcinoma.

Pediatric patients less than 12 years of age are ranked on the transplant waiting list according to the Pediatric End-Stage Liver Disease model. The pediatric end-stage liver disease score is similar in derivation to the MELD, but incorporates bilirubin, INR, albumin, age, and growth failure into the formula.

Laboratory values less than 1 are set to 1 to calculate a MELD score. The maximum serum creatinine considered within the MELD score equation is 4 g per dL. For patients receiving dialysis, creatinine is set to 4 mg per dL.

A.5. Describe the cardiovascular system of patients with end-stage liver disease (ESLD).

The cardiovascular system of patients with ESLD mimics the hyperdynamic circulatory changes of patients with sepsis. Tachycardia, elevated cardiac output, low arterial blood pressure, and low systemic vascular resistance are characteristic. Enhanced endogenous production or diminished hepatic clearance of vasodilating substances, such as nitric oxide, carbon monoxide, and endogenous cannabinoids, and the inflammatory response to bacterial translocation cause splanchnic arterial vasodilation. Increased venous capacitance from formation of portosystemic shunts because of portal hypertension increases venous capacitance and contributes to a hyperdynamic circulation. Despite the frequent finding of a high cardiac output in patients with cirrhosis, echocardiography may reveal myocardial contractile impairment similar to that seen in sepsis. Patients with portal hypertension may develop portopulmonary hypertension and right ventricular dysfunction. A mean pulmonary artery pressure greater than 25 mm Hg at rest and a pulmonary vascular resistance greater than 240 dynes/s/cm^{-5} define portopulmonary hypertension.

A.6. What causes acute kidney injury (AKI) in patients with cirrhosis?

Patients with AKI and cirrhosis have more complications and increased risk of mortality after liver transplantation than those without renal failure. Gastrointestinal bleeding, diarrhea from infection or lactulose administration, and diuretic medications change circulatory function via hypovolemia and can cause renal injury. As cirrhosis progresses, a reduction in systemic vascular resistance causes compensatory activation of the renin-angiotensin and sympathetic nervous systems, which leads to ascites, edema, and vasoconstriction of the intrarenal circulation and renal hypoperfusion.

Hepatorenal syndrome (HRS) is caused by functional renal vasoconstriction in response to splanchnic arterial vasodilation. Although histologic findings and diagnostic tests for HRS are lacking, diagnostic criteria are used to categorize two types of HRS. Criteria for HRS include (1) cirrhosis with ascites; (2) serum creatinine greater than 1.5 mg per dL; (3) no improvement of creatinine after 2 days of diuretic withdrawal and volume expansion with albumin; (4) absence of shock; (5) no current or recent treatment with nephrotoxic drugs; and (6) absence of parenchymal kidney disease. Type I HRS involves rapid and progressive impairment of renal function with a doubling of the initial serum creatinine to a level greater than 2.5 mg per dL or a 50% reduction in the 24-hour creatinine clearance to lower than 20 mL per minute in less than 2 weeks. Patients with type II HRS have impaired renal function and a serum creatinine greater than 1.5 mg per dL and do not meet the criteria for type I HRS. Compared with patients diagnosed with prerenal failure, patients with HRS lack a renal response to a 1.5 L volume challenge. Distinguishing between HRS and acute tubular necrosis is difficult. A fractional excretion of sodium less than 1% suggests tubular function and favors a diagnosis of HRS. The presence of renal tubular epithelial cells in urinary sediment favors a diagnosis of acute tubular necrosis.

Medical management of HRS is marginally effective, but liver transplantation usually reverses HRS. Kidneys transplanted from patients with HRS function normally in new hosts, suggesting the essential role of hepatic disease in the pathogenesis.

A.7. What causes hyponatremia in patients with cirrhosis?

Patients with advanced cirrhosis have decreased effective blood volume and then circulatory dysfunction. They develop hypervolemic hyponatremia from increased secretion of antidiuretic hormone, which acts on the vasopressin-2 receptors of the renal tubular collecting duct to impair excretion of solute-free water. These patients have expanded extracellular volume, ascites, and edema.

Patients who develop hypovolemic hyponatermia via loss of extracellular fluid from the kidneys (overdiuresis) or gastrointestinal tract rarely have ascites or edema. These patients may have prerenal failure from low plasma volume and dehydration or hepatic encephalopathy from a rapid reduction in serum osmolality.

A.8. Discuss the neurologic manifestations of acute and chronic liver disease.

Hepatic encephalopathy is a neuropsychiatric complication of acute and chronic liver disease with features that range from mild confusion to cerebral edema with intracranial hypertension. Patients have disturbances in consciousness, cognitive abilities, behavior, neuromuscular function, concentration, reaction time, memory, and/or electroencephalogram readings. The pathogenesis of hepatic encephalopathy is not understood, but most theories implicate elevated levels of ammonia, a gut-derived neurotoxin, which is shunted to the systemic circulation from the portal system. Bacteria in the gut produce ammonia, which crosses the blood–brain barrier into astrocytes that detoxify it to glutamine. Astrocytes regulate neurotransmission, but their function is decreased when they swell because of increased concentrations of intracellular glutamine. High serum ammonia levels characterize patients with hepatic encephalopathy, even though the degree of elevation of ammonia does not correlate with neurologic severity. This observation suggests that other factors, such as hyponatremia, gastrointestinal bleeding, and infection contribute to the development of hepatic encephalopathy. Left untreated, cerebral edema can progress to intracranial hypertension and herniation of the brain.

A.9. Why do patients with ESLD have abnormalities of hemostasis?

Patients with ESLD have hemostatic changes that promote both bleeding and thrombosis. Inadequate synthesis of all coagulation factors (except for von Willebrand factor), thrombocytopenia, platelet function defects, dysfibrinogenemia, and elevated tissue plasminogen activator (tPA) levels cause bleeding. Elevations of von Willebrand factor and factor VIII, and decreased levels of a disintegrin and metalloproteinase with a thrombospondin type 1 motif, member 13 (ADAMTS-13), protein C, protein S, antithrombin, alpha 2-macroglobulin, plasminogen, and heparin cofactor II favor thrombosis. Thrombin generation is normal in cirrhosis, and in coagulation tests (prothrombin time [PT] and activated partial thromboplastin time [aPTT]), thrombin generation is considered a function of procoagulant factors and anticoagulant factors that inhibit thrombin are not considered.

Levels of fibrinogen, an acute phase reactant, are normal or increased in liver disease. Patients with severe hepatic dysfunction, however, may synthesize fibrinogen poorly, which increases the risk of bleeding. Although high concentrations of fibrinogen are found in patients with chronic hepatitis, cholestatic jaundice, and hepatocellular carcinoma, clot formation is not enhanced because fibrinogen is dysfunctional. Patients may have an abnormal thrombin time with normal PT and aPTT values.

Thromboyctopenia and platelet dysfunction are characteristic of ESLD. Thrombocytopenia results from several factors: hypersplenism, which sequesters

platelets; consumption of platelets during systemic intravascular coagulation; and impaired hepatic synthesis of thrombopoietin, which produces platelets in the bone marrow. Defective signal transduction; uremia from AKI; and intrinsic defects of adenosine diphosphate (ADP), arachidonic acid, collagen, and thrombin prevent platelet aggregation.

There may be little evidence of deranged coagulation when normal hepatic parenchyma is preserved, such as in an isolated hepatoma.

A.10. What is the differential diagnosis for hypoxemia in patients with cirrhosis?

Potential causes of preoperative hypoxemia and respiratory failure in patients with cirrhosis includes atelectasis from the compressive effects of ascites, hepatic hydrothorax, hepatopulmonary syndrome (HPS), and underlying chronic pulmonary disease. Muscle wasting and intra-abdominal hypertension from ascites increase the work of breathing.

Ascites fluid can enter the pleural space through small channels in the diaphragm to cause a hepatic hydrothorax (usually on the right side). Negative intrathoracic pressure during inspiration facilitates movement of fluid from the peritoneum to the pleural space to minimize ascites.

A diagnosis of HPS is considered in patients without cardiopulmonary disease who have a Pao_2 less than 60 mm Hg. The triad of liver disease and/or portal hypertension, widened age-corrected alveolar-arterial oxygen gradient (more than 15 to 20 mm Hg) while breathing room air, and documented intrapulmonary vascular dilation (IPVD) define HPS. Enhanced production or impaired hepatic clearance of endogenous vasodilators (i.e., nitric oxide, vasodilator prostaglandins, substance P), or inhibition of vasconstrictive substances (i.e., tyrosine, serotonin, and endothelin) by a damaged liver may cause IPVD. IPVD causes hypoxemia via ventilation–perfusion mismatching, intrapulmonary shunt physiology, and diffusion limitation. Patients with HPS often complain of dyspnea and fatigue; they may have clubbing and spider angiomata on physical examination. Patients may experience platypnea (dyspnea in the upright position relieved by recumbency) or have orthodeoxia (arterial oxyhemoglobin desaturation in the upright position). Preferential perfusion of IPVD (while the patient is upright) may cause these clinical manifestations. Contrast-enhanced echocardiography detects intrapulmonary shunting suggestive of IPVD. Resolution of this syndrome after transplant has been reported.

A.11. What is portal hypertension? What are the sequelae of portal hypertension?

The normal portosystemic gradient between the portal vein and hepatic vein is less than 5 mm Hg. Intrahepatic vascular resistance and portal venous blood flow increase this gradient and characterize portal hypertension. Liver fibrosis, regenerative nodules, collagen deposition in the space of Disse, endothelial dysfunction, and an imbalance between endogenous vasoconstrictors (e.g., norepinephrine, thromboxane A, endothelin I, angiotensin II, leukotrienes) and vasodilators, such as nitric oxide, increase vascular resistance in the liver. As the pressure gradient between the portal vein and the hepatic vein increases, collaterals such as gastroesophageal and hemorrhoidal varices develop to decompress the portal system. Portal hypertension produces endogenous vasodilators that cause splanchnic vasodilation. Splanchnic vasodilation in turn increases portal blood flow and exacerbates portal hypertension.

Complications of portal hypertension include gastrointestinal bleeding from expansion and rupture of varices and intraoperative bleeding from intra-abdominal collaterals.

B. Preoperative Evaluation and Preparation

B.1. What preoperative workup is desirable?

Anesthesiologists face several preoperative challenges when patients with ESLD disease need surgery. Surgical and anesthetic management is complicated for patients with an encephalopathy, AKI, electrolyte abnormalities, ascites, myocardial and pulmonary dysfunction, or coagulopathy. Physiologic perturbations during the perioperative period may precipitate multisystem organ failure. To anticipate and prevent complications from transplantation, underlying conditions should be thoroughly evaluated before surgery. A multidisciplinary team including an anesthesiologist, hepatologist, and surgeon should be involved in preoperative preparation. Consultations may be requested with cardiology, pulmonary, infectious diseases, and nephrology (especially if renal replacement therapy is considered) for patients with comorbidities.

Echocardiography is useful to detect cardiac dysfunction. The chest radiograph rules out pulmonary edema or cardiomegaly in patients with signs and symptoms of pulmonary edema or heart failure. Electrolyte levels, blood urea nitrogen, creatinine levels, albumin levels, bilirubin levels, complete blood count, coagulation parameters, and glucose values should be obtained. In cases of altered mental status, a head CT scan often is indicated to evaluate intracranial bleeding, herniation, and/or the extent of cerebral edema. Patients who may have received multiple previous transfusions, such as patients with a history of gastrointestinal bleeding, should be evaluated in advance for crossmatching large quantities of blood products for a transplant operation.

Patients of advanced age or those with risk factors may undergo cardiopulmonary testing for myocardial ischemia (e.g., dobutamine stress echocardiography), cardiac dysfunction (e.g., transthoracic echocardiography), or lung disease (e.g., pulmonary function tests).

Risk factors for adverse cardiac outcomes after liver transplantation include history of stroke, coronary artery disease, and increased intraventricular thickness.

Preoperative myocardial evaluation is recommended, typically with functional stress echocardiography and dobutamine. The heart rate must reach 85% of the maximum predicted heart rate for the stress test to be considered adequate. A vasodilatory (e.g., adenosine, persantine) myocardial stress test is less useful because in patients with ESLD, the resting vascular tone is so low that provoking vasodilation with drugs is impossible. Transthoracic echocardiography is useful to estimate right ventricular systolic pressure as a gauge of pulmonary artery pressure. If elevated, pretransplant right heart catheterization may be warranted.

If intraoperative renal replacement (continuous venovenous hemofiltration) therapy is a consideration, a nephrologist should be consulted.

B.2. How is ascites managed preoperatively?

Ascites is initially managed with a low sodium diet and diuretic therapy. Patients with ascites refractory to treatment with diuretics may require large volume paracentesis and albumin replacement. Large-volume paracentesis is a risk factor for the development of HRS. Patients may be treated with a transjugular intrahepatic portosystemic shunt (TIPS) in refractory cases of ascites.

B.3. How is hyponatremia managed preoperatively?

Hyponatremia is associated with HRS, ascites, death from liver disease, and postoperative mortality after transplantation. Distinguishing between hypervolemic and hypovolemic hyponatremia guides treatment. Hypervolemic hyponatremia is managed with fluid restriction (1 to 1.5 L per day) and withholding of diuretics. Vaptans, medications that block the vasopressin-2 receptor, increase solute-free water excretion dose dependently and may preclude water restriction so that diuretics can be continued. Patients with hypovolemic hyponatremia are not given diuretics; instead saline is administered to increase plasma volume.

Patients who undergo orthotopic liver transplantation are at risk for central pontine myelinolysis (CPM) perioperatively. CPM is a neurologic condition characterized by symmetric noninflammatory demyelinating lesions in the basis pontis. The etiology of CPM is uncertain, but osmotic stress on central nervous system cells is theorized, and CPM correlates with rapid correction of hyponatremia. Rapid changes in concentration of serum sodium cannot be predicted and a "safe" rate of correction of hyponatremia has not been definitively established; some experts recommend sodium correction at a rate less than 12 mEq/L/day.

Preoperative correction of hyponatremia may prevent a rapid rise in serum sodium intraoperatively and postoperatively. During intraoperative fluid replacement, high sodium loads may cause rapid swings in serum sodium, or even hypernatremia, by the end of the case. Sodium bicarbonate should be administered cautiously because it has a high concentration of sodium.

B.4. What is a transjugular intrahepatic portosystemic shunt (TIPS) procedure? What is the role of TIPS in the management of patients with ESLD?

During a TIPS procedure, an expandable stent is placed into the liver parenchyma for portosystemic exchange and to decrease portal hypertension. This intervention may prevent recurrent variceal bleeding and manage refractory ascites. The procedure is performed under local or general anesthesia as a "bridge" to liver transplantation in patients with severe liver disease. Unlike older, surgically created portosystemic (e.g., splenorenal) and peritoneovenous (e.g., LeVeen shunt) shunts, a TIPS does not require abdominal operation or vascular diversion, both of which impose technical hazards to future liver transplantation.

Among the complications associated with the TIPS procedure are bleeding, infection, hemobilia, and stent migration. Encephalopathy may worsen from enhanced systemic delivery of biogenic amines normally cleared by the liver. The long-term patency of a TIPS is poor, and revisions may be needed before liver transplantation.

B.5. How are hepatic encephalopathy and elevated intracranial pressure (ICP) treated?

Initial therapy for hepatic encephalopathy identifies and treats reversible triggers (i.e., gastrointestinal bleeding and infection) of this neuropsychiatric syndrome. Nonabsorbable disaccharides such as lactulose decrease absorption of ammonia from the gut via catharsis. Excessive dosing of lactulose causes dehydration. Oral antibiotics (rifaximin, neomycin, vancomycin, paramomycin, or metronidazole) reduce ammonia-producing enteric bacteria. Rifaximin, in combination with lactulose, may prevent episodes of hepatic encephalopathy.

Patients who develop fulminant hepatic failure are at risk for hepatic encephalopathy, cerebral edema with increased ICP, and a threat of herniation. ICP monitoring should be seriously considered for patients with fulminant hepatic failure and encephalopathy, even given the bleeding risks associated with invasive monitors. Bleeding

risk seems to be the greatest deterrent to ICP monitoring. A review of recent data indicates a risk of approximately 10% for intracranial hemorrhage with insertion of a monitor. To minimize the risk, epidural transducers are recommended rather than intradural monitors. With or without ICP monitoring, 30-day outcomes are similar.

ICP elevations to greater than 25 mm Hg should be treated with mannitol to achieve hyperosmolarity. Preoperative hyperventilation has not been shown to improve outcome and corticosteroids are not indicated. Pentobarbital coma may be indicated for patients unresponsive to mannitol, but coma may worsen cerebral hypoperfusion by causing systemic hypotension. Many centers consider sustained cerebral hypoperfusion (cerebral perfusion pressure <40 mm Hg), a contraindication to transplant because of the high risk for brain death. In the future, transcranial Doppler ultrasonography may offer a noninvasive means of monitoring for elevated ICP in these patients. For anesthesia, drugs or conditions that exacerbate elevations in ICP should be avoided.

B.6. Should this patient be transfused with fresh frozen plasma prior to surgery?

Management of coagulopathy is challenging because blood tests such as PT and aPTT do not predict bleeding during liver transplantation.

Patients who need an orthotopic liver transplant usually have severe perturbations in coagulation, but it is neither necessary nor possible to correct them preoperatively. Patients with active sites of bleeding should be transfused with fresh frozen plasma, packed red blood cells, cryoprecipitate, or platelets as dictated by clinical assessment and laboratory tests. In addition, desmopressin (1-desamino-8-D-arginine vasopressin [DDAVP]) may be considered for patients with concomitant renal dysfunction and uremic bleeding. Potentially curative transplant surgery should not be postponed to correct coagulation defects.

C. Intraoperative Management

C.1. What monitors would you use? Why?

In addition to the monitors recommended by the American Society of Anesthesiologists (electrocardiogram, pulse oximetry, capnography, temperature, and noninvasive blood pressure), a radial arterial catheter is placed for beat to beat blood pressure monitoring and frequent sampling of blood. Pulse pressure variation, calculated from the invasive arterial tracing, assesses fluid responsiveness. A second arterial catheter is placed in the femoral artery to measure central aortic blood pressure. Peripheral arterial pressures may not be reliable in a patient with vasoconstriction, vasodilation, or compression of the subclavian artery with rib retraction.

Central line access is established to measure right atrial pressure and to administer drugs. Central venous pressure monitoring does not reliably measure blood volume or change in blood volume. The use of a pulmonary artery catheter depends on local practice and the physiologic state of the patient. Mixed venous oxygen saturation values are measured to assess cardiac output, but these measurements also are influenced by changes in oxygen-carrying capacity and oxygen consumption.

Transesophageal echocardiography (TEE) assesses ventricular filling, contractility, and function. Diagnoses such as myocardial ischemia, pulmonary embolism, pleural effusions, and inadequate inferior vena cava (IVC) reconstruction can be observed with TEE. The risk of rupture of esophageal varices with TEE is rare.

Krenn C, De Wolf, AM. Current approach to intraoperative monitoring in liver transplantation. *Curr Opin Organ Transplant*. 2008;13:285–290.

C.2. What are the considerations for the induction of anesthesia?

If there is evidence of tense ascites, recent food ingestion, or a propensity for delayed gastric emptying, a rapid-sequence induction of general endotracheal anesthesia is performed. AKI with elevated potassium levels or prolonged immobilization may preclude the use of succinylcholine. Compressive atelectasis from ascites and pleural effusions reduce functional residual capacity and decrease the time to oxygen desaturation. Vasodilating anesthetic agents may cause hypotension if intravascular volume is depleted (i.e., overdiuresis or gastrointestinal losses).

C.3. How does liver disease affect intraoperative medication management?

In patients with liver disease and edema, muscle relaxant doses are increased because fluid retention increases volume of distribution. The duration of action of muscle relaxants that are metabolized by the liver (i.e., vecuronium and rocuronium) is prolonged.

Many anesthetic drugs (i.e., opioids, barbiturates) bind to albumin in the circulation. Low albumin levels increase the free fraction of drug and can theoretically exaggerate the drug's clinical effect. ESLD, however, alters many other aspects of normal pharmacokinetics such as drug volume of distribution, hepatic extraction and metabolism, renal excretion, and levels of serum proteins other than albumin. The net effect of these changes is unpredictable, making general recommendations for drug administration difficult. A safe approach in these patients is to titrate the drug to the desired effect.

Patients with ESLD often exhibit coagulation disorders. The presence of a coagulopathy is a contraindication to regional anesthesia, particularly epidural anesthesia. Patients without an initial disorder of coagulation may develop a coagulopathy intraoperatively or postoperatively.

Wiklund RA. Preoperative preparation of patients with advanced liver disease. *Crit Care Med*. 2004;32:S106–S115.

C.4. What happens during the first stage (preanhepatic phase) of the liver transplant operation?

The preanhepatic phase begins with induction of anesthesia and ends with clamping of the hepatic artery. The diseased liver is mobilized; the suprahepatic and infrahepatic vena cava, portal vein, and hepatic artery are isolated; and the bile duct is divided. The anesthesia team manages disorders of coagulation and hemodynamic disturbances. Large losses of ascites cause hypotension and require early fluid resuscitation. Albumin solution and fresh frozen plasma are often used to replete intravascular volume.

C.5. What happens during the second stage (anhepatic phase) of the liver transplant operation?

The second stage of the liver transplant operation, the anhepatic phase, begins after removal of the diseased liver and ends with reperfusion of the new liver. If the IVC and portal vein are clamped, venous return to the heart and cardiac output decreases. In preparation for clamping and dividing the IVC, a test clamp maneuver (occlusion of the suprahepatic IVC) is performed to assess the resilience of the circulatory system. Hypotension is managed with vasoactive medications, fluid repletion, adjustment of anesthetic agents, correction of hypocalcemia, and venovenous bypass. Anastomoses between the recipient and donor liver are performed in the following order: caval, portal, hepatic artery, and biliary.

Polak WG, Peeters PM, Slooff MJ. The evolution of surgical techniques in clinical liver transplantation. A review. *Clin Transplant*. 2009:23:546–564.

C.6. What physiologic disturbances should be anticipated during the second stage (anhepatic phase) of the liver transplant operation?

Without a liver, the patient may develop acidosis and hypocalcemia because lactic acid and citrate are not cleared. Acidemia, reduced urine output, and the absence of hepatic uptake of potassium cause hyperkalemia. The liver regulates glucose levels, but in the anhepatic phase, gluconeogenesis is absent. Blood glucose levels are monitored for both hyperglycemia and hypoglycemia.

Merritt WT. Metabolism and liver transplantation: review of perioperative issues. *Liver Transpl*. 2000;6(4 suppl 1):S76–S84.

C.7. What is venovenous bypass? What are potential advantages and disadvantages of this procedure?

Some centers routinely use venovenous bypass to divert blood flow from the portal circulation and IVC to the right atrium. A Y-shaped tubing is used. One limb of the tubing is inserted into the recipient's portal vein to drain the splanchnic beds. Another limb of the tubing is placed, through a groin cut, down into an iliac vein or the distal IVC. The outflow tubing passes through a pump. Blood returns to the patient through a cutdown access to an axillary vein or through percutaneous access to an internal jugular or subclavian vein (Fig. 15.2).

Potentially, venovenous bypass can decompress the portal circulation and reduce congestion of the gut; decrease hemodynamic instability during clamping of the IVC; maintain normothermia via continuous warming of the bypass circuit; manage blood volume overload; preserve renal perfusion pressure; and improve surgical exposure during dissection. Disadvantages include the complications of venous cannula placement (bleeding, air, or thrombotic embolism); release of proinflammatory mediators; activation of complement, which may contribute to tissue injury and organ failure; and the time and cost of an expensive procedure.

The efficacy and benefits of routine use of venovenous bypass remain controversial. However, portal decompression clearly improves surgical visualization in certain circumstances, such as in Budd-Chiari syndrome. Other centers reserve venovenous bypass for situations in which interrupted venous return through the IVC depresses the recipient's circulating system.

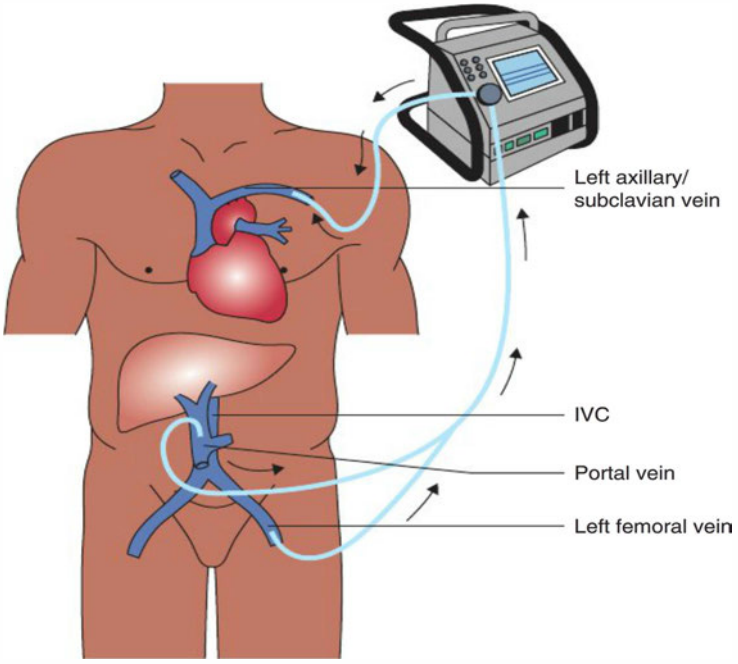

Figure 15.2 Schematic diagram of venovenous bypass circuit during liver transplantation. Venous return comes from the femoral and portal veins connected with the tubing connected together into a single venous return line. The centrifugal pump returns the blood into the axillary or subclavian vein. IVC, inferior vena cava.

C.8. What surgical techniques anastomose the donor and recipient inferior vena cava?

There are several techniques to anastomose the donor and recipient IVC. Conventionally, blood flow through the IVC is completely interrupted and a cylinder of the recipient's IVC is removed with the diseased liver. An end-to-end anatomosis is created between the donor's and the recipient's IVC (Fig. 15.3A). In the piggyback method, the diseased liver is dissected off the IVC. The recipient's IVC is preserved and blood flow is not completely interrupted. One end of the graft's segment of IVC is oversewn, and the orifice of the hepatic veins (the liver's venous outflow) is anastomosed to the preserved recipient's suprahepatic IVC (Fig. 15.3B). A third technique creates a side-to-side cavo-caval anastomosis (Fig. 15.3C).

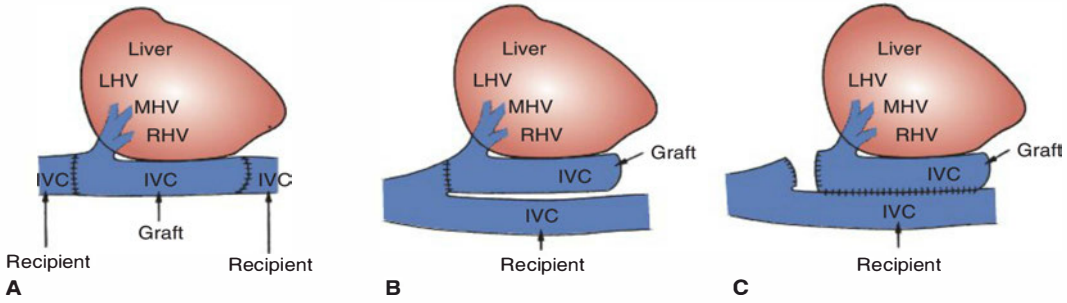

Figure 15.3 Three different techniques to reconstruct the hepatovenous outflow. **A.** End-to-end interposition of the donor vena cava to the recipient vena cava. **B.** End-to-end anastomosis of the vena cava to the hepatic veins. **C.** Side-to-side cavo-cavostomy. (Reproduced and modified with permission from Hesse UJ, Berrevoet F, Troisi R, et al. Hepato-venous reconstruction in orthotopic liver transplantation with preservation of the recipients' inferior vena cava and veno-venous bypass. *Langenbecks Arch Surg.* 2000;385:350–356.)

Polak WG, Peeters PM, Slooff MJ. The evolution of surgical techniques in clinical liver transplantation. A review. *Clin Transplant.* 2009:23:546–564.

C.9. What are the potential advantages of the "piggyback" (vena cava preservation) technique?

Potential advantages of the piggyback technique for vascular reconstruction include hemodynamic stability because cardiac filling is preserved; protected perfusion pressure; nonneed for the surgical interventions associated with venovenous bypass; reduced need for retrocaval dissection, which lessens the likelihood of damage to the adrenal vein; and shorter anhepatic time and warm ischemia time. A disadvantage of the technique is that outflow obstruction results in hepatic congestion. Unfavorable anatomy in the recipient may preclude the the piggyback technique.

Polak WG, Peeters PM, Slooff MJ. The evolution of surgical techniques in clinical liver transplantation. A review. *Clin Transplant.* 2009:23:546–564.

C.10. What hemodynamic changes are expected after removal of vascular clamps? What is postreperfusion syndrome?

Removal of the suprahepatic IVC clamp is not associated with hemodynamic changes. Unclamping the infrahepatic IVC restores venous return.

After unclamping of the portal vein, desaturated blood from the obstructed portal circulation, inflammatory mediators such as Il-6 and TNF alpha, potassium, protons, and cold components are released into the systemic circulation. Hemodynamic instability, characterized by a decrease in blood pressure, heart rate, systemic vascular resistance, cardiac output, and an increase in pulmonary arterial

pressures, may follow unclamping of the portal vein and reperfusion of the liver. Careful flushing of the graft just before completion of the anastomoses attenuates reperfusion disturbances by removing the cold hyperkalemic preservative solution. A sustained 30% decrease in mean arterial blood pressure for more than 1 minute during the first 5 minutes after reperfusion defines postreperfusion syndrome. A prolonged cold ischemic time and the absence of portocaval shunting are associated with the development of postreperfusion syndrome. Before reperfusing the new graft, the following measures should be considered: (1) preemptive administration of calcium to correct hypocalcemia; (2) sodium bicarbonate, dichloroacetate, or tris-hydroxymethyl aminomethane to adjust pH; and (3) inotropes or vasopressors for circulatory support. The surgical and anesthesia teams must be prepared to diagnose and treat dysrhythmias or cardiac arrest.

Paugam-Burtz C, Kavafyan J, Merckx P, et al. Postreperfusion syndrome during liver transplantation for cirrhosis: outcome and predictors. *Liver Transpl.* 2009;15:522–529.

C.11. How would you treat hyperkalemia?

Hyperkalemia is treated with diuretics, β-adrenergic agonists, insulin in combination with glucose, and alkalinization via administration of sodium bicarbonate or hyperventilation. Dysrhythmic effects of elevated potassium may be countered with calcium. Rarely, when hyperkalemia is refractory to the preceding treatments, continuous venovenous hemofiltration may reduce the elevated serum potassium level.

Xia VW, Ghobrial RM, Du B, et al. Predictors of hyperkalemia in the prereperfusion, early postreperfusion, and late postreperfusion periods during adult liver transplantation. *Anesth Analg.* 2007;105:780–785.

C.12. Why should you anticipate hypocalcemia?

The principal reason to anticipate hypocalcemia is a failure to clear citrate, which normally is metabolized by the liver. This calcium-chelating agent accumulates in patients who receive transfusions of citrated blood products.

C.13. What happens during the third stage of the liver transplant operation?

The third stage of the liver transplant operation, the neohepatic phase, follows reperfusion of the new liver. In the neohepatic phase, the biliary drainage system is constructed. Reconstruction may be straightforward, with an anastomosis between the graft's common bile duct and the biliary stump of the recipient. More complex reconstructions are sometimes required, such as the creation of a choledochojejunostomy. A donor cholecystectomy generally is performed. A T-tube is placed in the reconstructed biliary outflow system, with external drainage. An intraoperative cholangiogram, with contrast dye instilled through the T-tube, is used to assess the patency and integrity of the biliary reconstruction. The third stage ends with closure of all wounds and transport to the intensive care unit.

During the third stage of the procedure, an insidious coagulopathy may develop, requiring transfusion.

Polak WG, Peeters PM, Slooff MJ. The evolution of surgical techniques in clinical liver transplantation. A review. *Clin Transplant.* 2009:23:546–564.

C.14. What causes intraoperative bleeding during each phase of liver transplantation? How is coagulopathy monitored and treated? What is thromboelastography (TEG)?

The etiology of intraoperative bleeding during liver transplantation is multifactorial. Patients with ESLD have serious hemostatic defects, and coagulation is affected by alterations in body temperature, tissue perfusion, acid–base balance, and fluid balance.

During the preanhepatic phase, bleeding from the surgical technique is influenced by the patient's underlying coagulopathy. Excessive fluid administration may cause a dilutional coagulopathy and increase venous congestion of the splanchnic area, leading to more bleeding at the surgical site. Bleeding may be minimal in a hypercoagulable state such as hepatocellular carcinoma or cholestatic cirrhosis.

During the anhepatic phase, there is a net increase in systemic tPA derived from endothelial cells, which is normally cleared by the liver. Although PT and aPTT values may not change, hyperfibrinolysis is possible. Hyperfibrinolysis is confirmed by a decrease in alpha-2-antiplasmin and plasminogen activity and an increase in fibrin and fibrinogen degradation products.

Nonsurgical and insidious bleeding during reperfusion can be profound. Disseminated intravascular coagulation, increased fibrinolysis, release of heparin or heparin-like substances, and trapped platelets in the graft cause coagulopathy.

The coagulation status should always be monitored by inspection of the surgical field. Routine laboratory tests (PT, aPTT, platelet count, fibrinogen levels) are used in some centers for evaluating the coagulation status and directing treatment. Other centers use TEG, a test of whole blood clotting function, to diagnose disorders of coagulation. TEG assesses the viscoelastic properties of a whole blood sample as a function of time. TEG detects a hypercoagulable state, and distinguishes hyperfibrinolysis from other causes of coagulopathy, such as factor depletion or thrombocytopenia (also see Chapter 11, section A.22). Heparinase may be used to help diagnose coagulopathy resulting from the presence of heparinoids.

Senzolo M, Burra P, Cholongitas E, et al. New insights into the coagulopathy of liver disease and liver transplantation. *World J Gastroenterol.* 2006;12:7725–7736.

C.15. What are the complications of massive transfusion?

Uncontrolled hemorrhage and massive transfusion may cause the lethal triad of acidosis, coagulopathy, and hypothermia. Left uncorrected, each of these abnormalities can exacerbate the other, creating a "blood vicious cycle." Additional early complications of massive transfusion include (1) acute hemolytic transfusion reactions, (2) febrile nonhemolytic transfusion reactions, (3) transfusion-related acute lung injury, (4) transfusion-associated circulatory overload, (5) allergic reactions, (6) bacterial sepsis, (7) hypocalcemia, and (8) hyperkalemia.

Sihler KC, Napolitano L. Complications of massive transfusion. *Chest.* 2010;137:209–220.

C.16. How are the complications of massive transfusion prevented?

Warming the room, applying forced warming systems on the patient's body, administering blood products and fluids through a fluid warmer, and heating and humidifying inspired gases reduce the risk of hypothermia. Dilutional coagulopathy and thrombocytopenia may be prevented by transfusing packed red blood cells, fresh frozen plasma, and platelets in a 1:1:1 ratio. Occasionally, recombinant factor VIIa is administered. Potasssium, magnesium, and calcium levels are frequently monitored to correct abnormal levels. Metabolic acidosis is managed by improving hemodynamic parameters, adjusting minute ventilation, and administering sodium bicarbonate or tromethamine for severe metabolic acidosis. The risk of transfusion-related acute lung injury may be reduced by minimizing transfusions and transfusing packed red blood cells with a short storage time and fresh frozen plasma from men or nulliparous women.

Sihler KC, Napolitano L. Complications of massive transfusion. *Chest*. 2010;137:209–220.

C.17. How is hyperfibrinolysis managed?

tPA has been implicated as a causal agent in hyperfibrinolysis. A functioning graft liver will eventually clear excess tPA from the circulation. Pharmacologic therapy with antifibrinolytic agents (tranexamic acid, ε-aminocaproic acid [Amicar] or aprotinin [Trasylol]) blocks fibrin degradation by plasmin, but the full spectrum of their actions remains incompletely defined. The use of prophylactic antifibrinolytic agents in liver transplant surgery has been advocated, but this use is controversial. Potential disadvantages of antifibrinolytic agents include development of thromboses that may be catastrophic.

Groenland THN, Porte RJ. Antifibrinolytics in liver transplantation. *Int Anesthesiol Clin*. 2006;44:83–97.

Xia VW, Steadman RH. Antifibrinolytics in orthotopic liver transplantation: current status and controversies. *Liver Transpl*. 2005;11:10–18.

C.18. When is intraoperative renal replacement therapy indicated?

Managing patients with low urine output, renal dysfunction, or preoperative hyperkalemia who undergo liver transplantation is challenging. Continuous renal replacement therapy may be used intraoperatively to manage volume shifts, acid–base balance, and electrolyte disturbances. Patients who are receiving dialysis and patients who have AKI should have intraoperative continuous renal replacement therapy.

Townsend DR, Bagshaw SM, Gobney RT, et al. Intraoperative renal support during liver transplantation. *Liver Transpl*. 2009;15:73–78.

C.19. What intraoperative signs suggest that the hepatic graft is working?

Good texture and color of the graft, evidence of bile production, and hemodynamic stability are signs that the graft is working. Hypocalcemia often resolves quickly as the graft metabolizes citrate during the final phases of the procedure. Metabolic alkalemia can develop as a result of citrate metabolism. Potassium levels tend to normalize with the onset of hepatocyte function. A number of recipients exhibit hyperglycemia resistant to insulin.

D. Postoperative Management

D.1. What are the goals of immediate postoperative care of the liver transplant patient?

After liver transplantation, patients are admitted to the intensive care unit for monitoring of organ function, management of intraoperative complications, correction of coagulopathy, evaluation of graft function, and initiation of immunosuppression. Although many patients are extubated within 6 hours after the operation, the lungs of liver transplant patients often are mechanically ventilated for 24 to 48 hours.

D.2. What postoperative findings suggest that the hepatic graft is functioning?

Clearance of lactic acid, production of glucose, resolution of encephalopathy, normothermia, normalization of coagulopathy, decreasing total bilirubin levels, production of bile (through the biliary tube), and adequate urine output suggest a functioning graft. Preservation injury causes transaminases to rise immediately after surgery, but enzyme levels usually fall within 24 to 48 hours. New synthesis of coagulation factors will not correct factor depletion for hours to days after the transplant.

D.3. What coagulation disturbances should be anticipated in the postoperative period?

Typically, heparin effects, disseminated intravascular coagulation, or hyperfibrinolysis have been resolved in the operating room. However, dilutional coagulopathy, along with ongoing platelet and factor consumption in the early postoperative phase and poor graft function, may contribute to clinical bleeding. Postoperative uremia compromises platelet function. A functioning graft liver may not produce substantial levels of clotting factors for several days. Therefore, plasma, cryoprecipitate, and/or platelets may be needed in the early postoperative period.

D.4. Can renal function change after liver transplantation?

Postoperative renal function is correlated with preoperative glomerular filtration rate, and approximately 10% of liver transplant patients require postoperative dialysis. For patients with cirrhosis who have HRS resistant to diuretics, renal function may improve after transplantation. Postoperatively, sepsis and the nephrotoxic calcineurin inhibitors such as cyclosporin A and FK-506 (tacrolimus) may contribute to renal dysfunction. Balanced immunosuppression with steroids, mycophenolate mofetil, anti-CD25 (basiliximab/daclizumab) and antithymoglobulin can minimize posttransplant renal dysfunction. Chronic allograft nephropathy in patients who have received liver, heart, lung, or kidney transplants is now the third most common reason for patients to be on the waiting list for a kidney transplant.

Gines P, Schrier RW. Renal failure in cirrhosis. *N Engl J Med.* 2009:361:1279–1290.

D.5. What vascular and biliary complications occur after liver transplantation?

Arterial and venous vascular complications include anastomotic bleeding leading to hypovolemia and acute stenosis or occlusion from thrombosis or kinking of the graft vessels. Thrombosis of the portal vein or hepatic artery compromises viability of the graft. Abdominal Doppler ultrasound is used to assess the hepatic vessels. Hepatic artery thrombosis, which is more common than portal vein thrombosis, may cause severe liver failure from necrosis. Portal vein thrombosis may cause liver dysfunction, tense ascites, and variceal bleeding.

Patients with bile leaks experience fever, abdominal pain, and peritoneal irritation. Bile leaks develop early in the postoperative course and may be identified by ultrasonography showing abdominal fluid collections or cholangiography. Bile leaks are managed with endoscopic placement of a biliary stent or relaparotomy.

Mehrabi A, Fonouni H, Muller SA, et al. Current concepts in transplant surgery: liver transplantation today. *Langenbecks Arch Surg.* 2008;393:245–260.

D.6. What immunosuppressive agents will be given after liver transplantation? What are the major side effects?

The risk of organ rejection is balanced against the risk of medication toxicity. Protocols vary from center to center. A usual regimen includes cyclosporine or FK-506 (tacrolimus), azathioprine or mycophenolate mofetil, and prednisone. Antibodies directed against T-cell lymphocytes (e.g., OKT3 or antithymocyte globulin) may be substituted for cyclosporine or tacrolimus in patients with renal dysfunction or used in short courses to treat rejection. New drugs for immunosuppression in liver transplantation are monoclonal antibodies to IL-2 receptors (CD25) of T lymphocytes (basiliximab and daclizumab). The adverse effects of these medications are listed in Table 15.1.

Table 15.1 Adverse Effects of Immunosuppressant Medications

MEDICATION	ADVERSE EFFECTS
Cyclosporine	Nephrotoxicity Hypertension
FK-506 (tacrolimus)	Nephrotoxicity Hypertension
Mycophenolate mofetil	Hypertension Leukopenia Abdominal pain Diarrhea Vomiting
Azathioprine	Leukopenia Anemia Thrombocytopenia
Prednisone	Glucose intolerance Osteoporosis Peptic ulcer disease Adrenal suppression
OKT3	Symptoms of cytokine release (fever, chills, dyspnea, wheezing, chest pain) Leukopenia
Antithymocyte globulin	Fever Chills Leukopenia Thrombocytopenia
Basiliximab	Gastrointestinal upset
Daclizumab	Gastrointestinal upset

SECTION IV

The Nervous System

CHAPTER 16

Brain Tumor and Craniotomy

Kane O. Pryor and Hugh C. Hemmings, Jr.

A 47-YEAR-OLD WOMAN

who was previously healthy presents with a 4-month history of headache, with intermittent diplopia and gait disturbance developing over the last month. She is admitted after her husband witnesses an acute episode of profound lethargy, altered cognition, and vomiting. Neurologic examination is remarkable for abnormal right-sided cranial nerve V, VII, and VIII function, nystagmus, and ataxic gait. Magnetic resonance imaging (MRI) shows a large, right posterior fossa mass that is only slightly hyperintense on T2-weighted images, but is clearly demarcated after the intravenous injection of gadolinium contrast. The impression is of a petroclival meningioma, with mass effect on the pons and fourth ventricle. Magnetic resonance angiogram shows a highly vascular tumor drawing principal blood supply from the ascending pharyngeal branch of the ipsilateral external carotid artery. The patient improves clinically following the administration of dexamethasone and mannitol, and the infusion of 2% sodium chloride and is monitored in the neurosurgical intensive care unit (ICU). The day after admission, the patient undergoes uneventful cerebral angiography and partial embolization of the tumor under general anesthesia. She is now scheduled for posterior fossa craniotomy and resection of the tumor.

A. Medical Disease and Differential Diagnosis

1. What are the determinants of intracranial pressure (ICP)?
2. How does the presence of a mass alter the ICP in this patient?
3. What are the determinants of cerebral blood flow (CBF), and how are they altered by the presence of an intracranial tumor?
4. Are there any issues specific to posterior cranial fossa pathology?
5. What are the cerebral steal syndromes?
6. What is the role of preoperative embolization therapy?

B. Preoperative Evaluation and Preparation

1. What are special considerations in the preoperative evaluation of the patient scheduled for posterior fossa craniotomy?
2. In a patient who presents with intracranial hypertension, what management may have already been initiated preoperatively and what are the implications for anesthetic management?
3. How will intraoperative electromyography (EMG), sensory evoked potential (SEP), or brainstem auditory evoked response (BAER) monitoring affect the anesthetic management plan?
4. What are the options for patient positioning during posterior fossa surgery?
5. What are the principal disadvantages associated with the common posterior fossa craniotomy positions?
6. How should the patient position ultimately be determined?
7. How does the sitting position affect your preoperative assessment and planning?
8. Should this patient receive premedication?

C. Intraoperative Management

1. What are the anesthetic goals for craniotomy?
2. What monitors should be used during craniotomy?
3. What specific risks are associated with induction of anesthesia?
4. How would you induce anesthesia?
5. What are the effects of anesthetics on cerebral metabolic rate of oxygen ($CMRo_2$), CBF, and ICP? With this in mind, how would you maintain anesthesia?
6. How would you manage ventilation and maintain arterial carbon dioxide?
7. How would you approach diuretic therapy?
8. How would you manage serum glucose?
9. How would you approach fluid management?
10. Once the bone plate is removed and the dura retracted, the surgeon reports that the brain is still "tight." What would be your response?
11. If deliberate hypotension is indicated, how will you achieve it?
12. While the surgeon is resecting tumor from near the brainstem, the patient's heart rate suddenly drops to 20 beats per minute. What is your assessment and management?
13. Would you monitor for venous air embolism? What are the monitoring options?
14. Are there any measures you can take to prevent venous air embolism?
15. During the procedure, the precordial Doppler becomes loud and turbulent. The end-tidal CO_2 ($ETco_2$) drops from 31 mm Hg to 13 mm Hg, and the systemic blood pressure from 121/63 mm Hg to 64/32 mm Hg. What is your assessment and management plan?
16. What is your approach to emergence? What if the patient does not wake up?

D. Postoperative Management

1. What postoperative complications are of greatest concern? What level of monitoring is required?

A. Medical Disease and Differential Diagnosis

A.1. What are the determinants of intracranial pressure (ICP)?

The intracranial cavity is a rigid structure with minimal compliance. The structures within this cavity can be conceived of as belonging to one of three compartments:

- The *parenchymal compartment*, which is composed of two subcomponents—
  - a cellular component, which consists of the normal neuronal and glial cellular material, but also includes abnormal cellular volume from tumors;
  - a fluid component, which consists of the intracellular and extracellular fluid—capable of significant dynamic changes as a result of inflammatory responses and osmolarity gradients
- The *cerebrospinal fluid (CSF) compartment*
- The *blood compartment*, consisting of the arterial and venous subcompartments

If the volume of any one of these compartments increases, there is limited compensatory potential, especially if the expansion is rapid. Initially, CSF can drain to the spinal CSF reservoir and venous blood to the extracranial veins. Therefore, during the early phase of intracranial volume expansion, only a minimal increase in ICP may occur. At a critical point, these compensatory mechanisms are exhausted, and even small increases in intracranial volumes will result in significant increases in ICP. Because diminished intracranial compliance reserve can be clinically silent up to this point, review of MRI or computed tomography (CT) of the brain is critically important. As ICP increases, sedation, cognitive slowing, and nausea are likely to be early signs. Further increases in ICP can eventually lead to herniation of brain tissue through a noncompliant space—rapidly resulting in irreversible injury and often death.

Normal ICP is 5 to 15 mm Hg. Normal adult brain tissue volume is approximately 1400 mL, intracranial CSF volume is 75 to 100 mL, and cerebral vascular volume is approximately 150 mL.

Ursino M, Lodi CA. A simple mathematical model of the interaction between intracranial pressure and cerebral hemodynamics. *J Appl Physiol.* 1997;82:1256–1269.

A.2. How does the presence of a mass alter the ICP in this patient?

As the intracranial cavity is essentially of fixed volume, the volume of any intracranial mass must be accommodated by reduction in the volume of other intracranial contents, as described earlier. However, because the structures within the intracranial cavity are highly organized, the three-compartment model is overly simplistic. Thus, the neurologic sequelae of a mass, including effects on ICP, will vary significantly with its anatomic location and rapidity of growth. Elevated ICP is most often the result of direct space-occupying effects, resulting from both the tumor mass and surrounding edema. Thus, slow-growing tumors, such as meningiomas, can become astoundingly large without causing substantial increases in ICP as volume remodeling occurs; this is especially true of supratentorial hemispheric tumors. In contrast, even small masses in the posterior fossa can cause a noncommunicating hydrocephalus and elevated ICP by obstructing CSF outflow at the fourth ventricle. It is important to remember that

although compensatory mechanisms can maintain a normal or near-normal ICP, the patient with an intracranial mass will always have diminished reserve to accommodate increases in the volume of other intracranial contents.

In this patient, a slow-growing meningioma has been able to attain a large size before becoming symptomatic. The patient's earliest signs and symptoms were most likely due to a localized mass effect. Nevertheless, the acute decompensation, with rapidly developing signs and symptoms of elevated ICP, probably represent the added component of CSF outflow obstruction at the fourth ventricle. Even with the clinical improvement provided by steroid therapy and osmotic diuresis, this patient certainly has very little volume reserve and intracranial compliance even small further increases in volume—such as an increase in cerebral blood volume (CBV) precipitated by a minimum alveolar concentration (MAC) of volatile anesthetic—have the potential to cause a precipitous spike in ICP.

Ropper AH. Lateral displacement of the brain and level of consciousness in patients with an acute hemispheral mass. *N Engl J Med.* 1986;314:953–958.

Schaller B, Graf R. Different compartments of intracranial pressure and its relationship to cerebral blood flow. *J Trauma.* 2005;59:1521–1531.

A.3. What are the determinants of cerebral blood flow (CBF), and how are they altered by the presence of an intracranial tumor?

The brain receives a disproportionate percentage of cardiac output because of its high metabolic requirement (~3.5 mL O_2/min/100 g brain tissue). CBF flow is coupled to $CMRO_2$. At a wide range of mean arterial pressures (MAPs), the cerebral circulation alters its resistance to maintain a constant CBF—a process known as *autoregulation*. It has classically been taught that in the otherwise healthy brain, autoregulation maintains a relatively constant CBF between MAPs of approximately 50 and 150 mm Hg; above and below these values, CBF is pressure dependent. Based on recent studies in humans, the extremes of this range should be approached with caution, especially the lower boundary; CBF can decrease at MAPs of 60 or even 70 mm Hg. Special caution is required in patients with chronic systemic hypertension, in whom autoregulation right-shifts to accommodate the higher MAPs. Without active blood pressure support, many of these patients are at risk for extended periods during surgery at pressures below their autoregulation threshold.

CBF also varies with changes in $Paco_2$ between values of approximately 25 and 100 mm Hg. Increasing the partial pressure of carbon dioxide ($Paco_2$) from 40 to 80 mm Hg will roughly double CBF, and decreasing from 40 to 20 mm Hg will halve CBF. Importantly, the presence of hypercapnia decreases pressure-dependent autoregulation.

The presence of an intracranial mass can cause localized regions of high tissue pressure gradients, inflammation, and ischemia. These all contribute to dysfunction of normal autoregulation such that, in the brain regions surrounding the mass, regional CBF becomes pressure dependent over a greater range of pressures than in normal tissue. Further, if ICP becomes elevated above the level of the central venous pressure (CVP), the cerebral perfusion pressure (CPP = MAP − the greater of ICP or CVP) decreases. The ability of autoregulation to compensate for decreases in CPP is limited; therefore, if ICP is elevated, CBF can be low even in the presence of normally adequate MAPs. A conservative approach to management of CPP would suggest that it should not be allowed to fall below 70 mm Hg for any extended period in the baseline normotensive patient. Although a more moderate approach targeting CPPs in the 60- to 70-mm Hg range is commonly used, most neuroanesthesiologists agree that sustained CPP values under 60 mm Hg place the brain at risk, despite the possible neuroprotection afforded by the presence of a GABAergic anesthetic agent.

Sharma D, Bithal PK, Dash HH et al. Cerebral autoregulation and CO_2 reactivity before and after elective supratentorial tumor resection. *J Neurosurg Anesthesiol*. 2010;22:132–137.

A.4. Are there any issues specific to posterior cranial fossa pathology?

Surgery for tumors in the posterior fossa presents several challenges not seen with supratentorial surgery. The posterior fossa is a tightly enclosed space in which tumors are often in direct contact with critical brainstem structures, including the cranial nerves and brainstem nuclei. The margin for error when operating near these structures is extremely small, as can be the spatial reserve for postoperative inflammation. The patient with a posterior fossa tumor, especially one close to the brainstem, can worsen neurologically in the hours following surgery as a result of postsurgical inflammation causing edema. This possibility must be considered when determining the appropriateness of extubation and postoperative management. Even with a successful resection and apparently adequate hemostasis, it might be appropriate to leave the patient intubated in anticipation of neurologic compromise as edema develops around the resected tumor bed.

In addition to the risk of neuronal damage, surgery in proximity to brainstem nuclei can trigger significant intraoperative autonomic and collateral hemodynamic instability, which can be extremely challenging to manage. The most common autonomic event is an acute increase in vagal tone, which in some instances can lead to a prolonged period of asystole, and can be immediately followed by a reflexive surge in sympathetic tone. Further, the risk to cranial nerves and other structures often demands intraoperative neurophysiologic monitoring—such as SEPs, brainstem auditory evoked potentials, or EMG—all of which can substantially restrict and dictate anesthetic management.

Finally, the posterior fossa cannot be accessed with the patient in the conventional supine position. In the past, the sitting position was highly favored by neurosurgeons and presented marked anesthetic challenges because of the increased risk of venous air embolism. Although still common in some centers, the sitting position has fallen out of favor; nonetheless, all of the positions that permit access to the posterior fossa pose management difficulties that must be considered. The risk of venous air embolism, although reduced, often still exists. Other considerations include loss of jugular outflow, deterioration of pulmonary compliance, strain on the cervical spine and brachial plexus, and a lack of access to central venous lines and the airway. In patients who are critically ill or otherwise at risk for life-threatening intraoperative events, it must be remembered that cardiopulmonary resuscitation will always require that the patient be rapidly returned to the supine position.

A.5. What are the cerebral steal syndromes?

Any intracranial pathology, including marginal ischemia and inflammation surrounding a mass lesion, can cause localized dysfunction of normal cerebral autoregulation and response to vasoactive agents. The microvasculature in the pathologic region can have an essentially fixed resistance. In this case, if vasodilation occurs in other normal regions of the brain, the decreased vascular resistance in the normal tissue can theoretically shunt blood flow away from the pathologic regions, which are already most vulnerable. This phenomenon is known as *cerebral steal*. In anesthesia management, cerebral steal is most relevant in the context of hypercapnia and the use of high concentrations (greater than 1 MAC) of volatile anesthetics. Both of these cause vasodilation of normal vasculature and potentially cause decreased regional CBF in pathologic areas. During hypocapnia, when there is vasoconstriction in normal tissue, the opposite may occur. In this case, blood flow to pathologic regions can actually increase. This phenomenon is known as *inverse steal* or the *Robin Hood effect*. Although there is a sound basis in the animal literature, the clinical relevance of steal and inverse steal phenomena in human patients has never been established. Nonetheless, it is prudent to consider it in anesthetic management.

A.6. What is the role of preoperative embolization therapy?

Highly vascular tumors, especially those that are anatomically difficult to access, present a high risk for substantial intraoperative bleeding. In addition to the systemic risks associated with gross blood loss, surgical exposure can be severely compromised and neuronal and neurovascular inflammation and irritation can be exacerbated by excessive tracking of blood into brain tissue.

To reduce this risk, patients often undergo embolization of the vessels feeding the tumor in the days immediately before surgery. An arterial catheter is inserted, usually in the femoral artery, and guided under fluoroscopy until it rests in any of the vessels that have evolved to supply only the tumor and not normal brain. At this point, a viscous embolic agent is slowly delivered to occlude the vessel, reducing its vascular supply, and thus the degree of bleeding during the operative resection. Because of collateralization and reestablishment of blood supply, embolization is effective for only a short period and is usually performed within 48 hours before the intracranial resection. Tumor embolization comes with its own risks and challenges: Vascular anatomy might not always permit embolization, and the embolization itself can precipitate swelling around the tumor and hyperemic changes in blood flow dynamics. These changes are particularly relevant in this patient with a posterior fossa tumor proximate to the brainstem. Deposition of embolic agent into vessels supplying normal brain amounts to an embolic stroke can have catastrophic consequences. Further, embolizations almost always require general anesthesia, and thus assume all of the associated general and neurospecific risks.

B. Preoperative Evaluation and Preparation

B.1. What are special considerations in preoperative evaluation of the patient scheduled for posterior fossa craniotomy?

In addition to the routine thorough preoperative evaluation, the evaluation of the patient for craniotomy should answer several questions that critically influence anesthesia management:

- What is the ICP? If ICP is still in the normal range, how much intracranial compliance reserve is likely to exist?
- How is autoregulation likely to be affected by the pathology and chronic changes in blood pressure? What range of arterial pressures will be required to preserve adequate CPP and CBF?
- Does the patient have any of the electrolyte and endocrine abnormalities associated with intracranial pathology or treatment, such as neurogenic diabetes insipidus, or hypernatremia resulting from hypertonic saline therapy?
- Is the lesion highly vascular, difficult to access, or situated proximate to one of the large draining veins—all of which increase the probability of significant bleeding?
- What is the likely positioning, and does it incur a risk of venous air embolism, obstruction of jugular venous outflow, or neck hyperextension?
- Is the tumor located in a position close to the brainstem such that severe autonomic dynamics are likely?
- Will the baseline neurologic status affect the ability to extubate or to establish an early neurologic assessment after general anesthesia?
- Will the anesthetic technique need to accommodate specific monitoring requirements, such as electroencephalography (EEG), electrocorticography, BAERs, or SEPs?

B.2. In a patient who presents with intracranial hypertension, what management might have already been initiated preoperatively and what are the implications for anesthetic management?

A patient with evidence of intracranial hypertension will be aggressively monitored and treated preoperatively; it is likely that the preoperative assessment will occur in an intensive care setting. The anesthesiologist must be familiar with the management of intracranial hypertension. These therapies will likely need to be initiated or continued in the operating room. Further, the anesthesiologist must be mindful of potential sequelae that can arise from various perioperative therapies and interventions such as:

- *Corticosteroids*. They can result in hyperglycemia, which should be aggressively treated to maintain plasma glucose less than 150 to 180 mg/dL.

