- If pulmonary edema or hypotension develops, invasive hemodynamic monitoring is recommended. This will serve as a guide for pharmacologic support and fluid administration.
- If significant blood loss is suspected, the administration of packed red blood cells should be considered. In general, intravenous fluids should be administered cautiously because of the propensity of these patients to develop pulmonary edema.

C.22. Is normal saline administration always necessary to correct hyponatremia? Explain. What are the risks of rapidly correcting hyponatremia?

The administration of hypertonic saline to correct hyponatremia is not always necessary and sometimes can be detrimental. Unless the patient develops clinical signs of hyponatremia, saline administration is not recommended. Spontaneous or induced diuresis usually corrects the hyponatremia within a few hours.

Patients who have undergone TURP often sustain circulatory overloading during surgery; consequently, saline administration in these patients can induce pulmonary edema. In addition, rapid administration of hypertonic saline has been associated with central pontine myelinolysis (osmotic demyelination syndrome)—a poorly understood and fatal neurologic complication.

To reduce the hazards of saline administration, serum osmolarity should be monitored and corrected aggressively only until symptoms substantially subside; then hyponatremia should be corrected at a rate no faster than 1.5 mEq/L/hour.

C.23. What are the toxic effects of glycine? Is there an antidote to glycine toxicity? What are the metabolic byproducts of glycine?

Glycine is an inhibitory neurotransmitter similar to γ-aminobutyric acid in the spinal cord and brain. When absorbed by the patient in large amounts, glycine has direct toxic effects on the heart and retina. In patients who have undergone TURP with

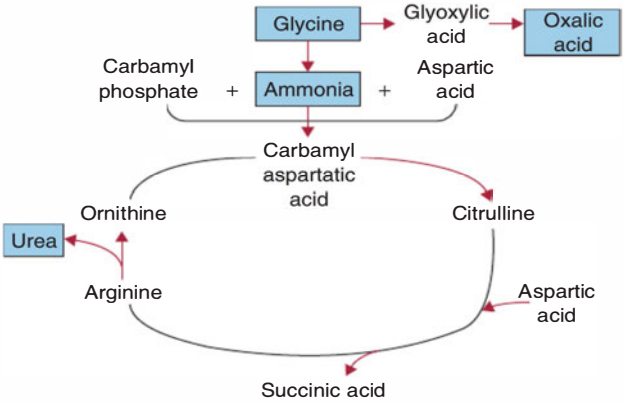

Figure 24.5 Metabolic pathways of glycine. (From McGilvery RW, Goldstein GW. *Biochemistry: A Functional Approach.* 3rd ed. Philadelphia: WB Saunders; 1983:584, with permission.)

glycine absorption, it has been shown to cause an average decrease of 17.5% in cardiac output. In animal studies, the administration of the amino acid arginine reversed the myocardial depressing effect of glycine. The mechanism by which glycine depresses cardiac function and the mechanism by which arginine protects the heart is unknown.

Hyperglycinemia may cause transient visual disturbance (blindness) during TURP. However, glycine toxicity in patients who have undergone TURP is uncommon, probably because most of the absorbed glycine is retained in the periprostatic and retroperitoneal spaces, where access to the circulation is limited.

The most common metabolites of glycine are ammonia and glyoxylic and oxalic acids (Fig. 24.5). In some patients, excessive absorption of glycine during TURP leads to hyperammonemia. Hyperoxaluria could compromise renal function in patients with coexisting renal disease, which is often present in elderly patients undergoing TURP.

Glycine may cause encephalopathy and seizures through its ability to potentiate the effects of *N*-methyl-D-aspartate, an excitatory neurotransmitter. Magnesium exerts a negative control on the *N*-methyl-D-aspartate receptor, and hypomagnesemia caused by dilution may increase the susceptibility to seizures. For this reason, a trial of magnesium therapy may be indicated in patients who develop seizures during TURP.

C.24. What are the symptoms and clinical course of TURP-induced hyperammonemia?

The signs and symptoms of hyperammonemia usually appear within 1 hour of surgery. Typically, the patient becomes nauseated, vomits, and then becomes comatose. Blood ammonia level rises to more than 500 mmol per L. The patient remains comatose for 10 to 12 hours and eventually awakens when ammonia blood level decreases to less than 150 mmol per L. The hyperammonemia tends to linger postoperatively, probably because glycine absorption from the periprostatic space continues after surgery.

Oester A, Madsen PO. Determination of absorption of irrigating fluid during transurethral resection of the prostate by means of radioisotope. *J Urol.* 1969;102:714–719.

C.25. Why do some patients who have undergone TURP develop hyperammonemia and others do not? Is there a preventive treatment for hyperammonemia in these patients?

Because ammonia is metabolized primarily in the liver, it has been speculated that hyperammonemia after TURP is a result of liver dysfunction. However, liver dysfunction has not been found in these patients. Further, there is no evidence that patients with a known liver dysfunction are susceptible to hyperammonemia after TURP.

A more plausible explanation for the hyperammonemia is arginine deficiency. Normally, the ornithine cycle in the liver converts ammonia to urea (see Fig. 24.5). Arginine is an important intermediate product of this cycle. Apparently, patients who have undergone TURP while having arginine deficiency cannot detoxify the excess ammonia produced from glycine metabolism, and they therefore develop hyperammonemia. The time necessary to deplete the endogenous arginine stores may be as brief as 12 hours, which approximates the preoperative fasting time.

Several studies support this hypothesis. In dogs, the administration of arginine concurrently with glycine reduced the secretion of ammonia by the liver (Fig. 24.6). In humans, prophylactic administration of arginine or ornithine prevents hyperammonemia that otherwise follows rapid intravenous administration of glycine. Routine administration of arginine in patients undergoing TURP, however, is not recommended because they rarely develop hyperammonemia.

C.26. What are the clinical characteristics, causes, and prognosis of TURP-related blindness?

Transient blindness is one of the more alarming complications of TURP. The patient complains of blurred vision and of seeing halos around objects. This can occur either during surgery or later in the recovery room. Although it is sometimes accompanied by other TURP-related complications, the blindness usually occurs as an isolated symptom. Examination of the eyes reveals dilated and unresponsive pupils. Postoperatively, TURP-related blindness gradually recedes and eyesight returns to normal within 8 to 48 hours of surgery.

The cause of TURP-related blindness is unclear. The intraocular pressure and optic discs remain normal. In the past, edema of the cerebral optical cortex was suspected; however, the clinical signs of TURP-related blindness are consistent with retinal rather than cortical dysfunction. Unlike cortical blindness, TURP-related blindness allows perception of light and the blink reflex is preserved. TURP-related blindness is most likely caused by a toxic effect of glycine on the retina. This theory is supported by the fact that glycine is a known inhibitory neurotransmitter. In animals, glycine has been shown to inhibit neuronal visual pathways. Also, the severity of TURP-related blindness is directly related to glycine blood level. Postoperatively, vision gradually improves as the glycine blood level declines.

C.27. What gynecologic procedure has been associated with a syndrome similar to TURP syndrome?

Hysteroscopy has been associated with symptoms not unlike those of TURP syndrome. The procedure involves visualization of the interior lining of the uterus for diagnostic purposes and, on occasion, for transcervical resection of the endometrium or submucous myomectomy. The latter often requires electrical cauterization. As with TURP, hysteroscopy requires irrigation with nonionic isotonic solutions. Commonly used solutions contain either glucose or glycine. Side effects such as hyponatremia, hyperglycemia, circulatory overloading, and coagulopathy have been reported.

Carson SA, Hubert GD, Schriock ED, et al. Hyperglycemia and hyponatremia during operative hysteroscopy with 5% dextrose in water distention. *Fertil Steril.* 1989; 51:341–343.

C.28. What are the causes of excessive bleeding during TURP?

Patients undergoing TURP commonly bleed perioperatively. One possible cause is dilutional thrombocytopenia resulting from excessive absorption of irrigation solution. Another possible cause is local release fibrinolytic agents (plasminogen and urokinase) from the mucosa of the lower urinary tract. During and immediately after TURP, these agents cause local fibrinolysis and promote bleeding from the raw surfaces of the prostatic gland. The existence of a local fibrinolytic mechanism is supported by the observation that prophylactic administration of ϵ-aminocaproic acid (an antifibrinolytic agent) reduces bleeding from the prostatic bed.

Systemic coagulopathy can also occur during TURP. Contrary to common misconception, the coagulopathy is caused by disseminated intravascular coagulation (DIC), rather than by primary fibrinolysis. Characteristically, the platelet count and fibrinogen blood level are abnormally low. At autopsy, multiple microthrombi are observed in various parts of the body. The high level of fibrin-degradation products found in the blood of these patients is caused by secondary fibrinolysis, which commonly accompanies DIC.

Smith RB, Riach P, Kaufman JJ. Epsilon aminocaproic acid and the control of postprostatectomy bleeding: a prospective double blind study. *J Urol.* 1984;131: 1093–1095.

C.29. What triggers disseminated intravascular coagulopathy in patients undergoing TURP? How would you treat it?

Apparently, DIC is triggered during TURP by prostatic particles rich in thromboplastin that enter the bloodstream during surgery. The recommended treatment for DIC is

replacement of blood loss and administration of platelets, cryoprecipitates, and fresh frozen plasma. Heparin administration is controversial.

Malhotra V. Transurethral resection of prostate. *Anesthesiol Clin North America* 2000;18: 883–897.

C.30. What are the causes, signs, symptoms, and treatment of bladder perforation during TURP?

The incidence of bladder perforation during TURP is approximately 1% and stems from trauma by surgical instrumentation, overdistention of the bladder, and, rarely, explosion of traces of hydrogen gas inside the bladder.

An early sign of bladder perforation is a sudden decrease in the return of irrigation solution from the bladder. This sign often goes unnoticed until a significant amount of irrigation solution accumulates in the abdomen, causing abdominal distress. Other clinical signs are hypotension, followed by hypertension and nausea. Reflex-type movements of the limbs have been observed under both general and regional anesthesia. When the perforation is intraperitoneal, symptoms develop faster, and include severe shoulder pain caused by diaphragmatic irritation.

Diagnosis of bladder perforation is confirmed by cystourethrography. Treatment is immediate suprapubic cystotomy.

Malhotra V. Transurethral resection of prostate. *Anesthesiol Clin North America*. 2000;18: 883–897.

C.31. What are the causes, signs, symptoms, and preventive measures for bladder explosion during TURP?

A rare but extremely dangerous complication of TURP is gas explosion inside the bladder during surgery. Various explosive gases, particularly hydrogen, are generated by the cauterization of prostatic or bladder tissue during TURP. The explosion is triggered by the hot metal loop of the resectoscope. After a loud thump, the patient complains of sudden abdominal pain. This is accompanied by an abrupt decline in the return of irrigation solution. The concentration of oxygen in the bladder is usually too low to support combustion or explosion. However, if air is allowed to enter the irrigation system during surgery, oxygen concentration in the bladder will rise and this in turn may trigger an explosion.

Strict precautions should be taken to prevent entry of air into the bladder during TURP. If air is observed in the bladder at the beginning of surgery, it must be evacuated before cauterization starts. The bladder should be emptied regularly in order to avoid accumulation of explosive gases during surgery.

Hansen RI, Iverson P. Bladder explosion during uninterrupted transurethral resection of the prostate: a case report and experimental model. *Scand J Urol Nephrol*. 1979;13:211–212.

C.32. What are the causes of hypotension during TURP?

The more common causes of hypotension during TURP are circulatory overloading with CHF, MI or myocardial ischemia, severe anemia resulting from blood loss, and severe hyponatremia and water intoxication.

D. Postoperative Management

D.1. What is the source of postoperative bacteremia in patients who have undergone TURP? What factors increase the incidence of bacteremia?

The prostatic gland often harbors large amounts of various bacteria. TURP facilitates the entry of these bacteria into the bloodstream, leading to postoperative bacteremia. Also, a preoperative indwelling catheter promotes bacterial growth in the urethra. Approximately 30% of patients undergoing TURP have infected urine preoperatively, and half of them sustain bacteremia postoperatively.

Surgical disruption of the prostatic venous sinuses and excessive hydrostatic pressure of the irrigation solution facilitate the entry of bacteria into the bloodstream.

Barash PG, Cullen BF, Stoelting RK, eds. *Clinical Anesthesia*. 6th ed. Philadelphia: Lippincott Williams & Wilkins; 2009:1365–1368.

Malhotra V. Transurethral resection of prostate. *Anesthesiol Clin North America*. 2000;18: 883–897.

D.2. What are the signs of post-TURP septicemia? What preventive measures are generally recommended?

The signs of septicemia usually appear postoperatively in the postanesthesia care unit. They include fever, chills, low blood pressure, and tachycardia.

Antibiotics administered prophylactically before TURP do not sterilize the urine because they do not easily penetrate the prostatic gland. Nevertheless, the preoperative administration of antibiotics is recommended to render the bloodstream hostile to bacteria. The prophylactic administration of antibiotics in patients undergoing TURP is particularly important because of the grave prognosis of septicemia in these patients.

If sepsis is suspected postoperatively in a patient who has undergone TURP, broad-spectrum antibiotics should be started immediately without waiting for blood culture results.

Barash PG, Cullen BF, Stoelting RK, eds. *Clinical Anesthesia*. 6th ed. Philadelphia: Lippincott Williams & Wilkins; 2009:1365–1368.

Malhotra V. Transurethral resection of prostate. *Anesthesiol Clin North America*. 2000;18: 883–897.

D.3. What bacteria-related cause may possibly lead to sudden postoperative shock in patients who have undergone TURP?

Occasionally, patients who have undergone TURP develop postoperatively a short episode of hypotension, severe chills, and fever. However, these symptoms persist only a few hours, and then the patient recovers uneventfully. The cause of these symptoms is not clear; however, absorption of bacterial endotoxins has been suspected. Experimentally, the administration of bacterial endotoxins in humans induced symptoms similar to those described.

Bennett IL. Pathogenesis of fever. *Bull N Y Acad Med.* 1961;37:440–447.

Malhotra V. Transurethral resection of prostate. *Anesthesiol Clin North America.* 2000;18: 883–897.

D.4. Is postoperative hypothermia a risk factor for myocardial ischemia?

Yes. Unexpected hypothermia is associated with a significantly higher incidence of postoperative myocardial ischemia. Therefore, it is important to maintain normothermia during the perioperative period. (See section D.4 in Chapter 13.)

D.5. How would you diagnose perioperative MI?

An intraoperative MI can be totally silent, or the anesthesiologist may become aware of it by a sudden decrease in blood pressure. This sudden decrease in blood pressure may be accompanied by tachycardia, which is indistinguishable from the hypovolemic hypotension resulting from acute blood loss.

The ECG is a good monitor of the adequacy of coronary circulation. Only the appearance of Q waves more than 0.03 seconds in width is definitively diagnostic of MI. However, the Q waves usually appear postoperatively, not intraoperatively. Postoperative measurements of the myocardial isoenzymes of creatine phosphokinase may confirm the diagnosis. However, cardiac-specific enzyme elevations such as troponin I (cTn I), or troponin T (cTn T) are currently the standard of care for biochemical diagnosis of a perioperative MI because they demonstrate sensitivity and tissue specificity superior to other available biomarkers. (See section D.5 in Chapter 13.)

E. Comparing Monopolar, Bipolar, and Laser TURP

E.1. What differentiates monopolar from bipolar TURP?

Monopolar TURP uses high energy, which allows a fast cutting technique of prostatic tissue with minimal coagulation in the process. The body is the conduit of the energy dispersed from the monopolar electrode to complete the electrical circuit to a large-surface skin grounding pad placed on the patient. It also requires the use of an electrolyte-free bladder irrigating fluid. In bipolar TURP, the electrical circuit is completely contained within the resectoscope. This prevents energy from traveling through the body. Instead, the energy remains confined to the site of prostatic resection and is returned via the second limb of the bipolar resectoscope. It has been suggested that with the bipolar electrode, less bleeding occurs at the prostatic tissue site and normal saline can be used as the bladder irrigating fluid.

Issa MM. Technological advances in transurethral resection of the prostate: bipolar versus monopolar TURP. *J Endourol.* 2008;22:1587–1595.

E.2. Are decreased morbidity and mortality associated more closely with monopolar TURP than with bipolar TURP?

In a meta-analysis that reviewed the safety of monopolar versus bipolar TURP in a small number of TURP patients (1,802), a significant benefit was reported in the bipolar group in overall complication rate, need for transfusion, and the absence of TURP syndrome. Recent randomized controlled trials have confirmed this.

Issa MM. Technological advances in transurethral resection of the prostate: bipolar versus monopolar TURP. *J Endourol*. 2008;22:1587–1595.

Qi Chen, Li Zhang, Qi-Liang Fan, et al. Bipolar transurethral resection in saline vs traditional monopolar resection of the prostate: results of a randomized trial with a 2-year follow-up. *BJU International*. 2010;106(9):1339–1343.

E.3. What differentiates the technologies for laser TURP?

Laser prostatectomy has generated renewed interest among urologists, and it is being used in several centers. It is challenging monopolar TURP as an alternative TURP technique. Holmium yttrium–aluminum–garnet (YAG), photoselective high-powered potassium titanyl phosphate (KTP; also known as the Green Light laser), and Greenlight High Performance System (HPS) lasers are the three most recent systems used in TURP. The yttrium–aluminum–garnet laser wavelength is highly absorbed by water, which limits tissue cutting penetration. The potassium titanyl phosphate and High Performance System lasers have a wavelength absorbed by oxyhemoglobin and blood-rich tissue, which vaporizes a very thin prostatic tissue zone. Both techniques create a coagulation zone during resection, which minimizes bleeding and irrigating fluid absorption. There are five advantages of laser TURP: (1) It uses sterile water or normal saline as the irrigating bladder solution; (2) it minimizes the absorption of irrigating fluid; (3) it minimizes or altogether eliminates TURP syndrome; (4) it produces significantly less bleeding, which allows the procedure to be performed on an anticoagulated patient; and (5) it de-emphasizes regional anesthesia as the preferred anesthetic technique.

Hanson RA, Zornow MH, Conlin MJ, et al. Laser resection of the prostate: implications for anesthesia. *Anesth Analg*. 2007;105:475–479.

Shingleton WB, Farabaugh P, May W. Three-year follow-up of laser prostatectomy versus transurethral resection of the prostate in men with benign prostatic hyperplasia. *Urology*. 2002;60:305–308.

Tan AH, Gilling PJ. Holmium laser prostatectomy: current techniques. *Urology*. 2002;60:152–156.

Wosnitzer MS, Rutman MP. KTP/LBO laser vaporization of the prostate. *Urol Clin North Am*. 2009;36:471–483.

F. Are there preferred anesthetic and preferred surgical TURP techniques for this patient?

This 79-year-old man needing TURP has a history of ICD, MI, and recommendation to avoid interruption of antiplatelet therapy due to cardiac stents. With an anticoagulated patient, regional anesthesia would be avoided. This leaves the choice of general anesthesia with consideration of intra-arterial blood pressure monitoring. The advantages of laser TURP would include minimization of prostatic tissue bleeding and lowering the risk of TURP syndrome.

CHAPTER 25

Kidney Transplant

PANCHALI DHAR, PETER FLEISHUT, AND FUN-SUN F. YAO

A 40-YEAR-OLD MAN

with a 10-year history of type 1 diabetes mellitus and hypertension is scheduled to have a living donor renal transplant. He has been on hemodialysis for 5 years.

A. Medical Disease and Differential Diagnosis

1. What are causes of chronic renal disease that can progress to renal failure?
2. How is kidney disease diagnosed and treated?
3. What are the common clinical manifestations of end-stage renal disease (ESRD)?
4. How should anemia be managed in patients with chronic renal disease?
5. What electrolyte imbalances occur in patients with impaired renal function, and how are they treated?
6. When would you correct the metabolic acidosis? What are the dangers of overzealous correction?
7. Are patients with renal disease at increased risk for cardiovascular disease?
8. What is cardiorenal syndrome, and how is it treated?
9. What are the important aspects of immunosuppressive drugs in kidney transplant?
10. Who are expanded criteria kidney donors?
11. What is a living donor transplant program?
12. What is a paired donor exchange transplant program?
13. Is HIV-positive status a contraindication to renal transplant?
14. What surgical techniques are available for donor nephrectomy?
15. How is a donor kidney preserved prior to transplant?
16. Describe the operative procedure of kidney transplantation.

B. Preoperative Evaluation and Preparation

1. What preoperative workup would you order for a recipient?
2. How are routine medications and immunosuppressive medications managed in the perioperative period?

C. Intraoperative Management

1. What type of anesthetic techniques can be used for renal transplant?
2. Is central venous pressure (CVP) monitoring required for the procedure?
3. Is an arterial line required for the transplant procedure?
4. Is a pulmonary artery catheter required for the transplant procedure?
5. What type of intravenous fluid can be used intraoperatively?
6. How would you conduct the anesthesia induction?
7. Is succinylcholine contraindicated in patients with renal failure?
8. How are the nondepolarizing muscle relaxants affected by renal failure?
9. What unusual situations can prolong neuromuscular blockade?
10. How would you maintain anesthesia during the case? What drugs would you use?
11. What are the effects of inhalation anesthetics on renal blood flow (RBF), glomerular filtration, and urine output?
12. What are the potential nephrotoxic effects of inhalation anesthetics? What are the nephrotoxic metabolites of inhalation anesthetics?
13. How does renal failure affect the pharmacology of opioids?

D. Postoperative Management

1. How is the diagnosis of acute transplant rejection made?
2. What are some side effects of immunosuppressive agents of which anesthesiologists should be aware?
3. What is posttransplant erythrocytosis?

A. Medical Disease and Differential Diagnosis

A.1. What are causes of chronic renal disease that can progress to renal failure?

Chronic kidney disease has many potential causes that differ among the world populations. In developed countries, age, hypertension, cardiovascular disease, diabetes, increased body mass index, and smoking are associated with chronic kidney disease. In the developing world, causes of kidney failure include bacterial infection (tuberculosis in India and the Middle East and streptococcal infection in Africa), viruses (human immunodeficiency virus [HIV] and hepatitis B and C in Africa), and parasites (schistosomiasis in Africa and Latin America, leishmaniasis in Africa and Asia, and malaria in Africa). In parts of the world such as Asia, Africa, and the Middle East, environmental and occupational exposure to lead, cadmium, and mercury damage the kidneys.

The most common etiologies of renal disease in the world leading to kidney transplant are:

- Diabetes, 31%
- Chronic glomerulonephritis, 28%
- Polycystic kidney disease, 12%
- Hypertension, 9%
- Systemic lupus erythromatosus, 3%
- Interstitial nephritis, 3%

James MT, Hemmelgram BR, Tonelli M. Early recognition and prevention of chronic kidney disease. *Lancet*. 2010;375:1296–1309.

Wang Y, Chen X, Song Y, et al. Association between obesity and kidney disease: a systematic review and meta-analysis. *Kidney Int*. 2008;73:19–33.

A.2. How is kidney disease diagnosed and treated?

ESRD is established when glomerular filtration rate (GFR) is less than 15 mL per minute.

The Modification of Diet in Renal Disease (MDRD) formula for estimated GFR is:

$$\text{GFR} = 175 \times (\text{standardized Scr})^{-1,154} \times (\text{age})^{-0.203} \times 0.742 \text{ (if female)}$$
$$\text{or} \times 1.212 \text{ (if black)}$$

where Scr is serum creatinine (milligrams per deciliter).

Dialysis is initiated when GFR reaches 10 mL per minute or less in a patient without diabetes or 15 mL per minute in a patient with diabetes. Patients with uremic symptoms (e.g., anorexia, vomiting, weight loss, pericarditis, pleuritis) or fluid overload should be started on dialysis even if GFR has not reached these levels. Other indications for dialysis in chronic kidney disease include hyperkalemia that causes electrocardiogram (ECG) changes or that is persistent (K^+ >6 mEq/L), heart failure poorly controlled with drugs, and metabolic acidosis that is difficult to control.

Stevens LA, Coresh J, Greene T, et al. Assessing kidney function: measured and estimated glomerular filtration rate. *N Engl J Med*. 2006;354:2473–2483.

A.3. What are the common clinical manifestations of end-stage renal disease (ESRD)?

The common problems related to ESRD are the following:

- Electrolytes: volume expansion, hyponatremia, hyperkalemia, metabolic acidosis, hyperuricemia, hyperphosphatemia, hypocalcemia
- Gastrointestinal: gastroparesis, nausea, vomiting, pancreatitis
- Cardiovascular: accelerated atherosclerosis, systemic hypertension, left ventricular hypertrophy, congestive heart failure, pulmonary edema, cardiomyopathy, pericarditis, hyperdynamic circulation
- Hematologic: anemia, B- and T-cell dysfunction, qualitative platelet dysfunction, bleeding diathesis
- Musculoskeletal: muscle weakness, uremic osteodystrophy (osteomalacia, osteosclerosis, osteitis fibrosa cystica)
- Neurologic: encephalopathy, loss of memory, seizures, peripheral neuropathy, autonomic dysfunction (postural hypotension), myoclonus, asterixis, dialysis disequilibrium (dehydration, weakness, nausea and vomiting, hypotension, and occasionally seizure and coma)
- Gastrointestinal: uremic gastroenteritis, nausea, vomiting, peptic ulcer disease, gastrointestinal bleeding
- Endocrine: vitamin D deficiency, secondary hyperparathyroidism, carbohydrate intolerance, hypertriglyceridemia

Thomas R, Kanso A, Sedor JR. Chronic kidney disease and its complications. *Primary Care Clin Office Pract*. 2008;35:329–344.

A.4. How should anemia be managed in patients with chronic renal disease?

Anemia is often a consequence of progressive renal insufficiency. The anemia is due to several factors, including chronic blood loss, hemolysis, marrow suppression by uremic factors, and reduced renal production of erythropoietin. The decreased production of erythropoietin is the result of a reduction in functioning renal mass. This manifests as a normochromic normocytic anemia. These patients may have hemoglobin levels of 5 to 7 g per dL corresponding to hematocrits of 15% to 25%.

Additional factors that contribute to anemia are iron and folate deficiency, aluminum toxicity, hemolysis, bone marrow fibrosis due to hyperparathyroidism, chronic infection, and hemoglobinopathies. The body compensates for the decrease in oxygen carrying capacity, with an increase in cardiac output and an increase in red blood cell 2-,3-diphosphoglycerate. The increase in 2,3-diphosphoglycerate shifts the oxygen dissociation curve to the right, improving tissue oxygenation.

Patients can be treated with erythropoiesis-stimulating agents (ESAs) to increase hemoglobin levels. The preponderance of the evidence suggests that although ESAs raise hemoglobin A_1c and improve quality of life, targeting the complete correction of anemia with ESA is inadvisable. If patients with renal failure are returned to a normal hematocrit, they run a higher risk for composite death resulting from stroke, myocardial infarction, congestive heart failure, poorly controlled blood pressure, and thrombotic events. The practice at this time is to maintain a conservative target hemoglobin of 11 to 12 g per dL, but not greater than 13 g per dL with ESA treatment.

Intravenous or oral iron supplements are also used to treat anemia. Other novel agents are under investigation. For example, a continuous erythropoietin receptor activator allows less frequent dosing of an ESA. An intravenous iron nanoparticle (ferumoxytol) can raise hemoglobin more than oral iron.

A.5. What electrolyte imbalances occur in patients with impaired renal function, and how are they treated?

Chronic renal insufficiency and ESRD are associated with impaired excretion and balance of electrolytes.

Sodium and H_2O balance are closely related. In patients with chronic renal failure, the total body content of sodium and H_2O may be increased. This can be due to glomerular disease promoting sodium retention or excessive ingestion of sodium leading to extracellular fluid expansion. The extracellular fluid expansion contributes to hypertension. Nonanuric patients may be treated with loop diuretics and salt restriction.

The renal mechanisms for conserving sodium and H_2O may also be dysfunctional. If additional fluid loss (vomiting, fever) is imposed, such patients become severely volume depleted. The usual indices of prerenal azotemia (high urine osmolality, low urine sodium, and low fractional excretion of sodium) are not applicable because the kidneys cannot conserve sodium or H_2O. These patients have to be hydrated carefully with normal saline.

Chronic hyperkalemia is usually caused by impaired renal potassium excretion. In patients with ESRD or in transplant recipient, hyperkalemia can be exacerbated by excessive dietary intake, hemolysis, hemorrhage, massive blood transfusion, metabolic acidosis, β-adrenergic blockade, angiotensin-converting enzyme inhibitors, angiotensin

receptor blockers, insulin deficiency or resistance, hyperosmolality, hyperglycemia, rhabdomyolysis, succinylcholine, digoxin overdose, or potassium sparing diuretics.

Metabolic acidosis accompanies hyperkalemia. As a general rule, for every 0.1 unit decrease in blood pH, the potassium level increases approximately 0.6 mEq per L. Treatment of hyperkalemia improves the acidosis as well. Severe hyperkalemia increases cardiac and skeletal muscle excitability. The earliest changes begin with levels above 6.5 mEq per L. The ECG shows peaked T waves, flattened P waves, lengthened PR interval, disappearance of P waves, and a widened QRS complex that can progress to a "sine wave," ventricular asystole or ventricular fibrillation. The correlation between serum potassium and ECG changes is not definite because there may be few ECG abnormalities in the presence of severe hyperkalemia. Muscle weakness can cause respiratory failure. Membrane excitability is in fact more dependent on the rate of increase in potassium than on potassium concentration per se. Treatment involves: (1) antagonizing the cardiac toxic effects and stabilizing the cardiac membrane with intravenous calcium salts; (2) shifting the extracellular fluid potassium into cells by administering glucose, insulin, β-adrenergic agonists (albuterol), and sodium bicarbonate (Table 25.1). Of note, calcium can potentiate digitalis toxicity. In such circumstances, the calcium gluconate should be added to 100 mL of D_5W and infused over 20 to 30 minutes. The anesthesiologist may also institute hyperventilation in mechanically ventilated patients. Loop diuretics can increase potassium elimination (nonanuric). Hemodialysis or peritoneal dialysis is the definitive treatment for patients with chronic renal failure.

Hypermagnesemia can accompany chronic renal failure, especially when the GFR decreases to less than 10 mL per minute.

High blood magnesium levels cause dose-dependent neuromuscular toxicity. Symptoms include diminished deep tendon reflexes, flaccid paralysis that may progress to respiratory failure. An increased sensitivity to depolarizing and nondepolarizing neuromuscular agents is noted. Bradycardia, hypotension, and heart block are due to the calcium channel blocking effects of magnesium. The acute toxicity can be antagonized by intravenous infusion of calcium. Hemodialysis or peritoneal dialysis can normalize blood magnesium levels.

Phosphate retention occurs when the GFR begins to decline. Retained phosphate promotes secondary hyperparathyroidism by lowering ionized plasma calcium levels, decreasing renal formation of calcitriol (1,25 dihydroxyvitamin D), and stimulating parathyroid hormone gene expression.

Ionized and protein bound calcium levels are lower in uremic patients. This is the result of hyperphosphatemia and reduced gastrointestinal absorption secondary to the decreased production of vitamin D.

Table 25.1 Drug Treatment for Hyperkalemia

DRUG	DOSE
Calcium chloride	5 mL of 10% solution IV over 2 min (monitor for bradycardia)
Calcium gluconate	10 mL of 10% solution IV over 2 min (monitor for bradycardia)
Insulin	5–10 units regular insulin with 1–2 amps $D_{50}W$ IV bolus
Sodium bicarbonate	1 mEq/kg slow IV push or continuous drip; not to exceed 50–100 mEq
β-agonists (albuterol)	2.5 mg mixed with 3 mL isotonic saline through nebulizer every 20 min as tolerated
Diuretic (furosemide)	20–40 mg IV push
Magnesium	1–2 g IV over 30–60 sec; repeat every 5–15 min as required or 3–10 mg/min IV infusion

Hamish T, Ross M. Fluid and electrolyte problems in renal dysfunction. *Anaesth Intensive Care Med*. 2009;10;289–292.

A.6. When would you correct the metabolic acidosis? What are the dangers of overzealous correction?

A mild-to-moderate acidosis is commonly noted when the GFR decreases to less than 20% to 25% of normal. The decreased renal mass results in decrease NH_4^+ production and excretion of proton load. The plasma bicarbonate concentration ranges between 12 and 22 mEq per L, and blood pH remains greater than 7.20. This does not routinely require correction. It may gradually evolve into a high anion gap acidosis when the GFR is below 20 mL per minute. Some patients with ESRD maintain close to normal acid–base parameters even when renal function is severely compromised. However, when exposed to an increased dietary acid load, these patients may have decreased ability to increase bicarbonate generation. Chronic acidosis promotes muscle wasting, reduces albumin synthesis, impairs bone formation, and decreases insulin sensitivity. There are no guidelines requiring the correction of acidosis to normal pH. Each case should be treated on an individual basis. The recommendations in regard to the amount of bicarbonate to be administered to the patient with acidosis is based on the space of distribution of bicarbonate, which in metabolic acidosis is 50% of lean body weight, and the maximum desired level of plasma bicarbonate, which is 24 mEq per L. The bicarbonate required can be calculated as follows:

$$HCO_3^- \text{ replacement} = 0.5 \times \text{weight in kg} \times (24 - \text{serum } HCO_3^-)$$

Only half of the calculated bicarbonate is given because doses exceeding 1 mEq/kg/min may lead to alkaline overshoot. Serial blood gases should be followed to monitor the response to treatment. Overzealous use of sodium bicarbonate may cause volume overload, promote metastatic calcification by decreasing the solubility of calcium phosphate, and decrease ionized calcium. For each 0.1 increase in pH, oxygen availability may decrease by 10% because of the shift of the oxygen–hemoglobin dissociation curve to the left. Severe symptomatic acidosis (pH <7.20) that is resistant to bicarbonate administration requires dialysis.

Fauci AS, Braunwald E, Kasper DL, et al. *Harrison's Principles of Internal Medicine*. 17th ed. New York: McGraw-Hill; 2008:289–90, 1764.

A.7. Are patients with renal disease at increased risk for cardiovascular disease?

Premature cardiovascular disease is a leading cause of death in patients with chronic kidney disease. The prevalence of hypertension, coronary artery disease, congestive heart failure, uremic cardiomyopathy, carotid artery stenosis, and aortic aneurysm is greater in the chronic kidney disease population. The mortality rate from myocardial infarction and after undergoing percutaneous coronary angioplasty, coronary artery bypass surgery, or even insertion of an implantable defibrillator is higher in those with renal disease compared to the general population.

The annual rate of sudden cardiac death of a patient with ESRD receiving dialysis is approximately 7%. In patients receiving dialysis, sudden cardiac death and heart failure—not myocardial infarction—are the prevailing modes of cardiovascular death. This increased risk for sudden death can be attributed to myocardial structural changes. Left ventricular hypertrophy is almost universal in the chronic kidney disease population. The left ventricular mass is correlated with survival. The uremic load results in cardiac fibrosis and in left ventricular systolic and diastolic dysfunction. These myocardial structural changes enhance the electrical irritability of the cardiac muscle.

Accelerated atherosclerosis is promoted by diabetes, dyslipidemias, and a decreased GFR. The enhanced calcification occurs throughout coronary and systemic arteries. Plaque formation in the aorta decreases its compliance and increases cardiac afterload. Intensive lipid lowering with statin medications is advocated.

Hypertension develops in 80% of patients with chronic kidney disease. It is due to volume expansion resulting from salt and water retention. High levels of renin-angiotensin secondary to relative intravascular volume depletion contribute to hypertension. An imbalanced autonomic system results in an exaggerated sympathetic drive with a loss of vagal tone. Autonomic neuropathy creates a setting for silent myocardial ischemia and ventricular tachycardia triggered by QTc interval prolongation.

Remppis A, Ritz E. Cardiac problems in the dialysis patient: beyond coronary disease. *Semin Dialysis*. 2008;21:319–325.

A.8. What is cardiorenal syndrome, and how is it treated?

Cardiorenal syndrome is disorder of the heart and kidneys in which acute or chronic dysfunction in one organ may induce acute or chronic dysfunction in the other organ.

The five types of cardiorenal syndrome are based on the initial onset of either heart or kidney dysfunction. Treatment modalities involve rapid volume removal with diuretics, hemodialysis, and ultrafiltration.

Type 1 cardiorenal syndrome is an abrupt worsening of cardiac function (e.g., acute cardiogenic shock or decompensated congestive heart failure) leading to acute kidney injury.

Type 2 cardiorenal syndrome involves chronic abnormalities in cardiac function (e.g., chronic congestive heart failure) causing progressive and permanent chronic kidney disease.

Type 3 cardiorenal syndrome consists of an abrupt worsening of renal function (e.g., acute kidney ischemia or glomerulonephritis) causing acute cardiac disorder (e.g., heart failure, arrhythmia, ischemia).

Type 4 cardiorenal syndrome is a state of chronic kidney disease (e.g., chronic glomerular disease) contributing to decreased cardiac function, cardiac hypertrophy, or increased risk for cardiovascular events.

Type 5 cardiorenal syndrome is a systemic condition (e.g., diabetes mellitus, sepsis) causing both cardiac and renal dysfunction.

Ronco C. Cardiorenal syndromes: definition and classification. *Contrib Nephrol*. 2010; 164:33–38.

A.9. What are the important aspects of immunosuppressive drugs in kidney transplant?

In order to decrease the incidence of graft rejection, several regimens of immunosuppressive agents have been devised. Centers throughout the world may use different combinations of these drugs, but the basic idea behind their use is to prevent acute and chronic T-cell alloimmune rejection. The regimens are separated into the induction phase and long-term maintenance phase. Four classes of immunosuppressive medications are used: corticosteroids, calcineurin inhibitors (cyclosporine and tacrolimus), antimetabolites (mycophenolate mofetil, mycophenolate sodium, and azathioprine), and the target-of-rapamycin inhibitor, sirolimus. The maintenance phase involves a combination of two or three of these drugs, each from a separate class

Immunosuppressant therapy is started in the immediate preoperative period. In the intraoperative period, induction therapy is targeted to eliminate lymphoid cells that may cause acute rejection of the graft. An induction agent may be withheld if immediate graft function occurs from a living donor kidney. After surgery, maintenance therapy is begun for the life of the recipient. Although lifelong immunosuppression helps prevent rejection of the allograft, it also increases the risk for malignancy and infectious diseases. The regimens may not prevent the slow deterioration associated with chronic graft rejection.

Corticosteroid-free regimens are increasing being used in some transplant centers. This is because the long-term use of corticosteroids contributes to cardiovascular disease or infectious disease complications. There is a slight initial increase in acute graft rejection without corticosteroids, but selected candidates have fared well.

A.10. Who are expanded criteria kidney donors?

There are an increasing number of persons awaiting a kidney transplant. The ideal donor is 5 to 49 years old and nonhypertensive, whose cause of death was not cerebrovascular accident and whose creatinine was 1.5 mg per dL or less. The term "expanded criteria donor" has been introduced as a part of an effort to increase the use of kidneys that might otherwise have been discarded and to minimize the length of cold ischemia to which they are subjected. Expanded criteria donors are defined as donors older than age 60 years or 50 to 59 years with two additional risk factors, including a history of hypertension, death as a result of cardiovascular accident, or serum creatinine 1.5 mg per dL or greater. Expanded criteria donor kidneys account for approximately 15% of deceased donor kidneys, but have at least a 70% increased risk for failure within 2 years compared with standard criteria kidneys. The long-term survival of single or dual kidney grafts from donors older than 60 years is excellent, provided that the grafts are evaluated histologically before implantation. Expanded criteria donor kidneys are offered only to patients willing to accept them. Often, this decision must be made within 2 hours. This has increased the number of transplants. The outcome data from expanded criteria donor programs indicate that patients younger than 40 years or scheduled for kidney retransplantation should not receive an expanded criteria donor kidney. Patients 40 years or older, especially with diabetic nephropathy or nondiabetic disease, but a long expected waiting time for kidney transplantation, show better survival receiving an expanded criteria donor kidney than remaining on dialysis therapy.

A.11. What is a living donor transplant program?

A living donor transplant program allows recipient and donor surgery to be scheduled simultaneously. It offers the advantage of minimal organ preservation time. The total ischemia time from removal of the kidney from the donor to the restoration of blood flow in the recipient can be less than 1 hour. A short preservation time allows immediate graft function, high volume urine output, and initiation of creatinine clearance.

A large number of recipients have preformed antibodies to potential living donors. These antibodies are the result of exposure to foreign antigens by blood transfusions, prior transplantation, or pregnancy. As a result, the recipients have positive cross matches against living donor tissue antigens. Preoperative measures can facilitate the transplant. The recipient undergoes several pretransplant plasmapheresis sessions to remove the offending antibodies and receives intravenous immunoglobulin to inhibit the return of antibodies. The living donor transplant is conducted when the cross match converts to negative. The recipient usually has to undergo additional plasmapheresis treatments and immunoglobulin infusions postoperatively.

A.12. What is a paired donor exchange transplant program?

The paired donor exchange transplant program is sometimes referred to as a "kidney swap." As an example, a pair of living donors may have an incompatible blood type or antigens to their intended recipient. The donors agree to exchange recipients. Each donor gives a kidney to an unknown but compatible individual. As a result, the donors provide two patients with healthy kidneys. Each recipient receives a compatible graft.

A chain of paired kidney donations was done in which the transplantations were initiated in July 2007 by a single altruistic donor (i.e., a donor without a designated recipient) and coordinated over a period of 8 months by two large paired-donation registries. These transplantations involved six transplantation centers in five states. In the case of five of the transplantations, the donors and their co-registered recipients underwent surgery simultaneously. In the other five cases, "bridge donors" continued the chain as long as 5 months after the coregistered recipients in their own pairs had received transplants.

There are many benefits to a paired donor exchange program:

- It expands the pool of donors.
- By using ABO-compatible but nonidentical donors, transplants can be performed at individual centers without requiring large sharing networks.
- Type O recipients with incompatible donors are likely to be the primary beneficiary of exchange programs.
- These programs reflect a paradigm shift for live donation, converting a private resource (the donor) to a shared one.

- Both donors and recipients are more willing to participate if their intended recipient or donor is enthusiastic about participating.

A.13. Is HIV-positive status a contraindication to renal transplant?

Chronic kidney disease now accounts for more than 10% of HIV-related deaths. HIV infection is no longer an absolute contraindication to kidney transplantation. The potential recipient should be clinically stable on highly active antiretroviral therapy (HAART), is RNA-negative, and has a CD4 count of 200 cells per mm^3 or greater. There is a risk for developing opportunistic infections, viremia, and malignancy while under immunosuppressive maintenance. Long-term allograft survival is lower among patients who are HIV-positive.

The diagnosis of AIDS (Centers for Disease Control and Prevention definition of CD4 count less than 200 cells per mm^3) is a contraindication to receiving a kidney.

A.14. What surgical techniques are available for donor nephrectomy?

Laparoscopic living-donor nephrectomy has increased in popularity. In some centers, it has replaced open donor nephrectomy as the standard technique.

The robotics system provides considerable potential benefits to minimally invasive surgery compared with standard laparoscopic approaches. In particular, the system restores the three-dimensional vision lost in the laparoscopic approach and enhances the ability of the surgeon to perform complex tasks in a laparoscopic environment.

The standard techniques for donor nephrectomy are open surgery, laparoscopic, and hand-assisted laparoscopic donor nephrectomy. Laparoscopic donor nephrectomy results in less blood loss, reduced operative time, and shorter hospital stay than open donor nephrectomy. Hand-assisted laparoscopic donor nephrectomy has the potential to decrease warm ischemia time for renal allografts. Donors managed laparoscopically had fewer complications, significantly less wound-related morbidity, and less delayed graft function than patients who underwent open donor nephrectomy.

Dolce CJ, Keller JE, Walters KC. Laparoscopic versus open live donor nephrectomy: outcomes analysis of 266 consecutive patients. *Surg Endosc*. 2009;23:1564–1568.

A.15. How is a donor kidney preserved prior to transplant?

Two different methods of organ preservation are used for deceased donor kidneys—static cold storage and hypothermic machine perfusion. In static cold storage, the kidney is flushed, cooled with one of several cold preservation solutions, and transported on ice. In hypothermic machine perfusion, after an initial washout of blood, the kidney is connected to a perfusion device and a solution is pumped continuously through the organ at temperatures between 1° and 10° C until the moment of graft placement.

Preservation solutions are agents that do not readily permeate the cell membrane and have an electrolyte composition similar to the intracellular environment (low sodium, high potassium), thus preventing loss of cellular potassium. The organ-preserving cold storage interval is called cold ischemia time. It extends from the initiation of cold preservation of donor organs to restoration of warm circulation in the organ recipient. There is a significant reduction in the mean cold ischemia time over the last decade, and fewer kidneys are being cold stored longer than 30 hours. The influence of improved immunosuppression, lower cold ischemia time have contributed to the recent improvements in graft function and survival.

Kidneys from living donors maybe flushed with preservation solution or iced lactated Ringer's solution containing heparin and mannitol. The ischemic time during implantation is usually 20 to 30 minutes because the transplant operation takes place immediately. Some practices place the living donor kidney in a pulsatile preservation machine that maintains organ viability for longer periods.

A.16. Describe the operative procedure of kidney transplantation.

Before the induction of anesthesia, a large-bore peripheral intravenous line (18- or 16-gauge) is required. Following induction of anesthesia, a triple-lumen central line may be placed for an internal jugular or subclavian route. A Foley catheter is placed in the bladder, and the bladder is irrigated with an antibiotic solution. Fluids are infused liberally through the central line and intravenous line. An arterial line may also be placed, depending on the patient's underlying clinical status.

A kidney is harvested from a living donor using a left-flank laparoscopic approach. Harvesting of the left kidney is favored because the left renal vein is longer. New surgical techniques allow preservation of longer arterial length on the harvested kidney. Longer vessel preservation facilitates a right kidney donation.

The donor kidney is placed in either the right or left iliac fossa. The right kidney is usually placed in the left groin and vice versa. The renal artery of the donor kidney is connected to the external or internal iliac artery in the recipient. The renal vein of the donor kidney is connected to the external iliac vein in the recipient. Occasionally, a donor kidney has multiple renal arteries. This is addressed using primary or secondary anastomosis. A multiple-artery donor kidney has a longer operative and ischemic time than a kidney with a single artery. In the event that the recipient weighs less than 20 kg, the kidney is placed intra-abdominally posterior to the right colon. Urinary continuity is restored by placing the distal ureter into the bladder through a tunnel without opening the bladder.

In deceased donor kidney transplant, before the release of the arterial clamp and following completion of the anastomosis, an intra-arterial injection of verapamil or papaverine may be given by direct push into the renal artery to prevent arterial vasospasm.

In dual kidney transplantation, two kidneys from a donor are placed into one recipient. Such kidneys have usually been refused for single kidney transplantation. Dual kidney transplant is done at the extremes of donor age. It is a reflection of donor shortage and reluctance to discard potentially functional organs. For donors younger than 2 years of age, both kidneys are transplanted en bloc with the donor aorta, which is then anastomosed to the external iliac artery.

If the donor is 60 years or older, the creatinine clearance should be less than 70 mL per minute. A dual kidney transplant procedure is of longer duration and involves more third spacing, greater volume requirements, and blood loss.

B. Preoperative Evaluation and Preparation

B.1. What preoperative workup would you order for a recipient?

The transplant recipient should have routine systemic tests such as ECG, chest radiograph, blood counts, platelet count, electrolytes, serum glucose, blood urea nitrogen, creatinine concentration, prothrombin time, partial thromboplastin time, liver function enzymes (aspartate aminotransferase [AST], alanine aminotransferase [ALT]), bilirubin, and albumin. Dialysis, if indicated, is done within 24 hours of the operation. It is best to avoid overzealous ultrafiltration because expanded filling pressures are desired. A urinalysis and urine culture should be performed on all urinating patients.

Dialysis-related problems such as dialysis dementia, disequilibrium syndrome after dialysis (cerebral edema), hypovolemia (hypotension after anesthetic induction following recent dialysis), and peritonitis (peritoneal dialysis), systemic anticoagulation (after dialysis) should be evaluated. It is important to know the time of the last dialysis. The dialysis records should be reviewed for predialysis and postdialysis body weight. The loss of more than 2 kg during dialysis suggests intravascular volume depletion, which may result in severe hypotension during or after anesthetic induction.

SarinKapoor H, Kaur R, Kaur H. Anaesthesia for renal transplant surgery. *Acta Anaesthesiol Scand*. 2007;51:1354–1367.

B.2. How are routine medications and immunosuppressive medications managed in the perioperative period?

Patients awaiting transplant often have comorbidities such as hypertension and diabetes. Antihypertensive drugs should be continued until the time of surgery. In spite of continuing antihypertensive therapy, patient hemodynamics remain labile. Approximately 50% to 70% of patients are noted to have exaggerated blood pressure responses to induction, laryngoscopy, intubation, and extubation. Oral hypoglycemic agents should be held on the morning of surgery. An aspart insulin (Novolog) sliding scale can be used to manage patients on insulin. The sliding scale may be used intraoperatively if high blood glucose

levels are measured. Antibiotic prophylaxis for infectious complications include a first-generation cephalosporin (cefazolin 1 g 30 minutes preoperatively) or if penicillin allergic, vancomycin (1 g intravenously).

Anxlioytic agents should be titrated carefully because these patients may have increased sensitivity to premedication drugs. For example, diazepam is highly bound to albumin, but with decreased albumin levels, the effect of the drug is increased. Midazolam is water soluble, less affected by albumin levels, and useful before induction.

Transplant recipients begin their immunosuppressive regimens before entering the operating room. Immunosuppressive medications are administered for an additional 4 days, at which time recipients are typically discharged.

At New York Presbyterian Hospital, a corticosteroid-sparing regimen is usually followed. Approximately 80% of our transplant recipients are judged to be suitable for corticosteroid-free immunosuppression and go home taking only tacrolimus (Prograf) and mycophenolate mofentil (CellCept).

Before entering the operating room, patients are given intravenous methylprednisolone (Solu Medrol), and mycophenolate mofentil (CellCept). Diphenhydramine and acetaminophen are given as prophylaxis before the rabbit antithymocyte globulin (Thymoglobulin) is infused intraoperatively. Under specific circumstances, basiliximab (Simulect) is substituted for Thymoglobulin. This is the case if the patient has history of reaction to thymoglobulin or is a perfect match to the donor kidney. No prophylactic premedication is required with basiliximab. Patients receive only five doses of methylprednisolone; corticosteroids are then discontinued. In the corticosteroid protocol, patients are continued on prednisone. Rituximab and plasmapheresis followed by intravenous immunoglobulin are incorporated into the regimens of those patients with a positive crossmatch.

New York Presbyterian Hospital-Cornell Medical Center Kidney Transplantation Protocol 2009. New York: New York Presbyterian Hospital-Cornell Medical Center; 2009.

C. Intraoperative Management

C.1. What type of anesthetic techniques can be used for renal transplant?

General anesthesia is the preferred technique for renal transplantation. The use of epidural or combined spinal epidural anesthesia is controversial. If the decision is made to use regional anesthesia, certain factors should be considered by the anesthesiologist. General anesthesia with epidural anesthesia has been also used in the past.

It is important to note that uremic bleeding tendency combined with the effects of residual heparin given during dialysis increases the risk of hemorrhage into the epidural space. Underlying hepatic disease can also alter platelet function and decrease coagulation factor levels. Studies have not demonstrated higher plasma concentrations of local anesthetic because of hyperdynamic circulation or acid–base changes in renal patients. The duration of surgery is the major determinant of anesthetic technique. Epidural anesthesia has been used successfully in renal transplant surgery. Hypotension has been shown to be one of the most common hemodynamic changes with the use of an epidural anesthesia. Studies have shown no overall difference in mortality or major morbidity between patients randomly assigned to general anesthesia or combined spinal–epidural anesthesia for renal transplantation. The advantages of the combined technique are rapid onset and good muscle relaxation from the subarachnoid block, with the ability to supplement analgesia through the epidural catheter during and after the surgery. With longer operative times, general anesthesia is preferred.

C.2. Is central venous pressure (CVP) monitoring required for the procedure?

Adequate hydration is an important part of the anesthetic management in renal transplant. Measuring the CVP is not an absolute requirement. External jugular venous pressure has been used as an alternative to CVP monitoring. The CVP or pulmonary artery pressure can be used to guide fluid therapy. Adequate hemodialysis should be performed within 48 hours of surgery. These postdialysis patients have intravascular volume depletion. To decrease the incidence of postoperative acute tubular necrosis, a liberal hydration policy is employed intraoperatively. Hydration guided by CVP monitoring has been shown to maintain stable hemodynamics and promote diuresis. The systolic blood pressure is maintained between 130 and 160 mm Hg, and the CVP is maintained between 12 and 14 mm Hg. Maintaining adequate CVP is especially important in pediatric recipients because reperfusion of an adult-size kidney graft may divert a significant amount of their own blood volume.

CVP may decline 1 to 2 hours after revascularization despite aggressive fluid management in the operating room. The decline in CVP is similar in recipients of both cadaveric and living related donor kidneys. It may decline 25% to 50% below the CVP measured in the operating room at reperfusion of the transplanted kidney. The reason for the decline is not clear but may be multifactorial, such as redistribution of fluids, changes in vascular permeability, or increased nitric oxide levels. This is why postoperative hydration is an essential factor in maintaining renal function. Increased hydration likely works by atrial distention and the subsequent release of atrial natriuretic peptide and increased renal perfusion. The patient should receive an equal amount of fluid replacing the urine output. This approximates to 1 L per hour.

Trzebicki J, Flakiewicz E, Nowakowski P, et al. Is external jugular venous pressure a good predictor of volume status in kidney graft recipients? *Transplant Proc*. 2009;41: 3033–3035.

C.3. Is an arterial line required for the transplant procedure?

An arterial line is not absolutely required for the transplant procedure, but many transplant surgeons prefer its placement. It should be placed if a patient has an advanced comorbid condition(s) that requires close monitoring of blood pressure or acid–base status. Often, placement of an intra-arterial line is difficult, because many recipients have poor arterial access secondary to diabetes, peripheral vascular disease, arteriovenous fistulas, and shunts. Major swings in blood pressure may occur, with

hypotension (49.6%) being more likely than hypertension (26.8%). Administration of induction drugs and maintenance agents should be titrated carefully. The main utility of instantaneous blood pressure reading is toward the end of the procedure. Hypotension may occur after unclamping of the iliac vessels or from partial systemic absorption of the vasodilator (verapamil or papaverine) injected by the surgeon into the graft vessels.

Miller RD, ed. *Miller's Anesthesia.* 7th ed. Philadelphia: Churchill Livingstone; 2010:2164–2165.

C.4. Is a pulmonary artery catheter required for the transplant procedure?

A pulmonary artery catheter is not routinely placed for kidney transplantation. Patients with severe comorbid conditions, such as symptomatic coronary artery disease, left ventricular dysfunction, congestive heart failure, valvular heart disease, or severe chronic obstructive pulmonary disease, can be monitored precisely with a pulmonary artery catheter. A transesophageal echocardiography can help determine if hypotension is caused by hypovolemia or myocardial dysfunction.

Miller RD, ed. *Miller's Anesthesia.* 7th ed. Philadelphia: Churchill Livingstone; 2010:2164–2165.

C.5. What type of intravenous fluid can be used intraoperatively?

The administration of normal saline and normal saline–based fluids (5% albumin) is the standard of care for fluid management in patients undergoing renal transplant surgery. This practice is primarily based on avoidance of potassium-containing fluids, which can contribute to intraoperative hyperkalemia. One study suggests a higher risk of acidosis when using normal saline solutions versus lactated Ringer's solution. The typical fluid requirement for a 70-kg adult is about 3,000 to 4,000 mL. In addition, 500 mL of 5% albumin is given.

The recipient's blood is usually typed and screened, but blood loss is minimal, so transfusion is unlikely. The anesthesiologist should attempt to maintain a systolic blood pressure range of 130 to 160 mm Hg, CVP between 10 and 14 cm H_2O, and mean pulmonary artery pressure of 18 to 20 mm Hg.

The intravenous administration of adequate volumes of fluid is associated with earlier onset of graft function, lower postoperative serum creatinine, higher postoperative creatinine clearance, reduced incidence of delayed graft function, and improved graft survival.

Khajavi MR, Etezadi F, Moharari RS, et al. Effects of normal saline vs. lactated Ringer's during renal transplantation. *Renal Failure.* 2008;30:535–539.

New York Presbyterian Hospital-Cornell Medical Center Kidney Transplantation Protocol 2009, New York: New York Presbyterian Hospital-Cornell Medical Center; 2009.

C.6. How would you conduct the anesthesia induction?

The circumstances for renal transplant can vary between a scheduled or emergent procedure. Living donor transplants are scheduled surgical cases. Patients receiving cadaver kidneys may learn of the surgical procedure on short notice. Standard anesthesia monitors are required before induction. The central venous line or arterial line is usually placed after induction.

The induction of general anesthesia and intubation of the trachea can be safely accomplished with several of the commonly used drugs. The induction drugs should be given slowly to minimize the chance of drug-induced hypotension. Regardless of blood volume status, these patients often respond to induction of anesthesia as if they were hypovolemic. The sympathetic nervous system response may be attenuated by antihypertensive therapy or diabetic autonomic neuropathy. A blunted sympathetic response impairs compensatory peripheral vasoconstriction. In addition, the central nervous system may exhibit an increased sensitivity to the induction drugs. Low serum protein and albumin levels can increase the level of unbound drug crossing the blood–brain barrier into central nervous system receptors. Uremia can also disrupt the blood–brain barrier. The dose of induction agent may need to be adjusted based on volume status, acidic pH, and comorbidities. Propofol or etomidate can be used in routine circumstances. A reduced induction dose of propofol may be considered because lower plasma protein levels and postdialysis hypovolemia can exaggerate their cardiodepressant effects. Of note, an animal study model has noted reduced ischemia/reperfusion injury with the use of propofol anesthesia. Ketamine pharmacokinetics is not significantly altered by renal disease, but its hypertensive effects make it undesirable in patients with underlying hypertension. Etomidate is well tolerated and preserves hemodynamic stability.

Large fluctuations in blood pressure and heart rate may occur in patients with preexisting hypertension during intubation. Underlying coronary artery disease is a major consideration. Opioids can blunt the response to laryngoscopy. Fentanyl in moderate doses (5 μg per kg can be used, but a small risk for hypotension exists after induction and lack of stimulation). Remifentanil is also effective for heart rate control. A short-acting β-blocker such as esmolol (0.5 to 1 mg per kg) can blunt the response to intubation.

Various neuromuscular blocking agents can be used to facilitate tracheal intubation. Patients with uremia and diabetes may have gastroparesis. Pretreatment with a clear, nonparticulate antacid such as 30 mL of sodium citrate raises gastric pH. A rapid-sequence induction with cricoid pressure using either succinylcholine or rocuronium may be required to prevent reflux and aspiration. Succinylcholine can be used safely because potassium release is not exaggerated in patients with chronic renal failure. If the preoperative potassium is in the high normal range or if there is underlying metabolic acidosis, the additional increase of 0.5 to 1 mEq per L should be considered. When choosing a nondepolarizing agent for maintenance, it is better to use ones that are independent of renal clearance mechanisms (cis-atracurium, atracurium).

Yuzbasioglu MF, Aykas A, Kurutas EB, Sahinkanat T. Protective effects of propofol against ischemia/reperfusion injury in rat kidneys. *Renal Failure*. 2010;32:578–583.

C.7. Is succinylcholine contraindicated in patients with renal failure?

Normally, succinylcholine causes an increase in serum potassium of 0.5 to 1.0 mEq per L within 3 to 5 minutes after intravenous administration and lasts less than 10 to 15 minutes. Succinylcholine can be used safely in patients with chronic renal failure if the potassium concentration is less than 5.5 mEq per L and repeated doses are avoided. Potassium flux after administration of succinylcholine in patients with renal failure does not differ from normal patients. Plasma cholinesterase activity has been reported to be below normal in more than 20% of patients with ESRD whether they are receiving any form of dialysis. Values are rarely so low that they cause a prolonged block.

Miller RD, ed. *Miller's Anesthesia*. 7th ed. Philadelphia: Churchill Livingstone; 2010: 2114–2115, 2164–2165.

Table 25.2 Pharmacokinetics of Neuromuscular Blocking Agents in Normal versus Anephric Patients

DRUG	RENAL EXCRETION (%)	NORMAL $t_{1/2}$ (min)	ANEPHRIC $t_{1/2}$ (min)
Pancuronium	85	132	258
Rocuronium	10	42	58
Vecuronium	40–50	54	84
Atracurium	10–40	18	24
Cis-atracurium	16	34	No effect
Mivacurium	< 5%	1.8	3.6
Succinylcholine	< 25%	1	1

C.8. How are the nondepolarizing muscle relaxants affected by renal failure?