- *Head elevation*. Care should be taken to avoid rapidly lowering the head during transport.
- *Diuretics (mannitol, furosemide)*. These can result in electrolyte or acid–base abnormalities. Decreased preload can increase the risk of hypotension in the peri-induction period.
- *Isotonic or hypertonic saline therapy*. This can result in hypernatremia or a hyperchloremic, non–anion gap metabolic acidosis.
- *Intubation and institution of hyperventilation*. If prolonged, CBF response can be diminished or absent, with risk for increase in CBF and ICP if hyperventilation is rapidly ceased. It can lead to underlying compensatory metabolic acidosis. Care should be taken to avoid hypoventilation during transport.
- *Ventriculostomy*. This is usually clamped during transport to or from the ICU, as the level of the drain relative to the head is critical, and accidental changes in position can result in excessive draining of CSF. It should be attended to on arrival to the operating room, because even relatively short periods of clamping can result in elevations of ICP.
- *Manipulation of systemic pressures to optimize CPP*. Care should be taken to ensure drug infusions are maintained during transport to avoid rebound hypertension or hypotension.
- *Drug-induced cerebral vasoconstriction and coma*. Thiopental is usually used. This signifies a critical neurologic status. The therapy is often continued as the primary anesthetic.
- *Deliberate hypothermia*. This signifies a critical neurologic status. Requires discussion of intraoperative temperature management goals with the neurosurgeon and neurointensivist, because the neuroprotective benefits may be countered by hypothermia-induced coagulopathy.

B.3. How will intraoperative electromyography (EMG), sensory evoked potential (SEP), or brainstem auditory evoked response (BAER) monitoring affect the anesthetic management plan?

The most common EMG monitoring during posterior fossa surgery is for cranial nerve VII, although monitoring of V, IX, X, and XI is frequently encountered. Usually, the surgeon will deliver a very low current to a structure they believe could be the cranial nerve of interest, and muscular activity is monitored in the distribution of the nerve; mechanical manipulation of a nerve will often also cause muscular activity. Therefore, during EMG monitoring, neuromuscular blockers should not be used beyond the anesthetic induction. Some anesthesiologists advocate the use of succinylcholine for intubation; nevertheless, a low intubating dose of a medium-duration nondepolarizing agent such as vecuronium or cisatracurium allows adequate return of muscular function by the time monitoring is relevant and avoids the issues associated with succinylcholine.

The most common evoked potential monitoring encountered during resection of posterior fossa tumors is the BAER, which monitors cranial nerve VIII. Somatosensory evoked potentials (SSEPs) can also be used to monitor cortical integrity. Although BAERs are reasonably robust, many common anesthetic drugs cause decreases in

amplitude and increases in latency of the evoked responses, thereby mimicking neuronal ischemia or trauma. Volatile agents should be kept at less than 0.5 MAC, and nitrous oxide should not be used. The anesthetic plan will often rely heavily on opioids; propofol and dexmedetomidine infusions are also often incorporated, the latter of which may also offer improvements in overall hemodynamic stability. Perhaps more important than the specific anesthetic regimen is that a maintenance equilibrium is established for the baseline neurophysiology measurements and is then kept constant throughout the procedure. Pseudo-equilibrated steady-state continuous infusions are key to this strategy.

B.4. What are the options for patient positioning during posterior fossa surgery?

- *Sitting position*. Although used far less often now than two decades ago, it is critically important for the anesthesiologist to understand the sitting position: partly because it could still be encountered and partly because it provides the archetype for the risks and management of venous air embolism. The patient is in a reclined sitting posture such that the feet are at or near the level of the heart. The head is held in a flexed position with a skull fixation device, and the arms are crossed over the chest.
- *Prone position*. This is especially suitable for lesions in the midline, but can be adapted for more lateral approaches by having the head slightly rotated. Depending on body habitus, supporting rolls are placed horizontally across the chest and hips or in parallel along the longitudinal axis of the body. The head is held with a skull fixation device with the neck in a neutral to flexed position.
- *Lateral decubitus position*. This position is suited to cerebellopontine angle tumors and cerebellar hemispheric lesions.
- *Park bench (semiprone) position*. The patient is turned toward a more prone position, moving the upper shoulder out of the surgeon's view and permitting better access to midline lesions.
- *Supine position*. This can sometimes be used with the patient's head rotated. To reduce the amount of rotation of the neck, which can obstruct venous outflow, a supporting roll can be placed under the ipsilateral shoulder and the whole bed rotated away from the surgeon.

B.5. What are the principal disadvantages associated with the common posterior fossa craniotomy positions?

In the sitting position, the head is elevated well above the right atrium and usually greater than the height of the central venous fluid column. This will reduce venous bleeding; it will also enable large volumes of air to be entrained into the central venous circulation, especially through the large dural sinuses, which are tented open. When propagated to the right heart and pulmonary circulation, venous air embolism can range in severity from subclinical to severe, precipitating acute hemodynamic

collapse and death. In a patient with a patent foramen ovale—which can exist undetected—air can traverse to the arterial circulation, causing embolic strokes. Although venous air embolism can occur with other positions, the risk and severity are substantially higher in the sitting position. The risk is such that a right heart catheter, with the tip situated precisely at the entrance to the right atrium, is regarded by many neuroanesthesiologists as obligatory. Nonetheless, the placement of these catheters, which might not otherwise be required, incurs associated risks of pneumothorax, infection, bleeding, and arrhythmias and is of limited utility unless the placement is accurate (simple routine placement of a central line rarely offers benefit). Indeed, the treatment of venous air embolism is complicated by the sitting position, because it is difficult to rapidly move the patient's head below the level of the heart. The sitting position is also associated with increased hypotension. As neurosurgeons have gained experience in accessing the posterior fossa from other positions, the risks associated with the sitting position have caused its popularity to dramatically decrease.

In the prone position, the head is usually slightly elevated above the heart; therefore, the risk of venous air embolism is present, although the risk of massive entrainment is much less than in the sitting position. Prone positioning can cause a significant decrease in pulmonary compliance and will increase ventilation–perfusion mismatch, leading to atelectasis, venous admixture, and shunting. Virtually no access is available to the airway, chest, or limbs, and in the event of an airway, pulmonary, or cardiovascular emergency, the prone position places the anesthesiologist in a substantially compromised position.

The supine position alleviates many of these issues. Nevertheless, to access even the lateral posterior fossa from the supine position usually requires substantial rotation of the neck. This can cause obstruction of jugular venous outflow, leading to cerebral venous engorgement, with potentially undesirable effects on ICP, CPP, surgical exposure, and bleeding. The neck rotation can also cause brachial plexus injury as well as significant pressure on laryngeal structures with potential vocal cord injury. Placing supports to elevate the ipsilateral shoulder can reduce rotation at the neck.

B.6. How should the patient position ultimately be determined?

Surgical exposure must determine the first preference for patient position. Nonetheless, the interruption of a posterior fossa craniotomy for anesthesia crisis management poses extreme risk, and thus the anesthesiologist is obligated to discuss concerns with the neurosurgeon and advocate alternative positioning if appropriate. One approach is to trial the preferred position before commencing any surgical management. For example, a patient with compromised pulmonary compliance or reserve can be positioned prone and monitored during other preparations, with alternative positioning sought if the trial fails. The risk of venous air embolism is such that we are very reluctant to use the sitting position except where the surgical exposure considerations are overwhelming.

B.7. How does the sitting position affect your preoperative assessment and planning?

The first step is to establish whether the patient has any contraindications to the sitting position that might have been overlooked. The presence of intracardiac defects, pulmonary arteriovenous malformations, or carotid artery stenosis should be sought. The presence of a patent foramen ovale can lead to a catastrophic paradoxical air embolus if air is entrained; therefore, some neuroanesthesiologists advocate routine preoperative echocardiography if the sitting position is to be used, although in practice this is not commonly performed. The presence of any of these comorbidities—especially the presence of a right-to-left intracardiac shunt—argues against the sitting position, and a thorough risk–benefit assessment must be discussed with the neurosurgeon. Severe hypovolemia, cachexia, and extremes of age can diminish the ability of autonomic reflexes to maintain adequate cerebral and upper lung perfusion in the upright position, making intraoperative cardiopulmonary management extremely difficult. It must be remembered that the critical pressure is the CPP, not the MAP, and that blood pressure must therefore be evaluated at the level of the head. MAPs will need to be higher than would be required in the horizontal positions.

Anesthetic planning must recognize the physiologic implications of the sitting position. Venous pooling will result in lower left atrial filling pressures, leading to reduced stroke volume and cardiac output. Although there will be an increase in both systemic and pulmonary vascular resistance, the net effect is a tendency to arterial hypotension, with decreased CPP. The temptation to counter reduced preload with intraoperative fluid administration could run counter to attempts to diurese and result in an exaggerated increase in cardiac filling when the patient is repositioned supine at the conclusion of surgery. Conversely, because the hypotension is not the result of afterload reduction, use of vasopressors, while increasing arterial pressures, can reduce end-organ blood flow. Because of the beneficial effects of gravity, pulmonary compliance and functional residual capacity are greater in the sitting position than in horizontal positions; the simultaneous cardiovascular effects can lead to increased ventilation-perfusion mismatch, countering any significant benefit.

If the sitting position is to be used, there must be a preoperative plan for the detection and management of venous air embolism, should it occur. The patient's neck must be evaluated for any difficulties in the placement of a right atrial catheter. In some patients—such as those who have previously had chemotherapy or dialysis through central catheters, have received neck irradiation, or are morbidly obese—emergent placement of a right atrial catheter can be extremely difficult or impossible. This necessitates the consideration of alternative positions or preoperative radiologically guided placement.

B.8. Should this patient receive premedication?

A professional and unrushed visit by the anesthesiologist is the optimal approach to preoperative anxiolysis. With rare exceptions, pharmacologic approaches to anxiolytic, sedative, and analgesic premedication should be avoided or restricted to

short-acting agents in patients with intracranial pathology. It is absolutely critical to be able to assess whether a failure to emerge from anesthesia is the result of pharmacologic sensitivity or neurologic injury, and residual effects from benzodiazepines and other psychoactive drugs can confound the ability to accurately assess changes in the neurologic examination. Opioids will precipitate some degree of hypoventilation, leading to hypercapnia and a consequent increased CBF and CBV. In a patient with minimal intracranial compliance reserve, such as this patient, even a small increase in CBV secondary to hypoventilation might precipitate a dangerous increase in ICP. Preinduction opioid dosing should be performed only with complete monitoring and under the direct supervision of an anesthesiologist who is able to rapidly intervene and take over ventilation. Oral dosing of gabapentin and clonidine will attenuate the hemodynamic instability resulting from laryngoscopy and head pinning when given before anesthetic induction. The effects of clonidine can likely be mimicked by starting an infusion of dexmedetomidine—also an α_2-adrenergic agonist—as soon as the patient arrives in the operating room.

C. Intraoperative Management

C.1. What are the anesthetic goals for craniotomy?

Clearly the anesthetic goals for craniotomy include the basic principles of physiologic stability that are common to all anesthetic management. Craniotomy incurs several specific goals that follow from the effects—both helpful and unhelpful—of anesthetic drugs on the brain. Stated succinctly, the anesthetic goals specific to craniotomy are to protect the brain from injury resulting from mechanical or physiologic insult during the perioperative period. *Direct* protection (often referred to simply as *neuroprotection*) can be conceptualized as actions that facilitate the ability of neural tissue to withstand ischemic episodes without neurosis or activation of the apoptotic cascade leading to infarction. Less discrete is the concept of *indirect* protection, which aims to minimize the anteceding ischemic episodes. The principal elements are as follows:

- Management of CBF and CPP
- Management of ICP while the skull is intact
- The provision of a "relaxed" brain. This optimizes surgical exposure, which is critically important in many cases because the field of view available to the surgeon in many craniotomy approaches can be extremely narrow. Further, relaxation reduces the pressure—resulting in ischemia exerted by the retraction devices on underlying brain tissue
- Implementation and timing of pharmacologic measures specifically intended to effect direct neuroprotection, traditionally involving anesthetic-induced induction of a burst-suppression pattern on the EEG (although experimental data suggest that anesthetics can be protective without burst suppression)
- Strict management of physiologic parameters that may contribute to brain injury, such as serum glucose, osmolarity, and acid–base balance

- Minimize the effect of anesthetic pharmacology, cerebral perfusion, and temperature on neurophysiologic monitoring, such as EEG, BAERs, or SSEPs
- Facilitate early neurologic assessment

C.2. What monitors should be used during craniotomy?

As with all patients undergoing general anesthesia, monitoring must include electrocardiography, blood pressure, pulse oximetry, temperature, and capnography. Placement of an arterial line is routine for tumor craniotomies and should be regarded as mandatory for everything except the most superficial and nonvascular supratentorial tumors. The case for arterial line placement is not restricted to hemodynamic arguments, because access to arterial blood for monitoring of carbon dioxide, glucose, acid–base physiology, and electrolytes usually affects management. Arterial lines can often be placed following induction, but are appropriate before induction in patients with significantly deranged autoregulation or minimal intracranial compliance reserve. In such patients, CBF and CPP are pressure dependent during this highly dynamic period. Clearly, other comorbidities also necessitate placement of a preinduction arterial line. The transducer should be set to zero at the level of the circle of Willis, which in sitting or semisitting positions is significantly higher than the level of the heart. The decision on whether to place a central venous line for CVP or right heart monitoring is generally determined by the patient's overall physiologic state; it usually offers very little, if any, benefit in the majority of patients. One notable exception is during posterior fossa procedures in the sitting position. Central access is required for the administration of some drugs, such as hypertonic saline.

In any case with risk for a venous air embolism, precordial Doppler monitoring or some other detection method such as transesophageal echocardiography or end-tidal N_2 monitoring should be used. That said, our experience is that suboptimal placement conditions and the high degree of interference render the precordial Doppler inadequately sensitive or specific, and it must be interpreted in the context of $ETco_2$ and hemodynamic parameters. The use of neurophysiology monitoring such as EEG, EMG, BAERs, or SSEPs is determined by the location of the tumor; although these methods are often performed by neurophysiologists, the anesthesiologist must understand the principles behind them and be aware of the effects of anesthetics, other drugs, and physiologic variables on their integrity.

C.3. What specific risks are associated with induction of anesthesia?

The patient with intracranial pathology will have a diminished ability to tolerate or compensate for the hemodynamic changes that can occur during induction. Hypotension can result in inadequate CPP and precipitate hypoperfusion cerebral ischemia in brain tissue that already has marginal perfusion, whereas hypertension and sympathetic activation can precipitate hyperemia, increased CBF and CBV, and

consequently increased ICP. Implications of rapid changes in $Paco_2$ are often underappreciated: high-dose opioids are frequently used to blunt the sympathetic response to laryngoscopy and to reduce the required MAC fraction of volatile agents. When given before induction, opioids can precipitate hypoventilation and an acute increase in $Paco_2$, leading to increased CBF and CBV. Significant doses of opioids should never be administered until the patient is under direct care of the anesthesiologist, because this increase in CBV may be sufficient to lead to decompensation in a patient with minimal ICP reserve. Episodes of coughing, especially relevant if the airway has to be secured by an awake technique, precipitate short but dramatic increases in ICP and cannot be tolerated. Hypoxia will be very poorly tolerated by brain tissue with marginal reserve.

Lanier WL, Albrecht RF 2nd, Laizzo PA. Divergence of intracranial and central venous pressures in lightly anesthetized, tracheally intubated dogs that move in response to a noxious stimulus. *Anesthesiology.* 1996;84:605–613.

C.4. How would you induce anesthesia?

To a large extent, the specific drug combinations used during induction are probably less important than the ultimate goal of maintaining tight hemodynamic stability during the peri-induction period. Dexmedetomidine can reduce hemodynamic instability during craniotomy and might afford some degree of neuroprotection. Because of its pharmacokinetics, one favored approach is to begin a dexmedetomidine infusion as soon as possible after the patient enters the operating room. The use of midazolam or another benzodiazepine as an anxiolytic and amnestic is frequently questionable, because its prolonged elimination has the potential to delay emergence and cloud the early neurologic examination in a patient with reduced cognitive reserve, especially after the additional insult of a retracted and handled brain. It should certainly not be used in elderly patients or those who already exhibit compromised neurologic function.

With adequate ventilation, the use of high-dose opioids during induction (e.g., fentanyl slowly titrated to a total dose of 5 to 10 μg per kg) offers many advantages: The sympathetic response to laryngoscopy and head pinning is blunted, and the requirement for other anesthetics is reduced. If the anesthetic plan involves the use of a volatile anesthetic, this latter point is of particular significance, because concentrations of volatile anesthetics should be kept low to avoid the undesirable effect of increased CBV, leading to elevated ICP. With high-dose opioid techniques, the airway can usually be taken over by the addition of a small dose of propofol, which serves as an excellent amnestic. A volatile anesthetic agent can be added to create a mixed intravenous-inhalational induction, but because of the effects on CBV (discussed later), caution should be used to keep values less than 1 MAC. Etomidate should be considered in patients with significant cardiac comorbidities or who are otherwise critically ill. A nondepolarizing muscle relaxant should be used for intubation; succinylcholine is not absolutely contraindicated, but because it can cause a transient increase in ICP, an effect that can be minimized by coadministration of lidocaine, its use should be reserved for situations in which it is strongly indicated. Although hypoventilation is obviously undesirable, care should also be taken to avoid excessive hyperventilation, because it can reduce CBF sufficient to cause hypoperfusion and ischemia.

This induction strategy, as with most others, incurs the risk of decreasing systemic vascular resistance and precipitating hypotension. In patients who are highly dependent on sympathetic vascular tone, the effective sympathectomy created by high-dose opioids can lead to hypotension, even if the need for drugs with direct vasodilatory properties—such as propofol or the volatile agents—is reduced.

The use of phenylephrine 40 to 120 μg during induction can be helpful. Alternatively, if high-dose opioids are not desired, lidocaine 1.5 mg per kg can be given 1 to 2 minutes before laryngoscopy and head pinning.

C.5. What are the effects of anesthetics on cerebral metabolic rate of oxygen ($CMRO_2$), CBF, and ICP? With this in mind, how would you maintain anesthesia?

Volatile Anesthetics

All volatile anesthetics reduce $CMRO_2$, with isoflurane having the most substantial effect at normal clinical doses. At concentrations up to 1 MAC, some degree of autoregulation is maintained such that there is a relationship between $CMRO_2$ and CBF. Nevertheless, volatile agents also have a direct vasodilatory effect, and at any given $CMRO_2$ the CBF will increase with increasing concentration of anesthetic agent. This effect is exaggerated at concentrations exceeding 1 MAC. The net result is that, despite a decrease in $CMRO_2$, there is an overall increase in CBF, greater in deeper structures than in the cerebral cortex. In most patients, this increased CBF would be potentially beneficial to the extent that it improves the supply–demand balance (often termed *luxury perfusion*). Nevertheless, in patients with intracranial pathology, this increase in CBF causes an increase in CBV and potentially elevation in ICP while the cranial bone is intact or can impede surgical exposure once the bone plate is removed. Finally, $PaCO_2$ reactivity is preserved in healthy brain at concentrations less than 1 MAC, but pathologic brain can have diminished or absent carbon dioxide responsiveness.

Nitrous Oxide

Studies have shown substantial variation in the effects of nitrous oxide (N_2O), which probably relates to the heterogeneity of the anesthetic combinations in which it has been studied. The balance of evidence suggests that N_2O increases $CMRO_2$, CBF, and ICP. ICP increases can be marked, especially if used in combination with a volatile agent; the effect can be attenuated by the addition of an intravenous anesthetic. At best, N_2O offers no neuroprotection, and at worst, its effects might be neurotoxic and counterproductive to surgical exposure. The use of N_2O has also been shown to worsen outcomes of other perioperative complications, including wound infection and deep venous thrombosis. With availability of alternative short-acting intravenous, volatile, and opioid anesthetics, N_2O is relatively contraindicated in craniotomy for intracranial pathology.

Intravenous Anesthetics

The intravenous anesthetics that act through GABAergic mechanisms (e.g., barbiturates, propofol, etomidate) cause a dose-dependent reduction in $CMRO_2$, CBF, CBV, and ICP. In contrast to volatile anesthetics, CBF–$CMRO_2$ coupling is preserved in the basal state, with no added vasodilatory effect. Thus, the direct drug effect of a drug such as propofol is to cause a reduction in $CMRO_2$, and the decreases in CBF, CBV, and ICP follow from intact normal physiologic responses. Carbon dioxide reactivity is preserved. $CMRO_2$ can be reduced to as low as 40% of resting values in the presence of

an isoelectric EEG. The preservation of CBF–$CMRO_2$ coupling affords many benefits, but also carries an underappreciated risk: If hyperventilation is instituted, it will have an additive effect on the decreases in CBF caused by an intravenous anesthetic. The result is an appreciable risk of inadequate CBF and hypoperfusion ischemia. It must be remembered that the mantra of "craniotomy → hyperventilation" owes its legacy to a time when most neuroanesthetics involved the use of MAC equivalents of vasodilating volatile agents. Etomidate can impair collateral perfusion of ischemic brain in animal experiments through inhibition of nitric oxide synthase and is thus relatively contraindicated in cerebral ischemia.

The N-methyl-D-aspartic acid (NMDA)-antagonist ketamine can increase $CMRO_2$, CBF, and ICP, although in small doses concerns about these effects are probably overstated. Indeed, while ketamine may change the oxygen supply–demand relationship in an adverse way, recent studies suggest that ketamine possesses direct neuroprotective effects, especially when combined with GABAergic agents. There is no definitive evaluation of its clinical use; nevertheless, judicious use of ketamine can probably be justified where there are appropriate indications.

Opioids

The effects of opioid drugs on $CMRO_2$, CBF, and ICP are generally far less significant than those of other intravenous or gaseous anesthetics. Most evidence suggests that opioids have no effect or only slightly reduce $CMRO_2$, CBF, and ICP. In the awake patient, opioids cause hypoventilation, elevated $PaCO_2$, and a consequent increase in CBF and potentially in ICP. As discussed earlier, vigilance must be maintained during preinduction sedation and in the immediate postextubation period.

Many neuroanesthesiologists favor a maintenance strategy of total intravenous anesthesia (TIVA) in an oxygen and air mixture, which is difficult to fault provided that hyperventilation is not excessive. A TIVA approach maximizes the ability to reduce $CMRO_2$ without impairing surgical exposure through increased CBF or causing cerebral steal, but it incurs the disadvantage of complex pharmacokinetics. Other neuroanesthesiologists (including the authors) favor a mixed volatile-intravenous regimen as a primary strategy in most patients. We typically use 0.3 to 0.5 MAC equivalent of a volatile agent, with propofol titrated to the EEG as an endpoint. Dexmedetomidine and (usually high-dose) opioids are added to blunt hemodynamic responses and confer hemodynamic stability. This strategy causes a reduction in $CMRO_2$, but with minimal impairment of surgical exposure. Unless precluded by monitoring, a nondepolarizing muscle relaxant is added to ensure that the patient does not move while the head is fixed. We revert to TIVA if there is inadequate brain relaxation or if monitoring dictates.

C.6. How would you manage ventilation and maintain arterial carbon dioxide?

A reduction of $Paco_2$ decreases CBF and CBV within minutes. Therefore, hyperventilation is a rapidly effective measure that can be instituted to decrease ICP and undoubtedly can improve surgical exposure. Nevertheless, hyperventilation has substantial limitations. At $Paco_2$ values less than 25 mm Hg, cerebral ischemia can result from a critical reduction in CBF combined with impaired oxygen unloading caused by a large left shift of the oxyhemoglobin dissociation curve resulting from respiratory alkalosis. Prolonged hyperventilation results in metabolic acidosis through normal compensatory mechanisms and can result in rebound acidosis if hyperventilation is rapidly terminated. Further, hyperventilation-induced alkalosis decreases in ionized Ca^{2+}, leading to hemodynamic difficulties and prolonged emergence from effects on synaptic function.

It is important to remember that the difference between $Paco_2$ and $ETco_2$ can vary greatly. Therefore, arterial blood gas analysis should be performed as soon as possible after induction to establish the arterial–end-tidal gradient in carbon dioxide partial pressure. A $Paco_2$ of approximately 35 mm Hg is reasonable unless ICP is elevated. If, once the bone plate is removed, the surgeons determine that exposure is suboptimal, hyperventilation to a $Paco_2$ of 30 mm Hg is usually helpful. Further hyperventilation is reserved for situations in which establishing adequate exposure is extremely difficult. To avoid postoperative acid–base instability, hyperventilation can be gradually reduced throughout the closure, permitting reestablishment of bicarbonate and Ca^{2+} equilibrium.

C.7. How would you approach diuretic therapy?

The purpose of diuretic therapy in intracranial procedures is to dehydrate the brain, thereby leading to a reduction in the volume of the fluid compartment. This facilitates surgical exposure and reduces the requirement for brain retraction. Through the same principal, mannitol is used as therapy for elevated ICP states when the cranium is closed.

Mannitol is an osmotic diuretic that is usually prepared in a 20% solution (20 g per 100 mL). It should initially be given in a dose of 0.5 to 1 g per kg; the total dose

can be increased to 1.5 g per kg if initial efforts are ineffective. Higher doses have been reported to lead to cardiac arrest from disruption of cardiac cellular function. Because mannitol initially draws water into the vascular space before it is excreted, rapid dosing can cause a transient increase in ICP, so it should be infused over 20 to 30 minutes. If there is very little intracranial compliance reserve, aggressive dosing should be synchronized with the removal of the bone plate.

If mannitol does not provide adequate surgical conditions, the loop diuretic furosemide can be used. In a naïve adult patient, a dose as low as 5 mg might be adequate. Furosemide does not have the problem of an initial increase in vascular volume and so is preferred in patients with marginal cardiac function who can develop congestive heart failure with a large mannitol load. The combination of mannitol and furosemide can cause electrolyte abnormalities and severe systemic dehydration, necessitating fluid resuscitation. Because mannitol therapy alone is often adequate, we do not administer furosemide routinely, instead reserving its use for situations when surgical exposure is suboptimal.

In cases of extreme cerebral edema, hypertonic saline in concentrations of up to 20% can be used—although the most common concentrations used are 2% or 3%. This can be effective in refractory intracranial hypertension and might even be superior to mannitol for routine diuresis. Its use requires caution because of the risk of severe hypernatremia, and central access is required. Thus, it is relatively unusual for hypertonic saline to be initiated intraoperatively. Patients who are already receiving hypertonic saline should usually have the infusion maintained during the operative period.

C.8. How would you manage serum glucose?

For reasons that are incompletely understood, hyperglycemia worsens both neurologic and nonneurologic critical care outcomes. This is almost universally relevant in patients with intracranial pathology, because even nondiabetic patients undergoing craniotomy are at risk for hyperglycemia secondary to corticosteroid therapy. No study has clearly identified the level of serum glucose that requires intraoperative treatment in craniotomy patients. Nevertheless, extrapolation from the ICU and brain trauma literature suggests that tight glucose control to a serum level of approximately 150 mg per dL is likely to confer benefit and unlikely to cause harm. Although some advocate for even tighter control (with target levels approximately 120 mg per dL), this approach can increase the risk of hypoglycemic episodes, which carry significant morbidity. Glycemic control is too often overlooked in the operating room, where it likely presents a significant opportunity to influence outcomes.

C.9. How would you approach fluid management?

If the blood–brain barrier (BBB) is intact, the principal determinant of brain tissue water is the osmotic gradient across the BBB. It is this importance of osmotic gradient that guides the use of hypertonic solutions such as mannitol or hypertonic saline to reduce interstitial water and reduce ICP or to optimize surgical exposure. By the same principle, hypotonic solutions such as lactated Ringer's solution are rarely used because they favor the transport of water into the brain interstitium, thereby promoting the development of edema.

In regions where the BBB is not intact because of pathology and surgical tissue injury, osmotic particles can cross from the capillaries into the interstitial tissue. Therefore, the benefits of hypertonic solutions are lost in these areas. It follows that the benefit obtained from the use of hypertonic solutions is because of an *overall* effect on the brain, not from a *specific* effect in localized regions of brain injury.

These considerations favor the use of isotonic normal (0.9%) saline as maintenance fluid in craniotomies. More controversial is the approach to volume management. Historically, craniotomy patients have been kept deliberately hypovolemic in the belief that this will increase the passage of free water from the brain in situations involving a disrupted BBB. Relatively recent evidence suggests that there is in fact very little reduction in interstitial water, and that it comes at the price of significant systemic hypoperfusion and hypotension. Therefore, the favored approach to fluid management is now maintenance of isovolemia with normal saline. In prolonged cases, the chloride loading can result in mild hyperchloremic non–anion gap metabolic acidosis. Dextrose-containing solutions should never be used except to treat hypoglycemia. Colloids such as 5% albumin can be used when volume expansion is a requirement. Albumin has a plasma half-life of 16 hours, and little is known about how the passage of albumin across a damaged BBB influences interstitial water movement over this time period. Therefore, its routine use is not recommended.

Scheingraber S, Rehm M, Sehmisch C, et al. Rapid saline infusion produces hyperchloremic acidosis in patients undergoing gynecologic surgery. *Anesthesiology.* 1999;90:1265–1270.

C.10. Once the bone plate is removed and the dura retracted, the surgeon reports that the brain is still "tight." What would be your response?

In almost all cases, the most effective initial response is to increase hyperventilation to a $Paco_2$ of approximately 27 to 30 mm Hg. If mannitol 1 g per kg has already been administered, furosemide can be given until a diuresis is established. If a volatile agent is being used, this should be discontinued and the maintenance strategy converted to TIVA. If the patient has a CSF drain, this can be opened and CSF removed in no greater than 10- to 20-mL aliquots, with reassessment in between. Hypertension should be addressed and treated, and the patient should be well anesthetized to attenuate CBF responses to surgical stimulation. Positioning should be reassessed to eliminate any obstruction to jugular venous outflow. Deliberate hypotension can reduce swelling, but incurs the risk of inadequate CPP and hypoperfusion ischemia and is thus instituted sparingly.

C.11. If deliberate hypotension is indicated, how will you achieve it?

Although sodium nitroprusside and volatile anesthetics are historically the most commonly used drugs to achieve sustained decreases in blood pressure, both are very far from ideal. Nitroprusside is highly effective and titratable over extremely short periods, but because it causes cerebral vasodilation, it can actually increase vascular engorgement. Nitroglycerin is also a potent cerebral venous vasodilator, and so it has the same limitation. Similarly, high levels of volatile anesthetic have direct cerebral vasodilatory effects. Further, the uncoupled cerebral vasodilation caused by nitrates and volatile anesthetics can theoretically produce cerebral steal.

In most cases, the required level of blood pressure reduction can be achieved with the use of high-dose remifentanil (or other opioid) and propofol, possibly with the addition of a β- adrenergic blocker. Remifentanil enables a profound but rapidly reversible opioid level without unfavorable effects on CBF or vasodilation. Similarly, propofol can produce hypotension through systemic vasodilation but does not cause cerebral vasodilation and is rapidly reversible. The mixed adrenergic receptor blocker labetalol is often effective as an adjunctive agent. However, the calcium channel blocker nicardipine is probably the most versatile drug for blood pressure control: It is titratable over relatively short periods and is an excellent choice if hypotension is required in situations in which opioids and anesthetic agents are not appropriate—such as during emergence or in the ICU—although it might impair autoregulation. Esmolol infusions can be utilized for a titratable β_1-adrenergic blockade, but are not especially effective if the problem is refractory hypertension. With the advent of these newer drugs, the ganglionic blocker trimethaphan is now rarely used.

C.12. While the surgeon is resecting tumor from near the brainstem, the patient's heart rate suddenly drops to 20 beats per minute. What is your assessment and management?

Surgery near the brainstem nuclei can result in dramatic autonomic disturbances. Profound vagal reflexes can be alarming, sometimes resulting in asystole. These are often followed by a compensatory parasympatholytic-sympathetic reflex. Under such circumstances, the hemodynamics can shift from extreme bradycardia and hypotension to tachycardia and hypertension in a matter of seconds.

The first step is to alert the surgeon to stop operating, which almost always alleviates the problem. Once the hemodynamic status has stabilized, an "autonomic blunting" prophylactic regimen can be given. Glycopyrrolate should be titrated until a 15% to 20%

increase in heart rate is observed; if sympathetic reflexes are also involved, β-adrenergic blockade can be added. This approach is usually effective in attenuating the reflexes. In surgery in which an elevated risk of autonomic instability is present, the institution of parasympatholytic prophylaxis should be strongly considered from the outset.

The sudden development of bradycardia should always alert the anesthesiologist to the possibility of a sudden increase in ICP, leading to the Cushing reflex. In this case, hypertension will be seen and the surgeon should be immediately notified.

C.13. Would you monitor for venous air embolism? What are the monitoring options?

Although the risk of venous air embolism is most marked when the sitting position is used, it can occur whenever the surgical site is farther above the heart than the venous column. This applies in many approaches to the posterior fossa; therefore, some form of monitoring for venous air embolism is recommended, with the caveat that invasiveness should be proportionate to risk.

A precordial Doppler ultrasound transducer, when optimally placed, is highly sensitive and noninvasive. We use it routinely for posterior fossa procedures. Nevertheless, placement over the right heart can be difficult with many positioning configurations and its sensitivity and specificity in many real-world scenarios is suboptimal. The ability to detect turbulent flow should be assessed by rapidly injecting 5 to 10 mL of saline intravenously and listening for the characteristic coarse change in sound quality. The combination of precordial Doppler, $ETCO_2$, and arterial pressure monitoring is extremely effective at detecting clinically significant venous air embolism. Transesophageal echocardiography is extremely sensitive and can detect air bubbles in the left heart, but it requires operator expertise and is often impossible in the horizontal operating positions. End-tidal nitrogen is noninvasive, but can be difficult to interpret if an air–oxygen mix is being used in the anesthetic. A pulmonary artery catheter can detect pulmonary hypertension resulting from reflex vasoconstriction and direct obstruction in the presence of venous air embolism, but because of its invasiveness, it is only recommended when a strong second indication is present.

The use of a right atrial catheter should be considered in any situation when the risk of venous air embolism is high. Traditionally, the tip of the catheter is guided to a position near the sinoatrial node by electrocardiographic guidance, although fluoroscopic placement is now frequently used as a primary or adjunctive technique. The catheter is flushed with $NaHCO_3$, and the right arm lead is attached to a conductive connector placed on the line. The catheter should then be advanced into the right ventricle, which can be detected by transducing the pressure waveform. It should then be drawn back until the P wave on the catheter lead is biphasic (midatrium), and then back further to the point at which the P wave and QRS complex are of equal amplitude. The catheter is then pulled back another centimeter and secured. The right atrial catheter can confirm the presence of venous air embolism through the aspiration of air, but its principal utility is therapeutic: It enables significant volumes of air to be rapidly extracted from the right atrium, thus breaking the "air lock" that causes the loss of cardiac output.

C.14. Are there any measures you can take to prevent venous air embolism?

The most effective prevention of venous air embolism derives from the surgical technique and the surgeon's tolerance of lower head positions. The anesthesiologist can contribute by ensuring adequate hydration (increasing the height of the venous column) and by avoiding drugs that dilate the venous capacitance vessels, such as nitroglycerin. Positive end-expiratory pressure does not reduce the incidence of venous air embolism, but it does impair surgical conditions through reducing venous return and increase the chance of a paradoxical air embolus in a patient with a patent foramen ovale. Therefore, it should not be used in craniotomies unless there is a strong rationale based on respiratory pathology. The release of positive end-expiratory pressure presents a period of elevated risk of venous air embolism.

Considerable controversy remains over the use of N_2O in the sitting position and other circumstances in which there is a high risk of venous air embolism. The controversy extends to the effect of N_2O on pneumocephalus; studies have shown conflicting results on changes in the size of the gas collection. No study has demonstrated an effect of N_2O on venous air embolism. When these controversies combined with the possible deleterious effects of N_2O on neuroprotection outlined earlier, we see no role for N_2O in posterior fossa craniotomy given the availability of viable alternatives in anesthetic management.

Schmitt HJ, Hemmerling TM. Venous air emboli occur during release of positive end-expiratory pressure and repositioning after sitting position surgery. *Anesth Analg.* 2002;94:400–403.

C.15. During the procedure, the precordial Doppler becomes loud and turbulent. The end-tidal CO_2 ($ETco_2$) drops from 31 mm Hg to 13 mm Hg, and the systemic pressure from 121/63 mm Hg to 64/32 mm Hg. What is your assessment and management plan?

This is a classic presentation of venous air embolism. Immediately inform the surgeon and institute 100% oxygen. The surgeon should flood the field with saline and urgently prepare the field for lowering the head (e.g., placement of a protective drape). Where possible, an assistant should reach under the drapes and apply pressure to the jugular veins to prevent further entrainment (but not enough to occlude carotid flow), although this should be only a transient measure. Intravenous fluids should be opened to full flow. The head should then be lowered to a level below the heart, or as much as is possible. The left lateral decubitus position has been advocated, but is probably of little benefit. If a right atrial catheter is in place, air should be aspirated. Other management is supportive.

If the venous air embolism is detected early, the episode will usually resolve. It is almost always appropriate to resume and complete the surgery, although placement of additional monitors before resumption might be warranted. Undetected, massive, or prolonged entrainment of air can lead to cardiac arrest. If cardiac arrest is present or imminent, and the patient is in a prone or semiprone position, the anesthesiologist must prepare the surgeon and others in the room for an emergent move to the supine position to enable resuscitation. For this reason, a stretcher must always be available outside the operating room when patients are in the prone position.

C.16. What is your approach to emergence? What if the patient does not wake up?

Providing an early neurologic assessment is one of the most valuable contributions of the anesthesiologist to outcome in neurosurgical patients. Therefore, it is imperative to have patients emerge quickly, even when surgery has been prolonged. At the same time, the emergence from anesthesia incurs substantial changes in pressure, $Paco_2$, CBF, and autonomic activity and therefore must be carefully planned. Transitioning from hyperventilation should be gradual in order to prevent rebound acidosis. Adrenergic blocking agents should be administered to attenuate the sympathetic effects often seen during and following emergence in these patients. Nicardipine can be considered if the patient exhibits refractory hypertension or hyperreactivity. Reversal of neuromuscular block should be carefully titrated to avoid autonomic instability, with care taken to ensure that the patient does not move while the head is fixed in pins. Antiemetic therapy should be aggressive, because the elevation in ICP caused by retching and vomiting are particularly undesirable in craniotomy patients.

Coughing or "bucking" during emergence causes dramatic spikes in ICP and must be avoided. Several approaches can be used to avoid this, including the use of intravenous lidocaine, an opioid-based anesthetic, or a deep extubation. In the case of a deep extubation, it must be kept in mind that there is always a risk that an intraoperative neurologic event might cause delayed or failed emergence. A strategy of converting the final phase of the anesthetic to a high-dose remifentanil 0.3 to 0.4 μg/kg/min infusion can be highly effective and enables the volatile agent to be eliminated without the patient reacting. After return of ventilation and cognition, remifentanil infusion is stopped and the patient is extubated.

A failure to emerge can represent a neurologic event resulting from the surgery, such as an intracranial bleed, vessel occlusion, embolic event, or seizure. In such cases, the time to diagnosis is a critical determinant of outcome. The anesthesiologist must be able to state with confidence that the delayed emergence is unlikely to be pharmacologic. The usual approach is to immediately perform a CT scan; the operating room should be left available in the event that an emergent return is required.

In some posterior fossa procedures—especially when near the brainstem—postoperative edema can lead to an anticipated worsening of neurologic status before subsequent improvement on the first or second postoperative day, thereby necessitating prolonged intubation. In these cases, the patient can be awakened at the conclusion of the surgery and once a neurologic assessment is obtained, resedated for transport to the ICU. A remifentanil infusion of approximately 0.1 μg/kg/min usually enables an intubated patient to perform a cognitive examination and tolerate the presence of the endotracheal tube.

D. Postoperative Management

D.1. What postoperative complications are of greatest concern? What level of monitoring is required?

Part of the neurologic assessment conducted immediately on emergence should be an evaluation of the lower cranial nerves. Damage to the nerves or to nuclei can result in difficulty swallowing and protecting the airway. The principal concern is the development of edema or hematoma causing compression of the brainstem or midbrain structures. The brainstem sits in an anatomic location with very low compliance; even small degrees of edema that would be well tolerated following supratentorial procedures can lead to catastrophic neurologic compromise. It is critical to appreciate that edema and hematoma can develop over the course of several hours following the procedure; a patient who had a satisfactory emergence might deteriorate neurologically in the middle of the night. In certain circumstances, the risk of postoperative edema is so high that the patient is left intubated prophylactically, as discussed earlier. Deterioration cannot always be anticipated, and these patients should be initially monitored in an intensive care setting in all cases.

CHAPTER 17

Carotid Endarterectomy

Maria Bustillo and Cynthia A. Lien

AN 85-YEAR-OLD WOMAN

is scheduled for a left carotid endarterectomy for asymptomatic left carotid stenosis. She has 90% occlusion of her left carotid artery and 60% occlusion of the right carotid artery. Her past medical history is remarkable for hypertension, insulin-dependent diabetes mellitus, and coronary artery disease. She had coronary artery bypass surgery 4 years ago. Her blood pressure is 170/80 mm Hg and her pulse is 59 beats per minute and regular.

A. Medical Disease and Differential Diagnosis

1. What are the presenting symptoms of carotid stenosis?
2. What is the prevalence of carotid artery disease?
3. What is the natural course of carotid artery disease?
4. Discuss diabetes mellitus as a risk factor for carotid endarterectomy.
5. What are the indications for surgical intervention in the management of carotid atherosclerotic disease?
6. Discuss the anatomy of the cerebral vasculature, including the carotid artery and the circle of Willis.
7. Discuss cerebral perfusion in the presence of carotid artery disease.
8. Discuss the different surgical approaches to carotid revascularization.
9. What is normal cerebral blood flow (CBF)?
10. What is critically low CBF as measured by the electroencephalogram (EEG)?
11. What is cerebral autoregulation?
12. How does $Paco_2$ affect CBF?
13. What are the principal determinants of CBF?
14. What is meant by the term *luxury perfusion*?
15. What is meant by the term *intracerebral steal*?
16. What is "inverse steal" or the "Robin Hood" syndrome?

B. Preoperative Evaluation and Preparation

1. What will you be looking for in your preoperative evaluation of this patient?
2. Is this patient's blood pressure too high for elective surgery?
3. What laboratory data are required preoperatively?
4. Will you premedicate this patient?

C. Intraoperative Management

1. How will you monitor this patient?
2. How will you know that the patient's cerebral perfusion is adequate during surgery?
3. Discuss the differences and relative advantages and disadvantages of the unprocessed EEG and the processed EEG.
4. How will you measure CBF intraoperatively? What are the relative advantages and disadvantages of each technique? How much CBF is considered adequate?
5. Does internal carotid stump pressure accurately reflect cerebral perfusion?
6. Discuss somatosensory evoked potentials (SSEPs) as a monitor of CBF during carotid endarterectomy.
7. Describe the role of the transcranial Doppler as a monitor of cerebral perfusion during carotid endarterectomy.
8. What type of anesthesia will you choose for this patient?
9. How will you induce and maintain general anesthesia in this patient?
10. How would you proceed if the patient were to receive regional anesthesia?
11. Discuss the effects of anesthetics on CBF.
12. Discuss the protective effects of anesthetic agents on cerebral function.
13. How will you manage this patient's ventilation under general anesthesia?
14. How will you manage this patient's blood pressure intraoperatively?
15. Discuss reperfusion injury following carotid endarterectomy and carotid artery stenting.
16. What intravenous fluids will you give this patient intraoperatively?

D. Postoperative Management

1. The patient does not "wake up" from general anesthesia. Why?
2. Postoperatively, the patient's blood pressure is 170/96 mm Hg. Will you treat this?
3. What immediate postoperative complications might you expect?
4. Discuss postoperative neurocognitive dysfunction following uncomplicated carotid endarterectomy.

A. Medical Disease and Differential Diagnosis

A.1. What are the presenting symptoms of carotid stenosis?

Carotid disease may manifest as only an asymptomatic bruit. It can also present, though, with amaurosis fugax, a transient ischemic attack (TIA), or a cerebrovascular accident. Amaurosis fugax is a temporary monocular blindness caused by a TIA of the retina. It is an indication of an evolving arterial thrombus in the internal carotid artery, which is the main blood supply to the optic nerve and retina through the ophthalmic artery. The symptoms of amaurosis fugax, which have been described as a shade descending over one eye, often last less than 10 minutes, and are ipsilateral to the evolving and symptomatic vascular disease.

Other manifestations of symptomatic carotid artery disease include episodes of paresthesias, clumsiness, or difficulties with speech that resolve spontaneously over a short period.

A.2. What is the prevalence of carotid artery disease?

Carotid artery disease is a manifestation of generalized arteriosclerosis. A review of data contained in the medical records of Mayo Medical Center shows the incidence of TIA to be 31 per 100,000 people in Rochester, Minnesota. The incidence increases with age. Its incidence is 1 per 100,000 in people younger than 45 years old and increases to 293 per 100,000 in people 75 years and older. In patients with an asymptomatic carotid stenosis of less than 75%, the risk of developing a TIA is 1% to 2% per year.

Similar rates have been reported in the former Union of Soviet Socialist Republics. Stroke remains the third most common cause of death in the United States. Heart disease and cancer are the first and second leading causes of death.

A.3. What is the natural course of carotid artery disease?

In carotid artery disease, atherosclerotic plaques develop at the lateral aspect of the bifurcation of the carotid artery. The severity of the process parallels that in other major vessels. Thrombosis is most likely to occur where the plaque narrows the lumen to the greatest degree. Thromboembolic stroke accounts for the greatest percentage of cerebrovascular accidents.

Sixty percent of thrombotic strokes are preceded by one or more TIAs. Most frequently one or two TIAs will occur before the final stroke and each will last less than 10 minutes. In more than 25% of cases, a complete stroke will follow a TIA within 1 month. In approximately 30% of cases, TIA do not precede a stroke. Embolic and hemorrhagic strokes are rarely preceded by TIAs.

In a patient population in Rochester, Minnesota, the 50% survival time after the first TIA was 7 to 8 years. The highest mortality rate was in the first 2 years following a TIA. However, 2 years following a TIA, the mortality rate stabilized at 1.5 times that of the general population.

Meyer FB, ed. *Sundt's Occlusive Cerebrovascular Disease*. 2nd ed. Philadelphia: WB Saunders; 1994:60.

A.4. Discuss diabetes mellitus as a risk factor for carotid endarterectomy.

Diabetes is a major risk factor for stroke. When matched for associated risk factors, symptomatic cerebrovascular disease is more common in patients who have diabetes mellitus than in those who do not have diabetes. The risk of stroke is at least 2.5 times greater in diabetic than in nondiabetic patients. Additionally, mortality and the severity of stroke are greater in patients with diabetes.

In a study from 1992 to 1995, 732 carotid endarterectomies were performed in diabetic and nondiabetic patients. A greater percentage of patients with diabetes, compared to patients without diabetes, who underwent carotid endarterectomy were women. Patients with diabetes were younger at presentation than nondiabetic patients and were more likely to have history of coronary artery disease. This may contribute to the higher incidence of postoperative cardiac morbidity in diabetic patients. By itself, diabetes mellitus is not a risk factor for postoperative cardiac morbidity in patients who undergo carotid surgery.

Diabetes mellitus and obesity are considered independent risk factors for neurocognitive decline after carotid endarectomy.

A.5. What are the indications for surgical intervention in the management of carotid atherosclerotic disease?

Currently in the United States, there are more than 700,000 new strokes per year and it is estimated that 20% to 30% are due to carotid atherosclerotic disease.

Accepted indications for surgery currently include the following:

- TIAs with angiographic evidence of stenosis
- Reversible ischemic neurologic deficits with greater than 70% stenosis of the vessel wall or an ulcerated plaque, with or without stenosis
- An unstable neurologic status that persists despite anticoagulation.

In the North American Symptomatic Carotid Endarterectomy Trial, carotid endarterectomy decreased the risk of an ipsilateral stroke from 26% to 9%, yielding an absolute risk reduction of 65%. Similar results were obtained in the European Carotid Surgery Trial, which demonstrated a 39% risk reduction, and the Veterans Affairs Cooperative Trial, which demonstrated a 60% risk reduction from a severe stroke with surgical versus medical therapy.

A multicenter study of 1,662 asymptomatic patients (asymptomatic carotid atherosclerosis study) with carotid stenosis of 60% or more as determined by Doppler studies, demonstrated that patients undergoing carotid endarterectomy in addition to medical therapy had a 53% reduction in aggregate risk for stroke or death compared to patients receiving only medical therapy. Additional outcome studies are warranted before carotid endarterectomy is recommended as a routine therapy for asymptomatic carotid artery disease.

A.6. Discuss the anatomy of the cerebral vasculature, including the carotid artery and the circle of Willis.

The common carotid arteries originate in the thorax. The right common carotid artery originates at the bifurcation of the brachiocephalic trunk, and the left originates from the aortic arch. In the neck, the common carotid arteries travel within the carotid sheath. At the level of the thyroid cartilage, each common carotid artery bifurcates into internal and external carotid arteries.

Branches of the external carotid artery include the superior thyroid, lingual, facial, ascending pharyngeal, occipital, and posterior auricular arteries.

The internal carotid artery passes through the neck without branching to enter the middle cranial fossa. It enters the middle cranial fossa through the carotid canal of the temporal bone, adjacent to the sphenoid bone. It supplies the hypophysis cerebri, the orbit, and the major portion of the supratentorial region of the brain. The cerebral arteries are derived from the internal carotid and vertebral arteries. The anastomosis they form at the base of the brain is known as the *circle of Willis*. The two anterior cerebral arteries form the circle anteriorly. They are connected through the anterior communicating artery. The two posterior cerebral arteries form the circle posteriorly, which then ends at the junction of the basilar artery. The posterior cerebral arteries are connected to the internal carotid arteries by the two posterior communicating

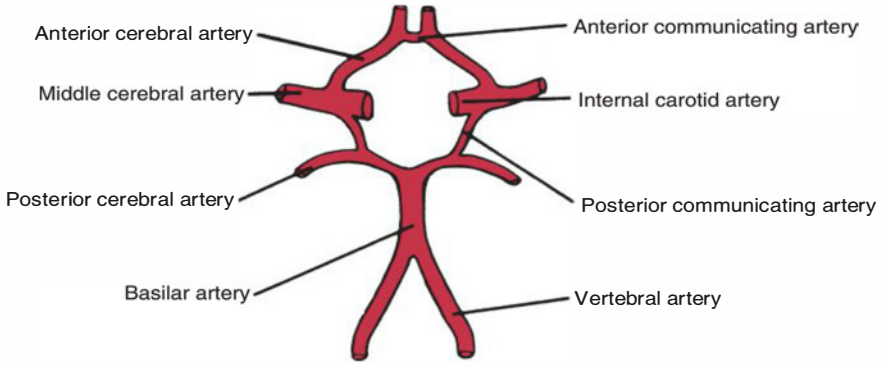

Figure 17.1 Arterial circle of Willis.

arteries (Fig. 17.1). The middle cerebral artery primarily supplies the lateral surface of each cerebral hemisphere. The anterior cerebral and posterior cerebral arteries supply the medial and inferior surfaces of the cerebral hemisphere.

Moore KL. *Clinically Oriented Anatomy*. 5th ed. Baltimore: Lippincott Williams & Wilkins; 2006;930–931.

A.7. Discuss cerebral perfusion in the presence of carotid artery disease.

Autoregulation is assumed to be lost in underperfused areas of the brain. Vascular regions subjected to chronic hypoperfusion and relative ischemia are maximally vasodilated and unresponsive to factors that induce vasoconstriction in normally reactive vascular beds. Therefore, in patients with carotid artery disease, blood flow through ischemic regions is passive and dependent on systemic blood pressure. For this reason, hypotension is best avoided in the period before restoration of unobstructed CBF.

A.8. Discuss the different surgical approaches to carotid revascularization.

Carotid endarterectomy involves the removal of atheromatous plaque from the vessel lumen through a fairly standardized surgical procedure. This involves occluding the common, external, and internal carotid arteries, isolating the diseased segment, opening the vessel wall, and removing the plaque. The vessel is then closed. If the

remaining intima is too thin, the vessel is closed with a vein graft or a synthetic (Dacron) patch. The use of a shunt during the period of carotid cross-clamping depends on whether evidence of cerebral ischemia becomes apparent with cross-clamping of the carotid artery. Variations in shunt usage exist because there is little evidence that one therapy is superior to the others. Placement of a shunt allows hemispheric CBF to be maintained during cross-clamping and may be especially advantageous when the endarterectomy is expected to be complex and require a long time.

On the other hand, shunt usage is not without its problems. It may make the surgery technically more difficult. Technical problems with shunts include plaque or air embolism, kinking of the shunt, shunt occlusion on the side of the vessel wall, and injury to the distal internal carotid artery. The use of a shunt does not guarantee adequate CBF nor prevent thromboembolic strokes.

Another intervention to treat carotid stenosis is percutaneous transluminal angioplasty and stenting by interventional radiologists. Advantages to endovascular techniques include avoidance of surgical incision; minimal anesthetic requirements; avoidance of minor complications associated with endarterectomy, including cranial nerve injury and wound infections; shorter duration of induced carotid occlusion by the balloon catheter than with surgical clamping of the carotid artery; and lower hospital costs for shorter hospital and intensive care unit stays.

Clinical trials comparing carotid endarterectomy with angioplasty have been done. Early trials were stopped prematurely because of significantly worse outcomes among patients treated with angioplasty.

The Carotid Revascularization Using Endarterectomy or Stenting Systems phase I study was a multicenter, prospective, nonrandomized trial designed to address the question of whether carotid artery stenting with cerebral protection was comparable to carotid endarterectomy in patients with symptomatic and asymptomatic carotid stenosis. A total of 397 patients (254 carotid artery surgery and 143 carotid artery stenting) were enrolled in the study: 32% were symptomatic and 68% were asymptomatic. There were no significant differences in patient demographics, symptoms, or surgical risk profiles between groups at baseline. There were no significant differences in combined death or stroke rates at 30 days or 1 year after treatment. Similarly, there was no significant difference in the combined end point of death, stroke, or myocardial infarction at 30 days or 1 year between the two groups. There were also no significant differences between the treatment groups in terms of the secondary end points of residual stenosis, restenosis, repeat angiography, carotid revascularization, or change in quality of life. The results of the Carotid Revascularization Using Endarterectomy or Stenting Systems phase I study suggest that the 30-day and 1-year risk for death, stroke, or myocardial infarction with coronary artery stenting is equivalent to that with carotid endarectomy in symptomatic and asymptomatic patients with carotid stenosis.

The Carotid and Vertebral Artery Transluminal Angioplasty Study was the first randomized trial comparing carotid endarterectomy to angioplasty. A total of 504 patients with symptomatic stenosis and more than 50% occlusion were randomly assigned to either endovascular treatment or surgery. Within 30 days of treatment, there were more minor strokes lasting less than 7 days in the endovascular group. The numbers of more major strokes or death were the same regardless of treatment group. None of the differences in stroke outcome measures was significant. The study results suggest that angioplasty and carotid endarterectomy are equally effective in preventing stroke. Additionally, disabling stroke and death rates were the same after surgery and stenting. The study, though, was underpowered.

The Stenting and Angioplasty with Protection in Patients at High Risk for Endarterectomy (SAPPHIRE) trial is the most recently published study comparing carotid artery stenting and carotid endarterectomy. In this trial, 334 high-risk patients with carotid stenosis were randomized to either stenting or surgery (167 each group). Randomization to stenting with embolic protection was found to not be inferior to carotid endarterectomy for reducing the primary clinical end points (composite of

death, stroke, or myocardial infarction within 30 days, and death or ipsilateral stroke between 31 and 365 days). There was a strong trend toward reduction of the primary end point with stenting and fewer required carotid revascularizations at 1 year.

Health-related quality of life outcomes were assessed at baseline, 2 weeks following treatment, and during an additional follow-up visits at 1, 2, 6, and 12 months. Patients treated with stenting had significant health benefits during the early recovery period when compared to those treated with surgery. The duration of any benefit, though, was limited to the first 2 weeks of the postoperative period, and all other measures of disease-specific health status, as well as general health and physical function, were similar at 1, 2, 6, and 12 months.

Although the results of the SAPPHIRE trial demonstrated similar results whether carotid artery stenosis was treated with stenting or surgery when stenting was done by surgeons experienced in the technique, the findings of another report, also published in 2010, demonstrated that physicians in a formalized training program with varied individual levels of experience could have results similar to those obtained in the SAPPHIRE trial.

A.9. What is normal cerebral blood flow (CBF)?

Normal CBF is approximately 50 mL/100 g/min for the entire brain. Blood flow is approximately four times higher in gray matter than it is in white matter, with the flows being 80 and 20 mL/100 g/min, respectively.

Hemmings HC, Hopkins PM, eds. *Foundations of Anesthesia Basic Science for Clinical Practice*. 2nd ed. Philadelphia: Elsevier Science; 2006:248–249.

Lassen NA, Munch O. The cerebral blood flow in man determined by the use of radioactive krypton. *Acta Physiol Scand.* 1955;33:30–49.

A.10. What is critically low CBF as measured by the electroencephalogram (EEG)?

Assuming a normal temperature and hematocrit, 100 mL of blood contains approximately 20 mL of oxygen. A normal global CBF flow of 50 mL/100 g/min delivers oxygen to the brain at a rate of 10 mL/100 g/min. This is in excess of the high metabolic requirements of the brain for oxygen (3 to 5 mL/100 g/min), which affords a relative margin of safety. The CBF at which ischemia becomes apparent in the EEG is approximately 20 ml/100 g/min. Changes on EEG may be delayed for up to 150 seconds following the onset of ischemia. It is impossible to define the specific changes that represent irreversible ischemia. In the setting of an isoelectric EEG, oxygen delivery to the brain may be adequate to keep the neurons alive but may provide insufficient energy for them to function.

The development of cerebral infarction depends on both the degree and duration of ischemia. Jones showed in an animal model of reversible ischemia that with CBF of 18 to 23 mL/100 g/min, animals would recover from impaired neurologic function when blood flow was returned to normal levels, regardless of the duration of the ischemic period. Infarction development at lower flows depends on both the degree of regional CBF reduction and the duration of ischemia. Neurons that are nonfunctional but will recover fully with restoration of adequate flow are said to be in an ischemic penumbra. Neuronal destruction occurs with CBF less than 10 mL/100 g/min.

A.11. What is cerebral autoregulation?

Cerebral autoregulation is the tendency of the brain to match cerebral metabolic oxygen requirements with oxygen delivery in spite of variations in blood pressure. In normotensive individuals, CBF is constant between mean arterial pressures of 50 and 150 mm Hg. What this means is that cerebrovascular resistance increases, through vasoconstriction, as mean arterial pressure increases from 50 to 150 mm Hg. At pressures greater than 150 mm Hg, the cerebral vasculature is maximally vasoconstricted and CBF increases with increasing pressure. At pressures less than 50 mm Hg, cerebral vessels are maximally vasodilated, so that CBF decreases as mean arterial pressure falls.

In hypertensive patients, the upper and lower limits of the autoregulatory curve are shifted to the right, to higher pressures (Fig. 17.2). What this means is that a mean arterial pressure of 60 mm Hg, which would be well tolerated in a normotensive individual, may actually be below the lower limit of autoregulation in the hypertensive individual, resulting in cerebral hypoperfusion. Conversely, hypertensive patients tolerate marked increases in mean arterial pressure much better than their normotensive counterparts. In treated hypertensive patients, the limits of autoregulation are shifted with time toward normal.