Table 25.2 notes the commonly used nondepolarizing agents and how they are affected by renal failure. The prolonged duration of action to nondepolarizing agents is primarily due to slow renal clearance. Cis-atracurium mainly undergo Hoffman elimination that is not altered in patients with chronic kidney disease. Renal failure may delay clearance of laudanosine, the principal metabolite of cis-atracurium. Laudanosine does not have effect at the neuromuscular junction, but at high plasma levels may act as a central nervous system stimulant. The long-acting muscle relaxant such as pancuronium is not suitable for use because the kidneys excrete most of the drug and its metabolite. The prolonged effect of a nondepolarizing agent may not be apparent after a single small dose. After a small dose, the termination of action is by redistribution rather than elimination. It is only after a single large dose, repeated dosing, or prolonged infusion that the increased elimination half-life becomes clinically apparent. It has also been shown that there are large differences in pharmacokinetics with patients with renal failure receiving rocuronium. Maintenance doses for patients with decreased renal function should be smaller, and the interval between doses should be increased. Monitoring of neuromuscular blockade with a nerve stimulator is recommended.

Miller RD, ed. *Miller's Anesthesia*. 7th ed. Philadelphia: Churchill Livingstone; 2010:2114–2115.

Staals LM, Snoeck MM, Driessen JJ, et al. Reduced clearance of rocuronium and sugammadex in patients with severe to end-stage renal failure: a pharmacokinetic study. *Br J Anaesth*. 2010;104:31–39.

C.9. What unusual situations can prolong neuromuscular blockade?

Drugs

- *Antibiotics.* The aminoglycosides (e.g., gentamicin) and tetracycline decrease the presynaptic release of acetylcholine by blocking the influx of calcium. Antagonism of antibiotic potentiated neuromuscular blockade by an anticholinesterase drug or calcium is unpredictable. Penicillins and cephalosporins do not have neuromuscular effects.
- *Local anesthetics.* Small doses of local anesthetics enhance neuromuscular blockade, and large doses block neuromuscular transmission. Depending on the dose,

local anesthetics interfere with the prejunctional release of acetylcholine, stabilize postjunctional membranes, and directly depress skeletal muscle.
- *Cardiac antidysrhythmic drugs.* Lidocaine can augment preexisting neuromuscular blockade. Quinidine interferes with the prejuctional release of acetylcholine and potentiates depolarizing and nondepolarizing drugs.
- *Diuretics.* Furosemide 1 mg per kg enhances nondepolarizing agents by inhibiting cyclic adenosine monophosphate (cAMP) production, leading to decreased prejunctional release of acetylcholine. Large doses of furosemide can inhibit phosphodiesterase, increasing cAMP levels leading to antagonism of nondepolarizing drugs.
- *Phenytoin.* Treatment with phenytoin causes resistance to nondepolarizing drugs.
- *Lithium.* This drug can enhance the effects of nondepolarizing and depolarizing drugs.
- *Calcium channel blockers.* Verapamil enhances nondepolarizing agents and may produce difficulty with obtaining adequate reversal.

Electrolytes

- *Potassium.* An acute decrease in potassium levels increases the transmembrane potential, causing hyperpolarization of cell membranes. This leads to resistance to depolarizing drugs and increased sensitivity to nondepolarizing drugs. An acute increase in potassium has the opposite effect by lowering the resting transmembrane potential and partially depolarizing the cell membrane. This increases the effect of depolarizing drugs and opposes the action of nondepolarizing drugs.
- *Magnesium.* Hypermagnesemia enhances nondepolarizing agents by decreasing the prejunctional release of acetylcholine and postjunctional sensitivity to acetylcholine. Phase II block may occur more readily when succinylcholine is administered in the presence of elevated plasma concentrations of magnesium

Acid–Base Imbalance

- Respiratory acidosis enhances d-tubocurarine (d-Tc)- and pancuronium-induced neuromuscular blockade and opposes their reversal with neostigmine.
- The effects of metabolic acidosis and respiratory and metabolic alkalosis are inconsistent.

Temperature

- *Hypothermia*. A decrease in temperature reduces hepatic enzyme activity responsible for metabolizing d-Tc and pancuronium, prolonging drug effect. Hypothermia can have a direct mechanical effect on the muscle, slowing contraction and relaxation and thereby enhancing the block.

Stoelting RK, Hillier SC. *Pharmacology and Physiology in Anesthetic Practice.* 4th ed. Philadelphia: Lippincott Williams & Wilkins; 2006:224–227.

C.10. How would you maintain anesthesia during the case? What drugs would you use?

General anesthesia is the preferred technique for kidney transplantation. Volatile agents, opioids, and a muscle relaxant are required to provide optimal operating conditions.

The choice of inhaled anesthetic includes desflurane and isoflurane. Sevoflurane may be avoided because the metabolism of sevoflurane has been implicated in renal toxicity as a result of production of fluoride and compound A. Desflurane and isoflurane do not have any nephrotoxic potential secondary to fluoride accumulation.

Opioids such as fentanyl, sufentanil, alfentanil, and remifentanil can be used during the procedure. Morphine and meperidine have metabolites that depend on renal clearance and can accumulate. A muscle relaxant that is not dependent on renal clearance such as atracurium, cis-atracurium, and mivacurium can be used.

Hypotension may occur after unclamping the iliac vessels and reperfusion of the graft. It is important to maintain the blood pressure because renal function is critically dependent on adequate perfusion. It is critical that the patient is adequately hydrated throughout surgery in preparation for reperfusion of the graft. Close monitoring of CVP can prevent hypotension. Vasopressors with α-agonist action should be avoided because they can comprise blood flow to the transplanted organ. Additional fluid may be required to maintain blood pressure and replace urine output. Furosemide and mannitol can enhance urine output. Loop diuretics block the Na and K channels in the thin ascending loop of Henle. This prevents reabsorption of electrolytes in this part of the nephron. The high-osmolar fluid prevents reabsorption of water in the distal tubule. A large volume of fluid with high electrolyte content is excreted. Mannitol is freely filtered in the glomerulus, but not reabsorbed. It causes osmotic expansion of urine volume.

The estimated blood loss during the procedure ranges between 200 and 500 mL. In some cases, greater blood loss may require transfusion of packed red cells. Packed red cells should be cytomegalovirus negative. At the end of surgery, patients can be given reversal agents and extubated promptly. Patients are then transferred to the postanesthesia care unit for continued monitoring of urine output and electrolytes.

Morris P, Stuart K. *Kidney Transplantation: Principles and Practice.* 6th ed. Philadelphia: Saunders; 2008:191.

C.11. What are the effects of inhalation anesthetics on renal blood flow (RBF), glomerular filtration, and urine output?

All volatile anesthetics produce a dose-related transient and reversible decrease in RBF, GFR, urine output, and the urinary excretion of sodium. This is primarily in response to a decline in systemic blood pressure and cardiac output. Reduced RBF, loss of renal autoregulation, and neurohumoral and neuroendocrine factors also contribute. Specific differences among the agents on renal function are to be noted. Halothane does not alter autoregulation of RBF and decreases renal vascular resistance and perfusion pressure proportionally. Isoflurane minimally alters RBF with light levels of anesthesia (1 minimum alveolar concentration and significantly decreases renal vascular resistance. As the depth of anesthesia with isoflurane is increased, RBF decreases because of a greater decrease in perfusion pressure than in vascular resistance.

Miller RD, ed. *Miller's Anesthesia.* 7th ed. Philadelphia: Churchill Livingstone; 2010:2164–2165.

C.12. What are the potential nephrotoxic effects of inhalation anesthetics? What are the nephrotoxic metabolites of inhalation anesthetics?

Fluoride-induced nephrotoxicity is a potential hazard following metabolism of volatile anesthetics. Desflurane (0.02%), isoflurane (0.2%), enflurane (2%), sevoflurane

(2% to 3%), and halothane (12% to 20%), are metabolized in the body (rule of 2). When serum inorganic fluoride reaches 50 to 80 mmol per L, subclinical renal toxicity (laboratory abnormalities) occurs. Clinical nephrotoxicity usually becomes apparent when the serum fluoride level is more than 80 mmol per L. The high-output renal failure is dose related and characterized by vasopressin-resistant polyuria, hypernatremia, serum hyperosmolarity, increased serum urea nitrogen, and inorganic fluoride concentration. Despite the potential for relatively high plasma levels of fluoride after long exposure to newer anesthetics, the minimal amount of sevoflurane and enflurane renal defluorination may explain the relative absence of serious renal concentrating defects with these anesthetics. Although the conventional measurements of renal function (blood urea nitrogen, creatinine) are not altered, evidence shows transient impairment of renal concentrating ability and renal tubular injury in patients receiving sevoflurane or enflurane. Nevertheless, it has not been confirmed whether administration of sevoflurane in patients with pre-existing renal disease could further deteriorate renal function. Fluoride levels after isoflurane and halothane increase by 3 to 5 μM per L and 1 to 2 μM per L, respectively. These agents do not pose a risk for nephrotoxicity. Desflurane is resistant to biodegradation because fluorine is the only halogen in the desflurane molecule. Mean inorganic fluoride concentration after 1 MAC hour exposure to desflurane is less than 1 μmol per L. Prolonged exposure to desflurane (7.0 MAC hours) has been associated with normal renal function in patients without renal disease. Neither desflurane nor isoflurane lead to a deterioration of creatinine clearance in patients with pre-existing renal impairment.

Sodium or barium hydroxide lime absorbents react with sevoflurane, resulting in a by-product called *compound A*. The nephrotoxic potential of compound A has been noted in animals and is inconclusive in human studies. The concentrations that occur in humans are far below the nephrotoxic levels in animals. A fresh gas flow of 1 L per minute or higher is recommended to minimize the accumulation of compound A in the breathing circuit. Low-flow sevoflurane (1 L per minute) has been used on many occasions with no effect on renal function. Carbon dioxide absorbents that contain calcium hydroxide and calcium chloride do not result in compound A formation when exposed to sevoflurane. The U.S. Food and Drug Administration (FDA) recommends the use of sevoflurane with fresh gas flow rates at least 1 L per minute for exposures up to 1 hour and at least 2 L per minute for exposures greater than 1 hour. Nevertheless, it is important to note that other countries have not recommended such limitations on the clinical use of sevoflurane and problems have not been noted.

C.13. How does renal failure affect the pharmacology of opioids?

The effect of renal failure on individual opioids varies, so one must consider the effect of renal failure on drug metabolites as well as the parent compound.

Morphine is metabolized in the liver to morphine-6-glucuronide (M6G) (10%), morphine-3-glucuronide (M3G) (55%), and normorphine (4%), all of which are

excreted by the kidneys, along with about 10% of the parent compound, in subjects with normal renal function. M6G has been reported to mediate the central nervous system and causes respiratory depression when it accumulates in renal failure. Meperidine is metabolized in the liver to normeperidine, also excreted by the kidneys. Accumulation of this metabolite may lead to excitatory central nervous system effects such as seizures. Fentanyl is metabolized by the liver, with only 7% excreted unchanged in the urine. Fentanyl is suitable for use during surgery and is safe in the short term. Reports have shown the parent compound accumulating during renal failure, but clinical experience is that there are no adverse effects. If being used long term in patients with renal failure, the pharmacodynamics effects should be monitored carefully. The clearance and half-life of sufentanil and alfentanil are not significantly different in patients with reduced renal function. Remifentanil is metabolized by blood and tissue esterases. The principle metabolite of remifentanil (GR90291) is eliminated by the kidney. The reduced renal elimination of this metabolite is not of clinical significance because the potency is 1 in 4,000 of the parent compound. Alfentanil metabolism occurs by inducible cytochrome c enzymes in the liver, making it suitable for renal failure patients.

D. Postoperative Management

D.1. How is the diagnosis of acute transplant rejection made?

There are various forms of rejection, for example, hyperacute, accelerated acute, acute, and chronic. Acute rejection is the most common, but less common with immunosuppressive agents. It is usually seen within days to a few months after transplant. The diagnosis is made with a renal biopsy. In patients with prolonged delayed graft function, surveillance biopsies can detect or exclude acute rejection episodes. The process is associated with systemic symptoms such as fever, chills, malaise, and arthralgias. However, with current immunosuppressive drugs, most acute rejection episodes are generally asymptomatic. Laboratory data note a rapid increase in creatinine of 10% to 25% over baseline with or without a decrease in urine output.

Brunicardi FC, Andersen DK, Billiar TR, et al. *Schwartz's Principals of Surgery.* 9th ed. New York: McGraw-Hill; 2010:274.

D.2. What are some side effects of immunosuppressive agents of which anesthesiologists should be aware?

Some of the side effects may be encountered if a posttransplant patient presents for other surgeries and are pertinent to anesthetic care:

- *Calcineurin inhibitors (cyclosporine, tacrolimus).* Nephrotoxicity, hypertension, hyperchloremic acidosis, hyperkalemia, hypomagnesemia, hypocalcemia, glucose intolerance, coarse tremor, dysesthesia, headache, seizure, prolonged QT interval, hypercoagulability, acute microvascular disease (similar to thrombotic thrombocytopenic purpura)
- *Mycophenolate mofentil.* Nausea, vomiting, cytopenia (leukopenia, anemia, thrombocytopenia), leukocytosis

- *Target of rapamycin inhibitors (sirolimus, everolimus).* Mucocutaneous ulceration, hypokalemia, hypomagnesemia, impaired wound healing, interstitial pneumonia, cytopenia
- *Azathioprine.* Cytopenia, hepatitis

Danovitch GM. *Handbook of Kidney Transplantation.* 4th ed. Philadelphia: Lippincott Williams & Wilkins; 2005:72–134.

van Hoof JP, Christiaans MHL, van Duijnhoven, EM. Tacrolimus and posttransplant diabetes mellitus in renal transplantation. *Transplantation.* 2005;79:1465–1469.

D.3. What is posttransplant erythrocytosis?

Posttransplant erythrocytosis is a persistently elevated hematocrit (greater than 51%) after engraftment. This usually occurs 8 to 24 months after engraftment. It occurs in 10% to 15% of graft recipients. Predisposing risk factors are male gender, retention of native kidneys, smoking, transplant renal artery stenosis, adequate erythropoiesis before transplantation, and rejection-free course. The most effective treat for posttransplant erythrocytosis is inactivation of the renin-angiotensin system by an angiotensin-converting enzyme inhibitor.

Vlahakos DV, Marathias KP, Agroyannis B, et al. Posttransplant erythrocytosis. *Kidney Int.* 2003;63:1187–1194.

CHAPTER 26

Robotic-Assisted Laparoscopic Surgery

JUDITH WEINGRAM

A 72-YEAR-OLD MAN

with biopsy-proved carcinoma of the prostate had a prostate-specific antigen (PSA) of 22 ng per mL but negative pelvic computed tomography (CT) and bone scans. He weighed 120 kg. Despite hypertension and a 50 pack-year smoking history, he was vigorous and active. He was scheduled for a robotic-assisted laparoscopic radical prostatectomy.

A. Medical Disease and Differential Diagnosis

1. What is the incidence of carcinoma of the prostate?
2. How is prostate cancer diagnosed?
3. How is prostate cancer treated?
4. Define laparoscopy.
5. Describe the development of robotic-assisted laparoscopy. How does the surgeon control the robot?
6. What are the advantages and disadvantages of laparoscopy?
7. What are the differences in pulmonary function after laparoscopic cholecystectomy compared with open cholecystectomy?
8. What are the contraindications to laparoscopic surgery? Is pregnancy a contraindication to laparoscopic surgery?
9. What other specialties commonly perform laparoscopic or minimally invasive surgery?
10. Why is carbon dioxide (CO_2) the gas of choice for laparoscopy? What are its disadvantages?
11. How much endogenous CO_2 is produced at basal level and at maximal exercise?
12. How much CO_2 is stored in the body? Where is it stored? Of what significance is this to laparoscopy?
13. Describe the diffusion and solubility properties of CO_2 and their significance in laparoscopy.
14. Is CO_2 soluble in water or plasma? Is it soluble in blood? Why?

B. Preoperative Evaluation and Preparation

1. What do you want to know about this patient's history and physical condition that may affect whether or not you clear him for laparoscopic surgery?
2. What factors increase this patient's risk of pulmonary complications?
3. What laboratory tests should be performed preoperatively?
4. What specific information should the patient be given about laparoscopic surgery before obtaining informed consent?
5. What additional procedures should be done before surgery?
6. What are the three major forces that uniquely alter the patient's physiology during laparoscopy?

C. Intraoperative Management

1. What is the anesthetic technique of choice for laparoscopy? Why?
2. Can a laryngeal mask airway (LMA) be used?
3. What anesthetic agents or adjuvant drugs are recommended for laparoscopy? Are any anesthetic agents contraindicated?
4. Should nitrous oxide (N_2O) be used during laparoscopy? What are the pros and cons? Does N_2O cause bowel distention during laparoscopy? Does N_2O cause nausea and vomiting after laparoscopy?
5. Can laparoscopy be performed under local anesthesia or regional anesthesia?
6. What monitors and devices would you apply to the patient? Why?
7. How is the patient to be positioned? What special precautions are required for robotic laparoscopy?
8. How will you ventilate the patient? What are the respiratory and circulatory effects of the Trendelenburg position during laparoscopy?
9. What two techniques are available for initial laparoscopic access to the peritoneal cavity? What anesthetic problems can arise during insufflation?
10. What intravenous (IV) solution and how much fluid volume do you plan to deliver?
11. What is the purpose of the heparinized saline irrigation-suction device used by the surgeon and why should you be concerned with it?
12. Under what circumstances should laparoscopy be converted to laparotomy?
13. What are the arterial to end-tidal CO_2 gradients ($Paco_2$–$PETCO_2$) in the normal awake patient? What is the cause of the gradient? Does the gradient change during laparoscopy? Why?
14. Is an arterial line necessary? Why? Does end-tidal CO_2 tension accurately reflect arterial CO_2 tension? Under what circumstances may the $PETCO_2$ exceed the $Paco_2$? Why?
15. What are the possible causes of hypercarbia?
16. What factors play a role in the unusually rapid and marked elevation of CO_2 that is sometimes seen in laparoscopy?
17. How rapidly does the $Paco_2$ rise in the apneic patient (endogenous CO_2)? How rapidly does the $Paco_2$ rise if 5% CO_2 gas is inhaled (exogenous)? How rapidly can the CO_2 rise during laparoscopy? What factors explain the differences?
18. What are the direct and indirect effects of hypercarbia on the cardiovascular system? How are these effects altered by increased intra-abdominal pressure and patient position?

19. What are the direct and indirect effects of hypercarbia on the respiratory system? How does the Trendelenburg position and the increased intra-abdominal pressure of pneumoperitoneum alter these effects?
20. What are the direct and indirect effects of hypercarbia on the central nervous system?
21. What are the neuroendocrine changes that occur during laparoscopy?
22. What are the direct and indirect effects of laparoscopy on the renal system?
23. What is the effect of hypercarbia and laparoscopy on the bowel and gastrointestinal system?
24. How would you recognize CO_2 embolism during laparoscopy? How does this differ from air embolism? Why should N_2O be discontinued during suspected embolization? Will N_2O increase the size of the CO_2 emboli?
25. What is the mechanism of increase in shunting resulting from embolization?
26. How is gas embolism (CO_2 or air) treated?
27. What are the causes of pneumothorax or pneumomediastinum during laparoscopy? How would you diagnose it? How would you treat it?
28. How would you decide when to extubate?

D. Postoperative Management

1. What are some of the unique complications of laparoscopy?
2. What postoperative orders will you write? When would you remove the Foley catheter and arterial line? Under what circumstances would you order a chest x-ray film?
3. What is the incidence of postoperative nausea and vomiting?

A. Medical Disease and Differential Diagnosis

A.1. What is the incidence of carcinoma of the prostate?

Carcinoma of the prostate is the second most common cause of death from cancer in American men. In 1983, the incidence of carcinoma of the prostate was approximately 75,000 new cases along with 25,000 deaths of old cases. In 2010, the American Cancer Society estimates that the incidence will be 217,730 (or 28% of all new cancers), along with 32,050 deaths (or 11% of all cancer deaths).

This "epidemic" increase in carcinoma of the prostate is believed to result from new methods for early detection rather than from a true rise in incidence of the disease. Undetected microscopic prostate cancer cells are believed to be present in 30% to 40% of men over the age of 50, and in 75% of men over the age of 75, but it is estimated that only approximately 8% of these will become clinically significant. It has been stated that more men die *with* prostate cancer than *from* it. Therefore, it is not yet known whether early detection of subclinical disease, much of which may have remained clinically insignificant, will improve survival.

Carcinoma of the prostate is rare in Asian men, whereas African-American men have about twice the incidence as white American men.

Potosky AL, Miller BA, Albertsen PC, et al. The role of increasing detection in the rising incidence of prostate cancer. *JAMA.* 1995;273:548–552.

A.2. How is prostate cancer diagnosed?

The most reliable methods for diagnosis include digital rectal examination plus the serum PSA level. Palpation of a tumor or indurated area and finding an elevated PSA should be followed by prostatic needle biopsies, perhaps under transrectal ultrasound guidance.

Oesterling JE. Prostate-specific antigen: improving its ability to diagnose early prostate cancer [Editorial]. *JAMA.* 1992;267:2236–2238.

A.3. How is prostate cancer treated?

Treatment choices vary not just with the stage of the disease but also with the patient's age and life expectancy, associated medical conditions, and lifestyle. In patients with localized disease, treatment choices include "watchful waiting," brachytherapy (in which radioactive seeds are implanted in the prostate gland), external beam radiation, and surgery. Surgical options include open radical prostatectomy, or laparoscopic radical prostatectomy, which can be hand-assisted or robot-assisted.

A patient with nonlocalized disease can choose to be treated with radiation, hormones, chemotherapy, or other nonsurgical options, or even to have no treatment.

D'Alonzo RC, Gan TJ, Moul JW, et al. A retrospective comparison of anesthetic management of robot-assisted laparoscopic prostatectomy versus radical retropubic prostatectomy. *J Clin Anesth.* 2009;21(5):322–328.

A.4. Define laparoscopy.

Laparoscopy (or peritoneoscopy) is a "minimally invasive" procedure allowing endoscopic access to the peritoneal cavity after insufflation of a gas (CO_2) to create space between the anterior abdominal wall and the viscera. The space is necessary for the safe manipulation of instruments and organs. Laparoscopic surgery can also be extraperitoneal. It can also be gasless with abdominal wall retraction, and, more recently, it may be hand-assisted or robotically assisted.

Weingram J. Laparoscopic and laser surgery. In: Malhotra V, ed. *Anesthesia for Renal and Genito-urologic Surgery*. New York: McGraw-Hill; 1996:151–176.

A.5. Describe the development of robotic-assisted laparoscopy. How does the surgeon control the robot?

The era of open incisions in which surgeons could directly see, touch, and manipulate organs was superceded by the era of minimally invasive surgery in which tiny cameras and laparoscopes could be inserted through small ports in the patient's body. However, this technique of conventional laparoscopy is limited by poor depth perception (visualization on a two-dimensional monitor) and the use of long, straight instruments, which limit mobility and dexterity.

Robotic devices were initially designed by NASA for the purpose of performing tasks outside the Space Shuttle while being controlled remotely from inside the spacecraft or from earth. This technology was adapted for surgery as the DaVinci computer-assisted robotic system.

The surgeon sits at a remote control console near the patient and operating room table and views the operative field as a high-resolution magnified three-dimensional image transmitted by the video camera. By using two hand-and-finger control devices, the surgeon can precisely manipulate the two mechanical arms of the robot. Foot pedals also allow the surgeon to more precisely control the robot, camera, and cautery.

A.6. What are the advantages and disadvantages of laparoscopy?

The advantages include the cosmetic results of small, non–muscle-splitting incisions, decreased blood loss, less postoperative pain and ileus, shorter hospitalization and convalescence, and ultimately lower cost. Postoperative respiratory muscle function returns to normal more quickly than in open surgery, especially in laparoscopic cholecystectomy and other upper abdominal procedures. Wound complications such as infection and dehiscence are less frequent, and host defense mechanisms may be greater in laparoscopic than in open surgery.

The disadvantages include the long learning curve for the surgeon (most complications occur during the first 10 laparoscopies), the narrowed two-dimensional visual field on video in conventional laparoscopy, the need for general anesthesia, and the often longer duration. Ideally, surgeons should have more advanced laparoscopic skills, especially in knot tying, suturing, and working two instruments simultaneously. The use of simulators to enhance these skills has been advocated.

Robotic-assisted laparoscopy, by virtue of its better visualization and greater precision, offers greater likelihood of nerve sparing and, therefore, retention of continence and potency. The disadvantages of the robot include the high cost (in millions of dollars) of purchase and maintenance, and the need for a permanently dedicated operating room location for this heavy and bulky equipment.

A.7. What are the differences in pulmonary function after laparoscopic cholecystectomy compared with open cholecystectomy?

Pulmonary function is substantially impaired after a large upper abdominal or subcostal muscle-splitting incision, as in open cholecystectomy. Marked diaphragmatic dysfunction occurs postoperatively, caused by both reflex diaphragmatic changes and incisional pain. Vital capacity and functional residual capacity (FRC) may be reduced by 20% to 40% of preoperative values, and they may not return to normal until 2 to 3 days after surgery. The mini incision of laparoscopic cholecystectomy results in far less pulmonary and diaphragmatic loss of function as well as less ileus.

A.8. What are the contraindications to laparoscopic surgery? Is pregnancy a contraindication to laparoscopic surgery?

Increasing experience with the laparoscopic technique has made most contraindications relative rather than absolute. However, it is probably best to avoid or to use extreme caution in patients with coagulopathy, diaphragmatic hernia, severe cardiovascular or pulmonary disease (including bullae), increased intracranial pressure or space-occupying masses, retinal detachment, impending renal shutdown, a history of extensive surgery or adhesions, sickle cell disease (because sickle crisis may be precipitated by acidosis), peritonitis, a large intra-abdominal mass, tumor of the abdominal wall, or hypovolemic shock. Patients with shunts (e.g., ventriculoperitoneal) are at risk for gas emboli, shunt obstruction, and intracranial hypertension, all of which may occur during laparoscopy and may require intracranial pressure monitoring and ventricular drainage if laparoscopic surgery is necessary. In summary, most of the contraindications concern patients who are unable to tolerate extremes of position, pneumoperitoneum, and/or hypercarbia.

Although pregnancy has been considered a contraindication to laparoscopic surgery in the past, an increasing number of such procedures are being performed in the parturient. Laparoscopic cholecystectomy is now more frequent than open cholecystectomy in the pregnant patient. The overall objective of laparoscopic and open surgery is to preserve fetal and maternal well-being and to prevent premature labor. In addition to the general problems of anesthesia for the parturient, the anesthesiologist also must consider the specific problems that result from the interplay between the anatomic and physiologic changes of pregnancy and the anatomic and physiologic triad of pneumoperitoneum, hypercarbia, and positional changes.

Factors to consider in the management of the pregnant patient include awareness of her increased blood volume, increased cardiac output, decreased systemic vascular resistance (SVR), hypercoagulability, the supine hypotensive syndrome, increased respiratory minute volume, decreased residual volume, decreased FRC, increased oxygen consumption, mild hypocapnia, increased risk of aspiration, and decreased anesthetic requirement.

This combination of factors tends to promote hypercarbia and hypoxemia. However, extreme hyperventilation may result in decreased uteroplacental perfusion. Arterial blood gas monitoring has been suggested to detect fetal acidosis because capnography may not reveal a large arterial to end-tidal difference in CO_2. In all cases, preoperative and postoperative fetal and uterine monitoring is essential.

A.9. What other specialties commonly perform laparoscopic or minimally invasive surgery?

Laparoscopic procedures in urology have become standard, especially for prostatectomy, uncomplicated adrenalectomy, and nephrectomy, including live donor nephrectomy. Laparoscopic gynecologic surgery includes tubal surgery (sterilization, treatment of ectopic pregnancy, etc.), cystectomies, hysterectomies, various ablations (endometriosis), and so on. Laparoscopy is performed in pregnancy and also in pediatrics. Complications include bladder and ureteral injuries and fistulae, but apparently these are not more prevalent than in standard surgery.

Laparoscopic general surgery includes cholecystectomy, hernia repair, antireflux procedures, splenectomy, appendectomy, bowel surgery including bariatric procedures, and various other upper and lower abdominal procedures.

Thoracoscopic surgery and neurosurgical intracranial surgery using modified laparoscopic instruments, but without the need for gas insufflation, are two of the more recent areas of minimally invasive surgery. Lumbar discectomies and other types of spinal surgery also have been done laparoscopically through an anterior approach. Even autopsies have been attempted laparoscopically. The list continues to grow.

A.10. Why is carbon dioxide (CO_2) the gas of choice for laparoscopy? What are its disadvantages?

CO_2 is the insufflating gas of choice because it is nonflammable, does not support combustion, readily diffuses across membranes, is rapidly removed in the lungs, and is highly soluble because of rapid buffering in whole blood. The risk of CO_2 emboliza-

tion is small. As much as 200 mL of CO_2 injected directly into a peripheral vein may not be lethal, whereas only 20 mL of air may prove to be so. In addition, CO_2 levels in blood and expired air can easily be measured, and its elimination can be augmented by increasing ventilation. As long as oxygen requirements are met, a high concentration of blood CO_2 can be tolerated. Also, medical grade CO_2 is readily available and inexpensive.

It is for these reasons that the following gases are unsatisfactory for pneumoperitoneum: nitrous oxide (does not cause pain intra-abdominally but does not suppress combustion); oxygen (flammable); helium; air and nitrogen (each has no hemodynamic or acid-base sequelae, but can cause gas emboli); and argon (adverse effect on hepatic blood flow, emboli).

It should be emphasized, however, that CO_2 plays a duel role in the body, and it is not inert. Under normal circumstances it is an intrinsic waste product of metabolism. Under the circumstances of laparoscopies, it acts as an extrinsic drug often present in quantities far larger than the body is physiologically capable of generating from even the most extreme exercise or hypermetabolic state.

The disadvantages mainly stem from the fact that CO_2 is not inert, and it has contradictory roles as an endogenous chemical and as an exogenous foreign substance. Changes in its concentration and tensions have enormous biochemical and physiologic consequences. Changes at the local tissue level are often at odds with the overall systemic effect. It causes direct peritoneal irritation and pain during laparoscopy under local anesthesia because it transiently forms carbonic acid when in contact with the moist peritoneum. In addition, CO_2 is not very soluble in the absence of red blood cells, and, therefore, it can remain in gaseous form intraperitoneally (subhepatic) after laparoscopy, causing referred shoulder pain. Hypercarbia and respiratory acidosis occur when the buffering capacity of blood is temporarily exceeded. In addition, CO_2 exerts widespread local and (often contradictory) systemic effects that may manifest overall as hypertension, tachycardia, cerebral vasodilation, hypercarbia, and respiratory acidosis.

A.11. How much endogenous CO_2 is produced at basal level and at maximal exercise?

CO_2 and water are the major end products of aerobic metabolism in the mitochondria of the cells. Carbonic acid, the major acid produced in the body, is uniquely volatile, and, therefore, it must be largely eliminated by the lungs. (Other acids are eliminated by the kidney.)

At basal rate, an average adult manufactures approximately 200 mL of CO_2 per minute (while consuming 250 mL of O_2) or 12 L of CO_2 (35 g) per hour. At maximal metabolic rate, it is estimated that the body can produce, transport, and excrete 90 to 100 L per hour, an increase of 800% over basal rate.

Kinney JM. Transport of carbon dioxide in the blood. *Anesthesiology.* 1960;21:615–619.

Lumb AB. *Nunn's Applied Respiratory Physiology*. 6th ed. Philadelphia: Butterworth-Heinemann; 2005:148–154.

A.12. How much CO_2 is stored in the body? Where is it stored? Of what significance is this to laparoscopy?

The body contains approximately 120 L of stored CO_2, most of it in the form of carbonate ion in bone. (This is approximately 100 times the amount of stored oxygen.) CO_2 in the blood is in equilibrium with CO_2 in different tissues. The rate of uptake and distribution of CO_2 from the blood (where it exists as bicarbonate ion) depends on the perfusion and storage capacity of those different tissues. The well-perfused tissues, including brain, kidneys, and blood come to rapid equilibrium. The medium-perfused compartment consists mainly of resting skeletal muscle. The slowly perfused compartment, mainly fat and bone (where it exists as the carbonate ion), has the largest CO_2 storage capacity. In contrast to rapidly changing oxygen levels, CO_2 levels reach equilibrium more slowly.

These storage sites serve to buffer and stabilize blood CO_2 levels because they provide a place for excess CO_2 to "park" until ventilation can catch up and restore equilibrium. The increase in CO_2 storage during laparoscopy is illustrated clinically by the decelerating rate of rise in $P_{ET}CO_2$ despite continuing insufflation. Blood or end-tidal CO_2 levels increase rapidly at first, then plateau at between 15 and 35 minutes, despite continuing low flow insufflation. At constant ventilation, CO_2 levels increase, but not as much as if no simultaneous storage processes were occurring. But if ventilation is increased to keep CO_2 constant, then the increase needed is only approximately 40% of the predicted volume of ventilation because of the drain off of CO_2 into the storage sites.

A.13. Describe the diffusion and solubility properties of CO_2 and their significance in laparoscopy.

Diffusion describes the process by which gases travel from an area of higher partial pressure to one of lower partial pressure. For a gaseous environment, Graham's law states that the rate of diffusion of a gas is inversely proportional to the square root of its density (i.e., the smaller the molecule, the more easily it will diffuse).

When that same gas molecule arrives at an aqueous membrane (e.g., a gas–liquid interface), the solubility of that gas in water now becomes the major factor in determining its diffusing capacity (as shown in Table 26.1). The water solubility of CO_2 is

Table 26.1 Influence of Physical Properties on the Diffusion of Gas through a Gas/Liquid Interface

GAS	MOLECULAR WEIGHT	DENSITY RELATIVE TO O_2	SOLUBILITY RELATIVE TO O_2	WATER DIFFUSION CAPACITY RELATIVE TO O_2
O_2	32	1.0	1.0	1.0
N_2	28	0.88	0.515	0.55
CO_2	44	1.37	24.0	20.5
N_2O	44	1.37	16.3	14.0
He	4	0.125	0.37	1.05

24 times that of O_2, whereas the diffusion capacity of CO_2 is 20.5 times that of O_2. The capacity of a gas to diffuse across a membrane is directly proportional to its solubility in water and inversely proportional to its molecular weight. However, the actual movement of that gas across the aqueous membrane depends not only on its diffusing capacity, but more importantly, on the pressure gradient across that membrane.

The fate of CO_2 gas insufflated into the peritoneal cavity is the same that would occur in any other closed but distensible cavity. The pressure obtained within the cavity varies directly with the volume of gas insufflated and indirectly with the compliance of the closed cavity.

Therefore, the ability of CO_2 to move from the closed peritoneal cavity to the lungs for excretion is dependent on its intrinsic diffusion and solubility properties, the rate of continuing CO_2 insufflation, the surface area of the cavity, and the partial pressure difference across membranes.

Lumb AB. *Nunn's Applied Respiratory Physiology*, 6th ed. Philadelphia, PA: Butterworth-Heinemann; 2005:148–152.

McHoney M, Corizia L, Eaton S, et al. Carbon dioxide elimination during laparoscopy in children is age dependent. *J Pediatr Surg*. 2003;38(1):105–110.

A.14. Is CO_2 soluble in water or plasma? Is it soluble in blood? Why?

CO_2 is relatively insoluble in plasma, interstitial fluid, and water. (Think of the rapid escape of gas from a freshly-opened carbonated soft-drink.) The solubility of CO_2 in water at 37° C (98.6° F) is only 0.03 mmol/L/mm Hg. This must be contrasted to the very high solubility of CO_2 in whole blood. This extremely important distinction exists because of a zinc-containing enzyme, carbonic anhydrase, that exists within the erythrocyte but not at all in plasma.

$$H_2O + CO_2 \xrightarrow{\text{carbonic anhydrase}} H_2CO_3 \rightarrow H^+ + HCO_3^-$$

In the equation shown, carbonic anhydrase catalyzes the left side of the equation (i.e., the hydration of CO_2 to H_2CO_3). Once formed, carbonic acid is unstable and immediately dissociates into H^+ and HCO_3^-. It is estimated that without carbonic anhydrase it would take 200 seconds at 38° C (100.4° F) for the previous reaction to come to 10% equilibrium. Because blood travels through the pulmonary capillaries in less than 1 second, carbonic anhydrase speeds up the reaction by a factor of 7,500 times.

Carbonic anhydrase, therefore, allows the insufflated CO_2 gas to be dissolved and carried as bicarbonate in the blood. The process is reversed in the lungs, and the reconstituted CO_2 gas is removed by respiration.

Christian G, Greene NM. Blood carbonic anhydrase activity in anesthetized man. *Anesthesiology*. 1962;23:179–186.

Lumb AB. *Nunn's Applied Respiratory Physiology*. 6th ed. Philadelphia: Butterworth-Heinemann; 2005:148–158.

B. Preoperative Evaluation and Preparation

B.1. What do you want to know about this patient's history and physical condition that may affect whether or not you clear him for laparoscopic surgery?

Because of his advanced age, it is best to form one's own observations of his mental and physical condition. Is he confused, short of breath, kyphoscoliotic, and so forth?

A glimpse at where and how this patient's body weight is distributed means more than just knowing that he weighs 120 kg. Ask about smoking, wheezing, or any change in exercise tolerance, cough, or recent upper respiratory infection. Perform your usual preoperative evaluation and obtain any consultations, which may be informative. Consult with the surgeon regarding the need for appropriate preoperative antibiotics.

Efron DT, Bender JS. Laparoscopic surgery in older adults. *J Am Geriatr Soc.* 2001;49: 658–663.

B.2. What factors increase this patient's risk of pulmonary complications?

- *The laparoscopic procedure itself*. The basic laparoscopic Trendelenburg position and the increased intraperitoneal volumes and pressures in a paralyzed, mechanically ventilated patient cause respiratory dysfunction. Insufflation pressures should not exceed 12 to 15 mm Hg. Lower pressures are especially advantageous in American Society of Anesthesiologists (ASA) class III and IV patients with diminished cardiopulmonary reserve. In addition, an increased CO_2 load might call for respiratory minute volumes that are so large that further cardiopulmonary compromise occurs.
- *Age*. Pulmonary function declines with age, especially in a patient older than age 70.
- *Smoking/chronic obstructive pulmonary disease (COPD)*. Smokers have increased tracheobronchial secretions with decreased ciliary transport function. They may already have significant pulmonary dysfunction, which may be manifested by diminished exercise tolerance. The forced vital capacity may be diminished in restrictive pulmonary disease, whereas the forced expired volume in 1 second is likely to be decreased in obstructive pulmonary disease.
- *Obesity*. Obesity compounds the problems of increased intra-abdominal pressure in the Trendelenburg position. Excessive weight and pressure on the diaphragm and lung bases can lead to marked ventilation and perfusion abnormalities, difficulty in inserting trocars, upward displacement of the carina (leading to possible endobronchial intubation), barotrauma, and so forth.
- *Overhydration*. Patients often experience oliguria during laparoscopy. This may be interpreted as insufficient hydration, and a relative overtransfusion may ensue. Unless frank pulmonary edema occurs, this cause of mild or moderate respiratory distress in the postanesthesia care unit (PACU) may not be recognized without a chest x-ray film.

Kendell AP, Bhatt S, Oh TE. Pulmonary consequences of carbon dioxide insufflation for laparoscopic cholecystectomies. *Anaesthesia.* 1995;50:286–289.

B.3. What laboratory tests should be performed preoperatively?

Basic tests should include complete blood count, urinalysis, clotting functions, electrocardiogram (ECG), and blood typing and screening. In addition, baseline electrolytes, chemistries, and renal function tests (blood urea nitrogen, creatinine) should be obtained because of the possibility of oliguria during a long laparoscopy. Baseline pulmonary function tests, arterial blood gas measurement, and oxygen saturation values while breathing room air would be helpful in this patient. Markedly abnormal values might suggest the need for bronchodilators, antibiotics, postural drainage, and delay in surgery until pulmonary function is optimal for this particular patient. Baseline chest films are necessary not only to rule out active disease but also for postoperative comparison of acute changes such as subcutaneous or mediastinal emphysema, pneumothorax, or interstitial or pulmonary edema. The presence of

bullae on preoperative chest x-ray films may represent a contraindication to laparoscopic surgery because of the accompanying large tidal volumes and high intrathoracic pressures.

In patients with cardiac issues, echocardiogram, stress test, and cardiology clearance may be advisable.

Miller RD, ed. Millere's *Anesthesia*. 7th ed. Philadelphia: Churchill Livingstone; 2010:1001–1052.

B.4. What specific information should the patient be given about laparoscopic surgery before obtaining informed consent?

In addition to the usual general complications of the planned surgery and anesthesia, the patient must also be told of the complications unique to laparoscopy, and consent for possible laparotomy must be obtained. Emergency laparotomy may be required in the event of such complications as hemorrhage or organ perforation or because of anatomic or technical reasons. The patient should also be advised of the possibility of postoperative referred shoulder pain.

B.5. What additional procedures should be done before surgery?

Although the surgery is described as minimally invasive, the patient must be ready for maximally invasive surgery if necessary. Therefore, the patient must comply with preoperative orders regarding:

- Diet—it should consist of clear liquids the day before surgery. Nothing orally after midnight.
- A complete bowel preparation is necessary.
- Preoperative antibiotics, as per surgeon.

B.6. What are the three major forces that uniquely alter the patient's physiology during laparoscopy?

- *Pneumoperitoneum*, and problems related to the creation, maintenance, and consequences of the increase in intra-abdominal pressure and volume.
- *Carbon dioxide*, including its chemical and physical properties, and its local and systemic effects.
- Extremes of patient *positioning* on the operating table, which in this case will be steep Trendelenburg.

It is vital that the anesthesiologist have a thorough understanding of the physiologic consequences of changes in these three forces. Separately or in combination, they have profound effects on the patient's hemodynamic, respiratory, and metabolic functions. The early gynecologic laparoscopies were usually brief, and they were performed on young healthy women who tolerated these physiologic trespasses with nearly insignificant changes. These same three forces, however, may produce significant physiologic changes in long, complex laparoscopies in older, sicker patients who may be unable to compensate.

C. Intraoperative Management

C.1. What is the anesthetic technique of choice for laparoscopy? Why?

The technique of choice for laparoscopy is general anesthesia with a cuffed endotracheal tube and controlled positive pressure ventilation, because of the following reasons:

- Duration may be long.
- Patient may be anxious.
- The Trendelenburg position may cause respiratory compromise and dyspnea in the awake or in the spontaneously breathing patient with abdominal contents under pressure. The obese patient may be especially uncomfortable in this position.
- A nasogastric or orogastric tube difficult to insert in a conscious patient is necessary to decompress the stomach and minimize the risk of aspiration or perforation by trocars. CO_2, as with N_2O, diffuses into the stomach.
- However, perhaps the most important reason relates to muscle relaxation. Muscle relaxation and paralysis are necessary because the increase in intra-abdominal pressure and splinting of the diaphragm make spontaneous breathing difficult. It provides a quieter surgical field and better surgical exposure. "Bucking" increases negative pressure in the chest, which increases the risk of pneumothorax or gas dissection. Coughing can further increase pressure in the abdomen and cause movement of, and perforation by, intra-abdominal instruments. Moreover, muscle relaxation is necessary to control and augment ventilation to compensate for the hypercarbia and respiratory acidosis that results from absorption of CO_2.

C.2. Can a laryngeal mask airway (LMA) be used?

Although successful use of the LMA has been reported by several British groups for very brief laparoscopic procedures in healthy patients, its use is not recommended. The LMA does not protect against aspiration. It also limits the ability to apply positive pressure ventilation and interferes with the use of an orogastric tube.

C.3. What anesthetic agents or adjuvant drugs are recommended for laparoscopy? Are any anesthetic agents contraindicated?

Almost any combination that provides amnesia, analgesia, and paralysis is suitable. Because closure of a laparoscopic procedure may be abrupt, because patients may be discharged soon after surgery, and because a large painful (stimulating) incision is absent, the most common combination probably includes an inhalation agent, a medium-duration narcotic, and an intermediate-acting muscle relaxant.

Use of an antiemetic is recommended to counteract the nausea resulting from peritoneal stimulation and bowel distention (secondary to diffusion of CO_2 into the bowel). Small doses of the antiemetic droperidol had been used effectively because it potentiated sedation, was long acting, could be given early in the procedure, and, as an α-blocker, helped counteract the hypertensive effects of systemic CO_2. Newer antiemetics include such 5-HT_3 receptor antagonists as ondansetron and dolasetron. These may be combined with dexamethasone.

Propofol also has an HT_3 antiemetic effect. However, a propofol-based maintenance anesthetic, when combined with neuromuscular block, may not adequately prevent patient awareness. A bispectral index (BIS) monitor may be helpful in that situation.

A vagolytic drug should be at hand because acute stretching of the peritoneum may cause reflex bradycardia. This is more likely to occur in young women than in older adults.

Halothane is the only anesthetic that should probably be avoided because it may cause arrhythmias in the presence of hypercarbia. Hypnotics and sedatives should be used cautiously in older adults because their duration may be prolonged.

C.4. Should nitrous oxide (N_2O) be used during laparoscopy? What are the pros and cons? Does N_2O cause bowel distention during laparoscopy? Does N_2O cause nausea and vomiting after laparoscopy?

The use of N_2O has been considered controversial. The controversies surrounding laparoscopic use of N_2O center on the causes of bowel distention during surgery and nausea and vomiting postoperatively.

In examining the issue of bowel distention with N_2O, note the following. The diffusion capacity of N_2O is approximately 14 times that of O_2 and 28 times that of nitrogen (see Table 26.1). Therefore, in a closed space that contains air, N_2O enters faster than N_2 can leave, thereby increasing the size of the closed space. It has been shown that the volume of an enclosed intestinal air pocket can be doubled by inhalation of 70% N_2O in 2 hours and up to tripled in 4 hours. When N_2O is limited to 50%, pocket volume increases no more than 50%. A much more rapid increase in gas volume occurs in the pleural space, where volume was shown to double in 10 minutes, triple in 45 minutes, and quadruple in 2 hours. The faster rate of pleural gas expansion as compared to bowel gas expansion may in part be due to the greater blood flow to the pleura, and possibly due to direct diffusion of N_2O from the alveoli adjacent to the pleura.

However, during laparoscopy, we are concerned about CO_2 pockets not air pockets. N_2O, which has a diffusion capacity almost as great as CO_2, will diffuse from the bloodstream into the intraperitoneal pocket of 100% CO_2 at a rate determined

by its solubility in water, its diffusing capacity through an aqueous membrane, and its pressure gradients (as discussed in section A.13). Similarly, CO_2 will leave the peritoneal cavity according to its pressure gradients and solubility and diffusion characteristics. Eventually, the amount of N_2O found in the peritoneal cavity can be significant, and theoretically it can form an ignition hazard. (However, Hunter states that it is necessary for methane or hydrogen to occupy at least 5.5% of the gas volume for nitrous oxide to support combustion, a condition that does not naturally occur.)

In the situation of an air pocket in the bowel, it is well known that N_2O will diffuse in according to its gradients, thereby enlarging the pocket. However, few realize that even in the absence of N_2O, CO_2 also will diffuse into this pocket and expand it in a manner that is clinically indistinguishable from N_2O.

N_2O is often blamed for a distended bowel during laparoscopy, without realizing that CO_2 is equally capable of diffusing into and distending the bowel. In a double-blinded study of bowel distention in patients undergoing laparoscopic cholecystectomy with either isoflurane 70%-N_2O-O_2 or isoflurane-air-O_2, the surgeon was able to identify the use of N_2O correctly only 44% of the time. In addition, postoperative nausea and vomiting was independent of the use of N_2O, because the incidence was similar in both groups. Another study found no difference in the incidence of postoperative nausea and vomiting between groups receiving propofol-air-O_2 or propofol-N_2O-O_2 in gynecologic laparoscopy. In fact, the propofol-N_2O-O_2 group had the advantages of significantly more rapid emergence, use of 30% less propofol, additional analgesia, and less risk of awareness.

Because of these issues, it is recommended that nitrous oxide, if used, be limited to not more than 50% of the inspired mixture during laparoscopy. Alternatively, a mixture of 75% air and 25% oxygen (FIO_2 = 40%) is probably a wiser choice.

C.5. Can laparoscopy be performed under local anesthesia or regional anesthesia?

Yes. However, under local anesthesia, CO_2 may cause pain intraperitoneally, which is referred to the shoulder. It is for this reason that N_2O, which is nonirritating to the

peritoneum, had been used as the insufflating gas for very brief diagnostic laparoscopy under local anesthesia without cautery. However, rapid peritoneal distention causes nausea, which may be worsened without a nasogastric tube. Because of patient discomfort, the surgeon may obtain suboptimal visualization of the surgical field. Also the possibility, although remote, of having to open the abdomen speaks against local anesthesia.

Regional anesthesia can be used for laparoscopy. However, it too has serious drawbacks. It requires a high level of sensory block, possibly causing dyspnea in the Trendelenburg position. A nasogastric tube may not be tolerated. Hyperventilation in response to hypercarbia may cause too much movement in the surgical field, and spontaneous ventilation may be inadequate to compensate for hypercarbia in the Trendelenburg position. Because the systemic response to hypercarbia is mediated primarily through sympathetic stimulation, the sympathetic denervation resulting from high regional anesthesia will result in hypotension and decreased cardiac output rather than the hypertension and increased cardiac output usually seen with general anesthesia.

Use of IV analgesics or propofol during regional anesthesia may result in respiratory depression or obstruction, especially in steep Trendelenburg position. Hypoxia in the presence of hypercarbia may have serious cardiovascular consequences.

C.6. What monitors and devices would you apply to the patient? Why?

The usual intraoperative monitors, including standard 5-lead ECG with ST trending, systemic blood pressure (BP) using automated oscillometry, pulse oximetry, capnography, a nerve stimulator, and indicators of inspired oxygen fraction, minute ventilation, and peak airway pressures are necessary. An esophageal probe may be used for both temperature monitoring (optimal at the distal esophagus) and for breath, heart, and murmur sound monitoring (at heart level). Body temperature should be maintained with a forced warm air heating blanket, warmed intravenous fluids, or other means. (For robotic procedures, we place the warming blanket under the patient.) Rarely, central venous pressure (CVP), pulmonary artery pressure, pulmonary artery occlusion pressure (PAOP) and cardiac output may be measured in patients with severe cardiac or pulmonary abnormalities. A BIS monitor may be used. Other possibilities include Doppler, transesophageal echocardiography, and noninvasive assessment of cardiac output by thoracic bioimpedance or thoracic ultrasound. An arterial line is suggested during longer, more complex laparoscopic procedures in sicker (ASA classes III and IV) patients.

Intermittent sequential compression antiembolic stockings should be applied. Shoulder braces or adhesive taping are used for support in the Trendelenburg position. After the patient is asleep, a nasogastric or orogastric tube and a Foley catheter is inserted for decompression of stomach and bladder. Use of an orogastric tube is not optional. In addition to the danger of regurgitation from the increased abdominal pressure, reports have been made of stomach perforation by trocars. The orogastric tube should not be clamped after initial placement, and intermittent suctioning should continue, because CO_2 gas continues to diffuse into the stomach and distend it.

In addition to mechanical monitoring, visual and tactile monitoring are necessary during laparoscopy. Skin color, skin turgor, and capillary refill should be monitored because they can change abruptly. The head, neck, and upper chest may assume a purplish color in the dependent position, especially during hypercarbia. The upper chest wall should be checked periodically for subcutaneous emphysema. The cornea and conjunctiva should be checked periodically for edema, especially in the Trendelenburg position, and also whenever oliguria occurs because the extent of the edema may influence your decision on when to extubate.

It is important to maintain accurate data on the volume of fluids infused, and the patient's hourly or half-hourly urine output, along with observations on its color and concentration. Despite adequate hydration, oliguria frequently occurs during pneumoperitoneum, especially at intra-abdominal pressures approaching or exceeding 15 mm Hg. The acute increase in intra-abdominal pressure is transmitted to the kidneys, and is believed to cause shunting from the cortex to the medulla of the kidney, resulting in decreased urine output. Diuresis usually occurs rapidly on release of intra-abdominal pressure.

C.7. How is the patient to be positioned? What special precautions are required for robotic laparoscopy?

In pyeloplasties the side to be worked on usually is elevated, enabling gravity to assist in separating the organs and allowing blood to pool away from the operative field. For other laparoscopies, the patient may be supine, in the Trendelenburg position (with possible lateral rotation) for urology; in dorsolithotomy for gynecology; in the head-up position for upper gastrointestinal and biliary tract surgery; and in the lateral decubitus position for thoracoscopy, nephrectomy, and adrenalectomy. For standard laparoscopy, you may or may not be able to keep one or both arms out on boards, depending upon the procedure and the surgeon's needs.

In robotically assisted laparoscopy, it is especially important to check that all lines (IVs, A-line if present) as well as BP cuff, ECG leads, and pulse oximeter are functioning properly after the arms have been carefully padded and tucked at the patient's sides. This must be done before the patient is lowered into Trendelenburg position. Once the robot is locked into position, you will no longer have access to check the arms or look under the drapes. It is a good idea to cut off the clamps on the IV tubing that may press into the patient's skin while the arms are tightly tucked.

Next, after satisfactory general endotracheal anesthesia has been obtained, the surgeons may place towels or sponges across the patient's chest, followed by criss-crossing of wide adhesive tape reaching from one side of the table and patient's chest to the opposite shoulder and opposite side of the table. This X-formation is designed to secure the patient to the table. While the surgeons are applying the tape, it is recommended that you put your hand under the chest sponge to make sure that the tape is not tight enough to restrict chest expansion. (Padded shoulder braces may

be used instead of the tapes, but the incidence of brachial plexus injury is higher with these.)

With the knees flexed in padded leg holders, the patient is now carefully lowered into steep Trendelenburg position.

C.8. How will you ventilate the patient? What are the respiratory and circulatory effects of the Trendelenburg position during laparoscopy?

Respiratory

Vital capacity and FRC are reduced. The abdominal contents restrict movement of the diaphragm, especially in the obese and in older adults. Decreased compliance, increased ventilation–perfusion abnormalities, and cephalad displacement of the mediastinum commonly occur.

Circulatory

In healthy patients, Trendelenburg position results in minimal circulatory changes. Venous return and cardiac output are increased, whereas CVP, pulmonary artery occlusion pressure (PAOP), systemic vascular resistance (SVR), and heart rate are essentially unchanged. In patients with cardiovascular disease, the Trendelenburg position may result in increased CVP, PAOP, and decreased cardiac output. The increase in venous return and myocardial oxygen demand that occurs in severe cardiovascular disease can precipitate acute heart failure.

These respiratory and circulatory changes caused by the Trendelenberg position are further amplified by the CO_2 insufflation. Ventilation may become difficult, especially in obese patients. Use of positive end-expiratory pressure (PEEP) is advised. To prevent peak inspiratory pressures from becoming excessive, switching from volume-controlled to pressure-controlled ventilation may be warranted.

C.9. What two techniques are available for initial laparoscopic access to the peritoneal cavity? What anesthetic problems can arise during insufflation?

Pneumoperitoneum can be achieved by a "blind" or closed technique of percutaneous insertion of the 2-mm diameter hollow Veress needle, which after verification of correct positioning, is connected to the CO_2 insufflator. (After Veress needle insertion, the first trocar is also inserted blindly.)

Alternatively, if previous surgery or adhesions are to be avoided, an "open" approach is taken. A mini incision is created, and the blunt-tipped Hasson cannula is inserted without prior pneumoperitoneum. The laparoscope is then inserted through the trocar to verify the intra-abdominal position before insufflation begins.

During insufflation, abdominal distention should be evenly distributed in all four quadrants. Respiratory variations of intraperitoneal pressure should be visible, and peak inspiratory pressures will gradually increase as the abdomen distends. It is at this time that the anesthesiologist should be alert to the possibility of vagally mediated reflexes. Bronchospasm, bradycardia, and even sinus arrest have been reported, especially in young women. Visceral and vascular perforations are also well-reported complications, especially with the blind technique. Cardiovascular collapse and gas emboli have been reported when CO_2 has been inadvertently insufflated directly into a blood vessel.

C.10. What intravenous (IV) solution and how much fluid volume do you plan to deliver?

Large-bore intravenous catheters should be placed because of the possibility of major hemorrhage. The amount of IV fluid infused is of vital importance, especially in older adults. Transient oliguria during laparoscopy is common. In our early cases, we increased our infusion rate in response to waning urine output, and we hydrated intraperitoneal laparoscopic cases as if they were open intraperitoneal cases. After several cases of "unexplained" pulmonary edema in the PACU we concluded that the oliguria seen in laparoscopy is not related to volume depletion, and we have decreased our fluid replacement to approximately 4 mL/kg/hour of Ringer's lactate solution, depending on the patient's preoperative hemodynamic status and the volume of residual intraperitoneal irrigation fluid used by the surgeon. In calculating fluid requirements during laparoscopy, it is important to remember that much less "third-spacing" occurs than in open surgery, no fluid loss is caused by evaporation, and the volume of retained (after suctioning) intraperitoneal saline used for irrigation by the surgeon should be added to the final total volume of infused IV fluids. In addition, the intra-abdominal humidification of the insufflated dry CO_2 gas results in only a negligible insensible water loss.

After pneumoperitoneum is ended, diuresis occurs promptly and renal function quickly returns to normal (see section C.22).

For robotic laparoscopies, surgeons prefer that IV fluids are minimized until the anastomoses are completed. This keeps excessive fluids out of the surgical field and also helps prevent edema of the face, eyes, and larynx while in steep Trendelenberg

position. After the anastomoses are complete, the surgeons prefer that we then hydrate the patient. At our institution, the average duration for robotic prostatectomy is 3 to 3½ hours, the average blood loss is under 200 mL, and the usual fluid replacement is 3 to 3.5 L of lactated Ringer's solution.

C.11. What is the purpose of the heparinized saline irrigation-suction device used by the surgeon and why should you be concerned with it?

The heparinized saline irrigation-suction device (5 L delivered by pressurized bag) is used by the surgeons to retard clot formation in the abdomen, to remove blood from the field, and to remove smoke from electrocautery. It takes the place of lap pads and sponges in open surgery. If the tip of the suction device is not kept under the fluid level, CO_2 gas will be aspirated and exposure of the field will be lost.

Its further significance to the anesthesiologist is twofold. First, the difference between the volume of saline missing from the irrigation bag and the volume in the suction collection bottle must be considered as part of the patient's fluid intake. Second, the temperature of the saline solution intraperitoneally can alter the patient's body temperature.

Moore SS, Green CR, Wang FL, et al. The role of irrigation in the development of hypothermia during laparoscopic surgery. *Am J Obstet Gynecol.* 1997;176:598–602.

C.12. Under what circumstances should laparoscopy be converted to laparotomy?

Laparotomy should be performed immediately in cases of bleeding or major organ damage. Other circumstances include persistent problems with inadequate exposure, procedure beyond the surgeon's capability, procedure taking too long, inability to create or maintain pneumoperitoneum, patient deterioration, equipment failure, and discovery of other unsuspected disease.

Tabboush ZS. When hypotension during laparoscopic cholecystectomy indicates termination of the laparoscopy [Letter]. *Anesth Analg.* 1994;79:195–196.

C.13. What are the arterial to end-tidal CO_2 gradients ($Paco_2$–$PetCO_2$) in the normal awake patient? What is the cause of the gradient? Does the gradient change during laparoscopy? Why?

In the awake person at rest, the normal arterial to end-tidal Pco_2 difference is small, perhaps ranging from 2 to 6 mm Hg. The gradient and its variations are measures of the alveolar dead space. The gradient is the sum of the difference between the arterial and alveolar CO_2 plus the difference between the alveolar and end-tidal CO_2. It is commonly increased in emphysema. The difference is increased when underperfused alveoli are ventilated, as often occurs during hyperventilation in laparoscopy.

The total physiologic dead space consists of the anatomic dead space (passageways that do not participate in gas exchange, approximately 150 mL) and the alveolar dead space (i.e., underperfused alveoli). The alveolar dead space gas is expired at the same time as the alveolar ideal gas from well-perfused alveoli in equilibrium with pulmonary capillary blood. The dilution of the ideal alveolar gas by the alveolar dead space gas is represented by the end-tidal CO_2.

Some of the factors resulting in a relative increase in ventilation-to-perfusion ratio include mechanical ventilation, hyperventilation, rapid or shallow ventilation, and Trendelenburg or lateral decubitus position.

Some of the factors resulting in a relative decrease in perfusion-to-ventilation ratio include hypotension, decreased cardiac output, myocardial depression from inhalational anesthetics, pulmonary emboli, high positive airway pressure, and ablation of the hypoxic pulmonary vasoconstriction reflex.