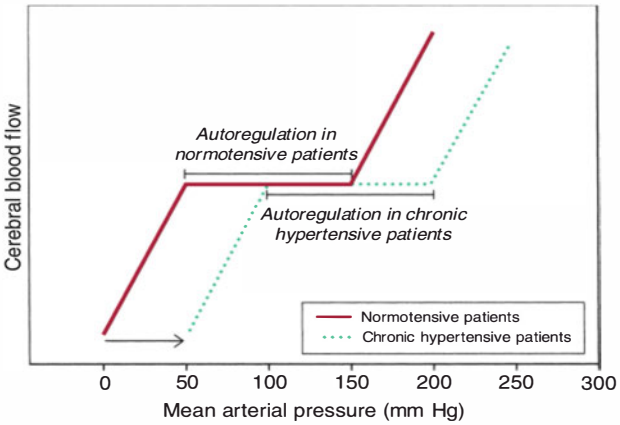

Figure 17.2 Cerebral autoregulatory curves in normotensive and chronic hypertensive patients. New autoregulation curve is achieved with chronic hypertension. The curve shifts back to normotensive range once hypertension is well controlled.

A.12. How does $Paco_2$ affect CBF?

Hypercarbia results in cerebral vasodilation and hypocarbia in cerebral vasoconstriction. CBF changes approximately 4% for each millimeter of mercury increase or decrease in arterial $Paco_2$ for partial pressures of arterial carbon dioxide between 20 and 80 mm Hg.

Hemmings HC, Hopkins PM, eds. *Foundations of Anesthesia Basic Science for Clinical Practice*. 2nd ed. Philadelphia: Elsevier Science; 2006:249–250.

Skinhoj E, Paulson OB. Carbon dioxide and cerebral circulatory control: evidence of a nonfocal site of action of carbon dioxide on the cerebral circulation. *Arch Neurol*. 1969;20:249–252.

A.13. What are the principal determinants of CBF?

The principal determinants of CBF are nerve cell activity, cerebral perfusion pressure, $Paco_2$, the pH of the extracellular fluid in the brain, Pao_2, and neurogenic influences.

Cottrell JE, Smith DS. *Anesthesia and Neurosurgery*. 4th ed. St. Louis, MO: Mosby; 2001:19–32.

Hemmings HC, Hopkins PM, eds. *Foundations of Anesthesia Basic Science for Clinical Practice*. 2nd ed. Philadelphia: Elsevier Science; 2006:247–250.

A.14. What is meant by the term *luxury perfusion*?

Luxury perfusion is blood flow that is in excess of metabolic need (increased CBF relative to cerebral metabolic rate for oxygen). It is most frequently observed in tissues surrounding tumors or areas of infarction. It has also been described in tissues that have been manipulated during surgery.

Paulson OB. Cerebral apoplexy (stroke): pathogenesis, pathophysiology and therapy as illustrated by regional blood flow measurements in the brain. *Stroke.* 1971;2:327–360.

A.15. What is meant by the term *intracerebral steal*?

Intracerebral steal is a paradoxical response to carbon dioxide in which hypercapnea decreases the blood flow in an ischemic area. It is the consequence of the vasodilatory effect of carbon dioxide on the normally perfused arterioles at the periphery of an ischemic lesion. Because chronically ischemic vascular beds are maximally vasodilated, they cannot dilate further in response to hypercapnea.

Paulson OB. Cerebral apoplexy (stroke): pathogenesis, pathophysiology and their therapy as illustrated by regional blood flow measurements in the brain. *Stroke.* 1971;2:327–360.

A.16. What is "inverse steal" or the "Robin Hood" syndrome?

Inverse steal is the effect of hypocapnea producing increased blood flow to ischemic regions of the brain. Vasoconstriction occurs in adjacent, normal arterioles, thereby causing a local increase in perfusion pressure and augmenting collateral flow to the ischemic, unreactive, maximally vasodilated area of the brain.

Betz E. Cerebral blood flow: its measurement and regulation. *Physiol Rev.* 1972;52:595–630.

B. Preoperative Evaluation and Preparation

B.1. What will you be looking for in your preoperative evaluation of this patient?

Once the presence of a carotid lesion amenable to surgical treatment has been documented through Doppler, angiographic, or oculoplethysmographic studies, the anesthesiologist will be asked to evaluate the patient regarding her readiness for surgery. The anesthesiologist should determine whether other manifestations of generalized arteriosclerosis, such as coronary artery disease, hypertension, and renal disease are present. Evidence of medical conditions associated with arteriosclerosis, such as obesity, diabetes mellitus, and pulmonary disease secondary to cigarette smoking, should be sought. The patient's neurologic status and airway will need to be evaluated.

Because 30% to 50% of patients undergoing carotid endarterectomy have coronary artery disease, evidence of heart disease should be sought in the patient's history. Patients should be specifically asked whether they have angina or have had a myocardial infarction or congestive heart failure. An indication of daily activity level should be obtained. A patient unable to ambulate for distances because of claudication may never develop angina or left ventricular failure. Therefore, more invasive evaluation of the patient's cardiac function may be required. Evidence of cardiac disease should

also be sought on physical examination. This would include heart rate and rhythm, and presence of jugular venous distention, basilar rales on auscultation of the chest, cardiac enlargement as determined by lateral displacement of the point of maximal impulse, and an S_3 gallop.

Based on the Cardiac Risk Stratification for Noncardiac Surgical Procedures by the American Heart Association/American College of Cardiology Task Force on Assessment of Therapeutic Cardiovascular Procedures, carotid endarterectomy is classified as an intermediate-risk procedure with a reported cardiac risk generally less than 5%.

Whether the patient has hypertension should be determined. Hypertension is present in 55% to 80% of patients with carotid artery disease, and its presence would alter intraoperative blood pressure management. Blood pressure should be measured in both arms with the patient in both the supine and the upright positions. A range of acceptable blood pressures readings, in which the patient is free of symptoms of both cardiac and cerebral ischemia, should be determined. This is done, in part, by reviewing the patient's chart and making note of the highest and lowest blood pressures that were measured. Knowing this range allows the anesthesiologist to determine the range of blood pressures that may be tolerated without treatment in the operating room. Raising the blood pressure excessively to improve cerebral perfusion may exacerbate myocardial ischemia, and lowering the blood pressure to reduce the work of the heart may compromise cerebral perfusion, exacerbating cerebral ischemia.

The presence of other disorders associated with vascular disease, such as obesity, diabetes, and cigarette smoking with their sequelae, should be determined. Evidence of other end-organ effects of vascular disease, such as renal dysfunction, should also be sought.

The patient's neurologic status also needs to be evaluated preoperatively. Although it would be preferable to medically optimize the patient with uncontrolled hypertension or untreated metabolic disease, or if possible, delay surgery in the patient with a recent myocardial infarction, the presence of crescendo TIAs may not allow that option.

The patient's airway needs to be assessed for ease of ventilation and intubation. A patient in whom it is difficult to establish ventilation may become hypercarbic during induction, and the increase in $Paco_2$ may have adverse effects on regional CBF. As part of the airway evaluation, the range of motion of the patient's neck that is tolerated without evidence of cerebral ischemia needs to be determined so that relative extremes of extension and lateral rotation of the neck during ventilation, intubation, and finally patient positioning can be avoided. Extreme extension and rotation of the neck may occlude the patient's vertebral artery and contribute to postoperative neurologic deficits.

B.2. Is this patient's blood pressure too high for elective surgery?

Although hypertension is present in most patients presenting for carotid endarterectomy, its rapid correction is not recommended because this may exacerbate cerebral

ischemia. If this patient had evidence of myocardial ischemia at this blood pressure and was stable from a neurologic standpoint, blood pressure could be gradually decreased with antihypertensive medications.

Normal myocardial and cerebral function need to be preserved. These goals are not necessarily at odds with each other. To decrease myocardial oxygen consumption, one would want to decrease heart rate, blood pressure, and myocardial contractility. In this patient population, decreasing heart rate can decrease myocardial work, whereas cerebral perfusion pressure is maintained with an adequate mean arterial pressure. If a hypertensive patient presents with an unstable neurologic status, it may be necessary to control blood pressure only once the obstruction to CBF has been relieved.

A single blood pressure measurement is of little use in the preoperative assessment of the patient. It is the range of the blood pressures normally tolerated by the patient that will guide perioperative blood pressure management. For example, if a patient's blood pressure is measured at 80/50 mm Hg and at 170/100 mm Hg preoperatively and at these blood pressures, she does not develop any new neurologic deficits or myocardial ischemia, the clinician will be inclined to treat blood pressures only beyond these two extremes.

Because this patient is hypertensive, one can expect that wide swings in her blood pressure will occur while she is receiving anesthesia. The anesthesiologist must be prepared for these fluctuations by having both vasopressors and vasodilators readily available. Variations in blood pressure should be minimized because these have been related to increased cardiac and neurologic morbidity.

B.3. What laboratory data are required preoperatively?

Laboratory tests should be ordered to determine the patient's baseline cardiac, respiratory, and metabolic status.

Hemoglobin and hematocrit levels should be obtained preoperatively because values may be abnormal in a patient with advanced age or renal or pulmonary disease and because significant blood loss may occur intraoperatively.

A urine analysis and data on blood urea nitrogen and creatinine should be obtained to determine the patient's baseline renal status.

An electrocardiogram (ECG) should be examined preoperatively to look for arrhythmias, evidence of ischemia, previous myocardial infarctions, or left ventricular hypertrophy. Where appropriate, the preoperative ECG should be compared with earlier studies to determine whether interval changes have occurred.

A chest radiograph should be examined to look for cardiomegaly, evidence of pulmonary edema, chronic obstructive pulmonary disease, or pneumonia. If the patient has a history of chronic obstructive pulmonary disease, a preoperative arterial blood gas reading should be obtained to identify the patient's baseline $Paco_2$. In patients who are chronically hypercarbic, rapid adjustment to normocarbia intraoperatively will be interpreted by the body as relative hypocarbia. CBF will be reduced accordingly. Management of intraoperative ventilation should be aimed at maintaining the patient's normal arterial carbon dioxide level.

Further preoperative evaluation would be based on the presence of concurrent disease.

Barash PG, Cullen BF, Stoelting RK, eds. *Clinical Anesthesia*, 6th ed. Philadelphia: Lippincott Williams & Wilkins; 2009:1117–1122.

B.4. Will you premedicate this patient?

Ideally, the patient should present to the operating room calm and awake. Preoperative anxiety should be alleviated in these patients because it can lead to hypertension, which has been associated with adverse neurologic outcome. Increases in heart rate in the anxious patient lead to increased myocardial oxygen consumption and, potentially, ischemia, ventricular dysfunction, and arrhythmias.

Premedication, however, may lead to ventilatory depression, with resultant hypercarbia and alterations in CBF that can exacerbate cerebral ischemia. Sedation can also interfere with the immediate postoperative neurologic assessment of the patient because it may cause delayed awakening from anesthesia. One of the anesthetic goals for carotid endarterectomy under general anesthesia is to have a patient who promptly emerges from anesthesia and is able to cooperate with a basic neurologic evaluation. A patient who is too sedated at the end of surgery is problematic.

To achieve these goals, a thorough and reassuring preoperative visit alone may provide sufficient anxiolysis. The anesthesiologist should explain the preoperative procedure and what can be expected in the postoperative period, answering any questions that the patient has. If pharmacologic premedication is required, a benzodiazepine (e.g., diazepam 5 mg orally, 1 hour preoperatively; or midazolam 1 to 2 mg intravenously) should provide anxiolysis and minimal respiratory depression.

C. Intraoperative Management

C.1. How will you monitor this patient?

Patients who are about to undergo carotid endarterectomy are managed with routine monitoring of cardiovascular, pulmonary, and metabolic function, including ECG leads II and V_5, noninvasive blood pressure monitor, pulse oximetry, end-tidal capnometry, and esophageal temperature.

An intra-arterial catheter should be used to monitor the patient's blood pressure closely. Its presence will permit immediate identification of blood pressure changes and allow for repetitive sampling of arterial blood gases.

Whether a pulmonary artery catheter is required to monitor the patient's cardiac function would be dictated solely by the patient's preoperative cardiac status. Carotid endarterectomy is not an operation in which large fluid shifts are anticipated. A pulmonary artery catheter should not be required in the patient with normal left ventricular function.

Barash PG, Cullen BF, Stoelting RK, eds. *Clinical Anesthesia*, 6th ed. Philadelphia: Lippincott Williams & Wilkins; 2009;1117–1122.

C.2. How will you know that the patient's cerebral perfusion is adequate during surgery?

In the awake patient undergoing carotid endarterectomy under local anesthesia, repeated neurologic examinations can be done to assess the adequacy of cerebral perfusion.

If the patient receives general anesthesia, cerebral perfusion or function should be monitored. No currently available clinical monitor is as sensitive and specific for cerebral dysfunction as repeated neurologic examinations, and no one monitor is routinely used in all operating rooms. Some monitors have been used to monitor cerebral perfusion or function. These include the electroencephalograph, somatosensory evoked potentials, transcranial Doppler, internal carotid stump pressure, and jugular venous oxygen saturation.

Current interest has considered cerebral oximetry as a monitor because it is noninvasive, continuous, and easy to use. In recent studies, a relative decrease of 20% or greater in regional cerebral oxygen saturation suggested cerebral ischemia. The monitor, though, has a low positive predictive value and low specificity. If used exclusively, it would suggest the need for unnecessary shunting and lead to overshunting of patients.

C.3. Discuss the differences and relative advantages and disadvantages of the unprocessed EEG and the processed EEG.

The EEG is neither a measure of CBF nor a way to determine whether irreversible neuronal damage has occurred. Rather, it is an indicator that areas of the brain may be at risk for infarction. Changes that occur in the EEG with hypothermia, hypocarbia, hypoxemia, and deep anesthesia mimic those of ischemia. In patients who have had a cerebrovascular accident, the processed EEG does not predict cerebral ischemia.

Problems associated with intraoperative monitoring of the 16-lead EEG have detracted from its popularity. These include difficulty in obtaining a meaningful recording in the electrically noisy environment of the operating room, the bulk of the equipment required, and the need for specially trained personnel for interpretation. The 16-channel EEG is, nevertheless, a sensitive indicator of ischemia.

The processed EEG has eliminated many of the problems associated with the 16-channel EEG. The equipment is generally compact and the data display allows for ease of interpretation. The most commonly used processed encephalogram is the power spectrum analysis. For this analysis, the EEG is studied in short time intervals of 2 to 16 minutes, called *epochs*. Each epoch then is subjected to a fast Fourier transform analysis during which the complex waveform of the unprocessed EEG is broken down into its component sine waves of varying amplitudes and frequencies. The power spectrum is calculated by squaring the amplitude of the individual frequency components. The power spectrum can then be displayed in various graphic forms, two of which are the compressed spectral array and the density modulated spectral array. Data are displayed in these two forms as relative power versus frequency (Fig. 17.3).

It must be remembered that the processed EEG is only as good as the original from which it was obtained. Therefore, meticulous recording techniques are required even when monitoring a processed EEG. During carotid endarterectomy, generally two or four channels of the EEG are monitored to determine right and left symmetry in neuronal activity during interruption of CBF.

C.4. How will you measure CBF intraoperatively? What are the relative advantages and disadvantages of each technique? How much CBF is considered adequate?

Measurement of regional CBF is the single best method for detecting decreases in CBF during general anesthesia. Multiple different ways are used to measure this. These include the Kety-Schmidt method and later modifications on this, the intracarotid injection method, and the inhalation and intravenous techniques.

The Kety-Schmidt method, as originally described, involved 10 to 16 minutes of inhalation of 15% nitrous oxide. During this period, equilibration would occur among arterial, venous, and tissue concentrations of nitrous oxide. Blood samples would intermittently be taken from a peripheral artery and the jugular bulb to determine tracer concentration. The amount of tracer taken up by the brain in a certain period is equivalent to the amount delivered to the brain in the arterial blood supply minus that recovered in the cerebral venous blood in the same period. If it is assumed that the brain concentration of the tracer is proportional to the tracer concentrations in the cerebral venous blood, global CBF can be determined with knowledge of the blood brain partition coefficient for the tracer used.

Later modifications of this technique employ the radioactive tracers krypton-85 (^{85}Kr) or xenon-133 (^{133}Xe). CBF, as measured using the Kety-Schmidt method and its modifications, may be overestimated in the case of low perfusion states in which brain and venous blood may not equilibrate. One cannot measure regional CBF using these techniques because jugular venous blood is a mixed venous sample with varying amounts of contamination from the contralateral hemisphere.

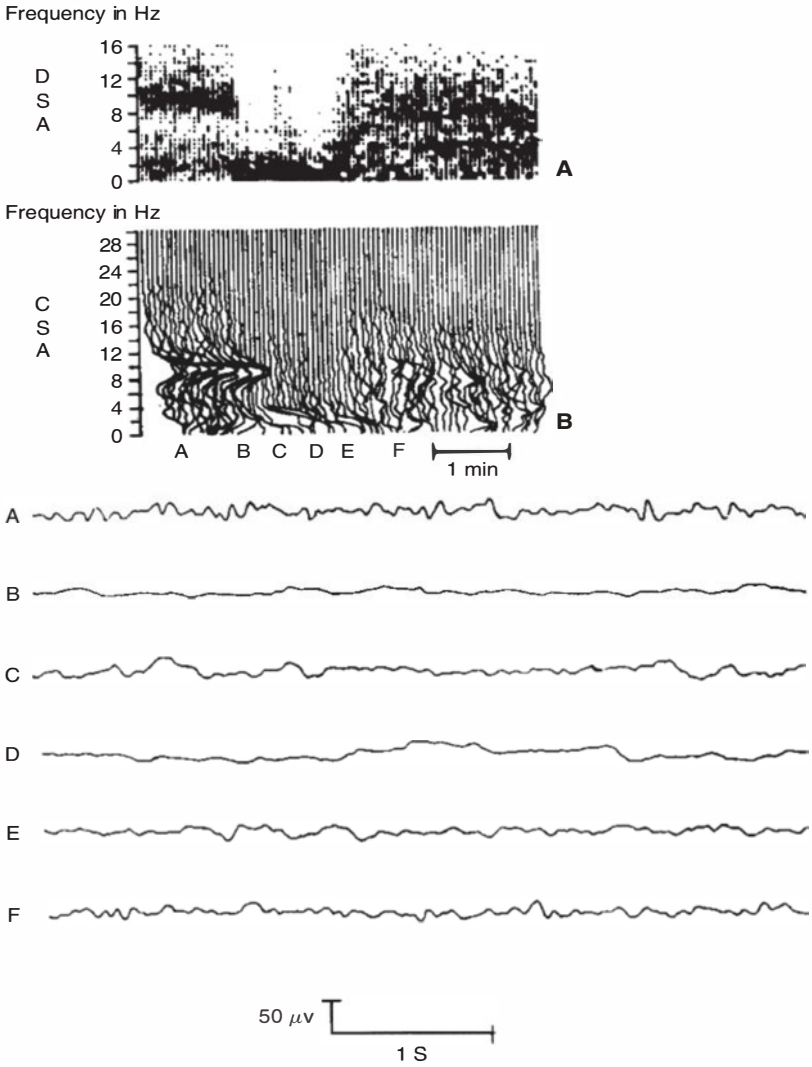

Figure 17.3 An example of density spectral analysis **(A)** and the unprocessed electroencephalogram (EEG) **(B)** compressed during a period of marked hypotension during initiation of bypass. Slowing waveform activity in the unprocessed EEG (B to E) is also evident in the density modulated spectral array (DSA) and compressed spectral array (CSA). (Reprinted with permission from Levy W, Shapiro HM, Maruchak G, et al. Automated EEG processing for intraoperative monitoring. *Anesthesiol.* 1980;53:223.)

In 1961, Lassen and Ingva described the intracarotid injection method of CBF determination. The technique involves injecting a radioactive tracer, ^{85}Kr or ^{133}Xe, as a bolus into the cerebral arterial supply and following the cerebral washout with external scintillation counting. Use of external scintillation counters makes it possible to determine regional CBF, and the sensitivity of the technique is improved by increasing the number of detectors. The tracer is injected directly into either an

internal carotid or vertebral artery, minimizing the number of counts obtained from the extracranial circulatory distribution. This method assumes that the tracer mixes completely with brain. Because the tracer is almost completely exhaled on passage through the lungs, it has essentially no recirculation. A typical tracer washout curve in normal brain is the summation of two exponential curves. Two separate flows, fast (gray matter) and slow (white matter), can be calculated using compartmental analysis.

The more noninvasive techniques to determine CBF are the inhalation and intravenous techniques. The inhalation method involves a 1-minute period of inhalation of ^{133}Xe followed by a 10-minute period of washout with external detection. The washout of tracer from the brain is similar to that obtained with intra-arterial injection except that, because of mixing in the heart and the lungs, the input of tracer is not instantaneous. Because the slow component of CBF is contaminated by extracranial clearance of the tracer, the noninvasive methods are suited primarily for determination of gray matter flow. The inhalation and intravenous methods may be less reliable in the presence of pulmonary disease because the end-tidal concentration of tracer may not adequately reflect arterial concentration. With these techniques, extracranial contamination can result in an underestimation of CBF, and under extremely low flow states, they may not give reliable quantitative information.

One thing to bear in mind with all tracer washout techniques is that, in general, they only provide flow information about cortical blood flow and not about deeper structures. Furthermore, with any of these techniques, CBF is a calculated number, and it will vary depending on the specific technique used to measure it. Average global CBF is 50 mL/100 g/min, gray matter flow is 80 mL/100 g/min, and white matter flow is 20 mL/100 g/min. A measured flow intraoperatively of greater than 24 mL/100 g/min is considered to be sufficient and that of less than 18 mL/100 g/min is inadequate. The specific flow differences compatible with ischemia depend on the anesthetic agents used. The expense and expertise required to collect and interpret CBF data have limited its use to only a few centers.

C.5. Does internal carotid stump pressure accurately reflect cerebral perfusion?

The internal carotid stump pressure, the pressure in the portion of the internal carotid artery cephalad to the carotid cross-clamp, has been used to determine whether CBF during cross-clamping was adequate to avoid neuronal damage. The stump pressure presumably reflects pressure transmitted through collateral vessels. Maintaining stump pressures from 25 to 70 mm Hg has been described as necessary to avoid neurologic injury. Nevertheless, this range of stump pressures may not reliably represent the adequacy of collateral CBF, because it does not correlate consistently with changes in the EEG, regional CBF, or changes in the neurologic status of the awake patient. Furthermore, anesthetic agents can alter carotid stump pressure without changing regional CBF. Inadequate stump pressures have been demonstrated when measured regional CBF was adequate. Therefore, if shunting during carotid endarterectomy were to be done only on the basis of stump pressures, some patients would unnecessarily receive shunts.

C.6. Discuss somatosensory evoked potentials (SSEPs) as a monitor of CBF during carotid endarterectomy.

SSEPs are a specialized form of electrophysiologic monitoring that reflects the presence of intact sensory pathways from a stimulated peripheral nerve to the cortex, where electrical activity is monitored. Evidence exists that distortion of certain waveforms is associated with ischemia. These SSEP changes are not consistently associated with changes in the EEG. Questions have been raised regarding whether SSEPs can overpredict the presence of ischemia and the need for shunting. If SSEPs are a useful indicator of ischemia, they may be used when ischemia cannot be detected on an electroencephalographic tracing, such as during barbiturate anesthesia. During barbiturate anesthesia, the isoelectric EEG can only indicate that neurons are quiet. It cannot indicate whether these same neurons are ischemic. The SSEP tracing would remain intact with barbiturate anesthesia and, therefore, would potentially be more useful as a clinical monitor. Patients who have had strokes have some asymmetry in baseline SSEP waveforms. This asymmetry does not appear to affect the SSEP as an effective clinical monitor, which may also be a relative advantage over the EEG in patients with prior cerebral vascular accidents.

C.7. Describe the role of the transcranial Doppler as a monitor of cerebral perfusion during carotid endarterectomy.

By allowing for continuous assessment of the velocity of the blood flow in the ipsilateral middle cerebral artery, transcranial Doppler may be useful throughout carotid endarterectomy. It can aid in determining the need for a shunt by detecting a decrease in the middle cerebral artery blood flow velocity with placement of the carotid cross-clamp. It allows for continuous assessment of shunt function. It can be used to assess the adequacy of pharmacologically induced intraoperative hypertensive therapy. Transcranial Doppler also allows for the detection of air or particulate embolization. The disadvantage of transcranial Doppler is that it is technically demanding and not obtainable in approximately 20% of patients.

A good correlation has been shown between intraoperative electroencephalography and transcranial Doppler. Patients who have unchanged EEGs have a middle cerebral artery velocity of 24.1 cm per second during cross-clamping, whereas those with a middle cerebral artery velocity of 14.7 cm per second develop electroencephalographic changes. The ratio of the mean velocity while the cross-clamp is in place compared with the mean velocity before placement of the clamp may also be used to predict alteration in neurologic function. A ratio below 0.4 detects 97% of patients with electroencephalographic evidence of cerebral ischemia.

C.8. What type of anesthesia will you choose for this patient?

Patients undergoing carotid endarterectomy may have either regional or general anesthesia. Each type of anesthesia has advantages and disadvantages that must be considered when choosing the optimal anesthetic for each patient. Benefits of general anesthesia include a still patient and a quiet operative field, early control of the airway and ventilation, and the ability to "protect" the brain should ischemia, which cannot be eliminated, develop. A disadvantage of general anesthesia is the inability to perform repeated neurologic evaluations during surgery. Therefore, patients receiving general anesthesia should have their CBF or neurologic function monitored as previously discussed.

The primary advantage of a regional anesthetic is that the patient remains awake allowing for repeated neurologic evaluations. Although anecdotal reports support that regional anesthesia allows for greater stability of blood pressure, decreased requirement for vasoactive medications to support blood pressure, and decreased incidence of perioperative myocardial infarction, further outcome studies are warranted. Potential complications associated with regional anesthesia include the following:

- Seizures
- Alteration of mental status with cerebral ischemia
- Loss of patient cooperation associated with cerebral hypoperfusion, inadequate ventilation, and sedation

A meta-analysis of three randomized studies of 143 patients and 17 nonrandomized retrospective studies demonstrated that within 30 days of operation, there was a 50% reduction in the relative odds for death, stroke, myocardial infarction, and pulmonary complications with regional anesthesia. Nevertheless, there are still no large randomized prospective studies to draw definitive conclusions in terms of which type of anesthesia is optimal.

C.9. How will you induce and maintain general anesthesia in this patient?

Following preoxygenation, all anesthetics should be titrated slowly with special attention to their effect on the patient's blood pressure. Control of the airway should be taken as soon as the patient is no longer able to breathe adequately to maintain normocarbia. While breathing oxygen, the patient is given small doses of fentanyl and reminded to breathe to maintain normocapnea. Opioids are administered until the patient is comfortably sedated. Lidocaine is administered intravenously at least 2 minutes before laryngoscopy and intubation to blunt the hyperdynamic response to airway manipulation. Following administration of thiopental, propofol, or etomidate, controlled ventilation is instituted with 100% oxygen to avoid hypoxia and hypercarbia. A muscle relaxant is administered to facilitate endotracheal intubation. Succinylcholine should be avoided in hemiparetic patients because of the possibility of a hyperkalemic response to its administration. Nondepolarizing muscle relaxants with significant hemodynamic effects such as sympathomimetic activity, vagolysis, or histamine release should be avoided. Once the patient is relaxed, an expeditious laryngoscopy and intubation are performed. The time spent intubating the patient's trachea is minimized to decrease the hemodynamic response to airway manipulation.

During the induction and intubation sequence, the patient's blood pressure is kept in her normal range by the use of vasopressors or vasodilators as indicated. Short-acting and easily titratable vasoactive medications should be chosen to facilitate blood pressure control.

Anesthesia can be maintained with a combination of volatile anesthetics and opioids. The addition of opioids to an isoflurane anesthetic will decrease heart rate, reduce the requirements for volatile anesthetics, and, when properly dosed, allow for a prompt, smooth emergence from general anesthesia. Their use should not be avoided because of anecdotal reports of adverse neurologic outcome after focal ischemia in rodents. Any anesthetic regimen is suitable if it provides hemodynamic stability, does not exacerbate cerebral ischemia, and allows for a prompt emergence from anesthesia at the conclusion of surgery.

Maintenance of a light anesthetic appears to have several advantages over deep anesthesia. It allows ischemic patterns on the EEG to be recognized easily. It also facilitates maintenance of the patient's blood pressure. In addition, administration of a light anesthetic, compared to a deep anesthetic using phenylephrine to maintain blood pressure, results in a lower incidence of perioperative myocardial infarction.

C.10. How would you proceed if the patient were to receive regional anesthesia?

Patient cooperation is essential for a regional anesthetic to proceed successfully. For a patient to be adequately anesthetized, a sensory blockade is required in the C2 to C4 dermatomes. This can be accomplished with either deep or superficial cervical plexus

blocks. In doing the blocks, care must be taken not to excessively palpate the neck, because part of the plaque in the carotid artery may dislodge and embolize.

Superficial cervical plexus blocks are performed by infiltrating along with middle third of the posterior border of the sternocleidomastoid muscle with local anesthesia. Deep cervical plexus blocks are performed with three injections along a line drawn from Chassaignac tubercle (C6) to the mastoid process. The C4 nerve root is located at the intersection of that line with one drawn horizontally from the lower border of the mandible. C2 and C3 are located by dividing the distance between the mastoid process and the horizontal line into thirds. Alternatively, a single injection of local anesthetic can be made on the line between the mastoid process and Chassaignac tubercle at the level of C4 with the needle directed medially and slightly caudad.

Patients receiving regional anesthesia must be both cooperative and not oversedated with intravenous medications. If they are unable to cooperate and become obtunded, the primary advantage of regional anesthesia (which is continuous neurologic evaluation) is lost. Intravenous sedation therefore must be given judiciously, if at all, to these patients.

C.11. Discuss the effects of anesthetics on CBF.

It is important to remember that all general anesthetics affect CBF and cerebral metabolic oxygen consumption. This can be used to the anesthesiologist's advantage when the decrease in oxygen consumption is greater than the decrease in CBF.

In general, volatile anesthetics are considered to be vasodilators and intravenous anesthetics to be vasoconstrictors. Ketamine is an exception because it will cause increases in both CBF and cerebral metabolic rate. Volatile anesthetics, as vasodilators, produce a dose-dependent increase in CBF. The magnitude of vasodilation is dependent on the balance between the anesthetic's intrinsic vasodilatory property and vasoconstriction secondary to its decrease in cerebral metabolic rate.

It has been suggested that anesthetic agents only affect the blood flow in normally perfused areas of the brain. If this is the case, volatile anesthetics will cause a steal phenomenon, in which the blood vessels in normal brain dilate and steal blood flow away from ischemic areas of the brain that are both already maximally vasodilated and unresponsive to the vasodilating effects of the anesthetics.

C.12. Discuss the protective effects of anesthetic agents on cerebral function.

Although it has not been proved that general anesthetics afford brain protection, agents that cause the greatest decrease in cerebral metabolic oxygen consumption should lessen the risk of cerebral ischemia. Whether a particular anesthetic is optimal

for these patients is an area of discussion. Obviously, avoiding or eliminating ischemia is preferable to protecting against it.

Messick examined the effects of volatile anesthetics on critical regional CBF, that is, the regional CBF at which EEG evidence of cerebral ischemia became apparent. He found that critical regional CBF in patients receiving isoflurane was less than 10 mL/100 g/min and in patients receiving halothane was 18 to 20 mL/100 g/min. This decrease in critical CBF suggests that isoflurane may offer some protective effect. Because of its potential to cause a decrease in blood pressure and reflex increase in heart rate, it probably should not be used at high concentrations as the sole anesthetic. A significant proportion of patients with carotid artery disease also have coronary artery disease and may not tolerate the hypotension and tachycardia associated with the use of high-dose isoflurane. By using this anesthetic in low concentrations in combination with other anesthetic agents, one can better maintain hemodynamic stability while perhaps providing for an increased tolerance of cerebral hypoperfusion. Other evidence, suggests that isoflurane may not offer protection during regional cerebral ischemia.

The newer agents, sevoflurane and desflurane, have been investigated for their possible role in neuroanesthesia. Compared to isoflurane, desflurane has no significant difference in its effects on decreasing cerebral glucose utilization, increasing blood flow, and maintaining coupling between local CBF and local cerebral glucose utilization. Although sevoflurane showed no significant difference in its effects on decreasing cerebral glucose utilization, and coupling between local CBF and local cerebral glucose utilization at 1 minimum alveolar concentration, it did show less of an increase in CBF. This difference between isoflurane and sevoflurane was independent of their effects on systemic blood flow and cardiac output. Hence, desflurane and sevoflurane may have similar neuroprotective effects as isoflurane and, with their lower blood gas solubility coefficients, may promote a more rapid recovery from anesthesia, allowing faster evaluation of neurologic status.

Thiopental affords cerebral protection against focal or incomplete global cerebral ischemia. It is a cerebral vasoconstrictor, as are most other intravenous anesthetics. It will also transiently decrease cerebral metabolism to 40% to 50% of baseline. The combined effect is that cerebral metabolic oxygen consumption is decreased more than oxygen delivery. The reduction in oxygen demand is the result of inhibition of functioning neurons, which can be seen as a quiet or isoelectric EEG. When dosing barbiturates for cerebral protection, the EEG should be monitored and repeated doses given to achieve and then maintain a burst suppression pattern. Once the EEG is isoelectric, indicating lack of neuronal function, further doses of thiopental do not provide additional protection. It is generally not recommended that thiopental be used for cerebral protection during carotid endarterectomy. As mentioned previously, avoidance of ischemia is preferable to its treatment. If thiopental is used, the EEG, because of its isoelectricity, becomes useless as a monitor of cerebral ischemia. This is especially problematic if selective shunting is to be done. Furthermore, the doses of thiopental required to suppress the EEG may cause hypotension and a delayed emergence from anesthesia.

Barbiturate use to minimize the possibility of cerebral ischemia has been advocated for the patient undergoing carotid bypass procedures in which temporary occlusion of the recipient vessel is required. Whether treatment of patients with a 3- to 5-mg per kg dose of thiopental affects their outcome in terms of neurologic deficit is not known, though it has been shown to be efficacious in animal models.

Dexmedetomidine is a selective α_2-adrenergic agonist with sedative, analgesic, and anxiolytic properties. It does not cause respiratory depression. In animal studies, dexmedetomidine reduces ischemic damage after transient and permanent ischemia. Its mechanism of neuroprotection is still unclear. One hypothesis suggests that with the onset of cerebral ischemia, one of the initial responses in the central nervous system is the excessive release of norepinephrine and glutamate during

energy failure. If the increase in norepinephrine release is a causative component of injury, an α_2-adrenergic agonist may decrease the damage afforded by cerebral ischemia. Dexmedetomidine has been shown to reduce arousal and decrease CBF in volunteers.

C.13. How will you manage this patient's ventilation under general anesthesia?

Because carbon dioxide is a potent cerebral vasodilator, it was initially recommended that patients undergoing carotid endarterectomy be hypoventilated intraoperatively to achieve hypercarbia and cerebral vasodilation. It is now well accepted that hypercapnea should be avoided in patients with carotid artery disease. Carbon dioxide causes vasodilation in normally reactive, nonischemic, vascular beds. In patients with carotid

artery disease, this means that blood flow is diverted away from the already maximally dilated vessels in the territory of the occluded carotid and toward normal areas of the brain. This decrease in regional CBF in ischemic areas of the brain with increased CBF in normal areas of the brain is known as *intracerebral steal*.

Other authors have recommended extreme hypocapnea during carotid endarterectomy, reasoning that this would result in an "inverse steal" or "Robin Hood" phenomenon. Hypocapnea will cause constriction of cerebral vessels in normally perfused areas of the brain, possibly diverting blood flow into the maximally vasodilated, unreactive, hypoperfused regions of the brain. Clinical trials have been unable to demonstrate any benefit from hypocapnea, and animal studies have shown that it may, in fact, exacerbate ischemia. This most likely happens not only because of intense vasoconstriction, but also because of a leftward shift of the oxyhemoglobin dissociation curve so that hemoglobin is less able to give its oxygen to tissues.

The general recommendation for patients with cerebrovascular disease is that normocarbia or mild hypocarbia be maintained. After repair of their carotid stenosis, some patients will have a marked hyperemia with CBF of 100 mL/100 g/min. In these patients, decreasing both blood pressure and arterial carbon dioxide tension to decrease their CBF is indicated. Without a decrease in CBF, these patients are at risk for postoperative intracerebral hemorrhage.

C.14. How will you manage this patient's blood pressure intraoperatively?

Various factors need to be considered in the blood pressure management of patients undergoing carotid endarterectomy. In the patient with carotid artery disease, a loss of autoregulation occurs in ischemic areas of the brain. In areas of chronic hypoperfusion, vessels are maximally vasodilated and unresponsive to vasomotor stimuli. Perfusion in these ischemic areas is pressure dependent.

During cerebral arterial occlusion, systemic blood pressure may need to be increased to augment collateral blood flow. The primary collateral pathways include the Willisian channels. If Willisian channels are not available, either because of the patient's anatomy or a therapeutic intervention, secondary collateral channels are available that bridge adjacent major vascular territories. These pathways are known as the *pial-to-pial collateral* or *leptomeningeal* pathways.

Because of the adjustment of the autoregulatory limits in hypertensive patients and because of a lack of autoregulation in ischemic areas of the brain, hypotension should be avoided. The patient's blood pressure should be maintained in its high normal range. During arterial occlusion, the only practical way to increase collateral blood flow may be by increasing the collateral perfusion pressure by raising the systemic blood pressure. The extent to which the blood pressure should be raised depends on the nature of the disease. During deliberate hypertension, the systemic blood pressure is raised by 30% to 40% above the baseline or until ischemic symptoms resolve. Both maintenance of and increases in blood pressure can be accomplished with light anesthesia and, when necessary, infusion of the α-agonist phenylephrine. Phenylephrine has no direct effect on the cerebral vasculature; therefore, cerebral perfusion is increased by an elevation in the cerebral perfusion pressure. Phenylephrine increases blood pressure, cerebral perfusion pressure, stump pressure, and regional CBF. It also increases myocardial oxygen consumption. Because it increases after-

load, care must be taken when it is used in patients with coronary artery disease. It may exacerbate ischemia and failure. In patients with coronary artery disease, blood pressure should not be increased above baseline unless evidence of cerebral ischemia develops. Extreme increases in blood pressure can and should be managed with easily titratable intravenous vasodilators such as sodium nitroprusside or nitroglycerin.

After the bifurcation of the carotid artery is exposed, the surgeon often infiltrates the carotid sinus with lidocaine to eliminate the unpredictable hemodynamic response to manipulation of the carotid artery.

Once the stenosis has been relieved and the carotid cross-clamp removed, the patient's blood pressure should be maintained in its low normal range. This lowering of blood pressure offers several advantages. It decreases myocardial oxygen consumption by decreasing the work of the heart, it decreases the amount of stress on the suture line in the carotid artery, and finally, it minimizes the possibility of reperfusion hemorrhage.

C.15. Discuss reperfusion injury following carotid endarterectomy and carotid artery stenting.

Reperfusion injury involves cerebral hemorrhage or the development of cerebral edema after obstruction to flow through the carotid artery has been relieved. Although rare, it is an often fatal complication of carotid endarterectomy. Patients with a previous stroke are most likely to suffer reperfusion hemorrhage, but it can occur in otherwise normal brain tissue. Poorly controlled blood pressure after the carotid cross-clamp has been removed contributes to this complication. One proposed mechanism for this injury is that once flow is returned to normal, vascular beds in previously hypoperfused areas of the brain are unable to respond properly with vasoconstriction. They are unable to maintain normal flow with increased perfusion. Because hypoperfusion distal to the carotid stenosis has been long-standing, these vessels have lost their ability to autoregulate. Once the carotid stenosis is eliminated, the perfusion pressure distal to the former site of the stenosis is markedly increased. Because of the lack of autoregulation in this area, CBF increases with increasing perfusion. The patients at highest risk for reperfusion injury have the greatest degree of stenosis and the greatest pressure drop across the carotid lesion. Again, maintaining blood pressure control with antihypertensive medications once the carotid obstruction is eliminated decreases the incidence of reperfusion injury.

C.16. What intravenous fluids will you give this patient intraoperatively?

Because moderate hyperglycemia has been shown to worsen neurologic outcome after ischemia, care must be taken to avoid increasing the patient's glucose with exogenously administered dextrose. Intravenous fluids such as Normosol R, lactated Ringer's solution, or normal saline would be appropriate choices for patients undergoing carotid endarterectomy.

These patients should not be vigorously hydrated intraoperatively. It is best to limit their intraoperative fluids to what is required for maintenance, with additional colloid and blood replacement being given as needed. Intraoperative overhydration may lead to some of the frequently observed postoperative hypertension and in patients with myocardial disease may exacerbate congestive heart failure.

D. Postoperative Management

D.1. The patient does not "wake up" from general anesthesia. Why?

Once other causes of slow emergence from general anesthesia (such as hyperglycemia or hypoglycemia, hypothermia, anesthetic overdose, hypercarbia, and hypoxemia) have been ruled out, the possibility of an adverse intraoperative event having occurred needs to be considered. Patency of the carotid artery should be evaluated. This can be done by Doppler studies while the patient is still in the operating room. If no blood flow is seen in the carotid artery, the incision can be reexplored immediately. If Doppler studies are normal, the possibility of a cerebral infarction from prolonged hypoperfusion or from emboli must be considered. The patient should remain intubated while further studies, including a CT scan and cerebral angiography, are done as expeditiously as possible. The incidence of new perioperative neurologic deficits is 3% in centers where the operation is done commonly.

Paciaroni M, Eliasziw M, Kappelle LJ, et al. Medical complications associated with carotid endarterectomy. *Stroke.* 1999;30:1759–1763.

D.2. Postoperatively, the patient's blood pressure is 170/96 mm Hg. Will you treat this?

This patient's blood pressure needs to be carefully controlled because postoperative hypertension is associated with bleeding at the operative site, myocardial ischemia, arrhythmias, intracerebral hemorrhage, and cerebral edema.

Hypertension is observed more commonly than hypotension after carotid endarterectomy. Causes of hypertension include hypoxemia, hypercarbia, pain, and a full bladder. Obviously, if any or all of these causes are present, they need to be dealt with promptly and appropriately. Another common cause of postoperative hypertension and tachycardia is blunting of the carotid baroreceptor mechanism secondary to carotid sinus dysfunction caused by surgical trauma. If this is the cause of hypertension, therapy with antihypertensive agents should be started.

This patient's blood pressure should be maintained in her low normal range postoperatively. Elevated blood pressure can be treated with hydralazine in 5-mg increments or, if the patient is not bradycardic, labetalol may be used in 10-mg increments. Alternatively, infusions of sodium nitroprusside or nitroglycerin may be used. β-Blockade with metoprolol or an infusion of esmolol may be added to this regimen.

Wong JH, Findlay JM, Suarez-Almazor ME. Hemodynamic instability after carotid endarterectomy: risk factors and associations with operative complications. *Neurosurgery*. 1997;41:35–41.

D.3. What immediate postoperative complications might you expect?

Immediate postoperative complications include neurologic deficits, hemodynamic instability, and respiratory insufficiency. Evaluation of the North American Symptomatic Carotid Endarterectomy Trial showed that 8.1% of patients had medical complications: 1% with myocardial infarctions, 7.1% with other cardiovascular disorders such as arrhythmias and congestive heart failure, 0.8% with respiratory complications, 0.4% with transient confusion, and 0.7% with other complications. Carotid endarterectomy is 1.5 times more likely to be associated with complications in patients with a history of cardiac disease or hypertension.

Postoperative neurologic complications are usually embolic in nature, occurring during surgery. Other neurologic complications result from reperfusion injury and intracranial hemorrhage.

Circulatory instability is common after carotid endarterectomy, with either hypotension or hypertension being observed. Hypotension may have any of several causes, as does hypertension, as noted previously. These include hypovolemia, depression of the circulation by residual anesthetics, prolonged effect of intraoperatively administered antihypertensives, dysrhythmias, and myocardial ischemia. Each of these causes needs to be sought and, if present, treated appropriately. Another possible cause of hypotension is an excessive reflex response because of increased sensitivity of the carotid sinus after exposure of the baroreceptor mechanism to a higher pressure with removal of the plaque. If this is the cause, therapy needs to be instituted with fluids and vasopressors.

Postoperative respiratory insufficiency is a rare but potentially life-threatening complication. This can be due to vocal cord paralysis from intraoperative traction on the laryngeal nerves. Should this present with inability to protect the airway, the patient should be reintubated immediately.

A prospective trial found that 12.5% of patients had nerve injuries after carotid endarterectomy, but all were transient, lasting from 1 week to 37 months. No patient

had life-threatening respiratory insufficiency from the nerve injuries. The most commonly injured nerves were the hypoglossal, recurrent laryngeal, superior laryngeal, and greater auricular nerves.

Airway obstruction can also occur from hematoma formation at the operative site, from either arterial or venous bleeding. The hematoma needs to be evacuated as quickly as possible and, depending on ventilatory status, the patient may need to be intubated. This is most easily done after evacuation of the hematoma if the clinical condition allows.

Supraglottic edema may also be a rare cause of postoperative upper airway obstruction after carotid endarterectomy. CT analysis of airways postoperatively showed reduction in the volume of the airway in all patients, with a greater reduction seen in intubated patients (63% ± 9%) than in nonintubated patients (32% ± 7%).

Tension pneumothorax can result from air dissecting through the wound and the mediastinum to the pleura. This diagnosis should be considered in all patients after carotid endarterectomy who seem to have respiratory distress and no evidence of upper airway obstruction. Absence of breath sounds over half of the chest and hemodynamic instability would support this diagnosis.

Chemoreceptor function is irreversibly suspended in most patients after carotid endarterectomy for up to 10 months. Lack of chemoreceptor function means that there is a loss of circulatory response to hypoxia and an increase in resting $Paco_2$ of approximately 6 mm Hg. This complication is potentially very serious, and one needs to be most concerned about its development in patients who have had a previous contralateral carotid endarterectomy, where function may be lost bilaterally. In all patients after carotid endarterectomy, supplemental oxygen should be provided and opioids administered cautiously.

D.4. Discuss postoperative neurocognitive dysfunction following uncomplicated carotid endarterectomy.

Carotid endarterectomy will reduce the incidence of stroke in patients with high-grade carotid artery stenosis. Increasing evidence suggests that as many as 28% of surgical patients have significant neuropsychological dysfunction 1 day after carotid artery surgery. Between 9% and 23% of these patients continue to exhibit cognitive decline 1 month after surgery.

The APOE-ε4 allele has been associated with worse outcome following stroke. In a prospective trial, 75 patients undergoing carotid endarterectomy were studied. Of 75 patients, 12 (16%) possessed the APOE-ε4 allele. Of the 75 patients, 8 (11%) experienced cognitive dysfunction on postoperative day 30. One month after carotid endarterectomy, APOE-ε4-positive patients were more likely to have suffered a neurocognitive injury (42%) than APOE-ε4-negative patients (5%).

The presence of the APOE-ε4 allele increase the risk of neurocognitive dysfunction 62-fold 1 month after surgery. Diabetes and obesity also predisposed to injury.

Evidence also indicates cognitive dysfunction in patients with carotid stenosis treated with carotid artery stenting performed under cerebral embolic protection. In a prospective case control study, 41% of patients undergoing carotid stenting developed moderate to severe cognitive dysfunction compared to a matched control group. The average deficit score was significantly higher in the carotid artery stenting group at 1 day. These differences were independent of age and history of stroke or TIA. The absence of oral statin medication may increase the probability of cognitive dysfunction.

The influence of regional versus general anesthesia in postoperative subclinical cognitive dysfunction remains unclear. Most concur that multiple factors, including surgical technique, anesthetic technique, and patient status, influence postoperative outcome.

CHAPTER 18

Awake Craniotomy for Mapping and Surgery in the Eloquent Cortex

Thomas A. Moore II

A 47-YEAR-OLD RIGHT-HANDED PHYSICIAN presented after two episodes of acute onset of left-sided headache associated with a change in reading comprehension and difficulty with word finding. Each episode lasted several minutes without loss of consciousness or generalized seizure activity. Magnetic resonance imaging (MRI) revealed a 4 × 5 centimeter (cm) variably marginated mass in the inferior aspect of the left temporal lobe involving the middle and inferior temporal gyri, as well as the occipitotemporal gyrus (Fig. 18.1). He was started on corticosteroids, and his symptoms did not reappear. Diffusion tensor imaging was used to determine that his optic radiations and Meyer loop were not within the lesion. Magnetoencephalography (MEG) was used to determine the location of his primary motor area. He underwent an uncomplicated awake left craniotomy with motor and language area mapping. He was discharged to home the next day. Final pathology revealed an anaplastic astrocytoma World Health Organization grade III.

A. Medical Disease and Differential Diagnosis

1. What is the eloquent cortex?
2. What is the underlying pathology?
3. What determines intracranial pressure (ICP)?
4. How does a space-occupying mass alter ICP?
5. What is autoregulation, and why is it important?
6. How is cerebral blood flow (CBF) regulated?
7. What drug therapies may be associated with this pathology?

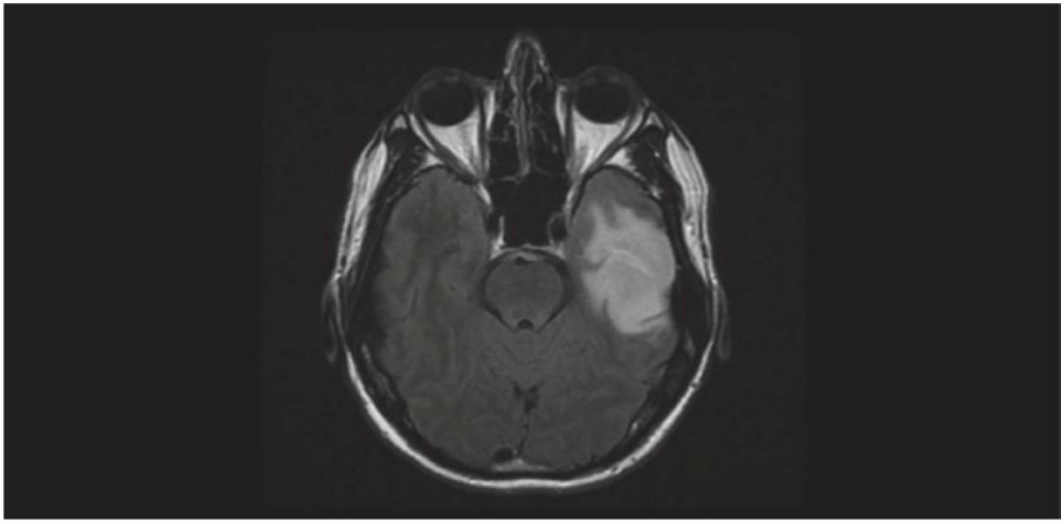

Figure 18.1 A 47-year-old man with two episodes of left-sided headaches associated with problems with reading comprehension and difficulty with word finding. He underwent an uneventful left awake craniotomy with motor and language area mapping. Final pathology was a World Health Organization grade III anaplastic oligoastrocytoma.

B. Preoperative Evaluation and Preparation

1. Why an awake craniotomy?
2. What are the current symptoms and why are they important?
3. Are there anesthetic implications from current treatment drugs?
4. What laboratory data are required?
5. What radiology data should be reviewed?
6. How do you prepare the patient for an awake craniotomy?
7. Should this patient receive premedications?
8. What precautions should be made for airway management?

C. Intraoperative Management

1. How should this patient be monitored?
2. Does this patient require invasive monitoring?
3. Can current drug therapy alter eloquent cortex mapping?
4. Why use hypertonic fluids during a craniotomy?
5. What intravenous fluids (IVFs) are recommended?
6. Would a lumbar drain for CSF removal benefit this patient?
7. Venous air embolism (VAE): Is it a concern in this case?
8. How is the eloquent cortex mapped?
9. How is an intraoperative seizure treated?
10. How will you conduct this anesthetic?

D. Postoperative management

1. What are the major concerns following craniotomy?

A. Medical Disease and Differential Diagnosis

A.1. What is the eloquent cortex?

Eloquent cortex is a term usually used to describe functional areas of the cerebral cortex associated with motor, language, and sensory activity. Traditionally, tumors or epileptic foci within or near these areas have been termed *inoperable* because of the devastation caused to the patient by injury to these neurons.

DeBenedictis A, Moritz-Gasser S, Duffau H. Awake mapping optimizes the extent of resection for low grade gliomas in eloquent areas. *Neurosurgery*. 2010;66(6):1074–1084.

A.2. What is the underlying pathology?

The underlying pathology requiring an awake craniotomy for mapping and resection within the eloquent cortex can be either a space-occupying lesion or epileptic foci. In either case, mapping of the cortical and subcortical structures with an awake and cooperative patient is necessary to minimize neurologic injury and maximize lesion resection. Mapping of the motor cortex is often done under general anesthesia, after reversal of any residual muscle relaxant, because the stimulated area(s) can usually be seen by an observer. Nevertheless, there are several potential problems. In the case of a space-occupying lesion, the neuronal pathways can become distorted secondary to the expanding mass and mislead the surgeon who is searching not only for the functional area, but also a "quiet" area of cortex through which to do the resection. In addition, these patients are frequently in a lateral decubitus position, with the side to be observed in the down position. Visualization of the patient can be further obstructed with sheets, blankets, forced warm-air blankets, and other patient-positioning devices. Hence, we tend to map the motor cortex in an awake craniotomy whenever possible.

Supratentorial brain tumors are about 31% gliomas (Fig. 18.1), 15% meningiomas, 12% metastatic lesions, and 8% pituitary tumors. Metastatic lesions are most frequently lung, breast, and gastrointestinal tract tumors. Additional space-occupying lesions include blood and blood vessels, infections, hydrocephalus, cerebral infarctions, radiation necrosis, arachnoid cysts, and cerebral edema.

These space-occupying lesions can present in various manners. The most common presentation of brain tumors is a progressive neurologic deficit (68%), usually motor weakness (45%), headache (54%), and seizures (26%). Others may present from progressive focal deficits resulting from destruction of brain tissue or compression of normal brain structures by the mass itself or peritumoral edema. Additional presentations include nausea or vomiting, vertigo, lethargy, apathy, and changes in mental status as several examples.

In addition to these various presenting signs and symptoms, asymmetric supratentorial tumors can enlarge to the point of causing a midline shift of the intracranial contents, possibly leading to herniation. The brain can be displaced across the midline beneath the falx or compressed through the tentorial incisura into the posterior fossa. As these various areas of the brain are compressed against these dense fibrous structures, stretching and shearing of the penetrating arteries can result in devastating neurologic injuries.

An area of cerebral edema surrounds most intracranial masses secondary to the disruption of the blood–brain barrier (BBB) usually associated with a localized acidosis. Vasogenic edema reflects a shift of fluid from the intravascular to the extravascular space. Cytotoxic edema represents a shift of fluid from the extracellular to the intracellular space. Vasogenic edema responds very well to corticosteroid treatment. Dexamethasone is frequently prescribed for this problem. This area of cerebral edema is known as the penumbral area and represents areas of autoregulatory dysfunction as well as BBB breakdown. The vasculature in this area of the brain is usually maximally

Table 18.1 Commonly Used Drugs in Seizure Control

TYPE OF SEIZURE	FIRST-LINE DRUG	SECOND-LINE DRUG
Generalized tonic-clonic	Carbamazepine	Clobazam
	Phenytoin	Clonazepam
	Valproate	Lamotrigine
		Phenobarbital
		Vigabatrin
		Felbamate
		Acetazolamide
Generalized absence	Valproate	Clonazepam
	Ethosuximide	Lamotrigine
		Acetazolamide
Tonic, atonic, atypical absences	Valproate	Carbamazepine
	Clobazam	Phenobarbital
	Clonazepam	Felbamate
	Lamotrigine	Acetazolamide
	Phenytoin	
Myoclonic seizures	Valproate	Phenobarbital
	Clonazepam	Acetazolamide
Simple partial, complex partial, secondarily generalized	Carbamazepine	Clobazam
	Valproate	Lamotrigine
	Phenytoin	Gabapentin
		Vigabatrin
		Phenobarbital
		Felbamate
		Acetazolamide

From Frost EAM, LaFleur JL. Awake craniotomy for deep brain stimulation. In: *Yao and Artusio's Anesthesiology: Problem-Oriented Patient Management*. 6th ed. Philadelphia: Lippincott, Williams and Wilkins; 2008:585. Used with permission.

vasodilated. Hypercapnia in surrounding normal brain causes vasodilation in the normal vasculature and may result in decreased flow to the ischemic area. Hypocapnia, on the other hand, causes vasoconstriction of the normal adjacent vascular beds, with the resultant redistribution of blood to the ischemic area. This has been referred to as the "Robin Hood" phenomenon. The formation of peritumoral edema increases the overall size of the tumor, which can lead to the same signs and symptoms as noted earlier.

Patients presenting for an awake craniotomy for excision of an epileptic foci have usually had a seizure disorder for many years and have been on numerous antiepileptic drugs (AEDs) in an attempt to control their disorder. Unfortunately, many of these patients develop adverse reactions or cannot tolerate the side effects of the AEDs and become, for practical purposes, medication failures. Table 18.1 lists the more common AEDs and the types of seizure disorder they treat.

Only patients with seizures in whom the foci are localized in an area of eloquent cortex require an awake craniotomy. Temporal lobe, hippocampal-localized foci are usually resected under general endotracheal anesthesia with intraoperative

electrocorticography. Most of these patients have had preceding intracranial strips, grids, or electrodes placed to help localize the seizure foci.

A.3. What determines intracranial pressure (ICP)?

The adult skull is a rigid, bony box with a fixed volume. Neonatal and infant skulls have several noncalcified portions, called fontanels, that allow the skull to deform during passage through the birth canal. These noncalcified areas also allow the volume of the skull to increase in the presence of increased ICP such as congenital hydrocephalus. Once these areas have calcified, the pediatric skull is also a rigid, fixed volume box.

The intracranial constituents are intravascular blood, cerebrospinal fluid (CSF), and the brain. As liquids, the blood and CSF are noncompressible. Although water can be extracted from the brain by use of osmotic diuretics and other hypertonic fluids, this does not result in much change in brain volume and its gel-like consistency also makes it virtually noncompressible.

ICP is a relationship of the homeostatic balance of the noncompressible contents within a fixed-volume container, the skull. The normal value is 10 to 15 mm Hg. In the early 19th century, the Monro-Kellie hypothesis was the first attempt to describe this relationship. Although several modifications of this doctrine have been made over the years as more has been learned, the basic principle still holds true: Because the intact skull is unyielding, an increase in volume of any one of the normal contents or the addition of a space-occupying lesion must be accompanied by a reduction in one or more of the normal constituents to maintain normal ICP.

Morki B. The Monro-Kellie hypothesis: adaption in CSF volume depletion. *Neurology.* 2001;56:1746–1748.

A.4. How does a space-occupying mass alter ICP?