C.14. Is an arterial line necessary? Why? Does end-tidal CO_2 tension accurately reflect arterial CO_2 tension? Under what circumstances may the $PetCO_2$ exceed the $Paco_2$? Why?

An arterial line is recommended whenever the laparoscopic procedure is unusually complex, long or when the patient has significant cardiopulmonary disease. In such cases, ventilation–perfusion abnormalities, intraoperative hypoxemia, marked hypercarbia, or high airway pressures may be expected. During these situations, and possibly in all laparoscopies, an unsteady state exists with respect to CO_2, and the assumption that $PetCO_2$ may accurately reflect a predictable relationship to $Paco_2$ is not valid.

End-tidal CO_2 tension can either estimate $Paco_2$; or, more often, it may underestimate $Paco_2$; or, less often, it may even exceed $Paco_2$. Furthermore, the values for these two measurements do not always change proportionally nor do they always change in the same direction. The relationship between $PetCO_2$ and $Paco_2$ varies during the course of the procedure. At the beginning of insufflation, $PetCO_2$ can be used as a rough estimate of $Paco_2$. However, when redistribution of the excess CO_2 from the well-perfused tissues to the less well-perfused tissues begins, $PetCO_2$ begins to underestimate the $Paco_2$. Characteristically, the arterial to end-tidal CO_2 difference progressively increases as hyperventilation (and dead space) increases.

Especially during strenuous exercise when metabolic CO_2 production is increased and during laparoscopy when excess exogenous CO_2 must be excreted, the $PetCO_2$ may be found to exceed the $Paco_2$. This condition has also been reported in a hyperventilating patient during cesarean section. This occurs because the $Paco_2$ fluctuates during each deep breath and may not represent the highest value at that

instant, whereas the $P_{ET}CO_2$ shows the maximal value (i.e., because of tidal ventilation and pulsatile blood flow in exercise, $P_{ET}CO_2$ may exceed mean alveolar and arterial CO_2).

C.15. What are the possible causes of hypercarbia?

- Hypoventilation.
- CO_2 in the inspired gas—rebreathing endogenous CO_2 will increase $Paco_2$ by 3 to 6 mm Hg per minute.
- Increased endogenous CO_2 production or from exogenous CO_2 supply—occurring in the hypermetabolic states of malignant hyperpyrexia, fever, and hyperthyroidism; and in laparoscopy, or following administration of bicarbonate or lactate (1 ampule of 50 mEq of bicarbonate liberates more than 1 L of CO_2).
- Increased dead space (rare) as in pulmonary embolism, ventilation of a lung cyst, or in advanced COPD.

Wolf JS Jr, Clayman RV, Monk TG, et al. Carbon dioxide absorption during laparoscopic pelvic operation. *J Am Coll Surg*. 1995;180:555–560.

C.16. What factors play a role in the unusually rapid and marked elevation of CO_2 that is sometimes seen in laparoscopy?

- Patients with significant cardiopulmonary disease
- Intra-abdominal pressure greater than 15 mm Hg
- Presence of subcutaneous emphysema
- Retroperitoneal rather than intraperitoneal approach
- Long duration of laparoscopy

C.17. How rapidly does the $Paco_2$ rise in the apneic patient (endogenous CO_2)? How rapidly does the $Paco_2$ rise if 5% CO_2 gas is inhaled (exogenous)? How rapidly can the CO_2 rise during laparoscopy? What factors explain the differences?

In the apneic patient, $Paco_2$ rises at the rate of 3 to 6 mm Hg per minute. Rebreathing, or inhalation of 5% CO_2 in oxygen, causes a much more rapid rise in $Paco_2$ up to 8 to 10 mm Hg per minute. The difference in rate of rise between endogenous and exogenous CO_2 is explained by the presence of large body stores of CO_2. Approximately 120 L of CO_2 exist in the body (100 times the amount for oxygen) distributed among well-perfused tissue (e.g., blood, brain), moderately perfused tissue (e.g., muscle), and poorly perfused tissue (e.g., fat, bone). These storage places adjust slowly to acute CO_2 changes. In the steady state, the amount of CO_2 produced metabolically in the body is equal to the amount expired through the lungs, and there is no change in the body stores of CO_2. During laparoscopy an unsteady state exists, with the rate of rise of Pco_2 being greatest during the first 20 to 30 minutes. After that time, new equilibrium levels are reached between the different compartments, and the Pco_2 rate of rise is slower.

Frumin et al. studied the hypercarbic state during their classic study of apneic oxygenation. In paralyzed apneic intubated denitrogenated oxygenated patients receiving only thiopental for amnesia, Frumin et al. demonstrated at least a 3-mm Hg average rise in $Paco_2$ per minute and an ultimate $Paco_2$ as high as 250 mm Hg (pH 6.72) while maintaining 98% to 100% O_2 saturation after 53 minutes of apnea. They also found that the hypercarbia was accompanied by hypertension (mean arterial pressure rise of 26%, followed by a fall of 14% on return of respirations and normocarbia). Other features accompanying apneic hypercarbic hypertension included normal sinus rhythm with an essentially unchanged rate, rising arterial epinephrine and norepinephrine concentrations, and rising arterial potassium levels (which rose still further after ventilation and normocarbia resumed) with unchanged sodium levels.

C.18. What are the direct and indirect effects of hypercarbia on the cardiovascular system? How are these effects altered by increased intra-abdominal pressure and patient position?

The effects of hypercarbia on the circulatory system are complex and often contradictory. At the cellular level, hypercarbia is a direct depressor of myocardial contractility and rate of contraction, and it is also a direct stimulant of myocardial irritability and arrhythmicity. These effects may be enhanced by the reduced pH caused by hypercarbia.

The direct effect of hypercarbia on isolated or denervated blood vessels is a diminished responsiveness to catecholamines and vasodilation especially on the venous side, leading to peripheral pooling, decreased venous return, and decreased cardiac output. The exception to the dilatory effect of hypercarbia and acidosis on blood vessels exists in the pulmonary vessels, which undergo vasoconstriction. It appears,

however, that the effects on the pulmonary vessels are actually due to acidosis rather than hypercarbia because if the pH is kept constant while the P_{CO_2} rises, then pulmonary vascular resistance (PVR) does not change.

In the patient, however, the direct or local effects of CO_2 can be overshadowed by a variety of systemic effects. Simultaneous with these local or direct effects, hypercarbia causes profound systemic changes secondary to stimulation of the central nervous system and sympathoadrenal system. The net effect usually includes an increase in cardiac output, heart rate, force of myocardial contraction, BP, CVP, vasoconstriction in the pulmonary (capacitance) vessels, and decreased peripheral resistance. The rise in cardiac output of up to 50% exceeds the rise in BP, because of the drop in peripheral resistance and increase in blood flow primarily in the cerebral and coronary circulations. This net stimulatory effect accompanies the elevation of P_{aCO_2} up to approximately 90 mm Hg. Above this level, further increases in CO_2 cause a marked drop in response.

In a normal anesthetized human breathing 7% to 15% inspired CO_2, these stimulatory changes were shown to correspond primarily to rising plasma concentrations of epinephrine and norepinephrine. When the sympathoadrenal response was prevented by subarachnoid block, ganglioplegics, or α-adrenergic blockers, the cardiovascular response to inhaled CO_2 was hypotension and decreased cardiac output. The stimulatory response also is diminished by general anesthesia.

Hypercarbia can cause arrhythmias during epinephrine infiltrations or in the presence of halothane but not other anesthetics. Other than in these two circumstances, hypercarbia is not arrhythmogenic unless hypoxia also is present.

The full range of possible effects of hypercarbia on the cardiovascular system are subject to many influences. Healthy (ASA class I) patients are less likely than ASA class III patients to undergo extreme changes. Similarly, a brief surgical duration, head-up positioning, low intra-abdominal pressures, and intraperitoneal (rather than extraperitoneal) surgery can limit the range of physiologic and metabolic responses to near normal.

In the patient with marginal cardiovascular function, however, peritoneal insufflation can result in significant increase in cardiac workload. In this situation, transesophageal echocardiography may provide a useful noninvasive method of estimation of left ventricular function.

Arrhythmias such as bradycardia, nodal rhythm, or even asystole can follow rapid peritoneal distention and vagal stimulation. In general, BP, pulse, cardiac output, and CVP will increase up to an intra-abdominal pressure of 15 mm Hg. At insufflation pressures of 20 to 30 mm Hg, a decrease in BP, cardiac output, and CVP will occur because of pressure on the inferior vena cava and decreased venous return. Pneumoperitoneum also may induce changes in the cardiac electrical axis, which may affect interpretation of the ECG seen on the monitor during the operation.

C.19. What are the direct and indirect effects of hypercarbia on the respiratory system? How does the Trendelenburg position and the increased intra-abdominal pressure of pneumoperitoneum alter these effects?

Hypercarbia and acidosis stimulate the respiratory center both directly and indirectly through chemoreceptors, hormones, and autonomic nerves. In the conscious patient breathing oxygen, the maximal stimulating effect occurs at 100 to 150 mm Hg, producing minute volumes of up to 75 L. Above these levels, CO_2 becomes a respiratory depressant. Current anesthetics blunt the stimulatory respiratory response to CO_2. (Diethyl ether, however, the only volatile anesthetic known to stimulate respiration, is reported to have caused a patient to continue to breathe spontaneously at an inadvertent P_{CO_2} of 234 mm Hg.)

In the awake patient, each mm Hg increase in Pa_{CO_2} increases ventilation by 2 to 3 L per minute (if Pa_{O_2} is constant). This response is diminished by anesthesia. Hypercarbia also produces bronchodilatation; acidosis rather than hypercarbia per se, causes pulmonary vascular constriction.

General anesthesia with intubation and mechanical ventilation results in a decrease in FRC, which is caused by loss of muscle tone, diaphragmatic displacement, and loss of thoracic volume. Lung compliance drops, airway pressures increase, and $\dot{V}/\dot{Q}$ abnormalities occur. However, most patients have no difficulty tolerating these changes. These changes are exaggerated in the Trendelenburg position, especially in older adults, the obese, and those with pre-existing cardiopulmonary disease. Intrathoracic, peak inspiratory, and plateau pressures increase and then increase even further when pneumoperitoneum creates an increase in pressure and volume. Endobronchial intubation can occur as a result of cephalad movement of the carina, and it should be ruled out if hypoxemia occurs.

C.20. What are the direct and indirect effects of hypercarbia on the central nervous system?

The brain is particularly sensitive to changes in $Paco_2$. Slight elevations of CO_2 cause direct cortical depression and increase the threshold for seizures. Higher levels of CO_2 (25% to 30%) stimulate subcortical hypothalamic centers, resulting in increased cortical excitability and seizures. This hyperexcitability level is enhanced by adrenal cortical and medullary hormones released secondary to hypercarbia-induced stimulation of the hypothalamus. Further elevations of CO_2 cause an anesthetic-like state of cortical and subcortical depression.

CO_2 was first used as an anesthetic by Hickman in 1824 and reintroduced by Leake and Waters in 1928. CO_2 caused an N_2O-like narcosis at approximately 90 to 120 mm Hg. However, hypercarbia also causes increased excitability of neurons so that seizures occurred shortly afterward. In dogs, however, general anesthesia is achieved at the higher level of $Paco_2$, approximately 245 mm Hg, probably by intracellular derangements caused by low pH.

CO_2, not H^+, crosses the blood–brain barrier and the brain cell membrane and affects the cell metabolism. Therefore, a change in $Paco_2$ also causes a rapid change in cerebrospinal fluid (CSF) pH. CO_2 is the most important factor in regulating cerebral blood flow (CBF). The relation between CBF and $Paco_2$ is essentially linear from 20 to 100 mm Hg, with maximal vasodilatation at approximately 120 mm Hg. Normal CBF is approximately 12% to 15% of cardiac output, or 50 mL/100 g/minute. For each 1 mm Hg increase in $Paco_2$ between 20 and 80 mm Hg, CBF increases by 2% to 4%. Hypercarbia decreases cerebral vascular resistance, causing CBF to increase.

Hypercarbia causes an increase in intracranial pressure, probably secondary to vasodilation. When the patient is placed in the Trendelenburg position, venous congestion of the head and neck occurs. Additional increases in intra-abdominal and intrathoracic pressures contribute to further increases in intracranial and CSF pressures.

Therefore, an acute rise in intra-abdominal pressure (pneumoperitoneum) causes an immediate rise in intracranial pressure. This occurs through intermediary steps that include compression of the inferior vena cava (resulting in decreased drainage in the lumbar plexus), increased CVP, increased mean arterial pressure, increased intrathoracic pressure, increased venous stasis and increased pressure in the sagittal sinus, and decreased resorption of CSF. Hypercarbia contributes to the increased intracranial pressure, but hyperventilation will not decrease the elevated intracranial pressure until the elevated intra-abdominal pressure is released.

C.21. What are the neuroendocrine changes that occur during laparoscopy?

Excessive intra-abdominal pressure and hypercarbia may activate the sympathoadrenal axis, resulting in increased plasma levels of epinephrine and norepinephrine. Renin, cortisol, aldosterone, antidiuretic hormone, and atrial natriuretic peptide levels are also increased. In awake patients in the Trendelenburg position, increased secretion of atrial natriuretic peptide occurs, probably in response to increased venous return and atrial stretch. During pneumoperitoneum, however, secretion of atrial natriuretic factor diminishes, suggesting interference with venous return.

C.22. What are the direct and indirect effects of laparoscopy on the renal system?

Oliguria has been observed frequently during laparoscopy despite adequate hydration. Although prerenal causes such as hypovolemia, positive pressure ventilation, and PEEP contribute to oliguria, it is believed that neurohumoral changes (e.g., antidiuretic hormone secretion) secondary to hypercarbia and increased intra-abdominal pressure secondary to insufflation may be responsible. Sympathetic stimulation causes a release of catecholamines, resulting in decreased renal cortical blood flow with shunting of blood to the adrenal medulla, constriction of glomerular afferent arterioles, and decreased glomerular filtration rate. It has been shown recently that when intraperito-

neal insufflation reaches a pressure of 15 mm Hg, renal cortical blood flow decreases approximately 60%, and a reversible 50% drop in urine volume occurs. In contrast, no decrease in urine output occurred when the abdominal wall was lifted with a force of 15 mm Hg during "gasless laparoscopy." It has also been shown that pneumoretroperitoneum, which causes a more gradual increase in intra-abdominal pressure, also caused a more gradual decrease in renal perfusion. Finally, it has been shown that unilateral retroperitoneal insufflation causes decreased renal cortical perfusion of only the ipsilateral kidney if the intra-abdominal pressure is not elevated.

C.23. What is the effect of hypercarbia and laparoscopy on the bowel and gastrointestinal system?

Although CO_2 directly causes vasodilatation of the splanchnic capillary beds, the increased intra-abdominal pressure of laparoscopy decreases perfusion, increases systemic vascular resistance, impairs gastric submucosal perfusion and metabolism, and may cause bowel hypoxia at high pressures. On release of intra-abdominal pressure, residual CO_2 again causes vascular dilation, allowing additional CO_2 to enter the blood stream. Myoelectric activity and recovery from ileus is faster after laparoscopic than after open surgery. The combined effect of the increase in abdominal pressure, stretching of the peritoneum by insufflation, and diffusion of CO_2 into bowel is probably responsible for any postoperative nausea.

C.24. How would you recognize CO_2 embolism during laparoscopy? How does this differ from air embolism? Why should N_2O be discontinued during suspected embolization? Will N_2O increase the size of CO_2 emboli?

Gas embolism can occur whenever the internal pressure of an open vessel is less than the external pressure. Gas embolism may cause increased ventilatory dead space, increased PVR, increased pulmonary artery pressure, and decreased cardiac output. Early signs include a rapid drop in end-tidal CO_2 and Pa_{O_2} and increased Pa_{CO_2}. During laparoscopy, insufflation of a large amount of CO_2 directly into a blood vessel can occur initially after blind Veress needle insertion, especially at high pressures. This should be suspected if the abdominal cavity does not distend equally in all four quadrants despite insufflation of several liters of CO_2. Hypotension, hypoxia, cyanosis, or cardiac arrest can occur. If the gas volume is large enough, a "mill-wheel" murmur may be heard through a precordial or esophageal stethoscope. If ventilation is kept constant, a sudden decrease in end-tidal CO_2 may be noted. The most sensitive means to detect gas emboli are the precordial and transesophageal Doppler and transesophageal echocardiography. Aspiration of foamy blood from a central venous catheter is diagnostic.

CO_2 embolism, however, must be distinguished from air embolism, a far more ominous event, as shown in Table 26.2. CO_2, being extremely soluble in the presence of red blood cells, is much less life threatening than an identically sized intravascular bolus of air. It has been reported that the lethal volume of intravascular CO_2 gas in cats is 30 times greater than the lethal volume of intravascular air.

Air emboli are likely to be entrained in open veins above the level of the heart, a condition that can exist during head and neck or neurosurgery. Other gases that are present, nitrous oxide, for example, will diffuse into that air space according to their diffusion capacities and pressure gradients. Therefore, nitrous oxide will diffuse in, oxygen will be consumed and/or diffuse out, and the size or pressure of the bubble will increase in proportion to the concentration and duration of N_2O being administered, until equilibrium is reached. Eger and Saidman demonstrated that inhalation of 70% N_2O increased the volume of intestinal gas pockets in dogs by twofold in 2 hours, and up to threefold in 4 hours. They calculated that at equilibrium bowel volume could increase up to a maximum of 400%. When N_2O is limited to 50%, however, the size of the gas pocket will not be more than doubled at equilibrium. They also demonstrated that inhalation of 68% to 78% N_2O would cause 300 mL of air in the pleural space to double in volume in 10 minutes and to triple in 45 minutes. A gas bubble composed of 100% CO_2, however, will not enlarge in a patient inhaling 50% or even 75% N_2O because more CO_2 will move out or be absorbed or buffered (also more quickly) than N_2O will move in. This is not to deny that CO_2 gas has caused fatal embolisms or that N_2O should not be discontinued

Table 26.2 Differences Between Air and Carbon Dioxide Emboli

EMBOLISM	AIR	CO_2
Composition	79% N_2, 21% O_2	100% CO_2
Position	Sitting upright	Any
Origin	Vein open to air	No contact with air
Pressure source	Hydrostatic	Insufflator
Solubility	Negligible	Large
Effect of N_2O	Enlarged	Not enlarged

if embolism is suspected. A recent study using transesophageal echocardiography in 16 patients undergoing laparoscopic cholecystectomy reported gas embolism in 11 of the 16 patients (5 during peritoneal insufflation and 6 during gallbladder dissection), but all were subclinical with no signs of cardiorespiratory instability. In addition, conditions for creating CO_2 embolism differ from conditions for air embolism. Other than direct insufflation of CO_2 into a vein, as during Veress needle insufflation, the capillaries and veins within the abdomen are collapsed by the positive pressure within the abdomen, thereby minimizing the chance for CO_2 to enter open vessels.

C.25. What is the mechanism of increase in shunting resulting from embolization?

Emboli in the pulmonary capillaries cause an increase in PVR (vasoconstriction), which leads to increased pulmonary artery, right ventricle, and right atrium pressures and opening of pulmonary precapillary arteriovenous anastomoses, resulting in shunt and hypoxemia.

Lumb AB. *Nunn's Applied Respiratory Physiology*. 6th ed. Philadelphia: Butterworth-Heinemann; 2005:116.

C.26. How is gas embolism (CO_2 or air) treated?

- Nitrous oxide should be discontinued, and the FIO_2 should be increased to 1.0.
- Identify and occlude the air entrainment site. Insufflation (in the case of CO_2) should be halted, and the pneumoperitoneum should be released immediately.
- An increase in the rate and volume of controlled ventilation with PEEP has been suggested as a method of minimizing air entrainment. However, this may decrease the cardiac output and excessively increase the airway pressure and PVR, and can lead to paradoxical air embolization.
- If possible, the patient should be placed in steep left lateral decubitus Trendelenburg position to prevent obstruction of the pulmonary outflow tract and right ventricular failure.

- A CVP catheter is useful for diagnosis and for therapeutic aspiration of air. Radial artery cannulation is useful to track improvement or deterioration.
- Therapy is essentially supportive and may include fluids, vasopressors, and pulmonary arterial catheterization. A large bolus of gas may form a gas lock in the right atrium, decreasing the cardiac output. Smaller bubbles can lodge in the lungs, causing pulmonary hypertension, right ventricular failure, and pulmonary edema. Venous gas emboli may also enter the arterial circulation through an atrial septal defect or open foramen ovale, a condition that may exist in 20% of patients.

C.27. What are the causes of pneumothorax or pneumomediastinum during laparoscopy? How would you diagnose it? How would you treat it?

Pneumothorax can result from migration of the laparoscopic gas under pressure or from direct pulmonary barotrauma.

During laparoscopy, CO_2 under pressure can pass from the abdominal cavity into the pleural and pericardial spaces through anatomic or congenital paths (e.g., the hiatus around the esophagus) or through acquired defects in the diaphragm. (Embryologically, before formation of the diaphragm, the peritoneal and pleural cavities derived from one sac.) CO_2 gas insufflated retroperitoneally gains rapid direct access to a vast space, and may result in widespread subcutaneous emphysema.

Pneumothorax can be diagnosed by a sudden decrease in pulmonary compliance, an increase in airway pressure, an increase in $P_{ET}CO_2$ and P_{aCO_2}, an unchanged or decreased P_{aO_2}, an unchanged or decreased BP, abnormal motion of the involved side hemidiaphragm, and absence of breath sounds without wheezing on the affected side. The shape of the capnogram usually is unchanged. Fiberoptic bronchoscopy will rule out endobronchial intubation, and intraoperative chest fluoroscopy or x-ray film will confirm the diagnosis.

Pneumothorax caused by laparoscopic gas is easily treated or it can resolve spontaneously. One study reports an incidence of pneumothorax in 7 of 46 patients undergoing laparoscopic fundoplication for repair of hiatus hernia. In these cases, intraoperative treatment consisted of PEEP and increased minute ventilation to reinflate the lung and increased pressure to decrease the gradient from abdomen to pleural cavity and possibly to seal the tear.

Alternatively, pneumothorax may be undetected until the patient wakes up and exhibits respiratory distress and restlessness, which can be misinterpreted as pain or inadequate reversal of the muscle relaxant. Treatment consists of 100% oxygen by mask. CO_2 will quickly diffuse out, as can be easily seen by serial blood gases and x-ray films, and invasive treatment is unnecessary.

Because of the increased volumes and pressures in the lung during laparoscopy, pneumothorax can also result from barotrauma. This cause of pneumothorax is far more serious and may require tube thoracostomy. Attempts at hyperventilating to decrease the $P_{ET}CO_2$ can result in overdistention and rupture of alveoli, with subsequent dissection of the anesthetic gases into the perivascular sheaths, mediastinum, pleura, and fascial planes of the head and neck. Large tidal volumes and rapid ventilator rates can be especially dangerous in patients with COPD or bullae because insufficient emptying time may increase air trapping.

Streich B, Decailliot F, Perney C, et al. Increased carbon dioxide absorption during retroperitoneal laparoscopy. *Br J Anaesth.* 2003;91:793–796.

C.28. How would you decide when to extubate?

In addition to the usual criteria for extubation, prolonged laparoscopy in the Trendelenburg position requires other considerations.

Delay extubation if the patient has edema, venous congestion, and duskiness of the head and neck. Sometimes the tongue becomes edematous. If unsure, check the eyes for periorbital, conjunctival, or lid edema, and keep the patient in head-up position until the conjunctivae no longer seem raised or watery.

Causes of edema include dependent stasis from the Trendelenburg position, resistance from elevated abdominal and thoracic pressures, and temporary fluid overload from oliguria or anuria. In some cases it is best to leave the patient intubated until diuresis has begun, especially because PACU pulmonary edema is not rare.

D. Postoperative Management

D.1. What are some of the unique complications of laparoscopy?

Injuries from instruments

Improper placement of Veress needle or trocars can cause abdominal wall bleeding, blood vessel or visceral puncture, subcutaneous emphysema, peritonitis, wound infections, hernia at the trocar site, and hemorrhage. Thermal injuries may occur from cautery or laser use. Staples and clips can cause nerve entrapment.

Complications of pneumoperitoneum

Increased intra-abdominal pressure can result in bowel ischemia, omental or bowel herniation, gastric regurgitation, excessive compression of vena cava, decreased venous return, venous stasis in legs, hypotension, increased intrathoracic pressure, mediastinal and subcutaneous emphysema, pneumothorax, barotrauma, CO_2 gas embolism, atelectasis, nausea and vomiting, bradyarrhythmias from vagal stimulation of trocar insertion and peritoneal distention, dysfunction of ventriculoperitoneal shunts, and referred shoulder pain from CO_2 gas retained under the diaphragm.

Systemic effects of CO_2 absorption

Among the systemic effects of CO_2 absorptions are hypercarbia, acidosis, increased sympathoadrenal stimulation, hypertension, tachycardia, increased intracranial pressure, embolization, and sickle cell crisis. Arrhythmias can occur from hypercarbia, hypoxia, and catecholamines and in combination with halothane.

Trendelenburg position

Venous congestion of head and neck, increased venous pressure, increased intracranial pressure, retinal hemorrhage, retinal detachment, increased intraocular pressure

and glaucoma attack, endobronchial intubation and hypoxemia, ventilation–perfusion mismatch and hypoxia, neuropathy, corneal and conjunctival edema, edema of airway including larynx, airway obstruction and closure, brachial plexus injury from shoulder braces, femoral nerve and peroneal neuropathies, and an assortment of respiratory complications have been reported with use of the Trendelenburg position.

Late complications

Among the late complications are bowel obstruction from injury, cautery burn, intestine or omentum herniation through the trocar site, adhesions, deep vein thrombosis, and nerve injury resulting from improper padding. Fever may indicate infection from bowel necrosis. Cutaneous metastasis can occur at the port site.

D.2. What postoperative orders will you write? When would you remove the Foley catheter and arterial line? Under what circumstances would you order a chest x-ray film?

Immediate chest x-ray film is ordered if respiratory distress, subcutaneous emphysema, and actual or suspected pneumothorax occurred; the case was prolonged and retroperitoneal; the patient was oliguric despite adequate hydration; intra-abdominal pressure was greater than 15 mm Hg; or the patient has a history of cardiac or pulmonary disease.

Do not remove the arterial line until the patient is stable and blood gas values are normal. Check urine volumes. Expect an immediate diuresis. Do not remove the Foley catheter until the patient is stable, with fluid intake and volume output stable. Order IV fluids. Check voiding after the catheter is removed. Appropriate medications for nausea and pain control must be written. Ketorolac may be given if the surgeon agrees and if there is no contraindication. Patient-controlled analgesia usually is not

necessary. For ambulatory patients, an adult escort must be available to take them home. Most patients, however, stay overnight.

Pavlin DJ, Chen C, Penaloza DA, et al. Pain as a factor complicating recovery and discharge after ambulatory surgery. *Anesth Analg.* 2002;95:627–634.

D.3. What is the incidence of postoperative nausea and vomiting?

The incidence of nausea and vomiting after laparoscopy has been reported to be as high as 42%. It is the most important factor in causing an overnight admission after ambulatory surgery. IV antiemetics such as ondansetron, often with dexamethasone, may be given, preferably during surgery. The cause of nausea and vomiting is believed to be rapid peritoneal distention. Neurogenic pathways are activated by traction reflexes and by splanchnic pressure and manipulation.

SECTION VII

The Reproductive System

CHAPTER 27

Placenta Previa/Placenta Accreta

Jill Fong

A 41-YEAR-OLD WOMAN

gravida 4 para 3, is electively scheduled for her third cesarean section at 36 weeks of gestation. She has placenta previa which was diagnosed by sonography after a single episode of painless vaginal bleeding at 28 weeks of gestation which resolved spontaneously. Her vital signs are as follows: blood pressure, 110 per 56 mm Hg; heart rate, 85 beats per minute; respiratory rate, 22 breaths per minute; and oxygen saturation (Spo_2) 98% on room air. Her hematocrit is 35%.

A. Medical Disease and Differential Diagnosis

1. What are the leading causes of maternal mortality, and what role does anesthesia play in this mortality?
2. What is the differential diagnosis for an antepartum hemorrhage?
3. How would you diagnose the etiology of antepartum bleeding?
4. What is the incidence of placenta previa, and what are the associated conditions?
5. What are the different types of placenta previa?
6. What is the usual obstetric management for placenta previa?
7. What is vasa previa? How is it diagnosed and managed?
8. What are the risk factors for the development of a placental abruption?
9. How is placental abruption diagnosed and managed?
10. What complications are associated with placental abruption?

11. Who is at risk for uterine rupture, and how is uterine rupture diagnosed?
12. What is the treatment for uterine rupture?
13. Is this patient at risk for postpartum bleeding?
14. What are the different types of placenta accreta?
15. How is placenta accreta diagnosed?
16. How is placenta accreta managed obstetrically?
17. Is an evaluation for fetal lung maturity indicated in this patient before cesarean section, and how is fetal lung maturity evaluated?

B. Preoperative Evaluation and Preparation

1. How does pregnancy change respiratory function, and what impact does this have on anesthetic care?
2. What are the maternal cardiovascular changes of pregnancy?
3. What are the maternal gastrointestinal changes of pregnancy?
4. What hematologic changes occur during pregnancy?
5. What laboratory data do you need before taking this patient to the operating room?
6. What preoperative medications would you administer to this patient?

C. Intraoperative Management

1. What monitors would you use for this patient?
2. What anesthetic could be used in this patient?
3. What are the absolute and relative contraindications for neuraxial anesthesia?
4. What is the usual amount of blood loss expected with delivery?
5. What are the physical findings associated with blood loss?
6. How is postpartum hemorrhage defined, and what are the etiologies of this bleeding?
7. After delivery of the fetus, the placenta is removed with some difficulty in one small area and generalized oozing from the placental implantation site is noted. What is the most likely cause of this patient's bleeding?
8. After delivery of the placenta in a cesarean section, what maneuvers and drugs can enhance myometrial contractility and therefore, decrease blood loss?
9. If this patient had ongoing bleeding intraoperatively, what guidelines help determine when red blood cell (RBC) transfusions should be given?
10. If this patient had a massive blood loss, what blood replacement therapy would be indicated?
11. What is the role of type O Rh-negative (universal donor) un-crossmatched blood in emergency transfusions, and how does this change your future management?
12. What complications can occur from the transfusion of blood products?
13. What is the role of autologous transfusion in obstetric patients?
14. Significant intraoperative blood loss required the transfusion of 8 units of type-specific, crossmatched packed RBCs (pRBCs). This patient had generalized oozing in the surgical field and hematuria. What is your differential diagnosis?
15. What is disseminated intravascular coagulation (DIC)?
16. What is the role of recombinant activated factor VII (rFVIIa) in obstetric patients?
17. What laboratory tests should be ordered during the resuscitation of this patient?
18. Define amniotic fluid embolism (AFE) and discuss treatment.

D. Postoperative Management

1. If the patient received epidural anesthesia and subsequently developed disseminated intravascular coagulation (DIC), when should the epidural catheter be removed?
2. You have successfully treated the patient's massive hemorrhage. Her laboratory values have returned to normal. Her central venous pressure (CVP) is within normal limits and urine output is appropriate. The patient, however, is still hypotensive despite appropriate intravascular volume replacement and support with vasopressors. What is your concern in this case?

A. Medical Disease and Differential Diagnosis

A.1. What are the leading causes of maternal mortality, and what role does anesthesia play in this mortality?

The maternal mortality ratio (MMR) is defined as the number of maternal deaths per 100,000 maternities. The exact definitions of "maternal" death and "maternities" are defined differently by the different agencies collecting the statistics. Developed versus developing countries have a markedly different incidence of maternal death; 99% of maternal deaths occur in developing countries. According to the World Health Organization in 2005, there were 400 maternal deaths per 100,000 live births globally. The MMR's were 9 and 450 for developed and developing regions, respectively. In developing countries, the leading causes of death are hemorrhage, hypertensive disorders of pregnancy, and sepsis. Obstetric hemorrhaging is the single most important cause of maternal mortality worldwide and accounts for almost half of all postpartum deaths. Anemia, obstructed labor, HIV/AIDS, and unsafe abortions also play a role. Early marriage (a girl <18 years old) is a major health risk for girls; for girls, ages 15 to 19, pregnancy is the leading cause of death worldwide. Women in their 20s are 5 times less likely to die in childbirth than girls less than 15 years old. In developed countries, hypertensive disorders of pregnancy, embolic disorders, and hemorrhage account for slightly less than 50% of maternal deaths; 14% are attributed to indirect deaths due most commonly to cardiovascular disease. In the United States, based on data from the Pregnancy Mortality Surveillance System of the Centers for Disease Control and Prevention, hemorrhage directly caused more than 17% of 4,200 pregnancy-related maternal deaths. Clark and coworkers found that 12% of maternal deaths were caused by obstetric hemorrhage in a report from the Hospital Corporation of America. In the United Kingdom, the Confidential Enquiry into Maternal and Child Health found that hemorrhage was a major factor in maternal deaths.

In developed regions, the estimated anesthesia-related MMR ranges between 1 to 3 deaths per 1,000,000 live births. If a maternal death can be attributed to an anesthetic complication and if an ideal anesthetic would have likely avoided this death, the death is considered anesthetic-related. For cesarean section, general anesthesia probably continues to be more hazardous than neuraxial anesthesia.

A.2. What is the differential diagnosis for an antepartum hemorrhage?

Antepartum hemorrhage typically refers to uterine bleeding after 20 weeks of gestation that is unrelated to labor and delivery. Four to five percent of pregnancies are complicated by antepartum hemorrhage. The most common causes of antepartum hemorrhage are placenta previa and placental abruption. Antepartum bleeding generally poses a greater threat to the fetus than the mother. Placenta previa is the abnormal implantation of the placenta over or adjacent to the cervical os and in front of the fetal presenting part. *Placental abruption*, or abruptio placentae, refers to the premature separation of a normally implanted placenta from the uterus' decidua basalis before delivery of the fetus.

Rare causes of antepartum bleeding include velamentous insertion of the umbilical cord with the involved placental vessels overlying the cervix, which is known as vasa previa, uterine rupture, cervicitis, and local genital tract lesions.

In the remaining cases, it is not always possible to identify the source of antepartum bleeding. Usually, this type of bleeding begins with minimal symptoms, if any, and stops; no anatomic cause is identified at delivery, and it is likely attributable to marginal placenta separation. However, these pregnancies have a higher risk of poor neonatal outcome and preterm delivery.

A.3. How would you diagnose the etiology of antepartum bleeding?

With antepartum bleeding, digital examination of the cervix *should be avoided* until the diagnosis of placenta previa has been excluded because digital examination of a placenta previa can cause immediate, severe hemorrhaging. Classically, it has been taught clinically that painless uterine bleeding is indicative of placenta previa, while painful uterine bleeding signifies placental abruption. The differential diagnosis, however, is not actually that straightforward; for instance, labor or placental separation accompanying a previa may cause pain, whereas pain from an abruption may mimic normal labor. Transabdominal sonography is a simple and safe method of locating the placenta in a suspected placenta previa. Transvaginal sonography has been shown to be superior to transabdominal sonography and is currently the imaging modality of choice. Recently, transperineal sonography has been shown to have a 98% positive-predictive value and 100% negative-predictive value of placenta

previa. On the other hand, sonography infrequently aids in the diagnosis of an acute placental abruption because fresh clot and placenta appear sonographically similar. Negative findings on sonographic examination do not rule out a placental abruption. Magnetic resonance imaging (MRI) has been used by numerous investigators to visualize placental abnormalities, including placenta previa, but is unlikely to replace sonography any time soon due to availability and cost limitations.

Based on the accuracy and safety of transvaginal sonography in detecting placental position, the "double setup" is rarely, if ever, used. The double setup was a vaginal examination done in an operating room with the patient and medical personnel completely prepared to do an emergency cesarean section if hemorrhaging should occur.

A.4. What is the incidence of placenta previa, and what are the associated conditions?

The incidence of placenta previa in the United States is about 1 in 300 deliveries. The risk of having placenta previa increases with advancing maternal age, multiparity, multifetal gestations, previous cesarean delivery, prior uterine surgery, cigarette smoking, cocaine use, and unexplained increases in maternal serum alpha-fetoprotein levels. Sanderson and Milton found that 12% of placentas were "low lying" at 18 to 20 weeks. As pregnancy progressed, more than 90% of these "low-lying" placentas move away from the cervix and out of the lower uterine segment. If the internal os was not covered, none of these patients had a placenta previa or bleeding. If the internal cervical os was partially covered by placenta at midpregnancy, approximately 40% persisted as a previa. After sonographic identification of a placenta previa before 28 weeks gestation, the likelihood that the previa persists is greater in prior cesarean section patients.

Placenta previa is associated with an increased risk of antepartum bleeding, intrapartum and postpartum hemorrhage, abnormalities of placental adherence, hysterectomy, blood transfusions, preterm birth with perinatal morbidity and mortality, congenital malformations, septicemia, and thrombophlebitis. Zaki et al. found that 10% of 112 consecutive placenta previa cases had an associated placenta accreta. Additionally, in the presence of a prior cesarean section, the patient with placenta previa is at greater risk for having a placenta accreta; this risk increased as the number of cesarean sections increased. The association between placenta previa and placenta accreta with its abnormally firm uterine attachment of the placenta might be due to poor development of the decidua in the lower uterine segment.

A.5. What are the different types of placenta previa?

Placenta previa is a term used to describe a placenta that is implanted over or very near the internal cervical os with classifications based on the degree to which the os is covered. Normally, the placenta implants in the upper uterine segment, but in placenta previa the placenta totally or partially implants in the lower uterine segment. If the placenta completely covers the internal os, it is a total placenta previa. A partial placenta previa covers only part of the os, while the placenta in a marginal placenta previa just reaches the os and covers only the margin of the internal os. This differs from a low-lying placenta, which is implanted in the lower uterine segment but does not reach the os. In vasa previa, the fetal vessels course through the membranes and cover the internal cervical os.

Cunningham FG, Leveno KJ, Bloom SL, et al., eds. *Williams Obstetrics*. 23rd ed. New York: McGraw-Hill; 2010:769.

A.6. What is the usual obstetric management for placenta previa?

Obstetric management of placenta previa patients depends upon whether the fetus is preterm with no other indications for delivery, the fetus is reasonably mature, labor has begun, or hemorrhage is so severe as to mandate delivery despite gestational age. With many previas, the first episode of bleeding usually begins without warning or pain, stops spontaneously, and, fortunately, rarely causes maternal or fetal compromise. A mature fetus with or without labor should be delivered. With a preterm fetus and no persistent active uterine bleeding, management consists of close observation for bleeding and activity restriction in an inpatient setting or, in certain selected patients, an outpatient setting. The goal of this expectant management is to delay delivery until the fetus is mature. Maternal vital signs and hemoglobin (Hgb) are checked at regular intervals depending on when the bleeding, if it exists, subsides. Fetal well-being also is assessed regularly. Fetal maturity is done as indicated. Between 24 and 34 weeks of gestation, betamethasone, a corticosteroid, often is given to the patient with placenta previa to accelerate fetal lung maturity. In previa patients with preterm labor, tocolytic therapy may be used to prolong gestation if both the mother and fetus are stable.

As gestational age increases, there is an increased risk of significant bleeding that would necessitate delivery. It is, therefore, preferable to perform a cesarean delivery under controlled, non-emergent conditions. After documenting fetal lung maturity by amniocentesis at 36 to 37 weeks of gestation, an elective cesarean section can be done at this time. If lung maturity does not exist, an elective cesarean should be done at 38 weeks without another amniocentesis. The necessity of fetal lung maturity testing in relation to exact gestational age and the timing of delivery varies slightly between obstetricians. Patients with placenta previa almost always are delivered by cesarean section. When the placenta is greater than 2 cm away from the cervical os, however, small studies suggest that vaginal delivery may be safe. Normally, with placenta removal, the myometrium of the uterus contracts and re-establishes vascular integrity by constricting the open vessels in the placental bed. In patients with placenta previa, bleeding after placenta removal can be brisk because the lower uterine segment contracts poorly and therefore, does not constrict the avulsed vessels. There is a known association between placenta previa and placenta accreta that may further exacerbate uterine bleeding and require additional surgical and/or radiologic interventions to staunch the bleeding.

As needed, adequate intravenous access and laboratory studies, including a complete blood count, coagulation profile, and a type and screen/crossmatch should be obtained as circumstances dictate. Rh (anti-D) immune globulin should be administered to Rh-negative women with an acute bleeding episode, and a Kleihauer-Bettke test for quantification of fetal-maternal transfusion should be done to determine if additional immune globulin is required.

A.7. What is vasa previa? How is it diagnosed and managed?

Vasa previa refers to intramembranous fetal vessels, unprotected by placenta or umbilical cord, coursing through the membranes over the cervical os and under the fetal presenting part. The incidence is approximately 1 in 2,500 deliveries and associated risk factors include a second trimester low-lying placenta, a placenta with accessory lobes, multiple pregnancies, and pregnancies from in vitro fertilization. An undiagnosed vasa previa is associated with a high fetal mortality (about 60%). Because fetal blood volume is small, any bleeding puts the fetus in jeopardy. When membranes rupture, either spontaneously or artificially, the fetal vessels running through these membranes often rupture. Vaginal bleeding with fetal distress or death when the membranes rupture are seen in an undiagnosed vasa previa and necessitate an emergency cesarean section based on fetal distress. If vaginal blood is present, the presence of fetal (RBCs) can be determined using a Kleihauer-Bettke test or Apt test, although there is rarely time for this. Fortunately, the majority of cases of vasa previa can be diagnosed prenatally by routinely evaluating placental cord insertion by ultrasound examination and transvaginal sonographic color Doppler if the insertion site cannot be delineated clearly. Good outcomes in patients with vasa previa require a prenatal diagnosis and delivery by cesarean section before the membranes rupture.

Oyelese Y, Smulian JC. Placenta previa, placenta accreta, and vasa previa. *Obstet Gynecol*. 2006; 107:927–941.

A.8. What are the risk factors for the development of a placental abruption?

The frequency of placental abruption is about 1 in 200 deliveries. The premature separation of the normally implanted placenta can be total or partial and can lead to external or concealed bleeding. Concealed hemorrhage is associated with greater maternal and fetal risks. The most common conditions associated with placental abruption are gestational hypertension, preeclampsia, and chronic hypertension. The incidence of placental abruption is increased with increased maternal age, high parity, African-American or Caucasian race, prematurely ruptured membranes, cigarette smoking, cocaine use, thrombophilias, leiomyomas, history of previous abruption, and external trauma. The bleeding almost always is maternal because the placental separation is within the maternal decidua.

Cunningham FG, Leveno KJ, Bloom SL, et al., eds. *Williams Obstetrics*. 23rd ed. New York: McGraw-Hill; 2010:761–769.

A.9. How is placental abruption diagnosed and managed?

The signs and symptoms of placental abruption vary considerably. Ultrasonography often does not confirm the diagnosis as the placenta and fresh clots have similar appearances. In severe placental abruptions, the diagnosis often is obvious with fetal distress and demise common. With a live fetus and vaginal bleeding, milder abruptions may be difficult to diagnosis and become a diagnosis of exclusion.

Treatment depends on fetal gestational age and fetal and maternal condition. If the diagnosis is uncertain and the fetus is uncompromised, inpatient expectant management with close observation can be practiced. However, further placental separation can occur at any time and lead to serious fetal compromise or death. Rapid delivery of the compromised, but alive, fetus is by cesarean delivery. If placental separation has led to fetal death, a vaginal delivery usually is preferred; there are two exceptions: a massive hemorrhage that cannot be managed with vigorous blood replacement and obstetric complications that prevent vaginal delivery will necessitate an operative delivery.

Cunningham FG, Leveno KJ, Bloom SL, et al., eds. *Williams Obstetrics*. 23rd ed. New York: McGraw-Hill; 2010:761–769.

A.10. What complications are associated with placental abruption?

Maternal complications with severe abruption can include postpartum hemorrhage, hemorrhagic shock, a consumptive coagulopathy, acute renal failure, and Sheehan syndrome (pituitary failure). Placental abruption can lead to fetal compromise or fetal demise.

Cunningham FG, Leveno KJ, Bloom SL, et al., eds. *Williams Obstetrics*. 23rd ed. New York: McGraw-Hill; 2010:761–769.

A.11. Who is at risk for uterine rupture, and how is uterine rupture diagnosed?

Uterine rupture is typically classified as either complete, with all of the uterine wall layers separated, or incomplete (uterine dehiscence), with the uterine muscle separated but the visceral peritoneum intact. Uterine dehiscence is more common; it is less likely to cause adverse maternal and fetal derangements or necessitate cesarean delivery. The morbidity and mortality rates are higher when the rupture is complete. Prior cesarean delivery is the greatest risk factor associated with uterine rupture. Fortunately, uterine ruptures are rare. Other risk factors associated with uterine rupture include uterine trauma, previous uterine surgery involving the myometrium, a tumultuous labor, midforceps delivery, fetal malpresentation, external and internal version, inappropriate uterotonic medication use, uterine anomalies, placenta increta/percreta, tumors, and uterine over-distention by fetal macrosomia, hydramnios, or multifetal pregnancy. Uterine rupture can be difficult to diagnose because of the varied symptoms and physical findings that can occur. The most consistent sign of uterine rupture is a nonreassuring fetal heart rate pattern. In some patients, the symptoms of uterine rupture will be indistinguishable from those of placental abruption. Other signs that may be present include hypotension, vaginal bleeding, abdominal pain, change in the uterine contour, changes in the uterine contraction pattern, and cessation of labor. There may be little pain, and because most of these ruptures occur during labor, any pain may be masked by the analgesics given to treat the discomfort of labor.

Chestnut DH, Polley LS, Tsen LC, et al., eds. *Chestnut's Obstetric Anesthesia: Principles and Practice*. 4th ed. Philadelphia: Mosby/Elsevier; 2009:817–818.

Cunningham FG, Leveno KJ, Bloom SL, et al., eds. *Williams Obstetrics*. 23rd ed. New York: McGraw-Hill; 2010:573–574, 784–785.

A.12. What is the treatment for uterine rupture?

With a complete uterine rupture, fetal distress and maternal bleeding occur; an emergent cesarean delivery is imperative to deliver the fetus and stabilize the mother. After delivery of the fetus, the uterus can be repaired, the uterine arteries can be ligated, or a hysterectomy can be performed, depending on the size of the rupture and the patient's condition. Fetal distress and/or death are common while maternal death in the developed world is not.

Cunningham FG, Leveno KJ, Bloom SL, et al., eds. *Williams Obstetrics*. 23rd ed. New York: McGraw-Hill; 2010:573–574.

A.13. Is this patient at risk for postpartum bleeding?

Yes, this patient has a higher chance of postpartum bleeding because of her known placenta previa and the increased risk of having an associated placenta accreta. There is a strong association between placenta previa, prior uterine surgery, and placenta accreta. Clark et al. found that placenta previa patients had a 5%, 24%, and 67% risk of having an associated placenta accreta with no, one, and four or more prior cesarean sections, respectively. Similarly, in patients with placenta previa, Silver et al. found a 3%, 11%, 40%, 61%, and 67% incidence of placenta accreta with zero, one, two, three, four, or more prior cesarean sections, respectively.

A.14. What are the different types of placenta accreta?

Placenta accreta refers to a placenta that adheres abnormally to the uterus. The normal placenta has three general layers: the decidua, which is maternal in origin and adherent to the uterus; the chorion, including the chorionic villi; and the amnion. Both the chorion and amnion are of fetal origin. Normally, in the first few minutes after delivery of the neonate, the placenta separates from its implantation site at a physiologic cleavage line through the spongy layer of the decidua basalis. In placenta accreta, the decidua basalis is scanty or absent and the placental chorionic villi are attached directly to the uterine myometrium. With placenta increta, the villi invade into the myometrium, and with placenta percreta, the villi penetrate through the myometrium and serosa of the uterus and, sometimes, into adjacent organs. The abnormal adherence may involve the entire placenta (total placenta accreta), several placental lobules (partial accreta), or part or all of a single lobule (focal placenta accreta). The term placenta accreta often is used as a general term to describe all of these conditions.

The incidence of placenta accreta is increasing due mainly to rising cesarean section rates. The incidence was approximately 1 in 2,500 deliveries in the 1980s, 1 in

535 deliveries in 2002, and 1 in 210 deliveries in 2006. Decidual formation is commonly defective over a previous cesarean section scar, in the lower uterine segment, and/or after uterine curettage. Maternal age greater than 35 years, increasing parity, endometrial defects (Asherman syndrome), submucous leiomyomata, and otherwise unexplained elevations in maternal serum alpha-fetoprotein concentration are other risk factors associated with placenta accreta.

A.15. How is placenta accreta diagnosed?

In patients with conditions such as placenta previa and previous uterine surgery that are highly associated with placenta accreta, it is important to have a high index of suspicion and to look carefully for signs of accreta beginning at 20 to 24 weeks of gestation. Prenatal diagnosis of placenta accreta allows for effective planning that helps minimize maternal morbidity. Transabdominal and transvaginal ultrasonography are useful modalities for evaluating placental position and implantation; the loss of the hypoechoic boundary between the placenta and bladder, placental continuity with the bladder wall, and intraplacental sonolucent spaces, venous lakes, or placental lacunae adjacent to the involved uterine wall are strongly suggestive of placenta accreta. The sensitivity and specificity of ultrasound in detecting placenta accreta are approximately 0.77 and 0.96, respectively. Color flow Doppler and MRI can be used as adjunctive diagnostic tools when the diagnosis is uncertain or the placenta is posteriorly placed; they also can help gauge the depth of placental invasion. Although antepartum diagnosis of placenta accreta would be ideal, currently, there is no single diagnostic modality that determines the diagnosis of placenta accreta with absolute accuracy. Unfortunately, the diagnosis of placenta accreta often is made postpartum during the third stage of labor when separation of the placenta does not occur. The first clinical manifestation of placenta accreta is usually profuse, potentially life-threatening bleeding that occurs at the time of attempted manual placental separation. During vaginal delivery, uterine inversion can occur. Placenta accreta has become one of the most common reasons for peripartum hysterectomy.

A.16. How is placenta accreta managed obstetrically?

Optimal management of placenta accreta has yet to be defined because of the scanty outcome data in the current literature. Prenatal diagnosis and management appear to improve outcome. The problems associated with placenta accreta depend upon the site of implantation, depth of myometrial penetration, and the number of placental lobules involved. Only a focal placenta accreta may not require aggressive surgical intervention. Otherwise, surgical management can be difficult and requires

a multidisciplinary approach in order to minimize maternal complications. If placenta accreta is known to exist antenatally, it is generally accepted that it is ideally treated with an elective cesarean section and hysterectomy; the placenta should be left in place during surgery. The optimal timing for the delivery of the patient with placenta accreta remains controversial. If fetal lung maturity is documented, delivery often is scheduled at 35 to 36 weeks of gestation; some patients with placenta accreta, especially after 35 weeks, will experience hemorrhaging that necessitates immediate delivery. In a retrospective series, Warshak et al. found that patients with a predelivery diagnosis of accreta, who had a planned en bloc hysterectomy without the removal of the placenta at 34 to 35 weeks of gestation after betamethasone administration, had decreased maternal hemorrhagic morbidity and no significant increase in neonatal morbidity. Chestnut et al. found that women having elective peripartum hysterectomies had significantly less intraoperative blood loss, blood transfused, and hypotension than those having emergent obstetric hysterectomies. For women with suspected placenta accreta, some suggest preoperative placement of balloon catheters into the internal iliac arteries. After delivery of the fetus, the catheters may be inflated intermittently during hysterectomy, which may potentially decrease blood loss and provide optimum exposure of the operative field. They also may be used for intraoperative or postoperative embolization of persistent bleeders. The placement of these catheters is not risk free; thrombosis and thromboemboli have been reported. Similarly, some investigators suggest that the placement of preoperative ureteral stents reduced morbidity in cesarean hysterectomies; others use stents intraoperatively as needed.

Because a hysterectomy renders the patient infertile, there has been some interest in attempting to leave the uterus intact. Timmermans et al. reviewed publications using "conservative" management. They found that in some reports, the placenta was partially removed, while in others, it was left intact; some reported the use of methotrexate and/or uterine artery embolization. Overall, 15% of this whole patient population required hysterectomy for hemorrhaging and 3% for infection; approximately 13% of the patients had subsequent pregnancies. They concluded that only in highly select cases when blood loss is minimal and maintenance of fertility is desired can "conservative" management be considered.

A.17. Is an evaluation for fetal lung maturity indicated in this patient before cesarean section, and how is fetal lung maturity evaluated?

Gestational age and fetal lung maturity should be established prior to an elective induction of labor or cesarean delivery before 39 weeks of gestation; ultrasound is used to establish gestational age, and amniotic fluid studies assess fetal pulmonary maturation. Ultrasound documentation of gestational age in the first trimester or early in the second trimester has proven extremely reliable in timing elective inductions or cesarean deliveries. Evaluation for fetal lung maturity is indicated in this patient because both the mother and fetus are stable. If fetal lung maturity is demonstrated, preterm elective scheduling of this patient's delivery is advised

because of the increased risk of bleeding from placenta previa and the danger that this poses to both the mother and fetus. If there was profuse maternal hemorrhaging, fetal maturity would not impact the decision to perform an immediate cesarean delivery.

With the exception of amniotic fluid specimens obtained from the vaginal pool, amniotic fluid analysis obtained by amniocentesis is used to confirm fetal lung maturity. The pulmonary system is one of the last of the fetal organ systems to mature. Respiratory distress syndrome (RDS) is caused by a deficiency of pulmonary surfactant; the surfactant decreases the pressure required to distend the lungs and prevents alveolar collapse. Type II alveolar cells are the major site of surfactant synthesis. Surfactant is packaged in lamellar bodies, discharged into the alveoli, and expelled into the amniotic fluid with pulmonary fluid. Phospholipids make up more than 80% of the surface active material within the lung, and dipalmitoyl lecithin is more than 50% of this phospholipid. Phosphatidylglycerol is the second most abundant lipid in surfactant and significantly improves its properties. There are two types of tests used to determine pulmonary maturity. One type measures the concentration of particular components of pulmonary surfactant, and the other evaluates the surfactant function of these phospholipids. None of the tests perform significantly better than another, and it is recommended that only one test be done. All of the tests are better at predicting the absence, rather than the presence, of respiratory distress developing. *Fluorescence polarization*, the recently modified *TDx-FLM II*, is used by many hospitals as their first-line test of pulmonary maturity; this automated assay measures the surfactant-to-albumin ratio in uncentrifuged amniotic fluid and yields results in approximately 30 minutes. For many years, the labor-intensive *lecithin–sphingomyelin (L/S) ratio* was the gold-standard test. By approximately 32 weeks of gestation, lecithin and sphingomyelin concentrations in amnionic fluid are similar, but after that, the concentration of lecithin compared to sphingomyelin begins to rise. By about 35 weeks of gestation, the L/S ratio is approximately 2.0, and a ratio of 2.0 or greater predicts that 98% of the neonates will not have RDS. *Lamellar body counts* increase with maturity; a count greater than 30,000 to 50,000 per μL is highly predictive of fetal lung maturity. *Phosphatidylglycerol*, which appears after 35 weeks of gestation and increases rapidly between 37 and 40 weeks, can be measured and is an indicator of completed lung maturity. The *foam stability* or *shake test* depends on the functionality of surfactant in amniotic fluid; when amniotic fluid is mixed appropriately with ethanol, the formation of stable foam at the air–liquid interface indicates lung maturity. Other tests exist, and the choice of test should be based upon availability, presence or absence of contaminants, and physician preference.

Neonatal survival increases as birth weight and/or gestational age increases. The use of maternal antenatal steroids and neonatal exogenous surfactant has help decrease neonatal morbidity and mortality. Between 24 and 34 weeks of gestation, a corticosteroid, such as betamethasone, often is given to the parturient with placenta previa to accelerate fetal lung maturity. Infants who are greater than 30 weeks of gestation are not given prophylactic surfactant. These larger neonates, usually greater than 1,250 g, have a lower risk for developing severe RDS, and clinical trials found no benefit in prophylactic versus rescue treatment.

B. Preoperative Evaluation and Preparation

B.1. How does pregnancy change respiratory function, and what impact does this have on anesthetic care?

A number of maternal respiratory changes are seen:

- Capillary engorgement of the mucosa is found throughout the respiratory tract, causing swelling of the nasal and oral pharynx, larynx, and trachea; this begins in the first trimester and increases progressively throughout pregnancy.
- By term, there are increases in minute ventilation (45%), tidal volume (45%), and oxygen consumption (30% to 40%); respiratory rate does not change. These changes do not return to their prepregnancy state for at least 6 to 8 weeks after delivery.
- Arterial $Paco_2$ decreases to about 30 mm Hg by 12 weeks of gestation and remains there until it slowly increases after delivery over about 6 to 8 weeks postpartum.
- Arterial pH increases to about 7.44, and there is a partial metabolic compensation for the respiratory alkalosis (HCO_3^- 20 mEq per L).
- Functional residual capacity (FRC) begins to decrease by the fifth month and by term is 20% below prepregnancy values. After delivery, FRC increases and by 1 to 2 weeks postpartum returns to its prepregnant level. Additionally, the supine position will further decrease the FRC to approximately 70% of prepregnant volume.

Capillary engorgement of the airway mucosa necessitates the use of a smaller, 6.0, 6.5, or 7.0 mm, cuffed endotracheal tube in pregnant women. This vascular engorgement results in airway edema and increased airway friability, which may potentially make tracheal intubation more difficult. Because epistaxis is more likely to occur, nasal intubation is relatively contraindicated. Pilkington et al. showed that the number of pregnant women with a Mallampati class IV airway increased 34% between 12 and 38 weeks of gestation. Boutonnet et al. found that the incidence of Mallampati classes III and IV increased during labor when compared to the prelabor period; these changes are not fully reversed by 48 hours after delivery. No predictive factors for the increase in airway class were found; these changes occurred irrespective of any increase in body weight, the duration of first and second stages of labor, or volume of intravenous fluid. Regardless of the cause, difficult and failed intubations are more common in the pregnant than in the nonpregnant population.

The combination of a decreased FRC and increased oxygen consumption make the pregnant patient more susceptible to the rapid onset of hypoxemia in the apneic state. Therefore, before the induction of general anesthesia, the parturient should be "preoxygenated" with 100% oxygen for 3 to 5 minutes while taking normal tidal breaths or, if time is limited, for four vital capacity breaths. This effectively washes nitrogen out of FRC and provides maximal maternal oxygen reserves to allow longer apneic time during tracheal intubation. The reduced FRC combined with the increased minute ventilation increase the rapidity of changes in the depth of anesthesia while employing an inhaled anesthetic technique. In addition, the minimum alveolar concentration (MAC) of inhaled anesthetic agents has been found to be decreased by about 40% in pregnancy.

B.2. What are the maternal cardiovascular changes of pregnancy?

Most cardiovascular changes of pregnancy begin early in the first trimester and peak by 30 to 34 weeks of gestation. At term, the cardiovascular changes include the following:

- Cardiac output increases 40% to 50%. During the first trimester of pregnancy, the cardiac output increases to 40% or 50% above normal and plateaus at approximately 28 weeks of gestation. It remains fairly stable until the stresses imposed by labor increase it further. During labor, cardiac output increases approximately 15% with uterine contractions during the latent phase, 30% in the active phase, and 45% in the expulsive phase when compared to prelabor values. The greatest increase in cardiac output occurs immediately postpartum when it increases an average of 80% above prelabor values. Cardiac output and heart rate decline to prelabor values within 1 hour of delivery. Postpartum, over the next 2 to 4 weeks, cardiac hemodynamic parameters return towards pregravid levels. It can take a year, however, for the residual effects of cardiovascular remodeling to subside.
- Stroke volume increases approximately 30%.
- Heart rate increases to about 15%.
- Systolic blood pressure is minimally affected by pregnancy.
- Diastolic blood pressure decreases up to 20% by midpregnancy, but returns to its prepregnant level at term.
- Systemic vascular resistance decreases 20%.
- CVP remains unchanged.
- Aortocaval compression refers to the gravid uterus compressing the inferior vena cava and/or the abdominal aorta. The extent of the compression depends on the patient's position and weeks of gestation. In the supine position, compression of the inferior vena cava occurs as early as 13 to 16 weeks of gestation. At term in the supine position, the inferior vena cava is occluded almost completely with venous return from the lower extremities occurring through the dilated paravertebral collateral circulation. At term, compression of the aorta also occurs to some degree when supine. Despite this impaired blood flow and concomitant decrease in cardiac output, the majority of supine women are not hypotensive or symptomatic because of the compensatory rise in systemic vascular resistance. However, up to 15% of supine women at term develop supine hypotension syndrome with hypotension, bradycardia, and symptoms of dizziness, lightheadedness, nausea, and even syncope. Aortocaval compression decreases uteroplacental perfusion by decreasing maternal venous return and maternal arterial blood pressure, by compressing the internal iliac arteries, and by obstructing uterine venous drainage which decreases uterine perfusion pressure. For these reasons, all patients after 20 weeks of gestation should be positioned with left uterine displacement.

Chestnut DH, Polley LS, Tsen LC, et al., eds. *Chestnut's Obstetric Anesthesia: Principles and Practice*. 4th ed. Philadelphia: Mosby/Elsevier; 2009:18–23.

Gabbe SG, Niebyl JR, Simpson JL, eds. *Obstetrics–Normal and Problem Pregnancies*. 5th ed. Philadelphia: Churchill Livingstone/Elsevier; 2007:57–62.

B.3. What are the maternal gastrointestinal changes of pregnancy?

Parturients are considered to be at an increased risk for aspiration of gastric contents. Pregnancy itself does not alter gastric emptying of liquid or solid materials, but during labor, gastric motility does decrease. Gastric acid secretion appears to be unchanged. Because of the upward displacement of the stomach by the gravid uterus, tone in lower esophageal high pressure zone, however, is decreased. This zone normally

prevents the reflux of gastric contents. In the first trimester, the tone in this zone may be unchanged, but in the second and third trimesters, lower esophageal high pressure zone tone falls gradually to about 50% of its preconceptual level. By 36 weeks of gestation, it reaches its lowest point and does not return to prepregnancy levels until 1 to 4 weeks postpartum. As a result, 30% to 50% of women experience heartburn during pregnancy. The increased aspiration risk is thought to be due to the parturient's decrease lower esophageal high pressure zone tone and the increased risk of having difficulty with intubation.

Chestnut DH, Polley LS, Tsen LC, et al., eds. *Chestnut's Obstetric Anesthesia: Principles and Practice.* 4th ed. Philadelphia: Mosby/Elsevier; 2009:23–25, 647.

B.4. What hematologic changes occur during pregnancy?

The hematologic changes seen by term are as follows:

- Intravascular fluid volume increases 45%.
- Plasma volume increases 55%.
- RBC volume increases 30%.

The disproportionate increase in plasma volume compared to RBC volume results in the relative, or physiologic, anemia of pregnancy. By midgestation, hematocrit has typically fallen approximately 15% below prepregnant levels; the Hgb and hematocrit are approximately 11.2 g per dL and 34%, respectively. In late gestation, RBC volume increases, and at term, maternal Hgb and hematocrit are approximately 11.6 g per dL and 35.5%, respectively. This decreased viscosity may aid in maintaining the patency of the uteroplacental vascular bed.

In addition, the following coagulation factors are increased at term: factors I (fibrinogen), VII, VIII, IX, X, and XII. Plasminogen, fibrin degradation products, and fibrinopeptide A are also increased. Factors II and V are unchanged. Factors XI and XIII are decreased as is antithrombin III. Overall, pregnancy is associated with an accelerated, but compensated, rate of intravascular coagulation. Both, the prothrombin time (PT) and activated partial thromboplastin time (aPTT) are shortened 20%, and thromboelastography suggests a hypercoagulable state. The platelet count is typically unchanged at term. However, 0.9% of otherwise normal women will have a platelet count less than 100,000 per mm^3; gestational thrombocytopenia refers to maternal platelet counts of less than 150,000 mm^3 in otherwise normal women.

Chestnut DH, Polley LS, Tsen LC, et al., eds. *Chestnut's Obstetric Anesthesia: Principles and Practice.* 4th ed. Philadelphia: Mosby/Elsevier; 2009:21–23.

B.5. What laboratory data do you need before taking this patient to the operating room?

The laboratory values needed in this healthy parturient having an elective scheduled cesarean section are minimal. A complete blood count with platelets and a type and cross should be sent as this patient is at an increased risk for bleeding and may require the transfusion of blood products. There is no consensus on the type or amount of blood products that should be available. However, many obstetricians and anesthesiologists suggest that at least four units of pRBCs be immediately available with other blood products readily available. Unless the patient has a coagulation disorder or is actively bleeding, a PT, an aPTT, and a fibrinogen level are not needed because the values should be within normal limits.

Chestnut DH, Polley LS, Tsen LC, et al., eds. *Chestnut's Obstetric Anesthesia: Principles and Practice.* 4th ed. Philadelphia: Mosby/Elsevier; 2009:814, 826.

B.6. What preoperative medications would you administer to this patient?

Patients at increased risk for aspiration should receive a nonparticulate oral antacid such as sodium citrate 30 minutes prior to the induction of anesthesia. Intravenous H_2 receptor antagonists, such as ranitidine, and/or metoclopramide may also be given preoperatively for aspiration prophylaxis. This patient is having an elective cesarean delivery and should have a fasting period for solids consistent with the hospital's policy for nonobstetric patients undergoing elective surgery.

American Society of Anesthesiologists Task Force on Obstetric Anesthesia. Practice guidelines for obstetric anesthesia: an updated report by the American Society of Anesthesiologists Task Force on Obstetric Anesthesia. *Anesthesiology.* 2007;106(4): 843–863.

C. Intraoperative Management

C.1. What monitors would you use for this patient?

Standard monitors should be used and include the following: electrocardiogram (ECG), blood pressure cuff, pulse oximeter, end-tidal carbon dioxide monitor, and Foley catheter. In addition, two large-bore intravenous lines, a forced air body warming blanket, intravenous fluid warmers, and intermittent pneumatic compression stockings should be used. If hemorrhaging occurs and urine output falls below 0.5 mL/kg/hour, despite adequate volume replacement, central venous line placement should be considered. A radial arterial line should also be considered if multiple blood samples will be needed and/or hemodynamic instability occurs. Equipment for the rapid infusion of intravenous fluids and blood products should be readily available.

Chestnut DH, Polley LS, Tsen LC, et al., eds. *Chestnut's Obstetric Anesthesia: Principles and Practice.* 4th ed. Philadelphia: Mosby/Elsevier; 2009:814.

C.2. What anesthetic could be used in this patient?

In the patient with placenta previa, a regional or general anesthetic technique could be used. Many anesthesiologists would choose to perform a continuous neuraxial anesthetic in this patient. The choice of anesthetic depends on the cesarean section indication and urgency and the maternal volume status. All patients with placenta previa are at risk for increased intraoperative blood loss due to the poor contractility of the lower uterine segment, the increased risk of an associated placenta accreta, and the possibility of an anterior placenta being cut during uterine incision. Hong et al. prospectively compared epidural to general anesthesia in women undergoing cesarean section for placenta previa. They found that postoperative hematocrits were lower in the patients receiving general anesthesia; there were no group differences with respect to operative times, estimated blood loss, urine output, or Apgar scores. Chestnut et al. found that none of the patients receiving continuous epidural anesthesia for elective or emergency peripartum hysterectomy required an intraoperative induction of general anesthesia in a multi-institutional study. Although these studies looked at epidural anesthesia, options for neuraxial include continuous spinal, combined

spinal-epidural, and continuous epidural anesthesia. Single injection spinal anesthesia can be used, but the unpredictable length of the surgery may make this a poor choice. All patients having neuraxial anesthesia should be informed that if the need arises, general anesthesia may be induced.

If the patient had a known placenta accreta, neuraxial anesthesia could still be used depending upon the urgency of the cesarean section and the maternal volume status. If continuous epidural anesthesia was chosen and internal iliac balloons were to be placed preoperatively to assist with intraoperative hemostasis, the epidural anesthetic could be utilized during their placement. If hemorrhaging occurs intraoperatively and the patient becomes hemodynamically unstable, conversion to general anesthesia may be necessary. This possibility should be discussed with the patient and obstetric team before surgery. On the other hand, if the patient has a suspected placenta percreta, a general anesthetic is the usual choice for the operative cesarean section and hysterectomy because of the extensive surgery that may be required.

If postpartum hemorrhaging occurs, a coordinated team approach aimed at early recognition and treatment is essential. Good communication between *all* the involved specialties is imperative. In Lewis and Drife's report, poor communication between specialties was believed to have been a contributor to maternal death.

C.3. What are the absolute and relative contraindications for neuraxial anesthesia?

Absolute contraindications

- Patient inability to cooperate or patient refusal
- Uncorrected maternal hypovolemia or hypovolemic shock
- Infection at the site of needle insertion
- Frank coagulopathies
- Mass lesions causing increased intracranial pressure
- Providers' lack of experience in techniques

Relative contraindications have included maternal systemic infection, neurologic disease, and some isolated blood coagulation test abnormalities. Most cases of properly treated systemic infection or neurologic disease, however, do not currently contraindicate the use of neuraxial anesthesia. Each patient should be treated individually with careful consideration of the benefits and risks of neuraxial anesthesia.

C.4. What is the usual amount of blood loss expected with delivery?

The usual amount of delivery-related blood loss depends upon the type of delivery. The average blood loss is 500 mL for a vaginal delivery, 1,000 mL for a cesarean delivery, and 1,500 mL for a cesarean hysterectomy. These values often are underestimated clinically, owing to the significant blood volume expansion that accompanies normal pregnancy.

Pritchard JA, Baldwin RM, Dickey JC, et al. Blood volume changes in pregnancy and the puerperium. II. Red blood cell loss and changes in apparent blood volume during and following vaginal delivery, cesarean section, and cesarean section plus total hysterectomy. *Am J Obstet Gynecol.* 1962;84:1271.

C.5. What are the physical findings associated with blood loss?

The physical findings in relation to percentage of blood loss are listed in Table 27.1.

The effect of blood loss on physical findings reflects the volume deficit, which may not be the same as volume loss. Depending on the nonpregnant blood volume and the corresponding magnitude of pregnancy-induced hypervolemia, a dangerous feature of postpartum bleeding is the failure of the pulse and blood pressure to undergo more than moderate alterations until large amounts of blood (>1,500 mL) have been lost.

Gabbe SG, Niebyl JR, Simpson JL, eds. *Obstetrics–Normal and Problem Pregnancies.* 5th ed. Philadelphia: Churchill Livingstone/Elsevier; 2007:456, 466.

C.6. How is postpartum hemorrhage defined, and what are the etiologies of this bleeding?

In the literature, the definition of postpartum hemorrhage has been variable and has included subjective assessments of blood loss greater than the standard norms (>500 mL for vaginal deliveries and >1,000 mL in cesarean sections), a 10% decline in hematocrit, and/or the need for a blood transfusion. There is no absolute numeric definition of postpartum hemorrhage. The etiologies of postpartum hemorrhage generally can be categorized as those occurring early within 24 hours of delivery and those occurring late from 24 hours until 6 weeks postdelivery. Because the obstetrician typically is faced with early postpartum hemorrhage, the remainder of this discussion will focus on its causes. The two broad etiologies of early postpartum hemorrhage are based on bleeding from the placental implantation site and genital tract trauma. Within the category of placental site bleeding, bleeding is usually due

Table 27.1 The Physical Findings in Relation to Percentage of Blood Loss

BLOOD LOSS	PHYSICAL FINDINGS
<15%–20%	None
20%–25%	Tachycardia (>100 beats/min) and tachypnea
	Narrowed pulse pressure and orthostatic hypotension
	Peripheral vasoconstriction
30%–35%	Worsening tachycardia and tachypnea
	Hypotension
	Oliguria
>40%	Shock
	Altered consciousness
	Anuria

to either myometrial hypotonia, such as that seen with uterine atony and placenta previa, or retained placental tissue as can be seen with invasive placentation such as placenta accreta. Genital tract traumas that lead to postpartum bleeding include genital tract lacerations and uterine rupture. Coagulation defects intensify the bleeding that occurs with any of the above abnormalities.

Cunningham FG, Leveno KJ, Bloom SL, et al., eds. *Williams Obstetrics.* 23rd ed. New York: McGraw-Hill; 2010:759–761.

Gabbe SG, Niebyl JR, Simpson JL, eds. *Obstetrics–Normal and Problem Pregnancies.* 5th ed. Philadelphia: Churchill Livingstone/Elsevier; 2007:466.

C.7. After delivery of the fetus, the placenta is removed with some difficulty in one small area and generalized oozing from the placental implantation site is noted. What is the most likely cause of this patient's bleeding?

The most likely causes of bleeding in this patient are myometrial hypotonia due to the poor contraction of the lower uterine segment and a focal placenta accreta. Near term, at least 600 mL per minute of blood flows through the intervillous space carried by about 120 spiral arteries and their accompanying veins. With placental separation, these vessels are avulsed; hemostasis at the placental implantation site is first achieved by contraction of the myometrium that compresses these relatively large vessels and reestablishes vascular integrity. Subsequently, clotting occurs and the vessel lumens are obliterated. Ineffective myometrial contractions, such as occur with retained placenta or massive blood clots, can impair hemostasis at the implantation site. In this patient, the lower uterine segment, which contains less myometrial tissue, contracts poorly, and hemorrhaging can result despite normal coagulation. Bleeding that occurs after placenta delivery is usually a steady, not a sudden massive, hemorrhage. The constant seepage, however, can lead to an enormous blood loss. Severe postpartum hemorrhage, therefore, can result from uterine atony despite normal coagulation. Conversely, even if coagulation is impaired, vigorous myometrial contraction within and adjacent to the denuded placental implantation site makes severe hemorrhage from this implantation site unlikely. During rapid bleeding, the hematocrit may not accurately reflect the amount of blood lost due to the lack of equilibration with other fluid compartments.

Cunningham FG, Leveno KJ, Bloom SL, et al., eds. *Williams Obstetrics.* 23rd ed. New York: McGraw-Hill; 2010:759–761.

C.8. After delivery of the placenta in a cesarean section, what maneuvers and drugs can enhance myometrial contractility and therefore decrease blood loss?

McCurdy et al. found that spontaneous delivery of the placenta during cesarean delivery reduced blood loss by 30% when compared to manual removal. Manual uterine massage stimulates the myometrium to contract. Uterotonic medications, such as oxytocin, also cause myometrial contractions. Synthetic oxytocin (Pitocin, Syntocinon) is the drug of choice and is given once the fetus is born and the placenta is delivered. Oxytocin increases the frequency and duration of uterine contractions; these contractions are most likely mediated through an increase in intracellular calcium levels. The number of oxytocin receptors in the uterus increases from about 20 weeks of gestation to 34 weeks of gestation, and receptor sensitivity increases during labor. Intravenous therapy is the preferred route of administration, but intramuscular and intrauterine dosing is possible. Initial intravenous treatment usually starts with 20 units of oxytocin

in 1,000 mL of crystalloid solution. Munn et al. found that higher doses (80 units in 500 mL over 30 minutes) were safe, efficacious, and reduced the need for additional uterotonic therapy by 20% when compared with standard dosing of 10 units in 500 mL over 30 minutes. The posterior pituitary produces the polypeptide hormones, oxytocin and antidiuretic hormone. Because they differ from one another by only two amino acids, oxytocin exhibits a small antidiuretic effect that is clinically insignificant unless very large doses are given; in this situation, water intoxication might occur. A bolus of oxytocin can decrease peripheral vascular resistance leading to hypotension that on occasion requires treatment with appropriate vasopressors (ephedrine or phenylephrine). Patients may also exhibit tachycardia and arrhythmias.

When oxytocin fails to produce adequate uterine tone and uterine atony is present, other uterotonic medications should be used. Uterine atony is the most common cause of postpartum hemorrhage and accounts for up to 80% of the cases. The second-line agent chosen depends on its side-effect profile and contraindications. Ergot alkaloids, methylergonovine (Methergine) and ergonovine (ergometrine), are effective uterotonic agents; they are usually given intramuscularly and produce tetanic contractions of the uterus that may be mediated through α-adrenergic receptors. Their usefulness is limited because the induced hypertension, due to vasoconstriction, can be prominent. These agents should be avoided in patients with pre-existing hypertensive disease. Other cardiovascular affects include coronary artery spasm leading to myocardial infarction, arrhythmias, or cerebrovascular accidents. Pulmonary complications have been reported including pulmonary artery vasoconstriction and pulmonary hypertension. Associated side effects include headache, dizziness, nausea, and vomiting.

Prostaglandins are uterotonic agents. The prostaglandins cause an increase in myometrial intracellular calcium levels leading to an increase in myosin light-chain kinase activity and uterine contraction. Intramuscular and intrauterine administration of 15-methyl prostaglandin $F_{2\alpha}$ (Hemabate, carboprost tromethamine) can be used to control of uterine atony. Due to its bronchoconstrictive properties, its use is strongly contraindicated in asthma patients. Rectally administered prostaglandin E_2 (Prostin) is a naturally occurring uterotonic agent that has not been tested in clinical trials for postpartum bleeding, and its unfavorable side effects include fever/chills, nausea/vomiting, diarrhea, and headaches. Finally, Mousa and Alfirevic recently reported that rectally administered misoprostol (Cytotec), a synthetic prostaglandin E_1 analogue, provided no added benefit when compared to standard therapy with oxytocin and ergometrine (ergonovine) in primary postpartum hemorrhage patients.

If pharmacologic methods fail to control atony-related hemorrhage, alternative measures, including uterine tamponade, selective arterial embolization, and surgical intervention must be undertaken.

C.9. If this patient had ongoing bleeding intraoperatively, what guidelines help determine when red blood cell (RBC) transfusions should be given?

Treatment of serious bleeding demands prompt and adequate refilling of the intravascular compartment. Normovolemia should be maintained, and usually non–dextrose-containing crystalloid solutions are used for the initial volume resuscitation. These solutions rapidly equilibrate into the extravascular space, and therefore, the volume of crystalloid given should be three times as much as the estimated blood loss. Colloid solutions can also be used to maintain normovolemia but confer no greater benefit than crystalloid solutions. Depending on colloid solution (e.g., 5% albumin), the volume that should be administered is the same as that of the estimate blood loss; this may be helpful in facilitating a more rapid repletion of a pre-existing volume deficit.

Defining a universal hematocrit (Hct) or Hgb value below or above which transfusion is either mandatory or contraindicated is difficult. RBCs carry oxygen to the tissues, and the goal of RBC transfusions is to maintain adequate tissue oxygenation. The 2006 American Society of Anesthesiologist Practice Guidelines state that patients with a Hgb concentration $\geq$ 10 g per dL usually do not require RBC transfusion, and if a patient's Hgb concentration is $<$6 g per dL, RBCs should usually be administered. RBC transfusions should be considered in all patients with clinical evidence of inadequate oxygen carrying capacity. In most bleeding obstetric patients, maintaining a Hgb level above 7 g per dL is suggested unless evidence of impaired pulmonary or cardiac function indicates a need for a higher Hgb level.

C.10. If this patient had a massive blood loss, what blood replacement therapy would be indicated?

When blood replacement therapy is indicated, compatible whole blood is ideal for maintaining intravascular volume in the treatment of hypovolemia from catastrophic acute hemorrhage. One unit of whole blood raises the Hct by 3 to 4 volume percent and replaces many coagulation factors, especially fibrinogen. Importantly, using whole blood versus packed red cells and components decreases the exposure of women with severe hemorrhage to blood donors. When whole blood transfusions were compared with packed red cell transfusions or blood product combinations, Alexander et al. reported that the incidence of renal failure, adult RDS, pulmonary edema, hypofibrinogenemia, admission to an intensive care unit, and maternal death decreased significantly in women delivered at Parkland Hospital. However, availability of whole blood is limited; few units of whole blood are kept in the modern blood bank as over 90% of donor blood is fractionated into blood components. For women who do not have massive blood loss, pRBC transfusions are suitable, and component therapy provides better treatment because only the specific component needed is given.

Blood component therapy provides the patient with only the components that they require. The products available are pRBCs, fresh frozen plasma, cryoprecipitate, and platelets. A unit of pRBC is prepared from one unit of whole blood; its plasma is removed and replaced with additives such as citrate, phosphate, dextrose, and adenine. Its volume is about 250 to 325 mL with a hematocrit of 55 to 80 volume percent depending upon the method used for preparation and storage. A unit of pRBCs increases the patient's hematocrit approximately 3 volume percent and Hgb

by about 1 g per dL. Crystalloid infusion and pRBC transfusion are the mainstays of therapy in the bleeding obstetric patient. Fresh frozen plasma (FFP) contains all the necessary coagulation factors, and a unit has a volume of approximately 250 mL. When replacement of coagulation factors is needed for hemostasis as occurs after massive transfusion, FFP transfusion is indicated. In a parturient with surgical bleeding, a fibrinogen level of less than 100 mg per dL, a prolonged PT, and/or a prolonged aPTT are indications for fresh frozen plasma administration in initial doses of 10 to 15 mL per kg. FFP administration is not indicated for hypovolemia. Cyroprecipitate is prepared from FFP and 15 mL contains 200 mg fibrinogen, factor VIII:C, factor VIII:von Willebrand, Factor XIII, and fibronectin. Ten pooled bags (10–15 mL per bag) of cryoprecipitate will increase the fibrinogen level by 65 to 70 mg per dL. In the bleeding obstetric patient, general clotting factor replacement with cryoprecipitate provides no advantage over FFP and should not be used unless volume is problematic or there is a specific factor deficiency. With obstetric hemorrhage, the platelet count should be maintained above 50,000 per mm^3 with the infusion of platelet concentrates. One unit of platelets increases the platelet count 5,000 to 10,000 per mm^3 in an adult woman. A single donor platelet apheresis unit provides the equivalent amount of platelets as six random donor platelet units and should be used if available. Platelets are difficult to store and have a short shelf life (5 days). Typically, the blood bank provides platelets from and ABO- and Rh-compatible donors, but ABO-compatibility is not essential.

Recently, the impact of massive transfusion, defined as 10 or more units of blood with resultant coagulopathy, has been studied by both civilian trauma groups and military combat hospitals. Although replacement therapy with plasma, platelets, and red cells generally should not be based upon any set formula, the results from these studies suggest that patients with severe trauma, massive blood replacement, and coagulopathy have improved survival when the ratio of transfused pRBCs (units) to FFP (units) to platelets (units) approaches 1:1:1. Because there are only a limited number of studies in patients requiring massive transfusion and no data in the obstetric setting, the value of this approach is still controversial and remains to be proven.

C.11. What is the role of type O Rh-negative (universal donor) uncrossmatched blood in emergency transfusions, and how does this change your future management?

When typed and screened/crossed blood is unavailable and the hemodynamically unstable, hemorrhaging obstetric patient requires an RBC transfusion in addition to crystalloid and/or colloid solutions, un-crossmatched type O Rh-negative blood can be given. People with type O blood are considered universal donors because they lack A and B antigens, and therefore, their erythrocytes are not hemolyzed by a recipient's anti-A or anti-B antibodies if present. Some type O donors, however, produce high titers of hemolytic anti-A and anti-B antibodies. pRBCs, therefore, are preferable to whole blood because packed erythrocytes have a smaller volume of

plasma and therefore, a minimal amount of anti-A and anti-B antibodies if present. If whole blood is to be used, the blood bank should supply type O blood that is free of anti-A and anti-B antibodies. Some confusion exists as to when it is safe to switch back to the patient's native blood type. After a patient has received two units of type O Rh-negative un-crossmatched whole blood, the patient should not be switched to their type specific (A, B, AB) blood; additional transfusions should be continued with type O blood. The patient must not receive a transfusion of her correct blood type until the blood bank determines that switching back to the patients native blood type is safe. Patients who have received un-crossmatched type O Rh-negative pRBCs can receive many more units without concern for antibody reactions. Individual centers have different policies governing the maximum number of un-crossmatched type O Rh-negative blood units that can be given before switching back to the patient's specific blood type. Most centers do recommend switching to the patient's native blood type as soon as safely possible in order to conserve the emergency supply of type O Rh-negative blood. Recommendations should be received from your local blood bank representative.

Miller RD, Eriksson LI, Fleisher LA, et al., eds. *Miller's Anesthesia.* 7th ed. Philadelphia: Churchill Livingston/Elsevier; 2009:1744–1745.

C.12. What complications can occur from the transfusion of blood products?

Blood transfusion safety has improved over the past several decades. Currently, the most serious and common known risks are administrative errors leading to ABO-incompatible blood transfusion, transfusion-related acute lung injury and infection. Other transfusion-related adverse reactions include delayed hemolytic transfusion reactions, febrile and allergic nonhemolytic transfusion reactions, and transfusion-associated graft-versus-host disease.

The accidental transfusion of ABO-incompatible blood can result in acute intravascular hemolysis. This is typically characterized by the symptoms of fever, chills, nausea, flushing, chest and flank pain, tachycardia, hypotension, DIC, hemoglobinuria, acute renal failure, and potentially death. The rate of such errors in the United States is estimated to be 1 in 14,000 units. Immediate supportive care includes the discontinuation of the transfusion, treatment of the hypotension and hyperkalemia, administration of a diuretic, and urine alkalinization. The unused blood product should be sent back to the blood bank along with a new patient specimen for a second crossmatch. Assays for urine and plasma hemoglobin concentration and a direct antiglobulin antibody screen confirm the diagnosis.

Transfusion-related acute lung injury is a noncardiogenic pulmonary edema that occurs about 6 to 72 hours after transfusion; this life-threatening complication is characterized by severe dyspnea and hypoxia, occurring about 1 in 5,000 transfusions. Its pathogenesis is incompletely understood, but the lung injury appears to involve lipid products from stored components as well as leukocyte reactivity.

The risk of bacterial contamination is less than 1 per million units in the United States, but the transfusion of a contaminated blood component is associated with a high (about 60%) mortality rate making bacterial contamination the leading cause of transfusion-related death. Platelets present the greatest risk of bacterial contamination; the introduction of culture-negative platelets has decreased the risk of an infected platelet transfusion to 1 in 75,000 units.

The use of serologic screening and nucleic acid amplification testing (NAT) on donor blood products have decreased the risk of viral infection transmission. The risk of contracting HIV or hepatitis C is approximately 1 in 2 million units transfused. The risk of *hepatitis B* transmission is estimated to be less than 1 per 200,000 to 500,000

units transfused. The risk of other transfusion-transmitted infectious diseases, such as malaria and cytomegalovirus, is estimated to be less than 1 in 1 million units transfused. However, due to risks to the fetus, pregnant women should receive blood that is seronegative and leukocyte-depleted to further decrease the risk of cytomegalovirus infection. There have been reports of West Nile virus infection and variant Creutzfeldt-Jakob disease acquired via transfusion.

The biochemical changes that occur with the storage of blood can lead to problems in the recipient especially when large amounts are rapidly infused. Hypokalemia, hypocalcemia. and hypothermia can occur and should be promptly corrected.

C.13. What is the role of autologous transfusion in obstetric patients?

Autologous blood transfusion may avoid the risks of alloimmunization, hemolytic reactions, and viral infections, may potentially decrease the demands on the allogenic blood supply, and may provide a psychological benefit to the patient. There are three methods of autologous transfusion, preoperative (antepartum) donation, normovolemic hemodilution, and intraoperative blood salvage. Each technique may have potential benefits in the properly selected patient population, but applicability is limited and safety anecdotal. Due to the inability to correctly anticipate which patients will require transfusions and the limited amount of transfusable blood obtained, preoperative donation and normovolemic hemodilution are ineffective strategies for avoiding allogenic transfusions in the obstetric patient.

Intraoperative blood salvage has been used in obstetric patients. During cesarean section after placenta delivery, blood is suctioned from the surgical site, collected, and processed through a cell salvage machine that yields a washed, pRBC product for transfusion. There are no prospective randomized studies evaluating the safety of intraoperative blood salvage in obstetrics, but the review of over 400 case reports by Allam et al. did not reveal any complications leading to poor maternal outcome that were directly attributable to the use of this technique. The safety of blood salvage during cesarean section has been questioned because of the theoretical risk of developing an amniotic fluid embolism (AFE); unfortunately, the pathophysiology of AFE is unknown. In the United States, the American Society of Anesthesiologists recommends that "in cases of intractable hemorrhage when banked blood is not available or the patient refuses banked blood, intraoperative cell salvage should be considered if available." Intraoperative blood salvage during cesarean section is more widely accepted in United Kingdom. Leukocyte depletion filters may improve the margin of

safety of the salvaged pRBC product. Because washed pRBCs may contain fetal RBCs, isoimmunization of the mother is possible; anti-D immune globulin should be given when appropriate.

Jehovah's Witness patients have an increased risk of maternal death due to maternal hemorrhage because their religious beliefs prevent them from receiving blood transfusions. In 2004, the society's official magazine, The Watchtower, stated that "Though all witnesses should refuse autologous or heterologous transfusions of blood or one of its major components, the society states that each member should decide for him- or herself whether or not to accept treatment with other blood products like coagulation factors and erythropoietin." The use of intraoperative blood salvage during surgery sometimes is accepted because continuity of the salvaged blood with the patient's circulatory system can be maintained. The exact possibilities for acceptable treatment options should be discussed with each individual patient early in pregnancy.

C.14. Significant intraoperative blood loss required the transfusion of 8 units of type-specific, crossmatched packed RBCs (pRBCs). This patient had generalized oozing in the surgical field and hematuria. What is your differential diagnosis?

The obstetric patient can rapidly develop a coagulopathy. It may be a dilutional coagulopathy or DIC. A dilutional coagulopathy can occur when massive blood loss is replaced with crystalloid solutions and pRBCs leading to a relative depletion of platelets and soluble clotting factors. Thrombocytopenia is the most frequent coagulation defect found in women with blood loss and multiple transfusions. Pregnancy-related causes of DIC include hemorrhagic shock, AFE, placental abruption, intrauterine fetal demise, and sepsis due to uterine infection. Additionally, hemolytic transfusion reactions with acute intravascular hemolysis can cause DIC. Acidosis and hypothermia both interfere with the normal functioning of the coagulation system and worsen any coagulopathy.

C.15. What is disseminated intravascular coagulation (DIC)?

DIC, a consumptive coagulopathy, is a pathologic activation of the coagulation system that occurs in response to a variety of diseases. The process of coagulation is dysregulated and widespread intravascular clotting and resultant bleeding due to the inappropriate consumption of factors and platelets occurs. Thrombi are deposited in the microcirculation and can diminish blood flow to the organs and lead to multisystem organ failure. Simultaneously, increased fibrinolysis occurs with the formation of fibrin degradation products (also called fibrin split products). Once DIC begins, the pathophysiology is the same regardless of the inciting cause. Resolution of DIC requires treatment of the underlying cause. Supportive treatment is aimed at replacing the consumed blood products-"feeding the fire." Laboratory values are indicative of this consumption of clotting products and the increased fibrinolysis that this excess clotting activates and can help guide management. Thrombocytopenia, decreased levels of fibrinogen and coagulation factors, increased levels of fibrin degradation products, increased PT, and increased aPTT are seen.

Cunningham FG, Leveno KJ, Bloom SL, et al., eds. *Williams Obstetrics*. 23rd ed. New York: McGraw-Hill; 2010:785–787.

C.16. What is the role of recombinant activated factor VII (rFVIIa) in obstetric patients?

RFVIIa (NovoSeven), a synthetic vitamin K-dependent glycoprotein was approved by the Food and Drug Administration principally for the treatment of bleeding in individuals with hemophilia A or B, factor VII deficiency, and Glanzmann thrombasthenia. It has been used to facilitate hemostasis in patients bleeding from other coagulopathies, surgery, trauma, and severe obstetric hemorrhage. Use of rFVIIa in obstetrics has been reported in case series and international registries; no randomized controlled trials have been published. At pharmacologic doses, rFVIIa directly activates factor X on the surface of activated platelets at the site of injury independent of tissue factor and factors VIII and IX causing a "thrombin burst" with the conversion of prothrombin into large amounts of thrombin and the local formation of a stable fibrin clot that may control bleeding. Currently, it has not been ruled out that a small amount of tissue factor-dependent activity also might contribute to its hemostatic effect. There are case reports of rFVIIa being used in obstetric cases after massive hemorrhage with symptoms suggesting DIC. Franchini et al. reviewed the literature and found that a median dose of 81.5 μg per kg of rFVIIa has been effective in stopping or decreasing bleeding in 85% of obstetric cases where it has been utilized. Based on personal experience and literature review, they have outlined a treatment scheme for the off-label use of rFVIIa in the treatment of postpartum hemorrhage. They suggest that rFVIIa be considered only after the failure of medical treatment, blood component therapy, and conservative surgical/invasive treatment. Before administering rFVIIa, acidosis, thrombocytopenia, hypofibrinogenemia, hypocalcemia, and hypothermia should be corrected. Then, 90 μg per kg should be given intravenously over 3 to 5 minutes. If no response has occurred 20 minutes later, a second dose of 90 μg per kg should be given. If there is no response after

two doses, hysterectomy should be considered. Because to date all of the information about rFVIIIa in obstetrics is anecdotal, the use of rFVIIa should be determined on an individual case basis. There are unanswered concerns about the increased likelihood of thrombotic events, and the role of rFVIIa remains undefined. The ASA guidelines, however, recommend that rFVIIa administration be considered when "traditional well tested options for treating microvascular bleeding (i.e. coagulopathy) have been exhausted."

C.17. What laboratory tests should be ordered during the resuscitation of this patient?

Blood specimens for a hematocrit, hemoglobin level, platelet count, coagulation tests (aPTT, PT, and fibrinogen levels), and an arterial blood gas should be sent as soon as possible to determine an early baseline. During the resuscitation, the above blood tests should be sent periodically to help guide treatment including blood component therapy. If the volume of blood lost requires treatment with a massive transfusion, then electrolyte levels, including a potassium and calcium, also will need to be followed. Patients can develop hyperkalemia due to the elevated potassium levels in transfused blood and the cellular shifts caused by acidosis. Patients can develop hypocalcemia from citrate toxicity; citrate is the anticoagulant found in transfused pRBCs. Arterial blood gases and lactate levels also should be monitored to evaluate the acidosis that may develop due to poor tissue perfusion and the development of shock. If disseminated intravascular coagulation is a concern, the level of fibrin degradation product also should be checked.

C.18. Define amniotic fluid embolism (AFE) syndrome and discuss treatment.

AFE is a complex disorder that is poorly understood. Classically, it is characterized by the abrupt onset of a maternal collapse associated with hypotension, dyspnea, hypoxemia, cyanosis, loss of consciousness, seizures, cardiopulmonary arrest, and hemorrhaging associated with disseminated intravascular coagulation. There is, however, great individual variations in symptomatology from none to catastrophic systemic complications. The overall maternal mortality is reported to be between 22% and 90%. The reported incidence and outcome vary greatly in part because it is a diagnosis of exclusion and because of reporting bias with the syndrome being underdiagnosed in all but the most severe cases. The changing mortality rates may reflect improved intensive care and a recognition of the fact that "milder" cases do occur. Recently, Abenhaim et al. estimated an AFE incidence of 7.7 cases per 100,000 births in the United States. Advanced maternal age, placenta previa, and cesarean delivery

were risk factors, and maternal mortality was 21.6%. Clark et al. found a disappointingly high incidence of neurologic dysfunction among the surviving women that had a cardiac arrest as an initial symptom.

The cause of AFE syndrome is unknown. The detection of squamous cells, trophoblasts, and other debris of fetal origin is neither sensitive nor specific for AFE. Clark et al. suggested that the syndrome of acute peripartum hypoxia, hemodynamic collapse, and coagulopathy would be more aptly described as anaphylactoid syndrome of pregnancy than AFE. The suggestion that AFE may be related in some way to anaphylaxis has led to a number of reports describing tryptase levels in cases of AFE; however, some reported cases had elevated tryptase levels while others did not. A nine-case series suggests that complement activation, due to the low levels of complement found, rather than mast cell degranulation (anaphylaxis) plays a role in AFE. The diagnosis of AFE is a clinical one of exclusion; no diagnostic test exists. Treatment is prompt supportive resuscitation. There is no data that any type of intervention improves maternal prognosis with AFE although case reports using early hemofiltration or exchange transfusion exist.

D. Postoperative Management

D.1. If the patient received epidural anesthesia and subsequently developed disseminated intravascular coagulation (DIC), when should the epidural catheter be removed?

There is little information available concerning this topic. Sprung et al. made recommendations about the removal of an epidural catheter after DIC. First, they suggest that the patient's neurologic status be evaluated frequently and that the coagulopathy be treated; if there is no indication of intraspinal bleeding, they recommend removing the catheter as early as possible. If, however, bleeding is occurring around the catheter insertion site, the catheter may be left in place to tamponade this bleeding. Any neurologic deficits should be evaluated immediately; prompt surgical decompression may be needed. However, if a patient's neurologic status cannot be evaluated (e.g., postoperative intubation and sedation), an argument can be made for the removal of an indwelling catheter as soon as possible after the replacement of coagulation factors has created a state of normal coagulation even if it is temporary.

Chestnut DH, Polley LS, Tsen LC, et al., eds. *Chestnut's Obstetric Anesthesia: Principles and Practice.* 4th ed. Philadelphia: Mosby/Elsevier; 2009:847.

Sprung J, Cheng EY, Patel S. When to remove an epidural catheter in a parturient with disseminated intravascular coagulation? *Reg Anesth.* 1992;17(6):351–354.

D.2. You have successfully treated the patient's massive hemorrhage. Her laboratory values have returned to normal. Her central venous pressure (CVP) is within normal limits and urine output is appropriate. The patient, however, is still hypotensive despite appropriate intravascular volume replacement and support with vasopressors. What is your concern in this case?

She may have developed Sheehan syndrome. Sheehan syndrome refers to the development of a postpartum pituitary infarction with necrosis that is typically precipitated by an obstetric hemorrhage with severe hypotension. Sheehan syndrome is a rare complication. The damage to the pituitary may affect the secretion of one, several, or all of its hormones. Any of the manifestations of hypopituitarism (e.g., failure to lactate, amenorrhea/oligomenorrhea, hypotension, hyponatremia, hypothyroidism) can occur at any time from the immediate postpartum period to years after delivery. If the patient remains hypotensive after control of hemorrhage and adequate volume replacement, she should be evaluated and treated for adrenal insufficiency immediately; treatment of possible adrenal crisis should not be delayed while diagnostic tests are performed. Glucocorticoids have a role in maintaining peripheral vascular adrenergic tone, and the sudden loss of corticotropin (adrenocorticotropic hormone) secretion, particularly in conjunction with other serious physical stress, can lead to hypotension and shock. Prompt treatment with stress doses of glucocorticoids, (e.g., 4 mg dexamethasone by intravenous bolus) is necessary for survival. The work-up includes measuring adrenocorticotropic hormone, cortisol, thyroxine, prolactin, and growth hormone levels. The evaluation of other hormonal deficiencies is not urgent and can be deferred until 4 to 6 weeks postpartum.

CHAPTER 28

Hypertensive Disorders of Pregnancy

Sharon Abramovitz

A 39-YEAR-OLD WOMAN

gravida 1 para 0 at 29 weeks' gestation was admitted to the hospital because of an elevated blood pressure (BP) (182/111 mm Hg), headache, and proteinuria (6 g over a 24-hour period).

A. Medical Disease and Differential Diagnosis

1. What is the classification of hypertensive disorders in pregnancy as defined by the American College of Obstetricians and Gynecologists?
2. What is preeclampsia?
3. What is severe preeclampsia?
4. What is eclampsia?
5. What are the risk factors for developing preeclampsia?
6. What is the mortality associated with preeclampsia?
7. Discuss the pathogenesis of preeclampsia.
8. Discuss the pathologic alterations of preeclampsia.
9. Which component of BP best predicts the occurrence of preeclampsia?
10. What is the significance of increased pulse wave velocity (PWV) during pregnancy? How does this relate to birth weight?
11. What are some of the complications associated with preeclampsia?

B. Preoperative Evaluation and Preparation

1. What initial laboratory studies are recommended for patients with preeclampsia?
2. What are the important routine monitors for patients with preeclampsia? When is a central venous pressure monitor indicated?
3. What conditions mandate immediate delivery, regardless of the gestational age?
4. Discuss the obstetric management of preeclampsia.
5. In the United States, what drug therapy is the treatment of choice for seizure prophylaxis?

6. Discuss the treatment of magnesium sulfate toxicity.
7. Discuss the mechanism of action of magnesium sulfate.
8. What are the fetal effects of magnesium sulfate therapy?
9. Discuss the treatment of eclampsia.

C. Intraoperative Management

1. What is your choice of analgesia/anesthesia for patients with preeclampsia?
2. What is the advantage of prehydration?
3. How should patients be hydrated before epidural analgesia/anesthesia for labor and delivery?
4. Discuss bleeding time and platelet count evaluation during preoperative assessment of a patient with preeclampsia requesting epidural analgesia/anesthesia for labor and delivery.
5. What level of analgesia/anesthesia is required for labor and delivery?
6. Discuss the commonly used local anesthetics for labor analgesia.
7. Is the addition of epinephrine to local anesthetics advisable in preeclamptic patients?
8. What is the treatment for the abnormal fetal heart rate pattern seen with maternal hypotension after epidural analgesia/anesthesia is instituted?
9. What would you do after an accidental spinal tap? How do you treat postdural puncture headache?
10. How would you manage total spinal anesthesia?
11. Should ergonovine be given to preeclamptic patients?
12. When and how would you give spinal anesthesia?
13. Discuss a general anesthesia technique for the patient with preeclampsia presenting for cesarean delivery.
14. What agents can be used to prevent hypertension during the induction of general anesthesia for cesarean delivery?
15. What is HELLP syndrome?

D. Postoperative Management

1. Discuss the postpartum management of preeclamptic patients.

A. Medical Disease and Differential Diagnosis

A.1. What is the classification of hypertension disorders in pregnancy as defined by the American College of Obstetricians and Gynecologists?

Hypertensive disorders of pregnancy are classified as follows:

- Gestational hypertension
- Preeclampsia
  - Mild
  - Severe
- HELLP (hemolysis, elevated liver enzymes, low platelets) syndrome
- Chronic hypertension preceding pregnancy
- Chronic hypertension with superimposed preeclampsia

American College of Obstetricians and Gynecologists. *Hypertension in Pregnancy, ACOG Practice Bulletin, No. 33.* Washington, DC: American College of Obstetricians and Gynecologists; January 2002.

A.2. What is preeclampsia?

Preeclampsia is a multiorgan disease characterized by the development of hypertension with proteinuria after the 20th week of gestation. It is a disorder of unknown etiology affecting approximately 8% of all pregnancies, with most cases occurring during the first pregnancy. Hypertension is defined as a sustained systolic BP of at least 140 mm Hg or a diastolic BP of at least 90 mm Hg. Proteinuria is defined as 300 mg or more of protein in a 24-hour urine collection. Edema may manifest as a recent, rapid weight gain.

American College of Obstetricians and Gynecologists. *Hypertension in Pregnancy, ACOG Practice Bulletin, No. 33*. Washington, DC: American College of Obstetricians and Gynecologists; January 2002.

Sibai BM, Stella CL. Diagnosis and management of atypical preeclampsia-eclampsia. *Am J Obstet Gynecol*. 2009;200(5):481.e1–7.

A.3. What is severe preeclampsia?

Severe preeclampsia includes at least one of the following features:

- Blood pressure: systolic BP 160 mm Hg or higher or diastolic BP 110 mm Hg or higher on two occasions at least 6 hours apart; diagnosis not delayed if the diastolic BP exceeds 110 mm Hg
- Proteinuria: 5 g of protein or more in a 24-hour urine specimen (or 3 + to 4 + on semiquantitative urinalysis)
- Oliguria: urine output less than 500 mL in 24 hours
- Cerebral or visual disturbances: headache, blurred vision, or altered consciousness
- Pulmonary edema or cyanosis
- Epigastric or right upper quadrant pain, which may be caused by stretching of Glisson capsule by hepatic edema
- Hepatic rupture: rare complication
- Impaired liver function
- Thrombocytopenia: resulting from platelet adhesion to exposed collagen at sites of endothelial damage
- HELLP syndrome
- Evidence of fetal compromise (e.g., intrauterine growth retardation, oligohydramnios) or placental abruption

Chestnut DH, ed. *Obstetric Anesthesia: Principles and Practice*. 4th ed. Philadelphia: Elsevier Mosby; 2009:984.

Hines RL, Marschall KE, eds. *Stoelting's Anesthesia and Co-existing Disease*. 5th ed. Philadelphia: Churchill Livingstone; 2008:561–566.

A.4. What is eclampsia?

Eclampsia is defined as convulsions and/or coma not caused by coincidental neurologic disease (e.g., epilepsy), which occurs during pregnancy or the puerperium in a woman whose condition also meets the criteria for preeclampsia.

Broughton-Pipkin F. The hypertensive disorders of pregnancy. *Br Med J*. 1995;311:609–613.

Chestnut DH, ed. *Obstetric Anesthesia: Principles and Practice*. 4th ed. Philadelphia: Elsevier Mosby; 2009:998–999.

Hines RL, Marschall KE, eds. *Stoelting's Anesthesia and Co-existing Disease*. 5th ed. Philadelphia: Churchill Livingstone; 2008:561–566.

A.5. What are the risk factors for developing preeclampsia?

The risk factors for developing preeclampsia are as follows:

Hypertensive disease

- Previous preeclampsia
- Systolic hypertension during early pregnancy
- History of chronic hypertension
- Family history of hypertension during pregnancy
- Increase in pulse pressure during the first trimester

Coexisting vascular and endothelial disease

- Chronic renal disease
- Lupus erythematosus
- Protein S deficiency
- Activated protein C resistance
- Circulating anticardiolipin antibodies

Obstetric factors

- African American race
- Angiotensinogen gene *T235*
- Nulliparity
- Age older than 40 years
- History of smoking
- Obesity
- Increased trophoblastic mass (e.g., multiple gestation, molar pregnancy)
- Large for gestational age fetus
- Diabetes
- Erythroblastosis fetalis
- Polyhydramnios, particularly in young primigravidas

Chestnut DH, ed. *Obstetric Anesthesia: Principles and Practice*. 4th ed. Philadelphia: Elsevier Mosby; 2009:976–982.

A.6. What is the mortality associated with preeclampsia?

Hypertensive disorders of pregnancy account for 15% to 19% of maternal deaths in the United States and the United Kingdom.

American College of Obstetricians and Gynecologists. *Hypertension in Pregnancy, ACOG Practice Bulletin, No. 33*. Washington, DC: American College of Obstetricians and Gynecologists; January 2002.

A.7. Discuss the pathogenesis of preeclampsia.

Preeclampsia is most likely a disease of heterogeneous causes of both maternal and placental origin.

Immunologic factors

Immunologic disorders may arise from an abnormal maternal–fetal antigen–antibody response or from the contents of seminal fluids; spermatozoa may cause antibody formation or prostaglandins may initiate uterine vasoconstriction. The fetus acquires 50% of its genes from the father, which represents in part a paternal allograft that interacts with maternal tissue as the fetal trophoblast migrates into the maternal decidua after implantation. Migration normally occurs in two phases. Trophoblasts displace the muscular structure of the maternal spiral arteries before 20 weeks of gestation, causing their adrenergic denervation and converting them from high-resistance to low-resistance vessels. At the same time, biochemical adaptations occur in the maternal vasculature, with an increased dominance of endothelium-dependent vasodilators, prostacyclin (prostaglandin I [PGI]), and nitric oxide (NO). In preeclampsia, the second wave of trophoblastic migration fails. This failure can result in a high-resistance, low-flow uteroplacental circulation and consequent placental ischemia and hypoxia. These changes may represent an aberrant immunologic mechanism.

Genetic factors

A familial tendency toward preeclampsia exists in some populations, and it may result from a recessive genetic inheritance.

Endothelial factors

Vascular endothelial damage or dysfunction is the common pathologic feature of preeclampsia and occurs in the placental decidual vessels and renal microvasculature. Endothelial cell dysfunction in response to unknown factors may cause a hormonal imbalance in women with preeclampsia (Fig. 28.1).

The metabolic end products of normal vascular endothelium include PGI_2 and endothelium-derived relaxing factor (EDRF), which is either NO or a related nitrosyl substance. Both PGI_2 and EDRF are potent vasodilators. In patients with preeclampsia, the failure of the trophoblast to invade the uteroplacental vascular bed may encourage an increased production of free radicals and lipid peroxides by the decidual lymphoid tissue. As a result, an imbalance occurs between the production of the vasoconstrictor thromboxane A_2 (TXA_2), which is derived from platelets, and the production of endothelium-derived PGI_2. This imbalance results in a reduced perfusion of the intervillous space. Some investigators have concluded that hypoxia-induced impairment of NO production by the syncytiotrophoblast results in uteroplacental insufficiency and production of a toxin responsible for the clinical manifestations of preeclampsia.

It has been shown that production of endothelin 1 (ET-1), which is the most potent endogenous vasoconstrictor and produced mainly by vascular smooth muscle cells as well as by the vascular endothelium, is markedly increased in preeclampsia and correlates inversely with NO production. Therefore, the imbalance between NO and ET-1 may play a significant role in the pathophysiology of preeclampsia.

Fetoplacental blood vessels, namely, the human placental chorionic plate arteries, constrict in response to ET-1. Moreover, there is now some evidence that amniotic concentration of ET-1 is elevated in pregnancies associated with preeclampsia. Margarit et al. found a statistically significant increase in ET-1 concentration in the aminionic fluid of women at 17 weeks' gestation who developed preeclampsia, as compared to those who did not develop preeclampsia. By the second trimester, higher levels of ET-1 have also been shown in the amniotic fluid of women with preterm premature rupture of the membranes.

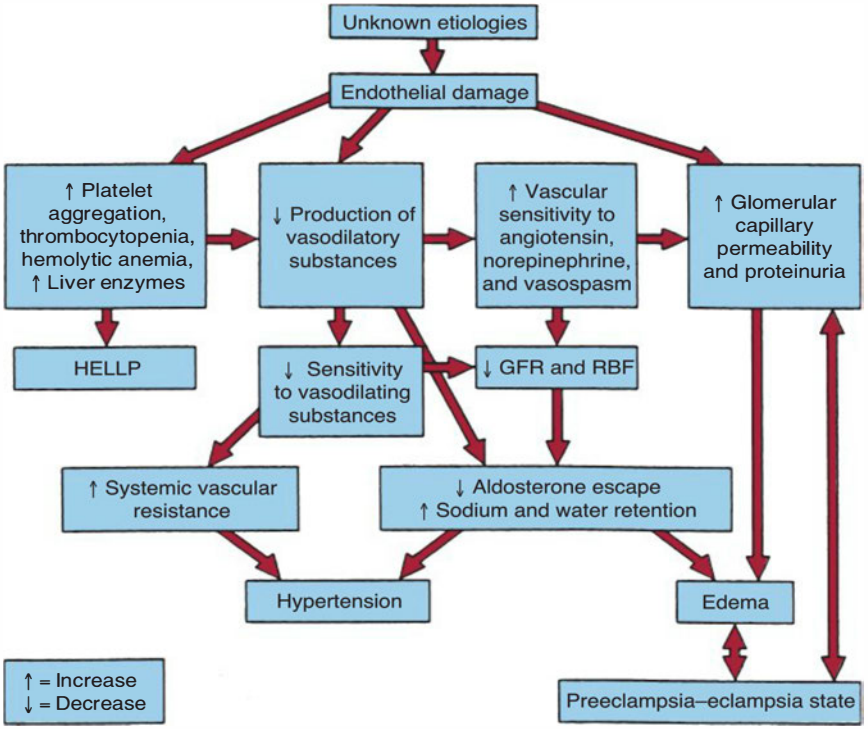

Figure 28.1 Endothelial cell dysfunction in response to unknown factors may cause a hormonal imbalance in women with pregnancy-induced hypertension. GFR, glomerular filtration rate; HELLP, hemolysis, elevated liver enzymes, low platelets; RBF, renal blood flow. (From Chestnut DH, ed. *Obstetric Anesthesia: Principles and Practice.* 3rd ed. Philadelphia: Mosby; 2004:798, with permission.)

Platelet factors

In mild preeclampsia, serotonin (5-HT) released from aggregating platelets interacts with endothelial 5-HT_1 receptors, resulting in the release of prostacyclin and NO (EDRF). The released prostacyclin induces angiotensin II release, improving uteroplacental perfusion. In early-onset severe preeclampsia, damaged uteroplacental vessels cannot respond to 5-HT_1 effects. Instead, serotonin interacts with 5-HT_2 receptors on vascular smooth muscle cells, inducing vasoconstriction. Platelet-derived serotonin also activates 5-HT_2 platelet receptors, establishing a positive feedback loop and intensifying platelet aggregation. The loss of 5-HT_1 receptors prevents stimulation of angiotensin II release (Fig. 28.2).

Calcium

In normal pregnancy, the intracellular free calcium concentration increases slowly, but this increase is significantly greater in the third trimester in women with preeclampsia. The increase in cytoplasmic calcium levels is enhanced by angiotensin II, and the enhancement is greater in women with preeclampsia compared with normotensive women. This response to angiotensin II occurs long before signs of preeclampsia become evident and is a sensitive indicator of its subsequent development.

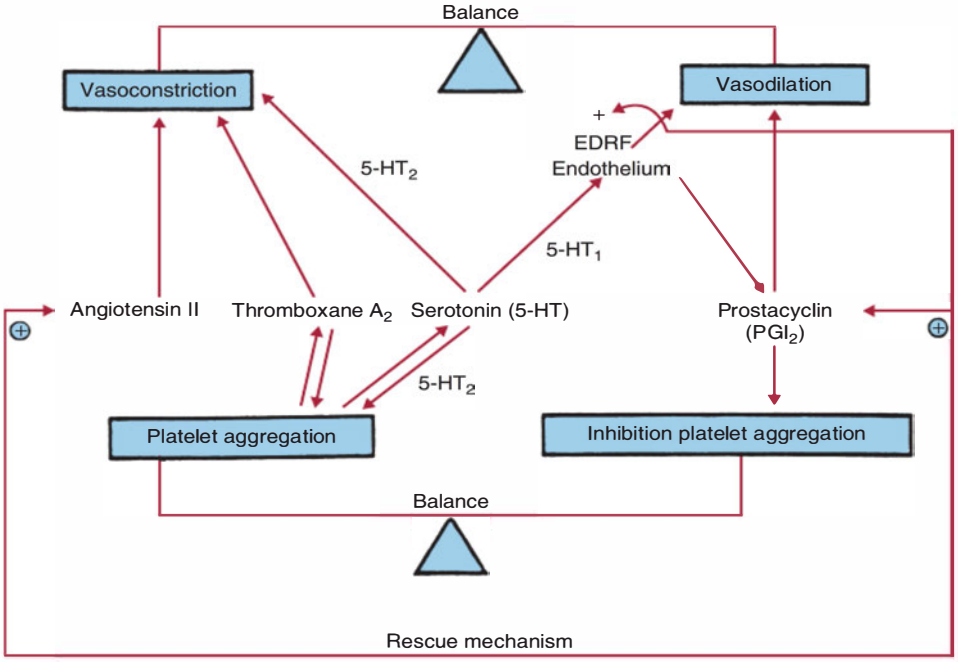

Figure 28.2 The loss of 5-HT_1 receptors prevents stimulation of angiotensin II release. EDRF, endothelium-derived relaxing factor. (From Chestnut DH, ed. *Obstetric Anesthesia: Principles and Practice.* 3rd ed. Philadelphia: Mosby; 2004:797, with permission.)

Coagulation factors

Platelet activation in preeclampsia is surface mediated. Women with preeclampsia have an increased tendency toward thromboembolism, which may result in part from an alteration in the plasma ratio between von Willebrand factor and factor VIII coagulant activity.

Fatty acid metabolism

Altered handling of fatty acids by the liver is a key factor in the pathogenesis of preeclampsia. Both increased hepatic uptake of free fatty acids and hypertriglyceridemia are seen more frequently in women who develop preeclampsia.

Markers of angiogenesis

Preeclamptic patients have elevated plasma levels of endoglin and soluble FLT-1, the receptor for vascular endothelial growth factor, throughout gestation. Recent research suggests that these molecules are not just disease markers but are involved in the pathogenesis of preeclampsia.

A.8. Discuss the pathologic alterations of preeclampsia.

Cardiovascular changes

- *Blood pressure*. Increase in BP results from an increase in peripheral vascular resistance secondary to a state of sympathetic overactivity. Alternatively, systolic BP increases as a result of increased cardiac output (increased plasma volume—typical of pregnancy) and a noncompliant aorta. In such cases, the systemic vascular resistance (SVR), which is predominantly determined by the smaller arterioles, is not increased but due to aortic stiffness, the ejected stroke volume causes the systolic component to rise significantly.
- *Blood volume*. Reduction in blood volume causes a greater degree of hemoconcentration.

Hemodynamic changes

- Three hemodynamic subsets exist:
  - *Hyperdynamic* with increased cardiac output, normal or slightly increased SVR, and normal or slightly decreased blood volume and filling pressures
  - *High SVR* with normal cardiac output and lower filling pressures
  - *Markedly increased SVR* with decreased blood volume and depressed left ventricular function
- Poor correlation between central venous pressure (CVP) and pulmonary artery (PA) occlusion pressure
- Decreased colloid oncotic pressure in pregnancy with further reduction in preeclampsia. The low colloid oncotic pressure, coupled with increased vascular permeability and the loss of intravascular fluid and protein into interstitial tissues, increases the risk of pulmonary edema.

Hematologic changes

- Hypercoagulable state (Table 28.1)
- Platelet activation: Thrombocytopenia occurs in 15% to 30% of women with preeclampsia or eclampsia. Preeclampsia may be associated with a significant defect in *both* platelet function and platelet number. Thrombocytopenia without other coagulation abnormalities but with evidence of hemolysis and increased liver enzymes characterizes HELLP syndrome.

Table 28.1 Changes that Imply Hypercoagulation in Preeclampsia

↑ Common pathway activity
↓ Fibrinogen
↑ Fibrin-degradation products
D-Dimer positive
↑ Fibrinopeptide A
↑ Factor VIII antigen; factor VIII activity
↓ Antithrombin-III
↑ Antithrombin-III/antithrombin complex
↓ Platelets
↑ β-Thromboglobulin
↑ Platelet aggregability
↓ Sensitivity to prostacyclin

From Chestnut DH. *Obstetric Anesthesia: Principles and Practice.* 3rd ed. Philadelphia: Mosby, 2004:803, with permission.

Renal changes

- Glomerular enlargement results in ischemia, leading to decreased glomerular filtration rate.
- Proteinuria occurs as a result of an increased permeability to most large molecular weight proteins.
- Urate clearance decreases and serum uric acid concentrations increase. Hyperuricemia may provide an early indication of preeclampsia.
- Oliguria parallels the severity of preeclampsia.

Endocrine changes

In women with preeclampsia, a breakdown of the normal balance between vasodilators (PGI_2, NO) and vasoconstrictors (angiotensin II, TXA_2, serotonin, endothelin) occurs. There is also a decrease in plasma renin concentration and a suppression of the renin–angiotensin–aldosterone system.

Respiratory changes

- Pharyngeal and laryngeal edema may make airway management difficult, necessitating the use of smaller endotracheal tubes.
- Pulmonary edema occurs in 3% of cases, with some cases occurring postpartum.

Hepatic changes

- Serum transaminase levels frequently increase in patients with mild preeclampsia.
- Epigastric or subcostal pain is an ominous symptom that is typically caused by distension of the liver capsule by edema or subcapsular or parenchymal bleeding. Hepatic swelling produces epigastric pain.
- Liver rupture is associated with more than 80% mortality.

Neurologic changes

- The classic manifestations of preeclampsia include severe headache, visual disturbances, central nervous system hyperexcitability, and hyperreflexia.

- The occurrence of seizures indicates eclampsia until proved otherwise. Etiologies of seizures include hypertonic encephalopathy, vasospasm, microinfarctions and punctate hemorrhages, thrombosis, and cerebral edema.
- Postpartum eclampsia may occur up to 10 days after delivery.

Uteroplacental perfusion

- Uteroplacental perfusion is decreased in preeclampsia with the potential for intrauterine growth retardation.

A.9. Which component of BP best predicts the occurrence of preeclampsia?

Pregnancy induces several cardiovascular responses and adaptation that include increases in vascular and extravascular volume, higher cardiac output, and marked reduction in peripheral resistance that effectively causes a relatively lower BP by the second trimester of pregnancy. Multiple attempts have been made to correlate first and second trimester systolic, diastolic, and mean arterial pressures (MAP) with development of preeclampsia. Unfortunately, there is significant variability in the aforementioned components of BP throughout pregnancy, complicated further by factors such as ethnicity, age, nulliparous versus multiparous state, and gestational differences at the time of measurements. In addition, the anxiety component of an office visit (white-coat effect) frequently contributes to variability in measures of BP, limiting their predicatibility of preeclampsia. Ravi et al. reported that although systolic, diastolic, and MAP were elevated in women who developed hypertensive disorder of pregnancy as compared to normotensive women, these parameters did not correlate with ensuing preeclampsia. Conversely, elevations in pulse pressure at 7 to 15 weeks of gestation was a significant predictor of preeclampsia but not of gestational hypertension. In fact, for every 1 mm Hg increase in pulse pressure, the associated risk of preeclampsia increased by 6%.