There are limits to the balanced relationship described by the Monro-Kellie hypothesis. Figure 18.2 represents an idealized ICP–volume curve and diagrams these limitations.

The flat portion of the curve represents increasing volume with no increase in ICP. Several compensatory mechanisms are at work to keep the ICP steady. The most effective of these mechanisms is the dynamic nature of CSF. The rate of absorption increases or the rate of production decreases in light of an increase in ICP. Cerebral blood volume (CBV) is decreased by a redistribution primarily of the intracranial venous blood volume. These mechanisms work to keep the ICP at its normal value of 10 to 15 mm Hg. As the volume continues to increase, these compensatory mechanisms become exhausted and ICP starts to rise as represented by the "knee" of the graph. It is important to note that at this area of the curve, small increases in volume give rise to a much larger increase in ICP. The sharp rise in the graph demonstrates rapidly increasing ICP with even smaller increases in volume. It is vitally important to understand that as the volume continues to rise and ICP continues to increase, the risk of cerebral herniation also increases. Cerebral perfusion pressure (CPP) is also adversely affected with a rise in ICP. CPP is defined as: CPP = MAP – ICP (CVP), where MAP = mean arterial pressure and CVP = central venous pressure. This equation readily shows that an increase in ICP will lead to a decrease in CPP.

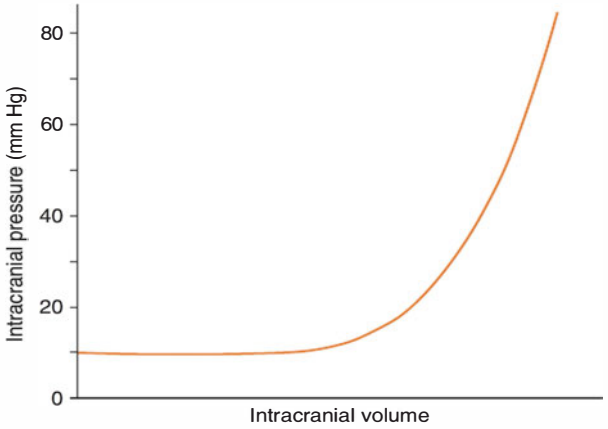

Figure 18.2 Idealized intracranial pressure–volume curve. (From Kass IS. Physiology and metabolism of the brain and spinal cord. In: Newfield P, Cottrell JE, eds. *Handbook of Neuroanesthesia*. 3rd ed. Philadelphia: Lippincott Williams & Wilkins; 1999:18. Used with permission.)

Figure 18.3 shows that CBF remains at 100% for CPPs ranging from 50 to 150 mm Hg. Some have recently advocated that the lower threshold for autoregulation should be shifted more toward 70 mm Hg and the upper threshold shifted more toward 180 mm Hg. In the supine position, ICP in the normal state is effectively zero, making CPP directly related to MAP.

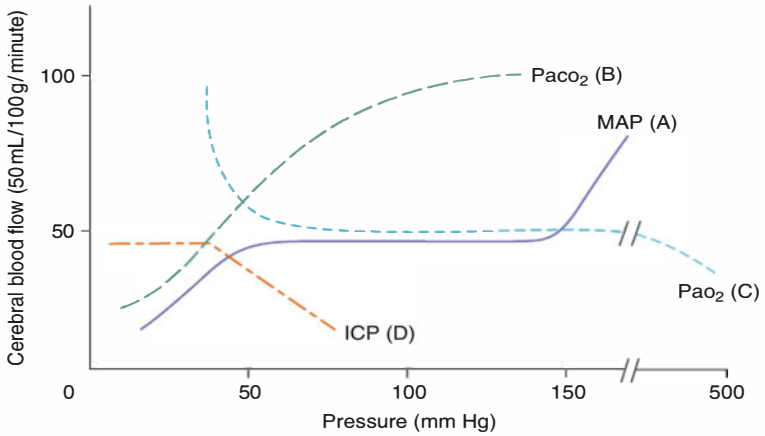

Figure 18.3 Pressure–cerebral blood flow relationships. **A.** Cerebral blood flow (CBF) autoregulation. CBF is maintained at 50 mL/100 g/min for mean arterial pressure (MAP)/cerebral perfusion pressure (CPP) = 50 to 150 mm HG. **B.** Linear relationship between $Paco_2$ and CBF for $Paco_2$ = 20 to 80 mm Hg. **C.** Pao_2 and CBF. **D.** Intracranial pressure (ICP) and CBF. (From Ravussin PA, Wilder-Smith OHG. Anesthesia for supratentorial tumors. In: Newfield P, Cottrell JE, eds. *Handbook of Neuroanesthesia*. 3rd ed. Philadelphia: Lippincott Williams & Wilkins; 1999:146. Used with permission.)

A.5. What is autoregulation, and why is it important?

In its simplest form, autoregulation is a myogenic response of the vascular smooth muscle of the intracranial cerebral arterioles to maintain a nearly constant CBF in the face of changing CPP. Not all of the mechanisms controlling this action are fully understood.

When CPP becomes less than 50 mm Hg or greater than 150 mm Hg, the CBF becomes pressure passive. This response is important to keep in mind when considering the use of deliberate hypotension. A MAP of less than 50 mm Hg could theoretically cause a decrease in CPP and thereby decrease CBF to the point of causing cerebral ischemia. On the other side of the spectrum, MAPs greater than 150 mm Hg can cause disruption of the BBB and cause vasogenic edema throughout the brain, not only in the area of vasogenic edema surrounding the tumor.

The autoregulation curve is shifted to the right in the presence of chronic uncontrolled hypertension, as shown in Figure 18.4.

This is important because now the lower threshold for cerebral ischemia is higher than in the normal state. Although there is not a direct correlation between degree of hypertension and rightward shift of the autoregulatory curve, it is possible that where signs of cerebral ischemia might not have become obvious until the CPP was 30 to 40 mm Hg in the normotensive person, these signs may now occur with the CPP at 80 to 90 mm Hg, a usually normal CPP. Therefore, great care must be taken to keep the MAP near the patient's usual levels in the uncontrolled or poorly controlled hypertensive patient. On the other end of the curve, it is possible that the rightward shift adds some form of cerebral protection against perfusion breakthrough at the higher CPPs. Treatment with antihypertensive drugs modifies this rightward shift back toward the normal range. The degree to which this occurs depends both on the length of time the hypertension has been treated and the resultant decrease in blood pressure.

The type of drug used to treat hypertension may also determine the effect on autoregulation. Systemic direct-acting vasodilators without action on cerebrovascular smooth muscle and α-adrenergic and ganglionic blocking drugs should have no effect on cerebrovascular autoregulation. Systemic direct-acting vasodilators that do have

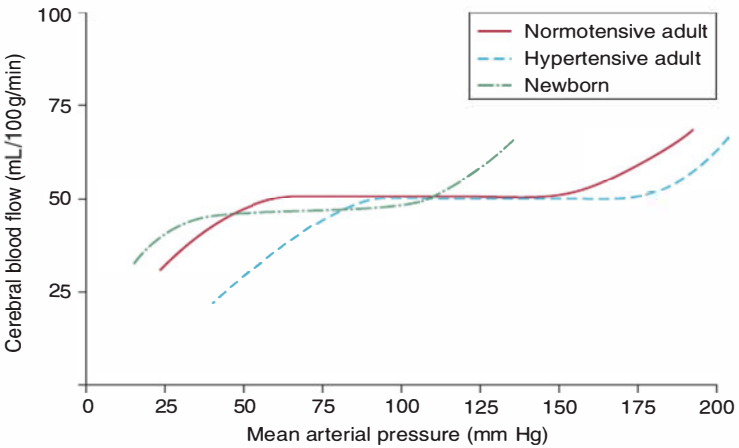

Figure 18.4 Autoregulatory curve of the cerebral vasculature in the normotensive adult, the hypertensive adult, and the newborn. (From Ravussin PA, Wilder-Smith, OHG. Anesthesia for supratentorial tumors. In: Newfield P, Cottrell JE, eds. *Handbook of Neuroanesthesia*. 3rd ed. Philadelphia: Lippincott Williams & Wilkins; 1999:14. Used with permission.)

an action on the cerebrovascular smooth muscle, such as hydralazine, sodium nitroprusside, nitroglycerin, and calcium channel blockers may influence autoregulation. Treating congestive heart failure may also improve CPP by lowering CVP and thereby decreasing cerebral venous outflow pressure.

A.6. How is cerebral blood flow (CBF) regulated?

CBF also responds to chemical modulation. Figure 18.3 demonstrates these relationships in the $Paco_2$ (arterial carbon dioxide partial pressure) and Pao_2 (arterial oxygen partial pressure) curves. Carbon dioxide (CO_2) concentration is the most potent modulator of CBF. Insonating the middle cerebral artery of a volunteer by means of transcranial Doppler device and asking the subject to hyperventilate will show an increase in cerebral blood velocity reflecting a decrease in CBF secondary to cerebral vascular constriction, usually within 3 to 4 breaths, a very rapid response. This principle is utilized to treat increased ICP by decreasing CBV secondary to the hyperventilation. However, this mechanism is self-limited after approximately 6 to 10 hours and will no longer provide the decreased ICP.

As shown in Figure 18.3, there is a near linear response in CBF at a $Paco_2$ between 20 and 80 mm Hg, with CBF increasing about 2% to 4% for each millimeter of mercury change in $Paco_2$. In general, doubling $Paco_2$ from 40 to 80 mm Hg doubles CBF and likewise halving $Paco_2$ from 40 to 20 mm Hg halves CBF. This represents maximal vasodilation at extreme hypercapnia and maximal vasoconstriction at extreme hypocapnia, respectively.

CBF also responds to the oxygen partial pressure. As shown in Figure 18.3, when the Pao_2 reaches approximately 50 mm Hg, a steep increase in CBF occurs as the Pao_2 continues to fall. At normal Pao_2 levels, CBF is not affected. Hyperoxia can actually cause a 10% to 15% decrease in CBF at 1 atm. Temperature can also have an effect on CBF. For each 1° C decrease in body temperature, the cerebral metabolic rate for oxygen consumption ($CMRO_2$) decreases by approximately 7%. The regulation of CBF is known to be closely coupled to the cerebral metabolism and is reflected by a parallel decrease. These changes are not homogenous with more changes seen in the cerebral and cerebellar cortices; less so in the thalamus and no difference in the hypothalamus and brainstem. During hypothermic cardiopulmonary bypass, lowering the body temperature to 26° C resulted in a 56% calculated reduction in $CMRO_2$ and a 55% reduction in CBF.

The potent inhalational agents can also increase CBF in the presence of decreasing $CMRO_2$, thus uncoupling their relationship. Increasing levels of minimum alveolar concentration can also blunt the CO_2 response or render CBF pressure passive. CO_2 reactivity is preserved during intraoperative use of opioids such as fentanyl and remifentanil.

A.7. What drug therapies may be associated with this pathology?

Patients can present with intracranial pathology at any age. Patients with comorbidities may be taking medications for hypertension, diabetes mellitus, congestive heart failure or prior myocardial infarction (MI), as examples. It is not uncommon today for many patients to be on some form of antiplatelet drug whether they have suffered a MI or not. The effects of some of these drugs can be reversed with fresh frozen plasma, whereas others are not immediately reversible and need 7 to 10 days before their effect is gone.

Patients with epilepsy may be on several medications in an attempt to control their seizures. These drugs are listed in Table 18.1. Presenting signs and symptoms have been described earlier. AEDs are indicated in 26% of patient's presenting with seizures who are later diagnosed with a brain tumor.

Another 20% to 45% of patients with brain tumors will eventually develop a seizure after diagnosis. The current standard (2006) is that prophylactic AEDs should not be started in this group of patients. As a guideline, in patients with brain tumors undergoing craniotomy, prophylactic AEDs may be used, and if there is no seizure activity, they may be tapered, starting 1 week postoperatively.

As previously discussed, most intracranial mass lesions are surrounded by an area of vasogenic edema to varying extents. The use of steroids, in particular dexamethasone, are commonly used to help alleviate the problems associated with this. Dexamethasone is more beneficial, and the effect often much more dramatic in metastatic tumors than primary tumors in reducing the area of edema. The usual dosage in the corticosteroid-naïve patient is a loading dose of 10 mg IV, then 6 mg by mouth or IV every 6 hours. Doses of up to 10 mg every 4 hours have been given for severe vasogenic edema. For the patient previously diagnosed and on corticosteroids, doubling the current dose is doubled for acute deterioration.

Greenburg MS. Tumor. In: Greenburg MS, ed. *Handbook of Neurosurgery*. 7th ed. New York: Thieme; 2010: 582–769.

B. Preoperative Evaluation and Preparation

B.1. Why an awake craniotomy?

An awake craniotomy is performed when the pathologic lesion, be it a tumor or an epileptic focus, is in or near an area of eloquent cortex, as defined earlier, in an effort to preserve neurologic function.

The extent of the craniotomy is variable. Some neurosurgeons advocate a carefully planned, limited-exposure craniotomy defined with neuronavigational devices to encompass primarily the area of the lesion and immediate surrounding brain. Others advocate a large craniotomy exposing a wide cortical area for mapping. In either case, the primary goal of the surgical procedure is to obtain the greatest degree of tumor resection with as little damage to the eloquent cortex as possible and hence the least postoperative neurologic deficit.

Even with the cortex exposed, there are many challenges in identifying these areas of eloquent cortex that demand an awake and cooperative patient. As a tumor within or near the eloquent cortex grows and expands, the various neuronal pathways can become distorted from their normal anatomic locations. Ultrasonography may assist the neurosurgeon in identifying the lesion borders so testing can proceed in the surrounding areas of the cortex. Areas that do not elicit a response, respective of the area being tested, are also identified as areas of negative mapping and may serve as an entrance site for both cortical and subcortical resection as needed. Several studies have indicated that surgery through these areas of absolute negative mapping have a significantly lower incidence of both intraoperative and postoperative

neurologic deficits. There is also increasing realization that there are more cortical areas that relate to an acceptable quality of life other than the areas of eloquent cortex. Nonlanguage areas that have to do with visual and or vestibular functions, spatial awareness, cognitive function, understanding and judgment, memory, calculation, and emotion can be mapped both cortically and subcortically to help prevent postoperative complications that are usually not discussed or described.

DeBenedictis A, Moritz-Gasser S, Duffau H. Awake mapping optimizes the extent of resection for low-grade gliomas in eloquent areas. *Neurosurgery*. 2010;66(6):1074–1084.

Kim SS, McCutcheon IE, Suki D, et al. Awake craniotomy for brain tumors near eloquent cortex: correlation of intraoperative cortical mapping with neurological outcomes in 309 consecutive patients. *Neurosurgery*. 2009;64:836–846.

B.2. What are the current symptoms and why are they important?

In order to successfully complete an awake craniotomy, the patient must be motivated to undergo the demanding procedure and able to effectively communicate with the neurosurgeon, the neurologist, and the neuroanesthesiologist. The patient must also be able to read short phrases, identify various objects, and describe pictures.

A patient who presents with some form of dysphasia may not be able to participate at all. Expressive dysphasia and global dysphasia are extreme examples, but not uncommon presentations. At times, a short course of corticosteroids will decrease the penumbral area enough that verbal testing is practical. Some patients will present greatly agitated. Although this is usually their presenting symptom, they cannot cooperate in any fashion, even with minimal commands, and other means are necessary to care for these folks.

Areas of muscular weakness or paralysis, either from the current problem or past injury, must be identified preoperatively to differentiate between postoperative worsening and new neurologic deficits. Rarely will the patient show improvement in the immediate postoperative period; however, pre-existing problems can actually be accentuated in the postoperative period.

Overall, patients who cannot communicate effectively or cooperate do not make good candidates for an awake craniotomy.

B.3. Are there anesthetic implications from current treatment drugs?

Refer to Table 18.1 once again. Many of the AEDs currently available for treating patients with seizure disorders or those secondary to a brain tumor are listed here.

Many of these drugs, such as the benzodiazepines, hydantoids, analogs, and phenytoins, can interfere with drug metabolism in the liver, requiring increased dosages of IV anesthetic agents and narcotics.

In those patients started on dexamethasone, one may encounter several related abnormalities. Potential side effects associated with corticosteroid use include, but are not limited to, increased white blood (WBC) cell count, glucose intolerance, corticosteroid "stress ulcers," corticosteroid-induced psychosis, hypertension, water and electrolyte imbalance, suppression of the hypothalamic–pituitary–adrenal axis, weight gain, and impaired wound healing.

B.4. What laboratory data are required?

Although the current practice is to minimize the number of preoperative laboratory tests obtained, several are necessary in the patient undergoing a craniotomy, awake or under general anesthesia, for tumor or epileptic foci resection.

Coagulation studies are a must. Although some tumors can have a significant amount of blood loss associated with their pathology (meningiomas), bleeding from an abnormal coagulation system into a tumor bed can pose very serious and at times life-threatening problems. Partial thromboplastin time, prothrombin time, international normalized ratio, and fibrinogen and platelet counts are routinely obtained. In patients who are or have recently taken clopidogrel bisulfate or other antiplatelet, adenosine diphosphate inhibitors, a platelet activity test might prove beneficial. Check with your local laboratory. This test requires specialized equipment and may be done only at certain times of the day; it may require some form of prenotification to the laboratory to ensure that pretesting preparation is completed before the blood sample arrives. Some AEDs may cause thrombocytopenia, but leukopenia is more common.

Electrolyte studies are necessary. This patient population can have imbalances from substances secreted by the tumor, such as atrial natriuretic factor, or secondary to drug effect, such as hyponatremia or hypokalemia. Blood glucose levels are also included and should be controlled to 120 mg per dL or less, but hypoglycemia (less than 55mg per dL) should be avoided, although this may differ among patients. Complete blood count with differential will give information about the hematocrit and white blood cell count. The differential will be normal if the WBC count is elevated from degranulation of the WBCs caused by preoperative corticosteroids. If not, an infection may be present and must be addressed. A routine urinalysis will rule out an asymptomatic urinary tract infection.

Blood type, antibody screen, and crossmatch are also required. In the case of a positive antibody screen, at least four units of crossmatched blood are recommended to be available before starting the procedure. My worst case experience was having a patient with several major antibodies present and compatible with only 1 in 10,000 blood donors. It took 4 days to find the acceptable blood and we settled for only 2 units. It was never taken out of the blood refrigerator, was not needed, and was shipped to the next destination early the following morning. Transfusion during an awake craniotomy is uncommon because these lesions are usually small. Nevertheless, if it does become necessary, you need that blood immediately, not 30 to 45 minutes from now. For a negative antibody screen, 2 units of blood readily available is acceptable.

Depending on comorbidities, an electrocardiogram (ECG) can be obtained.

B.5. What radiology data should be reviewed?

Reviewing the most recently obtained MRI or CT scans can give you a great deal of insight about the intracranial pathology. Characteristics of the tumor such as ring enhancement, cystic or lobulated nature, or variously weighted CT studies may give the neuroradiologist and neurosurgeon some insight regarding the diagnosis of the tumor as well as the location of the lesion. The location of the lesion may confirm the presenting symptoms. Vasogenic edema is readily seen, and the progress of resolution with corticosteroids is possible by reviewing a series of CT scans since presentation. Additional information can be gained, but is not always present for the smaller lesions usually associated with the awake craniotomy. A midline shift would be evidence of increased ICP, as would loss of sulci and gyri, not to mention the presence of uncal or falcine herniation (Fig. 18.5). The presence of hydrocephalous from blockage of CSF pathways is also readily seen and could be a source of increased ICP. Previous areas of stroke are usually easily visualized and need to be noted. This is a very rapidly changing field, so there should be no hesitation in calling on the neuroradiologist or neurosurgeon to point out the pathology and their major concerns. A neuroanesthesiologist can never overcommunicate with the neurosurgeon.

B.6. How do you prepare the patient for an awake craniotomy?

Many things can help prepare the patient for this very demanding procedure. The most important, though, is proper patient selection, which was alluded to earlier.

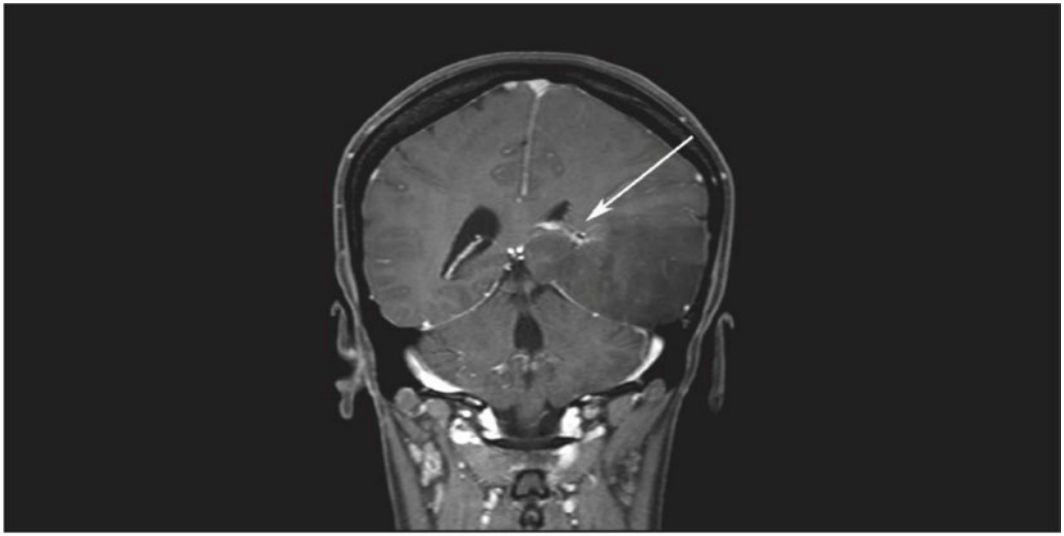

Figure 18.5 MRI scan of a 29-year-old female school teacher with a 2-week history of word-finding difficulty and no other symptoms. Note the rather significant uncal herniation (arrow). The patient underwent an uneventful left, awake craniotomy with language area mapping and was discharged to home the next day. Final pathology revealed a World Health Organization grade III anaplastic oligoastrocytoma.

A patient who cannot effectively communicate and cooperate will not do well with this procedure regardless of how precisely everything else is done.

The need for an awake craniotomy is usually first broached by the neurosurgeon during the workup. It is not at all unusual then to have a rather concerned and anxious patient arrive in the preanesthetic clinic. Ideally, the neuroanesthesiologist who will handle the case will conduct the interview, though this is frequently not the case. If not, then the neuroanesthesiologist must make every effort to see the patient well before the time to go to the operating room. In either case, a direct and detailed explanation of what will happen should proceed. Assure the patient, as often as needed, that adequate means will be taken to control any pain. Reassure the patient that he or she can ask for more medications if needed, but also discuss limitations secondary to needing the patient awake and cooperative. Discuss additional IV lines, invasive monitors if deemed necessary and why they are used, and when they will be placed.

A discussion about the anesthetic itself is essential. Usually, if patients have a good understanding of the sequence of the procedure and that they may not be exactly fully awake for the entire time they are in the operating room, they are more at ease. Describe everything in detail. This may be the first surgical procedure they have ever had and its going to be awake.

B.7. Should this patient receive premedications?

Any premedications that might affect the intraoperative ability to adequately map the cortex are contraindicated. This includes medication that might not only cause prolonged sedation, but in the case of epilepsy surgery, interfere with intraoperative intracranial electrocorticography to define the epileptic foci. In particular, benzodiazepines and barbiturates should be avoided for these reasons. Most of the time, the calm and reassuring neuroanesthesiologist is the best "premedication."

B.8. What precautions should be made for airway management?

Airway evaluation is extremely important in this patient population. The head will most likely be fixed in a three-prong head-holding device, making the ability to intubate the patient via direct laryngoscopy virtually impossible. Further limitations include the surgical drapes and the instrument table, which often extends over the patient completely. The patient is often positioned in the lateral decubitus position, making moving the patient to a flat position time consuming, if even possible at all. Patient body habitus can also make this very challenging in the nonsupine position. Obese and morbidly obese patients present exceptionally difficult challenges; edentulous patients have bone erosion of both the axilla and mandible that could make mask ventilation difficult in any position. Patients on phenytoin can have rather impressive gingival hypertrophy and associated bleeding that can interfere with intubation if required; teeth can be loose and easily displaced. All of these problems can make placement of an airway or laryngeal mask airway (LMA) difficult at best, impossible at worst. The next section suggests that the use of an LMA or even endotracheal intubation for these cases is for some the preferred method.

Having an airway cart immediately available and prepared for a fiber-optic intubation with an assorted and readily available selection of LMAs is recommended. At baseline, a nasal cannula for oxygen delivery and CO_2 measurement should be placed before starting sedation.

C. Intraoperative Management

C.1. How should this patient be monitored?

Monitoring should be in accordance with the guidelines of the American Society of Anesthesiologists. These include pulse oximetry, electrocardiography, noninvasive blood pressure monitor, capnography, and temperature measurement as a minimum.

American Society of Anesthesiologists. Standards for basic anesthetic monitoring. Available to members at http://www.ASAhq.org.

C.2. Does this patient require invasive monitoring?

In general, for an awake craniotomy, invasive blood pressure monitoring is not a requirement. Nevertheless, some circumstances might be better served with an arterial line. Blood pressure measurement with an oscillometric device can be problematic in patients with atrial fibrillation; it also overestimates both systolic and diastolic blood pressure readings in patients with stiff arteries, such as diabetics. The diabetic patient may also require frequent blood glucose measurements, and the presence of an arterial line facilitates this and avoids multiple venous blood draws in the operating room.

A central venous line (CVL) for pressure measurement is not required in the awake patient. Nevertheless, at times, venous access is so poor that one needs to be placed merely for that purpose.

Remember, the best monitoring system for this case is the awake, cooperative patient.

Van Popele NM, Bos WJW, deBeer NAM, et al. Arterial stiffness as underlying mechanism of disagreement between an oscillometric blood pressure monitor and a sphygmomanometer. *Hypertension.* 2000;36:484–488.

C.3. Can current drug therapy alter eloquent cortex mapping?

For mapping of the language areas, any drug that would cause long-lasting, deep sedation, as discussed earlier, would be contraindicated. Patients presenting with new onset of seizures associated with the new diagnosis of brain tumor may have been started on any one or several of the AEDs listed in Table 18.1. These drugs may interfere with mapping of the eloquent cortex. In patients undergoing epilepsy surgery, the surgeon has usually stopped these drugs several days in advance so as not to interfere with intraoperative electrocorticography, the placing of electrodes directly on the surface of the exposed brain. Corticosteroids and opioids would not interfere, but propofol can leave a pattern of high-frequency, high-amplitude beta activity on the electroencephalogram for at least 20 minutes, which can cloud the abnormal activity being sought and should be stopped appropriately.

C.4. Why use hypertonic fluids during a craniotomy?

The intact brain, primarily the BBB, acts as an osmometer. Water will freely cross this semipermeable membrane in response to various osmotic pressures created by dissolved solutes until there is an equal water pressure across the membrane. This is a function of the number of osmotically active, dissolved solutes (osmoles) present in a solution: The greater the number of osmoles, the greater is the osmolarity or osmotic activity of the solution. At times, this is also called the *osmolality*. This term describes the same principle, but does have several differences. *Osmolarity* is defined as osmoles per liter of fluid and is a calculated value. Osmolality is one of the four colligative properties of a solution. It is defined as osmoles per kilogram of fluid and is a measured value, usually by a freezing point depression method.

Table 18.2 lists several commonly used IV fluids and compares their osmolarity and osmolality. The osmolality is lower secondary to the presence of undissolved solutes in the solution. When solutes are given IV, the intact BBB prevents the solutes from crossing into the brain, thus sequestering the particles to the intracranial intravascular space and creating a high osmotic pressure. The result is a water concentration in the vessels that is less than that in the brain, with resultant movement of water from the brain into the vascular space. This reduces brain bulk, which may provide better visualization of the tumor by the surgeon and hopefully decreases the need to apply retractors to the brain surface to enhance visualization. This in turn may help

Table 18.2 Osmotic Values of Common Intravenous Fluids

FLUID	OSMOLARITY (mOsm/L)	OSMOLALITY (mOsm/kg)
Water	0	0
D_5W	252	259
NS	308	282
LR	273	250
3% Saline	1,027	921
6% Hetastarch	310	307
20% Mannitol	1,098	1,280
5% Albumin	290	283
Normosol–R	294	281
D_5W/0.2 NaCl	325	321

D_5W, 5% dextrose in water; NS, normal saline; LR, lactated Ringer's solution; D_5W/0.2 NaCl, 5% dextrose and 0.2% sodium chloride.

decrease ischemic injury to the brain directly under the retractors. It also decreases ICP in the intact brain. Intravascular proteins create a much smaller oncotic pressure in the intracranial vasculature than do the dissolved solutes, secondary to the intact BBB, and play a lesser role than they do in the systemic circulation, where they are the primary determinant of fluid moving extravascular to intravascular.

C.5. What intravenous fluids (IVFs) are recommended?

Commonly used IVFs during craniotomy, awake or under general anesthesia, are 0.9% saline, 3% saline, lactated Ringer's solution, 20% mannitol, and 5% albumin.

Normal plasma osmolality is 285 to 295 mOsm per kg. Therefore, any solution with a higher osmolality could act to pull water from the brain. The exception to this is any solution containing 5% dextrose. These solutions have an effective osmolality 259 mOsm less than the measured osmolality because glucose (osmolality 259 mOsm per kg) is rapidly metabolized by the brain. D_5W thus has an effective osmolality of zero and D_5W/0.2 NaCl an effective osmolality of 62 mOsm per kg as examples. These dextrose-containing solutions would present a very high concentration of free water within the intracranial intravascular space and result in water movement into the brain causing an increase in ICP or brain bulk.

It is now well accepted that hyperglycemia before or during an episode of cerebral ischemia worsens outcomes. The mechanism is not clear. One hypothesis is that during a hyperglycemic episode, the increased level of intraparenchymal glucose reacts with substances for lactic acid production during the ischemic period, which is thought to have a negative effect leading to neuronal death. This being said, solutions containing D_5 are not routinely used during intracranial surgery.

Twenty percent mannitol is the most widely used IVF for treatment of elevated ICP. It also acts to decrease CSF production and acts as a scavenger of oxygen free radicals. Mannitol should be given IV over 10 to 15 minutes to prevent a sudden exposure of the cerebral circulation to extreme hyperosmolality (mannitol has an osmolality of 1280 mOsm per kg), which could lead to a vasodilatory effect with resultant increased CBV, possible brain engorgement, and increased ICP. Increased urine output secondary to this diuresis should be replaced with normal saline. The usual mannitol dose is 0.25 to 1 g per kg.

Hypertonic saline comes in a range of concentrations, with 3% probably being the most commonly used during intracranial surgery. A recent study has shown no difference between equiosmolar mannitol and hypertonic saline infusions for providing brain relaxation.

Normal saline has traditionally been the fluid of choice for intracranial procedures and is used to cover fluid requirements and replace blood loss until red blood cells are required. A drawback to its use is that a hyperchloremic, hypokalemic metabolic acidosis can occur when large volumes are given. This can mask any other form of acidosis and cloud the diagnostic picture. Lactated Ringer's solution (osmolality 250 mOsm per kg) would not theoretically, based on the prior discussion, be an ideal replacement for blood loss, insensible loss, or third-space losses. Nevertheless, it is being used in many centers without problems. Some authors have suggested alternating normal saline and lactated Ringer's solution one after the other in the setting of large-volume administration.

The crystalloid versus colloid debate seems to be never ending and is usually centered on head injury. Colloid, in the form of 5% or 25% albumin is rarely, if ever, needed in an awake craniotomy.

C.6. Would a lumbar drain for CSF removal benefit this patient?

The lesions in the eloquent cortex are usually small, so a lumbar drain is not indicated. Historically, neurosurgeons have placed a lumbar drain before the start of the surgery to allow CSF to be drained slowly, usually 10 mL per hour, to decrease brain bulk. This might have been placed in an "open" position when the time came to open the dura, allowing for maximal brain relaxation and visualization in addition to preventing any intracranial contents from herniating through the craniotomy site proper.

C.7. Venous air embolism (VAE): Is it a concern in this case?

Venous air embolism is the entrainment of air into open, noncollapsible vascular structures located above the level of the heart. Therefore, the short answer is yes, because the level of the surgical site meets this definition.

VAE is usually associated with posterior fossa craniotomies and cervical spine surgery in the sitting position. Fatal VAE has been described with as little as 3 to 5 cm of surgical site elevation above the heart during lumbar spinal surgery, with the patients supported on a four-poster support device in the prone position.

In this case, the tumors are usually small and within the cortex, and the patient is either supine or in a nearly horizontal lateral decubitus position. Parasagittal and falcine meningiomas encroaching on the posterior portion of the sagittal sinus are the most common situations for VAE development. Fortunately, the eloquent cortical areas are not in this location. Nonetheless, VAE has been reported after pin head-holder placement and after craniotomy, but before dural opening. This implies that free air can be entrained through the diploic space of the skull unless adequately sealed during the cranial opening. This is usually done with wax. Therefore, as stated earlier, VAE is a possibility during an awake craniotomy.

Although transesophageal echocardiography is the most sensitive means of detecting VAE, it is impractical in the setting of the awake craniotomy. The precordial Doppler device is the monitor of choice for this particular scenario if the head will be elevated above the level of the heart. When placed in the right or left parasternal region between the third and fourth ribs, Doppler has a high detection rate for VAE. Often, the awake patient may experience an episode of paroxysmal coughing with entrainment of air. The best chance of aspirating a VAE is through a properly placed, multiorificed central line that is positioned 2 cm below the superior vena caval–atrial junction. This is accomplished by using intravascular ECG. Lead two is observed while the electrode of the CVL is attached to the leg lead. An equibiphasic P wave indicates that the tip of the catheter is in the midatrial position.

Treatment for VAE is supportive. If venous air embolism is suspected, the surgeon must be immediately informed and the surgical field flooded with water to help prevent further air entrainment. Jugular compression and lowering the head are also maneuvers to help stop air entrainment. If it is present, an attempt should be made to aspirate air through the CVL simultaneously with the surgeon addressing the surgical field. Vasopressors or inotropes as needed are given to support hemodynamics, and cardiopulmonary resuscitation initiated if all else fails.

C.8. How is the eloquent cortex mapped?

Before the start of the case, the neurologist will go over the intraoperative testing procedure with the patient. This usually consists of various confrontational type testing in which the patient may be asked to simply count. At other times, the patient may be asked to name items on a card preceded with the phrase "that is a . . . ." Patients are sometimes asked to do simple math problems. It is important to realize that a patient who speaks multiple languages may need to have each of those languages tested separately. Not all learned languages are "laid down" in the same cortical area. This requires extensive preoperative planning to have the needed interpreters available to help with this testing.

Once the craniotomy is completed, the dura opened, and the patient awakened, testing can begin. The tumor surface is often visible and helps guide the surgeon as to where to start the mapping. A handheld wand with two probes, separated by 5 mm, is gently placed on the brain surface about 2 cm from the tumor edge. This is connected to a constant-current, biphasic stimulator. Our neurologists usually stimulate for 2 to 5 seconds with a frequency of 50 Hz and a pulse width of 200 ms. Responses are usually noted with a stimulus power range of 4 to 6 mA. After each test, the surgeon moves the wand freely to other areas of the cortex, repeating this procedure until satisfied that functional areas of the cortex have been localized and marked and that an area of negative mapping has been identified through which the tumor or epileptic foci can be resected.

In the case of seizure focus resection, there are no visible signs to follow. Often, the areas of eloquent cortex in danger will have been mapped out by MEG. This is a noninvasive technique for mapping brain activity by recording the magnetic fields produced by the electrical currents of the brain. These studies can then be "laid over" an MRI study and appear as colored squares representing areas of the eloquent cortex tested and can be used for tumor or epilepsy surgery to help identify the functional areas. Mapping can then start outside of these designated areas looking, again, for a quiet area.

Moore TA, Markert JM, Knowlton RC. Dexmedetomidine as a rescue drug during awake craniotomy for cortical mapping and tumor resection. *Anesth Analg*. 2006;102:1556–1558.

C.9. How are intraoperative seizures treated?

Intraoperative seizures can be either the baseline type, for which the patient presented, or they can be caused by the cortical surface stimulation used to map the cortex.

The surgeon usually will not stimulate the same area more than two consecutive times, to avoid this complication. If a seizure should occur, it usually will take the form of the patient no longer answering any questions, but maintaining their airway, and at times maybe a slow moaning sound will be made. This usually responds rapidly to the application of a cold irrigation solution, usually lactated Ringer's solution, to the cortex by the surgeon. If this fails, small doses of propofol, 10 to 20 mg, will usually suffice to stop the seizure.

Schubert A, Lotto M. Awake craniotomy, epilepsy, minimally invasive, and robotic surgery. In: Cottrell JE, Young WL, eds. *Cottrell and Young's Neuroanesthesia*. 5th ed. Philadelphia: Mosby Elsevier; 2010:296–316.

C.10. How will you conduct this anesthetic?

The conduct of this type of anesthetic actually begins long before the patient ever enters the operating room. As discussed earlier, the patient must be very motivated for this experience to be successful. The patient must realize fully that this is a lengthy procedure and 4 to 6 hours is not an unusual expectation for being in the operating room. The patient's family must also be involved and have the same understanding. Most important is a motivated and experienced neurosurgeon and neurologist. Each must realize that time is of the essence and the procedures must be completed as quickly as is safely possible.

The neurosurgeon will be the first person to suggest or inform the patient that this form of surgery is necessary to preserve their language or motor-sensory function.

Ideally, the neurosurgeon and the neuroanesthesiologist have a successful history of performing this procedure. They have developed a technique that has allowed them to have an awake, cooperative patient when the time comes for cortical or subcortical mapping and resection.

In the operating room, before patient arrival, several steps are taken to make the patient as comfortable as possible during this long and demanding procedure. A full-length gel pad is placed on the operating room table under the sheets and the room temperature is set at 70° F or higher. Additional gel pads and foam sheets are available as needed, as well as warm blankets.

Following the preoperative visit and IV line placement, the patient is brought to the operating room. As previously discussed, premedications that interfere with the patient's ability to cooperate and follow instructions are contraindicated. Standard intraoperative monitors are placed as described earlier, and a carbon dioxide monitoring nasal oxygen cannula is placed.

The literature is replete with reports of anesthetic techniques for the awake craniotomy. The common theme is a triphasic "asleep-awake-asleep" technique. The approach is as varied as the number of neuroanesthesiologists who perform these procedures.

Some of these techniques use intubation of the trachea and the use of potent inhalational agents until approximately 20 to 30 minutes before cortex mapping when the anesthetic is discontinued and the patient extubated. Others describe the use of an LMA in the same fashion. The use of propofol, fentanyl, remifentanil, dexmedetomidine, and various combinations of these drugs have been described as being added to these approaches as a means of transitioning the patient from a general anesthetic to the awake state for mapping and surgery within the eloquent cortex. The use of total intravenous anesthesia using the same drugs has also been described with the airway controlled by an LMA with controlled or spontaneous breathing or an unprotected airway with spontaneous respirations.

The literature describes cases in which similar, but not identical, approaches for mapping or other tasking has been successful for one group and not for another. This can lead to tremendous frustration in trying to decide how to administer this

anesthetic. Many times, the technique is institutionally defined and has worked well for many years.

One of the most important things is to fully understand the pharmacology of the anesthetic regimen chosen.

Our institution uses a triphasic total intravenous anesthesia technique with spontaneous breathing without LMA or tracheal intubation. After standard monitors are placed, two separate infusions are started. Dexmedetomidine is started at 0.35 μg/kg/hr and propofol is started at 75 μg/kg/min. These drugs are titrated as needed to achieve a sedated, yet spontaneously breathing patient. When the patient no longer responds to name call, a Foley catheter, additional IV lines, and an arterial line, as deemed necessary, are placed. Small bolus doses of propofol 10 to 20 mg are given depending on patient response to these procedures.

A loading dose of dexmedetomidine is given at the discretion of the attending neuroanesthesiologist. The recommended administration is 1 μg per kg over 10 minutes, and then the maintenance infusion is started. Several reports have described levels of persistent bradycardia and hypotension with this approach versus starting the infusion without the loading dose. We prefer the dexmedetomidine and propofol combination because it provides good sedation, anxiolysis, and some amnesia without causing respiratory depression.

The anesthesiologist must realize from the beginning that the success of this procedure lies almost entirely with the precision and adequacy of the scalp blocks performed by the anesthesiologist or the neurosurgeon. No amount of sedation will compensate for poorly performed blocks. In our institution, the scalp block addresses the supratrochlear, supraorbital, zygomaticotemporal, auriculotemporal, and greater auricular and the lesser and greater occipital nerves. A combination of equal volumes of 1% lidocaine with epinephrine 1:100,000 and 0.25% bupivacaine with epinephrine 1:200,000 is used as the local anesthetic solution. The mixing of local anesthetic solutions to obtain a solution for injection has been performed in an attempt to obtain an anesthetic solution that will have a rapid onset and longer duration than either of the component solutions separately. In reality, no convincing data support this practice. The use of ropivacaine singularly for the same purpose is described numerous times in the literature. Following the individual nerve blocks, an intradermal ring of the local anesthetic solution is placed around the operative side of the scalp. Each pin site for the pin head-holder device is injected, as is the surgical incision site, by the surgeon, after the patient is prepped and draped.

The dexmedetomidine and propofol infusions are continued as the cranial opening proceeds. When the surgeon has placed the final burr hole, the propofol is turned off and the dexmedetomidine is turned down to 0.2 μg/kg/hr. The cranial opening continues, and approximately 15 to 20 minutes later, the patient is awake and conversant. The neurosurgeon and neurologist begin the mapping process, which can take several hours, but on average, in our institution, this is accomplished in 50 to 60 minutes. The dexmedetomidine is continued at 0.2 μg/kg/hr throughput the mapping process. When satisfied that areas of the eloquent cortex adjacent to the tumor have been localized and an area of negative mapping have been demonstrated, the surgeon proceeds with tumor resection. If the patient is resting comfortably, we do not make any changes in the anesthetic. If they ask to be more sedated, the dexmedetomidine is increased to 0.35 μg/kg/hr; this usually keeps the patient comfortable for the remainder of the procedure. From time-to-time, the surgeon may ask to remap certain areas. The dexmedetomidine is again lowered to 0.2 μg/kg/hr, if needed, and the remapping with the neurologist commences. The dexmedetomidine is stopped with skin stapling. The pin head-holder is removed, dressings are placed, and preparations are made for leaving the operating room and transferring to the neurosurgery intensive care unit.

A transport monitor capable of providing pulse oximetry, blood pressure measurements, and ECG tracing is attached to the patient and nasal cannula oxygen is continued during the transport to the neurosurgery intensive care unit.

D. Postoperative Management

D.1. What are the major concerns following craniotomy?

Several problems can occur in the immediate postoperative period following craniotomy. In general, the patient is transported to the neurosurgery intensive care unit and monitored as previously described. The head of the bed is usually elevated 20 to 30 degrees to maximize cerebral venous drainage.

Emergence hypertension is not uncommon in the perioperative period, even after an awake craniotomy. The incidence of postcraniotomy hypertension has been reported to be 57%. In this series of 11,214 craniotomies, perioperative systemic hypertension was associated with postoperative intracranial hematomas with resultant increased mortality and increased length of hospital stay. Other possible causes are pain, hypercapnia, and shivering. Eighty-five percent of postoperative intracranial hematomas become evident within 6 hours of surgery and usually present as a progressive decrease in the level of consciousness. Up to 17% of these hematomas can present at sites remote to the surgical site. Aggressive efforts at controlling this hypertension are required to prevent possible devastating complications such as bleeding into the tumor bed, requiring a second surgical procedure to evacuate that clot.

If not contraindicated, bolus doses of labetalol 5 to 10 mg IV usually control this quite well. Nevertheless, at times, persistent hypertension, without signs of intracranial hypertension, may require additional treatment. Hydralazine 5 to 10 mg IV, an infusion of nicardipine 5 to 15 mg per hour, an infusion of sodium nitroprusside, or nitroglycerin are possible choices. A combination of enalapril and labetalol versus nicardipine alone has been reported, with little difference in the ability to control emergence hypertension.

Acute pain control is essential in the postoperative period. Not only are the patients more comfortable with adequate pain relief, but this also helps control postoperative hypertension and decreases the possibility of intracranial hematomas. Pain following craniotomy has probably been vastly understated secondary to concern about respiratory depression and sedation, as well as the traditional thought that

craniotomies are less painful than other operations. The incidence of postcraniotomy pain may be as high as 70%.

Codeine sulfate has traditionally been the opioid of choice for postcraniotomy pain control because it does not mask pupillary signs and it has a ceiling to its respiratory depressant effects. Nevertheless, it is only about half as potent as morphine sulfate and causes profound hypotension if given IV, leaving the oral, rectal, or intramuscular injection route for administration.

In the immediate postoperative period, almost all pain control medications are given IV. Morphine sulfate patient-controlled analgesia has been reported with good results and without incidence of respiratory depression or need for reintubation. This regimen consists of morphine 1.5 mg with a lockout period of 8 minutes and a total dose not to exceed 40 mg in 4 hours.

Nonsteroidal anti-inflammatory drugs have been associated with postoperative intracranial hematoma formation. Administration of antiplatelet agents (aspirin and nonsteroidal anti-inflammatory drug) was the most commonly associated risk factor. Therefore, this class of pain control medications should be avoided in the immediate postoperative period.

Postoperative nausea and vomiting is common following craniotomies and can cause hypertension and an increase in ICP. Infratentorial surgery, female gender, and a young age are associated risk factors. Ondansetron 1 to 4 mg IV can provide effective treatment.

Seizures can occur following intracranial tumor resections and can cause serious complications such as secondary intracranial bleeding, hypoxia, and possibly aspiration. An intracranial mass, such as a hematoma (Fig. 18.6), should be suspected if

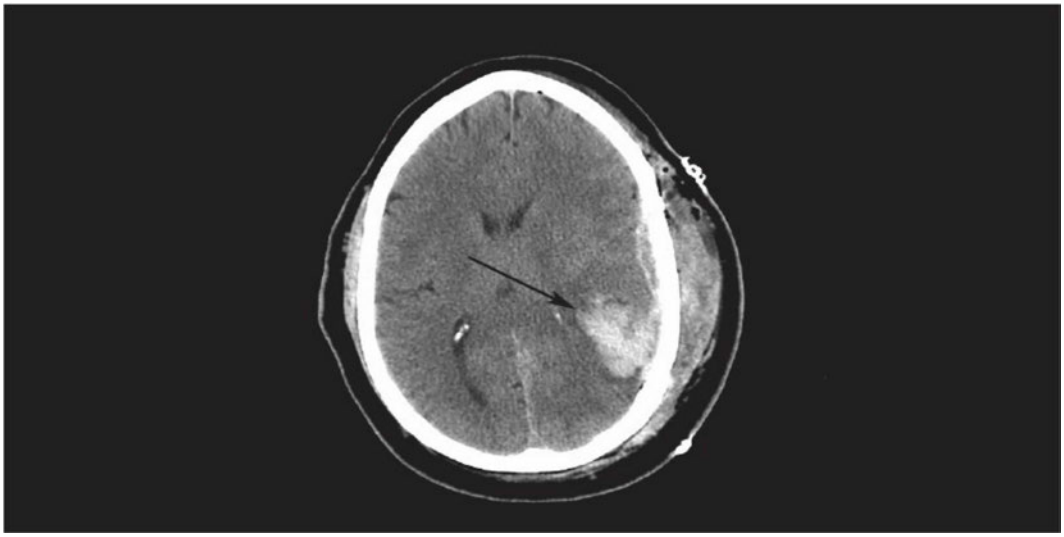

Figure 18.6 CT scan of a 73-year-old man who underwent an uneventful left, awake craniotomy with motor and language area mapping. On postoperative day 2, he suffered a generalized tonic–clonic seizure and was extremely slow to awaken. CT scan revealed the presence of a large intracranial hematoma (*arrow*) in the operative site requiring return to the operating room for evacuation. Also note the small epidural and subglial hematomas. Coagulation studies were normal. The patient was placed on antiepileptic drugs and was doing well on follow-up visits without further seizure activity. Antiepileptic drugs were successfully weaned over several weeks. Final pathology revealed glioblastoma multiforme.

the patient does not regain consciousness within a short period after the seizure has ceased. Small doses of midazolam, 1 to 2 mg, or other benzodiazepines can treat this problem effectively without compromising the airway.

Increased ICP commonly occurs after intracranial surgery, with the most common finding on CT scan being brain edema. Maximum pressures are usually recorded within 16 hours of surgery. Associated risk factors are glioblastoma resection and surgery lasting more than 6 hours. Continuing corticosteroids, dexamethasone 6 to 10 mg every 6 hours, usually controls this problem.

Peripheral nerve injuries are uncommon after awake craniotomy because patient comfort or discomfort can easily be assessed, and minor movements made if needed. We have experienced several episodes of blister formation along the down side of a morbidly obese patient's upper leg after about 5 hours in the lateral decubitus position in spite of the use of gel pads beneath the thigh. Supportive treatment was provided, and this was resolved by the first postoperative follow-up visit.

Acknowledgments

I would like to thank the following people for their assistance in making this endeavor possible: Dr. Mark R. Harrigan, University of Alabama School of Medicine (UABSOM), Department of Surgery, Division of Neurological Surgery, for his assistance in the acquisition and preparation of the radiographs used in this chapter; and Drs. Susan Black and Richard C. Cross, UABSOM, Department of Anesthesiology, for their critical reading, suggestions, and encouragement.

CHAPTER 19

Head Injury

EUGENE S. FU, JONATHAN JAGID, AND LEO T. HARRIS III

A 22-YEAR-OLD WOMAN

presented to the trauma center after sustaining multiple gunshot wounds on the head and face. On admission, the patient had a Glasgow Coma Scale (GCS) of 8 and vital signs were blood pressure, 134/72 mm Hg; heart rate, 138 beats per minute; respiratory rate, 20 breaths per minute; and oxygen saturation, 100%. The patient developed a coagulopathy as hemoglobin dropped from 12 g per dL to 5 g per dL, for which the patient was transfused with packed red blood cells and fresh frozen plasma. Eventually, recombinant human factor VIIa was given subcutaneously to correct the coagulopathy in preparation for surgical intervention. Head computed tomography (CT) scan showed an expanding intracerebral hematoma in the right frontal lobe (Fig. 19.1). The patient was taken to the operating room for a right craniectomy for evacuation of the anterior frontal lobe hematoma and debridement of bullet and bone fragments. Postoperatively, the patient underwent a cerebral angiography revealing a traumatic ophthalmic artery aneurysm (Fig. 19.2). On postoperative day 1, the patient developed polyuria and hypernatremia, indicative of diabetes insipidus (DI).

A. Pathophysiology and Differential Diagnosis

1. What types of intracranial injuries are most likely to have occurred in this patient?
2. What is the difference between primary and secondary injury? What factors contribute to secondary injury?
3. What are the risks and benefits of administering mannitol?
4. What is the effect of hyperglycemia on neurologic outcome following head trauma?
5. What alterations in sodium and potassium balance can occur in patients with head injury?
6. In addition to sodium and potassium, what other electrolyte abnormalities can be present after head trauma?

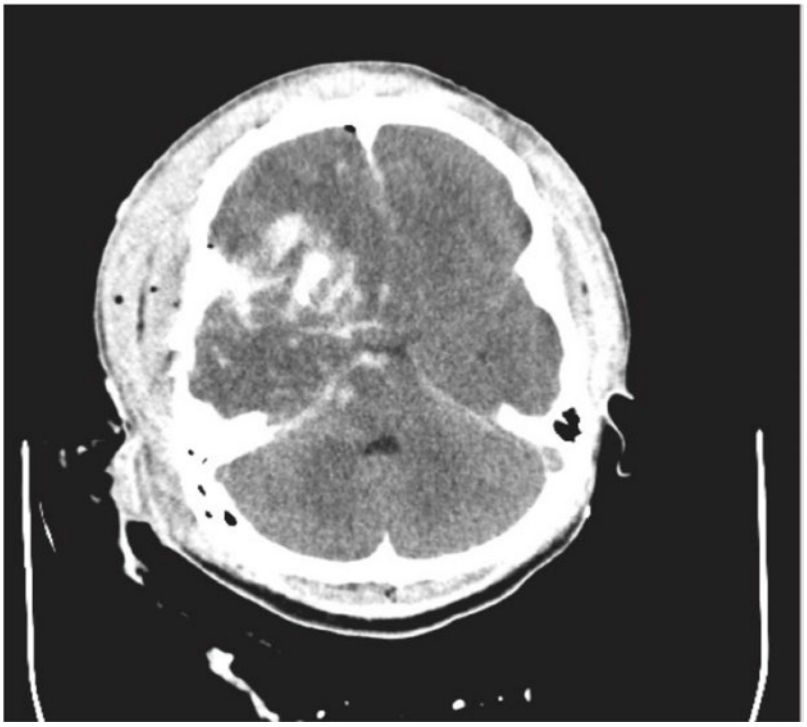

Figure 19.1 Head computer tomography scan showing expansion of intracerebral hematoma after gunshot wound.

7. What are the neuroprotective effects of administering magnesium?
8. What role do gender and female sex hormones have in the pathophysiology of traumatic brain injury (TBI)?
9. What is the role of decompressive craniectomy as a treatment option for intracranial pressure (ICP) control after head injury?
10. Do genetic factors play a role in the outcome after head injury?

B. Preoperative Evaluation and Preparation

1. What is the GCS? What is the significance of a GCS of 8 in this patient?
2. In addition to the GCS, what other assessments can be done to evaluate neurologic function?
3. What is the role of CT scanning in the initial evaluation of the patient with head injury? What management options can be done in patients whose neurologic condition is deteriorating before obtaining a CT scan?
4. What is the role of ICP monitoring in the management of head injury?
5. How can you clear this patient's cervical spine?
6. What are the benefits of early endotracheal intubation in this patient?
7. What is your plan for airway management in this patient? How would it change if the patient were combative? How would it change if the patient had facial fractures with significant swelling of the head and neck?

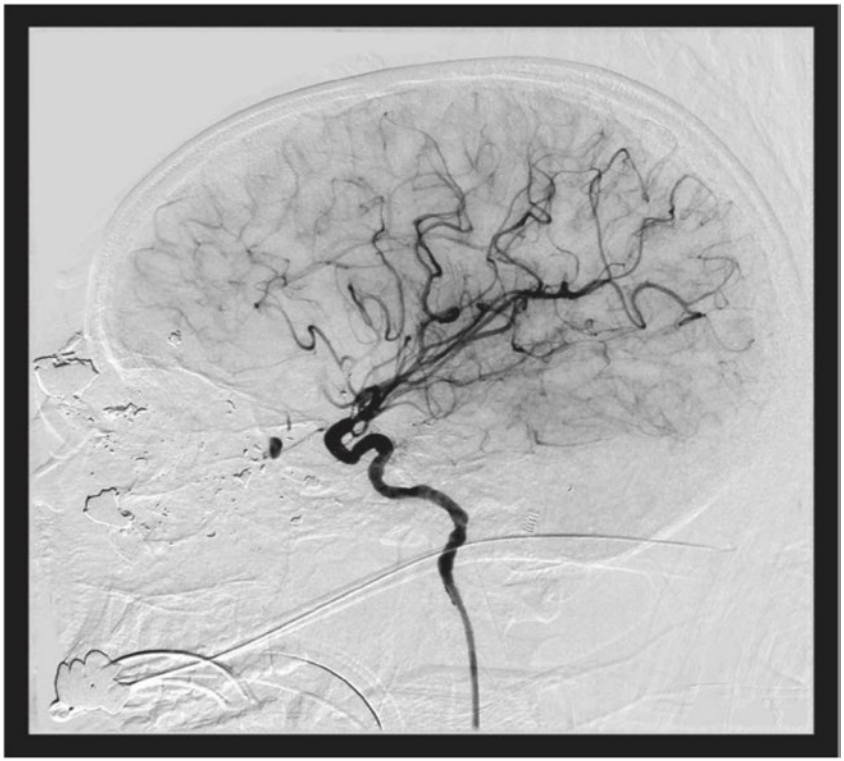

Figure 19.2 Cerebral angiogram showing an ophthalmic artery aneurysm.

8. What are the effects of succinylcholine on ICP? What is the significance of the effect, if any?
9. What coagulation abnormalities are present after TBI? What treatment modalities can be used to provide hemostasis and reduce intracranial hematoma expansion?

C. Intraoperative Management

1. What is appropriate hemodynamic monitoring during CT scanning and during craniotomy for evacuation of a subdural hematoma?
2. Should hyperventilation be used in this patient?
3. What are the implications of arterial hypertension in patients with head injury? How should blood pressure be managed?
4. What should be done about intravenous fluid replacement? Should corticosteroids be given empirically?
5. Should hypertonic saline be administered to this patient? How is hypertonic saline administered?
6. The patient underwent a craniectomy for evacuation of a frontal intracerebral hematoma. Should some anesthetic agents be avoided in this situation? Which ones? What agents might be preferred in this situation?
7. Should hypothermia be employed in this patient?

D. Postoperative Neurointensive Care Management

1. What are the postoperative ventilation considerations in this patient?
2. What specific measures should be used to control the patient's ICP? What type of monitoring devices can be used to monitor ICP?
3. What is neurogenic pulmonary edema? Would you avoid positive end-expiratory pressure (PEEP) in a patient with increased ICP?
4. What is the role of antiseizure prophylaxis in the perioperative management of head trauma?
5. How can cerebral oxygenation monitoring be used in the clinical management of TBI?
6. What methods can be used in the neurointensive care unit to prevent hyperthermia?

A. Pathophysiology and Differential Diagnosis

A.1. What types of intracranial injuries are most likely to have occurred in this patient?

The leading causes of traumatic brain injury (TBI) include falls, motor vehicle collisions, and assaults; and blasts are a leading cause of TBI in active military personnel. In a patient without obvious signs of localizing neurologic deficits, the most probable intracranial injury is cerebral contusion. This is usually a diffuse or multifocal process that results in disruption of the blood–brain barrier, causing widespread brain swelling as a result of edema. The diagnosis can be made with certainty only after ruling out other focal injuries, such as intracranial hematoma. Traumatic intracranial hematomas include epidural, subdural, and intracerebral hematomas. The clinical hallmark signifying a mass lesion is the presence of generalized elevated ICP in conjunction with focal deficits. Interestingly, most patients who were able to talk and then deteriorate into a coma had a mass lesion requiring surgery—indicating the importance of quickly diagnosing mass lesions with CT scanning. In fact, clinicians are in the process of determining how the magnitude of elevations in ICP correlate with radiologic measurements, including ventricular size, hematoma size, grade of hemorrhage, and extent of herniation.

Epidural hematomas, located between the skull and dura, are almost always caused by skull fractures. Most epidural hematomas occur in the temporoparietal region as skull fractures lacerate the middle meningeal artery. Consequently, arterial epidural hematomas can rapidly expand, constituting a true neurosurgical emergency. The classic presentation of an epidural hematoma is a patient who presents with loss of consciousness then regains consciousness only to deteriorate into coma, with a fixed dilated pupil ipsilateral and contralateral hemiparesis because of the rapidly expanding hematoma. Subdural hematomas are located between the inner surface of the dura mater and the pial surface of the brain. In contrast to epidural hematomas, subdural hematomas are caused by lacerations of the venous sinuses (e.g., lateral sinus or sagittal sinus) or cortical vasculature and tend to develop more insidiously.

Intracerebral hematomas are collections of blood ranging from petechial hemorrhages to large collections usually in the temporal or frontal lobes. Some lesions are pure hematomas or hemorrhagic contusions. Often, these hemorrhagic areas can be managed medically with serial CT scans. Indications for surgical evacuation of intracerebral hematomas include rapid mental deterioration, mass effect, and marked intractable elevations in ICP. Gunshot wounds to the head are often accompanied by intracerebral or subdural hematoma combined with the added challenge of vascular injury from bullet or bone fragments. Penetrating head injury carries the unique long-term complications of seizure, infection (abscess or empyema), and post-traumatic aneurysm. The goals of surgery include debridement of the wound with

evacuation of mass occupying lesions and retrieval of easily accessible bullet and bone fragments in the salvageable patient.

Schmidek HH, ed. *Operative Neurosurgical Techniques*. 4th ed. Philadelphia: WB Saunders; 2000:83–85.

A.2. What is the difference between primary and secondary injury? What factors contribute to secondary injury?

Primary injury represents neurologic damage that occurs at the time of impact. Secondary injury is the consequence of ischemic insults to the brain that occur subsequent to the primary injury. Prevention of further hypoxemia and hypotension are the mainstay of managing patients with head injury. Pathophysiologic processes contributing to secondary injury include (1) alterations in the balance between cerebral blood flow and metabolism, (2) disruption of cerebral autoregulation, (3) loss of cerebral vascular reactivity to carbon dioxide, and (4) cytotoxic vasogenic fluid accumulation leading to brain swelling.

Unfortunately, many patients with severe head trauma arrive to the hospital after having episodes of hypotension and hypoxemia. Improvement in outcomes depends on trauma centers having emergency teams that provide rapid treatment in the field and direct transport to the hospital. Initial management entails oxygenation by early intubation and maintenance of cerebral perfusion pressure (CPP) with rapid resuscitation to treat hemorrhagic or hypovolemic shock. The difficulty with fluid administration is that brain swelling increases ICP and increases the threshold of the mean arterial blood pressure necessary to prevent cerebral ischemia. Elevation in ICP, which heralds cerebral herniation, leads to further brain damage and increased morbidity. The use of ICP monitoring has been important in decreasing secondary injury as a means to quantify and treat cerebral hypoperfusion. Improved outcome in patients with severe head trauma has been attributed to the approach of "squeezing oxygenated blood through a swollen brain."

Ghajar J. Traumatic brain injury. *Lancet*. 2000;356:923–929.

A.3. What are the risks and benefits of administering mannitol?

Mannitol is currently the osmotic diuretic of choice and is initially given as a bolus of 0.25 to 1 g per kg. It reduces ICP after 15 minutes, and its effects typically last for 2 to 6 hours. Mannitol, for the management of intracranial hypertension, should be given as a bolus and *not* as a continuous infusion. Therapeutic effects of mannitol include initial improvements in red blood cell rheology and therefore blood flow and oxygen delivery to the brain, as well as delayed osmotic water withdrawal from the brain into the circulating blood volume. There is also weak evidence that concomitant use of loop diuretics, such as furosemide, result in a greater and more sustained decrease in ICP compared to mannitol use alone. Indications for administering mannitol before ICP monitoring include transtentorial herniation and progressive neurologic deterioration. Clinical effects seem to peak when serum osmolarity is kept between 300 and 320 mOsm, and elevations beyond 320 mOsm can result in renal failure. Some authors advocate the use of hypertonic saline, but evidence does not support a superior effect in TBI.

A.4. What is the effect of hyperglycemia on neurologic outcome following head trauma?

The release of catecholamines and hyperglycemia are manifestations of the stress response to severe head injury. Patients with severe head injury have higher blood glucose levels compared with patients with moderate and minor injury. Postoperative glucose levels above 200 mg per dL have been associated with a worse neurologic outcome. Early hyperglycemia is a significant indicator of severity of injury and a predictor of outcome. Nevertheless, hyperglycemia should be treated aggressively, especially when the risk of cerebral ischemia is present. Elevated plasma glucose levels provide a substrate for anaerobic metabolism, allowing increased production of lactate during ischemia. The approach to glucose control in patients with TBI is subject to debate because the downsides of aggressive therapy are hypoglycemia and cerebral glucopenia. In one study, intense insulin therapy, with the goal of maintaining blood glucose levels at 80 to 100 mg per dL, was associated with increased microdialysis levels of glutamate, which is a marker for cellular distress. Other studies have suggested that less restrictive glucose control may be as efficacious in patients with critical neurologic illness. (Also see Chapter 16, section C.8.)

A.5. What alterations in sodium and potassium balance can occur in patients with head injury?

Neurologically injured patients are at risk for electrolyte imbalance. Perioperative fluid administration, mannitol administration, syndrome of inappropriate antidiuretic hormone secretion (SIADH), and cerebral salt wasting syndromes are potential causes of hyponatremia. Severe hyponatremia (Na less than 120 mEq/L) may be associated with cerebral edema and seizures. The correction of hyponatremia must be gradual to avoid precipitating central pontine myelinolysis. Hypernatremia can occur as a result of enteral tube feedings, diuresis with mannitol, and DI. Basilar skull fractures may predispose to the development of DI as a consequence of shearing of the pituitary stalk. Treatment of DI entails administration of 1-deamino-8-D-arginine-vasopressin (DDAVP) in conjunction with hypo-osmolar fluids. Patients with partial

DI may respond to other agents such as chlorpropamide, clofibrate, and thiazide diuretics, which will stimulate the release of antidiuretic hormone.

Hypokalemia may result from potassium loss secondary to polyuresis in association with diuretic administration and high urine output states such as SIADH and cerebral salt wasting syndrome. Concurrent hypomagnesemia, as seen with alcoholic and diabetic patients, can aggravate hypokalemia. The loss of cellular magnesium depletes intracellular potassium, making hypokalemia more difficult to treat if magnesium supplementation is not given. In addition, serum potassium levels may decrease despite normal total body stores. Common causes of intracellular shifts of potassium include hyperventilation and insulin administration.

Prough DS. *Update on CNS Injury: Fluid and Metabolic Management of the Neurosurgical Patient. ASA Annual Refresher Course Lectures*. Park Ridge, IL: American Society of Anesthesiologists; 2008:331.

A.6. In addition to sodium and potassium, what other electrolyte abnormalities can be present after head trauma?

Potassium and sodium levels are routinely checked perioperatively. However, magnesium and phosphate levels are not routinely ordered, so low levels of these electrolytes are more likely to remain undetected. Hypomagnesemia has been associated with cardiac arrhythmia such as torsades de pointes, sudden death, seizures, and neuromuscular irritability. Hypophosphatemia has been associated with weakness of the respiratory muscles and respiratory infections.

Polderman KH, Bloemers FW, Peerdeman SM, et al. Hypomagnesemia and hypophosphatemia at admission in patients with severe head injury. *Crit Care Med*. 2000;28:2022–2025.

A.7. What are the neuroprotective effects of administering magnesium?

Magnesium homeostasis is altered after TBI because magnesium falls on the order of 50%. In addition to treating hypomagnesemia, administration of magnesium affords neuroprotection. Magnesium is an *N*-methyl-D-aspartate (NMDA) antagonist that suppresses excitotoxic mechanisms. Excitatory amino acids such as glutamate and aspartate are released after traumatic injury, which initiates a cascade of events leading to secondary injury. Glutamate-induced ionic depolarization leads to calcium influx and cell death. Magnesium works at the postsynaptic receptor to reduce the neurotoxic effect of glutamate. In animal models, TBI decreases intracellular free concentrations of magnesium. Magnesium crosses the blood–brain barrier. Repeated administration of magnesium attenuates brain edema and improves neurologic recovery. Although prophylactic magnesium administration has received some enthusiasm in the management of stroke, its clinical use in the treatment of head injury remains to be seen.

A.8. What role do gender and female sex hormones have in the pathophysiology of traumatic brain injury (TBI)?

Women account for approximately 20% to 30% of the head injury population. Laboratory evidence indicates that estrogen and progesterone mediate neuroprotection by decreasing lipid peroxidation and reducing production of inflammatory cytokines. Compared with women, increases in cerebrospinal fluid (CSF) levels of glutamate, lactate, and F_2-isoprostane (marker for lipid peroxidation) are observed in men after TBI. Nevertheless, there appears to be a paradox between the acute neuroprotective properties of female sex hormones and actual recovery for women as functional outcome has been worse for women. It has been suggested that female sex hormones may be detrimental to neuroplasticity and recovery. In addition to gender differences, the effect of hormonal status in female patients in the pathophysiology of head injury remains unclear. Consequently, gender selection and the relation of hormonal status at time of injury become important in the design of clinical trials involving therapeutic interventions in brain trauma patients. ProTECT, a National Institutes of Health–funded, randomized, double-blind phase III clinical trial, is underway to evaluate approximately 1140 patients over a 3- to 6-year period using the hormone progesterone to treat TBI at 17 medical centers across the United States.

A.9. What is the role of decompressive craniectomy as a treatment option for intracranial pressure (ICP) control after head injury?

The objective of a decompressive craniectomy is to avoid or treat increases in intracranial pressure because of brain edema, because high ICP is the most frequent cause of death and disability from head injury. Usually, the first line of treatment for high ICP is moderate hypocapnia, mannitol, sedation, and normothermia. When these measures fail, more aggressive approaches such as decompressive craniectomies are employed to allow the brain to expand and prevent brain herniation. Nevertheless, the benefits of decompressive craniectomy has not been proven in a randomized controlled fashion. Therefore, routine use of this therapy cannot be recommended. At this juncture, many clinicians feel that this procedure should be considered only in clinical situation in which maximal medical therapy failed to control ICP.

A.10. Do genetic factors play a role in the outcome after head injury?

An association exists between poorer outcomes after head injury in patients with the apolipoprotein E4 allele (APOE ε4). Two other isoforms, APOE 2 and APOE ε2, are other common isoforms to apolipoprotein E that have a different neurobiolgic function compared with that of APOE ε4, which appears to be less neuroprotective. In fact, APOE

ε4 is also associated with the risk of developing late-onset Alzheimer disease. In addition to apolipoproteins, interleukin (IL) proteins such as IL-1 have been implicated in neurodegeneration following ischemic insults and it is postulated that genetic polymorphisms in IL-1 may affect outcome after head injury. By understanding genetic polymorphisms in relation to head injury, targeted therapeutic approaches could be used on selected patients. One future drug on the horizon is bapineuzumab, which is used to treat Alzheimer disease in patients with a specific apolipoprotein E allele. Various authors have suggested that anti-inflammatory agents that block the cytokine and IL cascade could be used in patients with a certain IL-1 polymorphism.

B. Preoperative Evaluation and Preparation

B.1. What is the GCS? What is the significance of a GCS of 8 in this patient?

The GCS is the most widely used method to assess neurologic status and severity of brain dysfunction following head trauma. The GCS has been shown to have a significant correlation with outcome following severe head injury both as a sum score and the motor component. The scale, which ranges from 3 to 15 points, is based on evaluating the best motor response, the best verbal response, and the eye opening (Table 19.1).

Table 19.1 Glasgow Coma Scale

Eye opening:	None	1
	To pain	2
	To verbal command	3
	Spontaneous	4
Best verbal response:	No verbal response	1
	Incomprehensible sounds	2
	Inappropriate words	3
	Disoriented, conversing	4
	Oriented, conversing	5
Best motor response:	No response (flaccid)	1
	Extension (decerebrate)	2
	Abnormal flexion (decorticate)	3
	Flexion/withdrawal	4
	Localizes to pain	5
	Obeys verbal commands	6

Of the patients who initially survive TBI, 80% have minor injury (GCS 13 to 15), 10% have moderate injury (GCS 9 to 12), and 10% have severe injury (GCS ≥8). Serial determination of GCS is essential to monitor the patient's condition because GCS can change in a rapid or delayed manner. Decreases in the GCS of three or more points are indicative of catastrophic neurologic deterioration.

Glasgow Coma Scale. *J Neurotrauma*. 2000;17:563–571.

Schmidek HH, ed. *Operative Neurosurgical Techniques*. 4th ed. Philadelphia: WB Saunders; 2000:83–85.

B.2. In addition to the GCS, what other assessments can be done to evaluate neurologic function?

The GCS assesses spontaneous activity. Further neurologic evaluation includes pupillary examination, checking for brainstem reflexes in unconscious patients, and looking for lateralizing signs. Fixed bilateral enlarged pupils may signify an ominous prognosis, whereas unilateral pupillary enlargement occurs in the presence of an expanding hematoma or isolated ocular trauma. Deeply comatose patients lacking spontaneous eye opening should have evaluation of the brainstem reflexes. The oculocephalic reflex, or doll's eye maneuver, is elicited by rotating the head horizontally to one side. In the intact brainstem, the eyes deviate conjugately to the other side. This maneuver should be performed only when the cervical spine has been cleared. If the doll's eye response is abnormal, testing of the oculovestibular reflex (cold caloric test) is another method to evaluate brainstem function. The cold caloric test entails irrigation of the external auditory canal with ice water. In the intact brainstem, the eyes should deviate to the side of cold stimulation. Abnormal oculocephalic and oculovestibular reflexes signify severe brainstem dysfunction extending to the pons. However, other causes for abnormal responses need to be ruled out, which include drugs (e.g., phenytoin), nerve injuries (e.g., oculomotor, abducens, vestibular), and labyrinthine disease. Additional lateralizing signs include asymmetric posturing, hemiparesis, and facial weakness. The presence of these findings could indicate the possibility of a mass lesion.

Cucchiara RF, Black S, Michenfelder JD, eds. *Clinical Neuroanesthesia*. 2nd ed. New York: Churchill Livingstone; 1998:241–242.

B.3. What is the role of CT scanning in the initial evaluation of the patient with head injury? What management options can be done in patients whose neurologic condition is deteriorating before obtaining a CT scan?

Several checklist-based criteria for brain CT exist: the Canadian CT Head Rule and the New Orleans Criteria. These criteria have proven to be efficacious but, in general, if there has been a loss of consciousness or if the GCS is less than 15, a head CT scan should be obtained. Evidence of an intracranial hematoma that causes compression of the ventricles or a midline shift of greater than 5 mm is an indication for surgical intervention. Conversely, absence of a mass lesion or compression of the ventricles is an indication for conservative management. In a patient whose neurologic condition is deteriorating, securing the airway, hyperventilation, administration of hyperosmolar therapy, and sedation (with or without muscle relaxants) may provide sufficient time to obtain a preoperative CT scan. In rare circumstances, the surgeon may need

to initiate emergency surgical exploration of an expanding intracranial hematoma without CT scanning. Even more rare, in acute situations, urgent partial surgical decompression through a burr hole close to the fracture may be required.

Schmidek HH, ed. *Operative Neurosurgical Techniques*. 4th ed. Philadelphia: WB Saunders; 2000:83–85.

B.4. What is the role of ICP monitoring in the management of head injury?

Life-threatening emergencies such as impending herniation or hemorrhagic wounds in the abdomen or thorax require rapid surgical intervention. Definitive surgery for non–life-threatening cranial injuries should be delayed until the patient is hemodynamically stable to minimize hypotension, hypovolemia, and cerebral hypoxemia. If the patient is not emergently taken to the operating room, ICP monitoring becomes helpful in optimizing blood pressure management because CPP can be calculated by measuring mean arterial pressure (MAP) and ICP. Patients with head trauma often sustain other injuries requiring nonneurologic surgery. The decision to have an ICP monitor placed before nonneurologic surgery includes neurologic status in conjunction with CT findings, the nature and duration of the surgical procedure, and surgical procedures requiring occlusion of the aorta.

Although no prospective, randomized clinical trials have been conducted to establish the clinical efficacy of ICP monitoring, it has become widely used for the diagnosis and management of intracranial hypertension. ICP monitoring helps in the early detection of expanding hematomas and can be useful in reducing ICP by CSF drainage.

ICP monitoring is appropriate in this case because this patient has severe brain injury and an abnormal CT scan. In patients with severe head injury but a normal CT scan, ICP monitoring is indicated when systolic blood pressure is less than 90 mm Hg and there is motor posturing. ICP monitoring is rarely indicated in patients with mild to moderate injury.

Schmidek HH, ed. *Operative Neurosurgical Techniques*. 4th ed. Philadelphia: WB Saunders; 2000:83–85.

B.5. How can you clear this patient's cervical spine?

Patients presenting to trauma units following closed head injury may have a concomitant cervical spine fracture. Adequate cervical spine radiographs, especially in the uncooperative patient, are very difficult to obtain following many traumas. Furthermore, injuries in the atlanto-occipital region are especially difficult to identify radiographically, and up to 26% of lateral radiographs failed to show fractures.

Even in the face of normal radiographic studies, patients may still have significant ligamentous injuries with cervical instability necessitating particular care during airway management. Typically, patients are examined carefully, their cervical spine is palpated, and tenderness or weakness is identified. In the uncooperative or unconscious patient, the cervical spine should be considered not cleared, even in light of normal radiographs. On the other hand, if the cervical spine is cleared radiographically, the mental status is normal, and the patient is asymptomatic, then the examination can be considered cleared.

Todd MM. *Cervical Spine Motion: Cervical Spine Injury and the Unstable Neck. ASA Annual Refresher Course Lectures.* Park Ridge, IL: American Society of Anesthesiologists; 2008:506.

B.6. What are the benefits of early endotracheal intubation in this patient?

Endotracheal intubation not only provides a secure airway in a patient with an altered ability to protect the airway, but also allows for the ability to provide optimum oxygenation and hyperventilation of the patient, thereby providing a rapid tool for lowering ICP if necessary. Also, patients with facial trauma can often have progressive swelling and anatomic distortion, making subsequent intubation attempts more difficult.

Miller RD, ed. *Miller's Anesthesia*. 7th ed. New York: Churchill Livingstone; 2010.

Bendo AA. *Update on CNS Injury: Adult Head Injury Management—Are Guidelines Improving Outcome. ASA Annual Refresher Course Lectures.* Park Ridge, IL: American Society of Anesthesiologists; 2008:331.

B.7. What is your plan for airway management in this patient? How would it change if the patient were combative? How would it change if the patient had facial fractures with significant swelling of the head and neck?

Patients with a GCS less than 8 often require intubation and controlled ventilation to lower the ICP and protect the airway. Direct laryngoscopy following induction and muscle relaxation should be accompanied by in-line stabilization by an assistant, with many authors recommending leaving the posterior portion of the rigid collar in place, so that it can act as a stabilizer to prevent further movement. Earlier recommendations for in-line traction are no longer popular because of concerns for spinal cord damage in patients with gross instability. Emergency airway equipment should always be available in case of the inability to intubate with direct laryngoscopy. Another option is awake fiberoptic intubation, but a compliant patient is a necessity, because thrashing and fighting can cause more harm to the unstable spine than laryngoscopy itself. A combative patient would make one lean more toward rapid sequence induction and intubation with in-line stabilization, whereas a patient with facial fractures and facial swelling would lead one to fiberoptic intubation. Midface and basilar skull fractures should preclude attempts at nasal intubation because of concerns for entering the cranial vault inadvertently. Blood in the airway can complicate fiberoptic

intubation in these patients, and alternative intubation devices and plans should be readily available. In any event, the goals of preoxygenation and securing an airway with minimum cervical spine motion should be observed, while being cognizant of the risk for regurgitation and aspiration in a patient with a full stomach.

Miller RD, ed. *Miller's Anesthesia.* 7th ed. New York: Churchill Livingstone; 2010.

Todd MM. *Cervical Spine Motion: Cervical Spine Injury and the Unstable Neck. ASA Annual Refresher Course Lectures.* Park Ridge, IL: American Society of Anesthesiologists; 2008:506.

B.8. What are the effects of succinylcholine on ICP? What is the significance of the effect, if any?

Succinylcholine has been shown in animal and human studies to increase ICP through increased muscle spindle activation with depolarization. The effect can be avoided by using a defasciculating dose of a nondepolarizing drug before succinylcholine administration. It is important to remember that the elevation in ICP from succinylcholine will be much less than the elevation during intubation attempts in awake struggling patients.

Miller RD, ed. *Miller's Anesthesia*. 7th ed. New York: Churchill Livingstone; 2010.

B.9. What coagulation abnormalities are present after TBI? What treatment modalities can be used to provide hemostasis and reduce intracranial hematoma expansion?

Disseminated intravascular coagulation (DIC) is a consequence of TBI, presumably related to release of tissue thromboplastins. One explanation for secondary brain injury after intracranial bleeding is ischemia secondary to cerebral herniation, increased ICP, and direct blood vessel occlusion by the hematoma. An alternative explanation is intravascular microthrombosis secondary to DIC.

In an aging population, the number of individuals taking warfarin for the prevention of thromboembolic complications of atrial fibrillation, cardiac valve replacement, deep venous thrombosis, and thrombophilic states increases. These individuals are at increased risk for intracranial hemorrhage from trauma or spontaneous causes, and their management has a poorer outcome and necessitates urgent reversal of anticoagulation for rapid surgical intervention. Traditionally, administration of fresh frozen plasma and clotting factors has been used in correcting coagulation abnormalities after head injury. Early hemostatic therapy for acute hemorrhage has been proposed to reduce the growth of hematoma expansion. Recombinant activated factor VIIa has been administered to promote hemostasis in patients with acute intracerebral hemorrhage. There are no definitive values regarding the international normalized ratio (INR) threshold beyond which surgery cannot safely be performed. A high mortality rate has been reported in the postoperative period in patients with preoperative INR values greater than 1.25; an INR of 1.2 to 1.5 is considered to be sufficient for neurosurgical hemostasis. Other investigators have suggested an INR of 1.3 to be the goal of preoperative warfarin (Coumadin) reversal.

Recombinant activated factor VIIa acts in a tissue factor–dependent manner, binding with high affinity to the surface of activated platelets and enhancing thrombin formation after direct activation of factors IX and X on the surface of the activated platelets. Its efficacy has been evaluated in many areas of medicine because recombinant activated factor VIIa significantly slowed progression of hemorrhage and reduced the morbidity and mortality after spontaneous intracerebral hemorrhage. Algorithms

have been developed to determine the use of recombinant factor VIIa in coagulopathy intracranial hemorrhage states based on the answer to two principal questions: (1) What is the type of bleeding and what is the risk for expansion of the hematoma? and (2) How urgent is the indicated surgery (timing)? Studies have verified that in regard to outcomes, surgical intervention early from admission is recommended for epidural hemorrhage or subdural hemorrhage with prominent clinical impairment or progressive deterioration. If not deteriorating rapidly, patients can be operated on within 24 hours.

C. Intraoperative Management

C.1. What is appropriate hemodynamic monitoring during CT scanning and during craniotomy for evacuation of a subdural hematoma?

It is axiomatic that hemodynamic monitoring should be commensurate with the anticipated changes in cardiovascular status during the planned procedure. Assuming there is no evidence of occult blood loss or major intrathoracic injury, the most aggressive monitoring during CT scanning should consist of direct arterial pressure assessment. This is based on the requirement for arterial blood gas analysis and the possible need to administer vasoactive drugs to control blood pressure. Conversely, if there is evidence of occult bleeding or a major thoracic injury, placement of a central venous pressure (CVP) or pulmonary arterial catheter may be required in guiding fluid management before CT scanning.

If no invasive monitors were placed during CT scanning, an arterial line is needed before craniotomy surgery. Placement of a CVP or pulmonary artery catheter in the operating room is helpful in managing blood pressure in conjunction with fluid administration. If cardiac contusion is a consideration, placement of a pulmonary artery catheter would be preferable over placement of a CVP catheter, because both cardiac output and right ventricular pressures can be measured. Cardiac contusion is most often associated with right ventricular dysfunction.

C.2. Should hyperventilation be used in this patient?

The theoretical advantages of hyperventilation are control of ICP and reversal of acidosis in brain tissue. Cerebral blood flow in head-injured tissue is low, and

vasoconstriction can result in ischemia. In areas of severe injury (e.g., subdural hematomas, diffuse contusions), there is local variability in perfusion as well as loss of autoregulation and carbon dioxide reactivity. A randomized, clinical trial has shown that hyperventilation is potentially deleterious, suggesting that prophylactic hyperventilation ($Paco_2$ <35 mm Hg) should be avoided. It has been suggested that the use of monitors such as jugular venous hemoglobin oxygen saturation monitoring and cerebral oximeters may help determine the effects of hyperventilation on cerebral oxygenation. Measures of cerebral metabolism may predict which patients benefit from hyperventilation.

Currently, it has been recommended that hyperventilation be used on a selective rather than routine basis. Hyperventilation may be necessary to lower ICP for brief periods in which there is acute neurologic deterioration or intracranial hypertension that is refractory to other treatment modalities such as mannitol and CSF drainage. If ICP monitoring is present in the operating room, hyperventilation could be used to lower ICP to less than 20 mm Hg. Other goals such as facilitating surgical access and minimizing surgical retraction are still important considerations in the intraoperative management of head injury.

C.3. What are the implications of arterial hypertension in patients with head injury? How should blood pressure be managed?

Hypertension is a common feature of head injury in patients who do not have massive blood loss associated with their injuries. The etiology of hypertension appears to be catecholamine related. Some experts believe that cerebral perfusion is optimized when there is a high arterial pressure opposing the effects of elevated ICP. Others think that in the presence of a disrupted blood–brain barrier, arterial hypertension contributes to extravasation of edema fluid and aggravation of brain swelling.

Although some experts advocate maintaining CPP above 60 mm Hg, proponents of high CPP recommend maintaining CPP greater than 70 mm Hg with the use of volume expansion and vasoactive drugs. Several clinical studies have suggested improved outcomes when systemic arterial pressure is raised to keep CPP at 70 to 90 mm Hg, but they were not controlled, blinded, or randomized. Other studies have questioned the necessity of vasopressors to maintain cerebral perfusion above 70 mm Hg and the role of CPP as a determinant of cerebral blood flow. The consensus at this time is to maintain arterial pressure at normal to slightly elevated levels. Above all, arterial hypotension is to be avoided, because it profoundly increases neuronal damage in the presence of elevated ICP.

Miller RD, ed. *Miller's Anesthesia*. 7th ed. New York: Churchill Livingstone; 2010.

C.4. What should be done about intravenous fluid replacement? Should corticosteroids be given empirically?

Often, many head-injured patients sustain multiple injuries that require aggressive resuscitation with crystalloids, plasma expanders, and blood. Once the patient arrives to the operating room, packed red blood cells should be administered to maintain normal CVP along with crystalloid or colloid solutions in quantities sufficient to replace blood loss. The problem with aggressive resuscitation is that excessive crystalloid administration may exacerbate brain edema.

Rapid formation of brain edema is a common reaction associated with most neuropathologic processes, including intracranial hematomas. Although crystalloid administration decreases colloid oncotic pressure, the reduction of colloid oncotic pressure does not cause edema in normal or injured brain tissue. It is the administration of free water and the decrease in osmolality that appear to be important in edema formation. In experimental studies, D_5W solutions increase edema, increase blood glucose, and worsen neurologic outcome. Isotonic solutions such as isolyte and 0.9% saline have no adverse effect on edema formation, blood glucose, and neurologic outcome. The worsening of neurologic outcome with D_5W has been attributed to edema formation rather than hyperglycemia. Hypotonic solutions (D_5W, 1/2 normal saline) should *not* be used in the patient with TBI. The ideal volume state for a patient with brain injury is hypertonic and euvolemic, which can be achieved with normal saline or hypertonic solutions.

Corticosteroids have been shown to be effective in reducing cortical vasogenic edema associated with brain tumors and abscesses, but level I data, in the Corticosteroid Randomization After Significant Head Injury (CRASH) study, determined that they lack efficacy in head trauma. Corticosteroids failed to demonstrate any benefit and are occasionally associated with iatrogenic complications such as sepsis. Glucocorticoids do not lower ICP, and routine use is not recommended for head injury. Moreover, their potential for raising plasma glucose make their use less desirable in the setting of TBI.

C.5. Should hypertonic saline be administered to this patient? How is hypertonic saline administered?

The rationale for hyperosmolar therapy is to decrease cerebral edema by creating an osmolar gradient between the intravascular space and cerebral tissue. Water moves from the cells and interstitial spaces into the capillaries, to decrease cerebral water content and ICP. Hypertonic saline and mannitol are the modalities for hyperosmolar therapy. Hypertonic saline has been shown to decrease ICP even when other conventional measures such as barbiturates and mannitol have been exhausted. Hypertonic saline is a volume expander in the systemic circulation and does not impair renal function as seen with mannitol administration. Often, with hypertonic saline administration, the goal is to maintain normovolemia with the help of CVP or pulmonary arterial catheter monitoring.

Typically, a 3% saline solution is administered at a rate of 75 to 150 mL per hour; whereas a bolus of 250 mL may be given for aggressive therapy. Of further note, the use of 7.5% hypertonic saline has been reported. Preliminary evidence supports the use of hypertonic saline in reducing ICP, suggesting that controlled clinical trials should be performed to determine if hypertonic saline improves outcome. Currently, the human data are still inconclusive to recommend the use of hypertonic saline as a

standard of management. In one study, patients receiving 2 mL per kg of 7.5% saline had better control of ICP than patients receiving mannitol but no changes in mortality or neurologic outcome were observed. In another study involving the prehospital administration of hypertonic saline for resuscitation in patients with hypotension and TBI, ICP control was better in the patients receiving hypertonic saline, but again no differences in outcome were demonstrated.

C.6. The patient underwent a craniectomy for evacuation of a frontal intracerebral hematoma. Should some anesthetic agents be avoided in this situation? Which ones? What agents might be preferred in this situation?

The principles of anesthetic management for patients with rapidly expanding intracranial mass lesions are based on the idea of maximizing intracranial compliance by minimizing the volume within the intracranial compartment. This means that any maneuver that increases cerebral blood volume should be avoided. All intravenous induction agents (e.g., thiopental, etomidate, and propofol) except for ketamine are known for their vasoconstrictive effects and are reasonable choices provided that the hemodynamic stability is maintained. Ketamine has been out of favor in the neurosurgical setting because early studies showed that it increases cerebral metabolic rate, cerebral blood flow, and ICP. A more recent study showed that in ventilated patients receiving propofol sedation, ketamine actually decreased ICP and did not adversely alter cerebral hemodynamics. These authors surmised that when ketamine is added to a background anesthetic, the central nervous excitation effects of ketamine are blunted and it increases the depth of anesthesia. Because ketamine is an NMDA antagonist, with possible neuroprotective effects, it has been suggested that the use of ketamine in head injury warrants reevaluation.

All of the volatile inhalation agents and nitrous oxide have some cerebral vasodilatory effects. Caution must be exercised in using inhalation agents in patients with rapidly expanding intracranial mass lesions. When the surgical field is "tight," eliminating inhalation agents and going with a total intravenous anesthetic technique may be appropriate. For example, a propofol or thiopental infusion may render the patient sufficiently anesthetized for a craniotomy. Finally, concern exists that opioids may act as cerebral vasodilators and raise ICP. Several studies have shown that sufentanil increases ICP in patients with head injury possibly secondary to indirect cerebral vasodilatation caused by autoregulatory compensation when MAP decreases. Direct cerebral vasodilatation has been implicated in the increase in ICP seen after morphine and fentanyl administration.

C.7. Should hypothermia be employed in this patient?

In experimental models, hypothermia has been shown to decrease the amount of edema and necrosis volume after cerebral damage. A temperature of 33° C (91.4° F) has been considered to be the safe limit for patients with head injury. Several clinical trials, involving less than 100 patients, have shown that inducing moderate (32° C to 33° C [89.6° F to 91.4° F]) or mild hypothermia (33° C to 35° C [91.4° F to 95° F]) in patients with severe head trauma (GCS less than 8), improves neurologic outcome. Nevertheless, a multicenter phase III head injury trial, involving almost 400 patients, showed that inducing hypothermia in patients who had already arrived to the hospital normothermic did not improve outcome. In general, enthusiasm for the application of hypothermia in neurosurgical patients has faded as another multicenter trial of hypothermia involving cerebral aneurysm patients also demonstrated negative findings in improving neurologic outcome. Despite negative findings from the most recent comprehensive trials on hypothermia, various researchers contend that the complete abandonment of hypothermia is premature and newer technologies that induce hypothermia (e.g., intravascular cooling) should be further investigated.

D. Postoperative Neurointensive Care Management

D.1. What are the postoperative ventilation considerations in this patient?

If the patient had normal consciousness preoperatively, early extubation would be preferable once it is confirmed that the patient is able to follow commands and move extremities. Efforts should be made to avoid bucking and coughing on the endotracheal tube and to treat hypertension that occurs on emergence. Intravenous lidocaine is a useful drug to smooth the coughing associated with emergence. Short-acting opiates, particularly remifentanil, can provide a smooth emergence in patients that are hemodynamically stable, tolerating the endotracheal tube, and following commands. However, many patients with TBI undergoing emergency surgery remain intubated postoperatively because of the severity of the brain injury. In that case, blood pressure

control to prevent hypertension is needed to prevent further hemorrhage. In some patients, sedatives and muscle relaxants may be administered on transport to prevent changes in ICP associated with stimulation and agitation. In ventilated patients, the use of a cerebral oxygen monitor may be useful in optimizing brain oxygen delivery in relation to $Paco_2$.

Prough DS. *Perioperative Management of Traumatic Brain Injury. ASA Annual Refresher Course Lectures*. Park Ridge, IL: American Society of Anesthesiologists, 2004:221.

D.2. What specific measures should be used to control the patient's ICP? What type of monitoring devices can be used to monitor ICP?

After removal of a mass occupying lesion, control of ICP is of paramount importance in the patient's recovery. Briefly, those patients whose ICP can be maintained below 20 to 25 mm Hg tend to have significantly better outcomes than do patients whose ICP remain elevated. It has become common practice, therefore, to monitor ICP in the postoperative period in these patients. This enables the intensivist to adjust treatment with hyperventilation, mannitol, CSF drainage, and head-up tilt to the desired ICP response. If these maneuvers fail, the next intervention is to maintain barbiturate coma to a level at which the electroencephalogram shows burst suppression. This is continued until it is no longer necessary to control intracranial hypertension. After weaning from barbiturate therapy, the patient can be weaned from diuretics and hyperventilation, as appropriate. As mentioned earlier, the use of hyperventilation in patients with head injury must be on a selective basis because hyperventilation has potentially deleterious effects on cerebral perfusion.

The classic intraventricular catheter or ventriculostomy was introduced by Lundberg in 1960 and has been the gold standard for ICP monitoring and CSF drainage. Placement of an intraventricular catheter has been associated with the potential for infection and brain parenchyma injury. Placement of a subarachnoid bolt used to be a less invasive modality but limitations included accuracy and stability. Subarachnoid bolts have been supplanted by a variety of implantable pressure transducer devices. Current ICP monitoring systems use a twist drill for bolt placement in the skull to allow a catheter to be rapidly placed in the parenchyma or subarachnoid space. Some systems allow CSF drainage in which a catheter containing a transducer at the tip is placed into the ventricles.

D.3. What is neurogenic pulmonary edema? Would you avoid positive end-expiratory pressure (PEEP) in a patient with increased ICP?

Neurogenic pulmonary edema is a commonly seen disorder following head injury or intracranial bleed. The mechanisms are unclear, but are thought to be due to a combination of increased pulmonary pressures resulting from massive catecholamine release with increased ICP (Cushing response) and altered pulmonary capillary permeability from as yet undescribed neurogenic factors. The onset can be immediate or

delayed, and treatment consists of supportive care as with other cases of pulmonary edema, including PEEP.

Positive pressure ventilation, PEEP, and increased ICP have been studied in animal and human models, and although there is a slight increase in ICP with higher levels of PEEP (10 to 12 cm H_20) in patients with normal ICP, patients with elevated ICP do not seem to demonstrate a clinically significant change in ICP with even high levels of PEEP. On the other hand, avoidance of PEEP, in such setting, may lead to hypoxemia that, in turn, can exacerbate cerebral ischemia.

Rosen P, ed. *Emergency Medicine: Concepts and Clinical Practice*. 4th ed. St. Louis: Mosby; 1998:436.

D.4. What is the role of antiseizure prophylaxis in the perioperative management of head trauma?

Seizures may cause secondary injury as a result of increases in ICP, changes in oxygen supply and demand, and increases in neurotransmitter release. Early posttraumatic seizures occur in the first week after injury, mostly within the first 24 hours. Late posttraumatic seizures occur after the first week. Often, early posttraumatic seizures occur within hours after injury, especially in patients with depressed or open skull fractures and hemorrhagic brain contusions. Short-term prophylactic administration of anticonvulsant drugs (e.g., phenytoin, carbamazepine) for early posttraumatic seizures is recommended. Recently, levetiracetam has gained popularity as monotherapy for the prevention of posttraumatic seizures. Levetiracetam has a favorable side effect profile compared with phenytoin and carbamazepine. Nevertheless, administration of anticonvulsant medicines has not been shown to prevent late posttraumatic seizures. Therefore, routine antiseizure prophylaxis is not recommended later than 1 week following head injury. Penetrating head injury may require longer posttraumatic seizure prophylaxis.

D.5. How can cerebral oxygenation monitoring be used in the clinical management of TBI?

An indwelling parenchymal device that measures local oxygenation can be used to gain information regarding tissue oxygenation in real time at the bedside. In a severely injured brain, autoregulatory mechanisms fail. As a result, various areas of the brain will be ischemic. Use of an oxygen sensor allows for more precise management to optimize oxygen delivery and eliminate progression of ischemia. A cerebral oxygen monitor is placed either intraoperatively or at the bedside, much like a ventriculostomy. Many studies have shown it to be equally as useful as a jugular bulb catheter. The device can either be placed in an ischemic penumbra of a lesion or in an uninjured area of the brain. In the first case, the monitor will yield information that can be used to prevent further ischemia and cell death. In the second case, the device is used as a global indicator of cerebral oxygenation and may be useful in guiding ventilatory management.

Cerebral oxygenation monitoring also offers the ability to measure parenchymal temperatures simultaneous to oxygen content. This is of critical importance when using hypothermia or maintaining normothermia. By definition, brain oxygen tension or partial pressure (P_bO_2) is not adequate if it drops below 20 mm Hg. In recent studies, values less than 20 mm Hg for short intervals have correlated with worse neurologic outcome. A value greater than 30 mm Hg is optimal. Currently, there are several devices on the market that measure oxygen content.

D.6. What methods can be used in the neurointensive care unit to prevent hyperthermia?

Fever continues to be a problem in critically ill neurosurgical patients. One retrospective study noted that more than 50% of patients with closed head injury had one febrile episode in the neurointensive care unit. Fever and hyperthermia accentuate excitotoxic release of neurotransmitters, increase production of free radicals, and accelerate cytoskeletal protein degradation. Although the enthusiasm to induce perioperative hypothermia for neuroprotection has waned, interventions are needed to cool patients to prevent hyperthermia.

Acetaminophen remains the first line of treatment for fever. Conventional water-circulating cooling blankets have been considered to be ineffective because of poor surface contact with the skin. A newer external cooling device has been developed that utilizes self-adhesive, hydrogel-coated pads that circulate temperature-controlled water under negative pressure. Intravascular central venous catheters have been developed for both cooling and rewarming. These catheters contain special built-in balloons through which cooled or warmed saline is circulated in a closed loop design. The patient's temperature is continuously compared with a user-defined target temperature, and the controller system is equipped with a safety system that sounds an alarm when the temperature is above or below programmed levels or when there is a system malfunction. Figure 19.3 shows a comparison of brain and rectal temperatures after intravascular cooling through a femoral catheter. Intracranial temperature measurements were obtained through an indwelling cerebral oxygen catheter placed into the brain parenchyma of the left frontal region.

In view of the recent advances in technologies to lower temperature, experts contend that it is premature to completely abandon the use of hypothermia. Future avenues of research include evaluating the impact of fever and hyperthermia on neurologic outcome, treating refractory elevations in ICP with hypothermia, and exploring methods for intraventricular or lumbar irrigation for rapid brain cooling.

CHAPTER 20

Cerebral Aneurysm

Patricia Fogarty Mack

A 43-YEAR-OLD WOMAN presented to the emergency room 2 days ago, complaining of severe headache, nausea, and vomiting, followed by a witnessed 3-minute loss of consciousness. On regaining consciousness, the patient was noted by her family to be confused. A computed tomography (CT) scan showed subarachnoid bleeding. You are called to the angiography suite because four-vessel angiography has revealed an 18-mm basilar-tip aneurysm and a 10-mm right middle cerebral artery aneurysm. The interventional neuroradiologist wishes to coil the basilar tip aneurysm but believes the middle cerebral artery aneurysm will require craniotomy and clipping. At present, she was oriented only to person. She had no previous medical history; however, she had smoked one pack of cigarettes per day for the last 20 years. Blood pressure was 130/80 mm Hg, pulse 90 beats per minute, and respiration 18 breaths per minute. She had no focal neurologic deficits. Laboratory examination revealed normal electrolytes and complete blood count. Electrocardiogram demonstrated normal sinus rhythm with flipped T waves throughout the precordium.

A. Medical Disease and Differential Diagnosis

1. What are the incidence, prevalence, and causes of subarachnoid hemorrhage (SAH) and what are the risk factors associated with rupture of intracranial aneurysms?
2. What are common sizes and locations of intracranial aneurysms?
3. What is the pathophysiology of aneurysmal rupture and SAH?
4. What are symptoms and signs of SAH?
5. How does one assess the severity of SAH?
6. What are the cardiovascular effects of SAH?
7. How is the diagnosis of SAH made?
8. What is the risk for rebleeding for a patient with SAH?

B. Preoperative Evaluation and Preparation

1. What are some concerns in going to the interventional neuroradiology suite in the midst of an angiogram to follow immediately with coiling of an aneurysm?
2. What type of anesthesia is required for coiling of an aneurysm?
3. Would you proceed with induction of general anesthesia under these circumstances?
4. What types of emergencies can occur during coiling of an aneurysm and how should they be managed?
5. A craniotomy is planned for the following day to clip the middle cerebral artery aneurysm. Should surgery be postponed because of the patient's elevated creatinine phosphokinase (CPK) myocardial-bound (MB) fractions?
6. Would you premedicate this patient before craniotomy?

C. Intraoperative Management

1. What are the goals of the induction and maintenance of anesthesia for this patient?
2. Is placement of an arterial line necessary for induction of anesthesia in this patient in the interventional neuroradiology suite?
3. How would you assess fluid status in this patient?
4. Would monitoring central venous pressure (CVP) be useful in this patient for craniotomy for clipping?
5. What other forms of monitoring would you consider?
6. What are your particular concerns during induction of anesthesia in this patient?
7. How would you accomplish a smooth and safe induction and intubation of this patient?
8. Would you perform a rapid-sequence induction and intubation on this patient?
9. What are the effects of hypoxemia and hypercapnia, such as would be seen with loss of the airway on induction, on cerebral blood flow (CBF)?
10. What is optimal fluid management for aneurysm clipping? Would you use a dextrose-containing solution?
11. After the bone plate was removed and as the dura was being opened, the surgeon complained that the brain was "tight." What could you do to achieve better brain relaxation and facilitate surgical exposure?
12. How might transmural pressure be decreased to allow for aneurysm clip placement?
13. What is the purpose of controlled hypotension and how is it achieved?
14. What are some of the potential drawbacks of controlled hypotension?
15. What methods of cerebral protection might you employ during this operation?
16. Would you induce mild hypothermia as a means of cerebral protection?
17. What are the indications for deep hypothermic circulatory arrest?
18. What steps should be taken in the case of intraoperative rupture of an intracranial aneurysm?
19. How would you plan the emergence from an anesthetic for aneurysm clipping?

D. Postoperative Management

1. Would you extubate the patient postoperatively?
2. What would be the differential diagnosis if the patient did not return to her preoperative neurologic condition?

3. On postoperative day 2, the patient became disoriented and developed hemiplegia. A CT scan was obtained, which shows no new intracranial bleeding. What other diagnostic studies should be performed?
4. What is cerebral vasospasm and what causes it?
5. What are pathophysiologic changes seen in cerebral vasospasm?
6. How is the diagnosis of cerebral vasospasm made?
7. What steps can be taken to prevent cerebral vasospasm?
8. What treatments can be undertaken once a diagnosis of cerebral vasospasm is made?
9. What are other neurologic complications following SAH and aneurysm clipping?
10. What other organ systems may manifest problems postoperatively in aneurysm clipping patients?

A. Medical Disease and Differential Diagnosis

A.1. What are the incidence, prevalence, and causes of subarachnoid hemorrhage (SAH) and what are the risk factors associated with rupture of intracranial aneurysms?

The prevalence of SAH is 2% to 5% with an incidence of 10 to 28 per 100,000 people. Each year, 25,000 cases of SAH occur in the United States, comprising 10% of all cases of stroke. Sixty percent of the cases occur in young individuals between the ages of 40 and 60. Therefore, a poor neurologic outcome is a devastating condition to be endured over a potentially long period.

Approximately one-third of patients die as a result of the acute bleed. Of the two-thirds who survive the acute bleed, one-half (one-third of total) later die or are severely disabled and half (one-third of total) have an acceptable outcome.

Cerebral aneurysms account for 75% to 80% of SAH; arteriovenous malformations are the cause in 4% to 5%, whereas no specific cause can be found in 15% to 20% of SAH. Other causes of SAH include trauma, mycotic aneurysm, sickle cell disease, cocaine use, and coagulation disorders.

Risk factors for rupture of cerebral aneurysms include hypertension, pregnancy, and vascular abnormalities (e.g., type III collagen deficiency and elastase abnormalities). One-third of patients with polycystic kidney disease have been found to have intracranial aneurysms at autopsy. Genetic predisposition plays a role: 7% of berry aneurysms are familial, and 5% to 10% of patients with ruptured aneurysm have a first-order relative with ruptured aneurysm. The rupture rate for aneurysm has been estimated at 0.14% per year for a 5-mm lesion to 1.1% per year for a 10-mm lesion.

Smoking and alcohol abuse also appear to predispose to aneurysm formation and rupture. Smoking at any time and female gender are related to the presence of multiple intracranial aneurysms, as well as accelerated aneurysm growth. Cocaine abuse and resultant episodic hypertension may predispose to aneurysmal rupture at an early age.

Death and disability are primarily due to the initial bleed, vasospasm, and rebleeding. Other causes include surgical complications, parenchymal hemorrhage, hydrocephalus, and complications of medical therapy.

A.2. What are common sizes and locations of intracranial aneurysms?

Small (less than 12 mm) aneurysms make up 78% of the total, whereas large (12 to 24 mm) are 20%, and giant (greater than 24 mm) comprise 2%. Most aneurysms are located in the anterior circulation, with the junction of the anterior communicating and anterior cerebral arteries being the most common (39%). Thirty percent of aneurysms occur in the internal carotid artery, 22% in the middle cerebral artery, and 8% in the posterior circulation (posterior cerebral, basilar, and vertebral arteries).

Kasell NF, Torner JC, Haley C, et al. The international cooperative study on the timing of aneurysm surgery. Part 2. Surgical results. *J Neurosurg*. 1990;73:37–47.

A.3. What is the pathophysiology of aneurysmal rupture and SAH?

On the basis of experimental models, aneurysmal rupture leads to the leakage of arterial blood and a rapid increase in intracranial pressure (ICP), approaching diastolic blood pressure in the proximal intracerebral arteries. This increase in ICP causes a decrease in cerebral perfusion pressure (CPP) and a fall in CBF, leading to a loss of consciousness. The decrease in CBF diminishes bleeding and stops the SAH. A gradual reduction in ICP and an increase in CBF indicates improved cerebral function and possibly a return to consciousness. A persistent increase in ICP (perhaps resulting from thrombi in the cranial cisterns), however, indicates a persistent no-flow pattern with acute vasospasm, cell swelling, and death.

A.4. What are symptoms and signs of SAH?

Headache occurs in 85% to 95% of patients. Often, a brief loss of consciousness occurs, followed by diminished mentation; consciousness may be impaired to any degree or may be unaffected at the time of presentation. Symptoms may be similar to those of infectious meningitis (nausea, vomiting, and photophobia) secondary to subarachnoid blood. The patient may also experience motor and sensory deficits, visual field disturbances, and cranial nerve palsies. Finally, blood in the subarachnoid space may cause an elevated temperature.

A.5. How does one assess the severity of SAH?

Two grading scales are commonly used to assess neurologic status following SAH, the Hunt and Hess grade (Table 20.1) and the World Federation of Neurologic Surgeons' grade (Table 20.2), based on the Glasgow Coma Scale. The scales are useful in identifying a baseline neurologic status from which any acute changes should be assessed. In addition, the scales may correlate with physiologic status. Patients who are Hunt and Hess grades I and II have near-normal cerebral autoregulation and ICP.

Hunt WE, Hess RM. Surgical risk as related to time of intervention in the repair of intracranial aneurysms. *J Neurosurg.* 1968;28:14–20.

A.6. What are the cardiovascular effects of SAH?

Injury to the posterior hypothalamus from SAH causes the release of norepinephrine from the adrenal medulla and cardiac sympathetic efferents. Norepinephrine can cause an increase in afterload and direct myocardial toxicity, leading to subendocardial ischemia. Pathologic analysis of myocardium of patients who have died of acute SAH has revealed microscopic subendocardial hemorrhage and myocytolysis.

Electrocardiographic abnormalities are present in 50% to 80% of patients with SAH. Most commonly, these involve ST segment changes and T wave inversions, but also include prolonged QT interval, U waves, and P wave changes. ST-T wave changes are usually scattered and not related to a particular distribution.

Dysrhythmias occur in 80% of patients, usually in the first 48 hours. Premature ventricular contractions are the most common abnormality, but any type of dysrhythmia is possible. They include severely prolonged QT interval, torsades de pointes, and ventricular fibrillation. In one series, 66% of the arrhythmias were considered mild,

Table 20.1 Modified Hunt and Hess Clinical Grades

GRADE[a]	CRITERIA
0	Unruptured aneurysm
I	Asymptomatic or minimal headache and slight nuchal rigidity
II	Moderate to severe headache, nuchal rigidity, but no neurologic deficit other than cranial nerve palsy
III	Drowsiness, confusion, or mild focal deficit
IV	Stupor, mild to severe hemiparesis, possible early decerebrate rigidity, vegetative disturbance
V	Deep coma, decerebrate rigidity, moribund appearance

[a] Serious systemic disease such as hypertension, diabetes, severe arteriosclerosis, chronic pulmonary disease, and severe vasospasm seen on arteriography result in placement of the patient in the next less favorable category.
From Hunt WE, Hess RM. Surgical risk as related to time of intervention in the repair of intracranial aneurysms. *J Neurosurg.* 1968;28:14–20, with permission.

Table 20.2 World Federation of Neurological Surgeons (WFNS) Grading Scale

WFNS GRADE	GLASGOW COMA SCALE	MOTOR DEFICIT
I	15	Absent
II	14–13	Absent
III	14–13	Present
IV	12–7	Present or absent
V	6–3	Present or absent

From Drake CG. Report of World Federation of Neurologic Surgeons Committee on a universal subarachnoid hemorrhage grading scale. *J Neurosurg.* 1988;68:985–986, with permission.

29% moderate, and 5% severe. In addition to increased catecholamine secretion, hypercortisolism and hypokalemia have been suggested as causes for the dysrhythmias seen with SAH.

Ventricular dysfunction, possibly leading to pulmonary edema, is present in approximately 30% of patients with SAH.

Cardiac troponin I predicts myocardial dysfunction in SAH with a sensitivity of 100% and a specificity of 91%. This compares with a sensitivity and specificity of 60% and 94% for CK-MB in predicting myocardial dysfunction. In order to plan optional anesthetic management, it would be important to determine if cardiac dysfunction is due to myocardial infarction or reversible neurogenic left ventricular dysfunction. A retrospective study from Duke determined that reversible neurogenic cardiac dysfunction was associated with a troponin level of 0.22 to 0.25 ng per mL and an ejection fraction of less than 40% by echocardiograms.

Bulsara KR, McGirt MJ, Liao L, et al. Use of peak troponin value to differentiate myocardial infarction from reversible neurogenic left ventricular dysfunction associated with aneurysmal subarachnoid hemorrhage. *J Neurosurg.* 2003;98:524–528.

Cotrell JE, Young WL, eds. *Cottrell and Young's Neuroanesthesia.* 5th ed. Philadelphia: Mosby Elsevier; 2010:218–246.

A.7. How is the diagnosis of SAH made?

Noncontrast CT scan can determine the magnitude and location of the bleed. It may also be useful in assessing ventricular size and aneurysm location. High-resolution CT (CT angiogram) with contrast can more precisely determine the location of the aneurysm.

Lumbar puncture can be used to diagnose SAH if CT is negative, especially when the patient presents more than 1 week after an initial bleed. Xanthochromia, a yellow discoloration of the cerebrospinal fluid (CSF) after centrifugation, is present from 4 hours to 3 weeks after SAH. The lumbar puncture can cause herniation or rebleeding. Therefore, a CT scan should be performed first if the patient presents within 72 hours of suspected SAH, once subarachnoid blood is confirmed.

Four-vessel angiography (right and left carotid and vertebral arteries) has been considered the gold standard in the diagnosis of intracranial aneurysm; however, CT angiography has been used with increasing frequency. The goal is to visualize all intracranial vessels, to localize the source of bleeding, and to rule out multiple aneurysms (5% to 33% of patients). Three-dimensional reconstructive angiograms and magnetic resonance angiography also may be used.

Guy J, McGrath BJ, Borel CO, et al. Perioperative management of aneurysmal subarachnoid hemorrhage. Part 1. Operative management. *Anesth Analg.* 1995;81:1060–1072.

A.8. What is the risk for rebleeding for a patient with SAH?

The risk of rebleeding from a ruptured aneurysm is highest, 4%, in the first 24 hours after the initial bleed and 1.5% per day thereafter. Cumulative risk is 19% in 14 days and 50% at 6 months. After 6 months, the rebleeding risk is 3% per year.

Kassell NF, Torner JC. Aneurysmal rebleeding: a preliminary report from the Cooperative Aneurysm Study. *Neurosurgery.* 1983;13:479–481.

B. Preoperative Evaluation and Preparation

B.1. What are some concerns in going to the interventional neuroradiology suite in the midst of an angiogram to follow immediately with coiling of an aneurysm?

Whenever an anesthesiologist assumes care of a patient when the patient is already sedated, it may be more difficult to obtain an accurate medical history. In addition, the physical examination will be limited by the patient's position for the diagnostic study. Finally, the patient's capacity to consent may also be impaired by previous sedation.

B.2. What type of anesthesia is required for coiling of an aneurysm?

In most institutions, general anesthesia is required for coiling of an intracranial aneurysm. First, intraoperative neurologic testing is generally not required. Second, akinesis is very important not only when the coils are actually deployed but also while the interventionist is navigating the intracranial vessels to reach the aneurysm.

B.3. Would you proceed with induction of general anesthesia under these circumstances?

Yes, I would proceed. Obliteration of the aneurysm with coils has become the standard of care for basilar tip aneurysm, and it would be best for the patient to have this done in the same setting as the angiography, provided there were no contradictions to induction of general anesthesia (e.g., hemodynamic instability).

Cotrell JE, Young WL, eds. *Cottrell and Young's Neuroanesthesia.* St. Louis: Mosby; 2010:218–246.

Lee CZ, Young WL. Anesthetic considerations for interventional neuroradiology. *ASA Refresher Courses Anesthesiol.* 2005;33:145–154.

B.4. What types of emergencies can occur during coiling of an aneurysm and how should they be managed?

Basically, intraoperative emergencies can be divided into two categories—hemorrhage and thrombosis. Appropriate management requires constant communication between

the radiologist and surgeon and the anesthesiologist. If an intracranial hemorrhage occurs, the interventionalist may try to "glue" the hole in the aneurysm or embolize the parent vessel. If this is not possible, heparin should be rapidly reversed with protamine and a ventriculostomy will generally be placed by the surgical team. Management of $Paco_2$ can then be guided by the ICP. In the case of catheter-induced thrombosis, induced hypertension is usually desirable while tissue plasminogen activator or glycoprotein IIb/IIIa therapy is considered.

If a coil is malpositioned, anticoagulation would be continued while the interventional radiologist attempts to snare the coil. As in a thrombosis, it may be desirable to augment the blood pressure.

B.5. A craniotomy is planned for the following day to clip the middle cerebral artery aneurysm. Should surgery be postponed because of the patient's elevated creatinine phosphokinase (CPK) myocardial-bound (MB) fractions?

Fifty percent of patients will have an increase in CPK-MB fraction; however, CPK-MB per total CPK fraction is usually not consistent with transmural myocardial infarction. As discussed previously, troponin I levels are more sensitive. In addition, although some patients (0.7%) do sustain an myocardial infarction in the setting of SAH, little correlation is found between electrocardiographic abnormalities and ischemia in this population.

An echocardiogram may be useful in determining the severity of reversible neurogenic left ventricular dysfunction. If left ventricular function is found to be depressed, a pulmonary artery catheter or intraoperative transesophageal echocardiography may be helpful for intraoperative management.

The desire to delay surgery because of cardiac abnormalities must be weighed against the risk of rebleeding and vasospasm. In most cases, the risk of recurrent hemorrhage outweighs the risk of perioperative myocardial infarction. Furthermore, even if coronary artery disease is present, these patients are not candidates for angioplasty or myocardial revascularization, which requires heparinization. If pulmonary edema or malignant dysrhythmias are present, it may be prudent to postpone surgery until such problems are controlled medically. However, if these problems are not present, then clipping of the aneurysm may be indicated. Bulsara et al. found that 2.9% of patients had severe cardiac dysfunction. In this study, neurogenic left ventricular dysfunction resolved over 4 to 5 days.

Bulsara KR, McGirt MJ, Liao L, et al. Use of peak troponin value to differentiate myocardial infarction from reversible neurogenic left ventricular dysfunction associated with aneurysmal subarachnoid hemorrhage. *J Neurosurg.* 2003;98:524–528.

B.6. Would you premedicate this patient before craniotomy?

No. When the patient is in a Hunt and Hess grade III to V state, anxiety is unlikely. Furthermore, heavy sedation may decrease ventilation, raising $Paco_2$ and increasing CBF and ICP, which, at the very least, may hinder preoperative and postoperative neurologic evaluation. If patients are Hunt and Hess grade I to II and it appears that preoperative anxiety might lead to hemodynamic instability, a small dose of benzodiazepine may be appropriate.

Medications such as calcium channel blockers (nimodipine), anticonvulsants, and corticosteroids should be continued preoperatively on the day of surgery.

If the patient is at risk for aspiration, medications to decrease gastric acidity and volume are appropriate. Most patients will already be receiving a histamine-2 blocker if they are on dexamethasone.

Cotrell JE, Young WL, eds. *Cottrell and Young's Neuroanesthesia.* 5th ed. Philadelphia: Mosby Elsevier; 2010:218–246.