Ravi T, Ecker JL, Kettyle E, et al. Pulse pressure and risk of preeclampsia: a prospective study. *Obstet Gynecol*. 2001;97:515–520.

A.10. What is the significance of increased pulse wave velocity (PWV) during pregnancy? How does this relate to birth weight?

Similar to increase in pulse pressure, PWV can be a marker of arterial stiffness. In normal pregnancy, arterial stiffness decreases during the first trimester and remains low until the end of pregnancy due to either reduced smooth muscle tone or vessel

wall remodeling. However, there is a wide range in arterial stiffness even in normal pregnancy, suggesting a varying degree of cardiovascular adaptation. Maladaptation may lead to retardation in fetal growth as measured by birth weight and by postnatal catch-up growth. Elvan-Taspinar et al. found a significant relation between PWV during the last trimester of pregnancy and fetal birth weight and postnatal catch-up growth independent of MAP. For example, an increase in PWV of 1 m per second was associated with a decrease in birth weight by 17.6%. Similarly, a strong link was found between pulse pressure and birth weight, with an increase of 10 mm Hg in pulse pressure being associated with an 11.8% decrease in weight. Both PWV and pulse pressure appear to offer superior circulatory as well as prognostic information relating to fetal and neonatal outcome.

A.11. What are some of the complications associated with preeclampsia?

Maternal complications include disseminated intravascular coagulation, congestive heart failure with pulmonary edema, placental abruption, postpartum hemorrhage, acute renal failure, rupture of the liver, cerebrovascular accident, and septic shock. The leading cause of maternal death is intracranial hemorrhage.

Fetal complications include prematurity with respiratory distress, intrauterine growth retardation, oligohydramnios, intracranial hemorrhage, small for gestational age, and aspiration of meconium. The leading cause of intrauterine morbidity and mortality is uteroplacental insufficiency caused by placental infarcts, followed by placental abruption, and chorioamnionitis.

Datta S, ed. *Anesthetic and Obstetric Management of High-risk Pregnancy*. 3rd ed. New York: Springer; 2004:270–281.

B. Preoperative Evaluation and Preparation

B.1. What initial laboratory studies are recommended for patients with preeclampsia?

- Complete blood cell count
- Platelet count and aggregation when available
- Coagulation assay including activated partial thromboplastin time, prothrombin time, fibrinogen, D-dimer
- Serum electrolytes
- Blood urea nitrogen, creatinine, and uric acid concentration
- Liver function tests
- Urinalysis, microscopy, 24-hour specimen for protein and creatinine clearance
- Type and screen (cross-match if antibodies present)

Chestnut DH, ed. *Obstetric Anesthesia: Principles and Practice*. 4th ed. Philadelphia: Elsevier Mosby; 2009:975–1007.

Hines RL, Marschall KE, eds. *Stoelting's Anesthesia and Co-existing Disease.* 5th ed. Philadelphia: Churchill Livingstone; 2008:561–566.

B.2. What are the important routine monitors for patients with preeclampsia? When is a central venous pressure monitor indicated?

Important routine monitors are as follows:

- Noninvasive BP
- Maternal respiratory function assessment with oxygen saturation
- Hourly deep tendon reflexes
- Muscle strength
- Serial magnesium sulfate levels
- Foley catheter for assessing urine output
- Uterine contraction monitor
- Continuous fetal heart rate monitoring
- Consider invasive BP monitoring with an arterial line when severe refractory hypertension is present; when rapid-acting vasodilators, such as sodium nitroprusside (SNP) or nicardipine, are used; or when noninvasive BP measurement proves difficult (e.g., obesity).
- A CVP monitor or a PA catheter may be indicated for the following conditions:
  - Persistent oliguria
  - Difficulty in fluid management therapy in antepartum and/or postpartum period
  - Presence of pulmonary edema

A survey on the use of invasive hemodynamic monitoring among anesthesiologists who care for patients with preeclampsia indicates that central monitoring is used in 7.5% of patients. When invasive hemodynamic monitoring is used, 56% of anesthesiologists use an arterial line, 26% use an arterial line and central monitoring, and 20% use central monitoring only. Also, 92% of respondents use a CVP monitor, whereas only 8% use a PA catheter. The etiology of pulmonary edema, however, may be due to an increase in capillary permeability as well as from diastolic dysfunction, complicating assessment of cardiac function and volume status. Only in severe forms of preeclampsia is left ventricular systolic function markedly reduced. Further, there may be technical difficulties with placing the PA catheter that are both patient related (awake, anxious, short neck with poorly visible landmarks, coagulopathy) and physician related (inexperience with central venous catheterization), which may alter the balance between benefit and risk of invasive monitoring. Whenever possible, a bedside transthoracic echocardiogram may be obtained; however, there may be limited windows for imaging due to the gravid uterus—causing distention of the abdomen.

Ross VH, Moore CH, Fragneto RY, et al. Invasive hemodynamic monitoring in the management of PIH: a survey of practicing anesthesiologists. *Anesthesiology.* 2000;92:A89.

B.3. What conditions mandate immediate delivery, regardless of the gestational age?

- Severe hypertension that persists after 24 to 48 hours
- Progressive thrombocytopenia
- Liver dysfunction

- Progressive renal dysfunction (including severe oliguria)
- Premonitory signs of eclampsia
- Evidence of fetal jeopardy
- Persistent headache or other neurologic sequelae of preeclampsia

Datta S, ed. *Anesthetic and Obstetric Management of High-risk Pregnancy.* 3rd ed. New York: Springer; 2004:407–408.

B.4. Discuss the obstetric management of preeclampsia.

The goal of therapy is to stabilize the mother and to safely deliver the fetus and placenta.

- Improve intravascular volume.
- Administer seizure prophylaxis with magnesium sulfate.
- Administer antihypertensives for BP control.

Labetalol is a commonly used antihypertensive agent that decreases maternal SVR without increasing maternal heart rate or decreasing cardiac index, uterine blood flow, or fetal heart rate when it is given in a total dose of less than 1 mg per kg. When given in an initial intravenous bolus dose of 10 to 20 mg, it has a faster onset of action than hydralazine and, if necessary, the dose may be doubled every 10 minutes. It is useful in the management of refractory hypertension. If a second agent must be administered (e.g., hydralazine, SNP, or nicardipine), labetalol helps to prevent reflex tachycardia. It is important to note that the mechanism of hypertension is mediated greatly by circulating catecholamines, making labetalol a preferred antihypertensive agent that will antagonize the vasoconstrictive effects of norepinephrine, in particular. Other agents may reduce the BP as reflected by a peripheral BP monitor; however, unopposed vasoconstriction at the central and at the microcirculatory levels may cause end-organ injury.

Hydralazine is another antihypertensive agent that can be used because of its direct vasodilating effect. The full extent of its effect is evident in 20 minutes; therefore, if sufficient time is not allowed between injections, severe hypotension will be seen. It is used in 5- to 10-mg increments intravenously every 20 to 30 minutes until the diastolic BP is decreased, with a cumulative dose of 20 mg. Hydralazine directly decreases peripheral vascular resistance. Reflex sympathetic activity can result in tachycardia and increased stroke volume and cardiac output. Tachycardia can be treated with labetalol, 10 to 20 mg intravenously. The patient may complain of headache and flushing of the face during therapy.

Nitroglycerin (NTG) causes vascular smooth muscle relaxation by means of its intracellular degradation to NO. The primary effect of NTG is venodilation, but it is less effective in prehydrated patients. NTG readily crosses the placenta. The drug is most useful for short-term treatment (e.g., to control the pressor response to tracheal intubation). Small doses, 50 to 100 μg, may be given intravenously, or NTG may be given sublingually in a 400-μg metered spray.

SNP relaxes the arterial vessels, thereby reducing afterload. However, SNP also reduces venous return. The drug is most useful for short-term treatment, similar to NTG. Cyanide toxicity is proposed to be more likely with prolonged infusion rates that exceed 4 μg/kg/minute over several hours to days; however, Naulty et al. demonstrated that intravenous infusion of nitroprusside solution in pregnant ewes, maintained at a rate sufficient to decrease mean maternal arterial pressure by 20% for 1 hour, resulted in equilibration of maternal and fetal levels of nitroprusside at the 20-minute sample. Five of the eight animals exhibited tachyphylaxis

to nitroprusside, and their fetuses died in utero with lethal levels of cyanide. No significant changes were observed in uterine blood flow. There have been attempts to counteract the cyanide toxicity of nitroprusside by coadministration of sodium thiosulfate. Curry et al. administered sodium thiosulfate and nitroprusside to pregnant ewes and only nitroprusside to a control group. Although control ewes and fetuses suffered progressive increases in red cell cyanide concentrations into the toxic range, experimental ewes and fetuses never developed toxic red cell cyanide levels. These results suggest that coadministration of sodium thiosulfate with SNP to pregnant women at doses currently in use for nonpregnant patients will prevent fetal, as well as maternal, cyanide toxicity. Unfortunately, it is not known whether these findings are transferable to humans, raising major concern over ongoing clinical use of nitroprusside in obstetrics when safer drugs such as nicardipine and labetalol are available.

Nifedipine is a calcium entry blocker that affects predominantly arterial and arteriolar smooth muscle. Common maternal side effects include facial flushing, headache, and tachycardia. Nifedipine rapidly lowers BP after oral or sublingual administration. After an initial dose of 10 mg sublingually, it may be repeated in 30 minutes and subsequently given in a maintenance dose of 10 to 20 mg every 3 to 6 hours. Caution must be exercised in the patient receiving both magnesium sulfate and calcium entry blockers because of the risk of myocardial depression and resultant pulmonary edema.

B.5. In the United States, what drug therapy is the treatment of choice for seizure prophylaxis?

Magnesium sulfate is the initial therapy for seizure prophylaxis. The Eclampsia Trial Collaborative Group compared magnesium sulfate, phenytoin, and diazepam administration for the prevention of recurrent seizures in women with preeclampsia. They found that magnesium sulfate was more effective in preventing recurring seizures than either phenytoin or diazepam.

An initial bolus of 4 to 6 g of magnesium sulfate is administered over 20 minutes and followed with an intravenous infusion of 1 to 2 g per hour. Urine output, respiratory rate, and patellar reflexes are monitored during magnesium therapy. The serum magnesium sulfate concentration should be measured at least 4 hours after initiation of therapy. The therapeutic range for serum magnesium sulfate concentrations is between 4 and 6 mEq per L. Loss of deep tendon reflexes occurs at 10 mEq per L with evidence of prolonged P-Q intervals and widening QRS complexes. Respiratory arrest occurs at 15 mEq per L, and asystole occurs at 20 mEq per L.

Eclampsia Trial Collaborative Group. Which anticonvulsant for women with eclampsia? Evidence from the collaborative eclampsia trial. *Lancet*. 1995;345:1455–1463.

B.6. Discuss the treatment of magnesium sulfate toxicity.

Magnesium sulfate is excreted by the kidneys. Therefore, urine output must be followed closely and serial serum concentrations of magnesium sulfate must be checked, especially in women with renal dysfunction. If magnesium sulfate toxicity is suspected, the magnesium sulfate infusion should be immediately discontinued. Intravenous calcium gluconate, 1 g, or calcium chloride, 300 mg, should be administered if needed to antagonize the effects of magnesium sulfate. If respiratory distress occurs, the patient may require endotracheal intubation and mechanical ventilation.

Chestnut DH, ed. *Obstetric Anesthesia: Principles and Practice*. 4th ed. Philadelphia: Elsevier Mosby; 2009:975–1007.

B.7. Discuss the mechanism of action of magnesium sulfate.

Magnesium has the following effects:

- It is a central nervous system depressant and anticonvulsant.
- It inhibits the release of acetylcholine at the neuromuscular junction, decreases the sensitivity of the motor end plate to acetylcholine, and decreases muscle membrane excitability, thereby potentiating the effects of nondepolarizing and depolarizing muscle relaxants.
- It decreases uterine hyperactivity by its mild relaxant effect on vascular and uterine smooth muscle; it may improve uterine blood flow.
- It is a mild vasodilator in vascular beds (including small-diameter cerebral vessels) by a direct or indirect (calcium-competing) effect; and it has a mild antihypertensive effect.

Chestnut DH, ed. *Obstetric Anesthesia: Principles and Practice*. 4th ed. Philadelphia: Elsevier Mosby; 2009:975–1007.

B.8. What are the fetal effects of magnesium sulfate therapy?

Magnesium sulfate crosses the placenta. There can be evidence of decreased beat-to-beat variability in the fetal heart rate. Neonatal depression (e.g., respiratory depression and hyporeflexia) also can occur.

Chestnut DH, ed. *Obstetric Anesthesia: Principles and Practice*. 4th ed. Philadelphia: Elsevier Mosby; 2009:975–1007.

B.9. Discuss the treatment of eclampsia.

- Stop the convulsions (e.g., thiopental, 50 to 100 mg intravenously).
- Establish an airway.
- Turn patient to the left side; apply jaw thrust.
- Attempt bag and mask ventilation.
- Insert oropharyngeal airway if necessary.
- Maintain ventilation and oxygenation.
- Continue bag and mask ventilation.
- Apply pulse oximeter and monitor.
- Maintain circulation.

- Secure intravenous access.
- Check BP at frequent intervals.
- Monitor electrocardiographic (ECG) recordings.
- Administer magnesium sulfate.
- Treat hypertension.
- Deliver the baby expeditiously.

Chestnut DH, ed. *Obstetric Anesthesia: Principles and Practice*. 4th ed. Philadelphia: Elsevier Mosby; 2009:999.

C. Intraoperative Management

C.1. What is your choice of analgesia/anesthesia for patients with preeclampsia?

Most anesthesiologists and obstetricians consider epidural analgesia the preferred form of pain relief for labor and delivery in preeclamptic women. Epidural analgesia provides the following advantages:

- Epidural analgesia provides pain relief that is superior to all other analgesic methods.
- Epidural analgesia attenuates the exaggerated hypertensive response to pain of preeclamptic women.
- Epidural analgesia reduces circulating levels of catecholamines and stress-related hormones, which facilitates BP control.
- Epidural analgesia may improve intervillous blood flow in preeclamptic women.
- Epidural analgesia results in stable cardiac output.
- Preeclamptic women are at increased risk of cesarean delivery compared with normal parturients, and early administration of epidural analgesia for labor facilitates the subsequent administration of epidural anesthesia for emergent cesarean delivery.

Benedetto C, Zonca M, Marozio L, et al. Blood pressure patterns in normal pregnancy and in pregnancy-induced hypertension, preeclampsia, and chronic hypertension. *Obstet Gynecol*. 1996;88:503–510.

Chestnut DH, ed. *Obstetric Anesthesia: Principles and Practice*. 4th ed. Philadelphia: Elsevier Mosby; 2009:975–1007.

Cunningham FG, Lindheimer MD. Hypertension in pregnancy. *N Engl J Med*. 1992;326:927–932.

C.2. What is the advantage of prehydration?

Prehydration helps compensate for reductions in preload and afterload during the administration of epidural analgesia/anesthesia. Two studies have investigated the effects of intravenous volume loading with crystalloid on atrial natriuretic peptide (ANP) secretion in preeclamptic women. ANP is a vasodilator secreted from the cardiac atria in response to an acute volume load, and this response is more pronounced in preeclamptic women. ANP has properties that counteract vasospasm and improve renal elimination of excess extracellular fluid. These studies support the use of volume expansion before administration of regional anesthesia in preeclamptic women.

However, in current practice, lower concentrations of local anesthetics combined with an opioid are used for labor analgesia, and fluid preloading is of less clinical relevance. One still needs to be vigilant to the risk of pulmonary edema in the severely preeclamptic patient.

Chestnut DH, ed. *Obstetric Anesthesia: Principles and Practice*. 4th ed. Philadelphia: Elsevier Mosby; 2009:992–993.

C.3. How should patients be hydrated before epidural analgesia/anesthesia for labor and delivery?

Most preeclamptic patients may receive prehydration with crystalloid in a 10 mL per kg bolus. Attention must be given to evidence of recent excessive weight gain or a fluid balance chart suggesting overhydration. Also, one must monitor for the development of pulmonary edema. Additional crystalloid (e.g., 250 to 500 mL) can be infused if hypotension ensues during epidural analgesia/anesthesia.

Datta S, ed. *Anesthetic and Obstetric Management of High-risk Pregnancy*. 3rd ed. New York: Springer; 2004:285–286.

C.4. Discuss bleeding time and platelet count evaluation during preoperative assessment of a patient with preeclampsia requesting epidural analgesia/anesthesia for labor and delivery.

The bleeding time does not specifically measure platelet function, and it can be abnormal in a number of coagulation disorders, such as factor deficiencies. No evidence suggests that the skin bleeding time predicts the potential for bleeding from a traumatized epidural vein in a woman with severe preeclampsia. Therefore, the bleeding time should not be used to measure platelet function. A specific platelet count that predicts the risk of complications from regional anesthesia has not been determined. The *trend* in platelet count is important to note, as preeclampsia is a dynamic disorder, and a rapid decrease in platelet count in a short interval may warrant concern.

Many anesthesiologists will place an epidural anesthetic at a platelet count of 80,000 per μL and some at lower platelet counts. The patient must be individualized and a thorough bleeding history, along with the trend in platelet count, should be considered.

Beilin Y, Zahn J, Comerford M. Safe epidural analgesia in thirty parturients with platelet counts between 69,000 and 98,000 mm(−3). *Anesth Analg*. 1997;85:385–388.

Chestnut DH, ed. *Obstetric Anesthesia: Principles and Practice*. 4th ed. Philadelphia: Elsevier Mosby; 2009:992.

C.5. What level of analgesia/anesthesia is required for labor and delivery?

- First stage of labor: T10-L1
- Second stage of labor: S2–4

Chestnut DH, ed. *Obstetric Anesthesia: Principles and Practice*. 4th ed. Philadelphia: Elsevier Mosby; 2009:387–392.

C.6. Discuss the commonly used local anesthetics for labor analgesia.

Bupivacaine, ropivacaine, and levobupivacaine (amide local anesthetics) are commonly used because they provide potent analgesia. They provide analgesia with less motor block than an equipotent concentration of lidocaine. Moreover, dilute solutions cause less hypotension than more concentrated solutions.

Bupivacaine is four times more potent than lidocaine. It is 90% to 95% bound to maternal plasma protein. It is known to be more cardiotoxic than lidocaine. The mechanism relates to its action on cardiac sodium channels. Bupivacaine and lidocaine both block sodium channels to the nerves and to the heart. They are similar because they both cause a rapid block of cardiac sodium channels on depolarization. They differ in their recovery from block. The lidocaine block is complete within less than 1 second, whereas bupivacaine takes five times longer. Bupivacaine is a "fast-in, slow-out" agent. Its main advantage is that it has a longer duration and a weak motor block when given in analgesic concentrations.

Ropivacaine is a homolog of mepivacaine and bupivacaine, but it is formulated as a single levorotatory isomer rather than as a racemic mixture. It appears to be less cardiotoxic than bupivacaine.

Levobupivacaine is also a single levorotatory isomer formulation of a local anesthetic. Levobupivacaine appears to be less cardiotoxic than bupivacaine.

2-Chloroprocaine is an ester type of local anesthetic. It is hydrolyzed by plasma cholinesterase, and it has a rapid metabolism, allowing for a very quick onset of action.

Chestnut DH, ed. *Obstetric Anesthesia: Principles and Practice*. 4th ed. Philadelphia: Elsevier Mosby; 2009:247–252.

Mazoit JX, Boico O, Samii K. Myocardial uptake of bupivacaine, II: pharmacokinetics and pharmacodynamics of bupivacaine enantiomers in the isolated perfused rabbit heart. *Anesth Analg*. 1993;77:477–482.

Valenzuela C, Snyders DJ, Bennett PB, et al. Stereoselective block of cardiac sodium channels by bupivacaine in guinea pig ventricular myocytes. *Circulation*. 1995; 92:3014–3024.

C.7. Is the addition of epinephrine to local anesthetics advisable in preeclamptic patients?

Clinical evidence supports the safety of epidural administration of an epinephrine-containing local anesthetic in preeclamptic women. However, care must be taken when using epinephrine-containing local anesthetic solutions in severe preeclamptic women as inadvertent intravascular injection may result in acute severe hypertension.

Chestnut DH, ed. *Obstetric Anesthesia: Principles and Practice*. 4th ed. Philadelphia: Elsevier Mosby; 2009:993.

Dror A, Abboud TK, Moore J, et al. Maternal hemodynamic responses to epinephrine-containing local anesthetics in mild preeclampsia. *Reg Anesth*. 1988;13:107–111.

Heller PJ, Goodman C. Use of local anesthetics with epinephrine for epidural anesthesia in preeclampsia. *Anesthesiology*. 1986;65:224–226.

C.8. What is the treatment for the abnormal fetal heart rate pattern seen with maternal hypotension after epidural analgesia/anesthesia is instituted?

- Administration of oxygen with face mask
- Left uterine displacement
- Increased hydration

- Elevation of lower extremities to facilitate venous return
- Administration of small increments of ephedrine, 2.5 to 5 mg or phenylephrine, 50 to 100 μg intravenously, if the BP falls more than 20% of baseline.

Vercateren M. Obstetric spinal analgesia and anesthesia. *Curr Opin Anesthesiol.* 2003;16:503–507.

C.9. What would you do after an accidental spinal tap? How do you treat postdural puncture headache?

Accidental dural puncture can be managed with one of two options. First, the epidural needle may be repositioned in another interspace. Local anesthetic must be administered slowly because now there is a direct communication with the intrathecal space through the dural hole, and thereby, a more profound analgesic/anesthetic block may appear. The incidence of a postdural puncture headache after an accidental wet tap with an epidural needle is more than 50%. After delivery of the fetus, the catheter should be removed. Intravenous and oral caffeinated beverages should be encouraged. Intravenous caffeine and oral analgesics may be used as well. If symptoms worsen (e.g., tinnitus, blurry vision, neck pain, difficulty sitting or standing), one should consider an epidural blood patch. Immediate relief occurs in almost 90% of patients on first attempt. Transient side effects include backache and neck pain. Second, an epidural catheter (20 gauge) can be inserted intrathecally for use as a continuous spinal catheter. After delivery, one can remove the catheter and follow the guidelines as listed earlier, or one can consider maintaining the intrathecal catheter in place for 24 hours to allow for an inflammatory reaction to develop around the intrathecal catheter. This inflammatory reaction may decrease the leakage of cerebrospinal fluid and thereby the incidence of postdural puncture headache.

Gaiser R. Postdural puncture headache. *Curr Opin Anaesthesiol.* 2006;19:249–253.

C.10. How would you manage total spinal anesthesia?

- High spinal anesthesia may occur several minutes after an epidural injection of local anesthetic. It is vitally important to communicate with the patient. Agitation, dyspnea, and difficulty speaking may herald the onset of total spinal anesthesia.
- Avoid aortocaval compression.
- Administer 100% oxygen to the mother.
- Provide positive pressure ventilation, preferably through an endotracheal tube.
- Monitor maternal BP, ECG recordings, and fetal heart rate.
- Support maternal circulation with intravenous fluids and ephedrine as needed. Do not hesitate to give epinephrine if needed.

Chestnut DH, ed. *Obstetric Anesthesia: Principles and Practice.* 4th ed. Philadelphia: Elsevier Mosby; 2009:462–463.

C.11. Should ergonovine be given to preeclamptic patients?

Preeclampsia is a relative contraindication to the use of ergot alkaloids because of the risk of inducing a hypertension crisis. In preeclamptic patients, uterine atony unresponsive to oxytocin may be treated with 15-methylprostaglandin $F_{2\alpha}$.

Chestnut DH, ed. *Obstetric Anesthesia: Principles and Practice*. 4th ed. Philadelphia: Elsevier Mosby; 2009:821.

Secher NJ, Arnsbro P, Wallin L. Haemodynamic effects of oxytocin and methyl ergometrine on the systemic and pulmonary circulations of pregnant anaesthetized women. *Acta Obstet Gynecol Scand*. 1978;57:97–103.

C.12. When and how would you give spinal anesthesia?

Spinal anesthesia may be used for cesarean delivery, even in a patient with severe preeclampsia. Hyperbaric bupivacaine 0.75% in a dose of 11.25 mg to 12 mg with or without fentanyl, 15 to 20 μg, or morphine, 100 to 200 μg, may be given.

Advantages of spinal anesthesia in severe preeclampsia include:

- Avoidance of general anesthesia and risks of difficulty with an edematous airway
- Elimination of risk of severe hypertensive response to laryngoscopy and endotracheal intubation, which can result in intracranial hemorrhage
- More reliable anesthesia than with an epidural anesthetic technique
- Smaller needle size than an epidural and therefore possibly less risk of trauma to epidural veins

One study by Aya et al. noted that the risk of hypotension was almost six times less in severely preeclamptic women than in healthy pregnant women receiving spinal anesthesia for elective cesarean section.

Aya AG, Mangin R, Vialles N, et al. Patients with severe preeclampsia experience less hypotension during spinal anesthesia for elective cesarean delivery than healthy parturients: a prospective cohort comparison. *Anesth Analg*. 2003;97:867–872.

Chestnut DH, ed. *Obstetric Anesthesia: Principles and Practice*. 4th ed. Philadelphia: Elsevier Mosby; 2009:993–995.

C.13. Discuss a general anesthesia technique for the patient with preeclampsia presenting for cesarean delivery.

- Aspiration prophylaxis. Acceptable methods include 30 mL of an oral nonparticulate antacid, and/or an H_2-blocker intravenously and possibly metoclopramide, 10 mg intravenously.
- Preoxygenation and denitrogenation with 100% oxygen through face mask
- Induction of anesthesia with cricoid pressure and sodium pentothal, 4 to 6 mg per kg
- Succinylcholine, 1.5 mg per kg, for effective intubation conditions
- Use a smaller endotracheal tube (6.0 or 6.5 mm internal diameter) because of airway edema.
- May consider use of nondepolarizing muscle relaxants for maintenance of neuromuscular block once the patient has demonstrated recovery from succinylcholine. Magnesium sulfate potentiates the effects of both depolarizing and nondepolarizing muscle relaxants.
- Use two-thirds of the minimum alveolar concentration of inhalation agent of the nonpregnant adult to ensure an adequate depth of anesthesia.
- Continue magnesium sulfate administration during intraoperative and postoperative periods.
- Consider arterial line placement before induction in patients with severe preeclampsia for continuous BP measurement. The transient but severe hypertension that accompanies tracheal intubation in preeclamptic women can significantly increase maternal intracranial pressure, with the attendant risks of cerebrovascular accident.
- Antihypertensive drugs can be given as required.

Chestnut DH, ed. *Obstetric Anesthesia: Principles and Practice*. 4th ed. Philadelphia: Elsevier Mosby; 2009:995–996.

C.14. What agents can you use to prevent hypertension during the induction of general anesthesia for cesarean delivery?

Before induction, labetalol, 5- to 10-mg increments, nitroglycerin (NTG), 50 to 100 μg increments; or sodium nitroprusside (SNP), 50-μg increments, can be used to attenuate the pressor response to laryngoscopy and intubation. Also, the short-acting opioid remifentanil can be used.

Chestnut DH, ed. *Obstetric Anesthesia: Principles and Practice*. 4th ed. Philadelphia: Elsevier Mosby; 2009:995–996.

C.15. What is HELLP syndrome?

HELLP syndrome is a severe form of preeclampsia characterized by hemolysis (*H*), elevated liver enzymes (*EL*), and low platelets (*LP*). It can occur antepartum or postpartum. Delivery represents the only definitive treatment of HELLP syndrome. HELLP syndrome is associated with maternal and neonatal morbidity and mortality. Hemolysis is defined by an abnormal peripheral blood smear and an increased bilirubin level (1.2 mg per dL or greater). Elevated liver enzymes are defined as an increased serum glutamic-oxaloacetic transaminase (aspartate aminotransferase) of at least 70 U per L and a lactate dehydrogenase level of more than 600 U per L. A low platelet count is defined as a count of less than 100,000 per mm^3. Patients with HELLP syndrome have a high incidence of serious maternal complications including disseminated intravascular coagulation, placental abruption, need for blood transfusion, pleural effusion, acute renal failure, and wound infection.

D. Postoperative Management

D.1. Discuss the postpartum management of preeclamptic patients.

- Provide adequate analgesia.
- Maintain strict intake/output for at least 24 hours postpartum or until diuresis develops.
- Continue magnesium sulfate for at least 24 hours postpartum or until evidence of diuresis.
- Maintain hemodynamic control with antihypertensives if necessary.

Chestnut DH, ed. *Obstetric Anesthesia: Principles and Practice*. 4th ed. Philadelphia: Elsevier Mosby; 2009:997.

CHAPTER 29

Breech Presentation, Fetal Distress, and Mitral Stenosis

Jill Fong

A 25-YEAR-OLD UNREGISTERED PRIMIGRAVIDA at 38 weeks of gestation presented to the labor room contracting. The patient had a history of rheumatic fever with no subsequent medical follow-up. On physical examination, she had a diastolic murmur and an opening snap. She reported having shortness of breath when climbing two flights of stairs. She was attached to an external fetal heart rate (FHR) monitor and tocodynamometer; recurrent variable decelerations without any beat-to-beat variability were noted. Simultaneously, the patient was found to have ruptured membranes, meconium-stained amniotic fluid, a fetal foot in her vagina, and a prolapsed umbilical cord. She was rushed to the operating room for an emergency cesarean section. Her blood pressure was 100/60 mm Hg; pulse rate, 100 beats per minute; respiratory rate, 18 breaths per minute.

A. Medical Disease and Differential Diagnosis

1. How are fetal lie, presentation, and position defined and determined?
2. What is the approximate frequency of the various lies and presentations at or near term?
3. What are the different types of breech presentation, and what is their incidence?
4. What is the cause of breech presentation?
5. What are the problems associated with breech presentation?
6. What is the usual obstetrical management for patients with breech presentation?
7. What is the incidence of heart disease in pregnancy?
8. What is the mortality rate associated with maternal cardiac disease?
9. What is the functional classification of heart disease by the New York Heart Association (NYHA)?
10. What are the cardiovascular changes of pregnancy?
11. What changes may normally occur in heart sounds during pregnancy?

12. What are the normal electrocardiographic and echocardiographic changes seen during pregnancy?
13. What causes rheumatic heart disease?
14. What are the physiologic consequences of mitral stenosis?
15. What are the ausculatory findings associated with mitral stenosis?
16. What may be seen on the electrocardiogram (ECG) in patients with mitral stenosis?
17. What are the echocardiographic findings associated with mitral stenosis?
18. What is the effect of the physiologic changes of pregnancy on patients with mitral stenosis?
19. If mitral stenosis is first recognized during pregnancy and symptoms develop, how would you treat the patient?
20. What are the determinants of fetal oxygenation?
21. What are the determinants of uterine blood flow?

B. Preoperative Evaluation and Preparation

1. How is fetal well-being assessed during labor?
2. How are FHR and maternal contractions monitored?
3. What is the normal FHR with beat-to-beat variability?
4. What are periodic decelerations?
5. How accurate is FHR monitoring in predicting fetal well-being?
6. In the fetus with a nonreassuring FHR pattern, what other modalities can be used to evaluate fetal well-being?
7. What is the significance of meconium-stained amniotic fluid?
8. What is meconium aspiration syndrome?
9. What are the usual noninvasive tests used to evaluate the pregnant cardiac patient?
10. What preoperative medications would you give this patient?

C. Intraoperative Management

1. What monitors would you use in this NYHA class II patient during her cesarean section?
2. When would you use invasive monitoring in a pregnant patient with cardiac disease?
3. What are the hemodynamic goals of intraoperative management of the pregnant patient with mitral stenosis?
4. What anesthetic technique would you use for emergency cesarean section?
5. What technique could you use for general anesthesia in this patient?
6. If you had unexpectedly been unable to intubate this patient, how would you have managed the airway?
7. Would this patient benefit from the use of β-blockers?
8. What is the effect of the inhalation agents on uterine contractility?
9. What is the Apgar scoring system?
10. What is the significance of Apgar scores?
11. At birth, what should be done to minimize an infant's risk of meconium aspiration syndrome?
12. The Apgar score of the newborn was 3 at 1 minute. How would you treat the newborn?
13. Blood gases are sent immediately after delivery. What are the normal values for umbilical vein and artery blood gases?

D. Postoperative Management

1. Immediately after the baby was delivered, the patient's oxygen saturation decreased. What is the differential diagnosis?

A. Medical Disease and Differential Diagnosis

A.1. How are fetal lie, presentation, and position defined and determined?

- Fetal lie describes the position of the long axis of the fetus in relative to the long axis of the mother. Longitudinal, transverse, and oblique lies exist. Longitudinal lies are either cephalic or pelvic (breech) depending on which fetal structure enters the maternal pelvis. Transverse lies are either back up or back down with the long axis of the fetus perpendicular (90 degrees) to the mother's long axis. An oblique lie results when the long axis of the fetus is at an acute angle to that of the mother. It is usually only transitory and converts to a transverse or longitudinal lie when labor begins.
- Presentation describes the part of the fetus that is lowermost in the pelvis: cephalic, breech, or shoulder. Cephalic presentations are further subdivided into vertex, brow, and face presentations.
- Position of the presenting part is described as a relationship between a certain pole of the fetal presenting part and the maternal surrounding pelvis.
- Fetal lie, presentation, and position can often be determined by manual pelvic and abdominal examination. Ultrasonography is also useful, particularly, when palpation is inconclusive, as can occur with multiple gestations, placenta previa, and hydramnios.

Cunningham FG, Leveno KJ, Bloom SL, et al., eds. *Williams Obstetrics*. 23rd ed. New York: McGraw-Hill; 2010:527.

A.2. What is the approximate frequency of the various lies and presentations at or near term?

Cephalic presentation, 97%; breech presentation, 3% to 4%; transverse lie, 0.3%; and face presentation, 0.5%.

Cunningham FG, Leveno KJ, Bloom SL, et al., eds. *Williams Obstetrics*. 23rd ed. New York: McGraw-Hill; 2010:527.

A.3. What are the different types of breech presentation, and what is their incidence?

- *Frank breech*: Both fetal lower extremities are flexed at the hips and extended at the knees. The incidence is approximately 60% (48% to 73%) of breech presentations.
- *Complete breech*: The knees are flexed, as are the hips. The incidence is approximately 10% (5% to 12%).
- *Incomplete or footling breech*: One or both hips are extended and a foot or knee hangs below the breech. The incidence is approximately 30% (12% to 38%).

Gabbe SG, Niebyl JR, Simpson JL, eds. *Obstetrics–Normal and Problem Pregnancies*. 5th ed. Philadelphia: Churchill Livingstone/Elsevier; 2007:436.

A.4. What is the cause of breech presentation?

The etiology of breech is unknown, but certain factors are associated with this presentation including prematurity, hydramnios, uterine relaxation associated with high parity, multiple fetuses, oligohydramnios, hydrocephaly, anencephaly, previous breech delivery, uterine anomalies, pelvic tumors, and cornual–fundal placenta implantation. A twofold increase in the incidence of breech presentation after a prior cesarean delivery was reported by Vendittelli et al.

Cunningham FG, Leveno KJ, Bloom SL, et al., eds. *Williams Obstetrics*. 23rd ed. New York: McGraw-Hill; 2010:527.

Venditelli F, Riviere O, Creen-Hebrert C, et al. Is a breech presentation at term more frequent in women with a history of cesarean delivery? *Am J Obstet Gynecol*. 2008; 198(5):521.e1.

A.5. What are the problems associated with breech presentation?

There is an increased incidence of prolapsed cord, perinatal morbidity and mortality resulting from difficult delivery, preterm delivery, fetal anomalies, placenta previa, and uterine anomalies.

Cunningham FG, Leveno KJ, Bloom SL, et al., eds. *Williams Obstetrics*. 23rd ed. New York: McGraw-Hill; 2010:529.

A.6. What is the usual obstetrical management for patients with breech presentation?

An external cephalic version can be attempted to convert the breech to a vertex presentation in patients who are candidates for vaginal deliveries. External cephalic version is often used in patients with breech presentation fetuses; however, the best time to attempt the version is unclear. Ylikorkula and Hartikainen-Sorri found that before 34 weeks' gestation, many breech infants will spontaneously convert to cephalic, and few will do so after that time. In general, external version should be considered in patients when a breech presentation is recognized prior to labor at or after 36 weeks' gestation. The reported success rates vary from 35% to 86%. A version success rate of 65% was reported by Zhang, and almost of all of the fetuses stayed in cephalic presentation. Successful version is more common in parous than nulliparous women, and more successful between 37 and 39 weeks than after 40 weeks. Tocolysis has been shown to be variably effective in improving version success rates. Epidural anesthesia during version has been shown by Schorr et al. and Mancuso et al. to improve the success rate of external cephalic version. While others have found no improvement in version success associated with neuraxial analgesia/anesthesia, Collaris and Oei found that maternal and fetal complications increased when conduction anesthesia had been used, and they concluded that the decreased maternal pain associated with these versions encouraged an overzealous application of force. If the version is successful, labor and vaginal delivery may proceed.

The 2006 recommendation from American College of Obstetricians and Gynecologists (ACOG) for breech delivery of the singleton fetus states "the decision regarding mode of delivery should depend on the experience of the health care provider," and "planned vaginal delivery of a term singleton breech fetus may be reasonable under hospital-specific protocol guidelines." Cesarean delivery is commonly used in the following circumstances: incomplete or footling breech, hyperextended fetal head, fetal macrosomia, unfavorable pelvic shape, severe fetal growth retardation, delivery needed in absence of spontaneous labor, healthy preterm fetus with maternal labor, previous perinatal death/trauma, maternal sterilization request, and lack of operator experience.

American College of Obstetricians & Gynecologists. Mode of term singleton breech delivery. Committee Opinion No. 340, July 2006.

A.7. What is the incidence of heart disease in pregnancy?

The incidence of clinically significant cardiac disease has fallen to less than 1%. This decrease in incidence is due to the successful treatment of intrinsic cardiac disease and infections that cause cardiac disease. Congenital heart disease, not rheumatic heart disease, is now the major cause of heart disease in pregnancy in the developed world. Heart disease is the leading cause of death in women 25 to 44 years old according to the Centers for Disease Control and Prevention.

Kung HC, Hoyert DL, Xu J, et al. Deaths: final data for 2005. *Natl Vital Stat Rep*. 2008;56(10):121.

A.8. What is the mortality rate associated with maternal cardiac disease?

Maternal mortality rate correlates well with the NYHA functional classifications. It is less than 1% in class I or II patients and between 5% and 15% in class III and IV patients. Patients with pulmonary hypertension, Eisenmenger syndrome, and severe Marfan syndrome have a high mortality rate regardless of functional class.

Chestnut DH, Polley LS, Tsen LC, et al., eds. *Chestnut's Obstetric Anesthesia: Principles and Practice*. 4th ed. Philadelphia: Mosby/Elsevier; 2009:881.

A.9. What is the functional classification of heart disease by the New York Heart Association (NYHA)?

The NYHA classification of a complete diagnosis of cardiovascular disease is not widely used now. The grading of dyspnea and/or fatigue resulting from heart failure is, however, often still classified using the old functional NYHA classification.

- *Class I* : no limitation of physical activity
- *Class II* : slight limitation of physical activity; symptoms with ordinary activity
- *Class III* : marked limitation of physical activity; symptoms with less than ordinary activity
- *Class IV* : unable to carry on any physical activity without discomfort; symptoms may be present at rest

On the basis of an analysis of 562 pregnant patients with heart disease, Siu et al. expanded on the NYHA classification and developed a system for predicting complications during pregnancy. Their predictors of cardiac complications included the following:

1. Prior heart failure, arrhythmia, transient ischemic attack, or stroke
2. A baseline NYHA III or IV classification or cyanosis
3. A left-sided heart obstruction defined as a mitral valve area less than 2 cm^2, aortic valve area less than 1.5 cm^2, or an echocardiographically demonstrated peak left ventricular outflow tract gradient exceeding 30 mm Hg
4. Less than 40% ejection fraction

With one of these factors, the risk of sustained arrhythmia, pulmonary edema, stroke, or cardiac death was increased, and if two or more factors existed, the risk was enhanced. Similarly, Stangl et al. found that pregnant patients with acquired and congenital cardiac disease were at increased risk of maternal and fetal morbidity and mortality if they had a left ventricular ejection fraction $< 50\%$, a NYHA class $> II$, a peak left ventricular outflow gradient > 60 mm Hg, or were cyanotic.

A.10. What are the cardiovascular changes of pregnancy?

During the first trimester of pregnancy, the cardiac output increases to between 40% and 50% above the normal nonpregnant level and plateaus at approximately 28 weeks of gestation. It remains fairly stable until the stresses imposed by labor increase it further. The increase in cardiac output is due to a 30% increase in stroke volume and a 15% increase in heart rate. Blood pressure, however, is not elevated because peripheral vascular resistance decreases. Central venous pressure, pulmonary capillary wedge pressure, pulmonary artery diastolic pressure, and left ventricular stroke work index are unchanged when compared to nonpregnant values.

During labor, cardiac output increases approximately 15% with uterine contractions during the latent phase, 30% in the active phase, and 45% in the expulsive phase when compared to prelabor values. The greatest increase in cardiac output occurs immediately postpartum when it increases an average of 80% above prelabor values. Cardiac output and heart rate decline to prelabor values within 1 hour of delivery, and by approximately 24 hours, mean blood pressure and stroke volume return to their prelabor values. In the first 3 to 6 months after delivery, the cardiovascular changes of pregnancy resolve. It can take a year, however, for the residual effects of cardiovascular remodeling to subside.

A.11. What changes may normally occur in heart sounds during pregnancy?

In a study of 50 normal pregnant women at varying stages in pregnancy, a phonocardiographic study found that the first heart sound might have an exaggerated split with increased loudness of both components. In up to 84% of pregnant patients, a third heart sound is also evident. Functional systolic murmurs, which disappear shortly after delivery, occur in more than 90% of pregnant women. Soft transient diastolic murmurs occur in 18% of these women, and 10% have continuous murmurs apparently arising from the breast vasculature. These murmurs alone, therefore, are not indicative of organic heart disease. Similarly, venous distention, tachycardia, edema, and breathlessness may be seen with pregnancy and not be a sign of heart disease. Audible diastolic murmurs on auscultation are uncommon, however, and warrant further investigation.

Gabbe SG, Niebyl JR, Simpson JL, eds. *Obstetrics–Normal and Problem Pregnancies*. 5th ed. Philadelphia: Churchill Livingstone/Elsevier; 2007:61.

A.12. What are the normal electrocardiographic and echocardiographic changes seen during pregnancy?

Normal pregnancy has no characteristic electrocardiographic change. Premature atrial and ventricular contractions can occur. The QRS axis may be deviated to the right during the first trimester but to the left in the third trimester. In lead III, inverted P waves and small Q waves may be seen that disappear with inspiration. Some ST-segment depression and flattening or inverting of the T waves may occur.

Normal echocardiographic findings include an increase in atrial diameters bilaterally. Left ventricular wall mass is increased. Left ventricular function is unchanged or slightly improved. The annuli of the pulmonary, tricuspid, and mitral valves dilate progressively, and term pregnant women may have mild tricuspid, pulmonic, and/or much more infrequently mitral regurgitation. A small pericardial effusion may develop as well.

A.13. What causes rheumatic heart disease?

Rheumatic heart disease may occur in patients who have had acute rheumatic fever, which is an autoimmune disease. The diagnosis of acute rheumatic fever is a clinical one, and the manifestations are extremely variable. There are no specific laboratory tests to confirm the diagnosis, and the exact pathogenetic mechanism is unknown. All cases of acute rheumatic fever follow a group A streptococcal upper respiratory tract infection. The diagnosis is made using the original Jones criteria and the 1992

American Heart Association committee update. In addition to the requirement of supporting evidence of an antecedent group A streptococcal tonsillopharyngitis infection, there are five major criteria: carditis, polyarthritis, Sydenham chorea, erythema marginatum, and subcutaneous nodules. Several minor criteria exist. The presence of one major and two minor or two major criteria are needed for the diagnosis.

Rheumatic fever usually first occurs in 5- to 15-year-old children. Rheumatic heart disease is the only long-term sequela of acute rheumatic fever. With the improved ability to prevent recurrent attacks, the prognosis of these patients has improved greatly. An individual's prognosis is related directly to the severity of cardiac involvement during the acute phase. On 10-year follow-up after acute rheumatic fever, only 6% of patients with no history of carditis had heart murmurs. Heart disease occurred, however, in 30%, 40%, and 68% of the patients who had apical systolic murmurs, basal diastolic murmurs, and pericarditis and/or congestive heart failure, respectively, during the initial attack. In temperate climate zones, such as in the United States and Europe, the time from an acute episode to the development of mitral stenosis (if it occurs) is about 15 to 20 years, and the progression from mild to severe mitral stenosis takes about 5 to 10 years. In tropical climates, the onset and progression are much more rapid. Mitral stenosis is the most common valvular lesion in women with a history of rheumatic heart disease. Mitral valve insufficiency and aortic valve stenosis and insufficiency can also occur in these patients.

Libby P, Bonow RO, Mann DL, et al., eds. *Braunwald's Heart Disease: A Textbook of Cardiovascular Medicine*. 8th ed. Philadelphia: Saunders/Elsevier; 2008:1651, 2079.

Mandell GL. *Mandell, Douglas, and Bennett's Principles and Practice of Infectious Diseases*. 7th ed. Philadelphia: Churchill Livingstone; 2010:2611–2622.

A.14. What are the physiologic consequences of mitral stenosis?

The normal mitral valve orifice area is 4 to 6 cm^2. With mitral stenosis, the valve area is reduced. When the valve area reaches 2 cm^2, cardiovascular hemodynamics become impaired. When the valves cross-sectional area is between 1.0 and 1.5 cm^2, the mitral stenosis is classified as moderate. As the area decreases further to 1 cm^2, it is considered severe, and mean left atrial pressure increases to at least 25 mm Hg to maintain an adequate cardiac output. Left ventricular diastolic pressure is usually normal. Pulmonary venous and capillary pressures increase, leading to exertional dyspnea. If pulmonary capillary pressure exceeds blood oncotic pressure, pulmonary edema can develop. Pulmonary hypertension can result from elevated left atrial pressure and pulmonary arteriolar constriction. If severe pulmonary hypertension develops, right-sided heart failure can occur. Factors that may increase pulmonary pressure include tachycardia, increased cardiac output, and atrial fibrillation.

Libby P, Bonow RO, Mann DL, et al., eds. *Braunwald's heart disease: a textbook of cardiovascular Medicine*. 8th ed. Philadelphia: Saunders/Elsevier; 2008:1646.

A.15. What are the ausculatory findings associated with mitral stenosis?

The first heart sound is increased. There may be an opening snap heard along the left sternal border. A diastolic rumbling murmur is present at the mitral area and may be best heard with the patient in the left lateral decubitus position.

Fuster V, O'Rourke RA, Walsh RA, et al., eds. *Hurst's the Heart*. 12th ed. New York: McGraw Hill; 2008:1760.

A.16. What may be seen on the electrocardiogram (ECG) in patients with mitral stenosis?

There may be broadened diphasic P waves in lead V_1 with a larger negative terminal component that is indicative of left atrial enlargement. There may be signs of right ventricular hypertrophy. Atrial fibrillation may be present.

Dubin D. *Rapid Interpretation of EKGs*. 6th ed. Fort Myers, FL: Cover Publishing; 2000:249.

Libby P, Bonow RO, Mann DL, et al., eds. *Braunwald's Heart Disease: A Textbook of Cardiovascular Medicine*. 8th ed. Philadelphia: Saunders/Elsevier; 2008:1651.

A.17. What are the echocardiographic findings associated with mitral stenosis?

Two-dimensional (2D) echocardiography and Doppler ultrasonography are the mainstays of diagnosis and characterization of mitral stenosis. On 2D echo, the hallmark of mitral stenosis is thickening and restriction of motion of both mitral valve leaflets with the main process being fibrosis and fusion of the leaflets tips and proximal chordae. Early on due to inflammation and leaflet tip thickening that restricts tip but not leaflet motion, a characteristic "doming" of the valve occurs during diastole and the anterior leaflet has a "hockey-stick" configuration (Fig. 29.1). As the stenosis progresses, the body of the leaflet may become involved, and calcification can occur within the leaflets and on the subvalular apparatus including the chordae and papillary muscle tips. Left atrial enlargement can be seen. Pulmonary valve motion abnormalities and right ventricular enlargement may

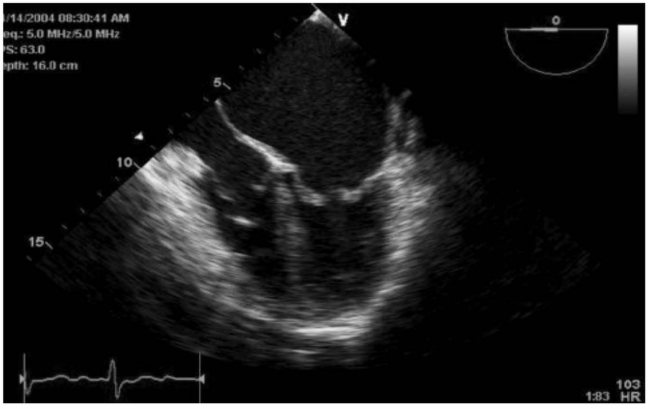

Figure 29.1 Two-dimensional echocardiography of the mitral valve showing severe mitral stenosis with the typical "hockey-stick" appearance.

signify pulmonary hypertension. In addition to reduced excursion and thickening of the leaflets, M-mode echocardiography shows a decrease in the closure rate of the anterior mitral leaflet during early diastole; this results in a reduced E-F slope. M-mode and 2D echocardiography do not reliably predict the severity of mitral stenosis. In addition to determining the anatomic extent and severity of the lesion, Doppler echocardiography can assess the physiologic significance of the lesion. Doppler studies can provide an estimate of valve area that is within ± 0.4 cm^2 of those obtained by cardiac catheterization. During pregnancy, however, mitral valve area calculations by Doppler may be inaccurate. Transesophageal echocardiography is helpful in assessing atrial thrombi.

Rokey R, Hsu HW, Moise KJ, et al. Inaccurate noninvasive mitral valve area calculation during pregnancy. *Obstet Gynecol*. 1994;84:950.

A.18. What is the effect of the physiologic changes of pregnancy on patients with mitral stenosis?

The increased physiologic cardiovascular load of pregnancy can cause patients to deteriorate and advance from one NYHA classification to another. Hameed et al. found that more than half of NYHA class I and II patients with mitral stenosis had worsening clinical symptomatology during pregnancy. The incidence of maternal and fetal complications was related to the severity of the mitral stenosis. Similarly, Silversides et al. found the incidence of maternal cardiac complications with mild mitral stenosis to be lower (26%) than those occurring with moderate (38%) and severe (67%) disease. Maternal mortality is low, although isolated deaths have been reported in parturients with NYHA III and IV classified mitral stenosis .

A.19. If mitral stenosis is first recognized during pregnancy and symptoms develop, how would you treat the patient?

Heart rate reduction and a decreased left atrial pressure are the standard therapeutic goals for women with moderate to severe mitral stenosis. Therefore, β-adrenergic receptor blockade is the cornerstone of medical therapy in the symptomatic patient. It is useful in preventing tachycardia and prolonging diastolic filling time, which can result in a marked improvement of symptoms. Atrial fibrillation or flutter should be treated aggressively; a rapid ventricular response compromises diastolic flow time and can lead to pulmonary edema. Emergency treatment includes digoxin, β-adrenergic receptor blockade, and/or cardioversion if needed. Atrial fibrillation not only increases the risk of pulmonary edema, but it also increases the likelihood of a thromboembolic event. Salt restriction and cautious use of diuretics can decrease left atrial pressure by decreasing blood volume. Avoidance of hypovolemia and decreased uteroplacental perfusion are essential.

If symptoms are uncontrolled by medical therapy, the mitral valve should be repaired or replaced. Percutaneous balloon valvuloplasty can be done using echocardiography or with appropriate radiation shielding of the fetus if radiographic imaging is required. For those with severe mitral stenosis, valve area less than 1 cm^2, a surgical commissurotomy or valve replacement is well tolerated by the mother, but fetal loss exceeds 10%.

A.20. What are the determinants of fetal oxygenation?

Fetal oxygenation is dependent on uteroplacental blood flow, oxygen-carrying capacity, oxygen affinity, arterial oxygen tension, placental diffusion capacity, placental vascular geometry, and placental oxygen consumption.

Cunningham FG, Leveno KJ, Bloom SL, et al., eds. *Williams Obstetrics*. 23rd ed. New York: McGraw-Hill; 2010:85–86.

Datta S, Kodali BS, Segal S. *Obstetric Anesthesia Handbook*. 5th ed. New York: Springer; 2010:66–68.

A.21. What are the determinants of uterine blood flow?

Uterine blood flow is derived from the Ohm's law, which states that pressure equals flow multiplied by resistance. Therefore, uterine blood flow is shown as follows:

$$\text{Uterine blood flow} = \frac{\text{uterine artery pressure} - \text{uterine venous pressure}}{\text{uterine artery resistance}}$$

Normally, 10% of maternal cardiac output goes to the uterus. Of this, the placenta receives 80%, and the myometrium receives the rest. Uterine blood flow is directly related to blood pressure; the uterine vessels do not autoregulate.

B. Preoperative Evaluation and Preparation

B.1. How is fetal well-being assessed during labor?

Fetal well-being is dependent on an intact uteroplacental unit. Simultaneous monitoring of FHR and uterine contractions aids in the detection of fetal distress.

B.2. How are FHR and maternal contractions monitored?

FHR can be monitored noninvasively using the Doppler technique or invasively using a fetal scalp electrode. Uterine contractions may be monitored noninvasively by a tocodynamometer, which measures the tightening of maternal abdominal muscles, or invasively by a transcervical pressure catheter hooked to a strain gauge.

Cunningham FG, Leveno KJ, Bloom SL, et al., eds. *Williams Obstetrics*. 23rd ed. New York: McGraw-Hill; 2010:410, 437.

B.3. What is the normal FHR with beat-to-beat variability?

Interpretation of FHR patterns can be confusing because of the lack of uniformity on definitions and nomenclature. During a 10-minute tracing segment, the baseline FHR is the approximate mean rate rounded to 5 beats per minute increments. In the third trimester, the normal mean baseline FHR is 120 to 160 beats per minute with beat-to-beat variability. Internationally, some recommend that 110 beats per minute be the lower limit of normal. A baseline FHR <110 beats per minute is termed *bradycardia* and >160 beats/min is called *tachycardia*. Normal beat-to-beat variability is 6 to 25 beats per minute.

Cunningham FG, Leveno KJ, Bloom SL, et al., eds. *Williams Obstetrics*. 23rd ed. New York: McGraw-Hill; 2010:413, 415.

B.4. What are periodic decelerations?

Periodic FHR patterns refer to changes in baseline FHR in relation to uterine contractions. An acceleration is an increase and a deceleration is a decrease in FHR from its baseline. In the United States, periodic decelerations in FHR fall into the following three categories—early, late, or variable—depending on their shape and timing with respect to maternal contractions (Fig. 29.2).

- Early, or type 1, decelerations are uniform FHR decreases that coincide with the onset, peak, and end of uterine contraction. This is a vagal response caused by fetal head compression and is usually not associated with fetal hypoxia.
- Late, or type 2, decelerations are a gradual decrease in FHR that begins after the onset of a contraction and lasts beyond the end of the contraction. They can indicate uteroplacental insufficiency, and require prompt evaluation and treatment.
- Variable, or type 3, decelerations occur variably and usually abruptly in relationship to contractions. They usually result from fetal blood pressure changes due to umbilical cord compression or changes in fetal oxygenation. Significant variable decelerations are defined by the ACOG as those that decrease to < 70 beats per minute and last longer than 60 seconds.

A prolonged deceleration is an isolated deceleration from baseline that lasts 2 or more minutes but less than 10 minutes. These are difficult to interpret, and management is based on bedside clinical judgment.

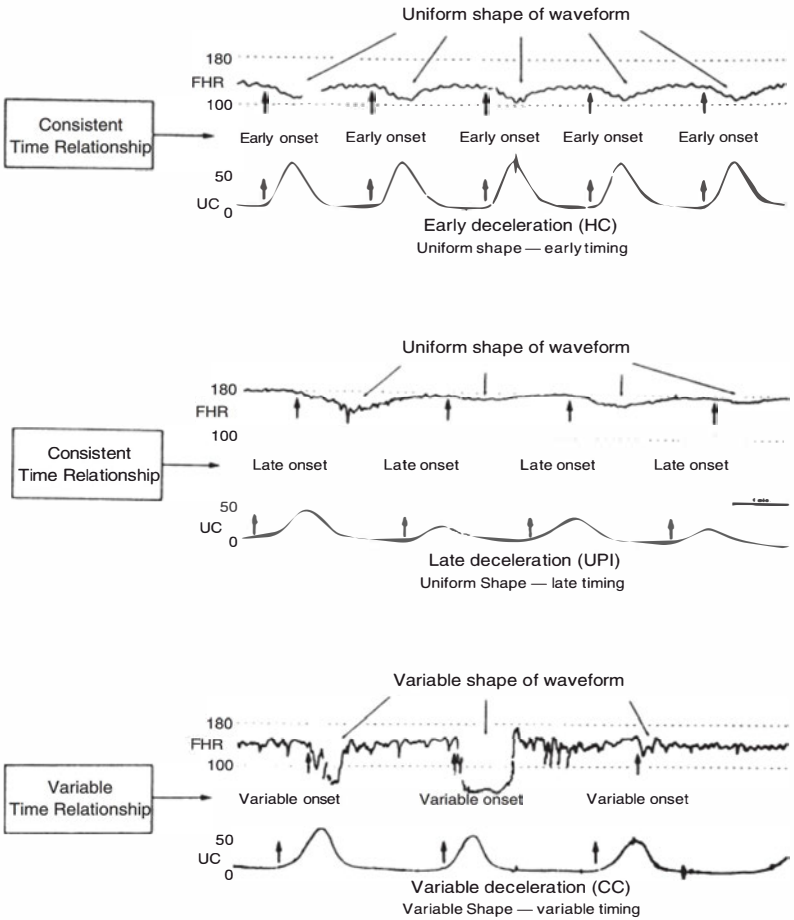

Figure 29.2 Fetal heart rate decelerations in relation to the time of onset of uterine contractions. (From Hon EH. *An Atlas of Fetal Heart Rate Patterns.* New Haven: Harty Press; 1968, with permission.)

B.5. How accurate is FHR monitoring in predicting fetal well-being?

Uncertainty about diagnosing fetal distress from FHR patterns has given rise to the descriptions of these patterns as reassuring or nonreassuring. After more than 40 years of FHR pattern interpretation, there is finally some evidence emerging that certain combinations can be used meaningfully to identify normal and severely abnormal fetuses. Normal FHR patterns include a baseline rate of 110–160 beats per minute, moderate beat-to-beat variability, and no late or variable decelerations; early decelerations and accelerations may or may not be present. Abnormal FHR patterns have absent baseline FHR variability and recurrent late decelerations, recurrent variable decelerations, or bradycardia. Sinusoidal patterns are also abnormal. *Reduced beat-to-beat variability is generally believed to be the single most reliable sign of fetal compromise.* True fetal distress patterns seem to be those where there is no beat-to-beat variability in conjunction with severe decelerations, persistent baseline

rate changes, or both. FHR patterns that do not fall into the aforementioned classifications of normal or abnormal represent an appreciable fraction of nonreassuring FHR tracings. These fetal assessments are subjective clinical judgments and are inevitably and knowingly open to imperfection. Management options depend upon whether or not the cause of the fetal insult can be identified and corrected.

Paul RH, Suidan AK, Yeh S-Y, et al. Clinical fetal monitoring, VII: the evaluation and significance of intra-partum baseline FHR variability. *Am J Obstet Gynecol*. 1975;123(2):206–210.

B.6. In the fetus with a nonreassuring FHR pattern, what other modalities can be used to assess fetal well-being?

Intrapartum fetal stimulation and fetal scalp capillary blood pH are additional methods to assess fetal well-being. In the fetus with a nonreassuring FHR tracing, any spontaneous or induced (scalp or vibroacoustic stimulation) FHR accelerations may indicate the absence of acidosis but are less than perfect. Fetal capillary scalp pH is now uncommonly used. According to the ACOG, fetal outcome cannot be predicted by either normal or abnormal scalp pH results. Currently, fetal electrocardiography is still being investigated while fetal pulse oximetry has been abandoned. In a parturient with a breech fetus, any technique that requires access to the fetal head would not be applicable.

B.7. What is the significance of meconium-stained amniotic fluid?