C. Intraoperative Management

C.1. What are the goals of the induction and maintenance of anesthesia for this patient?

The primary goal is to prevent aneurysm rupture on induction or intraoperatively while maintaining adequate CPP. The goal of matching anesthetic depth to surgical stimulation is more important than which specific drugs are used. In general, the anesthesiologist should provide for rapid and reversible titration of blood pressure, maintain CPP, and protect against cerebral ischemia. An additional goal is to provide a relaxed brain for ease of surgical exposure with minimal brain retraction. Finally, the anesthetic should be planned to achieve a rapid, smooth emergence, allowing prompt neurologic assessment. This can be accomplished with a combination of balanced anesthesia, muscle relaxation, and sympathetic blockers.

Bendo AA. Intracranial vasculary surgery. *Anesthesiol Clin North Am.* 2002;20:377–388.

Cotrell JE, Young WL, eds. *Cottrell and Young's Neuroanesthesia.* 5th ed. Philadelphia: Mosby Elsevier; 2010:218–246.

C.2. Is placement of an arterial line necessary for induction of anesthesia in this patient in the interventional neuroradiology suite?

In this case, because a femoral sheath is in place at the time that anesthesia is being induced, one may transduce femoral arterial pressure during induction. However, because the patient has two aneurysms and because the sheath will be removed at the end of the procedure, it would be prudent to place an additional arterial line at some point before removal of the sheath. When a large coaxial catheter is placed through the femoral sheath, systolic pressure is underestimated. The mean pressure, though, should be accurate. Recent studies have suggested that placement of an arterial line for induction is not essential when an unruptured aneurysm is to be coiled. At Weill Cornell Medical Center, we do not usually place an arterial line before induction for embolization of unruptured aneurysm.

Lai YC, Manninen PH. Anesthesia for cerebral aneurysms: a comparison between interventional neuroradiology and surgery. *Can J Anaesth.* 2001;48:391–395.

C.3. How would you assess fluid status in this patient?

Several issues in interventional radiology complicate fluid management. First, contrast material acts as an osmotic diuretic. Often, these patients have had a CT scan with contrast before the angiograms and may become intravascularly depleted. Second, the femoral sheath and other catheters are constantly flushed with a heparinized saline solution. It is not uncommon for a patient to receive 1,000 mL or more of flush fluid during the case. This must be taken into account when calculating fluid balance.

C.4. Would monitoring central venous pressure (CVP) be useful in this patient for craniotomy for clipping?

Many have suggested that CVP monitoring is essential in assessing volume replacement needs because urine output will be affected by osmotic or loop diuretics administered to facilitate surgical exposure. In addition, should vasoactive medication become necessary, it may be most effectively administered through a central venous catheter.

One disadvantage of CVP placement in the neurosurgical patient is catheter placement. Some clinicians are concerned that placement of an internal jugular venous CVP will compromise venous outflow of the head, thereby predisposing to bleeding or brain swelling, though this remains controversial. A "long-arm" or antecubital CVP line may be more difficult to insert and have a higher incidence of thrombophlebitis. Multiple studies have shown the complication rate of central catheter placement to be as high as 14%. When including failure to place the catheter, the complication rate rises to 54%. Nevertheless, use of an ultrasound-guided approach to placement of central venous catheters reduces the complication rates to less than 2% to 5% and should be the standard of care whenever possible.

Finally, a poor correlation between CVP and left ventricular end-diastolic pressure has been documented in SAH, so a pulmonary artery catheter may be more useful in assessing volume status as well as providing a monitor of cardiac output in those patients who have had preoperative cardiac problems. Patients who are expected to be candidates for hypertensive hypervolemic hemodilution therapy for vasospasm or for barbiturate coma may also benefit from placement of a pulmonary artery catheter.

Central pressure monitoring is usually instituted after the patient is asleep to minimize stress to the patient. One should be careful to use the minimal degree of head-down tilt necessary to access the central circulation, because a severe Trendelenburg position may have deleterious effects on ICP and CPP.

In view of this evidence, at our institution, we reserve placements of CVP and pulmonary artery catheters for those patients who have documented cardiac dysfunction or if we are unable to secure large-bore peripheral intravenous access. Volume status may be assessed by noninvasive monitors or by careful assessment of the arterial waveform.

C.5. What other forms of monitoring would you consider?

Electroencephalography (EEG) and somatosensory evoked potentials (SSEPs) have been advocated by some authors, though they are not standard monitoring in most hospitals. Although EEG has been used to monitor cerebral ischemia, scalp electrodes may not reflect activity of brain areas most at risk. Cortical electrodes, such as those used in epilepsy surgery, may avoid the problem of attenuation of the scalp electroencephalographic signal by CSF drainage and air between scalp electrodes and brain surface during surgery. EEG is useful in titrating barbiturate or propofol infusion if burst suppression is desired during temporary clipping.

SSEPs may detect reversible ischemia during temporary vessel occlusion, but they may not detect ischemia in subcortical structures and motor cortex. Furthermore, SSEPs have relatively high false-positive (38% to 60%) and false-negative (5% to 34%) rates. Brainstem auditory evoked responses may be useful in monitoring during posterior circulation aneurysm clipping. Motor evoked potentials may be superior in

detecting subcortical ischemia. The use of SSEP and motor evoked potential monitoring usually warrants the use of total intravenous anesthesia and elimination of muscle relaxants from the anesthetic.

Microvascular Doppler ultrasound evaluation may detect inadvertent vessel occlusion, but it cannot assess for adequacy of collateral perfusion.

Monitoring of ICP is common, with the probability of increased ICP greatest at 24 to 48 hours after SAH. An intraventricular catheter not only allows for ICP monitoring but also allows for CSF drainage to improve operating conditions. If an intraventricular catheter is not present, lumbar spinal drain may be placed. One must be careful not to allow substantial CSF drainage before dural opening because this may decrease ICP allowing for an increase in transmural pressure and possible rupture.

Intraoperative angiography is one means by which to ensure complete obliteration of the aneurysm without clip occlusion of the parent artery or perforating branches. Use of this modality may increase with the installation of more "hybrid" operating rooms, which are fully equipped with advanced angiography equipment in the operating room suite.

C.6. What are your particular concerns during induction of anesthesia in this patient?

If an aneurysm ruptures during anesthetic induction, mortality is high (approximately 75%). Therefore, precise control of transmural pressure is important in preventing aneurysm rupture.

$$\text{Transmural pressure} = \text{CPP} = \text{MAP} - \text{ICP or CVP (whichever is greater)},$$
where MAP = mean arterial pressure

On the other hand, one does not want CPP to be so low that ischemia develops, especially in areas of vasospasm.

Tsementzis SA, Hitchcock ER. Outcome from "rescue clipping" of ruptured intracranial aneurysms during induction of anesthesia and endotracheal intubation. *J Neurol Neurosurg Psychiatry.* 1985;48:160–163.

C.7. How would you accomplish a smooth and safe induction and intubation of this patient?

Assuming that evaluation of the airway indicated that intubation would not be difficult, one would begin with preoxygenation. Thiopental 3 to 5 mg per kg, propofol 1.5 to 2.5 mg per kg, and etomidate 0.5 to 1 mg per kg have similar effects on CBF and cerebral metabolic rate. Given that this patient had no other medical problems, thiopental is a reasonable choice. One may want to avoid ketamine for induction because of its associated increase in CBF and ICP.

After loss of consciousness and apnea, care must be taken to maintain a normal $Paco_2$ and avoid extreme hyperventilation. Vigorous hyperventilation will lower $Paco_2$,

decreasing CBF. This may lower ICP to such a degree that if MAP is maintained or increased, transmural pressure may be increased, leading to rupture of the aneurysm.

A nondepolarizing muscle relaxant, which has no effect on ICP or CBF, should be added to facilitate intubation. The neuromuscular junction should be monitored to ensure that paralysis is adequate to avoid coughing with intubation.

Fentanyl 3 to 5 μg per kg, sufentanil 0.5 to 1 μg per kg, or remifentanil 0.25 to 1 μg per kg can be added 3 to 5 minutes before laryngoscopy to blunt the hemodynamic response. Isoflurane, desflurane, or sevoflurane is added to deepen the anesthetic. Finally, approximately 90 seconds before laryngoscopy, lidocaine 1.5 to 2 mg per kg or esmolol 0.5 mg per kg can be added to further blunt the hemodynamic response to intubation.

Lidocaine decreases both CBF and cerebral metabolic rate for oxygen, and at high concentrations, it can cause seizures. Esmolol and labetalol have no effect on CBF and ICP, even in brain areas where autoregulation may not be intact. Extreme reductions in MAP (greater than 35%) may compromise CPP in patients with increased ICP.

Cotrell JE, Young WL, eds. *Cottrell and Young's Neuroanesthesia*. 5th ed. Philadelphia: Mosby Elsevier; 2010:218–246.

C.8. Would you perform a rapid-sequence induction and intubation on this patient?

No indication is seen for a rapid-sequence induction and intubation in this patient. Overall risk of aspiration during general anesthesia has been estimated at 0.05%; nevertheless, the risk of aneurysm rupture during induction is 1% to 2%. Therefore, unless a clear indication exists for rapid-sequence induction, it is best avoided.

If rapid-sequence induction is indicated, one may consider using vecuronium 0.15 to 0.20 mg per kg or rocuronium 0.9 mg per kg rather than succinylcholine. Succinylcholine may cause an increase in ICP, although this increase can be attenuated or eliminated by deep anesthesia or prior defasciculation. Succinylcholine, more importantly, may lead to hyperkalemia and possibly ventricular fibrillation in those patients presenting with motor deficits following SAH.

In the case of a full stomach or an anticipated difficult airway, careful awake fiber-optic intubation, with use of appropriate sedation and topical application of local anesthesia, is an appropriate alternative. Under such circumstances, it is useful to have an assistant so that while one person is securing the airway, the other is solely focused on controlling the hemodynamics with titration of appropriate medication.

C.9. What are the effects of hypoxemia and hypercapnia, such as would be seen with loss of the airway on induction, on cerebral blood flow (CBF)?

Each millimeter of mercury increase in $Paco_2$ increases CBF 3% to 4%, when $Paco_2$ is in the range of 20 to 80 mm Hg. In addition, the hypoxia that will ensue if the airway is not secured in a timely manner will also cause an increase in CBF once Pao_2 is less than 60 mm Hg (Fig. 20.1).

C.10. What is optimal fluid management for aneurysm clipping? Would you use a dextrose-containing solution?

Maintenance fluid requirements and blood loss should be replaced. One wants to avoid profound hypovolemia not only for its detrimental cardiovascular effects but also because it is associated with cerebral ischemia and perioperative neurologic deficits resulting from vasospasm. Some authors advocate mild hypervolemia to maximize cerebral CBF and minimize vasospasm; however, one must keep in mind the possibility of cerebral edema as well as acute congestive heart failure.

In general, dextrose-containing solutions should be avoided because an increased incidence of neurologic deficits associated with glucose administration has been found in experimental models of focal cerebral ischemia. At Weill Cornell Medical Center, we try to maintain blood glucose less than 180 mg per dL.

Use of crystalloid versus colloid for fluid management and which type of crystalloid solution, lactated Ringer's solution versus normal saline or Normosol, has long been a matter of controversy. Although some authors advocate colloid solutions to diminish the risk of brain swelling, no evidence exists that the solution may predispose to brain edema and contribute to hyponatremia, which may increase the incidence of delayed ischemic neurologic deficits. Therefore, normal saline is the fluid of choice.

A moderate degree of hemodilution to a hematocrit of 30% to 35% usually lowers blood viscosity, thereby increasing CBF. The goal is to increase oxygen delivery by increasing CBF, without allowing the hematocrit to decrease to the degree that reduction in oxygen content negates the increase in CBF. Hematocrit, serum sodium, and serum osmolality measurements may be followed to guide fluid therapy. Serum sodium should be maintained within normal limits, both to maintain serum oncotic pressure and to avoid the hyponatremia associated with cerebral salt wasting.

C.11. After the bone plate was removed and as the dura was being opened, the surgeon complained that the brain was "tight." What could you do to achieve better brain relaxation and facilitate surgical exposure?

Any method that rapidly decreases ICP before dural opening may suddenly increase transmural pressure and lead to aneurysm rupture. After dural opening, one of the fastest ways to decrease cerebral blood volume and improve exposure is through hyperventilation. Mild hypocarbia ($Paco_2$ = 30 to 35 mm Hg) can usually be established before dural opening, with moderate hypocarbia ($Paco_2$ = 25 to 30 mm Hg) after dural opening. Because of the risk for cerebral ischemia secondary to diminished CBF, normocarbia should be maintained whenever possible in patients with vasospasm.

Mannitol is the most frequently used diuretic at our institution. It is given as an infusion for a total dose of 0.7 g per kg (0.25 to 1 g per kg). Its immediate effect is a transient rise in intravascular volume, which may pose problems in patients with impaired ventricular function. In addition, too rapid infusion can lead to decreases in systemic vascular resistance. Its onset of diuretic action is in 10 to 15 minutes, with peak effect occurring at 60 to 90 minutes. If mannitol does not produce the desired brain relaxation and the serum osmolality is greater than 320 mOsm, additional mannitol is unlikely to produce additional effect. In those patients who may not tolerate the initial effects of mannitol, intravenous furosemide 0.1 to 0.3 mg per kg can be substituted. Both medications can cause derangements in fluid status and serum electrolytes that require close monitoring.

Drainage of CSF from either a lumbar drain or an intraventricular catheter is usually effective in optimizing surgical exposure. One must be careful to avoid significant CSF drainage before dural opening to prevent either brainstem herniation or a sudden decrease in transmural pressure. Similarly, hemodynamic instability can ensue if CSF is drained too rapidly at any point in the operation.

If tight brain remains a problem, one must ascertain that there is no hypoxemia or hypercarbia. In addition, one should consider eliminating N_2O if it is in use and reducing the amount of volatile anesthetic, because all inhalational agents are cerebral vasodilators and may potentially increase ICP. Of course, if inhaled agents are reduced, appropriate intravenous agents should be substituted to ensure adequate anesthesia.

One may give a bolus of thiopental to decrease $CMRo_2$ and CBF; nevertheless, one must maintain MAP to maintain CPP. At the time of patient positioning, one must ensure that no impediment exists to venous outflow of the brain (i.e., that extreme flexion or rotation of the head is avoided and that no monitor cables [electrocardiogram] leads are draped across the neck).

C.12. How might transmural pressure be decreased to allow for aneurysm clip placement?

The most widely accepted method for producing a slack aneurysm to allow for clip placement is the use of temporary clip occlusion of one or more parent vessels. For example, to place a permanent clip on an anterior communicating artery aneurysm, a temporary clip can be placed on either the right or left anterior cerebral artery or both. Advantages of temporary clip use include a greater reduction in transmural pressure and greater ease in clipping, decreased incidence of intraoperative rupture, and avoidance of controlled hypotension.

The maximal duration of temporary clip application before a neurologic deficit occurs is unknown, but it is probably related to the location of the aneurysm and distribution of perforating vessels distal to the temporary clip. White matter and major deep nuclei are likely to be more susceptible than gray matter to temporary ischemia. Risk factors for neurologic deficit following temporary clip placement include poor preoperative neurologic condition, age older than 61 years, and distribution of perforating arteries in distal basilar and horizontal segments of middle cerebral artery.

C.13. What is the purpose of controlled hypotension and how is it achieved?

In the past, controlled hypotension was used to decrease transmural pressure, making the aneurysm neck slack enough to allow placement of a clip without vessel rupture. Various agents were used to achieve controlled hypotension, including volatile agent, nitroprusside, esmolol, labetalol, nitroglycerin, and trimethaphan. Specific agents were selected based on the patient's pre-existing medical conditions, especially coronary ischemia or poor ventricular function. In an otherwise healthy patient, sodium nitroprusside infusion may be used for its rapid onset, easy titratability, and quick offset. An esmolol infusion can be added to augment hypotension and counteract the reflex tachycardia and cyanide toxicity seen with nitroprusside. Side effects of nitroprusside include cyanide toxicity, rebound hypertension, and intrapulmonary shunting. Direct measurement of CVP is useful when planning to use controlled hypotension in these patients.

During controlled hypotension, MAP is usually maintained at a minimum of 50 mm Hg in previously normotensive individuals. Neurologic function monitors (EEG, SSEP, brainstem auditory evoked response, and cerebral oximetry) may be useful in guiding target level of MAP.

C.14. What are some of the drawbacks of controlled hypotension?

The main drawback of controlled hypotension is that it leads to a global decrease in CPP. CPP is then further diminished in the presence of vasospasm or in areas of brain retraction. In a retrospective study, multiple regression analysis indicated that

patients who underwent even limited periods of controlled hypotension had a worse outcome, both in terms of Glasgow Outcome Scale (multiple regression) and higher incidence and severity of vasospasm. At Weill Cornell Medical Center, we avoid controlled hypotension in neurosurgery.

C.15. What methods of cerebral protection might you use during this operation?

Cerebral protection has long been a matter of much investigation and controversy. Barbiturate loading has been shown in animals to be protective against focal ischemia, though no controlled human studies have been performed. Barbiturates decrease cerebral metabolic rate for glucose and oxygen and lower CBF and ICP. The dose is usually titrated to electroencephalographic silence or burst suppression. At doses used to suppress electroencephalographic activity, the patient may experience cardiovascular depression. The dose of barbiturate traditionally used for cerebral protection may also prolong emergence and hinder postoperative neurologic evaluation. Although barbiturates were originally thought to protect against ischemia through metabolic depression, other factors such as redistribution of blood flow to ischemic areas, blockade of the sodium channels and glutamate receptors, attenuation of *N*-methyl D-aspartate (NMDA) and α-amino-3-hydroxy-5-methyl- 4-isoxazole propionic acid (AMPA)-mediated glutamate toxicity all play a role.

Propofol has also been used as an alternative to thiopental sodium. Cerebral protection from propofol is thought to result from scavenging of free radicals, inhibition of glutamate release, and prevention of lipid peroxidation. In studies involving both volatile anesthetics and propofol, apoptotic cell death is delayed, but not prevented, if the ischemic result is mild.

Etomidate decreases cerebral metabolic rate at electroencephalographic burst suppression and prevents an increase in excitatory neurotransmitters during cerebral ischemia in animal models; nevertheless, it has been associated with a greater volume of injured brain than thiopental and control groups in focal ischemia in hypertensive rats.

Deliberate mild hypothermia (32.5° C to 35.5° C), although promising in animal models, did not demonstrate efficacy with patients with good-grade aneurysm in the Intraoperative Hypothermia for Aneurysm Surgery Trial (IHAST) 2. Magnesium has been proposed as a cerebroprotective agent during aneurysm clipping. Magnesium is a cerebral vasodilator that, in animal models, blocks voltage-dependent calcium channels and reverses experimental vasospasm. In humans, magnesium has been found to attenuate brain tissue hypoxia during temporary occlusion. Finally, erythropoietin is being investigated as a cerebroprotectant.

C.16. Would you induce mild hypothermia as a means of cerebral protection?

Hypothermia causes a greater reduction in cerebral metabolic rate for glucose and oxygen than the level attained at electroencephalographic silence because its reduction of metabolism is caused by a reduction in both neuronal electrical activity and enzyme activity related to maintenance of cellular function. Hypothermia also reduces the release of excitatory neurotransmitters. Significant reduction in infarct size after global and focal ischemia has been demonstrated in several animal studies. Unfortunately, these advantages have not been documented in clinical trial. The IHAST study showed no differences in Glasgow Outcome Scale at 3 months in patients at good grade.

Disadvantages of unintentional hypothermia documented in the literature include an increased incidence of myocardial ischemia in peripheral vascular surgery, increased incidence of postoperative wound infection in abdominal surgery, coagulopathy, prolonged drug clearance, and hyperglycemia. In the IHAST study, the hypothermic group had a small increase in infection rate. As a result of IHAST, we no longer deliberately induce hypothermia in patients at good grade for aneurysm clippings.

C.17. What are the indications for deep hypothermic circulatory arrest?

Hypothermic circulatory arrest at body temperature less than 22° C (71.6° F) is reserved for giant aneurysms, difficult basilar artery aneurysms, and anatomically complex aneurysms that are not clippable without complete cessation of blood flow and are not amenable to the use of temporary clips. Deep hypothermic circulatory arrest requires cooperation between several services, including anesthesiology, neurosurgery, cardiac surgery, and perfusionists. In addition to the concerns mentioned regarding anesthesia for the person with an intracranial aneurysm and the need for prompt awakening for ease of neurologic assessment, deep hypothermic circulatory arrest adds concerns regarding institution of and separation from cardiopulmonary

bypass, systemic heparinization and protamine reversal, and, of course, rewarming from profound hypothermia. This is rarely performed now that coil embolization is possible for many of these aneurysms.

Young WL, Lawtom MI, Gupta DK, et al. Anesthetic management of deep hypothermic circulatory arrest for cerbral aneurysm clipping. *J Neurosurg Anesthesiol.* 2003;15: 274–277.

C.18. What steps should be taken in the case of intraoperative rupture of an intracranial aneurysm?

The incidence of intraoperative rupture is 2% to 19%. The stage of the operation at which rupture occurs affects outcome, with rupture at induction being the worst. After induction, the most common times for rupture are when the dura mater or arachnoid mater are being opened, during intracranial hematoma removal, and, of course, during dissection exposure of the aneurysm. At any point in the operation, a sudden sustained increase in blood pressure with or without bradycardia is suggestive of rupture. If rupture is suspected on induction, one must institute measures to control ICP while maintaining CPP.

If rupture occurs during surgical dissection, mortality is lower. The primary concern is to control bleeding while maintaining systemic perfusion. Bleeding is controlled by placement of temporary clips or by clamping or compression of the ipsilateral carotid artery in the neck if the aneurysm is too proximal. If bleeding is not controlled in a timely manner and a significant amount of blood accumulates in the subarachnoid space, severe brain swelling that is refractory to all treatment may develop. At Weill Cornell Medical Center, we do not use controlled hypotension at any point in the surgery even in the face of intraoperative rupture.

Hawkin K, Kuroda S, Takahashi A, et al. Intraoperative premature rupture of the cerebral aneurysms: analysis of the causes and management. *Acta Neurochir (Wien).* 1999;141: 1255–1263.

C.19. How would you plan the emergence from an anesthetic for aneurysm clipping?

The goal is to have a patient comfortable and not coughing or straining or subject to hypercarbia or wide variations in blood pressure.

After discontinuing all anesthetic agents and reversing neuromuscular blockade, the use of a lidocaine 1.5-mg per kg bolus may minimize bucking and reaction to the endotracheal tube. Strict control of blood pressure must be observed especially in the presence of ischemic heart disease or in patients suspected of having multiple aneurysms. One should keep the blood pressure within 20% of the patient's normal measurement.

D. Postoperative Management

D.1. Would you extubate the patient postoperatively?

Most patients who are in Hunt and Hess grades I and II can be extubated postoperatively with no need for airway support. Patients in grades IV and V usually require mechanical ventilation postoperatively, whereas grade III patients may or may not require intubation and mechanical ventilation. Patients with vertebral or basilar

artery aneurysms may require airway protection secondary to cranial nerve damage and loss of protective reflexes.

If this patient was able to follow commands, was clinically recovered from the effects of muscle relaxants, and had established an adequate ventilatory pattern with return of protective airway reflexes, extubation would be appropriate.

Bendo AA. Intracranial vascular surgery. *Anesthesiol Clin North Am.* 2002;20:377–388.

D.2. What would be the differential diagnosis if the patient did not return to her preoperative neurologic condition?

If the patient had a focal neurologic deficit on awakening in the operating room, the cause most likely would be a surgical one, although new-onset vasospasm is also a possibility.

If the patient failed to awaken, the first step would be to ensure that all inhalational and infused anesthetics had been discontinued. Second, one should make sure that neuromuscular blockade was fully reversed. One should make sure that the patient had been appropriately rewarmed, because hypothermia would prolong the duration of action of most intravenous medications. While considering reversal of benzodiazepines and narcotics, one should rule out other causes such as hypoxia, hypercarbia, hyponatremia, and hypoglycemia. One should consider the possibility of intraoperative seizure, with delayed emergence resulting from a postictal state. If after reversal of all anesthetic agents the patient had not awakened, a CT scan should be obtained to rule out subdural hematoma, intracranial hemorrhage, hydrocephalus, and pneumocephalus. An angiogram may also be obtained to rule out vascular occlusion. An electroencephalogram might be appropriate to rule out subconvulsive status epileptics.

Cotrell JE, Young WL, eds. *Cottrell and Young's Neuroanesthesia.* 5th ed. Philadelphia: Mosby Elsevier; 2010:218–246.

D.3. On postoperative day 2, the patient became disoriented and developed hemiplegia. A CT scan was obtained, which shows no new intracranial bleeding. What other diagnostic studies should be performed?

If transcranial Doppler is available, an increased value for cerebral arterial flow velocity would be suggestive for vasospasm, leading to delayed cerebral ischemia. Tissue oximetry may also be useful as a monitor for vasospasm. Angiography is the gold standard for the diagnosis of cerebral vasospasm and should be performed to confirm the diagnosis and characterize the number and location of the vessels involved.

Cerebral vasospasm may be localized to the area of aneurysm rupture or in an area of the brain remote from SAH. The worst prognosis is in those patients in whom vasospasm is diffuse. Of course, as these studies are being done, laboratory values should be checked to make sure no new or worsening metabolic derangement is contributing to the neurologic deterioration.

D.4. What is cerebral vasospasm and what causes it?

Vasospasm, which occurs in 35% of patients with SAH, is a segmental or diffuse narrowing of the lumen of one or more intracranial arteries. It is the most common cause of delayed cerebral ischemia and may be seen angiographically in 60% of patients, even if clinical manifestations are not apparent.

The severity of vasospasm is apparently related to the amount and location of subarachnoid blood. Injection of blood into the subarachnoid space causes vasospasm in experimental animals and antifibrinolytics apparently worsen the spasm. On a molecular level, one theory is that oxyhemoglobin causes the production of superoxide radicals that lead to a decrease in nitric oxide production in endothelial cells. This decrease in nitric oxide increases protein kinase C and intracellular calcium, resulting in myofilament activation and vasospasm. Other theories involve prostaglandins and lipid peroxidases. There may also be a genetic predisposition to development of vasopasm. Preliminary studies suggest that patients with a certain polymorphism of haptoglobin ($\alpha_1\alpha_1$) may be protected against vasospasm compared to patients with haptoglobin $\alpha_2\alpha_2$, which is less effective at neutralizing free radical formation by free hemoglobin.

Borosody M, Burke A, Caplin W, et al. Haptoglobin and the development of cerebral vasospasm after subarachnoid hemorrhage. *Neurology.* 2006;66:634–640.

Vollrath AM, Weir BKA, Macdonald RL, et al. Intracellular mechanisms involved in the responses of cerebrovascular smooth-muscle cells to hemoglobin. *J Neurosurg.* 1994;80:261–268.

D.5. What are pathophysiologic changes seen in cerebral vasospasm?

Structurally, leukocytes, red blood cells, and macrophages are seen in arterial walls. Inflammatory mediators, such as eicosanoids, interleukin 1, and immune complexes, are increased. Eventually, the vessel wall thickens, and smooth muscle proliferation and collagen deposition accompany degenerative changes in the tunica intima and media.

Functionally, carbon dioxide reactivity is impaired, and autoregulation is often impaired, perhaps correlating to the degree of delayed cerebral ischemia. CBF in some areas appears to be pressure dependent, hence the reasoning behind hypertensive therapy.

Weyer GW, Nolan CP, Macdonald RL. Evidence-based cerebral vasospasm management. *Neurosurg Focus.* 2006;21:E8.

D.6. How is the diagnosis of cerebral vasospasm made?

The clinical diagnosis of cerebral vasospasm is made when the patient experiences an altered level of consciousness (drowsiness, disorientation) or a new focal neurologic deficit. These may be accompanied by increasing headache, meningismus, and fever. Vasospasm is rare in the first 3 days following SAH. It reaches peak incidence at 3 to 10 days and usually resolves by 10 to 14 days after SAH. In this patient, the new onset of hemiplegia suggests that the middle cerebral artery is involved. If vessels in the posterior fossa are involved, respiratory and hemodynamic abnormalities may develop.

The differential diagnosis includes rebleeding, hydrocephalus, seizure, hyponatremia, and drug effects. Transcranial Doppler, CBF, velocity greater than 120 cm per second in association with a new focal neurologic deficit are usually sufficient to make the diagnosis of cerebral vasospasm; however, a change in transcranial Doppler values over time may be more useful than an absolute value. CBF velocity greater than 200 cm per second is associated with a high risk of cerebral infarct, whereas a velocity less than 100 cm per second indicates that cerebral vasospasm is unlikely. Recent evidence shows that transcranial Doppler had only 63% sensitivity in identifying delayed cerebral ischemia, with a positive predictive value of only 22% in grade II and III patients.

Angiographic cerebral vasospasm can be found in 60% of patients following SAH, but only 50% of these patients will develop clinical focal neurologic deficits.

Cotrell JE, Young WL, eds. *Cottrell and Young's Neuroanesthesia.* 5th ed. Philadelphia: Mosby Elsevier; 2010:218–246.

McGrath BJ, Guy J, Borel CO, et al. Perioperative management of aneurysmal subarachnoid hemorrhage. Part 2. Postoperative management. *Anesth Analg.* 1995;81:1295–1302.

D.7. What steps can be taken to prevent cerebral vasospasm?

Calcium channel blockers are standard prophylactic therapy to prevent vasospasm. The mechanism is unknown, but presumably calcium channel blockers aid in maintaining cellular integrity by preventing calcium entry into ischemic cells. Nimodipine, taken orally, improves neurologic outcome. Patients given nimodipine have no change in overall incidence of vasospasm, but they have a lower incidence of severe narrowing. In addition, although no improvement is found in mortality, there is improvement in outcome for survivors. Intravenous nimodipine is not available in the United States.

Nicardipine, an intravenous agent, showed a lower incidence of vasospasm but no improvement in outcome versus a placebo group; both groups received hypertensive hypervolemic hemodilution therapy. The main complication of calcium channel blocker therapy is hypotension (0% to 8%), which may make this therapy difficult to achieve.

Other steps to limit cerebral vasospasm include the removal of subarachnoid blood as quickly as possible, instillation of thrombolytic agents (e.g., tissue plasminogen activator), and use of pharmacologic agents to reduce inflammatory response (high-dose glucocorticoids, ibuprofen). In Europe and Japan, protease inhibitors have been used in the treatment of vasospasm.

Weyer GW, Nolan CP, Macdonald RL. Evidence-based cerebral vasospasm management. *Neurosurg Focus.* 2006;21:E8.

D.8. What treatments can be undertaken once a diagnosis of cerebral vasospasm is made?

Treatment for cerebral vasospasm is multifactorial and includes continuation of prophylactic measures. Hypertensive hypervolemic hemodilution therapy is a plan to augment CBF past the stenotic areas. It begins with hypervolemic hypertension, with intravascular volume expansion with crystalloid or colloid to increase cardiac output. Some recommended target values are CVP of 10 to 12 mm Hg, pulmonary artery occlusion pressure of 15 to 18 mm Hg, cardiac index of 3.0 to 3.5 L/min/m^2, and hematocrit of 30% to 35%. Various blood pressure targets have been reported, but a reasonable plan is systolic blood pressure 160 to 200 mm Hg if the aneurysm is clipped and 120 to 150 mm Hg if unclipped. Vasoactive infusions are added if hypervolemia alone is inadequate. End points of therapy are resolution of neurologic deficits or occurrence of complications of therapy, such as pulmonary edema (26%), myocardial ischemia, and rebleeding or rupture of a secondary aneurysm. A pulmonary artery catheter is often indicated.

Fluid used for hypertensive hypervolemic hemodilution should be isotonic and have enough sodium to avoid hyponatremia. Vasopressin, fludrocortisone, or hydrocortisone may be administered to counteract excessive sodium and fluid loss.

Other treatments for vasospasm, including intra-arterial verapamil, papaverine or nitroprusside infusions, or angioplasty, are now more commonly used as an adjunct to hypertensive hypervolemic hemodilution therapy.

In spite of all attempted therapy, the outcome in patients with significant vasospasm is often poor. Most medications investigated to ameliorate the devastating consequences of vasospasm have had limited efficacy. Nimodipine, a calcium channel antagonist, has been found to have some efficacy in treating vasospasm and

improving outcome. A recent target of pharmacologic therapy has been endothelin, a potent long-lasting vasoconstrictor. An endothelin receptor antagonist is now in clinical trials.

D.9. What are other neurologic complications following SAH and aneurysm clipping?

Hydrocephalus, manifesting with a gradual decrease in level of consciousness, occurs in 25% of patients surviving SAH. Diagnosis is confirmed by CT scan. Treatment is by ventricular drainage.

Seizures, which occur in 13% of patients with SAH, may herald rebleeding or vasospasm. Seizures cause an increase in MAP, CBF, ICP, and lactate production, predisposing to rebleeding in those patients with unclipped aneurysms, and cerebral ischemia in those patients with vasospasm. Most patients receive prophylactic anticonvulsants.

Hyponatremia occurs in 10% to 34% of patients with SAH in a time course that parallels that of vasospasm. It may be due to syndrome of inappropriate antidiuretic hormone secretion, "cerebral salt wasting," or prolonged or excessive mannitol use. Cerebral salt wasting syndrome is thought to be mediated by release of atrial natriuretic factor by the hypothalamus secondary to distention of the cerebral ventricles from hydrocephalus. After SAH, patients also have elevated plasma volume. In these patients, fluid restriction is not the treatment of choice, because hypovolemia may predispose to vasospasm. Patients with brain natriuretic peptide may be treated with an isotonic or hypertonic salt-containing fluid. In addition, treatment with hydrocortisone may be considered.

Finally, patients may experience brain swelling or edema, which is treated with mannitol or dexamethasone, or both.

D.10. What other organ systems may manifest problems postoperatively in aneurysm clipping patients?

The lungs can be affected by pneumonia or neurogenic pulmonary edema, in which disruption of the pulmonary capillary membrane occurs secondary to increased sympathetic nervous system activity. Because of inactivity, patients may be predisposed to developing deep venous thrombosis and pulmonary embolism. Patients may have fever secondary to subarachnoid blood, which may make workup of postoperative infection more difficult. In addition, as in most patients with head injury, those with SAH may have increased metabolic rate.

SECTION V

The Endocrine System

CHAPTER 21

Thyrotoxicosis

Dana L. Gurvitch

A 48-YEAR-OLD MAN presented with diffuse neck swelling. History of present illness was significant for dyspnea, dysphagia, weight loss, paroxysmal palpitations, and heat intolerance. His blood pressure was 160/100 mm Hg, his heart rate was 120 beats per minute, and his hematocrit level was 29%.

A. Medical Disease and Differential Diagnosis

1. What diagnosis is compatible with these symptoms?
2. Describe the synthesis, release, and peripheral conversion of thyroxine (T_4) and triiodothyronine (T_3).
3. What is the role of the hypothalamic–pituitary axis in thyroid function?
4. Describe the effects of thyroid hormone.
5. What are the causes of hyperthyroidism?
6. What are the clinical signs and symptoms of thyrotoxicosis?
7. How would you distinguish thyroid storm from thyrotoxicosis?
8. What can precipitate thyroid storm?
9. Discuss innervation of the larynx.

B. Preoperative Evaluation and Preparation

1. Are there anatomic problems associated with an enlarged thyroid gland?
2. Describe the signs and symptoms of superior vena cava syndrome.
3. How would you assess the possibility of airway obstruction?
4. Discuss the laboratory assessment of thyroid function.
5. Describe medical strategies for achieving a euthyroid state.
6. What are the benefits of adrenergic blockade?
7. When is the hyperthyroid patient ready for elective surgery?
8. How would you premedicate this patient?
9. How would you prepare the thyrotoxic patient for emergent surgery?

C. Intraoperative Management

1. How would you monitor this patient?
2. How would you induce anesthesia?
3. Is endotracheal intubation necessary for this operation? Discuss the type and length of tube you would use.
4. How would you maintain anesthesia?
5. Intraoperatively, the patient became hyperthermic and tachycardic. Discuss the differential diagnosis of malignant hyperthermia and thyroid storm. How would you intervene?
6. How would you extubate this patient?

D. Postoperative Management

1. The patient became stridorous and dyspneic in the recovery room. What is your differential diagnosis and strategy of intervention?
2. When does thyroid storm most often present?

A. Medical Disease and Differential Diagnosis

A.1. What diagnosis is compatible with these symptoms?

These signs and symptoms are classic for hyperthyroidism. Differential diagnosis includes other hypermetabolic states such as anxiety states, carcinoid, carcinoma, choriocarcinoma, chronic infection, De Quervain thyroiditis, exertional heat stroke, Jod-Basedow thyrotoxicosis, hydatidiform mole, pheochromocytoma, polyostotic fibrous dysplasia, postpartum thyroiditis, struma ovarii, teratoma ovary, thyroid adenoma, and thyrotoxicosis factitia. In addition, certain drugs such as antipsychotic agents, anticholinergic agents, inhalation, anesthetics, serotonin antagonists, sympathomimetic agents, and strychnine poisoning must be considered.

A.2. Describe the synthesis, release, and peripheral conversion of thyroxine (T_4) and triiodothyronine (T_3).

The biosynthesis of thyroid hormone is shown in Figure 21.1. The synthesis of thyroid hormone is dependent on iodine. Sufficient amounts of iodine must come from dietary intake or from the deiodination of pre-existing thyroid hormone. Iodine is actively transported into thyroid cells mediated by the Na^+/I^- symporter and concentrated in the form of iodide. Organification occurs as iodine binds to tyrosine residues of thyroglobulin, the receptor protein for iodine. Coupling of iodinated tyrosine residues results in the formation of T_3 and T_4. Once cleaved from thyroglobulin as regulated by TSH, thyroid hormone is released into the circulation. Ninety percent of the hormone secreted from the thyroid gland is T_4, whereas only 10% is T_3, the biologically active form with a much shorter half-life. However, in the peripheral tissues, most of the T_4 is converted to T_3. T_4 can also be converted to reverse T_3, an inactive metabolite. In the circulation, most of the T_4 and

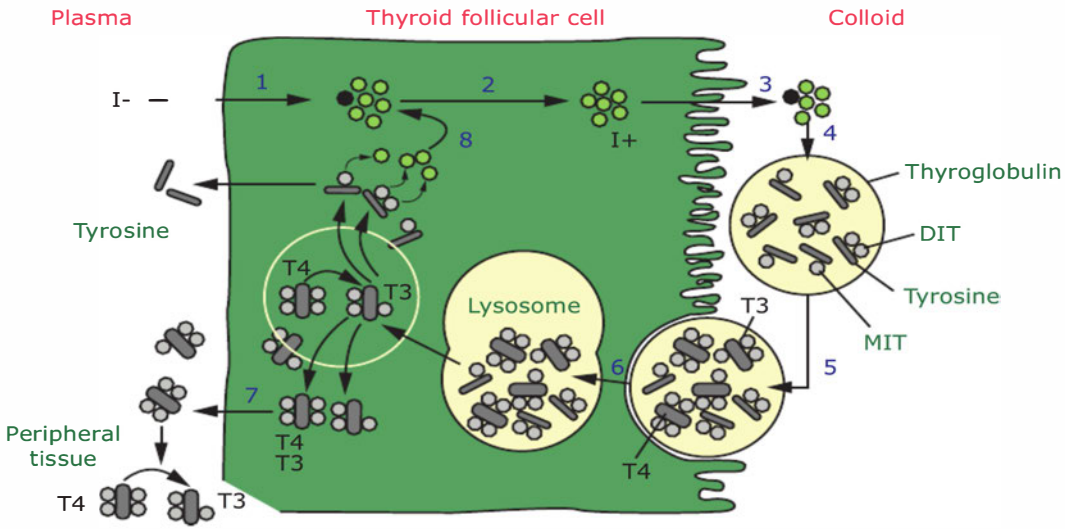

Figure 21.1 Thyroid hormone biosynthesis. Thyroid hormone synthesis includes the following steps: (*1*) iodide (I^-) trapping by the thyroid follicular cells; (*2*) diffusion of iodide to the apex of the cells; (*3*) transport of iodide into the colloid; (*4*) oxidation of inorganic iodide to iodine and incorporation of iodine into tyrosine residues within thyroglobulin molecules in the colloid; (*5*) combination of two diiodotyrosine (DIT) molecules to form tetraiodothyronine (thyroxine, T_4) or of monoiodotyrosine (MIT) with DIT to form triiodothyronine (T_3); (*6*) uptake of thyroglobulin from the colloid into the follicular cell by endocytosis, fusion of the thyroglobulin with a lysosome, and proteolysis and release of T_4, T_3, DIT, and MIT; (*7*) release of T_4 and T_3 into the circulation; and (*8*) deiodination of DIT and MIT to yield tyrosine. T_3 is also formed from monodeiodination of T_4 in the thyroid and in peripheral tissues. (Modified from Scientific American Medicine, Scientific American, New York, 1995.)

T_3 bind to plasma proteins; mainly thyronine-binding globulin. A small amount binds to albumin and transthyretin (formerly known as thyroxin-binding prealbumin), and less than 1% is unbound in the plasma. Approximately 99.8% of T_4 and 99.7% of T_3 are protein-bound. The unbound hormone is thought to be biologically available to tissues.

A.3. What is the role of the hypothalamic–pituitary axis in thyroid function?

Hypothalamic thyroid–releasing hormone stimulates the release of thyroid-stimulating hormone (TSH) by the anterior pituitary gland; somatostatin can inhibit its release. TSH stimulates the synthesis and secretion of thyroid hormones by the thyroid gland. Within pituitary cells, T_4 is converted to T_3. The intracellular level of T_3 within pituitary cells regulates the pituitary release of TSH. Low levels of T_3 stimulate the release of TSH, whereas increased levels of thyroid hormone decrease TSH secretion.

Fauci AS, Braunwald E, Kasper DL, et al, eds. *Harrison's Principles of Internal Medicine*. 17th ed. New York: McGraw-Hill; 2008:2224–2229, 2233–2242.

A.4. Describe the effects of thyroid hormone.

Thyroid hormone has effects at the cellular, organ, and systemic levels.

Cellular Effects

- Thyroid hormone regulates the nuclear transcription of messenger RNA in all cells. T_3 binds to a DNA domain named the *thyroid response element*. Once bound, T_3 initiates the transcription of an array of biochemical enzymes that regulate tissue metabolism. T_3 is also postulated to bind to mitochondrial T_3-binding proteins with resultant transcription and synthesis of cytochromes. The basal metabolic rate can increase as much as 60% to 100% when large quantities of thyroid hormones are secreted. One ubiquitous enzyme that is transcribed in response to thyroid hormone stimulation is Na,K-ATPase.
- In addition to its role in enzyme transcription, thyroid hormone regulates cellular energy use. It stimulates cellular glucose use by increasing glucose absorption from the gastrointestinal tract, glycogenolysis, gluconeogenesis, insulin secretion, and cellular uptake of glucose. Thyroid hormone increases free fatty acid availability by increasing lipid mobilization from adipocytes. Conversely, thyroid hormone decreases plasma levels of cholesterol, phospholipids, and triglycerides by increasing the rate of cholesterol secretion into the bile.

Organ Effects

- Thyroid hormone is believed to have a direct effect on the heart by increasing heart rate and contractility with resultant increases in cardiac output.
- Thyroid hormone increases oxygen consumption and carbon dioxide production with a compensatory increase in respiratory rate and tidal volume.
- Thyroid hormone increases bone formation and catabolism with resultant changes in parathyroid hormone levels.
- Normal reproductive behavior and physiology are dependent on having essentially normal levels of thyroid hormone.

Systemic Effects

- Increased cellular metabolism and production of metabolic end products result in vasodilation and enhanced tissue blood flow.

A.5. What are the causes of hyperthyroidism?

Graves disease accounts for 90% of all cases of hyperthyroidism. The prevalence varies mainly on iodine intake (high iodine intake is associated with an increased

prevalence of Graves disease). Graves disease also occurs more often in women, and in persons 20 to 50 years of age. The next most common cause is thyroiditis. Less commonly, toxic multinodular goiter, toxic solitary nodule, and excessive exogenous iodide consumption (Jod-Basedow phenomenon) and side effects of certain medications can cause hyperthyroidism. Trophoblastic tumors (e.g., hydatidiform mole and choriocarcinoma) are infrequent causes of hyperthyroidism. Surreptitious overdosing (factitious thyrotoxicosis) is occasionally seen.

A.6. What are the clinical signs and symptoms of thyrotoxicosis?

The clinical presentation depends on the severity of thyrotoxicosis, the duration of the disease, patient susceptibility to excess thyroid hormone, and the patients' age. Nonspecific constitutive signs such as sweating, heat intolerance, fatigue, polyuria, shortness of breath, weakness, and restlessness are common clinical signs and symptoms of thyrotoxicosis. Weight loss occurs despite a normal or increased appetite resulting from the increased metabolic rate. Fine tremor is a frequent finding, as is lid retraction, causing a staring appearance as a result of sympathetic overactivity.

Cardiovascular involvement is a prominent feature of thyrotoxicosis, with resulting increased cardiovascular morbidity and mortality, primarily caused by heart failure and thromboembolism. Alterations include tachyarrhythmias, increased stroke volume, increased cardiac output, increased oxygen consumption, and decreased systemic and pulmonary vascular resistance. In addition, patients demonstrate increased myocardial contractility, automaticity, and excitability. Pulse pressure can be widened with an increase in systolic blood pressure. In patients with coronary atherosclerosis, angina may be precipitated or worsened. Young adults usually tolerate hyperthyroidism without cardiovascular decompensation. However, high-output congestive heart failure can occur in older patients and in those with a previously damaged heart. Thyrotoxic patients may present with sinus tachycardia, atrial fibrillation, complete heart block, or ventricular dysrhythmias.

Hypercarbia and increased oxygen consumption resulting from the hypermetabolic state cause a compensatory increased minute ventilation with tachypnea and elevated tidal volumes. Vital capacity often decreases because of weak muscles and decreased compliance, whereas diffusing capacity remains normal. Exercise results in increased ventilation and increased oxygen uptake.

Neurologic manifestations include anxiety, agitation, tremors, insomnia, muscle weakness, and changes in cognition such as confusion and delirium. This can progress in severe cases to stupor, obtundation, and coma. Other manifestations include myopathies, periodic paralysis, seizures, chorea, and a fine resting tremor. On electroencephalogram, these patients may show an increase in fast-wave activity.

Thyrotoxicosis shortens gastrointestinal tract transit time and a secretory diarrhea may develop. Weight loss caused by increased caloric requirements is often observed. Acid secretion occasionally decreases (parietal cell antibodies in 30%), thereby potentially affecting drug absorption.

Hematologic derangements include anemia, neutropenia, and thrombocytopenia. Red blood cell mass increases because of the increased oxygen requirement.

Regarding renal involvement, tubular reabsorption and secretion are increased, leading to eventual decreased potassium excretion and increased sodium excretion.

A.7. How would you distinguish thyroid storm from thyrotoxicosis?

Thyrotoxicosis refers to all disorders of increased thyroid hormone concentrations. The clinical spectrum ranges from asymptomatic biochemical abnormalities to life-threatening crises with multisystem dysfunction and a high mortality rate. Thyroid storm exists when a patient's metabolic, thermoregulatory, and cardiovascular compensatory mechanisms fail. The clinical picture is characterized by hyperpyrexia (to 104° F to 106° F), tachycardia or supraventricular arrhythmias, along with congestive heart failure, central nervous system symptoms, and gastrointestinal symptoms that can include hepatic failure. Early recognition and aggressive treatment are fundamental in limiting morbidity and mortality. Criteria for the diagnosis of thyroid storm have been introduced by Burch and Wartofsky (see Table 21.1 for diagnostic criteria for thyroid storm). No laboratory test differentiates between thyroid storm and thyrotoxicosis. Thyroid function tests should be given. Nevertheless, once thyroid storm is suspected, treatment should be immediately instituted and not delayed for test results. Goals include reduction of circulating thyroid hormone levels, inhibition of the peripheral effects of circulating thyroid hormone, supportive care, and treatment of the underlying precipitating event.

Smallridge R. Metabolic and anatomic thyroid emergencies. *Crit Care Med*. 1992;20:276–291.

A.8. What can precipitate thyroid storm?

Thyroid storm has an abrupt onset and can be precipitated by conditions that cause a rapid rise in thyroid hormone levels such as thyroid surgery, withdrawal of antithyroid drug therapy, radioiodine therapy, iodinated contrast dyes, and vigorous thyroid manipulation. Nonthyroid illnesses such as nonthyroid surgery, infection, cerebrovascular accident, congestive heart failure, bowel infarction, pulmonary embolism, pregnancy, parturition, diabetic ketoacidosis, trauma, or administration of iodine containing materials (amiodarone) can also precipitate thyroid storm. It is the acute change of thyroid hormone levels, rather than the absolute levels that precipitates thyroid storm.

Table 21.1 Diagnostic Criteria for Thyroid Storm*

THERMOREGULATORY DYSFUNCTION		CARDIOVASCULAR DYSFUNCTION	
TEMPERATURE ° F (° C)	**SCORING POINTS**	**TACHYCARDIA**	**SCORING POINTS**
99–99.9 (37.2–37.7)	5	99–109	5
100–100.9 (37.8–38.2)	10	110–119	10
101–101.9 (38.3–38.8)	15	120–139	15
102–102.9 (38.3–38.8)	20	≥140	25
103–103.9 (39.3–39.9)	25	**CONGESTIVE HEART FAILURE**	
≥104.0 (>/= 40.0)	30	**Absent**	0
CENTRAL NERVOUS SYSTEM EFFECTS		**Mild** (Pedal edema)	5
Absent	0	**Moderate** (Bibasilar rales)	10
Mild (Agitation)	10	**Severe** (Pulmonary edema, Atrial fibrillation)	15
Moderate (Delirium, Psychosis, Extreme lethargy)	20	**ARTERIAL FIBRILLATION**	
Severe (Seizure, Coma)	30	**Absent**	0
GASTROINTESTINAL-HEPATIC DYSFUNCTION		**Present**	10
Absent	0	**PRECIPITATING EVENT**	
Moderate (Diarrhea, Nausea/ vomiting, Abdominal pain)	10	**Absent**	0
Severe (Unexplained jaundice)	20	**Present**	10

Scoring system: A score of 45 or greater is highly suggestive of thyroid storm; a score of 25-44 is suggestive of impending storm, and a score below 25 is unlikely to represent thyroid storm.

A.9. Discuss innervation of the larynx.

Innervation of the larynx comes from two branches of the vagus nerve: the superior laryngeal and the recurrent laryngeal nerve. The superior laryngeal nerve divides just superficial to the thyrohyoid membrane into the internal laryngeal nerve (sensory and autonomic) and external laryngeal nerve (motor). The internal laryngeal nerve pierces the thyrohyoid membrane and supplies sensory fibers to the larynx superior to the vocal cords. The external laryngeal nerve remains superficial to the thyrohyoid membrane to supply the cricothyroid muscle and a portion of the transverse arytenoid muscle. The recurrent laryngeal nerve supplies motor innervation to all of the remaining intrinsic muscles of the larynx and sensory innervation to the larynx inferior to the vocal cords.

The cricothyroid muscle is the only tensor muscle of the larynx. Bilateral recurrent laryngeal nerve injury will result in motor paralysis of all the intrinsic muscles of the larynx except the cricothyroid muscle and part of the transverse arytenoid muscle. Respiratory obstruction occurs as the vocal cords become approximated at midline. However, the cords are flaccid, not tense. The cricothyroid muscle requires resistance from the other intrinsic muscles to tense the cords. Unilateral recurrent laryngeal nerve injury results in one midline flaccid cord with the other cord being normal. Hoarseness and risk of aspiration are more problematic than respiratory obstruction.

B. Preoperative Evaluation and Preparation

B.1. Are there anatomic problems associated with an enlarged thyroid gland?

The thyroid gland incompletely encircles the trachea and esophagus. Glandular enlargement can cause tracheoesophageal compression with symptoms such as dyspnea and dysphagia. The anatomic location of the thyroid, suprasternal versus substernal, has important implications. Airway involvement can include deviation, compression, or luminal narrowing. With muscle relaxation, an enlarged substernal thyroid can cause unanticipated tracheal compression after the administration of agents that result in loss of respiratory muscle tone. Tracheal invasion or intratracheal hemorrhage can occur with thyroid carcinomas.

The anatomic position of the superior vena cava in the thorax makes it vulnerable to compression by mediastinal masses.

Acute respiratory insufficiency secondary to bilateral vocal cord paralysis from recurrent laryngeal nerve compression has been reported in patients with intrathoracic goiter.

Fauci AS, Braunwald E, Kasper DL, et al, eds. *Harrison's Principles of Internal Medicine*. 17th ed. New York: McGraw-Hill; 2008:2224–2229, 2233–2242.

Steenerson R, Barton R. Mediastinal goiter and superior vena cava syndrome. *Laryngoscope*. 1978;88:1688–1690.

B.2. Describe the signs and symptoms of superior vena cava syndrome.

Superior vena cava syndrome is an insidious gradual compression or obstruction of the superior vena cava. The low-flow, low-pressure, thin-walled superior vena cava is susceptible to compression from expanding mediastinal masses. The low intravascular pressure also allows for the possibility of thrombus formation, such as catheter-induced thrombus. The obstruction of venous drainage from the upper thorax results in interstitial edema and retrograde collateral flow and produces face, neck, and upper extremity edema; dilation of collateral veins of the upper thorax and neck; and symptoms of headache and vertigo. Because of the predominance of right-sided thyromegaly, compression of the right innominate vein is more common. As the superior vena cava becomes obstructed, collaterals such as the azygous, internal mammary, vertebral, and lateral thoracic venous plexuses form. Venography is the "gold standard" for anatomic delineation.

Ulreich S, Lowman R, Stern H. Intrathoracic goiter: a cause of the superior vena cava syndrome. *Clin Radiol*. 1977;28:663–665.

Walton A. Superior vena cava syndrome: an education sheet for patients. *Clin J Oncol Nurs*. 2005;9:479–480.

B.3. How would you assess the possibility of airway obstruction?

Chest radiograph, computed tomography, and magnetic resonance imaging of the neck are helpful in evaluating tracheal position and airway obstruction.

Pulmonary function testing is a noninvasive method used to evaluate patients with airway obstruction. Flow–volume loop analysis determines the extent and location of airway obstruction. Flow–volume loops are generated by inhaling to total lung capacity, exhaling to residual volume, and then inhaling back to total lung capacity. Differing patterns in flow–volume loops can distinguish intrathoracic versus extrathoracic airway obstructions (Fig. 21.2).

Fixed lesions of the upper airway, which include tracheal tumors, subglottic stenosis, and goiters cause flow limitation during both forced inhalation and forced exhalation, thus producing plateaus in both the inspiratory and expiratory cycle of the flow–volume loop (Fig. 21.2A).

Variable extrathoracic lesions are most often caused by vocal cord paralysis, vocal cord neoplasms, and neoplasms in the neck. The inspiratory limb of the flow–volume loop plateaus. During inhalation, the generation of negative intrathoracic pressure pulls the extrathoracic airway closed. During exhalation, airflow maintains the patency of the airway (Fig. 21.2B).

Variable intrathoracic lesions, which include endobronchial tumors, tracheal tumors, and tracheomalacia, produce plateau of the expiratory cycle only. Inhalation is unimpaired because negative intrathoracic pressure will stent the airway. During exhalation, positive intrathoracic pressure narrows the airway and results in plateau of the expiratory limb of the flow–volume loop (Fig. 21.2C). These patients will have preserved forced vital capacity but marked reductions of forced expiratory volume in 1 second.

B.4. Discuss the laboratory assessment of thyroid function.

Thyroid function tests are divided into three categories:

- Direct tests of thyroid function
- Tests related to concentration and binding of thyroid hormones
- Tests of homeostatic control of thyroid function

Direct tests of thyroid function involve administration of radioactive iodine and measurement of its uptake by the thyroid. Radioactive iodine uptake is measured 24 hours after administration of the isotope. Uptake will vary inversely with the plasma iodide concentration and vary directly with thyroid function.

The patterns of thyroid function tests during assessment of thyroid function are shown in Table 21.2. Tests related to hormone concentration and binding in serum include measurements of T_4 and T_3. Radioimmunoassays of both free and total T_3 and T_4 are available. Although some centers measure the percentage of T_4 or T_3 that is dialyzable or free, most use an in vitro uptake test. Serum is enriched with labeled T_4 or labeled T_3 and is then incubated with a resin that binds free hormone. Labeled T_3 will bind to unoccupied hormone-binding sites. If these sites are already occupied by endogenous thyroid hormone, such as during hyperthyroidism, labeled T_3 will be picked up by the resin. T_3 uptake will also be elevated when thyroid-binding sites are decreased, as in low-protein states such as malnutrition, nephrotic syndrome, and liver cirrhosis. T_3 uptake is low during hypothyroidism or when thyroid-binding globulin sites are increased, such as during pregnancy, with use of oral contraceptives, and in infectious hepatitis.

Though nonspecific, serum creatinine phosphokinase (CPK), lactate dehydrogenase, and aspartate aminotransferase levels are slightly depressed in hyperthyroidism.

Tests of homeostatic control include measurement of serum TSH and thyrotropin-releasing hormone–stimulating test. TSH levels will vary inversely with thyroid hormone levels. The thyrotropin-releasing hormone stimulation test assesses the hypothalamic–pituitary–thyroid axis.

Table 21.2 Patterns of Thyroid Function Tests during Assessment of Thyroid Function

SERUM TSH	SERUM FREE T_4	SERUM T_3	ASSESSMENT
Normal hypothalamic-pituitary function			
Normal	Normal	Normal	Euthyroid
Normal	Normal or high	Normal or high	Euthyroid hyperthyroxinemia
Normal	Normal or low	Normal or low	Euthyroid hypothyroxinema
Normal	Low	Normal or high	Euthyroid: triiodothyronine therapy
Normal	Low normal or low	Normal or high	Euthyroid: thyroid extract therapy
High	Low	Normal or low	Primary hypothyroidism
High	Normal	Normal	Subclinical hypothyroidism
Low	High or normal	High	Hyperthyroidism
Low	Normal	Normal	Subclinical hyperthyroidism
Abnormal hypothalamic–pituitary function			
Normal or high	High	High	TSH-mediated hyperthyroidism
Normal or low[a]	Low or low-normal	Low or normal	Central hypothyroidism

[a] In central hypothyroidism, serum TSH may be low, normal, or slightly high.
TSH, thyroid-stimulating hormone.

B.5. Describe medical strategies for achieving a euthyroid state.

Medical strategy is directed at blocking the production of thyroid hormone, the release of thyroid hormone, and the adrenergic effects of excessive hormonal levels.

Initial therapy is directed at blocking thyroid hormone synthesis using antithyroid drugs such as carbimazole, propylthiouracil, and the active metabolite of the latter, methimazole. These drugs are iodinated within the thyroid gland, thus diverting iodine away from new thyroid hormone synthesis. They do not block the release of thyroid hormone and are not effective until thyroid hormone stores are depleted. Propylthiouracil also inhibits deiodination of T_4 to T_3. In addition to blocking thyroid hormone biosynthesis, these drugs lower concentrations of TSH receptor antibodies and increase activity of suppressor T cells, suggesting they have an immunosuppressive effect. Side effects of antithyroid medications include fever, urticaria, arthralgias, arthritis, leukopenia, agranulocytosis, and rarely toxic hepatitis. Glucocorticoids inhibit peripheral conversion of T_4 to T_3, and they have an additive effect when given with propylthiouracil.

After initiation of antithyroid drug therapy, iodides, such as potassium iodide, are useful to inhibit thyroid hormone synthesis and block the conversion of T_4 to T_3, thus lowering thyroid hormone levels in the blood. Onset of action occurs within 24 hours. Iodine can also be given for 8 to 10 days preoperatively to decrease the vascularity of the thyroid gland. Iodine therapy requires 2 weeks for maximal effect. A euthyroid state should be achieved with antithyroid drugs before initiating iodine therapy, otherwise the exogenous iodine can be used as substrate for the synthesis of new thyroid hormone. Exogenous iodine administration destroys functioning thyroid cells and blocks the binding of intrinsic iodine. This Wolff–Chaikoff effect lasts only a few days. Thereafter, formation of thyroid hormone resumes despite the continued high intake of iodine. Iodides are mainly useful for thyroid crisis and for emergency surgery in hyperthyroid patients. Iodine is contraindicated in children, pregnant women and women who are breast-feeding; pregnancy is reportedly safe 4 months or more after treatment.

β-antagonists are useful to block the peripheral adrenergic manifestations of hyperthyroidism. Patients become clinically euthyroid; nevertheless, without additional intervention, they will remain chemically hyperthyroid. Propranolol is the most commonly used β-adrenergic antagonist because it additionally inhibits peripheral conversion of T_4 to T_3. In thyrotoxic patients, larger doses of β-antagonists may be required because of the accelerated metabolism. Central-acting adrenergic antagonists such as reserpine or guanethidine can be used in patients who cannot take β-blockers, as can calcium channel blockade with diltiazem. Finally, cholestyramine or colestipol will bind T_4 in the gut during enterohepatic circulation and may help to bring down the T_4 level more quickly.

B.6. What are the benefits of adrenergic blockade?

Catecholamines contribute to the symptoms of thyrotoxicosis. Pharmacologic agents that deplete stores or block the action of catecholamines will decrease heart rate, cardiac output, and cardiac irritability. Drugs used in the treatment of thyrotoxic symptoms include β-antagonists, combined α–β-antagonists, and central-acting agents such as reserpine and guanethidine. Side effects associated with use of these drugs include hypotension, sedation, depression, myocardial depression, bronchospasm, and diarrhea.

Hines RL, Marschall KE, eds. *Stoelting's Anesthesia and Co-existing Disease*, 5th ed. Philadelphia: Churchill Livingstone; 2008:380–384.

Ingbar S. Management of emergencies, thyrotoxic storm. *N Engl J Med*. 1966;274:1252–1254.

B.7. When is the hyperthyroid patient ready for elective surgery?

Emphasis should be placed on relief of symptoms. The patient should demonstrate a return of normal heart rate, pulse pressure, and sinus rhythm, as well as a resolution of recent-onset cardiac murmurs. Tremors, anxiety, palpitations, dyspnea, and heat intolerance should be relieved.

B.8. How would you premedicate this patient?

The goal of premedication of the thyrotoxic patient is to relieve anxiety and prevent the activation of the sympathetic nervous system. Benzodiazepines such as oral diazepam (5 to 10 mg) or central adrenergic blockers such as clonidine (3 to 5 μg per kg orally) are appropriate. Antimuscarinics such as atropine and scopolamine are not recommended, because they cause tachycardia and interfere with normal heat regulation.

Hines RL, Marschall KE, eds. *Stoelting's Anesthesia and Co-existing Disease*. 5th ed. Philadelphia: Churchill Livingstone; 2008:380–384.

Smallridge R. Metabolic and anatomic thyroid emergencies. *Crit Care Med*. 1992;20:276–291.

B.9. How would you prepare the thyrotoxic patient for emergent surgery?

When surgery is emergent, measures should be taken to prevent thyroid storm. Reduction of the hyperadrenergic state, along with decreased conversion of T_4 to T_3, can be attempted with propranolol. Esmolol, as an alternative, may offer some advantages because of its β_1 specificity and short half-life. However, esmolol has not been shown to decrease peripheral conversion. Antithyroid drugs should be given to prevent further thyroid hormone synthesis. Either propylthiouracil, 200 to 400 mg orally every 6 hours, or methimazole, 20 to 40 mg orally every 6 hours, should be administered as

soon as possible. Methimazole in an aqueous solution, but not propylthiouracil, can be administered rectally. Propylthiouracil and glucocorticoids can also block peripheral conversion of T_4 to T_3, and together they have an additive effect. Intravenous dexamethasone 2 mg every 6 hours or hydrocortisone 40 mg every 6 hours can be administered. Saturated solution of potassium iodide 5 drops orally every 6 hours or Lugol solution 30 drops orally every 6 to 8 hours can be given to acutely inhibit release of T_4 and T_3. Parasympatholytics such as atropine and pancuronium should be avoided, because unopposed sympathetic activity may result.

Therapy should also be directed at correcting systemic decompensation. Fluids and electrolytes must be replaced. Invasive monitoring may be needed to guide the administration of inotropes and vasopressors when hypotension is unresponsive to fluids. Supportive measure with fluids, oxygen, and a cooling blanket are important. Aspirin should not be used as an antipyretic, because it displaces thyroid hormones from binding proteins and thereby raises free hormone levels. If circulatory shock is present, a direct-acting vasopressor (phenylephrine) is indicated. Unfortunately, mortality rate for thyroid storm remains at approximately 20%.

Pronovost P, Parris K. Perioperative management of thyroid disease. *Postgrad Med*. 1995;98:83–96.

C. Intraoperative Management

C.1. How would you monitor this patient?

Once blood pressure, end-tidal carbon dioxide, pulse oximetry, electrocardiogram, and core temperature monitors are in place, the thyrotoxic patient is monitored to manage any cardiac decompensation and to recognize increased thyroid and adrenergic activity. If the patient presents to the operating room in thyroid storm, large-bore peripheral intravenous lines and an arterial line should be placed. If the patient is presently in or has a history of congestive heart failure, myocardial ischemia, renal failure, or hypotension, placement of a central venous or a pulmonary artery catheter is warranted. Invasive monitors should be placed before a skin incision is made. Once surgery has begun, access for placement of monitors will be difficult.

C.2. How would you induce anesthesia?

Induction and intubation can proceed with standard techniques if airway obstruction is not suspected. Patients with orthopnea, dyspnea, stridor, wheezing, or hoarseness require further preoperative evaluation. Preoperative studies, as described in section B.3, need to be reviewed. At a minimum, the chest radiographs must be evaluated by the anesthesiologist. Airway obstruction necessitates awake fiber-optic intubation or spontaneous inhalational induction. Inhalational induction using sevoflurane will maintain spontaneous respiration and airway patency. Isoflurane and desflurane may be too irritating to the airway for inhalational induction. Otherwise, intravenous induction with thiopental, secondary to its thiorylene nucleus and thus decrease peripheral conversion of T_4 to T_3, may have a slight advantage over other induction agents. Intubation should be attempted only after a deep plane of anesthesia is achieved. Patients with severe

obstruction may require awake intubation, which will require anesthetizing the glossopharyngeal, superior laryngeal, and recurrent laryngeal nerves. Judicious use of small amounts of amnestic or anxiolytic agents may be necessary to prevent the precipitation of thyroid storm.

A rigid bronchoscope should be available in the event of airway collapse. Emergency tracheotomies are difficult to perform because of anatomic distortion and an increase in tissue vascularity. Small reinforced endotracheal tubes should be available.

Hines RL, Marschall KE, eds. *Stoelting's Anesthesia and Co-existing Disease*. 5th ed. Philadelphia: Churchill Livingstone; 2008:380–384.

C.3. Is endotracheal intubation necessary for this operation? Discuss the type and length of tube you would use.

Endotracheal intubation is necessary for thyroid surgery. If tracheal obstruction is suspected, a reinforced anode endotracheal tube should be used to prevent airway collapse. The length of the tube should be sufficient to extend beyond the thyroid gland.

C.4. How would you maintain anesthesia?

Maintenance of anesthesia should avoid sympathetic nervous system activation. Muscle relaxants are not necessary. If muscle relaxants are selected, hyperthyroid patients may have reduced requirements for the nondepolarizing muscle relaxants because they often have coexisting muscle disease (i.e., myasthenia gravis). Opioids should be given to ensure an alert patient who can maintain the airway after extubation. Treatment of hypotension with sympathomimetic drugs must take into account possible exaggerated responses. Because of the high level of circulating endogenous catecholamines, direct sympathomimetics (such as epinephrine or norepinephrine) or α-agonists (such as phenylephrine) are more appropriate than indirect sympathomimetics (such as ephedrine).

Hines RL, Marschall KE, eds. *Stoelting's Anesthesia and Co-existing Disease*. 5th ed. Philadelphia: Churchill Livingstone; 2008:380–384.

C.5. Intraoperatively, the patient became hyperthermic and tachycardic. Discuss the differential diagnosis of malignant hyperthermia and thyroid storm. How would you intervene?

Differential diagnosis includes hyperthyroid storm, malignant hyperthermia, pheochromocytoma, and carcinoid crisis. Many of the clinical manifestations of malignant hyperthermia and thyroid storm are compensatory mechanisms for hyperthermia. However, malignant hyperthermia will result in metabolic acidosis, profound hypercarbia, and muscle rigidity, which are not present during thyroid storm. Hyperthyroidism decreases the level of CPK to approximately half the normal level, whereas CPK levels are increased during malignant hyperthermia. Both disorders progress rapidly and intervention is urgent.

Once thyroid storm is suspected, treatment must start immediately. Goals of intervention include the following:

- Diagnosis and treatment of inciting event: Without treatment of the underlying cause, therapy will be less effective.

- Supportive measures: Replace fluids, glucose, and electrolytes. Reduce temperature with acetaminophen, cold lavage of body cavities, cooling blankets, ice packs, and reduction of ambient temperature. Aspirin should not be used as an antipyretic. It displaces thyroid hormones from binding proteins, thus raising free hormone levels. Inotropes, diuretics, and supplemental oxygen may be needed for acute congestive heart failure.
- Reduce secretion and production of thyroid hormones: Antithyroid drugs prevent iodide binding in the thyroid within the hour and are administered through a nasogastric tube, orally, or rectally. One hour after the administration of methimazole or propylthiouracil, iodide can be started.
- Block the metabolic effects of thyroid hormones: Metabolic manifestations can be treated with β-adrenergic blockers such as propranolol or catecholamine-depleting agents such as reserpine or guanethidine.

Peters K, Nance P, Wingard D. Malignant hyperthyroidism or malignant hyperthermia. *Anesth Analg.* 1981;60:613–615.

C.6. How would you extubate this patient?

If tracheomalacia is suspected, direct visualization of airway patency is suggested. The fiber-optic bronchoscope can be used to assess for airway collapse and vocal cord movement as the endotracheal tube and bronchoscope together are slowly pulled back. If tracheal collapse is noted, the endotracheal tube and bronchoscope should be immediately readvanced. Vocal cord assessment must be done. If any question exists of the patient's ability to protect his airway, leave the endotracheal tube in place. A tracheostomy set, endotracheal tubes, and laryngoscope should be readily available at bedside.

D. Postoperative Management

D.1. The patient became stridorous and dyspneic in the recovery room. What is your differential diagnosis and strategy of intervention?

Causes of respiratory failure include hemorrhage, respiratory obstruction, recurrent laryngeal nerve palsies, tracheomalacia, pneumothorax, and hypocalcemia.

Signs of airway obstruction require emergent evaluation. Hematomas can cause compressive airway obstruction and restrict venous and lymphatic drainage of tracheal mucosa. Hematoma evacuation requires opening and drainage of incision sites. However, tracheal obstruction from mucosal edema may still persist. Patients should be intubated early before airway edema from compromised lymphatic and venous return occurs. Initially, patients should be seated upright at 45 degrees to facilitate venous drainage. Corticosteroids and racemic epinephrine via nebulization should be used to decrease laryngeal edema. If dyspnea worsens, the patient should be intubated.

Injury to bilateral recurrent laryngeal nerves results in respiratory obstruction. Patients demonstrate paramedian position of both of the true vocal cords. These patients require emergent airway intervention, including intubation or tracheotomy. Patients with unilateral recurrent laryngeal nerve paralysis present with hoarseness and minimal signs of airway obstruction.

If dissection is carried down to the mediastinum, pneumothorax must be ruled out as a cause of postoperative respiratory deterioration.

Hypocalcemia secondary to inadvertent excision of parathyroid tissue manifests within the first 3 days postoperatively. Acute airway obstruction in the immediate postoperative period is uncommon. The patient will complain of circumoral numbness and tingling of the hands and feet. If calcium is not supplemented, the patient can develop stridor and airway obstruction secondary to muscle weakness. Severe hypocalcemia can also be associated with seizures and tetany.

Netterville J, Aly A, Ossoff R. Evaluation and treatment of complications of thyroid and parathyroid surgery. *Otolaryngol Clin North Am.* 1990;23:529–550.

D.2. When does thyroid storm most often present?

Thyroid storm most often occurs 6 to 18 hours postoperatively, rather than intraoperatively. Treatment with the same regimen as outlined for emergency surgery is indicated (see section B.9). Supportive measures with fluids, oxygen, and a cooling blanket are important. Aspirin should not be used as an antipyretic, because it displaces thyroid hormones from binding proteins and thus raises free hormone levels.

Hines RL, Marschall KE, eds. *Stoelting's Anesthesia and Co-existing Disease*. 5th ed. Philadelphia: Churchill Livingstone; 2008:380–384.

CHAPTER 22

Pheochromocytoma

Gregory E. Kerr

THE PATIENT IS A 39-YEAR-OLD MAN

with a history of recurrent headaches, diaphoresis, and severe hypertension for several weeks. During a physical examination, he was found to have an exceptionally high blood pressure (BP) of 230/150 mm Hg with a heart rate of 112 beats per minute. Prior to this, the patient claims to have been in good health. Further studies were obtained to evaluate the etiology of his high BP and headaches.

A. Medical Disease and Differential Diagnosis

1. What are some common problems that should be included in a differential diagnosis for hypertension?
2. What is a pheochromocytoma?
3. Trace the embryology of the adrenal gland and describe its normal anatomy.
4. What substances does the adrenal medulla excrete?
5. What are the mechanisms of action of epinephrine and norepinephrine?
6. What is the pathway for synthesis and breakdown of catecholamines?
7. What does the adrenal cortex secrete?
8. What are the metabolic actions of the glucocorticoids and the mineralocorticoids?
9. What are some clinical features associated with a pheochromocytoma?
10. In whom do we find pheochromocytoma?
11. What is the incidence of pheochromocytoma?

B. Preoperative Evaluation and Preparation

1. How can you diagnose and localize the tumor preoperatively?
2. How do you pharmacologically prepare the patient with a pheochromocytoma for surgery?
3. What other aspects of preoperative management are important?

C. Intraoperative Management

1. What drugs should be avoided during the operation?
2. How would you monitor this patient?
3. Describe acceptable options for administering anesthesia to this patient.
4. What drugs are used to control the effects of catecholamine stimulation during surgery?
5. What are some management concerns after the tumor is removed?
6. If a pheochromocytoma is found complicating pregnancy, does magnesium sulfate ($MgSo_4$) have a role in managing the hypertension?
7. What are some of the concerns with laparoscopic adrenalectomy?

D. Postoperative Management

1. What is the significance of postoperative hypotension? How is it treated?
2. What other problems can arise in the postoperative period?

A. Medical Disease and Differential Diagnosis

A.1. What are some common problems that should be included in a differential diagnosis for hypertension?

The following is a partial list of differential diagnosis of hypertension:

- *Essential hypertension*. Unknown etiology
- *Primary renal disease*. Nephritis, renal artery stenosis, and renal infarction
- *Endocrine*. Adrenocortical hyperfunction, thyroid disease, pheochromocytoma, and acromegaly
- *Hemodynamic alterations*. Decreased peripheral vascular resistance and increased intravascular volume
- *Sympathetic stimulation*. Light anesthesia, hypoxia, and hypercarbia
- *Neurogenic*. Seizure activity, elevated intracranial pressure, and denervation of the carotid sinus
- *Miscellaneous*. Malignant hyperthermia, neuroleptic malignant syndrome, carcinoid syndrome, and toxemia of pregnancy

Fauci AS, Braunwald E, Kasper DL, et al., eds. *Harrison's Principles of Internal Medicine*. 17th ed. New York: McGraw-Hill; 2008:2269.

A.2. What is a pheochromocytoma?

Pheochromocytomas are catecholamine-secreting tumors of chromaffin tissue. They are usually located in the adrenal medulla or sympathetic paraganglia, but may be found anywhere chromaffin tissue exists. These locations extend from the base of the skull to the anus. Ninety percent of pheochromocytomas are found in the adrenal medulla and 10% occur elsewhere. These are commonly called paragangliomas.

Pheochromocytomas are entities that only account for 0.1% of all cases of hypertension. They occur in only 0.005% to 0.01% of people. When unsuspected or improperly managed during surgery, the physiologic effects of the released catecholamines can be profound.

The word pheochromocytoma is derived from the Greek words for dusky, *phaios*, and color, *chroma*. In 1912, Pick noted that these tumors stained a deep rust color when treated with chromium salts.

A.3. Trace the embryology of the adrenal gland and describe its normal anatomy.

The adrenal cortex and medulla have separate embryologic origins. The medullary portion is derived from the chromaffin ectodermal cells of the neural crest. These cells are split off very early from the sympathetic ganglion cells and migrate further ventrally, in order to lie ventrolateral to the aorta, where they form the paraganglia. Several such nodules near the cranial end of the gonads combine into a larger mass of cells lying between the dorsal aorta and the dorsomedial border of the mesonephros. Here they come into approximation with a group of mesodermal cells destined to become the adrenal cortex. These latter cells are derived principally from a narrow strip of coelomic mesothelium lying between the dorsal mesentery and the genital ridge. These cells, arising in numerous places in the suprarenal ridge, lose their connection with the mesothelium and form a complete layer of mesoderm around the ectodermal cells derived from the sympathetic ganglia. The chromaffin cells become enclosed within the cortex to form the medulla. The organs of Zuckerkandl are paraganglia around the aorta at the level of the kidney anterior to the inferior aorta. Accessory areas for the occurrence of pheochromocytoma are in the mediastinum, in the bladder, occasionally in the neck, in the sacrococcygeal region, or in the anal or vaginal areas.

Brunicardi FC, Andersen DK, Billiar TR, et al., eds. *Schwartz's Principles of Surgery*. 9th ed. New York: McGraw-Hill; 2009:1389.

Townsend CM, Beauchamp RD, Evers BM, et al. *Sabiston Textbook of Surgery*. 18th ed. Philadelphia: WB Saunders; 2008:997–998.

A.4. What substances does the adrenal medulla excrete?

The adrenal medulla primarily secretes three substances, all of which are catecholamines. The catecholamines are epinephrine, norepinephrine, and dopamine. These three compounds are found in the chromaffin cells of the sympathetic nervous system, which includes the adrenal medulla, aberrant tissue along the sympathetic chain, and paraganglia. Both norepinephrine and dopamine are found at the endings of the postganglionic fibers of the sympathetic nervous system and in the CNS.

Brunicardi FC, Andersen DK, Billiar TR, et al., eds. *Schwartz's Principles of Surgery*. 9th ed. New York: McGraw-Hill; 2009:1389–1392.

Townsend CM, Beauchamp RD, Evers BM, et al. *Sabiston Textbook of Surgery*. 18th ed. Philadelphia: WB Saunders; 2008:1001–1006.

A.5. What are the mechanisms of action of epinephrine and norepinephrine?

These catecholamines exert their effects by acting on β-adrenergic and α-adrenergic receptors. It is believed that the results of β-receptor stimulation are largely mediated by the stimulation of adenylate (adenylyl) cyclase, which results in the production and activation of cyclic adenosine monophosphate (cAMP). The stimulation of cAMP eventually leads to an increased inward calcium (Ca^{2+}) flux, thereby increasing cytoplasmic Ca^{2+} concentrations. The increased availability of Ca^{2+} ultimately results in enhanced actin and myosin interactions. The stimulation of α_1 receptors creates an increased inward flux of Ca^{2+} and also affects the formation of inositol triphosphate. The stimulation of α_2 receptors inhibits the action of adenylate cyclase (Fig. 22.1).

The pharmacologic response is dependent on the location of the receptors throughout the body. The distribution and density of the receptors will determine the predominant response to each catecholamine.

Brunton L, Lazo J, Parker K, eds. *Goodman and Gillman's The Pharmacologic Basis of Therapeutics*. 12th ed. New York: McGraw Hill; 2010:282–289.

Stoelting RK, ed. *Pharmacology and Physiology in Anesthetic Practice.* 4th ed. Philadelphia: Lippincott Williams & Wilkins; 2005:809–812.

A.6. What is the pathway for synthesis and breakdown of catecholamines?

The synthesis of endogenous catecholamines begins with the active transport of the amino acid tyrosine from the circulation into postganglionic sympathetic nerve endings. The hydroxylation of tyrosine generally is regarded as the rate-limiting step of the pathway (Fig. 22.2). Any drug containing the 3,4-dihydroxybenzene (catecholamine) structure is rapidly inactivated by catechol-*O*-methyltransferase (COMT) or monoamine oxidase (MAO). The most important aspect of the termination of the biologic activity of these catecholamines is reuptake into the nerve endings.

A.7. What does the adrenal cortex secrete?

The adrenal cortex secretes more than 30 different corticosteroids. These can be divided into two major classes, the mineralocorticoids and the glucocorticoids. The precursor of all corticosteroids is cholesterol. Aldosterone is the most important mineralocorticoid secreted by the adrenal cortex, whereas cortisol is the most important glucocorticoid secreted. The adrenal cortex is also responsible for secreting sex steroids. Each of these substances is secreted by different zones—the mineralocorticoids are secreted by the zona glomerulosa, the glucocorticoids are secreted by the zona fasciculata, and the sex steroids (the androgens and estrogens) are secreted by the zona reticularis.

Brunton L, Lazo J, Parker K. *Goodman and Gillman's The Pharmacologic Basis of Therapeutics*. 12th ed. New York: McGraw Hill; 2010:1209–1224.

Stoelting RK, ed. *Pharmacology and Physiology in Anesthetic Practice*. 4th ed. Philadelphia: Lippincott Williams & Wilkins; 2005:809–812.

A.8. What are the metabolic actions of the glucocorticoids and the mineralocorticoids?

The glucocorticoids have their predominant mechanism of action on intermediary metabolism. These effects include increased gluconeogenesis, fatty acid mobilization, protein catabolism, and anti-inflammatory effects. Cortisol may improve cardiac function by improving responsiveness of β-adrenergic receptors. Approximately 95% of the glucocorticoid activity is from the secretion of cortisol. The mineralocorticoids have their predominant action on the body minerals, sodium, and potassium. By conserving sodium ions, they sustain extracellular fluid volume. They also help maintain normal potassium plasma concentrations.

Czock D, Keller F, Rasche FM, et al. Pharmacokinetics and pharmacodynamics of systemically administered glucocorticoids. *Clin Pharmacokinet*. 2005;44(1):61–98.

A.9. What are some clinical features associated with a pheochromocytoma?

The classic triad is severe headache, diaphoresis, and palpitations. One or more of the following often signal the presence of a pheochromocytoma: sudden severe headaches, perspiration, weight loss, paroxysmal hypertension, pallor, palpitations, diabetes-like syndrome with elevated fasting blood sugar, nausea, vomiting, fever, encephalopathy, anxiety, myocardial infarction, stroke, or acute renal failure. Although hypertension can be paroxysmal, 65% of adults demonstrate sustained hypertension. The aforementioned symptoms are usually paroxysmal in nature. These "attacks" may last from a few moments to hours.

A pressor response to particular drugs suggests the presence of this tumor. These drugs include histamine, glucagon, droperidol, tyramine, metoclopramide, cytotoxic drugs, saralasin, tricyclic antidepressants, and phenothiazines.

Artusio J. Anesthesiology for pheochromocytoma. In: Malhotra V, ed. *Anesthesia for Renal and Genito-urologic Surgery*. 1st ed. New York: McGraw-Hill; 1996:80.

Manger WM. An overview of pheochromocytoma: history, current concepts, vagaries, and diagnostic challenges. *Ann N Y Acad Sci*. 2006;1073:1–20.

Table 22.1 Multiple Endocrine Adenomatosis

Type IIa (Sipple syndrome)	Parathyroid adenoma/hyperplasia
	Medullary carcinoma of thyroid
	Pheochromocytoma
Type IIb	Medullary carcinoma of the thyroid
	Mucosal adenomas
	Marfanoid appearance
	Pheochromocytoma
von Hippel-Landau syndrome	Hemangioblastoma of the retina, cerebellum, or other parts of the CNS, pheochromocytoma
Neurofibromatosis	Neurofibromas, café-au-lait spots, axillary or inguinal freckling, optic nerve glioma, pheochromocytoma

A.10. In whom do we find pheochromocytoma?

Pheochromocytomas occur in both sexes with peak incidence in the third to fifth decades of life. Approximately 5% of cases of pheochromocytomas are inherited as an autosomal dominant trait either alone or as part of the neoplastic syndrome, multiple endocrine adenomatosis (Table 22.1).

Young WF Jr. Clinical practice. The incidentally discovered adrenal mass. N Engl J Med. 2007;356(6):601–610.

A.11. What is the incidence of pheochromocytoma?

It is estimated that one to eight cases of pheochromocytoma occur per million persons annually. It seems that the incidence increases with advancing age. It also appears that there is a genetic predisposition with 10% to 20% of diagnosed patients with the disease having had a family history.

Manger WM. An overview of pheochromocytoma: history, current concepts, vagaries, and diagnostic challenges. *Ann N Y Acad Sci.* 2006;1073:1–20.

B. Preoperative Evaluation and Preparation

B.1. How can you diagnose and localize the tumor preoperatively?

The laboratory tests for pheochromocytoma are shown in Table 22.2. The biochemical diagnosis is based on the fact that pheochromocytomas release an excessive amount of catecholamines and metabolites. Urinary specimens that can be measured include urinary norepinephrine, epinephrine, dopamine, total metanephrines,

Table 22.2 Laboratory Tests for Pheochromocytoma

DIAGNOSTIC TEST	NORMAL VALUES	PHEOCHROMOCYTOMA
Blood		
Plasma catecholamines	<1,000 pg/mL	>2,000 pg/mL
Urine (24-hr collection)		
Catecholamines	<125 μg	>1,200 μg
Norepinephrine	<100 μg	Increased
Epinephrine	<1 μg	Increased
Metanephrines	<1.6 mg	>2.5 mg
Vanillylmandelic acid	<8 mg	>10 mg
Confirmation if test results are equivocal		
Clonidine suppression of norepinephrine secretion	Suppressed in essential hypertensive patients	Not suppressed
Localization of tumor		
Magnetic resonance imaging		
Computed tomography		
Scintigraphy with metaiodobenzyl guanidine (MIBG)		
Selective adrenal venous catheterization and sampling		

From Artusio J. Anesthesiology for pheochromocytoma. In: Malhotra V, ed. *Anesthesia for Renal and Genito-urologic Surgery.* New York: McGraw-Hill; 1996:84, with permission.

and vanillylmandelic acid (VMA), which are collected during a 24-hour period. The total metanephrines have given the highest true-positive results, approximately 98% to 99%.

In theory, the hydroxy-methoxy-mandelic acid (often misnamed VMA) level should be the most reliable laboratory test because it is the final common product of both catecholamine metabolic pathways. In practice, however, the intermediate metanephrines have proved to be better discriminators of pheochromocytomas. VMA is often used as an initial "case-finding" test because it has "acceptable" specificity and sensitivity and is relatively inexpensive.

Historically, 24-hour urine tests were generally considered superior to plasma tests in the diagnosis of pheochromocytomas because the tumor secretes catecholamines only intermittently and the catecholamines have a short half-life. These combined factors could result in relatively normal plasma catecholamine levels in the presence of an active tumor. Some authors have demonstrated that plasma-free metanephrines constitute the best test for excluding or confirming the presence of pheochromocytomas and should be the test of first choice for diagnosis of the tumor. Chromaginin A, a monomeric acidic protein found in the adrenal medulla, is secreted along with the catecholamines. It has been reported to have a sensitivity of 83% and a specificity of 96%. Measuring its plasma level may be useful along with the plasma levels of the catecholamines in making a diagnosis. High-pressure liquid chromatographic and radioenzyme methods for measuring levels in the plasma have also been known to improve diagnostic accuracy.

The clonidine-suppression test (which is still occasionally used) may be helpful in distinguishing the patient with a pheochromocytoma whose hypersecretion of

norepinephrine does not respond to the drug from the patient without the tumor whose high basal plasma concentration is decreased to normal by the drug.

Computed tomography (CT) with or without iodine131 (^{131}I)–labeled metaiodobenzylguanidine (MIBG) is extremely accurate in diagnosing and localizing the tumor. Use of arteriography, once popular, should be performed cautiously because dye can stimulate catecholamine release. CT scanning and magnetic resonance imaging (MRI) scanning are excellent imaging techniques that visualize normal adrenal glands when the diagnosis is equivocal. CT scanning has a sensitivity of 98%, whereas MRI is greater than 99%. For extra-adrenal locations and in pregnant patients, MRI scanning may be a more desirable choice. MIBG also has been useful in localizing extra-adrenal tumors as well as recurrent pheochromocytomas. MIBG has a specificity of greater than 95%, but a sensitivity of only 77%.

B.2. How do you pharmacologically prepare the patient with a pheochromocytoma for surgery?

The major goal is to partially block the responses to catecholamines and to avoid the pressor effects of the catecholamines. Although surgery remains the only definitive therapy, the above goals must be obtained as soon as the diagnosis is made by using pharmacologic methods.

Administration of α-adrenergic blockers has been the cornerstone of management. The most commonly used agents have been phenoxybenzamine (POB) (Dibenzyline 10 to 20 mg, three to four times per day orally); prazosin (2 to 5 mg two times per day orally); and phentolamine as a constant infusion. POB has been most widely used because of its relatively long duration of action and ease of administration. It irreversibly alkylates α_1-adrenergic receptors on vascular smooth muscle, thereby making them nonfunctional. It may cause postural hypotension and reflex tachycardia. These may be avoided with the careful administration of fluid volume as well as β-blockers. Be sure not to start β-blockade until the α-blockers have been started, otherwise congestive heart failure may be precipitated. Many feel that β-blockers should be used only when tachycardia or arrhythmias exist.

Prazosin has been used but does not seem to adequately prevent perioperative hypertensive episodes. Prazosin as well as $MgSO_4$, β-blockers, angiotensin-converting enzyme inhibitors, and calcium channel blockers have been used in combination with POB to attain hemodynamic stability.

α-Methyl-paratyrosine inhibits tyrosine hydroxylase. It may be given orally, gradually increasing the dose from 0.5 g per day to 4 g per day. This may decrease the catecholamine synthesis by 40% to 80%. It is very effective, but may cause diarrhea, sedative fatigue, anxiety, or agitated depression or tumors.

A study from the Cleveland Clinic suggests that preoperative use of α-blocking agents may not necessarily decrease the incidence of intraoperative hypertension or tachycardia. In fact, patients who did not receive preoperative POB had a few advan-

tages. Eighty percent of these patients did not require vasopressors in the postanesthesia care unit, although the rest did so for a very short period of time. Similarly, 79% of patients received no vasodilators in the postanesthesia care unit. There was no difference in intensive care unit length of stay between those patients who received preoperative POB/prazosin versus those who did not.

It is possible that advances in anesthetic and monitoring techniques as well as the availability of fast-acting drugs capable of correcting sudden changes in hemodynamics will allow operating on select patients without use of preoperative α-blockers. However, most physicians prefer to use α-blockers to obtund the intraoperative hypertensive responses.

B.3. What other aspects of preoperative management are important?

The circulating blood volume is decreased in many patients with pheochromocytomas. Therefore, many clinicians support the idea of administering volume (frequently blood) before surgery while patients receive α-blockade. One must be very careful with patients who have decreased myocardial function to avoid congestive heart failure. Many other clinicians feel volume loading is not necessary. They feel that if the patient has been on α-blockers for 2 weeks or more, then the volume has been restored.

Sedation for the preoperative period is considered by many clinicians to be important before surgery. Sedation may obviate the need to use high doses of antihypertensive agents before surgery.

C. Intraoperative Management

C.1. What drugs should be avoided during the operation?

As there are many agents to choose from, but many whose use is controversial, the controversial agents should be avoided (Table 22.3). This appears to be secondary to the inhibition of catecholamine reuptake. Atropine exacerbates the chronic effects of epinephrine by vagal inhibition. All drugs that release histamine (e.g., morphine, curare, atracurium) might be avoided because histamine has been known to provoke pheochromocytomas. Agents that cause an indirect increase in catecholamine levels (e.g., pancuronium, ketamine, ephedrine) should be avoided. It should be noted, however, that morphine, curare, atracurium, and pancuronium all have been used with clinical reports documenting their safe use.

Table 22.3	Suggested Drugs to Avoid in Patients with Pheochromocytoma
	Droperidol
	Morphine
	Atracurium
	Pancuronium
	Ketamine
	Ephedrine
	Halothane
	Cocaine
	Metoclopramide
	Curare

Myklejord DJ. Undiagnosed pheochromocytoma: the anesthesiologist nightmare. *Clin Med Res*. 2004;2(1):59–62.

C.2. How would you monitor this patient?

Monitoring in these patients generally includes an electrocardiogram with a V_5 lead, core temperature, pulse oximetry, intra-arterial BP monitoring along with central venous pressure monitoring, and a urinary catheter. For patients with known or suspected myocardial dysfunction, a pulmonary artery catheter should be considered. One also may want to consider noninvasive techniques for assessing cardiac function.

In recent years, most of the pheochromocytomas are excised laparoscopically with minimal volume shifts and blood loss, thereby eliminating the need for central venous pressure monitoring.

Kinney MA, Narr BJ, Warner MA. Perioperative management of pheochromocytoma. *J Cardiothorac Vasc Anesth*. 2002;16(3):359–369.

C.3. Describe acceptable options for administering anesthesia to this patient.

Either general anesthesia, regional anesthesia, or a combination of the two are considered acceptable. For all techniques, it is important to avoid wide swings in BP.

For general anesthesia, induction with thiopental has been most commonly used, but induction with propofol has recently been reported to be a safe technique. One can lessen the response to intubation by administering 1.5 μg per kg lidocaine intravenously 2 minutes before laryngoscopy. Other measures to attenuate hemodynamic responses to intubation are described in Chapter 10, sections C.5 and C.6. General anesthesia may be maintained with isoflurane, sevoflurane, or desflurane, although

desflurane may be associated with occasional tachycardia. Clinicians also seem to like the concomitant use of narcotics. Some authors advocate the avoidance of halothane because of its ability to increase the incidence of arrhythmias.

C.4. What drugs are used to control the effects of catecholamine stimulation during surgery?

Drugs used to control intraoperative hypertension are listed in Table 22.4.

Phentolamine, a short-acting α-blocking agent, can be given as a continuous infusion to control BP. Phentolamine along with isoflurane may maintain an appropriate BP. Many clinicians are becoming more comfortable with nicardipine as a way to control elevated BP.

$MgSO_4$ has been used in selected cases as an adjunct vasodilator. β-blockers are helpful during the preoperative period to control BP as well as heart rate and possible arrhythmias. Lidocaine also should be considered for the control of arrhythmias.

Table 22.4 Intravenous Drugs to Control Intraoperative Hypertension

DRUG	DOSE
Diltiazem	Load with 5- to 10-mg boluses and infuse at 0.25–0.5 μg/kg/min
Esmolol	5- to 10-mg boluses or infusion
Hydralazine	5- to 10-mg boluses every 30 min
Labetalol	10-mg boluses to total 150 mg
Magnesium sulfate	2-g boluses; be cautious in patients with renal failure and neuromuscular blockade
Nitroprusside	Infuse initially with 0.5–1.5 μg/kg/min to maximum of 8 μg/kg/min over 1–3 hr
Nicardipine	Infuse initially at 5 mg/hr; may alter rate by 2.5 mg/hr every 15 min; to maximum of 15 mg/hr
Phentolamine	1–5 mg every 5 min or infuse initially with 1 mg/min
Propanolol	1-mg boluses to total 10 mg

C.5. What are some management concerns after the tumor is removed?

It is important to be aware of the fact that BP may decrease very quickly after the blood supply of the tumor is interrupted. The BP may be maintained by administering norepinephrine as well as by administering fluids. Blood should be administered if the blood loss is substantial.

C.6. If a pheochromocytoma is found complicating pregnancy, does $MgSO_4$ have a role in managing the hypertension?

Reports indicate that $MgSO_4$ can be used in conjunction with several potent inhalation anesthetics to control BP. Hypomagnesemia may be present in the pregnant patient and should be corrected preoperatively. Where an adequate level of magnesium can be achieved, its use may be ideal as an adjunct to anesthetic management because it has been shown that the use of magnesium to control BP is not deleterious to the fetus.

C.7. What are some of the concerns with laparoscopic adrenalectomy?

Due to the advancement of imaging techniques, such as CT, ^{131}I MIBG scintigraphy, MRI, and positron emission tomography, localization of the tumor has become fairly accurate. These techniques allow for the selective surgical approach seen in laparoscopic surgery. Therefore, it is important to understand the issues associated with this form of adrenalectomy.

Creation of the pneumoperitoneum and, not surprisingly, manipulation of the tumor has been associated with an elevation in catecholamine and vasopressin levels in patients undergoing laparoscopic adrenalectomies. With this elevation in the catecholamine levels, there is an associated increase in cardiac output and BP. Insufflation of CO_2 into the peritoneum causes hypercarbia that can in turn increase sympathetic tone. Studies show that intraoperative hemodynamic values during laparoscopic surgery are in fact comparable to those of traditional surgery. Decreased blood loss, decreased postoperative pain, and the quicker postoperative recovery in patients who have undergone laparoscopic surgery make it the technique of choice.

D. Postoperative Management

D.1. What is the significance of postoperative hypotension? How is it treated?

Postoperative hypotension is often due to hypovolemia, residual effects of phenoxybenzamine because it has a long half-life—and due to the downregulation of receptors in patients with long-standing exposure to high levels of catecholamines. Postadrenalectomy hypotension should be treated with volume administration and, if needed, norepinephrine. The presence of alpha blockade and the downregulation of receptors may require higher than usual concentrations of norepinephrine to obtain desired response. Vasopressin has been used rarely by some to treat catecholamine-resistant hypotension. Be cognizant of the fact that persistent hypotension may be secondary to bleeding.

D.2. What other problems can arise in the postoperative period?

For the first 48 hours after surgery, these patients may be very somnolent. This is possibly due to the sudden removal of activating catecholamines. Frequently, this results in decreased narcotic requirements.

Be aware that these patients also are prone to significant hypoglycemia, which alone can make a patient somnolent. In more severe cases, hypoglycemia may cause loss of consciousness and respiratory arrest. The hypoglycemia may result from decrease in epinephrine levels (especially if it is an epinephrine-secreting tumor as 10% of these tend to be) or from an increase in plasma insulin level. Neoglycogenesis and glycogenolysis, which had sustained the high blood sugar, are no longer present. Therefore, one should consider switching to a glucose-containing intravenous fluid after removal of the tumor and monitor the glucose levels very closely for at least 24 hours in the postoperative period.

Persistent hypertension after removal of a pheochromocytoma occasionally signifies that a residual pheochromocytoma tumor is present. Be aware that plasma catecholamine levels (norepinephrine) may not decrease to normal levels for many days after removal of the tumor.

CHAPTER 23

Diabetes Mellitus

MARK E. NUNNALLY AND VINOD MALHOTRA

A 59-YEAR-OLD WOMAN

presents for hysterectomy for cervical cancer. She is obese (body mass index 32 kg per m^2) and has had diabetes mellitus (DM) type 2, hypertension, and dyslipidemia for 20 years. She takes enalapril, metoprolol, atorvastatin, metformin, acarbose, and recently started taking insulin glargine, 20 units subcutaneously, daily for refractory hyperglycemia. She measures her serum glucose intermittently at home. Values are generally 150 to 220 mg per dL. She experiences an early and prolonged sense of fullness after meals and an unpleasant sour taste at night two or three times per week. Laboratory values are notable for a serum creatinine of 2.2 mg per dL and a serum glucose of 206 mg per dL. She has not taken any medications today and has had nothing to eat since midnight.

A. Medical Disease and Differential Diagnosis

1. What is the epidemiology of DM in the general population?
2. What are the factors in the etiology of DM?
3. How do you classify DM?
4. What are the complications of DM?
5. How would you treat the different forms of this illness?
6. How do you adequately monitor control of the disease?
7. What are some of the factors that alter insulin requirements?
8. What are the principles of management of diabetic ketoacidosis (DKA)?
9. What is a hyperglycemic hyperosmolar state?

B. Preoperative Evaluation and Preparation

1. How would you evaluate this patient?
2. How would the stiff joint syndrome affect her airway management?
3. What are the signs and implications of autonomic neuropathy in the diabetic patient?

4. How would you prepare this patient for anesthesia and surgery?
5. For elective surgery, how do you manage the insulin and glucose requirements on the day of surgery?
6. How would you premedicate this patient?

C. Intraoperative Management

1. What are the effects of anesthesia and surgery on insulin and glucose metabolism?
2. What anesthetic techniques would you employ?
3. How would you monitor this patient?
4. How would you treat hyperglycemia intraoperatively?
5. How would you recognize and treat hypoglycemic shock intraoperatively?

D. Postoperative Management

1. How would you control diabetes in this patient postoperatively?
2. Does diabetes increase perioperative risk?
3. What are the common postoperative complications you expect in a diabetic patient?
4. Is it necessary to achieve tight perioperative control of glucose?

A. Medical Disease and Differential Diagnosis

A.1. What is the epidemiology of DM in the general population?

DM, literally "sweet urine," is a group of metabolic disorders defined by elevated serum glucose. Data from the National Health and Nutrition Examination Survey from 1999 to 2002 suggest a prevalence of DM in the adult population of 9.3%, with more than a quarter of those undiagnosed. For patients 65 years or older, the prevalence is 21.6%.

A majority of patients with diabetes (approximately 90%) have type 2 diabetes (DM2); a minority (approximately 10%) have type 1 (DM1). Finally, 1% to 14% of pregnant women develop gestational diabetes. DM1 and DM2 are very different diseases. In DM1, exogenous insulin is essential for cellular metabolism. Untreated, DM1 is a wasting disease associated with ketoacidosis and severe cumulative organ failure. DM2 is a metabolic disorder associated with resistance to insulin effects. Because of the presence of circulating insulin, ketoacidosis is rare in DM2. Nevertheless, hyperglycemic hyperosmolar state is a risk in the inadequately treated patient.

Cowie CC, Rust KF, Byrd-Holt DD, et al. Prevalence of diabetes and impaired fasting glucose in adults in the U.S. population: National Health and Nutrition Examination Survey 1999–2002. *Diabetes Care.* 2006;29:1263–1268.

McDonald M, Hertz RP, Unger AN, et al. Prevalence, awareness, and management of hypertension, dyslipidemia, and diabetes among United States adults aged 65 and older. *J Gerontol A Biol Sci Med Sci.* 2009;64:256–263.

Hillier TA, Vesco KK, Pedula KL, et al. Screening for gestational diabetes mellitus: a systematic review for the U.S. Preventive Services Task Force. *Ann Intern Med.* 2008;148:766–775.

A.2. What are the factors in the etiology of DM?

Because hyperglycemia defines DM, it is too easy to focus on elevations in serum glucose, ignoring other effects. Lipid and protein metabolism are deranged in both

varieties of DM. Tissue growth, signaling, and function are likewise impaired. Simple control of blood sugar may not adequately treat the complex hormonal and metabolic derangements of DM. Inflammation and immune dysfunction are also components of the disease.

In DM1, the immune system destroys insulin-secreting pancreatic beta cells. The diagnosis of DM1 is frequently made in childhood. DM2 manifests in a variety of processes that decrease the hypoglycemic effects of insulin. Among the processes are obesity and endocrine and inflammatory conditions. In both cases, genetic association is incomplete and there is association with other diseases, including autoimmune disorders, hypertension, and dyslipidemias. Gestational diabetes reflects insulin resistance exacerbated by the effects of pregnancy. It likely signals patients who are at risk for developing DM2.

Cowie CC, Rust KF, Byrd-Holt DD, et al. Prevalence of diabetes and impaired fasting glucose in adults in the U.S. population: National Health and Nutrition Examination Survey 1999–2002. *Diabetes Care*. 2006;29:1263–1268.

McDonald M, Hertz RP, Unger AN, et al. Prevalence, awareness, and management of hypertension, dyslipidemia, and diabetes among United States adults aged 65 and older. *J Gerontol A Biol Sci Med Sci*. 2009;64:256–263.

A.3. How do you classify DM?

Table 23.1. lists the criteria for the diagnosis of DM1, DM2, and gestational diabetes. Fasting hyperglycemia is a useful means to confirm metabolic derangement, but random hyperglycemia, classic symptoms (such as polyuria and polydipsia), or the inability to manage a glucose load are sufficient to make the diagnosis. Ketoacidosis and the need for insulin reflect DM1, whereas obesity, gradual onset (usually at an older age), and hyperosmolality without ketosis suggest DM2. Gestational diabetes resembles DM2 only in the setting of pregnancy.

Therapy for DM varies by type. Insulin is essential in DM1. In DM2 and gestational diabetes, diet, exercise, and drugs that modify insulin secretion or sensitivity can help correct hyperglycemia, although exogenous insulin may be necessary.

Cowie CC, Rust KF, Byrd-Holt DD, et al. Prevalence of diabetes and impaired fasting glucose in adults in the U.S. population: National Health and Nutrition Examination survey 1999–2002. *Diabetes Care*. 2006;29:1263–1268.

Table 23.1 American Diabetes Association Diagnostic Criteria for Diabetes Mellitus

1.	Symptoms of diabetes plus random plasma glucose level >200 mg/dL (11.1 mmol/L)
2.	Hemoglobin $A_1C \geq 6.5\%$
3.	Fasting plasma glucose level ≥126 mg/dL (7.0 mmoL/L)
4.	Two-hour plasma glucose level ≥200 mg/dL (11.1 mmol/L) during oral glucose tolerance test

American Diabetes Association. Diagnosis and Classification of Diabetes Mellitus. [Miscellaneous Article]. *Diabetes Care*. 33 (20100100)(Supplement 1):S62, January 2010.

A.4. What are the complications of DM?

Acute complications include DKA and hyperglycemic hyperosmolar state. Both are associated with severe systemic illness and a high mortality and will be discussed separately. Hypoglycemia is a serious risk of several diabetes therapies.

Chronically, DM affects virtually every organ system. Of most concern to the anesthetist are macrovascular disease, including accelerated atherosclerosis, and microvascular nephropathy, neuropathy, and cardiomyopathy. Tissues fail from a combination of advanced glycation end products, inflammation, connective tissue proliferation, and impaired perfusion. Renal failure, neuropathy, and accelerated coronary, cerebral, and peripheral vascular disease are common. Autonomic neuropathy and the stiff joint syndrome are both factors for preoperative evaluation (see later discussion). Hypertension frequently accompanies DM, exacerbating organ failure. Impaired immune function predisposes to infection. Hypercoagulability exacerbates macrovascular disease. Dyslipidemias accelerate atherosclerotic lesions and may directly contribute to metabolic toxicities.

Cumulatively, the systemic lesions caused or exacerbated by DM reduce life expectancy. When diagnosed before the age of 35, DM causes an estimated mean of 25.9 years of lost life. Because complications present and worsen with time, this effect decreases. About 50% of mortality in diabetic patients comes from cardiovascular disease.

Although it would be helpful to stratify diabetic patients according to their risk for complications, the complexity of the disease and its management has made stratification difficult. The assumption is that a diabetic is at high risk for coronary and other macrovascular disease, congestive heart failure, and renal insufficiency.

Stolar M. Glycemic Control and complications in type 2 diabetes mellitus. *Am J Med*. 2010;123:S3–S11.

A.5. How would you treat the different forms of this illness?

Diabetes care is different in chronic and acute settings. It is essential to differentiate between the agents used chronically and during acute perioperative stress.

Care of DM1 requires exogenous insulin. Figure 23.1 illustrates the pharmacodynamics of several insulin preparations. A combination of a short- and a long-acting insulin preparation can help achieve the goals of resting and postprandial glycemic control. In contrast, DM2 responds to insulin, oral insulin secretagogues, insulin sensitizers, glucose uptake inhibitors, gastrointestinal hormones, weight loss, dietary management, and exercise. Table 23.2 lists the major classes of drugs available for the treatment of DM, mechanisms of action, pharmacokinetics and particular concerns for the anesthetist.

Certain medications have side effects that deserve consideration. Biguanides, such as metformin, increase peripheral glucose uptake but also predispose patients to greater production of lactic acid and acidosis. The significance of this finding is not clear, but many recommend discontinuing these drugs perioperatively because hypoperfusion states are possible during surgery. Because of its long half-life, metformin may take up to 72 hours to clear from the bloodstream, so discontinuation on the day of surgery does not minimize the risk of acidosis. Thiazolidinediones have been associated with hepatic injury and congestive heart failure. Exanatide is associated with reports of kidney dysfunction. Sulfonylureas, pramlintide, and sitagliptin may be associated with hypoglycemia.

For these reasons, as well as unreliable pharmacokinetics, the best option for acute treatment of all types of diabetic hyperglycemia is insulin. Although subcutaneous

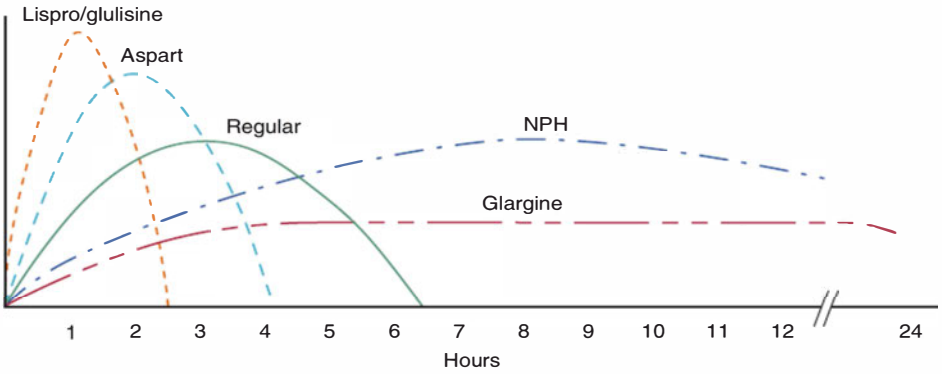

Figure 23.1 Onset and duration of action graphic for common subcutaneous insulin preparations. Regular insulin given intravenously fits the best profile for a titratable drug in the operating room, as onset peak and offset all occur within an hour.

dosing is often used in the hospital setting, intravenous insulin best meets the profile of an ideal titratable agent. It has a short time to onset (10 to 15 minutes), peak effect (less than 30 minutes), and duration of action (45 minutes). Frequent glucose monitoring is essential to titrate the therapy.

Although serum glucose or other markers of chronic hyperglycemia, such as hemoglobin (Hgb) A_1C are currently standard end points for therapy, other factors such as serum lipid and blood pressure management may be just as important. Anesthesiologists should inquire about agents treating these conditions during preoperative evaluation.

A.6. How do you adequately monitor control of the disease?

Self-monitoring of blood glucose is possible in all forms of diabetes, usually by using finger-stick blood samples and portable monitors. This method is the established standard of care in DM1 for carefully titrated control to prevent hypoglycemia and ketoacidosis. Many advocate self-monitoring for patients with DM2, especially if they take insulin, but compliance varies and self-monitoring may not be beneficial in all patients. Hgb A_1C, the product of hemoglobin exposure to hyperglycemic conditions, is a marker of long-term glycemic control. It may help identify subgroups of patients for whom the risk for complications is higher and can be a marker of disease control. The relationship between levels of glycemic control and Hgb A_1C is not linear, however, and the single laboratory value does not completely reveal the glycemic profile over time. Patients with DM should have blood pressure and serum lipid profiles monitored, because these factors increase the risk for complications.

In the operating room, glucose can be measured with samples from a pinprick or venous or arterial line. Samples from a venous or arterial line offer greater reliability during low perfusion. If insulin is being used, monitoring is recommended every hour.

Table 23.2 Common Therapies for Type 2 Diabetes (DM2)[a]

DRUG NAME/CLASS	MECHANISM	ROUTE	ONSET	DURATION	IMPORTANT CONSIDERATIONS
1st Generation Sulfonylureas	↑ Beta cell insulin secretion	PO			Hypoglycemia risk
Tolbutamide			1 hr	12 hr	
Acetohexamide			3 hr	24 hr	
Tolazamide			4 hr	16 hr	
Chlorpropamide			2 hr	24 hr	
2nd Generation Sulfonylureas	↑ Beta cell insulin secretion	PO			Hypoglycemia risk
Glyburide (Micronase)			30 min	24 hr	
Glipizide IR (Glucotrol)			30 min	24 hr	
Glipizide ER (Glucotrol XL)			2–4 hr	24 hr	
Glimepiride (Amaryl)			2–3 hr	24 hr	
Biguanides	↑ Peripheral glucose uptake in response to insulin	PO			Lactic acidosis risk may extend up to 72 hr after administration
Metformin (Glucophage)			1–3 hr	17 hr	
α-Glucosidase inhibitors	↓ Digestive carbohydrate breakdown	PO			No known adverse effects
Acarbose (Precose)			2 hr	NA	
Miglitol (Glyset)			2–3 hr	NA	
Thiazolidinediones (PPAR-γ mediators)	↑ Peripheral glucose uptake	PO			Risk for hepatic injury, fluid retention; ongoing concerns about myocardial ischemia
Pioglitazone (Actos)			hours	$T_{1/2}$ 3–7 hr	
Rosiglitazone (Avandia)			hours	$T_{1/2}$ 3–4 hr	

Glinides	↑ Beta cell insulin secretion	PO			Hypoglycemia risk
Repaglinide (Prandin)			15–60 min	4–6 hr	
Nateglinide (Starlix)			20 min	$T_{1/2}$ 1.5 hr	
Incretin-mimetics	↑ Insulin, ↓ glucagon, hepatic glucose production, gastric emptying, and appetite	SC			Observational data associate with renal failure
Exenatide (Byetta)			10 min	6–8 hr	
Liraglutide (Victoza)			minutes	$T_{1/2}$ 13 hr	
DPP-IV Inhibitors	Inhibits incretin breakdown	PO			May have effects on immune function
Sitagliptin (Januvia)			hours	days	
Saxagliptin (Onglyza)			hours	24 hr	
Amylin Analogues	↑ Satiety, ↓ glucagon, and appetite	SC			No confirmed hypoglycemia risk
Pramlintide (Symlin)			minutes	hours	

[a]Onset and duration data are approximate only and subject to variability.
PPAR, peroxisome proliferator-activated receptor; PO, per os (by mouth); SC, subcutaneous.

A.7. What are some of the factors that alter insulin requirements?

Insulin responsiveness is dynamic during stress or illness. Tissue injury, from surgery or trauma, or inflammatory states, such as infection, decrease responsiveness to insulin as part of the stress response. Under ideal circumstances, these effects are maximal 2 to 3 days after injury and resolve over the course of a week, but there is substantial variability. Besides stress, any other condition that increases counter-regulatory hormones such as glucagon, cortisol, and catecholamines decreases insulin sensitivity and increases insulin requirements. Cushing's disease and pheochromocytoma are examples of conditions that cause insulin resistance. Several medications, including corticosteroids, thyroid replacement preparations, oral contraceptives, and thiazide diuretics also increase insulin resistance. In solid organ transplant recipients, corticosteroids and the calcineurin inhibitor tacrolimus have been associated with insulin resistance or onset of diabetes. Exercise and ethanol can decrease insulin requirements.

A.8. What are the principles of management of diabetic ketoacidosis (DKA)?

A hyperglycemic patient should be assessed for DKA before surgery. Because DKA is associated with a higher perioperative mortality, patients should be monitored for intravascular volume and electrolyte abnormalities.

Withholding insulin contributes to DKA, as does infection or tissue injury, which exacerbates diabetes and sets off a chain of events that can result in DKA. Because of increased risk to the patient, DKA is corrected before surgery. When DKA is triggered by a surgical condition, time to correct it may be limited by the urgency of the surgery.

Patients with DKA have an anion gap metabolic acidosis in addition to hyperglycemia. Elevated serum ketone levels can help confirm the diagnosis, but urine ketones are frequently easier to assay. Commonly, a patient will be hypovolemic from polyuria and incomplete hydration, and resuscitation with isotonic fluids is appropriate. Because lactate and acetate are converted to glucose by the liver, solutions containing these fluids should be avoided in the initial resuscitation. Ketosis is corrected with insulin, which is best as an intravenous infusion. Because glucose levels frequently normalize before ketosis clears, insulin therapy is continued even after hyperglycemia corrects. Dextrose is administered simultaneously to avoid hypoglycemia. During acidemia, hyperkalemia is common from shifts in body stores. Frequently, a patient will have a net potassium deficit. Hypokalemia during correction, which can reflect a deficit of up to 10 mEq potassium per kg body mass, should be treated aggressively. Likewise, hypocalcemia and hypomagnesemia should be anticipated and treated.

Kitabchi AE, Matteri R, Murphy MB, et al. Is a priming dose of insulin necessary in a low-dose insulin protocol for the treatment of diabetic ketoacidosis? *Diabetes Care.* 2008;31:2081–2085.

Kitabchi AE, Nyenwe EA. Hyperglycemic crises in diabetes mellitus: diabetic ketoacidosis and hyperglycemic hyperosmolar state. *Endocrinol Metab Clin N Am.* 2006;35:725–751.

A.9. What is a hyperglycemic hyperosmolar state?

Any hyperglycemic patient should be evaluated for a hyperglycemic hyperosmolar state, another potentially fatal condition. The syndrome is more frequent in DM2. It includes hyperglycemia, hyperosmolarity, volume depletion, and changes in mental status. Adverse effects result from hyperosmolarity and hypovolemic shock. Glucose levels exceeding 1,000 mg per dL have been described. Mortality can be very high. Glycosuria and inadequate fluid intake contribute to the condition. Treatment consists of fluid resuscitation and intravenous insulin to correct the hyperglycemia. Sodium, potassium, calcium, and magnesium levels are evaluated and normalized.

Kitabchi AE, Nyenwe EA. Hyperglycemic crises in diabetes mellitus: diabetic ketoacidosis and hyperglycemic hyperosmolar state. *Endocrinol Metab Clin N Am.* 2006;35:725–751.