Although meconium staining occurs in 12% to 22% of all deliveries, most of the infants are not depressed; there is a high false-positive rate and low sensitivity for acidemia. The physiology of meconium passage and its adverse sequelae are incompletely understood. Three theories have been suggested to explain the passage of meconium by the fetus, and the wide differences in the proposed theories may help explain the tenuous connection between meconium detection and infant mortality. The pathologic explanation proposes that in response to hypoxia, the fetus passes meconium and that meconium, therefore, signals fetal compromise. Alternatively, in utero passage of meconium may indicate normal gastrointestinal tract maturation under neural control. A third alternative suggests that passage of meconium follows vagal stimulation from common but transient umbilical cord entrapment and resultant peristalsis.

Ramin et al. suggest meconium becomes an environmental hazard when fetal acidemia occurs rather than meconium release being solely a marker of preexisting fetal compromise. Importantly, because acidemia occurs acutely, meconium aspiration is unpredicatable and likely unpreventable. Greenwood et al. looked at women with clear amniotic fluid and emphasized that clear fluid is an unreliable sign of fetal well-being.

Evidence is accumulating that many infants with meconium aspiration syndrome have suffered hypoxia before birth. Blackwell et al. found that 60% of the infants with meconium aspiration syndrome had umbilical artery blood pH greater than or equal to 7.20; this suggests that this syndrome was unrelated to the neonates' condition at delivery. Meconium aspiration syndrome is more likely when meconium is thick, the pregnancy is post term, or the fetus is growth restricted.

Blackwell SC, Moldenhauer J, Hassan SS, et al. Meconium aspiration syndrome in term neonates with normal acid-base status at delivery: is it different?. *Am J Obstet Gynecol*. 2001;184:1422.

Ramin KD, Leveno KJ, Kelly MS, et al. Amniotic fluid meconium: a fetal environmental hazard. *Obstet Gynecol*. 1996;87:181.

B.8. What is meconium aspiration syndrome?

Of the 10% to 15% of births with meconium-stained amniotic fluid, 5% of the infants develop meconium aspiration pneumonia. Of these infants, 30% require mechanical ventilation, and 3% to 5% may die. Meconium inactivates surfactant.

Meconium aspiration syndrome is characterized by respiratory distress with a marked mismatch of ventilation to perfusion. Within 72 hours, the condition often improves, but when assisted ventilation is required, it may be severe and has a high associated mortality. Pneumothorax and/or pneumomediastinum are complications. With severe disease, pulmonary hypertension leading to persistent fetal circulation can occur.

Kliegman RM, Behrman RE, Jensen HB, et al., eds. *Nelson Textbook of Pediatrics*. 18th ed. Philadelphia: Saunders/Elsevier; 2007:742.

B.9. What are the usual noninvasive tests used to evaluate the pregnant cardiac patient?

Physical examination, exercise tolerance test, ECG, pulse oximeter oxygen saturation, Holter monitoring, and echocardiography with Doppler flow studies may all be useful in evaluating these patients. Cardiac magnetic resonance imaging is generally safe in pregnant women, but contrast dye should not be used. Tests using radiation should be avoided unless absolutely necessary. If a radiologic test is needed, delaying it until as late as possible in the pregnancy and protective fetal radiation shielding would be best. The risk of fetal anomalies is low with less than 5 rads of radiation exposure. Radiation exposure with a chest radiograph is approximately 20 millirads and with a radionuclide scan is about 40 millirads.

Fuster V, O'Rourke RA, Walsh RA, et al., eds. *Hurst's the Heart*. 12th ed. New York: McGraw-Hill; 2008:2192.

B.10. What preoperative medications would you give this patient?

Recommendations for antibiotic prophylaxis against endocarditis are dependent on the cardiac lesion and the procedure being performed. Prophylaxis has been overused. As recommended by the American Heart Association and endorsed by the ACOG, prophylaxis for bacterial endocarditis should be administered intrapartum to women at risk only in the presence of suspected bacteremia or active infection. In patients with acquired valvular dysfunction, endocarditis prophylaxis is not recommended for cesarean section or uncomplicated vaginal delivery. Only a few antibiotic regimens are recommended by the ACOG for prophylaxis if needed. Ampicillin 2 g intravenously (IV), cefazolin 1 g IV, or ceftriaxone 1 g IV should be given 30 to 60 minutes before the procedure. If the patient has penicillin allergy, clindamycin 600 mg IV should be given. If enterococci infection is suspected, vancomycin is recommended.

However, prophylactic antibiotics are given to patients having cesarean sections to prevent postcesarean section endomyometritis and wound infections. In the past, the antibiotic was given after cord clamping. Recently, however, the ACOG and the American Academy of Pediatrics, in a joint publication, have stated that "an antibiotic before the procedure [cesarean delivery] has been demonstrated to be more effective than administration immediately after umbilical cord clamping." They do not explicitly recommend preincision administration of antibiotic or use of an extended-spectrum regimen for endocarditis prophylaxis. However, in a comprehensive review, Tita et al. suggest using either cefazolin alone before surgical incision or an extended-spectrum regimen after cord clamp seems to reduce postcesarean maternal infection.

Pregnant patients are considered to be at an increased risk for aspiration of gastric contents. Gastric fluid volume and pH are not different in the pregnant patient versus their nonpregnant counterparts. Pregnancy itself may not decrease gastric emptying, but during labor, gastric motility does decrease. The increased risk is thought to be due to the parturient's decrease in lower esophageal sphincter tone, changes in the gastroesophageal junction angle, and an increased risk of having difficulty with intubation. Based on the chemical and physical nature of the aspirate and the volume, the risk of aspiration pneumonitis exists. With a nonparticulate aspirate, historically, patients were considered to be at risk for aspiration pneumonitis if greater than 0.4 mL/kg of fluid with a pH of less than 2.5 was aspirated. The volume guideline has been called into question. The goal of prophylactic therapy, however, remains the same. Ideally, the pH level should be greater than 2.5, and potential volume of the aspirate should be minimized. Although the exact time at which the risk increases is unclear, it seems prudent to consider the pregnant patient to be at increased risk for aspiration of gastric contents after 16 to 20 weeks' gestation. In this patient for emergency cesarean, an oral nonparticulate antacid such as 15 to 30 mL of 0.3 M sodium citrate given immediately before induction reduces the risk of developing aspiration pneumonitis. Ranitidine, cimetidine, and metoclopramide may also decrease this risk but require more time to be effective.

C. Intraoperative Management

C.1. What monitors would you use in this functional NYHA class II patient during her cesarean section?

Pregnant cardiac patients should be monitored with an ECG, blood pressure monitoring, pulse oximetry, temperature monitor, and urinary catheter. In addition, end-tidal carbon dioxide, bispectral index, and neuromuscular blockade monitoring is recommended if general anesthesia is used.

C.2. When would you use invasive monitoring in a pregnant patient with cardiac disease?

NYHA class I and II patients do not routinely require invasive hemodynamic monitoring. However, the paturient in class III or IV is usually monitored with a pulmonary artery catheter. An arterial line may be placed if serial blood gas determinations and/or continuous blood pressure monitoring seems warranted. The hemodynamic monitoring should be continued for at least 24 hours postdelivery since the sudden increase in preload immediately after delivery can precipitate pulmonary edema.

Cunningham FG, Leveno KJ, Bloom SL, et al., eds. *Williams Obstetrics*. 23rd ed. New York: McGraw-Hill; 2010:966.

Funai EF, Evans MI, Lockwood CJ. *High Risk Obstetrics: The Requisites in Obstetrics & Gynecology*. Philadelphia: Mosby/Elsevier; 2008:338, 359.

C.3. What are the hemodynamic goals of intraoperative management of the pregnant patient with mitral stenosis?

- Avoid tachycardia.
- Maintain sinus rhythm.
- Avoid marked decrease in systemic vascular resistance.
- Avoid marked increase in central blood volume.
- Avoid increase in pulmonary vascular resistance.

Increased heart rate should be avoided because decrease in the amount of diastolic time for blood to flow across the stenotic mitral valve can lead to pulmonary edema and a decreased cardiac output. Atrial fibrillation with a rapid ventricular response similarly can result in cardiac decompensation, and the loss of atrial contraction is detrimental. Marked decrease in systemic vascular resistance should be avoided because compensatory increase in heart rate can result. Elevation of pulmonary vascular resistance, as can occur with hypercarbia, hypoxia, and acidosis, is poorly tolerated by these patients.

Datta S, Kodali BS, Segal S. *Obstetric Anesthesia Handbook*. 5th ed. New York: Springer; 2010:261.

C.4. What anesthetic technique would you use for this emergency cesarean section?

The choices of anesthetic techniques for cesarean section are regional, spinal or epidural, or general anesthesia. In this case, a general anesthetic would be the anesthetic of choice. General anesthesia has a rapid onset, which is necessary because of the abnormal FHR tracing and the inability to free the compressed prolapsed umbilical cord. In addition, if the patient has not been adequately hydrated with an IV crystalloid

solution before a rapid regional anesthetic induction, the resulting decrease in systemic vascular resistance, hypotension, and reflex tachycardia might exacerbate fetal distress and lead to maternal cardiac decompensation in the patient with mitral stenosis. In the nonemergent setting, patients with mitral stenosis do well with epidural anesthesia for their vaginal delivery or cesarean section. Combined spinal–epidural analgesia has also been used successfully in these patients during vaginal delivery.

Chestnut DH, Polley LS, Tsen LC, et al., eds. *Chestnut's Obstetric Anesthesia: Principles and Practice*. 4th ed. Philadelphia: Mosby/Elsevier; 2009:894.

C.5. What technique could you use for general anesthesia in this patient?

- IV crystalloid solution through a large-bore cannula (if not already present) should be used.
- Place the patient on the table in the supine position with left lateral tilt to avoid aortocaval compression.
- Preoxygenate the mother and place monitors on her quickly. Preoxygenation may be accomplished by allowing her to breathe 100% oxygen by face mask for 3 to 5 minutes or to take four maximally deep inspirations if time is limited.
- After a team "time-out" and abdominal preparation and draping, perform a rapid sequence induction using thiopental sodium, 4 mg per kg, and succinylcholine, 1 mg per kg. Ketamine should be avoided because it could increase heart rate. Pregnant women do not experience severe fasciculations; therefore, a defasciculatory dose of nondepolarizing muscle relaxant is not recommended. Depending on the severity, mitral stenosis patients may benefit from a β-adrenergic receptor antagonist, such as esmolol, or a modest dose of opioid before or during induction of general anesthesia. Remember to inform the neonatologist in the delivery room about the medications that the mother has received. If hypotension occurs, phenylephrine, not ephedrine, would be the vasopressor of choice because it does not cause tachycardia.
- Endotracheal intubation: Mucosal swelling and capillary engorgement can make intubation more difficult. A smaller endotracheal tube, such as a 7-mm internal diameter tube, should be used. The value of using cricoid pressure has been questioned. Classically, cricoid pressure is maintained until the endotracheal tube cuff is inflated and the position is checked. In human cadavers, cricoid pressure effectively prevented regurgitation with gastric pressures as high as 50 to 94 cm H_2O. Smith et al. found that cricoid pressure in awake volunteers led to airway displacement and did not reliably produce midline esophageal compression. This may limit its protective effect against passive reflux and make intubation more difficult.
- Maintenance of anesthesia before the baby is delivered involves the following: N_2O with at least 50% oxygen, volatile anesthetic agent (e.g., 1% sevoflurane), and muscle relaxant as needed (vecuronium, cisatracurium, or rocuronium). Isoflurane and desflurane probably should be avoided in this patient because they may cause tachycardia. Eucapnea should be maintained.
- Maintenance of anesthesia after the baby is delivered no longer requires fetal consideration. A narcotic technique can be implemented using, for instance, fentanyl, midazolam, muscle relaxant, nitrous oxide, and oxygen.
- After the delivery of newborn, any bolus administration of oxytocin, methylergonovine or 15-methyl prostaglandin F2-α can increase pulmonary vascular resistance.
- Tracheal extubation is done after her protective laryngeal reflexes have returned and the patient has regained consciousness.

C.6. If you had unexpectedly been unable to intubate this patient, how would you have managed the airway?

Figure 29.3 shows one way to deal with the failed intubation in the obstetric patient with an unrecognized difficult airway. However, other anesthetic techniques may be used. For instance, some would let the patient breathe spontaneously, and others would administer muscle relaxants while continuing mask ventilation. Additionally, some prefer video versus direct laryngoscopy for additional intubation attempts. Remember that like face mask ventilation, the laryngeal mask airway does not prevent aspiration. The mother's life should not be endangered to deliver a distressed fetus. Calling for help promptly when difficulties arise is wise.

American Society of Anesthesiologists Task Force on Management of the Difficult Airway. Practice guidelines for the management of the difficult airway. *Anesthesiology*. 2003; 98(5):1269–1277.

Barker P, Langeton JA, Murphy PJ, et al. Regurgitation of gastric contents during general anesthesia using the laryngeal mask airway. *Br J Anaesth*. 1992;69:314.

C.7. Would this patient benefit from the use of β-blockers?

Since this patient is asymptomatic, β-blockade is unnecessary. Should compromising tachycardia occur, β-blockade with drugs such as propanolol, atenolol, or esmolol may be useful, as may digoxin or cardioversion depending on her dysrhythmia. Al Kasab et al. have shown that pregnant patients with symptomatic mitral stenosis who receive β-blockade with propanolol or atenolol to attenuate tachycardia have a significant decrease in the incidence of pulmonary edema with no adverse neonatal side effects.

Al Kasab SM, Sabag T, Zaibag MA, et al. β-Adrenergic receptor blockage in the management of pregnant women with mitral stenosis. *Am J Obstet Gynecol*. 1990;163:37.

C.8. What is the effect of the inhalation agents on uterine contractility?

If less than one minimum alveolar concentration of a potent volatile inhalation agent such as isoflurane or sevoflurane is used, there is no increase in blood loss or decrease in uterine contractility, because at these low concentrations, the uterus still responds to oxytocin. At higher concentrations, the uterine contractility is decreased and blood loss is increased.

C.9. What is the Apgar scoring system?

The Apgar scoring system is used in the delivery to assess the neonate's condition at 1 minute and 5 minutes. Each of five categories is given a rating of 0 to 2, and the final score at each time is the sum of the individual category scores. Ten points is the best possible neonatal Apgar score (Table 29.1).

Apgar V. A proposal for a new method of evaluation of the newborn infant. *Curr Res Anesth Analg*. 1953;32:260.

C.10. What is the significance of Apgar scores?

Overall, Apgar scores qualitatively measure basic neurologic reflexes and correlate with generalized neonatal depression. They only loosely correlate with acidosis and asphyxia. Apgar scores aid in predicting mortality but poorly predict morbidity; the longer the Apgar score is low, the higher the neonatal mortality.

Table 29.1 Apgar Scoring System

MNEMONIC	SIGN	SCORE 0	1	2
A	Appearance (color)	Blue, pale	Body pink, extremities blue	Pink
P	Pulse	Absent	<100/ min	>100/ min
G	Grimace (reflex irritability; response to catheter in the nose)	Absent	Grimace	Cough, sneeze
A	Activity (muscle tone)	Limp	Some extremity flexion	Active motion
R	Respiratory effect	Absent	Slow, irregular	Good cry

C.11. At birth, what should be done to minimize an infant's risk of meconium aspiration syndrome?

In the past, obstetricians suctioned the mouth and nose of the newborn before the infant's first breath and the delivery of its shoulders. Currently, the American Heart Association and American Academy of Pediatrics as well as the ACOG recommend against this practice of routine oropharyngeal and nasopharyngeal suctioning in the presence of meconium-stained fluid based on the work by Vain et al. Similarly, experts also recommend that vigorous newborns with meconium exposure not be intubated and suctioned. Depressed newborns, however, should be intubated and be suctioned directly via the endotracheal tube to remove meconium from the airway. Exogenous surfactant administration to infants with meconium aspiration syndrome on ventilatory support has decreased the need for extracorporeal membrane oxygenation support.

American College of Obstetricians and Gynecologists. Management of delivery of a newborn with meconium-stained amnionic fluid. Committee Opinion No. 379, September 2007. American Heart Association and American Academy of Pediatrics. 2005 American Heart.

Association Guidelines for Cardiopulmonary Resuscitation and Emergency Cardiovascular Care of Pediatric and Neonatal Patients. Neonatal Resuscitation guidelines. *Pediatrics.* 2006;117(5):e1029–e1038.

Kliegman RM, Behrman RE, Jensen HB, et al., eds. *Nelson Textbook of Pediatrics.* 18th ed. Philadelphia: Saunders/Elsevier; 2007:742.

Vain NE, Szyld EG, Prudent LM, et al. Oropharyngeal and nasopharyngeal suctioning of meconium-stained neonates before delivery of their shoulders: multicentre, randomized controlled trial. *Lancet.* 2004;364:597.

C.12. The Apgar score of the newborn was 3 at 1 minute. How would you treat the newborn?

This newborn is depressed with the Apgar score of 3 and should have his trachea intubated followed by endotracheal suctioning. If ventilation with 100% oxygen does not lead to prompt improvement, umbilical vessel catheterization and appropriate fluid and drug administration is required.

American Heart Association and American Academy of Pediatrics. 2005 American Heart Association Guidelines for Cardiopulmonary Resuscitation and Emergency Cardiovascular Care of Pediatric and Neonatal Patients: Neonatal Resuscitation guidelines. *Pediatrics* 2006;117(5):e1029–e1038.

C.13. Blood gases are sent immediately after delivery. What are the normal values for umbilical vein and artery blood gases?

Normally, umbilical artery blood has the following characteristics:

- pH value, 7.27 ± 0.069
- P_{CO_2}, 50.3 ± 11.1 mm Hg
- P_{O_2}, 22.0 ± 3.6 mm Hg
- Bicarbonate, 22.3 ± 2.5 mEq per L

Umbilical vein blood has the following characteristics:

- pH, 7.35 ± 0.05
- P_{CO_2}, 38.2 ± 5.6 mm Hg
- P_{O_2}, 29.2 ± 5.9 mm Hg
- Bicarbonate, 20.4 ± 2.1 mEq per L

Fetal conditions are reflected in the umbilical artery blood gas values, and umbilical vein blood gas determinations represent uteroplacental and maternal conditions. Ideally, both samples are collected. The ACOG recommends that cord blood gas measurements be performed when a cesarean section is done for fetal compromise or a low 5-minute Apgar score, severe growth restriction, abnormalities in FHR tracings, maternal thyroid disease, an intrapartum maternal fever, and/or multiple gestation exist(s). If any derangements exist, it is important to determine the metabolic versus respiratory contributions to the abnormalities. In 2003, the American Academy of Pediatrics and the ACOG defined metabolic acidosis as umbilical arterial pH <7.0 and a base deficit of at least 12 mmol/L; this acidosis may be considered a part of defining an acute intra-partum hypoxic episode that may be sufficient to cause cerebral palsy. Umbilical cord blood gas and pH measurements, however, are poorly predictive of immediate or long-term adverse neurologic outcome, but they do provide objective evidence of fetal metabolic state at birth.

D. Postoperative Management

D.1. Immediately after the baby was delivered, the patient's oxygen saturation decreased. What is the differential diagnosis?

The following may be likely causes of hypoxemia in this baby:

- Mechanical problems with the endotracheal tube
- Cardiac decompensation with pulmonary edema
- Pulmonary venous embolism: air, amniotic, thrombotic

CHAPTER 30

Appendectomy for a Pregnant Patient

FARIDA GADALLA

A 25-YEAR-OLD WOMAN

at 32 weeks' gestation presented to the emergency room with vague right sided abdominal pain. She had lost her appetite and had two episodes of vomiting. Temperature was 37.5° C (99.5° F), pulse rate, 100 beats per minute; hematocrit, 34%; and white blood cell count, 15,000/μL.

A. Medical Disease and Differential Diagnosis

1. What is the differential diagnosis for this patient?
2. How would you attempt to make the diagnosis of acute appendicitis clinically?
3. What is the incidence of appendicitis during pregnancy?
4. Is the incidence of gangrenous appendix higher in pregnant than in non-pregnant women? Why?
5. What is Alders sign?
6. What is the incidence of perforation of the appendix and in which trimester is it most likely to occur?
7. What is the incidence of surgery during pregnancy?
8. What are the main concerns associated with nonobstetric surgery in the pregnant patient?
9. What are the factors influencing teratogenicity in mammals? Discuss the teratogenicity of anesthetic agents.
10. Discuss the U.S. Food and Drug Administration (FDA) fetal risk categories for therapeutic agents and classify the most commonly used anesthetic agents.
11. How would you prevent intrauterine fetal asphyxia?
12. Although this patient presented with an acute abdomen, what is another reason for nonobstetric surgical intervention in the pregnant patient?

B. Preoperative Evaluation and Preparation

1. What would you discuss with this patient preoperatively?
2. Is there a difference in the aim of anesthesia for delivery and for nonobstetric surgery in a pregnant patient?
3. How would you premedicate this patient?

C. Intraoperative Management

1. What factors would alter your anesthetic technique from that used for a nonpregnant patient?
2. Describe your technique and dosage if you choose epidural anesthesia.
3. If the patient is in need of supplemental medication, what would be your choice?
4. What vasopressor would you choose to improve uteroplacental perfusion?
5. When this patient arrived in the operating room, she was panic-stricken and desired a general anesthetic. Describe your technique.
6. Does any controversy exist surrounding the use of nitrous oxide?
7. What is the incidence of fetal loss and what factors influence it?
8. If the patient were having surgery on her hand, what would you do differently?
9. What would you expect to see on the fetal monitor during a sevoflurane-nitrous oxide-oxygen anesthetic?
10. The surgeon schedules the procedure to be performed laparoscopically. Does this pose any problems?

D. Postoperative Management

1. When would you extubate this patient?
2. What monitors would you use postoperatively?
3. What other precautions would you take postoperatively?
4. What is the incidence of preterm delivery following nonobstetric surgery during pregnancy?
5. The next day, the patient went into premature labor having "failed" tocolytic therapy. She now needed a cesarean section for prematurity and breech presentation. She required another general anesthetic. In what way would your technique differ from your previous anesthetic technique?

A. Medical Disease and Differential Diagnosis

A.1. What is the differential diagnosis for this patient?

The differential diagnosis includes the following:

Medical conditions

- Sickle cell disease
- Porphyria
- Glomerulonephritis
- Pyelonephritis
- Pneumonia
- Withdrawal from drug addition

Obstetric conditions

- Labor
- Abruptio placentae
- Chorioamnionitis

Gynecologic conditions

- Salpingitis
- Degenerating myoma
- Ovarian cyst or tumor, either torted or ruptured
- Tubo-ovarian abscess

Surgical conditions

- Appendicitis
- Cholecystitis
- Pancreatitis
- Mesenteric adenitis
- Intestinal obstruction

Chestnut DH, Polley LS, Tsen LC, et al., eds. *Chestnut's Obstetric Anesthesia: Principles and Practice*. 4th ed. Philadelphia: Mosby; 2009:349.

A.2. How would you attempt to make the diagnosis of acute appendicitis clinically?

Diagnosis is based on a detailed history and the following symptoms:

- Vague abdominal pain, variable in position because of the growing uterus
- Anorexia
- Vomiting

The signs are the following:

- Abdominal tenderness
- Rebound pain
- Abdominal guarding
- Rectal tenderness
- Mildly elevated temperature, 37° C to 38° C (98.6° F to 100.4° F)
- Mildly elevated pulse rate
- An increase in white blood cell, although this is not useful because of the already existing relative leukocytosis in pregnancy

Chestnut DH, Polley LS, Tsen LC, et al., eds. *Chestnut's Obstetric Anesthesia: Principles and Practice*. 4th ed. Philadelphia: Mosby; 2009:349.

A.3. What is the incidence of appendicitis during pregnancy?

Appendicitis is the most common surgical emergency during pregnancy. The incidence varies from 1:350 to 1:10,000. Appendicitis is the reason for approximately 25% of operative indications for nonobstetric surgery during pregnancy. In epidemiologic studies, the reduced incidence of appendicitis in pregnant women compared to matched controls suggests a protective effect of pregnancy, especially in the third trimester.

Andersson REB, Lambe M. Incidence of appendicitis during pregnancy. *Internat J Epidemiol*. 2001;30(6):1281–1285.

Chestnut D. Polley LS, Tsen LC, et al., eds. *Chestnut's Obstetric Anesthesia: Principles and Practice*. 4th ed. Philadelphia: Mosby; 2009:349.

A.4. Is the incidence of gangrenous appendix higher in pregnant than in nonpregnant women? Why?

The incidence of gangrenous appendix has been reported to be higher during pregnancy because the enlarging uterus pushes the appendix away from the abdominal wall (Fig. 30.1), thereby causing the diseased appendix to produce little pain. This will delay the diagnosis and allow time for the appendix to become gangrenous. Recent studies using magnetic resonance imaging have confirmed that the appendix is displaced upward to a mean distance of 45 mm above the iliac crest at term. This will frequently result in flank pain instead of the typical right lower quadrant pain as the presenting symptom in some women. Another factor contributing to the delay in diagnosis of a nonobstetric abdominal crisis is that useful diagnostic procedures such as radiography and laparoscopy are postponed because of concern for the fetus.

Epidemiologic data, on the other hand, show no higher incidence of perforated appendix in pregnant women compared to matched controls.

Young BC, Hamar B, Levine D. Medical management of ruptured appendicitis in pregnancy. *Obstet Gynecol*. 2009;114(2):453–456.

A.5. What is Alders sign?

Alders sign is a clinical sign used to differentiate between uterine and appendiceal pain. The pain is localized with the patient supine. The patient then lies on her left side. If the area of pain shifts to the left, it is presumed to be uterine.

Alders N. A sign for differentiating uterine from extrauterine complications of pregnancy. *Br Med J*. 1951;2:1194.

A.6. What is the incidence of perforation of the appendix and in which trimester is it most likely to occur?

The incidence of perforation of the appendix is approximately 15%. Thirty percent of these occur in the first and second trimesters and 70% during the third trimester.

Chestnut DH, Polley LS, Tsen LC, et al., eds. *Chestnut's Obstetric Anesthesia: Principles and Practice*. 4th ed. Philadelphia: Mosby; 2009:337–357

Weingold AB. Appendicitis in pregnancy. *Clin Obstet Gynecol*. 1983;26:801.

A.7. What is the incidence of surgery during pregnancy?

The incidence of surgery is estimated at between 0.75% and 2.2%.

Baden JM, Brodsky JB, eds. *The Pregnant Surgical Patient*. Mt. Kisco, NY: Futura Publishing; 1985:223.

Shnider SM, Webster GM. Maternal and fetal hazards of surgery during pregnancy. *Am J Obstet Gynecol*. 1965;92:891.

A.8. What are the main concerns associated with nonobstetric surgery in the pregnant patient?

The main concerns are maternal and fetal safety. To ensure maternal safety, awareness of the physiologic changes of the parturient is of great importance. Special care should be taken to prevent aspiration pneumonitis and supine hypotension syndrome. For fetal safety, it is essential to avoid teratogenic anesthetic agents and intrauterine fetal asphyxia.

Hawkins JL. Anesthesia for pregnant patient undergoing nonobstetric surgery. *ASA annual meeting refresher course lectures*. Park Ridge, IL: American Society of Anesthesiologists; 2006:430.

Rosen MA. Management of anesthesia for the pregnant surgical patient. *Anesthesiology*. 1999;91:1159–1163.

A.9. What are the factors influencing teratogenicity in mammals? Discuss the teratogenicity of anesthetic agents.

The factors influencing teratogenicity are genetic factors, nature, and dose of the anesthetic agent used, access of the agent to the fetus, and fetal developmental stage.

In this case, teratogenicity is unlikely because the most susceptible time in the human is that of organogenesis between the 15th and the 30th day after conception; susceptibility declines thereafter to the 50th day. Almost all anesthetics are teratogenic in some animals. Before implantation of the ovum, teratogenicity leads to abortion. Later, malformation, functional deficiencies, and even death can occur. Large retrospective studies in the United States and United Kingdom suggest that female anesthesiologists and the wives of male anesthesiologists had significantly increased incidence of spontaneous abortion, and their children were more likely to have congenital anomalies than those of nonoperating room physicians. It has been suggested that chronic exposure to trace anesthetic gases was the causative factor. However, no documented reports are found of teratogenicity in humans ascribed to any anesthetic agent used during pregnancy. Nevertheless, we recommend that only time-tested anesthetics, rather than new agents, be used for the pregnant patient, especially in the first trimester of pregnancy.

Cohen EN, Bellville WJ, Brown BW Jr. Anesthesia, pregnancy, and miscarriage: a study of operating room nurses and anesthetists. *Anesthesiology*. 1971;35:343.

Hawkins JL. Anesthesia for pregnant patient undergoing nonobstetric surgery. *ASA annual meeting refresher course lectures*. Park Ridge, IL: American Society of Anesthesiologists; 2006:430.

Rosen MA. Management of anesthesia for the pregnant surgical patient. *Anesthesiology*. 1999;91:1159–1163.

A.10. Discuss the U.S. Food and Drug Administration (FDA) fetal risk categories for therapeutic agents and classify the most commonly used anesthetic agents.

The FDA Fetal-risk Categories for Therapeutic Agents introduced in 1975 are the following:

- *Category A*: Controlled studies have shown no risk to the fetus during the first trimester and later trimesters as well. Risk is remote (e.g., water).
- *Category B*: Animal studies have demonstrated no fetal risk, but no controlled studies have been performed in humans. Animal studies have shown adverse fetal effects, but these results were not confirmed in controlled human studies. No risk is evident after the first trimester.
- *Category C*: Either studies have shown fetal risk in animals (teratogenic or embryocidal), but no controlled human studies have been performed, or there are no available data in humans or animals for an agent. Drugs of this class should be given only if the benefits outweigh the risks.
- *Category D*: Confirmed evidence exists for human fetal risk, but benefits are acceptable despite known risk (i.e., life or limb situations or serious disease for which no safer drugs exist [e.g., diazepam]).
- *Category X*: Agents of this class are contraindicated in pregnant patients for any reason because animal or human studies have displayed teratogenicity, or there is

evidence of fetal risk from prior human experience. Fetal risk clearly outweighs any clinical benefit of their use in pregnancy (e.g., thalidomide).

The commonly used anesthetic agents are classified as follows:

Induction agents

- Thiopental—C
- Methohexital—B
- Ketamine—C
- Etomidate—C
- Propofol—B

Inhalational agents

- Halothane—C
- Enflurane—B
- Isoflurane—B
- Desflurane—B
- Sevoflurane—B
- Nitrous oxide (no classification)

Local anesthetics

- 2-chloroprocaine—C
- Bupivacaine—C
- Lidocaine—B
- Ropivacaine—B

Narcotics

- Fentanyl—B
- Demerol—B
- Morphine—C
- Sufentanil—C

Although the FDA initially introduced categories in 1975, it has recently proposed a rule to eliminate the categories A, B, C, D, X for drug labeling and introduce a one-sentence advisory on drug labels to alleviate confusion among prescribers.

Food and Drug Administration. *Federal Register* 1980;44:37434–37436.

Food and Drug Administration. *Federal Register* 2008;73 no. 104/30831.

A.11. How would you prevent intrauterine fetal asphyxia?

It is essential to maintain maternal homeostasis to ensure fetal well-being. Fetal oxygenation is directly dependent on maternal oxygen tension, oxygen saturation, hemoglobin content, oxygen affinity, and uteroplacental perfusion. Maternal hypoxia will result in fetal hypoxia and, if uncorrected, fetal abnormalities or death. Factors that decrease uterine blood flow must be avoided. Uterine blood flow is determined by uterine vascular resistance and uterine perfusion pressure. Uterine blood flow may be decreased by the following: maternal hypotension, stress (which releases maternal catecholamines), pain, anxiety, hypoxia, hypercarbia, hyperventilation, positive pressure ventilation, and pressor agents.

The following principles govern the administration of anesthesia to parturients:

- Delay elective surgery until after delivery.
- Try to avoid surgery during the first trimester.

- Use regional anesthesia when feasible.
- Attach greater importance to anesthetic management than to agents used.
- Change anesthetic management to conform to changes in maternal physiology.

No anesthetic technique is truly precluded for surgery in the pregnant patient. The avoidance of maternal hypoxia, hypotension, and hypovolemia is of greater importance than the choice of anesthetic technique.

Hawkins JL. Anesthesia for pregnant patient undergoing nonobstetric surgery. *ASA annual meeting refresher course lectures*. Park Ridge, IL: American Society of Anesthesiologists; 2006:430.

Mhuireachtaigh RN, O'Gorman D. Anesthesia in pregnant patients for nonobstetric surgery. *J Clin Anesth*. 2006;18:60–66.

Rosen MA. Management of anesthesia for the pregnant surgical patient. *Anesthesiology*. 1999;91:1159–1163.

A.12. Although this patient presented with an acute abdomen, what is another reason for nonobstetric surgical intervention in the pregnant patient?

Trauma occurs in 5% to 10% of all pregnancies and ranks first among nonobstetric causes of maternal death. Trauma, particularly blunt trauma to the abdomen, can cause uterine rupture, mainly if the patient has had a previous cesarean surgery. Trauma is caused predominantly by traffic accidents and domestic violence.

American Congress of Obstetricians and Gynecologists. *Educational Bulletin No. 251*; September 1998.

National Safety Council. *Accident facts*. National Safety Council, 1987.

B. Preoperative Evaluation and Preparation

B.1. What would you discuss with this patient preoperatively?

It is important to discuss her options concerning regional versus general anesthesia, emphasizing that, statistically, the fetal outcome is similar, but regional anesthesia is the technique of choice for the mother.

Chestnut DH, Polley LS, Tsen LC, et al., eds. *Chestnut's Obstetric Anesthesia: Principles and Practice*. 4th ed. Philadelphia: Mosby; 2009:337–357.

Shelley WC. Anesthetic considerations for nonobstetric surgery. *Clin Perinatol*. 1982;9:149.

B.2. Is there a difference in the aim of anesthesia for delivery and for nonobstetric surgery in a pregnant patient?

Yes. The aim of obstetric anesthesia is to permit pain-free labor and delivery without interfering with the progress of labor, whereas the aim of surgical anesthesia is to provide maternal anesthesia without stimulating uterine activity and precipitating premature labor. Second, obstetric anesthesia should provide maternal analgesia

without fetal neurologic depression and delayed neonatal breathing. Surgical anesthesia, on the other hand, is designed to maintain uteroplacental perfusion but without consideration for fetal neurologic or respiratory depression.

Chestnut DH, Polley LS, Tsen LC, et al., eds. *Chestnut's Obstetric Anesthesia: Principles and Practice*. 4th ed. Philadelphia, PA: Mosby; 2009:337–357.

Diaz JH. Perioperative management of the pregnant patient undergoing non-obstetric surgery. *Anesth Rev*. 1991;18:21–27, 27–34.

B.3. How would you premedicate this patient?

Premedication may be avoided by reassurance and support. If necessary, barbiturates can be given for sedation. Glycopyrrolate, which does not cross the placental barrier, can be used as a vagolytic and antisialagogue.

A nonparticulate antacid, such as 30 mL of 0.3 M sodium citrate, given about 30 minutes before surgery to prevent aspiration pneumonitis, and an H_2 receptor antagonist may also be given.

Chestnut DH, Polley LS, Tsen LC, et al., eds. *Chestnut's Obstetric Anesthesia: Principles and Practice*. 4th ed. Philadelphia: Mosby; 2009:353.

Shelley WC. Anesthetic considerations for non-obstetric surgery. *Clin Perinatol*. 1982;9:149.

C. Intraoperative Management

C.1. What factors would alter your anesthetic technique from that used for a nonpregnant patient?

The anatomic and physiologic changes of pregnancy alter the anesthetic technique in the following systems:

Cardiovascular system

- Increased blood volume (more increase in plasma than in red blood cell count)
- Increased cardiac output (stroke volume and heart rate)
- Decreased peripheral resistance
- Decreased mean arterial blood pressure
- Vena caval and aortic compression in the supine position as shown in Figure 30.2. Therefore, the pregnant patient should be tilted by a wedge under her right hip.

Respiratory system

- Increased minute ventilation
- Increased oxygen consumption
- Decreased functional residual capacity as shown in Figure 30.3

Gastrointestinal system

- Decreased gastrointestinal motility and increased gastric emptying time
- Decreased volume of gastrointestinal secretions
- Increased gastric acidity
- Decreased lower esophageal tone because of increased progesterone level. For these reasons, a pregnant patient beyond the first trimester should always be considered as having a full stomach and must be considered at risk for regurgitation and aspiration

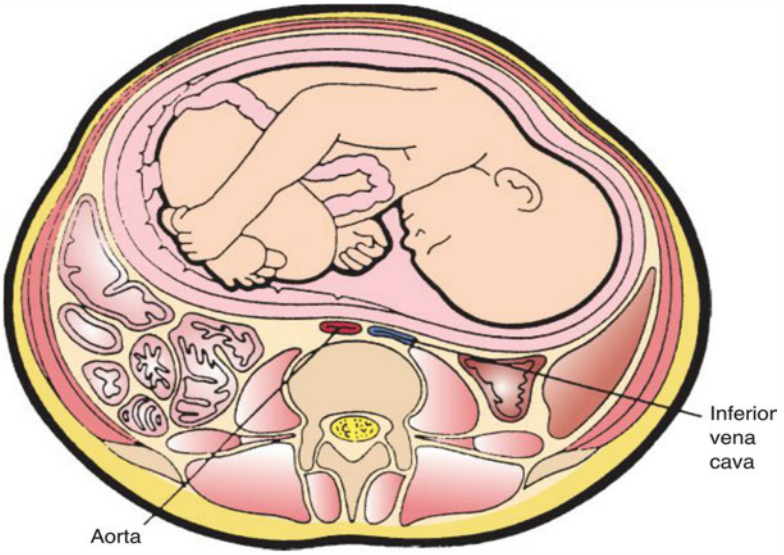

Figure 30.2 The pregnant uterus compressing the aorta and the inferior vena cava (aortocaval compression) in supine position. (Adapted from Ostheimer GW. *Regional Anesthesia Techniques in Obstetrics*. New York: Breon Laboratories; 1980.)

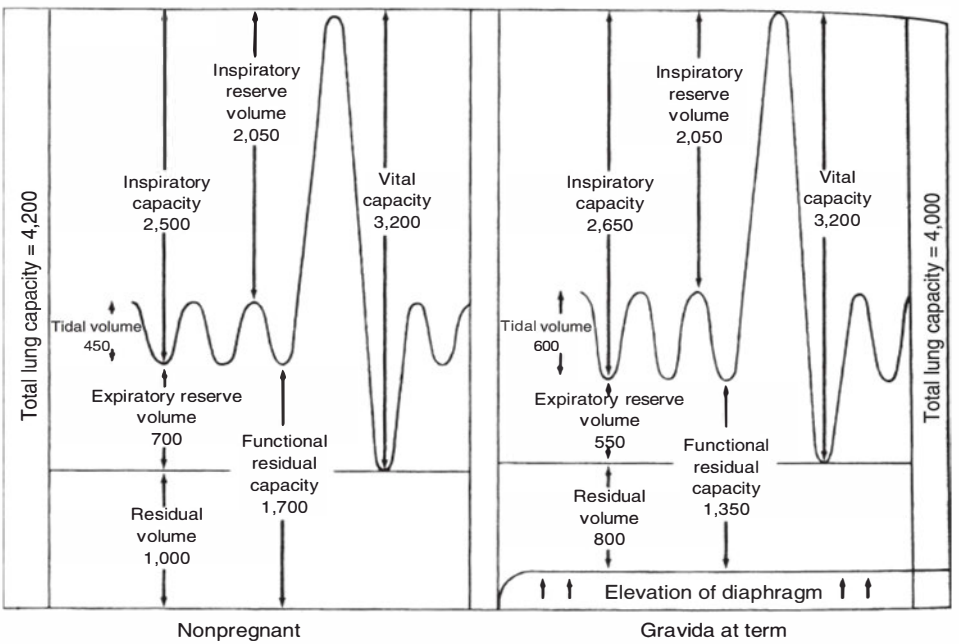

Figure 30.3 Pulmonary volumes and capacities during pregnancy. (From Bonica JJ. *Principles and Practice of Obstetric Analgesia and Anesthesia*. Philadelphia: FA Davis Co; 1967, with permission.)

Central nervous system

- Decreased minimal alveolar concentration (MAC) of inhaled anesthetics
- Increased sensitivity to local anesthesia
- Decreased volume of epidural anesthetic required, because of engorgement of epidural veins and consequent decrease in size of epidural space

Skin and mucous membranes

- More friable mucous membranes and engorged mucosal capillaries (Therefore, avoid insertion of nasal airways, nasotracheal, and nasogastric tubes.)

Metabolic

- Increase in oxygen consumption by 20%

Chestnut DH, Polley LS, Tsen LC, et al., eds. *Chestnut's Obstetric Anesthesia: Principles and Practice*. 4th ed. Philadelphia: Mosby; 2009:15–36.

C.2. Describe your technique and dosage if you choose epidural anesthesia.

The patient is placed on her side or in the sitting position for epidural placement. Adequate hydration is achieved with intravenous fluids. The epidural block is placed at L2–3 or L3–4 using the loss-of-resistance or hanging-drop technique. After testing for inadvertent spinal or intravascular placement, the local anesthetic is given in divided doses to attain a T4 level. This takes between one-half and two-thirds of the dose used for a nonpregnant patient (between 18- and 24-mL average volume). An inadvertent spinal injection is detected by the rapid onset of a solid motor block following a 2- to 5-mL test dose; and an intravascular injection is evidenced by signs of systemic toxicity (e.g., dizziness, tinnitus, circumoral numbness).

The patient is once again placed in the left lateral decubitus position, oxygen is delivered by nasal cannula, and her blood pressure is monitored closely.

The choices of local anesthetics are either 2% lidocaine or 0.5% bupivacaine. These agents afford good analgesia with a degree of motor blockade that provides muscular relaxation. The addition of epidural fentanyl promotes a quicker onset and more solid block.

Chestnut DH, Polley LS, Tsen LC, et al., eds. *Chestnut's Obstetric Anesthesia: Principles and Practice*. 4th ed. Philadelphia: Mosby; 2009:233–235.

Hughes SC, Levinson G, Rosen MA, eds. *Shnider and Levinson's Anesthesia for Obstetrics*. 4th ed. Philadelphia: Lippincott Williams & Wilkins; 2002:2249.

C.3. If the patient is in need of supplemental medication, what would be your choice?

It is best to use the narcotics that have been tried by time and appear to be safe, such as morphine and fentanyl. Small doses of ketamine (0.25 mg/kg intravenously) may also be given.

Chestnut DH, Polley LS, Tsen LC, et al., eds. *Chestnut's Obstetric Anesthesia: Principles and Practice*. 4th ed. Philadelphia: Mosby, 2009:353.

Hughes SC, Levinson G, Rosen MA, eds. *Shnider and Levinson's Anesthesia for Obstetrics*. 4th ed. Philadelphia: Lippincott Williams & Wilkins; 2002:249.

C.4. What vasopressor would you choose to improve uteroplacental perfusion?

Ephedrine was considered the safest vasopressor because it increases mean arterial pressure and uterine artery blood flow without a concomitant decrease in uteroplacental perfusion. The overall increase in cardiac output from the β-adrenergic stimulation of ephedrine will maintain uterine artery perfusion and compensate for its mild adrenergic vasoconstriction. Currently, the ban on pure alpha agonists has been lifted because a number of current studies involving the use of both ephedrine and phenylephrine to treat maternal hypotension during spinal anesthesia for cesarean section show that phenylephrine does not adversely affect neonatal outcome and decreases the incidence of fetal acidosis.

Chestnut DH, Polley LS, Tsen LC, et al., eds. *Chestnut's Obstetric Anesthesia: Principles and Practice*. 4th ed. Philadelphia: Mosby; 2009:347.

Diaz JH. Perioperative management of the pregnant patient undergoing non-obstetric surgery. *Anesth Rev*. 1991;18:21–27, 27–34.

Lee A, Ngan Kee WD, Gin T. A quantitative, systematic review of randomized controlled trials of ephedrine versus phenylephrine for the management of hypotension during spinal anesthesia for cesarean delivery. *Anesth Analg*. 2002;94(4):920–926.

Ngan Kee WD, Khaw KS, Tan PE, et al. Placental transfer and fetal metabolic effects of phenylephrine and ephedrine during spinal anesthesia for cesarean delivery. *Anesthesiology*. 2009;111(3):506–512.

C.5. When this patient arrived in the operating room, she was panic-stricken and desired a general anesthetic. Describe your technique.

- Check the adequacy of the intravenous.
- Preoxygenate for at least 3 minutes to ensure denitrogenation in the lungs and to avoid maternal and fetal hypoxemia during induction and intubation.
- Carry out induction using a rapid-sequence technique (thiopental sodium or propofol, succinylcholine, and intubation using a cuffed endotracheal tube with a 7-mm internal diameter or less).
- Carry out maintenance using agents with a long history of safety, including morphine, fentanyl, succinylcholine, nondepolarizing muscle relaxants, sevoflurane, desflurane, and nitrous oxide-to-oxygen 50:50. The inhalation anesthetics have the added advantage of relaxing the uterus in the hope of preventing premature labor. Air/oxygen can also be used with the understanding that the omission of nitrous oxide can result in a drop in maternal blood pressure because of the need to use a higher concentration of volatile agents.
- Avoid hyperventilation and hypoventilation.
- Extubate when the patient is awake and has regained laryngeal reflexes.

Chestnut DH, Polley LS, Tsen LC, et al., eds. *Chestnut's Obstetric Anesthesia: Principles and Practice*. 4th ed. Philadelphia: Mosby; 2009:353.

C.6. Does any controversy exist surrounding the use of nitrous oxide?

Yes, especially during early pregnancy. This is because nitrous oxide inhibits methionine synthetase, potentially affecting DNA synthesis.

Nitrous oxide also increases adrenergic tone and decreases uterine blood flow. This, however, can be prevented by the addition of a volatile agent.

Nitrous oxide can cause teratogenic effects in animals during prolonged exposure at critical times. However, teratogenicity has not been demonstrated in humans.

Chestnut DH, Polley LS, Tsen LC, et al., eds. *Chestnut's Obstetric Anesthesia: Principles and Practice*. 4th ed. Philadelphia: Mosby; 2009:347.

Rosen MA. Management of anesthesia for the pregnant surgical patient. *Anesthesiology*. 1999;91:1159–1163.

C.7. What is the incidence of fetal loss and what factors influence it?

Prenatal loss may be caused by premature labor, but it can also be caused by generalized peritonitis and sepsis. Fetal loss is related more to the severity of the disease than to the surgical procedure or the anesthetic. The perinatal mortality rate in cases of prematurity because of generalized peritonitis is 200 to 350 per 1,000. The perinatal mortality rate for nonperforated appendicitis is approximately 50 per 1,000 women.

Chestnut DH, Polley LS, Tsen LC, et al., eds. *Chestnut's Obstetric Anesthesia: Principles and Practice*. 4th ed. Philadelphia: Mosby; 2009:349.

Weingold AB. Appendicitis in pregnancy. *Clin Obstet Gynecol*. 1983;26:801.

C.8. If the patient were having surgery on her hand, what would you do differently?

Initially, offer the patient the choice of a brachial plexus block or an intravenous regional technique. It is possible to monitor the fetal heart during surgery and to monitor for uterine contractions using a tocodynamometer. Continuous fetal heart monitoring using transabdominal doppler is possible at approximately 18 weeks' gestation.

Hughes SC, Levinson G, Rosen MA, eds. *Shnider and Levinson's Anesthesia for Obstetrics*. 4th ed. Philadelphia: Lippincott Williams & Wilkins; 2002:249.

C.9. What would you expect to see on the fetal monitor during a sevoflurane-nitrous oxide-oxygen anesthetic?

One would expect to see a decrease in beat-to-beat variability during anesthesia using inhalation agents.

Chestnut DH, Polley LS, Tsen LC, et al., eds. *Chestnut's Obstetric Anesthesia: Principles and Practice*. 4th ed. Philadelphia: Mosby; 2009:352.

Liu PL. Clinical reports: fetal monitoring in patients undergoing surgery unrelated to pregnancy. *Can Anaesth Soc J*. 1985;32:525–532.

C.10. The surgeon schedules the procedure to be performed laparoscopically. Does this pose any problems?

Laparoscopy has been performed during pregnancy both for diagnostic and procedural surgery. CO_2 pneumoperitoneum can cause fetal respiratory acidosis. This leads to the recommendation of maintaining low intra-abdominal pressure, limiting the duration of surgery, and using arterial blood gas analysis. However, a recent study concluded that capnography is adequate to guide ventilation during laparoscopic surgery. End-tidal CO_2 should be maintained at approximately 32 mm Hg. Fetal outcomes were similar in patients undergoing laparoscopy versus laparotomy in pregnancies between 4 and 20 weeks of surgery.

D. Postoperative Management

D.1. When would you extubate this patient?

The patient can be extubated when she is fully awake, in command of her airway reflexes and able to avoid pulmonary aspiration.

Chestnut DH, Polley LS, Tsen LC, et al., eds. *Chestnut's Obstetric Anesthesia: Principles and Practice*. 4th ed. Philadelphia: Mosby; 2009:353.

Hughes SC, Levinson G, Rosen MA, eds. *Shnider and Levinson's Anesthesia for Obstetrics*. 4th ed. Philadelphia: Lippincott Williams & Wilkins; 2002:249.

D.2. What monitors would you use postoperatively?

- Electrocardiogram
- Pulse oximeter
- Urinary catheter (to be discontinued within 24 hours, unless specifically indicated)
- Intermittent blood pressure and temperature monitoring
- Tocodynamometer to detect premature labor
- Fetal heart monitor to ensure fetal well-being

Chestnut DH, Polley LS, Tsen LC, et al., eds. *Chestnut's Obstetric Anesthesia: Principles and Practice*. 4th ed. Philadelphia: Mosby; 2009:353.

Shnider SM, Levinson G, eds. *Anesthesia for Obstetrics*. 4th ed. Philadelphia: Lippincott Williams & Wilkins; 2002:262.

D.3. What other precautions would you take postoperatively?

- Provide adequate hydration.
- Continue left uterine displacement.
- Administer supplemental oxygen.

Many obstetricians use heavy sedation plus a course of β-agonist drugs to prevent premature labor. It is recommended that pregnant patients should be observed on the obstetric floor for a minimum of 12 hours following nonobstetric surgery. Magnesium sulfate is given intravenously if labor occurs.

Chestnut DH, Polley LS, Tsen LC, et al., eds. *Chestnut's Obstetric Anesthesia: Principles and Practice*. 4th ed. Philadelphia: Mosby; 2009:354.

Hughes SC, Levinson G, Rosen MA, eds. *Shnider and Levinson's Anesthesia for Obstetrics*. 4th ed. Philadelphia: Lippincott Williams & Wilkins; 2002:249.

D.4. What is the incidence of preterm delivery following nonobstetric surgery during pregnancy?

In a study of 778 women who underwent appendectomy while pregnant, 22% delivered during the following week if surgery occurred between 24 and 36 weeks' gestation.

Mazza RI, Källen B. Appendectomy during pregnancy. A Swedish registry study of 778 cases. *Obstet Gynecol*. 1991;77:835–840.

D.5. The next day, the patient went into premature labor having "failed" tocolytic therapy. She now needed a cesarean section for prematurity and breech presentation. She required another general anesthetic. In what way would your technique differ from your previous anesthetic technique?

- Do not administer a defasciculating dose of nondepolarizing muscle relaxants prior to administration of succinylcholine. Magnesium sulfate prevents the muscle fasciculations that normally occur following the administration of succinylcholine.
- Use smaller doses of muscle relaxants since magnesium sulfate potentiates their effects.
- Avoid the use of narcotics until after delivery, then stop the inhalation agent and begin using a narcotic technique.

Hughes SC, Levinson G, Rosen MA, eds. *Shnider and Levinson's Anesthesia for Obstetrics*. 4th ed. Philadelphia: Lippincott Williams & Wilkins; 2002:249.

SECTION VIII

The Hematologic System

CHAPTER 31

Hemophilia and Coagulation Disorders

Jonathan Leff, Linda Shore-Lesserson, and Robert E. Kelly

A 46-YEAR-OLD MAN

with hemophilia and HIV-positive status was scheduled for elective elbow synovectomy with resection of the radial head because of limited, painful range of motion.

A. Medical Disease and Differential Diagnosis

1. What are the differences between hemophilia A, B, and C?
2. Describe the typical history and pathophysiology associated with von Willebrand disease (vWD).
3. What are the different components of factor VIII?
4. What is the difference between platelet adhesion and platelet aggregation?
5. Describe the physiologic events that occur following endothelial interruption in the blood vessel.
6. What prevents the extension of a clot beyond the site of injury?
7. Describe the procoagulant factors involved in the extrinsic, intrinsic, and common coagulation cascade.
8. Describe the levels of factor VIII necessary for hemostasis.
9. Describe the various laboratory tests that evaluate the coagulation cascade and the specific components measured by each.
10. Would there be any differences in preoperative factor replacement therapy between a patient with hemophilia A or hemophilia B?

B. Preoperative Evaluation and Preparation

1. What steps would you take to correct this patient's coagulation status before surgery?
2. What is meant by 1 unit of factor VIII clotting activity and how much does 1 unit of factor VIII clotting activity per kilogram of body weight increase factor VIII concentrations?
3. Would you administer factor VIII using a bolus or infusion technique?
4. Can a hemophiliac patient fail to mount an appropriate coagulation response following factor VIII infusion?
5. If a patient with hemophilia does not respond to a bolus injection of factor VIII, can an infusion technique be effective?
6. How much factor VIII activity is present in fresh frozen plasma (FFP)? What are the risks associated with administration of FFP?
7. What are the indications for the administration of FFP?
8. How is cryoprecipitate prepared? What are the components in cryoprecipitate? How much factor VIII activity is present in cryoprecipitate? What are the indications for cryoprecipitate?
9. Describe the advantages and disadvantages of the products that are available for transfusion of factor VIII activity.
10. What is the role of desmopressin D-arginine vasopressin (DDAVP) for hemostatic management in this patient?
11. What is the role of ε-aminocaproic acid (EACA) in the perioperative period for the patient with hemophilia?
12. Is there a role for recombinant activated factor VII (rFVIIa) in the treatment of hemophilia?
13. What is the mechanism and dosing of rFVIIa?

C. Intraoperative Management

1. Is it safe to administer an intramuscular injection to this patient before surgery?
2. Would an axillary block be appropriate for this patient?
3. If general anesthesia is used as a technique, would it be safe to intubate the patient's trachea?
4. Would you use any special precautions for this patient who is positive for HIV?
5. What special considerations should be taken in choosing anesthetic drugs for this patient?
6. During the operative procedure, the surgeon indicated that significant blood loss had occurred. Would you transfuse this patient with packed red blood cells or whole blood?
7. During the transfusion of the first unit of whole blood, the patient's temperature rose from 36.8° C to 37.9° C (98.24° F to 100.22° F). What immediate steps should be taken by the anesthesiologist at this time?
8. Does giving blood intraoperatively increase the potential for the development of factor VIII inhibitors?
9. Can factor VIII be safely administered to patients who have developed circulating inhibitors?
10. The surgeon has requested the use of a tourniquet to minimize surgical bleeding. What are the physiologic and hemodynamic responses to tourniquet use?
11. Is it appropriate to suction the endotracheal tube and oropharynx of this patient before extubation?

D. Postoperative Management

1. What special consideration should be given to postoperative pain management for this patient?
2. What steps should be taken to enhance the coagulation status of this patient in the postoperative period while at home?
3. Can this patient be treated with factor VIII supplements using home infusion?

A. Medical Disease and Differential Diagnosis

A.1. What are the differences between hemophilia A, B, and C?

Hemophilia, one of the oldest known genetic disorders, can be classified into type A, B, or C. Hemophilia A (factor VIII deficiency) is the most common form, accounting for 85% of all patients with hemophilia. The World Federation of Hemophilia estimates 315,000 individuals in the world are afflicted with hemophilia A. It is an X-linked recessive disorder, and therefore occurs in men and homozygous women. Approximately 30% of patients have no family history of this disease; presumably their disease is caused by a new mutation. The disease results in a hemorrhagic tendency that, in its most severe form, can be life threatening. A screening test for hemophilia A is the partial thromboplastin time (PTT), which will be prolonged in all patients except those with mild disease. Measuring factor VIII activity will provide a definitive diagnosis.

Patients with hemophilia B present with either deficient or defective factor IX; this entity represents 14% of hemophilia patients. This X-linked genetic disorder has an inheritance pattern and clinical features that are similar to those of hemophilia A, but can be diagnosed by measuring both the concentration and function of factor IX.

The remaining 1% of hemophiliac patients suffer a deficiency in factor XI and is classified as hemophilia C, an autosomal disorder that is extremely rare except in Ashkenazi Jews. Hemophilia C can be distinguished from A and B by the absence of bleeding into joints and muscles. In addition, the degree of factor XI deficiency may not predict a patient's bleeding tendency in the postoperative period.

A.2. Describe the typical history and pathophysiology associated with von Willebrand disease (vWD).

vWD is the most common congenital bleeding disorder. The most common form of the disease is inherited as an autosomal dominant trait and has an incidence cited as high as 2% to 3%. Patients with vWD have a prolonged bleeding time, which clinically manifests as bruising, epistaxis, mucocutaneous bleeding, and menorrhagia in women. The diagnosis is suggested by the patient's history of a bleeding diathesis and the presence of a prolonged bleeding time, despite a normal platelet count. Laboratory analysis of vWD is useful for classifying the subtypes and to guide therapy. Type I vWD represents most afflicted patients and is marked by decreased levels of normal von Willebrand factor (vWF). First-

line treatment in type I disease is with desmopressin (L-deamino-8-D-arginine-vasopressin [DDAVP]). Cryoprecipitate and FFP also contain vWF and may be used in patients unresponsive to DDAVP. Type IIA vWD represents 15% to 30% of patients and is a qualitative defect in the platelet–vWF interaction. The number of vWF proteins can be normal, but there is an absence of high and middle molecular weight vWF multimers. Type IIB vWD represents that subset of patients with enhanced platelet aggregation in the presence of ristocetin. Ristocetin is an antibiotic formerly used to treat staphylococcus infection, which also initiates binding of vWF to platelet glycoprotein IB. In the absence of vWF, no agglutination will occur with the ristocetin cofactor activity assay. A second assay was developed, termed the *ristocetin-induced platelet agglutination*, which uses the patient's own platelets and plasma. This test is useful to distinguish a hyperaggregation tendency such as observed in type IIB vWD. In type IIN (Normandy) there is a decreased affinity of vWF, to factor VIII, and these patients are often misdiagnosed as having hemophilia A. The response to plasma can be helpful in distinguishing vWF deficiency from hemophilia. Hemophilia A patients will have a rapid rise of factor VIII levels following plasma or cryoprecipitate infusion, but this is not sustained. The patients with vWD experience a similar initial rise in factor VIII; in contrast to hemophilia A, these patients are able to sustain the increase for over 48 hours. Types I and II vWD are inherited as autosomal dominant. Patients with type III vWF deficiency have little or no vWF multimers. DDAVP is not of benefit because these patients have no endogenous production of vWF. Type III vWD is inherited as an autosomal recessive trait. Types IIB and III are extremely rare. It is important to distinguish the subtypes of vWD because the use of DDAVP in types IIB and III may cause thrombocytopenia and increase platelet agglutination.

Hines RL, Marschall KE, eds. Stoelting's *Anesthesia and Co-existing Disease*. 5th ed. Philadelphia: Churchill Livingstone; 2008:427–429

A.3. What are the different components of factor VIII?

Coagulant factor VIII is a plasma protein that has two components, factor VIII vWF and vWF VIII:c, each of which is under separate genetic control. The von Willebrand's component serves to adhere platelets to collagen in the subendothelial layer of blood vessels during primary hemostasis and to carry the factor VIII molecule. In hemophilia A, this factor VIII is deficient in quantity or quality.

Barash PG, Cullen BF, Stoelting RK, et al., eds. *Clinical Anesthesia*. 6th ed. Philadelphia: Lippincott Williams & Wilkins, 2009:389.

A.4. What is the difference between platelet adhesion and platelet aggregation?

Platelet adhesion is the affinity of platelets for nonplatelet surfaces, whereas platelet aggregation is the affinity of platelets for each other.

Barash PG, Cullen BF, Stoelting RK, et al., eds. *Clinical Anesthesia*. 6th ed. Philadelphia: Lippincott Williams & Wilkins, 2009:388.

A.5. Describe the physiologic events that occur following endothelial interruption in the blood vessel.

The small size of platelets relative to other blood components, such as red or white cells, results in slower transit in the blood vessel with resultant margination, the process in which the faster moving larger components push the platelets toward the walls of the blood vessel. As a result, platelets are in contact with the surface of the blood vessel and can immediately detect any break in the endothelium. Any endothelial break exposes platelets to subendothelial structures, including collagens and other activating proteins, which cause the glycoprotein receptors on the platelets to rapidly adhere to these substances. This adhesion begins the process of platelet activation, in which the shape of the platelet is changed and the contents of the cytoplasmic granule are released. These substances include factors such as adenosine diphosphate (ADP), which further stimulate platelet aggregation. The platelet plug that is formed in this process provides initial hemostasis; interaction with both fibrin and thrombin fuse the platelet plug for continued hemostasis. Activation of factor XIII produces cross-polymerization of the loose fibrin to produce a firm clot.

Barash PG, Cullen BF, Stoelting RK, et al., eds. *Clinical Anesthesia*. 6th ed. Philadelphia: Lippincott Williams & Wilkins, 2009:387–389.

Hines RL, Marschall KE, eds. Stoelting's *Anesthesia and Co-existing Disease*. 5th ed. Philadelphia: Churchill Livingstone, 2008:417–418.

A.6. What prevents the extension of a clot beyond the site of injury?

Localization of coagulation and control of primary hemostasis are controlled by many factors, including the dynamic tension between two prostaglandins, thromboxane A_2 and prostacyclin. Thromboxane A_2 is released at the site of vascular injury and stimulates vasoconstriction, ADP release, and platelet aggregation. In contrast, prostacyclin is produced by intact endothelial cells and prevents platelet aggregation and clot formation. In addition, clot localization is maintained by the dilution of procoagulants in the blood, the removal of activated factors by the liver, the action of circulating procoagulant inhibitors such as antithrombin III and protein C, and the release of the serene protease tissue plasminogen activator. The tissue plasminogen activator digests fibrinogen as well as factors V and VIII, initiating the physiologic process of fibrinolysis and resulting in fibrin degradation (split) products, which are removed by the mononuclear phagocyte system.

Barash PG, Cullen BF, Stoelting RK, et al., eds. *Clinical Anesthesia*. 6th ed. Philadelphia: Lippincott Williams & Wilkins, 2009:390–391.

Hines RL, Marschall KE, eds. Stoelting's *Anesthesia and Co-existing Disease*. 5th ed. Philadelphia: Churchill Livingstone; 2008:417–422

A.7. Describe the procoagulant factors involved in the extrinsic, intrinsic, and common coagulation cascade.

When normal blood is placed in a test tube, a clot will form without any added agents. The clotting factors involved in this reaction were originally classified as the "intrinsic" factors, because everything necessary for blood to clot was "intrinsic" to the test tube. The "extrinsic" path is another potent stimulus for thrombin formation and is initiated by exposure of tissue thromboplastin (tissue factor) to factor VII. The extrinsic and intrinsic pathways converge at factor X to form the common pathway.

This classic separation of procoagulant factors into extrinsic, intrinsic, and common coagulation cascades is not absolute because of the crossover of many factors. In fact, the current conception of coagulation uses a cell-based model and

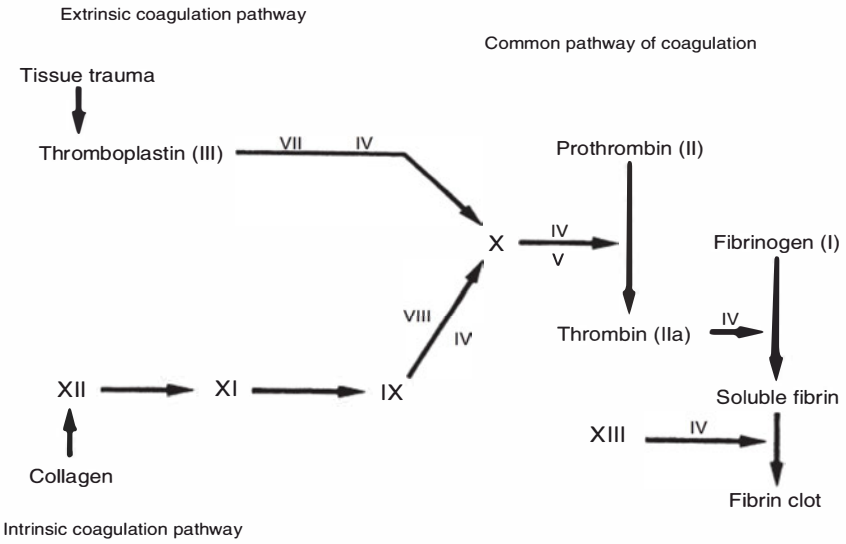

Figure 31.1 Schematic diagram of the procoagulant phase of coagulation depicting the cascade sequence in three steps, designated as the intrinsic, extrinsic, and common coagulation pathways. (From Stoelting RK, Dierdorf SF, McCammon RL, eds. *Anesthesia and Co-existing Disease*. 2nd ed. New York: Churchill Livingstone; 1988:577, with permission.)

takes into account many in vivo pathways and the contribution of the endothelium itself. Although the classic intrinsic and extrinsic coagulation pathways does lead to the formation and activation of thrombin (and hence the amplification of coagulation), it fails to take into account the cellular components, which play a vital role in hemostasis.

The cell-based theory is thought to occur in three stages: initiation, amplification, and propagation. Each stage represents a different aspect of hemostasis at a cellular level, with the end result being formation of thrombin and a stable clot. An appreciation of thrombin's role in the coagulation cascade is critical, and the coagulation cascade is the reason that all anticoagulation therapy is aimed at the inhibition of thrombin. In fact, the initiation phase of the cell-based model is marked by the exposure of tissue factor to circulating factor VII. This activates the other two phases and serves as a potent catalyst for hemostasis. An understanding of this mechanism helps to illustrate how the drug Novoseven (activated factor VII) is such an effective hemostatic agent. The common coagulation cascade is shown in Figure 31.1.

Hoffman M, Monroe DM III. A cell-based model of hemostasis. *Thromb Haemost*. 2001;85:958–965.

Hines RL, Marschall KE, eds. Stoelting's *Anesthesia and Co-existing Disease*. 5th ed. Philadelphia: Churchill Livingstone; 2008:417–419

A.8. Describe the levels of factor VIII necessary for hemostasis.

The levels of factor VIII necessary for hemostasis are described in Table 31.1. When life-threatening airway or neurologic bleeding has occurred, factor VIII levels of 100% should be achieved. Similarly, when major surgery is anticipated, correction to 100% factor VIII levels should be done preoperatively and maintained postoperatively (see section D.2).

Table 31.1 Levels of Factor VIII Necessary for Hemostasis

CLINICAL PRESENTATION	FACTOR VIII CONCENTRATION (% OF NORMAL)
Spontaneous hemorrhage	1–3
Moderate trauma	4–8
Hemarthrosis and deep skeletal muscle hemorrhage	10–15
Major surgery	> 30

A.9. Describe the various laboratory tests that evaluate the coagulation cascade and the specific components measured by each.

Numerous laboratory tests evaluate specific components of the coagulation cascade. The standard skin bleeding time is one way to measure for platelet function, although bleeding time may be prolonged as a result of factors other than platelet dysfunction such as anemia, low platelet count, or patient movement. Moreover, no study has reported a correlation between an abnormal bleeding time and an increased risk for hemorrhage. More recent tests for analyzing platelet function include the VerifyNow and the platelet function analyzer (PFA-100). VerifyNow (Accumetrics, San Diego, CA), a point-of-care monitor designed specifically to measure the platelet response to a thrombin receptor agonist peptide. In whole blood, it measures thrombin receptor agonist peptide activation-induced platelet agglutination of fibrinogen-coated beads using an optical detection system. Because of the importance of the GPIIb IIIa receptor in mediating fibrinogen–platelet interactions, the Ultegra has been especially useful in accurately measuring receptor inhibition in patients undergoing invasive cardiologic therapy receiving GPIIb IIIa–inhibiting drugs. The platelet function analyzer, PFA-100 (Dade Behring, Miami, FL), is a monitor of platelet adhesive capacity that is valuable in its diagnostic abilities to identify drug-induced platelet abnormalities, Bernard-Soulier syndrome, 9vWD, and other acquired and congenital platelet defects. The test is conducted as a modified in vitro bleeding time. Whole blood is drawn through a chamber by vacuum and is perfused across an aperture in a collagen membrane–coated with an agonist (epinephrine or ADP). Platelet adhesion and formation of aggregates will seal the aperture, thereby indicating the "closure time" measured by the PFA-100. This test may be useful in detecting pharmacologic platelet dysfunction before cardiac surgery or may be able to accurately detect hypercoagulability after cardiopulmonary bypass.

Monitoring the coagulation cascade is usually performed with both prothrombin time (PT) and PTT. The PT is measured by adding tissue form thromboplastin (TF) to a blood specimen and measuring the time until clot formation. This test will detect abnormalities in factors I, II, V, VII, or X. A normal PT could occur with an abnormal

fibrinogen level because PT is only prolonged if the fibrinogen level is below 100 mg per day. In order to homogenize test results performed with different types of thromboplastin activating agents, standardization to the international sensitivity index has created the international normalized ratio (INR). The PTT is obtained when partial thromboplastin is added to a test tube of blood and time is measured until clot forms, measuring factors I, II, V, VIII, IX, X, XI, and XII. This test can be modified by the addition of the surface activating factors XI and XII before the addition of the partial thromboplastin, creating the activated partial thromboplastin time (APTT). The APTT is a faster test than the PTT and is a standard test used in clinical practice. The activated clotting time also is an accelerated version of the PTT and is activated by diatomaceous earth. This test is used most often to measure the efficiency of heparin use and is much less sensitive than the APTT to specific factor deficiencies. The thrombin time bypasses most of the coagulation cascade to measure the conversion of fibrinogen to fibrin, a useful test to determine both inadequate amounts of fibrinogen as well as inadequate fibrinogen molecules. The thromboelastogram (TEG) measures speed of clot formation and clot firmness. This monitor allows evaluation of a clot from early fibrin strand to fibrinolysis. The TEG tracing is made up of several parameters; reaction time (R value), coagulation time (K value), maximum amplitude (MA value), an α angle, and the amplitude 60 degrees after the MA (A60). A deviation from a prototypical tracing represents a specific abnormality in the patient's coagulation cascade. An abnormal TEG tracing can correspond to conditions such as thrombocytopenia or factor deficiencies, allowing systematic analysis of intraoperative coagulation defects and a more directed approach to therapy (see Chapter 13, section A.22).

Laboratory evaluation of the coagulation cascade can be defined as shown in Table 31.1.

Fischer GW, Shore-Lesserson L. Hematologic diseases. In: Fleisher L, ed. *Anesthesia and Uncommon Diseases*. 5th ed. Philadelphia: Elsevier Science; 2005:359–376.

A.10. Would there be any differences in preoperative factor replacement therapy between a patient with hemophilia A or hemophilia B?

The patient with hemophilia A would need transfusion of factor VIII before surgery to correct factor VIII levels to approximately 100% of normal. Further supplementation should be repeated approximately every 1.5 hours. The patient with hemophilia B would need high initial doses of factor IX because of a low recovery from the extensive distribution of factor IX both intravascularly and extravascularly. In addition, the longer half-life of factor IX (18 to 30 hours) requires less frequent dosing.

Table 31.2 Specific Components Measured by Different Coagulation Tests

LABORATORY TESTS	COMPONENTS MEASURED
Bleeding time	Platelet count, vascular integrity
Prothrombin time	I, II, V, VII, and X
Partial prothrombin time	I, II, V, VII, IX, X, XI, and XII
Thrombin time	I, II

Hines RL, Marschall KE, eds. Stoelting's *Anesthesia and Co-existing Disease.* 5th ed. Philadelphia: Churchill Livingstone; 2008:???.

B. Preoperative Evaluation and Preparation

B.1. What steps would you take to correct this patient's coagulation status before surgery?

Orthopedic surgical procedures requiring more factor replacement than might be expected are those in which a raw bone surface must heal or a small amount of bleeding into or around a prosthetic joint could lead to infection and destruction of the surrounding tissue. In contrast, when the extremity or operative site can be held firm with plaster, or if good surgical apposition of tissues can be achieved with sutures, less factor replacement is required. Factor VIII levels of 30% of normal will usually provide adequate hemostasis; nevertheless, most clinicians will correct abnormal factor VIII levels to normal levels.

For a major orthopedic procedure, the factor VIII level should be corrected to 100% of normal approximately 1 to 2 hours before the procedure. A repeat dose should be given if the surgical procedure lasts more than 1.5 hours or if the measured factor VIII level falls below 40% of normal.

Lofqvist T, Nilsson I, Petersson C. Orthopaedic surgery in hemophilia. *Clin Ortho Rel Res.* 1996;332:232–241.

B.2. What is meant by 1 unit of factor VIII clotting activity and how much does 1 unit of factor VIII clotting activity per kilogram of body weight increase factor VIII concentrations?

One unit of factor VIII clotting activity is defined as the amount present in 1 cc of fresh normal, pooled plasma. A single unit of factor VIII clotting activity per kilogram of body weight will increase plasma factor VIII levels approximately 2%. Therefore, to prescribe the factor VIII activity necessary to correct a 70-kg hemophilia patient with 5% factor VIII activity to 95% of normal, one would calculate as follows:

$$\frac{95\% - 5\%}{2\%} \times 70\text{kg} = 3{,}150 \text{ units of factor VIII}$$

Fauci AS, Braunwald E, Kasper DL, et al., eds. *Harrison's Principles of Internal Medicine.* 17th ed. New York: McGraw-Hill; 2008:726.

Pisciotto, PT. *Blood Transfusion Therapy: A Physician's Handbook.* 4th ed. Bethesda: American Association of Blood Banks, 1993.

B.3. Would you administer factor VIII using a bolus or infusion technique?

Factor VIII concentrates are very stable at room temperature after reconstitution and therefore are appropriate for infusion use. By titrating the infusion, the desired factor VIII level can be maintained, eliminating both the overshoot and the subtherapeutic levels seen with the bolus technique. Although the infusion technique requires close observation, less total factor VIII is infused and therapeutic levels are maintained.

Fauci AS, Braunwald E, Kasper DL, et al. eds. *Harrison's Principles of Internal Medicine*. 17th ed. New York: McGraw-Hill; 2008:726–727.

Schulman S, Martinowitz U. Continuous infusion instead of bolus injections of factor concentrate? *Haemophilia*. 1996;2:189–191.

B.4. Can a hemophiliac patient fail to mount an appropriate coagulation response following factor VIII infusion?

Approximately 10% to 20% of hemophiliacs will develop an antibody inhibitor against factor VIII and will not achieve the anticipated response following factor VIII infusion.

Hines RL, Marschall KE, eds. Stoelting's *Anesthesia and Co-existing Disease*, 5th ed. Philadelphia: Churchill Livingstone, 2008:421.

B.5. If a patient with hemophilia does not respond to a bolus injection of factor VIII, can an infusion technique be effective?

Some patients who do not respond well to bolus injections may have measurable low titers of inhibitors. A continuous infusion has proved effective in this situation to stop hemorrhage, because appropriate levels of the missing factor can be achieved relatively easily by the infusion method. Those patients with high titers and without measurable factor level during the infusion have also been known to stop bleeding with an infusion technique, likely because complete inhibition of the factor occurs only after 1 to 2 hours. If the factor is continuously infused, there will always be some that is circulating, unneutralized, and hemostatically active.

B.6. How much factor VIII activity is present in fresh frozen plasma (FFP)? What are the risks associated with administration of FFP?

FFP is prepared from a single donor and contains all plasma proteins, including factor VIII. Factor VIII activity is between 0.7 and 0.9 units of clotting activity per milliliter of FFP. Following blood donation and plasma separation, approximately 200 mL of FFP is extracted.

The risks associated with the transfusion of FFP are similar to those with any other single donor blood product. These include associated blood proteins and infectious processes such as hepatitis B and C and HIV. The incidence of transfusion-related infections has decreased over the years as screening procedures improved. Currently, the risk of transmitting hepatitis B infection following transfusion of FFP exceeds that of HIV and hepatitis C. The decrease in transfusion-related hepatitis C was secondary to nucleic acid testing, which was initiated in 1999. Hepatitis B currently occurs at a frequency of 1/60,000 to 1/200,000, and hepatitis C occurs at 1/800,000 to 1/1,600,000. HIV infection currently occurs at 1

per 1.5 to 2 million donor exposures. Current techniques for preparation of FFP, including heat, detergent treatments, and monoclonal antibody purifications, can minimize or eliminate the risk of viral pathogen transmission. Some risks associated with transfusion are not related to transmission of infectious organisms. These include transfusion-related acute lung injury (TRALI), which occurs with an incidence of 1/5000 units transfused and is more commonly seen after transfusion of FFP than other blood products. The incidence of TRALI after FFP transfusion is suspected to decrease with the introduction of male-only plasma donors. Multiparous female donors have been excluded from the donor pool because the antibodies in their plasma (anti-human leukocyte antigen and others) attack recipient antigens and are felt to be a cause of TRALI. Other aspects of immune modulation are seen after transfusion and may increase the risk of infection and postoperative complications.

Spahn DR, Casutt M. Eliminating blood transfusions: new aspects and perspectives. *Anesthesiology.* 2000;93:244–255.

B.7. What are the indications for the administration of FFP?

The National Institute of Health multidisciplinary consensus development panel determined that FFP was the most overused blood product for transfusion. Many clinicians have used FFP as a volume expander; nevertheless, indications for its use should be limited to documented evidence of isolated factor deficiency, reversal of antithrombin III deficiency, selected immunodeficiency's, thrombocytopenia purport, and massive blood transfusion.

Barash PG, Cullen BF, Stoelting RK, et al., eds. *Clinical Anesthesia.* 6th ed. Philadelphia: Lippincott Williams & Wilkins, 2009:380–381.

B.8. How is cryoprecipitate prepared? What are the components in cryoprecipitate? How much factor VIII activity is present in cryoprecipitate? What are the indications for cryoprecipitate?

Cryoprecipitate is the fraction of plasma that precipitates when FFP is thawed. In addition to factor VIII, this solution also contains significant levels of factor VIII: vWF, factor XIII, and fibrinogen. This product contains high concentrations of factor VIII in a small volume, usually between 5 and 13 units of factor VIII clotting activity per milliliter.

Cryoprecipitate is indicated for patients with hemophilia, vWD, hypofibrinogenemia, as well as uremic platelet dysfunction. Small amounts of red cell fragments may be present in cryoprecipitate; therefore, it may sensitize Rh-negative individuals to the Rh antigens if the donor is Rh positive.

White GC, McMillan CW, Kindon HS. The use of recombinant antihemophilic factor in the treatment of two patients with classic hemophilia. *N Engl J Med*. 1989;320:154.

B.10. What is the role of desmopressin D-arginine vasopressin (DDAVP) for hemostatic management in this patient?

This synthetic analog of the antidiuretic hormone is used to prepare patients with mild and moderate hemophilia for minor surgery. Intravenous DDAVP will rapidly release preformed factor VIII complex, which leads to a twofold to threefold increase in circulating factor VIII within 30 to 60 minutes of administration. In addition, factor VIII and vWF are released from the endothelial cells. In a patient with mild or moderate hemophilia A or vWD, this influx of factor VIII may provide adequate hemostasis for minor elective surgical procedures. The half time of this released factor is approximately 12 hours, and repeated administration of DDAVP will deplete the storage capacity in the endothelial cells.

Barash PG, Cullen BF, Stoelting RK, et al., eds. *Clinical Anesthesia*. 6th ed. Philadelphia: Lippincott Williams & Wilkins, 2009:404–405.

Hines RL, Marschall KE, eds. Stoelting's *Anesthesia and Co-existing Disease*. 5th ed. Philadelphia: Churchill Livingstone, 2008:427–428.

Table 31.3 The Advantages and Disadvantages of Factor VIII Products

COMPONENT	ADVANTAGE	DISADVANTAGE
Cryoprecipitate	Readily available, long shelf life, relatively low risk for hepatitis and AIDS	Allergic reaction, hyperfibrinogenemia if large volumes are used
Factor VIII concentrates	Easily stored and reconstituted, long life, known potency	Multiple plasma product with high risk of infectious disease
Monoclonal purified factor VIII	Stability, biologic safety	Cost (?)
Recombinant Factor VIII	Easily stored, reconstituted, long shelf life, +/− less risk for developing inhibitors	Allergic hypersensitivity Cost

B.11. What is the role of ε-aminocaproic acid (EACA) in the perioperative period for the patient with hemophilia?

EACA is an antifibrinolytic that has been used successfully in patients with hemophilia to prevent bleeding following minor surgical procedures. Its use in major surgical procedures has not been well documented. If DDAVP is to be used preoperatively, the release of plasminogen activator by DDAVP mandates the use of EACA as well.

Barash PG, Cullen BF, Stoelting RK, et al. eds. *Clinical Anesthesia*. 6th ed. Philadelphia: Lippincott Williams & Wilkins, 2009:405.

B.12. Is there a role for recombinant activated factor VII (rFVIIa) in the treatment of hemophilia?

Hemophilia A represents the majority of patients afflicted with hemophilia. Approximately 30% of patients with hemophilia A have inhibitory antibodies ("inhibitors") to FVIII. Fewer patients afflicted with hemophilia B develop inhibitory antibodies (1% to 3%). Risk factors for the development of "inhibitors" include race, severity of the disease (less than 1% FVIII levels), having a hemophiliac brother with "inhibitors," and certain mutations involving the FVIII gene. In patient's with "inhibitors," alternative treatment is occasionally necessary to address surgical and nonsurgical hemorrhagic crises. The U.S. Food and Drug Admininstration has approved the use of rFVIIa (NovoSeven, Novo Nordisk, Bagsvaerd, Denmark) in patients afflicted with hemophilia and inhibitory antibodies who experience a bleeding episode. Some studies have highlighted the effectiveness of rFVIIa for establishing hemostasis in this patient population.

Negrier C, Hay CR. The treatment of bleeding in hemophilic patients with inhibitors with recombinant factor VIIa. *Semin Thromb Hemost*. 2000;26:407–412.

B.13. What is the mechanism and dosing of rFVIIa?

Factor VIIa binds to TF exposed at the site of injury and generates enough thrombin to activate factors V, VIII, and XI, as well as platelets. In high doses, rFVIIa binds to thrombin-activated platlets and activates factor X independent of factor VIII or IX. This mechanism of activating factor X and generating thrombin bypasses the need for FVIII and FIX. This alternative pathway for providing hemostasis makes rFVIIa a potent treatment for patients afflicted by hemophilia with "inhibitors." The typical doing schedule for hemostatic prophylaxis in patients undergoing elective surgery is 90 to 120 μg/kg, with repeated doses every 2 to 3 hours. This dosing regimen has been

shown to be effective 90% of the time in treating mild to moderate bleeding episodes in patients with hemophilia patients with "inhibitors." Recent studies support the use of larger bolus doses of rFVIIa (greater than 200 μg/kg) in patients experiencing more significant bleeding. The increased dosing of rFVIIa is thought to enhance thrombin generation on activated platelets and thus promote the formation of a more stable fibrin clot.

C. Intraoperative Management

C.1. Is it safe to administer an intramuscular injection to this patient before surgery?

Intramuscular injections can be safely administered to any patient with a factor VIII activity greater than 30%. Therefore, if appropriate factor VIII correction has occurred before surgery, an intramuscular injection would be considered safe. It is unlikely, though, that an intramuscular injection would be necessary for this patient. If a sedative hypnotic or anticholinergic drug would be necessary before the induction of anesthesia, it would be prudent to use an intravenous route.

Hines RL, Marschall KE, eds. Stoelting's *Anesthesia and Co-existing Disease*. 5th ed. Philadelphia: Churchill Livingstone; 2008:420–421.

C.2. Would an axillary block be appropriate for this patient?

Regional anesthesia has long been considered contraindicated in patients with hemophilia because the concern of hematoma formation at the regional site. With proper management of the coagulation status, regional techniques have been successfully performed in patients with hemophilia. As with any patient, the benefit of regional technique must be weighed against the potential risk associated with this technique. Certainly, in a patient with a full stomach, a regional technique might be more appropriate because of the relative risk of aspiration. For a completely elective procedure in the patient with hemophilia, a more prudent course might be general anesthesia.

Sampson JF, Hamstra R, Aldrete JA. Management of hemophiliac patients undergoing surgical procedures. *Anesth Analg*. 1979;58:133–135.

C.3. If general anesthesia is used as a technique, would it be safe to intubate the patient's trachea?

Airway management of the patient with hemophilia presents a unique challenge for the anesthesiologist because of the risk of hemorrhage in the tongue or neck, which could completely compromise the upper airway of the patient. Therefore, manipulation of the airway during intubation should not be performed until appropriate replacement factors have been administered. Care should be used in placing the mask on the patient to avoid trauma to the lips, tongue, or face; elective laryngoscopy should be attempted only following preoperative factor correction and achievement of complete muscle relaxation. A smaller than predicted well-lubricated endotracheal tube should be used for intubation, and nasal intubation, with its propensity for epistaxis, should be avoided.

Bogdan CJ, Strauss M, Ratnoff OD. Airway obstruction in hemophilia (factor VIII deficiency): a 28-year institutional review. Laryngoscope 1994;104:789–794.

C.4. Would you use any special precautions for this patient who is positive for HIV?

Standard precautions should be used for all patients regardless of their HIV status. Strict attention to aseptic technique throughout the surgical procedure should be emphasized (postoperative infections are more common in HIV-positive patients undergoing orthopedic procedures such as these).

Hines RL, Marschall KE, eds. Stoelting's *Anesthesia and Co-existing Disease*. 5th ed. Philadelphia: Churchill Livingstone, 2008:419–421.

Thomason HC 3rd, Wilson FC, Lachiewiczpf PF, et al. Knee arthroplasty in hemophiliac arthropathy. *Clin Ortho*. 1999;360:169–173.

C.5. What special considerations should be taken in choosing anesthetic drugs for this patient?

Coexisting liver disease is a common complication in the patient with hemophilia as a result of hepatitis acquired from previous blood or factor transfusions. As a result, drugs that are metabolized by the liver should be used with caution in these patients. A balanced intravenous technique might be preferable to an inhaled anesthetic because of the reduced hepatic blood flow observed in an inhaled technique.

Hines RL, Marschall KE, eds. Stoelting's *Anesthesia and Co-existing Disease*. 5th ed. Philadelphia: Churchill Livingstone, 2008:419–421.

C.6. During the operative procedure, the surgeon indicated that significant blood loss had occurred. Would you transfuse this patient with packed red blood cells or whole blood?

In general, blood banks will fractionate donated blood into component parts, allowing individual transfusion of red cells, platelets, FFP, or cryoprecipitate. Following blood loss, oxygen-carrying capacity and volume expansion are required and usually packed red blood cells and a salt solution are sufficient. In a patient with hemophilia, transfusion of packed red blood cells will further dilute already depressed circulating

factor VIII levels; therefore, transfusion of whole blood in such a patient, if it can be obtained, would be appropriate. With this technique, both oxygen carrying capacity and all components of coagulation will be replenished.

Miller RD, ed. *Miller's Anesthesia*. 7th ed. Philadelphia: Churchill Livingstone, 2010:1758.

C.7. During the transfusion of the first unit of whole blood, the patient's temperature rose from 36.8° C to 37.9° C (98.24° F to 100.22° F). What immediate steps should be taken by the anesthesiologist at this time?

Ruling out an acute hemolytic transfusion reaction should always be considered when a patient becomes febrile during a blood transfusion. The anesthesiologist should immediately discontinue the transfusion, and blood should be drawn from the patient and sent to the blood bank with the questionable unit of blood to allow further cross-matching. An additional tube of blood should be collected and allowed to sit undistributed for 5 to 10 minutes, allowing separation of red cells from plasma. The presence of free plasma hemoglobin in the serum is diagnostic of a hemolytic reaction. In the presence of an acute hemolytic blood transfusion reaction, profound hypotension requiring the use of vasopressors is likely. Fluid and diuretic therapy may be required to maintain renal function. A febrile reaction that is not due to an acute hemolytic transfusion reaction can occur with blood transfusion; these are usually self-limited. Once a transfusion reaction is ruled out, further investigation of the increase in temperature is warranted.

Miller RD, ed. *Miller's Anesthesia*. 7th ed. Philadelphia: Churchill Livingstone, 2010:1752–1754.

C.8. Does giving blood intraoperatively increase the potential for the development of factor VIII inhibitors?

Although 10% to 30% of all patients with hemophilia will develop a circulating inhibitor of factor VIII, no evidence has been demonstrated that development of such an inhibitor is related to the number of transfusions that the patient receives. As a result, the administration of blood products in this setting should not be withheld for fear of inducing an inhibitor response.

Rodriguez-Merchan EC, Christine A. Lee. Inhibitors in Patients with Haemophilia, 2002:17–19.

C.9. Can factor VIII be safely administered to patients who have developed circulating inhibitors?

Occasionally, patients with the most severe variance of hemophilia (factor levels less than 1%) develop immunoglobulin G antibodies to the deficient factor. The inhibitors may be of low titer and transient or of extremely higher titer and very persistent. The "Bethesda unit" of inhibition is defined as the amount of inhibitory activity in 1 mL of plasma that decreases the factor VIII level in 1 mL of normal plasma from 1 to 0.5 units. It is almost impossible to overpower a high-titer inhibitor, but, when life-threatening hemorrhage occurs, massive doses of factor VIII concentrates or plasmapheresis with replacement of factor VIII can be given and

may be of temporary benefit. Replacement with large amounts of factor VIII concentrate may provide temporary hemostasis but will stimulate an increase in the antibody titer. Porcine factor VIII may provide hemostasis because of its distinct antigenicity, even in the presence of circulating inhibitor. Immunosuppressive therapy is of no value.

Alternative approaches to therapy of the hemophilic patient with inhibitors involve the use of other agents, such as activated prothrombin complex concentrated, which contain activated vitamin K–dependent enzymes as well as recombined factor VIIa. These activated coagulants enter the coagulation cascade distal to the level of factor VIII and therefore bypass the effects of the inhibitor. Factor eight inhibitor bypass activity is one such prothrombin complex concentrate that is used in the United States to treat hemophilia with inhibitors. Thrombosis is a possible complication when using activated prothrombin complex concentrated.

Porcine factor VIII is effective in patients with hemophilia with inhibitors. The porcine factor VIII provides adequate factor VIII activity in patients with less than 50 Bethesda units of inhibitor. The usual starting dose is 100 to 150 porcine units per kg.

Behrman RE, Kliegman RM, Jenson HB, eds. *Nelson Textbook of Pediatrics*. 16th ed. Philadelphia: WB Saunders; 2000:1508–1511.

Perkins JT, Vender JS. Transfusion therapy. In: Collins VJ, ed. *Physiologic and Pharmacologic Bases of Anesthesia*. Baltimore: Williams & Wilkins; 1996:219–221.

C.10. The surgeon has requested the use of a tourniquet to minimize surgical bleeding. What are the physiologic and hemodynamic responses to tourniquet use?

Although the tourniquet will provide optimal surgical conditions, the physiologic and hemodynamic consequences are significant. Anaerobic metabolism distal to the tourniquet begins approximately 8 minutes after inflation; a decrease in nicotinamide adenine dinucleotide and creatine phosphate stores in muscle will occur over the next 30 to 60 minutes. As a result, cellular acidosis will cause the release of myoglobin, intracellular enzymes, and potassium. In addition, the limb loses internal heat and may approach room temperature.

Hemodynamic changes are seen when the tourniquet is inflated and deflated. Exsanguination of the limb and tourniquet inflation expands central venous blood volume, which may have significant hemodynamic consequences in a patient with limited cardiac reserve. Tourniquet deflation and reperfusion of the limb can be associated with profound decreases in central venous and arterial blood pressure, as a result in a decrease in vascular resistance with the washout of metabolites produced during the ischemic period. Prolonged inflation (greater than 45 to 60 minutes) can result in systemic hypertension for reasons that are likely due to the presence of a critical level of ischemia in the muscle or nerve.

Miller RD, ed. *Miller's Anesthesia*. 7th ed. Philadelphia: Churchill Livingstone, 2010:2252.

C.11. Is it appropriate to suction the endotracheal tube and oropharynx of this patient before extubation?

Removal of secretions that might be aspirated is essential before the extubation of any patient; nevertheless, suctioning of the oropharynx of hemophiliac patient can trap

mucosa in the suction catheter and result in the formation of an oral hematoma. In a patient with hemophilia, gentle oral suctioning under direct vision is appropriate to remove all secretions.

Hyderally H, Stark DCC. Hemophilia: anesthetic implications. *Mt. Sinai J Med.* 1977;44:397–399.

D. Postoperative Management

D.1. What special consideration should be given to postoperative pain management for this patient?

It is important to avoid any postoperative pain supplements that might produce a bleeding diathesis in the patient with hemophilia. Analgesics containing aspirin or nonsteriodal anti-inflammatory drugs should obviously be avoided. Antihistamines and antitussives can inhibit platelet aggregation and prolong bleeding time. Opioid analgesics or acetaminophen-based products should be appropriately titrated for postoperative pain management. If regional blockade with a catheter technique was used for anesthesia, postoperative analgesics should be administered through this route.

Miller RD, ed. *Miller's Anesthesia*. 7th ed. Philadelphia: Churchill Livingstone, 2010:2762–2764.

D.2. What steps should be taken to enhance the coagulation status of this patient in the postoperative period while at home?

It is important that factor VIII levels are supplemented for at least 2 to 4 weeks following surgery. It has been shown that allowing factor VIII levels to fall to the levels normally associated with these patients can result in postoperative hemorrhage. Postoperatively, many clinicians recommend maintaining levels at 80% of normal for the first 4 postoperative days, whereas others feel that levels of at least 40% of normal are adequate. The consensus is that factor VIII levels on postoperative days 5 to 8 should be maintained at 30% to 40% of normal, whereas levels of 10% to 20% of normal should be maintained for the following 2 to 4 weeks.

Lofqvist T, Nilsson I, Petersson C. Orthopaedic surgery in hemophilia. *Clin Ortho Rel Res.* 1996;332:232–241.

D.3. Can this patient be treated with factor VIII supplements using home infusion?

Administration of factor VIII concentrate by continuous infusion is routinely used at medical centers for postoperative patients with hemophilia being treated on an inpatient basis. In the transition of many surgical procedures to the outpatient arena, home infusion of factor VIII can provide the same level of hemostatic protection. Home infusion of purified factor VIII concentrate has been shown to be safe, efficacious, and convenient for postoperative patients and should be used for this patient.

CHAPTER 32

Sickle Cell Disease

CHRIS R. EDMONDS AND VINOD MALHOTRA

A 30-YEAR-OLD AFRICAN-AMERICAN WOMAN with avascular necrosis of her right hip was admitted for a total hip arthroplasty. Her hematocrit was 22%, blood pressure was 130/90 mm Hg, and pulse was 107 beats per minute. She has a past medical history of recurrent joint pain, bone pain, jaundice, and abdominal pain requiring multiple hospitalizations for analgesia. Her past surgical history was remarkable for a cholecystectomy, and her postoperative course was remarkable for a prolonged hospitalization for respiratory complications.

A. Medical Disease and Differential Diagnosis

1. What was the most likely underlying medical problem in this patient? How would you confirm the diagnosis of sickle cell anemia (SCA)?
2. What is sickle cell disease (SCD)?
3. What is sickle cell trait (SCT)?
4. What are some of the other hemoglobinopathies and what are their clinical features?
5. What are the clinical features of SCD?
6. Describe the different types of sickle cell crises.
7. Discuss the pathophysiologic effects of SCD.
8. What is acute chest syndrome?

B. Preoperative Evaluation and Preparation

1. What preoperative evaluation would you perform on this patient before anesthesia?
2. How would you prepare this patient for general anesthesia and regional anesthesia?
3. Discuss the indications for preoperative exchange transfusion in this patient.
4. What are the indications for blood transfusion in SCD?

C. Intraoperative Management

1. Discuss the anesthetic management for this patient. Discuss both regional and general anesthesia considerations.
2. Discuss how the comorbidities associated with SCD can affect your anesthetic management.
3. What precautions should one take to prevent sickling in this patient?

D. Postoperative Management

1. Discuss the postoperative management of this patient.
2. What complications might occur in this patient in the immediate postoperative period?
3. What is the treatment of sickle cell crisis?
4. What is the role of hyperbaric oxygen therapy in treatment of sickle cell crisis?

A. Medical Disease and Differential Diagnosis

A.1. What was the most likely underlying medical problem in this patient? How would you confirm the diagnosis of sickle cell anemia (SCA)?

For a young African-American patient presenting with a history of joint pain, bone pain, abdominal pain, and anemia, the most likely diagnosis is SCD. Other diagnoses to consider include other hemoglobinopathies, dermatomyositis, glucose-6-phosphate dehydrogenase (G6PD) deficiency, and porphyria. Nevertheless, given the constellation of symptoms and the laboratory findings, SCD is the most likely diagnosis. A hemoglobin (Hgb) electrophoresis will confirm the diagnosis and provide the percentage of abnormal hemoglobin S (HgbS).

Firth PG. Anesthesia and hemoglobinopathies. *Anesthesiol Clin*. 2009;27:321–336. doi:10.1016/j.anclin.2009.05.001.

A.2. What is sickle cell disease (SCD)?

SCD is a hereditary hemoglobinopathy resulting from inheritance of a *β-globin* gene mutation located on chromosome 11. This mutation leads to a single-point mutation where adenine is replaced with thymine. The mutant β-allele codes for production and assembly of a variant Hgb (β-S). The molecular basis of SCD has been demonstrated to be the substitution of valine for glutamic acid in the sixth position from the *N*-terminus of the β-chains of Hgb. This substitution replaces a hydrophilic negative-charged amino acid (glutamic acid) with a hydrophobic nonpolar amino acid (valine). This greatly destabilizes the structure of Hgb and exposes highly reactive hydroxyl groups on the protein surface. The mutation in β-S Hgb accelerates the denaturation of the Hgb molecule and significantly decreases its solubility. Decreased oxygen tension causes conformational changes in the Hgb molecule, allowing hydrophobic bonds to form between the BS-6 valine of one chain and the BS-85 phenylalanine and the BS-88 leucine of a second chain. This bond forms insoluble tetramers that bond with other tetramers to form long helical strands that subsequently polymerize, causing deformation of the red blood

cell membrane into a sickle shape. The result is a red blood cell that is less able to transverse the capillaries of the microcirculation, disposing the end organ to hypoxia and ischemic damage when sickle cells are present in sufficient quantity. In the United States, the estimated prevalence of Hgb SS disease is 1:625 (0.2%) in people of African descent. Patients with SCA have early mortality, with the median age of death in the late 40s to early 50s.

A.3. What is sickle cell trait (SCT)?

SCT is the heterozygous or carrier state of SCD. Large-scale screening for SCD in American military recruits revealed an incidence of SCT (HbAS) of 8% to 10% in African-Americans and 0.05% to 0.08 % in others. HbAS cells begin to sickle only when oxygen saturation of Hgb is less than 20%. No difference has been found between normal persons (HbAA) and those with HbAS regarding survival rates or incidence of severe disease, with one exception: patients with HbAS have a 50% increased risk for pulmonary infarctions. Studies have suggested that SCT provides a survival advantage over hematologic normal individuals when infected by the malarial parasite *Plasmodium falciparum*.

A.4. What are some of the other hemoglobinopathies and what are their clinical features?

The most common hemoglobinopathies include the thalassemias, Hgb C disease, and SCA. Thalassemia arises from alterations in one or more of the four genes that

code for the α-chain. The mildest form of thalassemia (loss of one α-gene) presents as a mild form of anemia, whereas the most severe form (loss of all four genes) is incompatible with life. Hgb C results from a mutation in the *β-globin* gene. Hgb C disease is a relatively benign disease producing a mild hemolytic anemia and splenomegaly. However, when it is paired with a β-S mutation, the disease is more severe. Other rare hemoglobinopathies will not be discussed further.

Each Hgb gene mutation of the heterozygous form causes little or no clinical consequence, but when both genes of a heterozygote are abnormal, a disease state is evident. Heterozygous combinations such as HbS and HbC (HbSC disease), and β-thalassemia mutation (HbS-β-thalassemia) usually cause a milder clinical course than that of SCD.

A.5. What are the clinical features of SCD?

The clinical features of SCD are manifested through indolent end-organ damage with intermittent acute episodes of severe pain and pulmonary complications. Although SCD is a disease of Hgb, it ultimately affects all organ systems. It is usually the acute problems that bring these individuals to the attention of a physician. The clinical manifestations by organ systems are presented in Table 32.1.

The progression and severity of SCD is variable. Many of the patients have an indolent course, whereas a smaller subset suffer from an early end-organ failure and an early death. Pulmonary, neurologic, and renal disease are the leading causes of morbidity and mortality.

Table 32. 1 Clinical Manifestations of Sickle Cell Disease

SYSTEM	SYMPTOMS
Central nervous system/neurologic	• Stroke (cerebrovascular accident) in children as well as adults (50%–70% recurrence within 3 years) • Proliferative retinopathy/blindness • Painful crisis • Chronic pain • Peripheral neuropathy • Poor school performance
Cardiovascular	• Conduction abnormalities secondary to iron overload • Hypertension • Cor pulmonale • Left and right ventricular dysfunction • Chronic ulcers
Pulmonary	• Infarction, pulmonary fibrosis • Infection • Restrictive/obstructive lung disease • Acute chest syndrome • Pulmonary hypertension (30%–40%) • Airway hyperactivity
Genitourinary	• Hyposthenuria, hematuria, proteinuria • Chronic renal insufficiency (5%–20 %) • Renal failure • Priapism (10%–40% of men)
Gastrointestinal	• Cholelithiasis (70%) • Acute hepatic syndrome • Elevated liver function tests, hyperbilirubinemia • Hepatopathy • Cirrhosis (16%–29%) • Dyspepsia secondary to mucosal ischemia • Sickle girdle syndrome (mesenteric ischemia)
Musculoskeletal	• Osteomyelitis (*Staphylococcus/Salmonella*) • Dactylitis • Avascular necrosis • Infarction
Heme/immunologic	• Chronic anemia • Autosplenism • Susceptibility to infections with encapsulated organisms • Erythrocyte alloimmunization from blood transfusions • Sequestration crisis • Hemolytic crisis • Aplastic crisis • Immune dysfunction • Hypercoagulability • Chronic inflammation

Table 32.2 Types of Sickle Cell Crises

TYPE	PATHOPHYSIOLOGY	TREATMENT
Vaso-occlusive	Pain secondary to obstruction of flow in the microvascular beds leading to localized ischemia	• Hydration • Analgesia • Incentive spirometry
Splenic sequestration	Acute painful enlargement of the spleen Acute hypovolemia	• Restore circulatory volume, possible splenectomy
Aplastic	Sudden cessation of bone marrow activity Acute worsening of anemia usually associated with viral infection (parvovirus B19) Recovery in 7–10 days	• Supportive therapy • Blood transfusion
Hemolytic crisis	Acute accentuated decrease in hemoglobin level Secondary to red cell destruction Usually associated with coexisting G6PD deficiency	• Supportive therapy • Blood transfusion

G6PD, glucose-6-phosphate dehydrogenase.

A.6. Describe the different types of sickle cell crises.

Sickle cell crisis refers to the acute clinical picture generally caused by sickling of red blood cells in the *microcirculation*. Four main clinical types of crises have been described as follows in Table 32.2.

The most common crises in SCD is vaso-occlusive crisis, which is characterized with intermittent, recurrent acute episodes of severe pain. It is generally felt that the central cause of pain is ongoing acute ischemia, vaso-occlusion, and infarction. The precise pathophysiology and nociceptive pathways have not been elucidated. Patients in vaso-occlusive crisis present with fever, anemia, spine pain, limb pain, and abdominal pain. They are tachypneic and may have an enlarged liver and spleen in addition to abdominal tenderness. Serjent et al. reported that in 118 patients having 183 painful crises, the location was noted to be in the lumbar spine (49%), abdomen (32%), femoral shaft (30%), and the knee (21%). There is usually no identifying triggering agent for most vaso-occlusive crises. The average rate of painful crises per patient year is 0.8%. There is a subset of patients (5.2%) who average 8 to 10 crises a year, which accounts for 33% of all hospitalizations. Mortality positively correlates with increased pain rate in adults.

A.7. Discuss the pathophysiologic effects of SCD.

The pathophysiologic effects of SCD is not limited to the structure or deformation of the erythrocyte. The interaction and balance between the Hgb molecule,

cytoplasm, and cell wall and the vascular endothelium is drastically altered to create chronic systemic biochemical alterations that produce the clinical features of SCD. As in vaso-occlusive crisis, there is a triggering insult, such as infection, surgical stress, or ischemia-reperfusion injury, that catalyzes a complex interaction among sickled cells, endothelial regulation of flow, inflammatory cytokines, platelet aggregation factors, and vasoconstriction, leading eventually to ischemia, infarction, and cell death. This cascade leads to a vicious cycle that eventually causes end-organ damage and dysfunction. End-organ damage that occurs in sickle cell states is attributable to three pathways. In the erythrocyte cytoplasm, the loss of Hgb structural stability leads to increased oxidation of heme with subsequent denaturation, deterioration, and polymerization. Iron oxidation produces superoxides (O_2^-) and hydrogen peroxides ($H_2O_2^-$), which increases the formation of highly reactive hydroxyl radicals($-OH$). In the cell membrane, free iron and iron-containing compounds accumulate, leading to clustering of membrane surface membranes, abnormal cation permeability, and cellular dehydration. This complex series of events within the erythrocyte increases adherence to the vascular endothelium, exposing it to shear and oxidative stress. The interaction between the abnormal erythrocytes and the vascular endothelium produces chronic inflammation, upregulation of endothelial cell adhesion molecules and altered expression of endothelial nitric oxide synthetase. Systemically, there is an increase in leukocyte counts, activation of the coagulation pathways, increase in inflammatory compounds, and increase in circulating endothelial cells in the plasma. The complex pathologic interaction between sickling of cells in blood vessels and the vascular endothelium leads to infarcts, tissue destruction, and consequent end-organ failure. The pathogenesis is shown in Figure 32.1.

A.8. What is acute chest syndrome?

Acute chest syndrome is a term used to describe an acute pulmonary complication of SCD. It is defined by the finding of a new pulmonary infiltrate involving at least one complete lung segment on chest radiograph that is not due to atelectasis. It presents with a constellation of pulmonary symptoms and signs in a patient with SCD. These include fever (temperature 38.5° C [101.3° F]), wheezing, coughing, tachypnea, chest pain, and hypoxemia (less than 92% on room air). Pleural effusions (55%) are commonly seen on chest radiographs. Acute chest syndrome frequently follows vaso-occlusive crises; therefore, vaso-occlusive pulmonary infarction may be a precipitating factor. Other causes include infection (viral, chlamydia, mycoplasma, and bacterial) and pulmonary fat embolism resulting from bone marrow necrosis. Acute chest syndrome is a common postoperative complication in patients with SCD who have a history of pulmonary disease following general anesthesia. It is one of the most common causes of death in adults with SCD. Acute chest syndrome

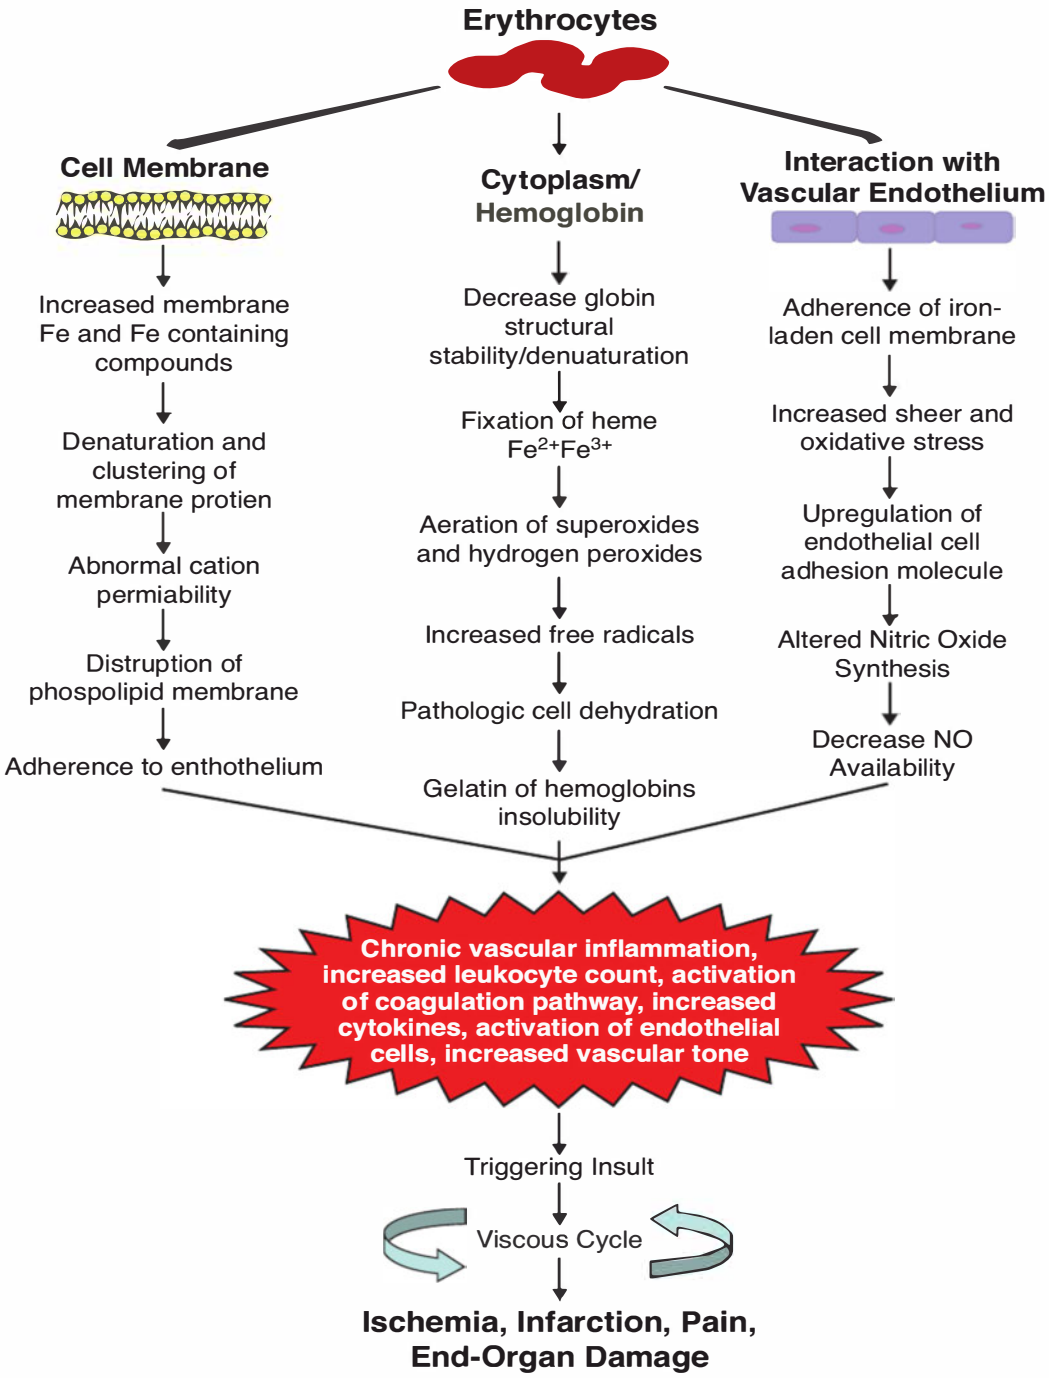

Figure 32.1 Pathogenesis of sickle cell damage.

can be prevented by judicious hydration, incentive spirometry, effective analgesia, and avoidance of even mild hypothermia during the crises. Acute chest syndrome should be treated with bronchodilators, antibiotics, and exchange transfusion, when necessary.

B. Preoperative Evaluation and Preparation

B.1. What preoperative evaluation would you perform on this patient before anesthesia?

The aim of the preoperative assessment in a patient with SCD is to determine the perioperative risk of this multisystemic disease and how the end-organ damage will affect the anesthetic management (see Table 32.1). A careful history should be obtained and physical examination done, and the cardiopulmonary status should be thoroughly investigated, in view of the increased incidence of cardiac and pulmonary morbidity in these patients. A history of frequent hospitalizations in the year before surgery significantly increases the likelihood of a vaso-occlusive crisis in the perioperative period. Immunization status for Pneumovax and *Haemophilus influenzae* vaccine should be checked. Other characteristics that increase the perioperative risk are age, pregnancy, and infection. One should correct hypovolemia and treat infection appropriately preoperatively. Laboratory investigation should include a complete blood count, blood urea nitrogen, serum creatinine, urinalysis, electrocardiogram, chest radiograph, pulse oximetry, and liver function tests. In addition, the following tests may be helpful:

- Arterial blood gas, if indicated
- Sickle cell preparation (if diagnosis is unclear)
- Hgb electrophoresis to determine HbS, quantitatively
- Reticulocyte count
- Type and cross (alloimmunization may make this difficult)
- Pulmonary function test (if severe pathology, paroxysmal dyspnea, or history of acute chest syndrome)
- Echocardiogram in patients with history of pulmonary hypertension or cardiomegaly
- Neurologic imaging (if there are psychological or behavioral changes)

Park KW. Sickle cell disease and other hemoglobinopathies. *Int Anesthesiol Clin.* 2004;42:77–93.

B.2. How would you prepare this patient for general anesthesia and regional anesthesia?

- Informed consent should be obtained to explain the options, risk, and benefits of the different types of anesthetics used.
- Preoperative hydration should be initiated to treat baseline volume deficit.
- Euvolemia should be maintained preoperatively (remembering that the patient is on nothing by mouth status and may have a urine concentration defect requiring volume replacement).
- Any infections should be treated preoperatively, if possible.
- End-organ dysfunction should be identified and treated appropriately.
- Type and crossmatching may be difficult in these patient's because of alloimmunization.
- Consider transfusion of red blood cells to maintain oxygen-carrying capacity. Transfusion guidelines should be based on comorbidities, surgical risk, and degree of anemia. Transfusions should be individualized and based on the patient's risk/benefit. Efforts should be made for leukocyte reduction techniques, as with buffy coat–poor red cells, to reduce the incidence of leukocyte antigen alloimmunization. The goals of transfusion are to achieve an Hgb concentration of greater than 8 g per dL and to ensure that Hgb A represents more than 40% of the total Hgb present. Past practices of reducing HgbS levels to less than 30% do not seem to improve outcome and increase transfusion-related complications.

B.3. Discuss the indications for preoperative exchange transfusion in this patient.

Controversy exists as to whether these patients benefit from preoperative exchange transfusion. For high-risk surgical procedures such as cardiopulmonary bypass an exchange transfusion may be recommended. Nevertheless, a series of reports of cardiopulmonary bypass cases in which exchange transfusions were not performed or only a partial exchange was performed. If an exchange transfusion is required, the

exchange transfusion should be performed with buffy coat–free packed red blood cells to reduce the HbS fraction to less than 40%. Nevertheless, growing evidence indicates that most surgical procedures can be safely performed in patients with SCD without aggressively transfusing. For example, for certain surgical procedures, it has been shown that a packed red blood cell transfusion done simply to increase the Hgb level to 10 g per dL is as effective in decreasing perioperative morbidity as is exchange transfusions to reduce the HbS(S) levels to less than 40%. Exchange transfusion is a therapy often used in patients with SCD complicated by acute chest syndrome. It is beneficial to keep the hematocrit lower than 35% with an exchange transfusion because an increased hematocrit will increase blood viscosity and stasis in the circulation.

Vichinsky EP, Haberkern CM, Neumayo L. A comparison of conservative and aggressive transfusion regimens in the perioperative management of sickle cell disease. *N Engl J Med*. 1995;333:206–213.

B.4. What are the indications for blood transfusion in SCD?

Blood transfusions should be guided by the clinical picture and the potential for blood loss. Prophylactic transfusion remains controversial and is of questionable benefit in mild-to-moderate risk cases. Some of the clinical indications for blood transfusion in SCD include the following:

Acute conditions

- Vaso-occlusive crises with organ infarction and dysfunction
- Sequestration syndrome
- Acute hemolysis with exacerbation of anemia
- Aplastic crisis
- Acute chest syndrome
- Acute multiorgan failure
- Severe unresponsive priapism
- Protracted painful crisis
- High-risk surgery (e.g., cardiovascular, thoracic)

Chronic conditions

- Intractable leg ulcers
- Complicated pregnancy
- Stroke
- Recurrent painful syndrome
- Recurrent acute chest syndrome

C. Intraoperative Management

C.1. Discuss the anesthetic management for this patient. Discuss both regional and general anesthesia considerations.

The definitive anesthetic technique has not been established secondary to the wide clinical spectrum of SCD and the different severities in the surgical procedures. Koshy et al. retrospectively reviewed 1,079 anesthetics and noted an apparent association between postoperative complications and the use of regional anesthesia. Nevertheless, this study did not control for obstetric procedures and the tendency that clinicians often use regional anesthesia for sicker patients. Other studies did not find an adverse effect of regional anesthesia. Theoretically, regional anesthesia, especially when used with epinephrine, may produce a compensatory vasoconstriction in the nonblocked area, but this has not been supported in the literature. Yaster et al. found that epidural analgesia markedly improved oxygenation in children in vaso-occlusive crises, either through superior pain control or opioid sparing effects. Therefore, almost any anesthetic technique can be used, provided the following principles are considered:

- Good intravenous access for maintenance of intravascular volume
- Adequate oxygenation
- Denitrogenation before induction of general anesthesia
- Endotracheal intubation for general anesthesia to ensure a controlled airway and adequate ventilation
- Maintenance of adequate oxygen-carrying capacity through judicious use of red cell transfusions
- Maintenance of normothermia
- Opioids for analgesia carefully titrated for perioperative and postoperative analgesia
- Avoidance of tourniquet use
- Considering regional analgesia for both intraoperative and postoperative courses
- Avoidance of hypotension and venous stasis to prevent sickling of red blood cells
- Considering invasive monitoring (arterial line, central venous pressure line) for beat-to-beat blood pressure monitoring, volume monitoring, and frequent laboratory test
- Avoidance of hypoventilation of lungs to prevent acidosis
- Possible increased inspired oxygen concentration to ensure maintenance of normal to increased Pa_{O_2}

C.2. Discuss how the comorbidities associated with SCD can affect your anesthetic management.

Sickle cell anemia is a disease that can affect every end organ. Therefore, evaluating the patient for end-organ dysfunction is paramount. This patient is anemic, tachycardic,

and hypertensive. She may have dyspepsia, a hyperreactive airway, chronic renal insufficiency, liver disease, and might be debilitated with cardiopulmonary complications. Patients with SCD often present with cardiomegaly, pulmonary hypertension, and heart failure. For this surgery, she will probably require transfusions and may be difficult to crossmatch. In the postoperative period, pulmonary infarcts and infection are common, which can lead to acute chest syndrome. These problems, in addition to the potential for sickling crisis or sequestration syndrome, pose a greater risk than normal for perioperative morbidity and mortality. The patients at greater risk include those with a homozygous state SCD, sickle C disease (HbSC), and sickle thalassemia. In contrast, patients with SCT do not present an increased risk for intraoperative morbidity. As a perioperative specialist, one can have a profound effect on outcome in these patients by attention to detail, with a multisystem approach to address all end-organ dysfunction to reduce morbidity by maintaining oxygen delivery and preventing ongoing sickling.

C.3. What precautions should one take to prevent sickling in this patient?

Sickling of red blood cells is triggered by a variety of factors. One should avoid or correct factors that can precipitate sickling. Special precautions include the following:

- Avoid hypoxia by preoxygenating the patient and employing higher than usual concentrations of inspired oxygen.
- Prevent acidosis by maintaining adequate oxygenation, normovolemia, and cardiac output.
- Prevent respiratory acidosis by avoiding hypoventilation.
- Prevent stasis. This requires proper hydration and good regional blood flow. Blood viscosity should be maintained at a low level by limiting a rise in hematocrit to 35% and avoiding over transfusion.
- Avoid hypovolemia.
- Avoid hypothermia by using body warming and intravenous fluid warming devices perioperatively.
- Replace blood loss to prevent anemia.
- The use of tourniquets is controversial. Some advise against the use of tourniquets, although they have been used without ill effects by others. If a tourniquet is to be used, it should only be used when absolutely necessary and for a short period as possible. Special attention should be paid to maintain adequate oxygenation and to prevent respiratory or metabolic acidosis at the time of tourniquet release.

D. Postoperative Management

D.1. Discuss the postoperative management of this patient.