B. Preoperative Evaluation and Preparation

B.1. How would you evaluate this patient?

The goals of preoperative evaluation should be to stratify perioperative risk, ensure optimal management of concurrent illness, and screen for specific anesthetic-related problems. A diabetic patient is evaluated for cardiovascular disease, renal function, stiff joint syndrome, autonomic neuropathy, aspiration risk, and acute diabetic emergencies that can be treated.

Both DM1 and DM2 increase the risk of coronary artery disease. The 2007 American College of Cardiology and American Heart Association Guidelines on Perioperative Cardiovascular Evaluation and Care for Noncardiac Surgery recommend the use of the Revised Cardiac Risk Index. This index uses a history of diabetes, ischemic heart disease, heart failure, cerebrovascular disease, and renal insufficiency to predict perioperative cardiovascular risk. When the patient's functional capacity is low and surgical risk is intermediate to high, the guidelines recommend that the index be used to determine whether the patient needs noninvasive testing (e.g., stress testing) before surgery. With diabetes, the answer is yes if it will change perioperative management. The guidelines recommend heart rate control when any risk factors, including diabetes, are present.

Testing is most useful when it changes management. Noninvasive testing for cardiovascular disease in the diabetic patient adds little if the anesthetic plan is the same regardless of the results. For this reason, the guidelines suggest testing before intermediate risk or vascular surgery plus one or two of the listed risk factors as an alternative to surgery with heart rate control. For three or more risk factors, coupled with intermediate risk or vascular surgery, the recommendation is to consider testing if it will change management. The guidelines emphasize that the literature is inconclusive, that testing improves outcome, and that surgery-specific risks, such as hemodynamic or oxygenation perturbations, be considered when assessing the need for testing. The overall impact of diabetes is to make noninvasive testing a consideration

in all but the lowest risk surgeries when a patient has poor exercise tolerance, if the results will change management.

Optimizing the patient's medical status is a consideration for all patients, but particularly for diabetics who have many comorbidities. Optimal management of coexisting hypertension and congestive heart failure can minimize perioperative risk. The decision to proceed or delay a procedure for medical management depends on the urgency of the surgery and the potential for improving the patient's medical condition.

Diabetes is a leading cause of renal insufficiency and failure. Because this patient already has an increased serum creatinine, she should be further screened for renal insufficiency and any fluid and metabolic derangements should be corrected. A metabolic panel, including serum creatinine, blood urea nitrogen, potassium, sodium, chloride, bicarbonate, and base deficit can be useful, especially because angiotensin mediators, beta-blockers, and insulin itself can affect serum potassium levels. Joint stiffness is assessed with a comprehensive airway examination and the "prayer sign," in which a patient's hands are placed against each other at the palmar surface to see whether the fingers touch. Other considerations in the patient with diabetes include the risks of aspiration and autonomic instability. Although Hgb A_1C levels correlate with perioperative risk, the test does not add any information to the decision paradigm.

In addition to its chronic consequences, diabetes may produce a hyperglycemic hyperosmolar state and DKA. Both syndromes reflect severe metabolic abnormalities, most commonly associated with infection. Because these syndromes may manifest as the result of a surgical emergency, patients with these conditions will present for perioperative management. Ideally, metabolic derangements should be corrected before anesthetic induction, but sometimes, patients must go to surgery urgently or emergently. Anesthesia providers should be prepared for hemodynamic instability, rapid fluid infusion, electrolyte repletion, and frequent serum glucose and electrolyte monitoring. In both cases, intravenous insulin infusion is indicated, titrated to normoglycemia in hyperglycemic hyperosmolar state and the clearance of ketones in DKA. Supplemental dextrose is usually necessary to maintain insulin infusion in the latter.

Fleisher LA, Beckman JA, Brown KA, et al. ACC/AHA 2007 guidelines on perioperative cardiovascular evaluation and care for noncardiac surgery: a report of the American College of Cardiology/American Heart Association task force on Practice Guidelines (Writing Committee to Revise the 2002 Guidelines on Perioperative Cardiovascular Evaluation for Noncardiac Surgery). *J Am Coll Cardiol*. 2007;50:e159–e242.

Lee TH, Marcantonio ER, Mangione CM, et al. Derivation and prospective validation of a simple index for prediction of cardiac risk of major noncardiac surgery. *Circulation*. 1999;100:1043–1049.

B.2. How would the stiff joint syndrome affect her airway management?

The stiff joint syndrome is thought to result from glycation of connective tissue with chronic exposure to hyperglycemia. The range of motion may be reduced in the cervical spine and temporomandibular and arytenoid joints, making endotracheal intubation difficult. As a screening tool, the prayer sign suggests the presence of joint stiffness. If the patient cannot completely oppose the palmer surface of her hands, she may also have reduced mobility in her glottic structures. Neck range of motion and oral aperture should be assessed; the prayer sign might suggest the need for a small endotracheal tube for a narrow glottis or difficult airway adjuncts.

Hogan KJ. Difficult laryngoscopy and diabetes. *Anesth Analg*. 1988;67:1162–1165.

Salzarulo HH, Taylor LA. Diabetic "stiff joint syndrome" as a cause of difficult endotracheal intubation. *Anesthesiology*. 1986;64:366–368.

B.3. What are the signs and implications of autonomic neuropathy in the diabetic patient?

Diabetic neuropathy involves both the peripheral and autonomic nervous system. In the autonomic system, gastric motility, heart rate, and vasomotor tone can be impaired. Cardiac ischemia can be asymptomatic. This patient can be at risk for pulmonary aspiration of gastric contents and/or hemodynamic instability. A history elicits early satiety, prolonged postprandial fullness, and significant reflux symptoms. Potential difficulties with mask ventilation and intubation are assessed. Heart rate variability, best seen on an electrocardiogram tracing in response to deep breathing, Valsalva maneuver, or position changes, identifies patients at risk for hemodynamic instability. Preparation is made to control hemodynamic instability, especially because this patient is taking angiotensin-converting enzyme inhibitors or angiotensin receptor blocking agents. Because of a high likelihood of hemodynamic instability, the anesthesiologist should prepare to use slow titration of anesthetic agents, frequent blood pressure monitoring, and vasoactive agents, if necessary.

Huang CJ, Kuok CH, Kuo TBJ, et al. Pre-operative measurement of heart rate variability predicts hypotension during general anesthesia. *Acta Anaesthesiol Scand.* 2006;50:542–548.

B.4. How would you prepare this patient for anesthesia and surgery?

This patient's cardiovascular risk is elevated, and insulin therapy is given for hyperglycemia. Because of her elevated serum glucose, she is asked about polyuria, a sign that she might be dehydrated from hyperglycemic diuresis. DKA is unlikely because she has DM2, but a metabolic panel is indicated to rule out electrolyte abnormalities.

If her exercise tolerance is below 4 metabolic equivalents, about the equivalent of climbing a flight of stairs or dancing, noninvasive stress testing may be considered. An ECG is indicated based on her risk factors for cardiovascular disease.

Her symptoms, consistent with gastroparesis and gastroesophageal reflux, will influence premedication and airway management. Results from a comprehensive airway examination, including assessment of neck and jaw mobility and a check for the prayer sign, affect anesthetic management decisions. A rapid-sequence intubation could minimize aspiration risk, but only if intubation is easy. If a difficult airway is suspected, awake intubation techniques should be considered.

B.5. For elective surgery, how do you manage the insulin and glucose requirements on the day of surgery?

The risk for hypoglycemia is balanced against the benefit of tight glycemic control. Anesthetized patients can have occult hypoglycemia, so serum glucose is checked frequently. Intravenous insulin is titrated for glycemic control. When administered intravenously, insulin has a fast onset and a short duration of action either as an infusion or as intermittent boluses. Subcutaneous insulin, with longer-lasting effects, is less predictable, especially during the hemodynamic changes of anesthesia and surgery. Subcutaneous insulin pumps should be turned down or off for all but the most minor procedures. Similarly, oral agents should be withheld on the day of surgery, except in very minor procedures. Ideally, metformin should be withheld for 72 hours to minimize the risk of lactic acidosis.

Initial enthusiasm for tight glycemic control in critically ill patients has given way to a much more cautious approach. Perioperatively, hyperglycemia is associated with

worsened neurologic and cardiac ischemia and poor wound healing. Even though tight control of serum glucose has been associated with better outcomes, there is risk associated with the therapy. Hypoglycemia is a serious risk with insulin; the drug has multiple other effects that remain poorly described.

Evidence is limited to support glycemic control to a "normal" range of 80 to 110 mg per dL in the operating room. Higher targets minimize hypoglycemia. Levels higher than 180 mg per dL should be avoided, in part, because of protein glycation and osmotic diuresis above this level. Targets within the range of 100 to 180 mg per dL are considered satisfactory.

Preoperative infusion of dextrose minimizes peripheral insulin resistance and reduces the risk of hypoglycemia. When it results in hyperglycemia, it increases the amount of insulin needed. Given that insulin resistance and hyperglycemia are parts of the stress response to surgery, hyperglycemia may be a sign that exogenous carbohydrate infusion is not necessary.

Lipshutz AKM, Gropper MA. Perioperative glycemic control. *Anesthesiology* 2009;110:408–421.

B.6. How would you premedicate this patient?

Concerns with premedication include sensitivity to sedatives and aspiration risk. Pre-existing cardiovascular, cerebrovascular, and renal disease temper the aggressiveness of administration of benzodiazepines and opioids. Because of the symptoms of gastroesophageal reflux and gastroparesis, histamine blockers, liquid antacids, or metoclopramide may be given. Metoclopramide, famotidine, and a liquid antacid such as sodium citrate will minimize aspiration risk in this patient.

C. Intraoperative management

C.1. What are the effects of anesthesia and surgery on insulin and glucose metabolism?

As part of the stress response to surgery, metabolism increases and resistance develops to the hypoglycemic effects of insulin. The response includes the mobilization of protein stores (mostly muscle), more hepatic gluconeogenesis, and greater breakdown and synthesis of triglycerides. Hormones, including catecholamines, cortisol, glucagon, and even insulin, contribute to the metabolic changes. Although glucose metabolism increases, production of glucose also increases, adding to the risk of hyperglycemia. Administration of exogenous dextrose can exacerbate hyperglycemia in patients with diabetes patients.

Anesthetic techniques influence metabolism, but generally to a lesser extent than the stress from surgical injury. Techniques that mitigate stress hormones, such as neuraxial anesthesia, also may mitigate hyperglycemia. Some drugs effect regulatory hormones directly. Etomidate blocks cortisol synthesis. Benzodiazepines can decrease cortisol secretion. Halogenated agents have in vitro effects on insulin secretion. Nevertheless, none of these effects have an impact on postoperative glycemic control as much as will the surgery itself.

McAnulty GR, Robertshaw HJ, Hall GM. Anaesthetic management of patients with diabetes mellitus. *Br J Anaesth*. 2000;85:80–90.

C.2. What anesthetic techniques would you employ?

Factors other than glycemic control may influence the choice of anesthetic technique in the patient with diabetes. Regional techniques should be chosen based on provider skill, patient preferences, and postoperative pain control. Techniques that speed the time to oral intake by reducing nausea or minimizing ileus make glycemic management easier postoperatively. For this reason, antiemetics and the spare use of opioids might be beneficial. Although not a contraindication to nerve blockade, peripheral neuropathy should be documented in a preoperative neurologic examination. Nerve injury from local anesthetics or abnormalities on neurologic examination may complicate postoperative management. Infection risk in patients with diabetes may be realized because of complications of regional techniques.

Sedated or anesthetized patients cannot complain of hypoglycemia symptoms in the same way unsedated patients can. Serum glucose is monitored regularly in all but the shortest cases.

In this patient, general endotracheal anesthesia with precautions to prevent aspiration, intravenous insulin titrated to a serum glucose of less than 180 mg per dL, and frequent blood glucose monitoring is a satisfactory choice.

Ljungqvist O, Nygren J, Soop M, et al. Metabolic perioperative management: novel concepts. *Curr Opin Crit Care.* 2005;11:295–299.

McAnulty GR, Robertshaw HJ, Hall GM. Anaesthetic management of patients with diabetes mellitus. *Br J Anaesth.* 2000;85:80–90.

C.3. How would you monitor this patient?

If preoperative evaluation reveals a risk for hemodynamic instability, cardiac ischemia, or congestive heart failure, added cardiovascular monitoring should be considered, based on the nature of the procedure. Peripheral vascular disease can complicate placement of an arterial catheter, but is not a contraindication, because in patients who have cardiovascular comorbidities, the benefits of monitoring outweigh the risks.

Frequent glucose monitoring, by finger stick, or ideally, by venous or arterial sample, in cases lasting more than an hour is recommended when hypoglycemic agents are being used. Serum glucose should be measured at least every hour when giving intravenous insulin.

In this patient, pulse oximetry, continuous ECG monitoring, end-tidal carbon dioxide and gas analysis, and noninvasive blood pressure monitoring are satisfactory, if no further concerns arise from cardiovascular evaluation.

McAnulty GR, Robertshaw HJ, Hall GM. Anaesthetic management of patients with diabetes mellitus. *Br J Anaesth.* 2000;85:80–90.

C.4. How would you treat hyperglycemia intraoperatively?

The high end of a normal range for fasting serum glucose is 110 mg per dl, but hyperglycemia in inpatients may be at a higher level.

The one good agent for treating intraoperative hyperglycemia is intravenous insulin. Onset takes minutes, peak effect is achieved in 15 to 30 minutes, and duration of effect is less than an hour, facilitating titration. Insulin may be administered by continuous infusion or as intermittent boluses; the bolus consumes less lead time and eliminates the risk of pump misprogramming or malfunction. Subcutaneous insulin is less ideal for use during general anesthetics or complex procedures because

variable peripheral blood flow will alter the uptake and duration of action of insulin. Most other therapies for DM2 are not fit for intraoperative use. Oral agents cannot be easily administered, are not reliably absorbed, and have too long a duration of action to be practical perioperatively. They may be taken on the day of surgery before minor procedures. Metformin, a biguanide, increases the risk of lactic acidosis during periods of hypoperfusion. Metformin is discontinued for 3 or more days before extensive procedures when a large-volume blood loss is possible.

Smiley DD, Umpierrez GE. Perioperative glucose control in the diabetic or nondiabetic patient. *South Med J.* 2006;99:580–589.

C.5. How would you recognize and treat hypoglycemic shock intraoperatively?

Hypoglycemia can lead to tissue energy failure and has been associated with hemodynamic collapse and brain injury. Any patient receiving insulin, pramlintide, sitagliptin, or sulfonylureas is at risk for hypoglycemia. Because risk is usually known beforehand, hourly or more frequent monitoring of serum glucose should detect hypoglycemia. If glucose levels are low or decrease rapidly, the fastest treatment is a bolus of intravenous dextrose, 50% solution, administered slowly. In an emergency, one full ampule is the starting dose. In less urgent settings when the serum glucose level is low but not critical, smaller doses can be titrated to serum glucose values.

Dierdorf SF. Anesthesia for patients with diabetes mellitus. *Curr Opin Anaesthesiol.* 2002;15:351–357.

D. Postoperative Management

D.1. How would you control diabetes in this patient postoperatively?

Unless a change in disease status occurs as a consequence of surgery or preoperative care was inadequate, this patient should be transitioned back to her preoperative regimen. Before transitioning, she must recover from the stress response to the surgery. If this were a simple outpatient procedure, such as a cataract extraction, she could return home on her outpatient medication regimen. In this case, the effects of tissue injury may not peak for several days; diabetes control is thus a dynamic challenge. Regular monitoring of glucose is required (at a minimum checks should be made every 6 hours).

She is monitored for hyperglycemia, and her nutrition regimen is adjusted to serum glucose measurements. Hourly glucose measurements and glucose infusions can control hyperglycemia. Most patients can be effectively managed with subcutaneous insulin and less-frequent measurements. Insulin dose should take into account preoperative requirements, insulin resistance from the stress response, and caloric intake. Many patients receive intravenous dextrose postoperatively; if they are hyperglycemic on this regimen, dextrose is discontinued.

Oral diabetes medications can be reintroduced once the acute stress response begins to wane and the patient is cleared for a normal diet. Resumption of an oral diet can increase the risk of hyperglycemia, so ongoing monitoring is essential.

Smiley DD, Umpierrez GE. Perioperative glucose control in the diabetic or nondiabetic patient. *South Med J.* 2006;99:580–589.

D.2. Does diabetes increase perioperative risk?

Because patients with diabetes are at a greater risk for atherosclerosis, infection, autonomic and cardiovascular instability, and metabolic abnormalities than those without diabetes, perioperative risk is higher in this patient population. After surgery, the diabetic patient is monitored for hyperglycemia and hypoglycemia, ischemic complications, circulatory compromise, and wound and nosocomial infection. As a group, patients with diabetes have an increased risk of complications and poor outcomes from complications.

Lipshutz AKM, Gropper MA. Perioperative glycemic control. *Anesthesiology*. 2009;110: 408–421.

D.3. What are the common postoperative complications you expect in a diabetic patient?

Hyperglycemia and hypoglycemia, wound infections, and organ ischemia are the most common and worrisome postoperative complications in patients with diabetes. After myocardial infarction or cerebrovascular accident, hyperglycemia is associated with a worse prognosis.

Smiley DD, Umpierrez GE. Perioperative glucose control in the diabetic or nondiabetic patient. *South Med J*. 2006;99:580–589.

D.4. Is it necessary to achieve tight perioperative control of glucose?

In the critical care setting, there is evidence for improved outcomes with tight glycemic control, variably defined as serum glucose between 80 and 120 mg per dL or higher, as well as evidence of no benefit or even harm. Some advocate for tight glycemic control in cardiac and noncardiac surgery. The risk of hypoglycemia and data from more recent studies have tempered the enthusiasm for tight glycemic control.

Potential benefits from tight glycemic control include improvement in metabolic, anti-inflammatory, organ, and circulatory function. Unfortunately, there is little evidence to suggest these benefits are substantial perioperatively. Unresolved issues are the best time for tight control, the goals of therapy, the effect of nutrition, and the magnitude and factors in the potential for significant hypoglycemia. The patient is transitioned to her preoperative level of control during recovery, and severe hyperglycemia is avoided by monitoring glucose closely. Glucose levels above 180 mg per dL increase the risk of protein glycation and osmotic diuresis; targeting serum glucose below this value makes physiologic sense.

SECTION VI

The Genitourinary System

CHAPTER 24

Transurethral Resection of the Prostate

Jerome F. O'Hara, Jr., Mauricio Perilla, Vinod Malhotra, and Fun-Sun F. Yao

A 79-YEAR-OLD MAN

with benign prostatic hypertrophy was scheduled for transurethral resection of the prostate (TURP). His past medical history includes myocardial infarction (MI) 7 months ago requiring drug-eluting coronary stent placement and an implantable cardioverter-defibrillator (ICD) inserted for episodes of ventricular tachycardia. His current left ventricular ejection fraction is 25%. The patient is taking diuretics, a β-blocker, ticlopidine (an antiplatelet agent), aspirin, and an angiotensin-converting enzyme (ACE) inhibitor. Medical assessment advice was to continue platelet therapy for 1 year postcardiac stent.

A. Medical Disease and Differential Diagnosis

1. Are there differences in morbidity and mortality rates between TURP and suprapubic or retropubic prostatectomy?
2. What chronic medical conditions are common in patients who have undergone TURP?
3. Does a history of prior MI increase the patient's risk of perioperative reinfarction?
4. In patients with a history of recent MI, would you recommend that the surgery be postponed for a certain period? If so, why? If not, why not?

B. Preoperative Evaluation and Preparation

1. How would you evaluate the patient's cardiac condition? What additional tests would you have liked to order? Would you recommend that the patient undergo coronary angiography before surgery? Explain.
2. Are patients with a Q-wave infarction at greater risk of reinfarction than those with a non–Q-wave infarction? If so, why? If not, why not?
3. Would you discontinue any antihypertensives or any medications for angina? Why or why not?
4. For a patient with an ICD, what information should you know? What precautions should be taken?
5. What types of coronary stents are available? What is their perioperative relevance?
6. What is the conventional recommendation for antiplatelet therapy in a patient with previous percutaneous coronary intervention (PCI) undergoing noncardiac surgery?
7. What risk is associated with perioperative antiplatelet therapy?
8. How should patients with coronary stents undergoing noncardiac surgery be approached?

C. Intraoperative Management

1. What monitors would you use for this patient?
2. What anesthetic technique is preferable for patients undergoing TURP, and why?
3. Does regional anesthesia result in a lower incidence of perioperative mortality than general anesthesia? Whether yes or no, explain why or why not.
4. What intravenous fluid would you use during TURP?
5. Forty minutes after a sensory level of T-10 was established with intrathecal anesthesia, and monopolar TURP resection was initiated with the use of glycine as the bladder irrigating solution, the patient becomes agitated and complains of nausea. Further sedation along with an antiemetic are administered. However, shortly thereafter, the patient becomes very restless, blood pressure rises, and heart rate decreases. The patient becomes cyanotic and obtunded, blood pressure precipitously falls, pupils are dilated and unresponsive to light. What is the most likely cause of these signs and symptoms, and would these occur during bipolar or laser TURP resection?
6. What are the important characteristics of irrigation solutions used during TURP?
7. Why is plain distilled water rarely used for irrigation during TURP? What types of irrigation solutions are available?
8. What is the effect on body temperature of continuous bladder irrigation during TURP?
9. What is the definition of TURP syndrome? What are the signs and symptoms of the syndrome?
10. How can hyponatremia occur if the bladder irrigating fluid is not absorbed via the prostatic vessels?
11. How does the patient absorb irrigation solution during TURP? How much irrigation solution is typically absorbed?
12. How can one estimate the volume of irrigation solution absorbed during TURP?
13. What is the relation between the duration of surgery and the incidence of TURP syndrome?
14. What factors increase the incidence of TURP syndrome?

15. What is the effect on cardiopulmonary, renal, and central nervous system (CNS) functions of excessive absorption of irrigation solution during TURP?
16. What causes CNS dysfunction in patients who have undergone TURP?
17. What is the physiologic role of sodium ions in the body? What is the effect of excessive absorption of irrigation solution on serum sodium level?
18. What is the relation between serum sodium level and the incidence of neurologic symptoms in patients who have undergone TURP?
19. How does acute hyponatremia affect the cardiovascular system?
20. What prophylactic measures may reduce the incidence of TURP syndrome?
21. What therapeutic measures are recommended for patients with TURP syndrome?
22. Is normal saline administration always necessary to correct hyponatremia? Explain. What are the risks of rapidly correcting hyponatremia?
23. What are the toxic effects of glycine? Is there an antidote to glycine toxicity? What are the metabolic byproducts of glycine?
24. What are the symptoms and clinical course of TURP-induced hyperammonemia?
25. Why do some patients who have undergone TURP develop hyperammonemia and others do not? Is there a preventive treatment for hyperammonemia in these patients?
26. What are the clinical characteristics, causes, and prognosis of TURP-related blindness?
27. What gynecologic procedure has been associated with a syndrome similar to TURP syndrome?
28. What are the causes of excessive bleeding during TURP?
29. What triggers disseminated intravascular coagulopathy in patients undergoing TURP? How would you treat it?
30. What are the causes, signs, symptoms, and treatment of bladder perforation during TURP?
31. What are the causes, signs, symptoms, and preventive measures for bladder explosion during TURP?
32. What are the causes of hypotension during TURP?

D. Postoperative Management

1. What is the source of postoperative bacteremia in patients who have undergone TURP? What factors increase the incidence of bacteremia?
2. What are the signs of post-TURP septicemia? What preventive measures are generally recommended?
3. What bacteria-related cause may possibly lead to sudden postoperative shock in patients who have undergone TURP?
4. Is postoperative hypothermia a risk factor for myocardial ischemia?
5. How would you diagnose perioperative MI?

E. Comparing Monopolar, Bipolar, and Laser TURP

1. What differentiates monopolar from bipolar TURP?
2. Are decreased morbidity and mortality associated more closely with monopolar TURP than with bipolar TURP?
3. What differentiates the technologies for laser TURP?

F. Are There Preferred Anesthetic and Preferred Surgical TURP Techniques for This Patient?

A. Medical Disease and Differential Diagnosis

A.1. Are there differences in morbidity and mortality rates between TURP and suprapubic or retropubic prostatectomy?

Many urologists and prostate surgeons consider TURP to be a simpler and safer procedure than "open" prostatectomy. However, despite many improvements in anesthesia and surgery, 7% of patients who have undergone TURP sustain major complications and approximately 1% die perioperatively. On the other hand, no differences have been observed in mortality rates between patients who have undergone TURP and those who have undergone retropubic or suprapubic prostatectomy.

Malhotra V. Transurethral resection of prostate. *Anesthesiol Clin North America.* 2000;18: 883–897.

A.2. What chronic medical conditions are common in patients who have undergone TURP?

TURP patients often are elderly and suffer from cardiac, pulmonary, vascular, and endocrinologic disorders. The incidence of cardiac disease is 67%; cardiovascular disease, 50%; abnormal electrocardiogram (ECG), 77%; chronic obstructive pulmonary disease, 29%; and diabetes mellitus, 8%. Occasionally, these patients are dehydrated and depleted of essential electrolytes because of long-term diuretic therapy and restricted fluid intake.

Gravenstein D. Transurethral resection of the prostate (TURP) syndrome: a review of the pathophysiology and management. *Anesth Analg.* 1997;84:438–446.

Malhotra V. Transurethral resection of prostate. *Anesthesiol Clin North Am.* 2000;18:883–897.

A.3. Does a history of prior MI increase the patient's risk of perioperative reinfarction?

Yes, a history of prior MI or ischemic heart disease is considered an intermediate predictor of perioperative cardiac morbidity; but conditions like unstable coronary syndrome, severe angina, or recent MI indicate major clinical risks. Also see Chapter 13, Section A.1.

A.4. In patients with a history of recent MI, would you recommend that the surgery be postponed for a certain period? If so, why? If not, why not?

An acute MI (7 days or less), or a recent MI (more than 7 days but less than or equal to 1 month), is considered an event requiring evaluation to determine if there is residual myocardium at risk. The stratification is based on the presentation of the disease; patients with active ischemia are at highest risk. Therefore, it seems prudent to wait at least 6 weeks after an MI before surgery is performed, although no evidence supports this precaution. Also see Chapter 13, Secton A.6.

Fleisher LA, Beckman JA, Brown KA, et al. ACC/AHA 2007 Guidelines on perioperative cardiovascular evaluation and care for noncardiac surgery: a report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines (Writing Committee to Revise the 2002 Guidelines on Perioperative Cardiovascular Evaluation for Noncardiac Surgery). *Circulation.* 2007;116:e418–e499.

B. Preoperative Evaluation and Preparation

B.1. How would you evaluate the patient's cardiac condition? What additional tests would you have liked to order? Would you recommend that the patient undergo coronary angiography before surgery? Explain.

The American College of Cardiology/American Heart Association guidelines suggest a stepwise approach that takes into account the clinical markers of cardiac risk, functional capacity, and surgery risk. The patient's medical history should focus on information about previous cardiac evaluations and interventions (coronary stent and automatic implantable cardioverter-defibrillator [AICD] placement). During physical examination of all organ systems, attention should be paid to the circulatory functions, especially in the presence of active cardiac conditions such as unstable coronary syndromes, decompensated congestive heart failure (CHF), significant arrhythmias, or severe valvular disease. The functional capacity of the patient is best evaluated by the activity history. Minimally, a routine ECG and chest radiograph should be obtained. If the patient presents signs and symptoms of CHF, angina, syncope, or arrhythmia, further cardiac testing should be considered if the results would impact the patient's management. Traditional indications for coronary angiography apply regardless of future surgical interventions.

Fleisher LA, Beckman JA, Brown KA, et al. ACC/AHA 2007 Guidelines on perioperative cardiovascular evaluation and care for noncardiac surgery: a report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines (Writing Committee to Revise the 2002 Guidelines on Perioperative Cardiovascular Evaluation for Noncardiac Surgery). *Circulation.* 2007;116:e418–e499. doi:10.1161/CIRCULATIONAHA.107.185699

B.2. Are patients with a Q-wave infarction at greater risk of reinfarction than those with a non–Q-wave infarction? If so, why? If not, why not?

Recent studies suggest that patients who survive a non–Q-wave infarction are at greater risk of reinfarction than those who survive a Q-wave infarction.

Antman EM, Braunwald E. ST-elevation myocardial infarction; pathology, pathophysiology and clinical features. In: Zipes D, Libby P, Bonow R, et al., eds. *Braunald's Heart Disease, A Textbook of Cardiovascular Medicine.* 7th ed. Philadelphia: WB Saunders; 2005:1141–1166.

Priebe HJ. Perioperative myocardial infarction—aetiology and prevention. *Br J Anaesth.* 2005;95:3–19.

B.3. Would you discontinue any antihypertensives or any medications for angina? Why or why not?

Antianginal agents and β-blockers should be continued until the day of the surgery to prevent rebound hypertension and tachycardia that may result from sudden withdrawal of these drugs. Patients taking ACE inhibitors or angiotensin II receptor antagonists might present intraoperative hypotension due to a decrease of intravascular volume. It has been suggested that ACE inhibitors or angiotensin II receptor antagonists be withheld on the day before surgery and readministered after adequate intravascular volume has been established in order to avoid renal dysfunction.

Fleisher LA, Beckman JA, Brown KA, et al. 2009 ACCF/AHA focused update on perioperative beta blockade incorporated into the ACC/AHA 2007 guidelines on perioperative cardiovascular evaluation and care for noncardiac surgery: a report of the American College of Cardiology Foundation/American Heart Association Task Force on Practice Guidelines 2007. *Circulation.* 2009;120:e169–e276.

B.4. For a patient with an ICD, what information should you know? What precautions should be taken?

Patients undergoing surgery with ICD need to be evaluated by the device clinic before surgery. Recent and accurate information should be collected about the device's features, the date of insertion, and the indication for placement. On the day of surgery, the device should be assessed for settings, pace dependency, baseline rhythm and rate, tachyarrhythmia history, effect of magnet, and battery status.

In the event of potential electromagnetic interference, the antitachycardia algorithm of the ICD should be turned off and external cardioversion paddles should be placed until the device is set to its initial functions after the procedure. Also see Chapter 7, sections B and C.

Practice Advisory for the Perioperative Management of Patients with Cardiac Implantable Electronic Devices: Pace makers and Implantable Cardioverter-Defibrillators: an updated report by the American Society of Anesthesiologists task force on perioperative management of patients with cardiac implantable electronic devices. *Anesthesiology.* 2011;114:247–261.

B.5. What types of coronary stents are available? What is their perioperative relevance?

Percutaneous coronary intervention (PCI) is a common procedure in the United States. Coronary stent placement was introduced in order to reduce the risk of thrombosis, dissection, and restenosis after angioplasty. Two types of coronary stents have been used: bare metal stents (BMS) and drug-eluting stents (DES). Two types of drug-eluting stents—sirolimus and plaquitaxel-eluting stents—have been used extensively to reduce the neointimal hyperplasic reaction seen with the use of BMS, which is the main cause of restenosis. Emerging evidence suggested that DES inhibited or delayed the endothelization of coronary stent struts. Patients with DES are at risk for late thrombosis if the antiplatelet therapy is prematurely interrupted.

Grines CL, Bonow RO, Casey DE Jr., et al. Prevention of premature discontinuation of dual antiplatelet therapy in patients with coronary artery stents: a science advisory from the American Heart Association, American College of Cardiology, Society for Cardiovascular Angiography and Interventions, American College of Surgeons, and American Dental Association, with representation from the American College of Physicians. *J Am Coll Cardiol.* 2007;49:734–739.

B.6. What is the conventional recommendation for antiplatelet therapy in a patient with previous percutaneous coronary intervention (PCI) undergoing noncardiac surgery?

Therapy with thienopyridines (ticlopidine or clopidrogel) and aspirin is recommended for 2 to 4 weeks after dilatation without stenting; surgery should be

postponed for 2 to 4 weeks. After BMS, antiplatelet therapy for 4 to 6 weeks is recommended; elective surgery should be postponed for 4 to 6 weeks. After the implantation of DES, at least 12 months of antiplatelet therapy is required; elective surgery should be delayed for 12 months. In patients with an indication of PCI and a projected elective surgery within the next 12 months, a balloon angioplasty or BMS may be considered. In general, daily aspirin should be continued during the perioperative period, but in the case of TURP, the risk of bleeding complications must be balanced against the risk of stent thrombosis, MI, and cardiac death (rebound effect). It may be noted, however, that continuation of aspirin is not a contraindication to neuraxial anesthesia. For more details, see Chapter 9, section A.5 and Figures 9.1 and 9.2.

Popescu WM. Perioperative management of the patient with a coronary stent. *Curr Opin Anaesthesiol*. 2010;23:109–115.

B.7. What risk is associated with perioperative antiplatelet therapy?

The results of studies on the risk of surgical bleeding with aspirin are inconsistent. In Burger's review and meta-analysis (aspirin withdrawal vs. low-dose aspirin), the low-dose group's relative risk of bleeding increased by a factor of 1.5, but there was no increase in bleeding complications or in perioperative mortality, with the possible exceptions of intracranial surgery and prostatectomy. Studies with ticlopidine or clopidrogel are also contradictory. Although some data support increased risk of major perioperative bleeding with dual-antiplatelet therapy (0.4% to 1%), there is no consensus regarding withholding thienopyridines. The risk of perioperative bleeding must be balanced against protection from a coronary event.

Fleisher LA, Beckman JA, Brown KA, et al. 2009 ACCF/AHA focused update on perioperative beta blockade incorporated into the ACC/AHA 2007 guidelines on perioperative cardiovascular evaluation and care for noncardiac surgery: a report of the American College of Cardiology Foundation/American Heart Association Task Force on Practice Guidelines. *Circulation*. 2009;120:e169–e276.

Howard-Alpe GM, de Bono J, Hudsmith L, et al. Coronary artery stents and non-cardiac surgery. *Br J Anaesth*. 2007;98:560–574.

B.8. How should patients with coronary stents undergoing noncardiac surgery be approached?

The preoperative evaluation of patients with coronary stents should include information regarding the date of stent placement, the coronary anatomy before the intervention, the type of coronary stent, the localization of the intervention, complications (if any) during the procedure, the residual anatomy after the intervention (e.g., possibility of incomplete

revascularization), and the antiplatelet strategy. Multidisciplinary discussions regarding how the risk of bleeding compares with the risk of coronary stent thrombosis are strongly encouraged. The most recently published *Practice Alert* indicates, "Elective surgery with a significant risk of bleeding should be postponed until the recommended course of thienopyridine therapy has been completed." For bare-metal coronary stents, postponement of 4 to 6 weeks is recommended, and for drug-eluting coronary stents, 12 months of postponement. If surgery must be performed and if thienopyridine therapy must be interrupted (surgery with high risk of perioperative bleeding), aspirin should be continued and thienopyridine should be readministered as soon as possible after the procedure. Bridge therapies have been proposed for patients who undergo surgical procedures, but this practice has not been shown to reduce the risk of thrombosis. Currently, continuing double antiplatelet therapy is recommended in patients with DES for surgery with minor or intermediate risk of perioperative bleeding. *A careful "case-by-case" consideration is advisable. Discussion between the anesthesiologist, the surgeon, and the treating cardiologist is recommended.* For more details, see Chapter 9, section A.5 and Figures 9.1 and 9.2.

C. Intraoperative Management

C.1. What monitors would you use for this patient?

The following monitors would be used for this patient:

- American Society of Anesthesiologists standard monitors, including multiple-lead ST-segment analysis
- Temperature
- Direct arterial blood pressure
- Transesophageal echocardiography or esophageal cardiac output probe if general anesthesia is planned.

C.2. What anesthetic technique is preferable for patients undergoing TURP, and why?

Regional anesthesia is assumed to be the best anesthetic technique for patients undergoing monopolar electrode TURP for the following reasons:

- It allows monitoring of the patient's mentation, thereby facilitating early detection of signs of TURP syndrome.
- It promotes vasodilation and peripheral pooling of blood, thereby reducing the severity of circulatory overloading.
- It reduces blood loss by lowering blood pressure during surgery.
- It provides postoperative analgesia, thereby reducing the incidence of postoperative hypertension and tachycardia, which often accompanies recovery from general anesthesia.

- Currently, less emphasis is placed on regional anesthesia (vs. general anesthesia) for TURP because of the increased use of bipolar electrode and laser resection surgical techniques.
- Regional anesthesia may not be a safe option in an anticoagulated patient.

C.3. Does regional anesthesia result in a lower incidence of perioperative mortality than general anesthesia? Whether yes or no, explain why or why not.

Although spinal anesthesia offers distinct advantages over general anesthesia for TURP surgery, mortality and many markers of patient outcome have been similar for both groups. The 30-day mortality rate associated with TURP was reported to be between 0.4% and 2.5% in 2000 and was dependent on the age of the patient. Mortality rates are reported to be similar in patients receiving regional anesthesia or general anesthesia. Increased morbidity was found in patients with resections exceeding 90 minutes, gland size greater than 45 g, acute urinary retention, and age older than 80 years. The incidence of postoperative complications, specifically MI, pulmonary embolism, cerebrovascular accidents, transient ischemic attacks, renal failure, hepatic insufficiency, and the need for prolonged ventilation, is similar in patients receiving regional anesthesia and those receiving general anesthesia. More recently, with the use of bipolar electrode and laser TURP resection surgical techniques, it is believed that mortality rates will likely decline.

C.4. What intravenous fluid would you use during TURP?

Because dilutional hyponatremia commonly occurs in patients undergoing monopolar electrode TURP, the intravenous fluid of choice perioperatively is normal saline that contains sodium, 154 mEq per L. It is important to remember, however, that circulatory overloading from absorbed irrigant is common in patients who have undergone monopolar or bipolar electrode TURP (but not laser TURP); therefore, the amount of intravenous fluid administered during surgery should be carefully monitored.

C.5. Forty minutes after a sensory level of T-10 was established with intrathecal anesthesia, and monopolar TURP resection was initiated with the use of glycine as the bladder irrigating solution, the patient becomes agitated and complains of nausea. Further sedation along with an antiemetic are administered. However, shortly thereafter, the patient becomes very restless, blood pressure rises, and heart rate decreases. The patient becomes cyanotic and obtunded, blood pressure precipitously falls, pupils are dilated and unresponsive to light. What is the most likely cause of these signs and symptoms, and would these occur during bipolar or laser TURP resection?

Restlessness and incoherence during TURP are particularly ominous signs of TURP syndrome. These are often caused by subtle pulmonary edema, hypoxemia, and cerebral edema. These signs must not be misinterpreted as signs of inadequate anesthesia. The administration of sedatives or general anesthesia in the presence of TURP syndrome is often fraught with severe complications, even death. In bipolar and laser TURP, normal saline can be used as the bladder irrigating solution and hyponatremia is not expected. In bipolar TURP, absorption of the intravascular bladder irrigating solution can occur via the prostatic venous sinusis, but is not expected in laser TURP.

C.6. What are the important characteristics of irrigation solutions used during TURP?

Ideal TURP irrigation solutions are either isotonic or nearly isotonic, electrically inert, nontoxic, and transparent. Electrolyte-containing solutions are avoided in monopolar electrode TURP because they can conduct electrical current to surrounding tissues and cause burns. Because significant absorption of bladder irrigating solution can occur during TURP, only solutions with nontoxic solutes are used. The solution must be transparent to allow the surgeon to visualize the surgical site. If intravascular hypotonic bladder irrigating solution is absorbed, absorption can lead to hyponatremia, hypoosmolality, and, in severe cases, hemolysis. These complications are avoided when normal saline is used with bipolar electrode and laser resection TURP.

Malhotra V. Transurethral resection of prostate. *Anesthesiol Clin North America*. 2000;18: 883–897.

C.7. Why is plain distilled water rarely used for irrigation during TURP? What types of irrigation solutions are available?

Although distilled water is totally transparent and electrically inert and was regularly used decades ago for irrigation during monopolar TURP, it is extremely hypotonic. Therefore, when it is absorbed, it may cause hemolysis, shock, and renal failure.

Over the years, a number of isotonic and nearly isotonic irrigation solutions have been introduced and they have almost totally replaced plain distilled water. The most commonly used solution is currently glycine (1.2% and 1.5%). Mannitol (3%), glucose (2.5% to 4%), Cytal (a mixture of sorbitol 2.7% and mannitol 0.54%), and urea (1%) solutions are also occasionally used. For maintenance of their transparency, these solutions are purposely prepared moderately hypotonic. Sterile water and glycine have been used as the bladder irrigation solution in laser resection TURP because they are minimally absorbed, but TURP syndrome has been reported when bladder perforation or urethral trauma occurred.

Miller RD, Eriksson LI, Fleisher MD, et al. *Miller's Anesthesia* 7th ed. Philadelphia: Churchill Livingstone; 2010:2119–2123.

C.8. What is the effect on body temperature of continuous bladder irrigation during TURP?

Several liters of irrigation solution pass through the bladder during TURP. This can reduce body temperature at the rate of 1° C per hour (Fig. 24.1). Approximately half the patients undergoing TURP become hypothermic and shiver at the conclusion of surgery.

Barash PG, Cullen BF, Stoelting RK, eds. *Clinical Anesthesia*. 6th ed. Philadelphia: Lippincott Williams & Wilkins; 2009:1365–1368.

Malhotra V. Transurethral resection of prostate. *Anesthesiol Clin North America*. 2000;18: 883–897.

Miller RD, Eriksson LI, Fleisher MD, et al. *Miller's Anesthesia*. 7th ed. Philadelphia: Churchill Livingstone; 2010:2119–2123.

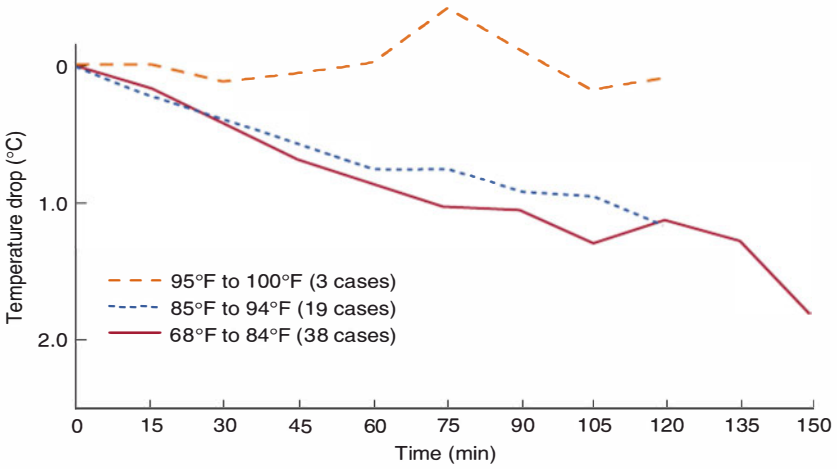

Figure 24.1 The decrease in body temperature during transurethral resection of the prostate (TURP) is related to the temperature of the irrigating solution and to the duration of surgery. (From Allen TD. Body temperature changes during prostatic resection as related to the temperature of the irrigating solution. *J Urol.* 1973;110:433–535, with permission.)

C.9. What is the definition of TURP syndrome? What are the signs and symptoms of the syndrome?

Rapid absorption of a large-volume, mainly hypotonic bladder irrigation solution during TURP can lead to TURP syndrome. TURP syndrome is characterized by intravascular volume shifts and plasma-solute (osmolarity) effects. The signs and symptoms of TURP syndrome are as follows:

Cardiopulmonary

Hypertension
Bradycardia
Dysrhythmia
Respiratory distress
Cyanosis
Hypotension
Shock
Death

Hematologic and renal

Hyperglycinemia
Hyperammonemia
Hyponatremia
Hypoosmolality
Hemolysis/anemia
Acute renal failure
Death

Central nervous system

Nausea/vomiting
Confusion/restlessness

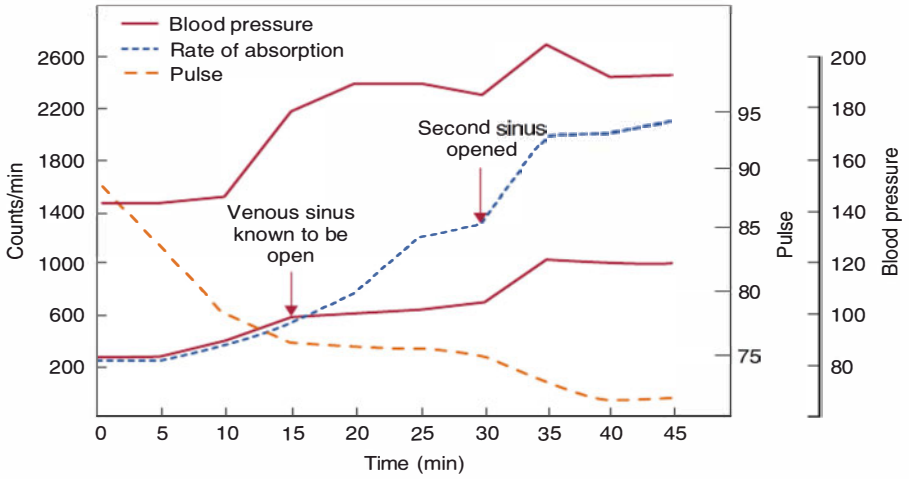

Figure 24.2 The blood pressure, heart rate, and absorption rate of radioactively tagged irrigation solution during transurethral resection of the prostate. (From Taylor RO, Maxson ES, Carter FH, et al. Volumetric gravimetric and radioisotopic determination of fluid transference in transurethral prostatectomy. *J Urol.* 1958;79:490–499, with permission.)

Blindness
Twitches/seizures
Lethargy/paralysis
Dilated/nonreactive pupils
Coma
Death

TURP syndrome can occur as early as a few minutes after surgery has started and as late as several hours after surgery. Patient complaints of dizziness, headache, nausea, chest or throat tightness, and shortness of breath are often early clinical signs. Then the patient becomes restless, confused, and starts to retch. Some patients complain of abdominal pain. The blood pressure often rises (both systolic and diastolic), and the heart rate decreases (Fig. 24.2). If not treated promptly, the patient becomes cyanotic and hypotensive and ultimately sustains cardiac arrest.

Occasionally, TURP syndrome manifests as neurologic signs. The patient becomes lethargic, then unconscious; and pupils dilate, reacting sluggishly to light. These signs may be followed by short episodes of tonic–clonic seizures and then coma lasting from minutes to hours.

If the patient is under general anesthesia, the presenting signs of TURP syndrome are typically a rise and then a fall in blood pressure, decreasing oxygen saturation, and severe refractory bradycardia. The ECG may show nodal rhythm, ST-segment changes, U waves, and widening of the QRS complex. Recovery from general anesthesia is usually delayed.

C.10. How can hyponatremia occur if the bladder irrigating fluid is not absorbed via the prostatic vessels?

If the complication of bladder perforation occurs, significant accumulation of irrigating fluid in the intraperitoneal or extraperitoneal (retroperitoneal) space can occur, resulting in significant intravascular absorption of a hypotonic irrigating solution and ultimately hyponatremia syndrome.

Dorotta I, Basali A, Ritchey M, et al. Transurethral resection syndrome after bladder perforation. *Anesth Analg*. 2003;97:1536–1568.

C.11. How does the patient absorb irrigation solution during TURP? How much irrigation solution is typically absorbed?

The bladder irrigation solution enters the bloodstream directly through open prostatic venous sinuses created during monopolar and bipolar resection techniques, and it accumulates in the periprostatic and retroperitoneal spaces. The latter accumulation occurs primarily when the prostatic capsule is violated during surgery.

Reports in the literature suggest that as many as 8 L of irrigation solution can be absorbed by the patient during TURP. The average rate of absorption is 20 mL per minute and may reach 200 mL per minute; the average weight gain by the end of surgery is 2 kg (Fig. 24.3). A very thin resection "zone" combined with a coagulating benefit during laser TURP prevents significant opening of the prostatic venous sinuses and absorption of the irrigating solution.

C.12. How can one estimate the volume of irrigation solution absorbed during TURP?

A practical method for estimating the absorbed volume of irrigation solution during TURP is based on the following equation:

$$\text{Volume absorbed} = \frac{\text{preoperative } [Na^+]}{\text{postoperative } [Na^+]} \times \text{extracellular fluid} - \text{extracellular fuild}$$

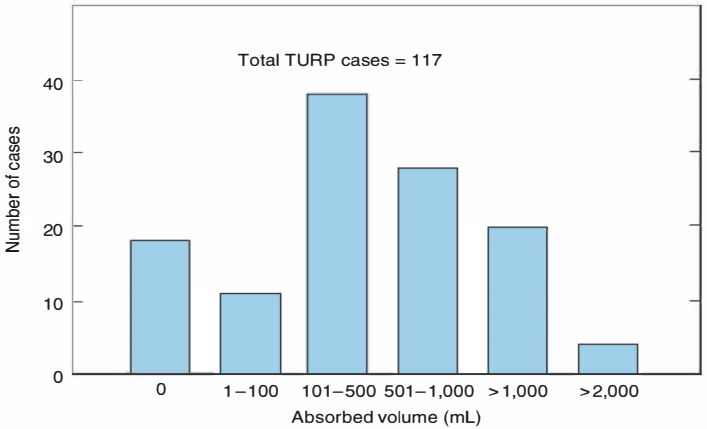

Figure 24.3 The volume of irrigation solution absorbed during transurethral resection of the prostate. (From Madsen PO, Madsen RE. Clinical and experimental evaluation of different irrigating fluids for transurethral surgery. *Invest Urol.* 1965;3:122–129, with permission.)

To use this equation, serum sodium level ($[Na^+]$) is determined at the beginning of surgery and again at the time when the volume absorbed is estimated. The extracellular fluid (ECF) volume is assumed to be 20% to 30% of body weight. For example, if the patient's preoperative body weight is 60 kg and the ECF is assumed to constitute 20% of the patient's body weight, then a decrease in serum sodium level from 140 to 100 mEq per L would suggest an absorption of 4.8 L:

$$140/100 \times ECF - ECF = 1.4\ ECF - ECF = 0.4\ ECF = 0.4 \times 60 \times 20\% = 4.8L$$

C.13. What is the relation between the duration of surgery and the incidence of TURP syndrome?

Many believe that the duration of surgery is the most important determinant in the incidence of TURP syndrome. However, several studies report severe TURP syndrome occurring as early as 15 to 20 minutes after surgery has started. In general, a poor correlation has been observed between the duration of surgery and the amount of irrigation solution absorbed. In a large series, morbidity and mortality of patients undergoing TURP did not correlate with length of surgery, except when surgery lasted more than 150 minutes. Similarly, the incidence and severity of hyponatremia did not correlate with the duration of surgery.

Miller RD, Eriksson LI, Fleisher MD, et al. *Miller's Anesthesia.* 7th ed. Philadelphia: Churchill Livingstone; 2010:2119–2123.

C.14. What factors increase the incidence of TURP syndrome?

TURP syndrome is more likely to occur if the prostatic gland is atypically large, the prostatic capsule is violated during surgery, or the hydrostatic pressure of the irrigation solution is excessively high. Large prostatic glands have rich venous networks that promote intravascular absorption of irrigation solution. The violation of the prostatic capsule during surgery promotes entry of irrigation solution into the periprostatic and retroperitoneal spaces. The hydrostatic pressure of the irrigation solution is an important determinant of the rate at which the patient will absorb the solution. This pressure depends primarily on the height of the irrigation solution pole. When the height of the pole exceeds 60 cm (~2 ft), the absorption of irrigation solution is greatly enhanced. Also, an excessively distended bladder during surgery facilitates absorption.

C.15. What is the effect on cardiopulmonary, renal, and central nervous system (CNS) functions of excessive absorption of irrigation solution during TURP?

Excessive absorption of irrigation solution during TURP causes hypervolemia and hypertension and may induce angina and pulmonary edema (Fig. 24.4). It may also have an adverse effect on renal function. An inverse relation has been observed between the amount of irrigation solution absorbed during surgery and postoperative urinary output.

Some patients with TURP syndrome exhibit neurologic signs resulting from water intoxication. They assume a decerebrate posture, exhibit clonus and positive Babinski reflex, and eventually convulse and lapse into coma. Examination of the eyes reveals papilledema and dilated and sluggishly reacting pupils. The electroencephalogram shows low voltage bilaterally. The patients may remain in a coma from a few hours to several days.

C.16. What causes CNS dysfunction in patients who have undergone TURP?

The crucial physiologic derangement of CNS function is not hyponatremia per se, but acute hypoosmolality, which is predictable because the blood–brain barrier is essentially

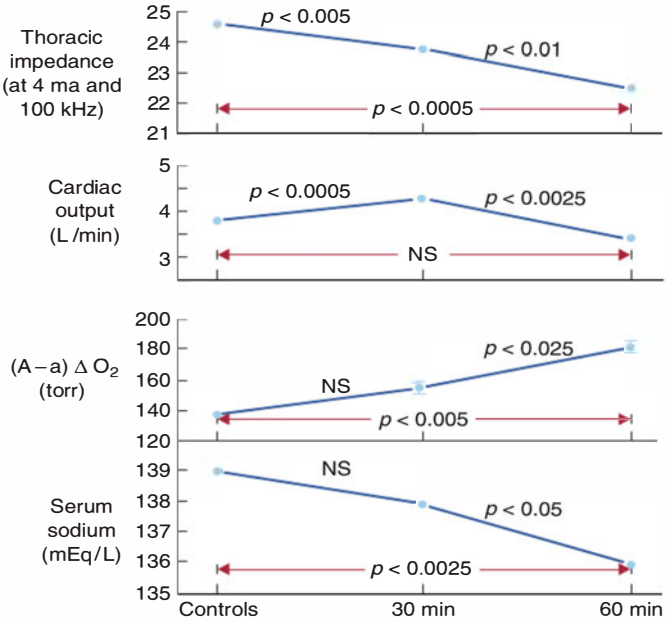

Figure 24.4 Mean changes in thoracic impedance, cardiac output, alveolar–arterial oxygen tension difference, and serum sodium level during transurethral resection of the prostate; NS = nonsignificant. (From Casthely P, Ramanathan S, Chalon J, et al. impermeable to sodium but freely permeable to water. Cerebral edema caused by acute hypoosmolality can increase intracranial pressure, which results in bradycardia and hypertension by the Cushing reflex. Furthermore, cerebral edema is not caused by decreased serum colloid oncotic pressure, but by decreased osmolality. Apparently, the hypervolemia and hyponatremia that often accompany TURP promote cerebral edema and this in turn raises intracranial pressure and induces neurologic symptoms. The rise in intracranial pressure is directly related to the gain in body weight during TURP.

C.17. What is the physiologic role of sodium ions in the body? What is the effect of excessive absorption of irrigation solution on serum sodium level?

Sodium is a ubiquitous electrolyte that is essential for proper function of excitatory cells, particularly those of the heart and brain. Extreme reduction in serum sodium level alters brain, cardiac, and renal functions.

During monopolar TURP, serum sodium level typically falls 3 to 10 mEq per L. However, the correlation between the severity of hyponatremia and the amount of irrigation solution absorbed during surgery is inconsistent. The fall in serum sodium level apparently depends primarily on the rate at which the irrigation solution is absorbed rather than on the total amount absorbed.

C.18. What is the relation between serum sodium level and the incidence of neurologic symptoms in patients who have undergone TURP?

Acute severe hyponatremia is often associated with abnormal neurologic symptoms, and it can lead to irreversible brain damage. The neurologic signs may be accompanied by electroencephalogram abnormalities such as loss of α-wave activity and irregular discharge of high-amplitude slow-wave activity. However, the correlation between the severity of the hyponatremia and the incidence of neurologic symptoms is inconsistent because hyponatremia may not be the sole or even primary cause of the neurologic manifestations of TURP syndrome. The crucial derangement of CNS function is not hyponatremia per se, but acute hypoosmolarity. In some cases, moderate hyponatremia is associated with severe neurologic symptoms; in others, severe hyponatremia manifests no symptoms at all. Apparently, the factor governing the manifestation of symptoms is the rate at which the serum sodium level falls rather than the total fall itself. The faster the fall in serum sodium level, the greater the incidence of neurologic symptoms. A slow fall in serum sodium level apparently allows the CNS to adapt to the hyponatremia.

C.19. How does acute hyponatremia affect the cardiovascular system?

When serum sodium level falls to less than 120 mEq per L, signs of cardiovascular depression can occur. A decrease of less than 115 mEq per L causes bradycardia, widening of the QRS complex, ST-segment elevation, ventricular ectopic beats, and T-wave inversion. Patients with a serum sodium level of less than 110 mEq per L can develop respiratory and cardiac arrest.

C.20. What prophylactic measures may reduce the incidence of TURP syndrome?

The incidence of TURP syndrome depends primarily on the surgeon's technical skills. However, if the patient is properly prepared before surgery and closely monitored during surgery, the incidence and severity of the syndrome can be reduced.

Fluid and electrolyte imbalance should be corrected preoperatively and special attention should be paid to the serum sodium especially in traditional monopolar electrode TURP. Patients with preoperative CHF should be treated vigorously with diuretics and fluid restriction. A conservative surgical approach should be considered for critically ill patients. A simple canalization or balloon dilation of the urethra or a staged TURP is less likely to induce TURP syndrome.

The most important preventive measure during surgery is preservation of the prostatic capsule. Another preventive measure is restriction of the hydrostatic pressure of the irrigation solution to 60 cm H_2O. This can be accomplished by maintaining the height of the irrigation pole to 60 cm (~2 ft) above patient level. Also, the bladder should not be allowed to overdistend and the duration of surgery should be restricted.

Serial serum sodium and osmolality are advisable in order to detect a decreasing trend. If clinical signs of TURP syndrome present, the surgeon should be informed and therapeutic measures immediately instituted. If serum sodium level approaches 120 mEq per L, surgery should be terminated as soon as possible.

Intravenous fluids should be cautiously administered during TURP. A microdrip is recommended particularly for patients with cardiac or renal disease. If regional anesthesia causes hypotension, a small dose of a vasoconstrictor is recommended to raise the blood pressure, rather than rapid infusion of intravenous fluids.

C.21. What therapeutic measures are recommended for patients with TURP syndrome?

When symptoms of TURP syndrome appear, the following therapeutic measures are recommended:

- Terminate surgery as soon as possible.
- Administer furosemide, 20 mg intravenously.
- Administer oxygen by nasal cannula or face mask to maintain oxygen saturation and consider intubation.
- Obtain arterial blood gas, serum osmolality, and sodium analysis.

- If the serum sodium level is abnormally low and clinical signs of hyponatremia are evident, intravenous administration of hypertonic saline (3% to 5%) may be recommended. The hypertonic solution should be given at a rate no faster than 100 mL per hour. In most cases, no more than 300 mL of saline is needed to correct the hyponatremia.
- If the patient develops seizures, a short-acting anticonvulsant such as diazepam (5 to 20 mg) or midazolam (2 to 10 mg) can be administered intravenously. If these drugs do not arrest the seizures, a barbiturate or phenytoin can be added. As a last resort, a muscle relaxant may also be used.