The postoperative period is a crucial time with SCD. Surgical pain, hypoventilation, a high incidence of pulmonary infarction, and an expected decrease in Pao_2 will predispose these patients to the formation of sickle cells, leading to the possibility of developing vaso-occlusive crisis or acute chest syndrome. The mainstay of postoperative management is supportive and preventive care. Supplemental oxygen, maintenance of intravascular fluid volume, maintenance of normothermia, and adequate analgesia are important considerations. Regional analgesia has been shown to decrease pain scores while improving oxygenation. Supportive and preventive care should be continued in the extended postoperative period. The basic outline of routine postoperative care includes the following:

- Early mobilization
- Maintenance of normothermia
- Supplemental oxygenation
- Early effective analgesia or adjunctive analgesics—nonsteroidal anti-inflammatory drugs, acetaminophen
- Maintain euvolemia
- Incentive spirometry
- Pulse oximetry
- Pulmonary monitoring
- Psychological support
- Considering extended postoperative cardiovascular monitoring
- Considering regional analgesia for postoperative pain management

D.2. What complications might occur in this patient in the immediate postoperative period?

The postoperative complications most likely to occur in the patient with SCD include deep vein thrombosis, vaso-occlusive crisis, pulmonary infarction, acute chest syndrome, and infection. Hypoxemic episodes are always a threat in the postoperative period secondary to pain, splinting, or oversedation and can precipitate a sickling crisis. The incidence of postoperative respiratory infection is high and is a leading

cause of morbidity and mortality. Acute chest syndrome is one of the most common causes of death in adult patients and is a potentially lethal postoperative complication in patients with SCD who undergo major or high-risk surgery. Sequestration syndrome with shock is another potentially lethal complication, especially in the obstetric patient immediately postpartum. Patients with cardiomegaly and pulmonary hypertension are susceptible to heart failure. Renal and hepatic dysfunction may result in prolongation of the effects of certain medications. Orthopedic patients with SCD are at risk for deep vein thrombosis, acute thrombosis, and pulmonary embolism. Antithrombotic therapy has to be geared toward decreasing this common complication.

D.3. What is the treatment of sickle cell crisis?

The treatment of sickle cell crisis is to break the vicious cycle of sickling, ischemia, infarction, pain, and end-organ failure. The principles of treatment of painful sickle cell crisis include the following:

- Rest
- Hydration
- Oxygen therapy
- Treatment of infection
- Analgesics (consider patient-controlled analgesia)
- Considering regional analgesia
- Transfusion to reduce the Hgb SS disease concentration
- Incentive spirometry
- Maintenance of normothermia

D.4. What is the role of hyperbaric oxygen therapy in treatment of sickle cell crisis?

Hyperbaric oxygen has been used empirically in some institutions for treatment of acute sickle cell crisis, though it is not widely available. Although some published reports claim instant improvement of symptoms, others have failed to show beneficial effects. There is better evidence that therapy is useful in management of ischemic

disorders of the anterior segment of the eye or in chronic leg ulcers. Studies have shown no apparent effects of hyperbaric oxygen on sickle cell morphology in vitro. It appears, then, that its reported benefit in vivo may be due to a decrease in the rate of sickling or improved tissue oxygenation by direct diffusion.

SECTION IX

Eye, Ear, Nose, and Throat

CHAPTER 33

Airway Trauma

Richard P. Dutton and LaRita Yvette Fouchè-Weber

A 46-YEAR-OLD MAN

was thrown from his motorcycle at a high rate of speed and impaled in the base of the neck by a tree branch. At presentation to the trauma center, he is awake and alert with heart rate (HR) of 122 beats per minute, blood pressure (BP) of 143/85 mm Hg, respiratory rate of 20 per minute, and oxygen saturation of 98% on 100% nonrebreathing mask. There is a 5-cm wide piece of wood protruding from his anterior lower neck at the sternal notch, without visible bleeding. The patient is neurologically intact but admits to consuming six beers in the hours before injury. His medical history is unremarkable.

A. Medical Disease and Differential Diagnosis

1. What variables mitigate injury from motorcycle collisions?
2. What other significant trauma may be present?
3. How is the initial assessment of a trauma patient organized?
4. How would you evaluate airway and breathing?
5. How would you evaluate the circulation?
6. How would you evaluate mental status and neurologic condition?
7. What diagnostic tests are indicated for this patient based on the mechanism of injury?
8. What are the zones of the neck and what is their clinical significance?
9. What immediate treatment is necessary before diagnostic studies?
10. When and where should the impaling object be removed?

B. Preoperative Evaluation and Preparation

1. What laboratory tests would you want?
2. What x-ray studies are most important to the anesthesiologist?
3. Is an electrocardiogram (ECG) necessary?
4. Should this patient be intubated before going for computed tomographic (CT) scanning?
5. When and where should this patient's airway be managed?
6. Are any prophylactic medications indicated?

C. Intraoperative Management

1. What monitors would you use? Is invasive monitoring necessary before definitive airway control?
2. What is the surgical approach to a zone I neck injury?
3. Is the patient likely to require tube thoracostomy? Should this be placed before managing the airway?
4. What are the options for managing this patient's airway?
5. What are the risks of rapid-sequence induction in this patient?
6. What anesthetic agents would you use for a rapid-sequence induction?
7. How can you minimize the risk of exacerbating cervical spine trauma?
8. How can you minimize the risks of aspiration?
9. How would you anesthetize the airway for an awake intubation?
10. What are the risks of awake fiberoptic intubation?
11. If the patient cannot be ventilated, what options are available?
12. Would a laryngeal mask airway (LMA) or other pharyngeal airway be of assistance?
13. What surgical airway options are available in this case?
14. What maintenance anesthetics are indicated or contraindicated in this patient?
15. What complications will the surgical plan introduce?

D. Postoperative Management

1. What are the criteria for extubation?
2. What techniques may be used during extubation?
3. How does alcohol abuse affect postoperative management?
4. What pain medication should be used?

A. Medical Disease and Differential Diagnosis

A.1. What variables mitigate injury from motorcycle collisions?

Trauma involving motorcycles accounts for 2% to 5% of all motor vehicle trauma, but a higher proportion of death and serious injury because of the relative exposure of the motorcycle rider to the environment. Factors such as youth, high speed, and intoxication contribute to motorcycle collisions just as they do for automobiles. Motorcycle riders also are much more susceptible to factors beyond their own control, such as lack of vigilance on the part of automobile and truck drivers, road conditions (oil or debris), and the weather.

Factors that can reduce the seriousness of motorcycle collisions when they do occur include helmets and protective clothing. Reenactment of a mandatory helmet law in the state of Washington in 1990 resulted in a decline in serious brain injury in motorcycle trauma victims from 20% to 9%, and a reduction in mortality from 10% to

6%. Full leather or synthetic "armor" reduces the risk of massive skin and soft-tissue injuries in the event of a high-speed collision.

Mock CN, Maier RV, Boyle E, et al. Injury prevention strategies to promote helmet use decrease severe head injury at a level I trauma center. *J Trauma*. 1995;39:29.

A.2. What other significant trauma may be present?

Motorcycle collisions are "high-energy" trauma that can result in injury to any organ system or region of the body. This patient will need a complete head-to-toe assessment and a number of diagnostic studies to establish the full extent of injury. Common injuries in motorcyclists include brain trauma from direct impact with the road and with other vehicles, pelvic fractures from impact with the frame of the motorcycle, abdominal trauma from impact with the handlebars, and lower extremity orthopedic and soft-tissue trauma from impact with the road.

A.3. How is the initial assessment of a trauma patient organized?

The initial management of trauma patients is best described by the tenets of the Advanced Trauma Life Support course, written by the American College of Surgeons Committee on Trauma. This course provides a unified philosophy and common language to organize practitioners from different specialties in the care of complex patients with the potential for multiple injuries. Assessment of the seriously injured patient begins with the ABCs: *A*irway, *B*reathing, and *C*irculation; followed by a brief neurologic examination and a catalogue of visible injuries. This "primary survey" is followed by diagnostic testing and a more detailed secondary survey to discover all of the patient's injuries. One important principle of Advanced Trauma Life Support is interruption of the diagnostic sequence as necessary to provide life-saving resuscitative care, up to and including surgery for airway management or hemorrhage control prior to completion of diagnostic studies.

Committee on Trauma, American College of Surgeons. *Advanced Trauma Life Support for Doctors*. 8th ed. Chicago: American College of Surgeons; 2008.

A.4. How would you evaluate airway and breathing?

On first contact with the patient, the provider should attempt verbal communication: "How are you?" A patient who answers coherently in a normal voice has no immediate airway issue, adequate circulatory function, and minimal traumatic brain injury. In an unconscious patient, initial assessment is by looking, listening, and feeling for airflow. If airflow is absent, the airway should be opened by jaw thrust (*not* head tilt, as this may exacerbate a cervical spinal column injury), clearance of any visible foreign bodies or secretions, and placement of an oral or nasopharyngeal airway.

Breathing is assessed by observation of the chest wall and diaphragm once the airway is open, and by immediate placement of a pulse oximeter probe. Patients who are not breathing adequately should be assisted with bag-valve-mask ventilation while preparations are made for securing a definitive airway and instituting mechanical ventilation.

A.5. How would you evaluate the circulation?

Initial assessment for shock is by vital signs (HR, blood pressure, pulse oximetry) and physical examination (pallor, diaphoresis, peripheral circulation, visible or suspected hemorrhage). Mental status is also a useful sign: The patient in hemorrhagic shock will be first agitated and then lethargic. Young patients have significant compensatory

reserves and will maintain a normal systolic blood pressure even in the face of hemorrhage as great as 40% of the blood volume. This state of compensated shock can be diagnosed by a narrowed pulse pressure (especially on automated sphygmomanometers), elevated HR, pallor, and abnormal lactate and base deficit. Shock in this patient could be the result of hemorrhage from chest or abdominal trauma (including a great vessel injury associated with the impalement) or tension pneumothorax in either side of the chest.

Committee on Trauma, American College of Surgeons. *Advanced Trauma Life Support for Doctors*. 8th ed. Chicago: American College of Surgeons; 2008.

Dutton RP. Initial resuscitation of the hemorrhaging patient. In: Speiss B, Shander A, eds. *Perioperative Transfusion Medicine*. Philadelphia: Lippincott Williams & Wilkins; 2006:289–300.

A.6. How would you evaluate mental status and neurologic condition?

The quick neurologic examination consists of questions to determine alertness and orientation (assuming the patient is responsive) followed by gross assessment of voluntary motion in all extremities. In the less responsive patient, the Glasgow Coma Score (GCS) (Table 33.1) is used to stratify the degree of impairment: GCS 3 to 8 is a severe injury, GCS 9 to 13 is moderate traumatic brain injury, and GCS 14 to 15 is mild injury. Cranial nerve, spinal cord, and peripheral nervous system function is assessed by specific motor and sensory testing of each extremity during the secondary survey.

Teasdale G, Jennet B. Assessment of coma and impaired consciousness: a practical scale. *Lancet*. 1974;2:81–84.

A.7. What diagnostic tests are indicated for this patient based on the mechanism of injury?

Because of the "high energy" mechanism of injury, this patient must be assessed from head to toe. Ultrasonography examination of the abdomen and chest is used to diagnosis free peritoneal fluid, pneumothorax (in the hands of a skilled operator), and pericardial tamponade. Chest and pelvis plain-film radiography will reveal fractures, pneumothoraces, and hemothorax. CT scanning should include the head, neck, chest,

Table 33.1 Glasgow Coma Scores[a]

EYE-OPENING RESPONSE	VERBAL RESPONSE	MOTOR RESPONSE
4 = Spontaneous	5 = Oriented to name	6 = Follows commands
3 = To speech	4 = Confused	5 = Localizes to painful stimuli
2 = To pain	3 = Inappropriate speech	4 = Withdraws from painful stimuli
1 = None	2 = Incomprehensible sounds	3 = Abnormal flexion (decorticate posturing)
	1 = None	2 = Abnormal extension (decerebrate posturing)
		1 = None

[a]The GCS is the sum of the best scores in each of three categories.

abdomen, and pelvis; newer technology will allow for 3D reconstructions of organs and vasculature with sensitivity and specificity equivalent to more traditional angiographic imaging.

This patient's obvious injury—to zone I of the neck—will necessitate a focused assessment of the trachea, great vessels, esophagus, and bilateral pleural cavities. Traditionally, this has been accomplished by a combination of plain-film radiography, angiography, bronchoscopy, and esophagoscopy. Increasing CT speed and resolution is leading to the increased use of this test at centers with experienced radiographers and traumatologists. The sequencing of diagnostic studies will depend on the patient's stability. In this case, he is likely to require intubation and perhaps exploratory surgery first. A noninvasive study such as contrast-enhanced CT (with angiographic reconstructions) may help to guide the surgical approach to removal of the impaling object if the patient is calm and stable enough to tolerate the test.

Henry SM, Scalea TM. Assessment and initial management in the trauma patient. In: Prough DS, Fleisher L, eds. *Prob Anesth Trauma Care.* Vol. 13, no. 3. London: Lippincott Wiliams & Wilkins; 2002:271–278.

A.8. What are the zones of the neck and what is their clinical significance?

Zone I of the neck includes the area from the inferior aspect of the cricoid cartilage down to the thoracic outlet. Zone I injuries require the complex diagnostic workup described in the previous section, followed by a surgical approach that allows access to both the neck and chest. Partial or complete median sternotomy is often necessary to access an injured great vessel or to repair the trachea or esophagus.

Zone II of the neck includes the area from the angle of the mandible down to the cricoid cartilage. Injuries in zone II are addressed through a lateral or transverse cervical incision, with the surgeon able to achieve both proximal and distal control of the carotid or jugular vessels before exploring the wound itself.

Zone III of the neck includes the area from the angle of the mandible upward to the base of the skull. Zone III vascular injuries pose a significant operative risk because distal control of an injured vessel cannot be achieved. Injuries in zone III are therefore approached angiographically or as part of a more complex neurosurgical operation.

Britt LD, Weireter LJ, Cole FJ. Management of acute neck injuries. In: Feliciano DV, Mattox KL, Moore EE, eds. *Trauma.* 6th ed. New York: McGraw-Hill; 2008:467–478.

A.9. What immediate treatment is necessary before diagnostic studies?

The key to this case will be control of the patient's airway. Once hemodynamic stability is confirmed, the timing and sequence of diagnostic studies will be determined by the patient's degree of cooperation and ability to protect his own spontaneous ventilation. Although a CT scan before a controlled intubation in the operating room (OR) would be ideal, it is possible that the patient will decompensate before this can be accomplished. Preemptive airway control will allow for a more secure and safer diagnostic workup before the OR.

A.10. When and where should the impaling object be removed?

All things being equal, the impaling tree branch is best removed in the OR in an anesthetized patient, with all of the personnel and equipment on hand to perform emergent median sternotomy and major vascular and/or tracheal surgery if necessary.

B. Preoperative Evaluation and Preparation

B.1. What laboratory tests would you want?

The patient should have a full set of laboratory studies, both to identify abnormalities and to establish a baseline for future changes. Hemoglobin and hematocrit will not indicate hemorrhage on the initial draw—the bleeding trauma patient is losing whole blood—but will drop with subsequent fluid resuscitation. Arterial blood gas and arterial or venous lactate measurement will be the most sensitive indicators of hypoperfusion and shock. Serum electrolytes will reveal baseline abnormalities, if any, and the effects of alcohol consumption and dehydration. Clotting studies are important to rule out congenital abnormalities or the effects of liver disease before what could be a major surgical procedure; coagulopathy at the time of trauma center admission is an indicator of substantial blood loss and severe hemorrhagic shock. Toxicology screening is indicated in every trauma patient and is important to rule out the use of drugs of abuse such as heroin or cocaine that have implications for the anesthesiologist.

Initial laboratory studies also should include a sample for the blood bank with the request for an urgent crossmatch of red cells and plasma. If there has been a major vascular injury, substantial blood loss is a possibility and should be treated with immediate transfusion of blood and coagulation factors.

Committee on Trauma, American College of Surgeons. *Advanced Trauma Life Support for Doctors*. 8th ed. Chicago: American College of Surgeons; 2008.

Hess JR, Lindell AL, Stansbury LG, et al. The prevalence of abnormal results of conventional coagulation tests on admission to a trauma center. *Transfusion*. 2009;49(1):34–39.

B.2. What x-ray studies are most important to the anesthesiologist?

Although all of the studies described in the preceding text will have some relevance, there are a few that have particular implications for the anesthesiologist. The chest radiograph and/or CT scan will suggest the degree of tracheal involvement of the impaling object, the risk that there is a major vascular injury, or the presence of a pneumothorax. Plain radiographs or CT scan of the cervical spine will be useful in ruling out bony or ligamentous injury that might be exacerbated by manipulation of the neck during airway management.

B.3. Is an electrocardiogram (ECG) necessary?

In the absence of dysrhythmias on the cardiac monitor, the criteria for ordering a preoperative ECG are the same as in any other surgical candidate: Patients presenting with symptoms or with a history suggestive of coronary artery disease. Dysrhythmias or visible injury to the precordium would be an indication for a baseline ECG and cardiac enzyme assay.

B.4. Should this patient be intubated before going for computed tomographic (CT) scanning?

The answer to this question involves an assessment of risks and benefits. If the patient is cooperative, vital signs are stable, CT scanner is close at hand, and anesthesia personnel are available to accompany the patient, then an immediate CT scan would be indicated. If the patient is deteriorating in any way, his degree of cooperation is in doubt, or a CT scan would place the patient far from expert resources for an extended period of time, then it would be wise to secure the airway first. In this case, there is a possibility that successful airway management will precipitate patient deterioration (e.g., hemorrhage, conversion from simple to tension pneumothorax), which suggests

that if airway management is attempted before CT, it should probably be done in the OR with the surgical team on hand.

One approach to this kind of complex decision is to define an ideal course of care that provides the best information for each of the experts involved while minimizing risk to the patient and maximizing flexibility in dealing with changing circumstances. In this case, the surgeon and anesthesiologist might define a plan that includes transport to the OR; induction, intubation, and mechanical ventilation in this (safest possible) environment; transport to CT or angiography with the anesthesiologist in attendance for diagnostic studies; then return to the OR for definitive surgery.

B.5. When and where should this patient's airway be managed?

Because of the potential for rapid deterioration and the desire to examine the airway closely before and during the intubation process, the patient should be moved as rapidly as possible to the OR before airway management is attempted. The surgical team should be on hand from the start and instruments should be available for video laryngoscopy and bronchoscopy, emergent tracheostomy, control of large vessel bleeding, and median sternotomy.

B.6. Are any prophylactic medications indicated?

Tetanus toxoid treatment is indicated for any trauma patient with an open wound who is more than 5 years removed from his or her last booster. Any patient with a significant open wound should receive prophylactic antibiotic therapy that covers gram-positive organisms for at least the first 24 hours following injury.

Prophylactic treatment to reduce the consequences of aspiration would be considered, but probably rejected in this case. Promotility agents such as metaclopramide and H_2 antagonists such as ranitidine will not have time to work before definitive airway control is achieved and the more immediate approach of administering oral bicitrate would be contraindicated because of the possibility of esophageal injury.

Because of the patient's history of intoxication, prophylactic intravenous administration of vitamins and thiamine is indicated. Prophylaxis against alcohol withdrawal and deep venous thrombosis are indicated in the immediate postoperative period.

C. Intraoperative Management

C.1. What monitors would you use? Is invasive monitoring necessary before definitive airway control?

Blood pressure, electrocardiography, capnography, and pulse oximetry should be employed as with any patient. A Foley catheter should be inserted once the patient is anesthetized, although urine output is not an accurate measure of intravascular volume status in a recently intoxicated patient. An arterial line is useful for moment-to-moment measurement of blood pressure and for easy access to blood for laboratory assay including arterial blood gases. A central venous catheter should be placed if there is need to monitor central venous intravascular volume, in anticipation of the need for rapid intravascular expansion (using a large-bore catheter such as a pulmonary artery introducer), and for the administration of vasoactive drugs. A pulmonary artery catheter is rarely indicated and seldom used acutely for resuscitation, although it may be helpful in selected patients with known coronary artery or valvular disease. Because of the potential for great vessel injury in this case, initial central access should be through the femoral vein.

Invasive monitoring lines usually are best placed after induction and intubation, when the patient is anesthetized and both surgeons and anesthesiologists can be working at the same time. Delaying surgical hemostasis in an unstable patient is

unwise. In the case under discussion, it would be appropriate to place an arterial line in the OR before airway management, as long as the patient remains cooperative and stable, and to place a femoral central line thereafter. Placing the arterial line on the right side also will allow for assessment of blood flow in the innominate artery during surgical exploration.

Dutton RP, McCunn M, Grissom TE. Anesthesia for trauma. In Miller RD, ed. *Miller's Anesthesia*. 7th ed. Philadelphia: Elsevier Churchill Livingstone; 2010:2277–2311.

C.2. What is the surgical approach to a zone I neck injury?

In the present case, the surgery is likely to start with a collar incision through the impalement wound to allow for better visualization of the path of injury. If injury to the trachea or a great vessel is discovered, a partial or complete median sternotomy would be the next step. It is the uncertain nature of this patient's injuries that makes preoperative diagnostic information so valuable, which is why a CT scan before definitive surgery (but after airway management) is a strong consideration.

C.3. Is the patient likely to require tube thoracostomy? Should this be placed before managing the airway?

Pneumothorax and hemothorax are common in trauma patients and should be suspected and definitively ruled out following any "high energy" blunt trauma (motor vehicle collision, pedestrian struck, fall from a height) or any penetrating trauma to the neck, thorax, or upper abdomen. Immediate temporizing needle decompression and/or tube thoracostomy are indicated in any hemodynamically unstable patient with a suspicious injury, even before chest radiograph. Intubation and the change to positive pressure ventilation may precipitate decompensation in a patient with chest injury, due to either decreased preload in the setting of hemorrhage or increased intrathoracic pressure caused by conversion from simple to tension pneumothorax.

In this case, there is the possibility of pathology in either or both hemithoraces. A portable anterior–posterior chest radiograph should be obtained at the earliest moment, followed by CT of the chest as outlined previously. If a simple pneumothorax is present, it is most prudent to prepare for chest tube placement (personnel, equipment) before airway management but to wait until the airway is secure before actually placing the chest tube.

C.4. What are the options for managing this patient's airway?

Choices for induction of anesthesia should be considered in concert with choices for securing the airway and transitioning to positive pressure ventilation. Airway management can occur with the patient awake under topical anesthesia or asleep, with either continued spontaneous ventilation (a "breathe down" induction with a volatile anesthetic) or an immediate transition to positive pressure, as in a rapid-sequence induction.

C.5. What are the risks of rapid-sequence induction in this patient?

Although most trauma patients are best managed with rapid-sequence induction and intubation, this case may represent an exception. Swelling or bleeding in the airway may make intubation physically difficult and the impaling object itself may prevent distal passage of an endotracheal tube. Further, dislodgement due to patient agitation or intubation attempts could precipitate hemorrhage or airway disruption. Finally,

the transition from spontaneous to positive pressure ventilation could precipitate a tension pneumothorax.

Stephens CT, Kahntroff S, Dutton RP. The success of emergency endotracheal intubation in trauma patients: a 10-year experience at a major adult trauma referral center. *Anesth Analg*. 2009;109:866–872.

C.6. What anesthetic agents would you use for a rapid-sequence induction?

Succinylcholine is the key component of a rapid-sequence intubation (RSI). No other relaxant provides as consistently good intubating conditions as quickly and as reversibly as succinylcholine. The usual dose for a trauma patient is 1.5 mg per kg—somewhat greater than normal to compensate for a potentially lower cardiac output due to hemorrhage.

Because succinylcholine has no amnestic or analgesic properties, an induction sedative is also indicated in most patients. Any induction agent, including ketamine or etomidate, will precipitate hypotension in the hypovolemic patient with a high endogenous catecholamine level, so care with dosing is required. In young and previously healthy patients, sodium thiopental in a titrated dose from 1 to 5 mg per kg or propofol 0.5 to 2 mg per kg are effective and inexpensive. Etomidate (0.1 to 0.4 mg per kg) is a reasonable choice in elderly patients or in those with known cardiovascular disease.

Dutton RP, McCunn M, Grissom TE. Anesthesia for trauma. In Miller RD, ed. *Miller's Anesthesia*. 7th ed. Philadelphia: Elsevier Churchill Livingstone; 2010:2277–2311.

C.7. How can you minimize the risk of exacerbating cervical spine trauma?

Appropriate precautions must be taken to avoid worsening an occult spinal cord injury. In the worst case, fractures or ligamentous injury can leave the cervical spine so unstable that the normal manipulation of a direct laryngoscopy will injure the spinal cord. This is a low probability event but is of concern to the healthcare team because quadriplegia is a catastrophic complication.

Manual in-line cervical stabilization has been shown to be safe and effective in protecting the cervical spine over tens of thousands of direct laryngoscopies and is the common approach to urgent intubations in the trauma population. Another option commonly used only in patients with known cervical instability is an awake intubation over a fiberoptic bronchoscope. This approach allows for the least manipulation of the neck but requires a cooperative patient who can tolerate the time required for topical anesthesia of the airway and a slower intubation. Awake fiberoptic intubation also may increase the risk of aspiration in patients with a full stomach, especially if topical anesthesia of the pharynx and vocal cords is provided.

Other intubation devices may also decrease the need for manipulation of the neck. Good results have been achieved with the newer generation of video laryngoscopes, lighted stylet intubations, and use of an intubating stylet with a less forceful laryngoscopy. Manual cervical stabilization is recommended with each of these approaches. In a difficult case such as the present one, the intubation technique chosen should be one that the anesthesiologist is experienced and comfortable with; this factor may be more relevant than the specific technology used.

Dutton RP, McCunn M, Grissom TE. Anesthesia for trauma. In Miller RD, ed. *Miller's Anesthesia*. 7th ed. Philadelphia: Elsevier Churchill Livingstone; 2010:2277–2311.

Karlin A. Airway management of trauma victims. *Prob Anesth Trauma Care*. 2002;13(3): 279–288.

C.8. How can you minimize the risks of aspiration?

Because any significant injury is associated with decreased gastrointestinal motility, all trauma patients are considered to have full stomachs. The risk of aspiration is further increased by intoxication with drugs or alcohol, obesity, the use of analgesics, and injuries to the face, neck, or abdomen that may lead to bleeding within the gastrointestinal tract.

Minimization of risk is a function of how quickly the intubation must be accomplished. One component of prophylaxis is the normal use of rapid-sequence induction to minimize the time during which the airway is at risk. Another is the use of cricoid pressure (the Sellick maneuver) to obstruct the upper esophagus against passive reflux. Although recent magnetic resonance imaging research has shown significant variability in the relative anatomy of the cricoid ring and the esophagus, casting doubt on the efficacy of cricoid pressure, there is no reason not to do it in most cases. In the case under consideration, there would be a risk of dislodging the impaling object, making cricoid pressure inadvisable. It would be reasonable to administer an H_2 antagonist such as cimetidine and a promotility agent such as metaclopramide if time allowed, but these agents would require 1 to 2 hours to have any substantial effect. An oral antacid is contraindicated because of the potential injury to the esophagus.

Smith KJ, Dobranowski J, Yip G, et al. Cricoid pressure displaces the esophagus: an observational study using magnetic resonance imaging. *Anesthesiology.* 2003;99(1):60–64.

C.9. How would you anesthetize the airway for an awake intubation?

Innervation of the airway can be separated into three neural pathways. If nasal intubation is planned, some method of anesthetizing maxillary branches from the trigeminal nerve is required. Involvement of the posterior tongue will require blockade of the glossopharyngeal nerve. Structures more distal in the airway to the epiglottis will require blockade of vagal branches, with the superior laryngeal nerve supplying the pharyngeal apparatus and the recurrent laryngeal nerve supplying the vocal cord and the tracheal mucosa.

The trigeminal nerve, which supplies sensory innervation to the nasal mucosa, can be anesthetized by inserting a nasal airway lubricated with lidocaine jelly into the patent naris. Mixing the lidocaine jelly with oxymetazoline 0.05%, phenylephrine 10 mg, or 4% cocaine may help vasoconstrict the nasal blood vessels and diminish bleeding from the nasal mucosa. The liquid local anesthetic and vasoconstrictor may also be applied in droplet form from a syringe.

The glossopharyngeal nerves of interest are the tonsillar nerves, which provide sensation to the mucosa overlying the palatine tonsil and continuous parts of the soft palate, and the sensory branches to the posterior one-third of the tongue. First, one must provide topical intraoral anesthesia with local anesthetic spray or nebulized lidocaine. Following topical anesthesia of the tongue, the mouth is opened wide and the posterior tonsillar pillar (palatopharyngeal fold) is identified. Then, a 22-gauge needle can be inserted at the caudad portion of the tonsillar pillar. The needle tip is inserted submucosally and following careful aspiration for blood, 5 mL of 0.5% lidocaine is injected. The block is then repeated on the contralateral side. A similar block can be performed with direct application of anesthetic soaked cotton to the bilateral tonsillar fossae.

The vagus nerve supplies innervation to the mucosa of the airway from the level of the epiglottis to the distal airways through both the superior and recurrent laryngeal nerves. A superior laryngeal nerve block and a translaryngeal block can be useful in anesthetizing these pathways. With the patient lying supine, a 22-gauge needle attached to a syringe is directed at the most posterior palpable part of the hyoid bone, near the greater cornu, and anterior to the carotid sheath. The needle must be parallel

to the table and never directed posteriorly for fear of penetrating the carotid sheath. When the needle strikes the hyoid, it is carefully walked caudad until it just slips off the hyoid, and then advanced a short distance through the hyothyroid membrane. Aspiration should produce nothing. Then 2 mL of 2% lidocaine is injected and the block repeated on the opposite side.

The translaryngeal block is performed with a 20- or 22-gauge needle attached to a syringe. The needle is inserted through the cricothyroid membrane in the midline and air is aspirated. The patient is asked to inhale deeply and then to exhale fully. At the end of expiration, 4 mL of 2% to 4% lidocaine is injected rapidly and the needle is quickly removed. The resultant coughing will ensure a wide distribution of local anesthetic droplets throughout the airway. If stability of the cervical spine is in doubt, then in-line stabilization should be held while the block is performed and coughing occurs. In the present case, both superior laryngeal and transtracheal blocks would be difficult to perform, and induced coughing might exacerbate the injury. Administration of nebulized lidocaine might be a safer choice.

Brown DL. *Atlas of Regional Anesthesia.* 4th ed. Philadelphia: WB Saunders; 2010:191–196.

Gotta AW, Sullivan CA. Anesthesia of the upper airway using topical anesthetic and laryngeal nerve block. *Br J Anaesth.* 1981;53:1055–1058.

C.10. What are the risks of awake fiberoptic intubation?

The greatest risk of awake fiberoptic intubation is deterioration of the patient's airway or mental status (or both) during the procedure. Ineffective topical anesthesia can lead to agitation and combativeness, which in turn leads to increased use of intravenous sedatives. Blood and secretions in the airway can cause coughing, laryngospasm, or aspiration. Oversedation causes respiratory depression and desaturation, which can pressure the anesthesia providers and lead to hasty decisions. More uncommon complications include injury to nerves or vessels during local nerve blocks, toxicity from local anesthesia ingestion, and direct injury to the laryngeal or pharyngeal mucosa.

This particular case also includes the possibility of inadvertent dislodgement of the impaling tree branch during sedation and topicalization or during the intubation effort itself. Bleeding from a loss of tamponade or open disruption of the airway could necessitate a sudden change in anesthetic and surgical plans. Although awake fiberoptic intubation in the OR is a reasonable starting point for this case, the anesthesiologists and surgeons involved must be prepared for other eventualities. These would include both RSI and emergency surgical airway access.

C.11. If the patient cannot be ventilated, what options are available?

Failure of awake fiberoptic intubation in this case should be followed by an immediate attempt at RSI. If RSI is not possible and the patient cannot be ventilated by mask or laryngeal mask airway (LMA), then a surgical airway may be required. An alternate technique involves placing a 14-gauge catheter over a needle through the cricothyroid membrane, removing the needle and using the catheter for jet ventilation. This technique provides a temporary route for oxygenation, as a bridge to a surgical airway, but is highly tenuous. Kinking or dislodgement of the jet catheter are common complications, with tension pneumothorax a possibility if the catheter tip is displaced into the paratracheal tissues. In this case, accessibility to the trachea or cricoid cartilage may be difficult due to the impaling object.

Benumof JL, Scheller MS. The importance of transtracheal jet ventilation in the management of the difficult airway. *Anesthesiology.* 1989;71:769–778.

C.12. Would a laryngeal mask airway (LMA) or other pharyngeal airway be of assistance?

Although an LMA or other supraglottic airway support device is often a great help in the difficult airway algorithm, this case may represent an exception. Establishing an efficient mask airway is beneficial if the cause of patient distress is neurologic (diminished respiratory drive due to anesthesia or traumatic brain injury) or related to pharyngeal anatomy (obstruction after muscle relaxation). Supraglottic ventilation will not help with more distal causes of airway obstruction, such as laryngospasm, tracheal disruption, or massive aspiration. Although an LMA or equivalent device should be on hand when this patient is brought to the OR, it is less likely to be of use.

C.13. What surgical airway options are available in this case?

As with the LMA surgical airway access is beneficial when the cause of airway obstruction is proximal to the intervention. Cricothyroidotomy—the fastest and most readily performed surgical airway procedure—is therefore of benefit in patients who cannot be intubated and have airway obstruction involving the pharynx or larynx. This procedure may be accomplished by surgical opening of the cricothyroid membrane and placing an endotracheal tube into the trachea. Operative cricothyrotomy can be performed more rapidly than conventional tracheostomy; however, it is more traumatic to the larynx, and the cricothyrotomy tube should be removed after 24 hours. If the patient cannot be decannulated at this time, a conventional tracheostomy should replace the cricothyrotomy.

Tracheostomy, performed lower in the airway, requires more extensive surgical dissection, takes longer, and carries a greater risk of hemorrhage secondary to thyroid tissue trauma. Surgical access to the lower trachea might be necessary in the present case if the impaling object has transected or significantly disrupted the airway. This would be accomplished essentially through the wound itself but would require a partial or complete median sternotomy and the full resources of the OR.

Britt LD, Weireter LJ, Cole FJ. Management of acute neck injuries. In: Feliciano DV, Mattox KL, Moore EE, eds. *Trauma*. 6th ed. New York: McGraw-Hill; 2008:467–478.

C.14. What maintenance anesthetics are indicated or contraindicated in this patient?

If initial awake fiberoptic examination of the trachea (at the time of intubation) rules out an airway injury, then muscle relaxation to facilitate surgical exploration would be appropriate for the duration of the case. Any of the commonly used intermediate-acting nondepolarizing relaxants could be used. If an airway injury is present, then management of the patient using inhalational anesthesia alone, with continued spontaneous ventilation, offers additional security in the event of airway discontinuity during the course of surgical repair. Sevoflurane, because of its greater palatability, is the easiest volatile anesthetic to administer without interrupting the patient's ventilation. Care must be taken to ensure adequate fluid volume replacement during a pure inhalational anesthetic as hemodynamic instability is possible. Nitrous oxide is contraindicated when the potential for pneumothorax exists or when airway continuity is in doubt.

Narcotics certainly will be required for postoperative analgesia and may offer some intraoperative advantages as well. Once airway patency is assured, a narcotic-based anesthetic provides for the lowest level of circulating catecholamines, making it

easier to assess and manage fluid resuscitation. The usual concern with delayed emergence in a patient receiving a large dose of narcotics is not relevant in this case, as the patient will most likely require postoperative mechanical ventilation. The only caveat to intraoperative narcotics is the potential need to sustain spontaneous ventilation while the airway is assessed; narcotic administration should, therefore, be delayed until the anesthetic and surgical plans have become clear.

C.15. What complications will the surgical plan introduce?

Maintenance of homeostasis in the face of surgical provocations is the theme of many anesthetics and the present case is no exception. At some point—ideally after anesthetic induction, successful airway management, and placement of lines and monitors—the impaling object is going to be removed from the patient's neck. Blunt object impalements in patients seen alive in the trauma center may produce less organ-specific damage than predicted from the location and course of the injury due to the ability of mobile anatomic structures to deform away from low-speed penetrations. Even so, it is entirely possible that this object has injured one of the great vessels or the trachea and that removing it might lead to torrential bleeding or significant disruption of the airway. The anesthesia team must be prepared to change course rapidly from a spontaneous breathing inhalational approach (assuming that airway continuity is the initial concern) to a hemodynamically friendly narcotic-based approach if blood loss and hemorrhagic shock become the major issue. An open team discussion of both surgical and anesthetic plans, including likely contingencies, is highly recommended before beginning definitive treatment.

Dutton RP. Pathophysiology and treatment of traumatic shock. In Smith C, ed. *Trauma Anesthesia: Basic and Clinical Aspects*. Cambridge: Cambridge University Press; 2008:55–68.

D. Postoperative Management

D.1. What are the criteria for extubation?

Assuming that the case goes well and the patient's anatomic injuries are successfully repaired, it is appropriate to consider emergence and extubation when the following criteria are satisfied:

- Hemodynamic stability with complete cessation of bleeding and normal systemic coagulation.
- Adequate respiratory drive and reserve including complete return of neuromuscular function and minimal requirement for ventilator support.
- Acceptable mental status. The patient should be calm, cooperative, comfortable, not overly sedated, and recovered from acute intoxication. The patient should be able to follow commands.
- Evidence of airway patency. Edema at the site of injury will not be an issue with an endotracheal tube in place but might obstruct the airway quickly following extubation. Although not 100% predictive, the presence of an air leak around the endotracheal tube when the cuff is deflated is very reassuring.
- Completion of the diagnostic workup for "high-energy" trauma, including indicated CT scans and laboratory studies, and completion of all procedures are likely to require general anesthesia. It would be poor judgment to extubate the patient after tracheal repair only to have the orthopedic surgeons schedule him for urgent pelvic surgery.

Dutton RP, McCunn M, Grissom TE. Anesthesia for trauma. In Miller RD, ed. *Miller's Anesthesia*. 7th ed. Philadelphia: Elsevier Churchill Livingstone; 2010:2277–2311.

D.2. What techniques may be used during extubation?

The best results from extubation will be achieved when the patient is most calm and comfortable and when the extubation itself is as nonstimulating as possible. The appropriate level of sedation and analgesia is a complicated, controversial, and very important question. Sedative agents such as benzodiazepines and propofol will diminish the patient's respiratory drive, cooperation, and ability to protect the airway, and should be minimized. The right level of narcotics, on the other hand, will allow for a comfortable patient with diminished airway reactivity, who can open their eyes and follow commands but is not otherwise distressed by the endotracheal tube or ventilator. The endotracheal tube should be suctioned ahead of time, and extubation deferred if there are copious secretions. Enough time should be allowed after suctioning for the stimulation to pass and the patient to relax. The posterior pharynx is then suctioned, the patient is asked to inhale deeply, the cuff is deflated, and the endotracheal tube is removed in one swift motion as the patient exhales.

The airway is in jeopardy immediately after extubation because edema and secretions may compromise respiratory function. Continuous pulse oximetry in a monitored setting is required and humidified oxygen should be administered for 24 hours postextubation.

D.3. How does alcohol abuse affect postoperative management?

Symptomatic withdrawal from alcohol usually occurs within 24 hours and manifests as agitation, tachycardia, and hypertension. Delirium tremens can occur thereafter if prophylactic therapy is not initiated. Prophylaxis should consist of a small basal dose of benzodiazepines or a low-dose intravenous alcohol infusion, with frequent assessment of mental status and the willingness to provide supplemental short-acting benzodiazepines if symptoms develop. The plan for delirium tremen prophylaxis should be coordinated with the pain management plan, ideally under the direction of a single individual, to provide for overall consistency and to avoid oversedation and respiratory arrest secondary to polypharmaceutical administration.

D.4. What pain medication should be used?

Postoperative analgesia in this case will depend on the extent of the surgical procedure and on the individual tolerance of the patient. Soft-tissue exploration of the neck, including surgery on the trachea or major vessels, requires relatively little postoperative analgesia. Titrated intravenous narcotics can be used in the first 24 hours with a rapid transition to an oral narcotic/acetaminophen preparation thereafter. Median sternotomy or other significant extension of the surgery into the chest will necessitate more intensive postoperative analgesia, including continuous narcotic infusion while the patient remains intubated, followed by intravenous patient-controlled analgesia after emergence and extubation. Nonsteroidal anti-inflammatory drugs are an appropriate adjuvant therapy once the risk of traumatic hemorrhage is past.

CHAPTER 34

Open-Eye Injury

THERESA T. KUDLAK

A 28-YEAR-OLD, OTHERWISE, HEALTHY MAN presented to the emergency room with a fishhook embedded in his eye. He had eaten a full meal just before the fishing accident.

A. Medical Disease and Differential Diagnosis

1. Why is this patient a particular challenge to the anesthesiologist?
2. What are the determinants of intraocular pressure (IOP) under normal circumstances? What is the normal range? What was the expected IOP in this patient's injured eye?
3. How is aqueous humor formed and eliminated?
4. How is IOP affected by arterial Pco_2, systemic blood pressure, coughing and vomiting, deep inspiration, and hypoxemia?
5. What is the role of the central nervous system (CNS) on IOP?
6. What is glaucoma?
7. Is atropine contraindicated in patients with glaucoma?
8. How do carbonic anhydrase inhibitors work to decrease IOP? By what mechanism may osmotic agents decrease IOP?
9. Are carbonic anhydrase inhibitors or osmotic diuretics indicated in open-globe injuries?
10. Are topically applied ophthalmic medications absorbed systemically? How can this absorption be reduced? Which eyedrops may have effects that are of concern to the anesthesiologist?

B. Preoperative Evaluation and Preparation

1. Is an open-globe injury always a surgical emergency?
2. What preoperative evaluation would you require?
3. The patient had eaten shortly before the accident. Would you attempt to pass a nasogastric tube or to administer emetics to empty the stomach?
4. Could this case be done with topical anesthesia or a retrobulbar block?
5. How would you premedicate this patient?

C. Intraoperative Management

1. What are some factors that may increase the risk of vitreous herniation during induction and maintenance of anesthesia?
2. Will you intubate this patient? Would you consider a laryngeal mask airway? How does intubation affect IOP? How can this effect be minimized?
3. Would you consider an awake intubation?
4. Is succinylcholine contraindicated in open-globe injuries? How does succinylcholine affect IOP?
5. Does pretreatment with nondepolarizing muscle relaxants prevent the succinylcholine-induced elevation in IOP?
6. How do nondepolarizing muscle relaxants affect IOP?
7. How will you perform a rapid-sequence induction and intubation without using succinylcholine?
8. What are the effects of ketamine on the eye?
9. Would you consider the use of etomidate as an induction agent? What about propofol?
10. How do inhalation agents affect IOP and by what mechanism?
11. During the procedure, the patient's pulse rate suddenly dropped to 40 beats per minute. What do you think was happening? What is the oculocardiac reflex (OCR)?
12. What are the afferent and efferent pathways of the OCR?
13. What factors contribute to the incidence of the OCR?
14. How do you diagnose and treat the OCR?
15. Is atropine useful for the OCR?
16. Can retrobulbar block prevent the OCR? Is it appropriate in this patient?

D. Postoperative Management

1. Would you reverse the neuromuscular blockade in this patient?
2. Do reversal doses of atropine affect IOP?
3. What would you do before extubating this patient?
4. When would you extubate this patient?
5. The patient awakened in the recovery room and complained of pain and tearing in the opposite eye. The conjunctiva was inflamed. What was the likely cause?
6. Will taping the eyes shut or applying ointment prevent corneal abrasions? Are there any contributing factors?
7. What should you do when you suspect that your patient might have a corneal abrasion?
8. A month after the surgical repair, the patient complained of impaired vision in the operative eye. He was examined and found to have a detached retina. As part of the surgical treatment, the ophthalmologist injected a gas bubble into the patient's posterior chamber. Why is this important to an anesthesiologist?

A. Medical Disease and Differential Diagnosis

A.1. Why is this patient a particular challenge to the anesthesiologist?

The combination of a full stomach and an open-globe injury presents a unique challenge to the anesthesiologist. In addition to the increased risk of aspiration of gastric contents, any drug or maneuver that raises IOP in the injured, open eye may cause extrusion of the vitreous humor and loss of vision when the globe is opened.

Miller RD, ed. *Miller's Anesthesia*. 7th ed. Philadelphia: Churchill Livingstone; 2010:2385.

A.2. What are the determinants of intraocular pressure (IOP) under normal circumstances? What is the normal range? What was the expected IOP in this patient's injured eye?

IOP is determined by the balance between production and drainage of aqueous humor, by changes in choroidal blood volume, and by vitreous volume and extraocular muscle tone. Resistance to outflow of aqueous humor in the trabecular tissue is probably the factor that maintains IOP within physiologic range, but the mechanism of homeostasis is unknown.

Normal IOP is 12 to 16 torr in the upright posture and increases by 2 to 4 torr in the supine position. IOP has been observed to nearly double in steep head down position in the operating room.

When the globe is open, the IOP is lowered and may be as low as ambient pressure. The concern in this case is for the relative volume of choroid and vitreous humor within the eye. If this volume should increase while the eye is opened, the vitreous humor may be lost. Any deformation of the eye by external pressure in the globe may cause an increase in IOP.

A.3. How is aqueous humor formed and eliminated?

Aqueous humor is a clear fluid that occupies the anterior and posterior chambers of the eye. Its total volume is 0.3 mL. Aqueous humor is produced primarily by an active secretory process from the ciliary body in the posterior chambers at an equilibrium rate of 2 μL per minute. The aqueous then circulates through the pupil to the anterior chamber, passes through the trabeculated Fontana spaces, and enters Schlemm canal. From here, the fluid drains into the episcleral veins and finally into the cavernous sinus or jugular venous systems (Fig. 34.1).

A.4. How is IOP affected by arterial Pco_2, systemic blood pressure, coughing and vomiting, deep inspiration, and hypoxemia?

The choroidal arterioles vasodilate in response to hypercapnia and constrict during hypocapnia, thereby changing intraocular volume and pressure. However, the effect is minimal within the normal physiologic range of Pco_2.

Minor fluctuations in arterial blood pressure also have minimal effects on IOP, although IOP may be seen to increase when hypertension is sustained and can fall significantly with induced hypotension. Changes in venous pressure, on the other hand, have a major impact on IOP. Vomiting, coughing, and bucking on the endotracheal tube cause a dramatic increase in IOP by 30 to 40 torr. These actions, and also Valsalva maneuver, cause congestion in the venous system, which impedes outflow of aqueous humor and increases the volume of choroidal blood. A deep inspiration may reduce IOP by 5 torr. Hypoxemia may increase IOP through choroidal vasodilatation.

A.5. What is the role of the central nervous system (CNS) on IOP?

The CNS influences IOP through alterations in extraocular muscle tone or, indirectly, by hormonal or hemodynamic changes.

Cunningham AJ, Barry P. Intraocular pressure: physiology and implications for anaesthetic management. *Can Anaesth Soc J*. 1986;33:195–208.

Miller RD, ed. *Miller's Anesthesia*. 7th ed. Philadelphia: Churchill Livingstone; 2010:2379.

A.6. What is glaucoma?

Glaucoma is a pathologic elevation of IOP caused by increased resistance to outflow of aqueous humor from the anterior chamber of the eye. It is classified as either open- or closed-angle glaucoma, depending on the anatomy and pathophysiology. Chronic elevation of IOP interferes with the intraocular blood supply and normal metabolism of the cornea. It can result in corneal opacities or decreased retinal blood flow.

The pathophysiology in glaucoma involves increased resistance to the flow of aqueous humor through Fontana spaces as a result of scarring of the trabecular network or thickening of the endothelial covering of these channels. In closed-angle glaucoma, the iris bulges forward blocking the access of aqueous humor to the trabecular network. This may occur with pupillary dilation or an acutely swollen lens.

LeMay M. Aspects of measurement in ophthalmology. *Br J Anaesth*. 1980;52:655–662.

A.7. Is atropine contraindicated in patients with glaucoma?

Topical atropine in the eye is generally contraindicated in patients with glaucoma, especially in those with narrow-angle glaucoma. Atropine, studied in a single dose of 0.01 mg per kg, administered intramuscularly (IM), or given orally as 0.6 mg in 2 doses 4 hours apart, caused no increase in IOP in either open- or closed-angle glaucoma because by calculation, only approximately 0.0001 mg reaches the eye, which is far less than topical dose. Intravenous atropine is associated with mydriasis and might be contraindicated in patients with glaucoma; however, preemptive topical use of pupillary constrictors such as pilocarpine and timolol avoid this problem.

A.8. How do carbonic anhydrase inhibitors work to decrease IOP? By what mechanism may osmotic agents decrease IOP?

Carbonic anhydrase inhibitors, such as acetazolamide, interfere with the sodium-pump mechanism necessary for secretion of aqueous humor. An intravenous dose acts in 5 minutes, with maximal effect in 20 to 30 minutes. Chronic acetazolamide therapy may result in potassium depletion.

Osmotic agents, such as mannitol, increase plasma oncotic pressure relative to that of aqueous humor and produce an acute, transient drop in IOP. The maximum reduction in IOP occurs after 30 to 45 minutes and the effect lasts 5 to 6 hours.

Barash PG, Cullen BF, Stoelting RK, eds. *Clinical Anesthesia*. 6th ed. Philadelphia: Lippincott Williams & Wilkins; 2009:1325–1327.

McGoldrick KE. Ocular drugs and anesthesia. *Int Anesthesiol Clin*. 1990;28(2):72–77.

A.9. Are carbonic anhydrase inhibitors or osmotic diuretics indicated in open-globe injuries?

No. If the globe is open, the IOP is low and these agents are not useful. In addition, they may cause transient choroidal congestion, which could lead to loss of ocular contents.

Smith GB. *Ophthalmic Anaesthesia*. Baltimore: University Park Press; 1983.

A.10. Are topically applied ophthalmic medications absorbed systemically? How can this absorption be reduced? Which eyedrops may have effects that are of concern to the anesthesiologist?

Topical ophthalmic drugs may be absorbed through the conjunctiva or may drain through the nasolacrimal duct and be absorbed through the nasal mucosa. Absorption is increased when the eye is instrumented, diseased, or traumatized. Finger pressure on the inner canthus for a few minutes after instillation of eyedrops will impede absorption by occluding the nasolacrimal duct.

Usage of the following topical medications may have implications for the anesthesiologist:

Atropine

Atropine is used to produce mydriasis and cycloplegia. The 1% solution contains 0.2 mg to 0.5 mg of atropine per drop. Systemic reactions, seen primarily in children and older adults, include tachycardia, flushing, thirst, dry skin, and agitation. Atropine is contraindicated in closed-angle glaucoma.

Scopolamine

One drop of the 0.5% solution has 0.2 mg of scopolamine. CNS excitement can be treated with physostigmine, 0.015 mg per kg intravenously (IV), repeated one or two times in a 15-minute period. Scopolamine is contraindicated in closed-angle glaucoma.

Cyclopentolate (Cyclogyl)

Cyclopentolate, a short-acting mydriatic and cycloplegic, may cause transient neurotoxic effects such as incoherence, visual hallucinations, slurred speech, ataxia, and seizures. It is contraindicated in closed-angle glaucoma.

Tropicamide (Mydriacyl)

Tropicamide is used to produce mydriasis for refraction or funduscopic examination. It may have central nervous system (CNS) effects and can elevate IOP in closed-angle glaucoma.

Phenylephrine hydrochloride (Neo-Synephrine)

Phenylephrine hydrochloride is used to produce capillary decongestion and pupillary dilatation. Applied to the cornea, phenylephrine hydrochloride can cause palpitations, nervousness, tachycardia, headache, nausea and vomiting, severe hypertension, reflex bradycardia, and subarachnoid hemorrhage. Solutions of 2.5%, 5%, and 10% (6.25-mg phenylephrine per drop) are available. The dose is 1 drop per eye per hour of the 2.5% solution (children) or the 5% solution (adults).

Epinephrine

Topical 2% epinephrine will decrease aqueous secretion, improve outflow, and lower IOP in open-angle glaucoma. Side effects include hypertension, palpitations, fainting, pallor, and tachycardia. The effects last approximately 15 minutes. One drop of 2% solution contains 0.5 to 1 mg of epinephrine. Epinephrine 1:200,000 in a balanced salt solution is sometimes continuously infused into the anterior chamber during cataract surgery. Systemic effects may occur.

Timolol maleate (Timoptic)

Timolol maleate is a β-blocker used in the treatment of chronic glaucoma. Side effects include light-headedness, fatigue, disorientation, depressed CNS function, and exacerbation of asthma. Bradycardia and bronchospasm may occur as well as potentiation of systemic β-blockers.

Betaxolol HCl (Betoptic)

Betaxolol HCl is a cardioselective (β-1) blocking agent used to treat glaucoma. It may be hazardous in patients with sinus bradycardia, heart block, or heart failure.

Acetylcholine

Acetylcholine may be injected intraoperatively into the anterior chamber to produce miosis. Side effects are due to its parasympathetic action and include hypotension, bradycardia, and bronchospasm. Intravenous atropine is an effective treatment.

Echothiophate iodide (Phospholine iodide)

Echothiophate iodide, a cholinesterase inhibitor, is used as a miotic agent. It may prolong the effect of both succinylcholine and ester-type local anesthetics. Levels of pseudocholinesterase decrease by 80% after 2 weeks on the drug. It takes 3 to 6 weeks for return to normal pseudocholinesterase activity after stopping the drug (4 weeks for return to 75% activity). Succinylcholine and ester-type local anesthetics should be avoided. Demecarium is another such cholinesterase inhibitor.

Cocaine

Cocaine is used to produce vasoconstriction and to shrink mucous membranes during dacryocystorhinostomy. One drop of 4% solution contains approximately 1.5 mg of cocaine, and the maximum dose is approximately 3 mg per kg. Systemic effects may be seen with a dose as low as 20 mg and involve the CNS, respiratory, and cardiovascular systems.

B. Preoperative Evaluation and Preparation

B.1. Is an open-globe injury always a surgical emergency?

No. In most cases, surgery is not required immediately and some time may be spent in adequately preparing the patient for anesthesia and surgery. However, the surgery should probably be performed within 12 hours to minimize the possibility of infection and other complications. Delaying surgery for gastric emptying to occur is not reliable as gastric emptying may be prolonged in this stressful situation.

Smith GB. *Ophthalmic Anaesthesia*. Baltimore: University Park Press; 1983:44–49.

B.2. What preoperative evaluation would you require?

An accurate, thorough history, and physical examination are the best means of evaluating this patient preoperatively and should reveal any existing medical problems that will guide your selection of preoperative laboratory tests.

In this otherwise healthy young patient, no routine laboratory tests are indicated, unless they are required by the institution in which you are practicing. In cases in which more extensive trauma is suspected, other injuries also must be addressed such as fractures to the skull and orbit, intracranial hemorrhage, and other injuries as suggested by the history and physical examination.

Miller RD, ed. *Miller's Anesthesia*. 7th ed. Philadelphia: Churchill Livingstone; 2010:2385.

B.3. The patient had eaten shortly before the accident. Would you attempt to pass a nasogastric tube or to administer emetics to empty the stomach?

Absolutely not. These procedures are contraindicated when there has been a perforation of the eye. Gagging, vomiting, and straining could cause a potentially

disastrous increase in IOP and extrusion of intraocular contents. A cough can increase central venous pressure and choroidal blood volume and may raise IOP by 34 to 40 torr.

Kohli R, Ramsingh H, Makkad B. The anesthetic management of ocular trauma. *Int Anesthesiol Clin.* 2007;45:83–98.

B.4. Could this case be done with topical anesthesia or a retrobulbar block?

General anesthesia is the preferred technique for open-globe injuries: the patient is fully immobile and there is no time limit for the procedure. In this case where the patient is not fasting, an endotracheal tube will guard against aspiration.

A retrobulbar or peribulbar injection has the potential to increase IOP because of the volume of local anesthetic used and the likelihood of the patient squeezing his eyes during the injection. However, there have been reports of successful use of blocks for repair of open-globe injuries. Topical anesthesia with intravenous (IV) sedation also has been used to repair the globe in select patients with limited injury when general anesthesia is contraindicated.

Boscia F, La Tegola MG, Columbo G, et al. Combined topical anesthesia and sedation for open-globe injuries in selected patients. *Ophthalmology.* 2003;110:1555–1559.

Scott IU, McCabe CM, Flynn HW, et al. Local anesthesia with intravenous sedation for surgical repair of selected open globe injuries. *Am J Ophthalmol.* 2002;134:707–711.

B.5. How would you premedicate this patient?

Premedications should be given parenterally because gastrointestinal absorption is unreliable. Sedatives and anxiolytics may be given as necessary. Metoclopramide (0.15 mg per kg IM or IV) may be used to facilitate gastric emptying and to increase the tone of the cardiac sphincter. Narcotics should be used cautiously because they may cause nausea and vomiting. Nonparticulate antacids and H_2 receptor antagonists (cimetidine 2 mg per kg IM) should be considered to reduce the risk of aspiration pneumonitis. Intravenous droperidol (0.01 mg per kg) or ondansetron (0.1 mg per kg) can be given for antiemesis.

Atropine or glycopyrrolate will be useful to reduce secretions and gastric acidity and they may also inhibit the OCR.

C. Intraoperative Management

C.1. What are some factors that may increase the risk of vitreous herniation during induction and maintenance of anesthesia?

Factors that may increase the risk of vitreous herniation during induction and maintenance of anesthesia include the following:

- Face mask pressing on the eyeball
- Increased pressure from coughing, straining, bucking, and head-down position
- Extraocular muscle spasm induced by depolarizing muscle relaxants or surgical stimulation during light anesthesia
- Poorly applied cricoid pressure that blocks venous drainage from the eye
- Choroidal congestion from hypercarbia, hypoxia, osmotic diuretics, intubation, or increases in blood pressure

Miller RD, ed. *Miller's Anesthesia*. 7th ed. Philadelphia: Churchill Livingstone; 2010:2378–2385.

C.2. Will you intubate this patient? Would you consider a laryngeal mask airway? How does intubation affect IOP? How can this effect be minimized?

It is imperative that this patient be intubated not only to maintain the airway, which is close to the surgical field, but also to avoid pressure by a face mask on the eyeball and to minimize the risk of aspiration. Although the laryngeal mask airway has been used successfully in ophthalmologic anesthesia, it is not appropriate in this case because it does not protect the airway from aspiration. Many studies have demonstrated a significant increase in IOP caused by laryngoscopy and intubation under varying states of anesthetic depth and muscle relaxation. IOP may be increased even when there is no visible reaction to intubation. This increase in IOP can be attenuated by topical laryngeal anesthesia and by increased depth of anesthesia to reduce coughing, straining, and increases in blood pressure. The cardiovascular response to intubation can also be reduced by intravenous lidocaine (1.5 mg per kg), β-blockers, α-2 agonists, or calcium channel blockers. Topical anesthesia of the larynx is not recommended in a full-stomach situation because of the increased risk of aspiration.

Smith RB, Aass AA, Nernoto EM. Intraocular and intracranial pressure during respiratory alkalosis and acidosis. *Br J Anaesth.* 1981;53:967–972.

C.3. Would you consider an awake intubation?

Awake intubation is frequently accompanied by coughing and bucking and is risky in an open-globe injury when other safe methods of intubation are available. However, when dealing with a possible compromised airway or difficult intubation, an awake fiber-optic intubation expertly done under careful sedation may be indicated to safely secure the airway.

C.4. Is succinylcholine contraindicated in open-globe injuries? How does succinylcholine affect IOP?

The use of succinylcholine in open-globe injuries is controversial. In the intact eye, following thiopental induction, succinylcholine has been shown to increase IOP by 6 to 8 torr between 1 and 4 minutes after administration. Tracheal intubation further increases IOP. IOP returns to baseline in 5 to 7 minutes. In open-globe injuries, succinylcholine use has been associated with loss of ocular contents. The increase in IOP may be mediated by prolonged tonic contraction of the extraocular muscles, although IOP has been shown to rise after succinylcholine even when the extraocular muscles have been severed. Other factors that may be contributory include choroidal blood flow, increased central venous pressure, and increased resistance to outflow of aqueous humor resulting from the cycloplegic effects of succinylcholine.

The hemodynamic response to laryngoscopy or intubation may have a much more significant effect on IOP than succinylcholine alone. Simply blinking will raise the IOP in a normal eye by 10 to 15 torr, similar to the effect of succinylcholine. Pretreating with nifedipine or lidocaine, which deepens the anesthesia, may attenuate the increase in IOP following succinylcholine and intubation.

Smith RB, Babinski M, Leano N. The effect of lidocaine on succinylcholine-induced rise in intraocular pressure. *Can Anaesth Soc J*. 1979;26:482–483.

C.5. Does pretreatment with nondepolarizing muscle relaxants prevent the succinylcholine-induced elevation in IOP?

Available data are contradictory on this question, probably reflecting different methods of IOP measurement under varying depths of anesthesia with a variety of anesthetic adjuvant agents. Many techniques have been tried to prevent succinylcholine-induced elevation of IOP, and none has been consistently effective. However, there is no published report of loss of ocular contents when succinylcholine use has been preceded by pretreatment with a nondepolarizing relaxant and barbiturate for induction, and many anesthesiologists feel this is a safe combination for rapid-sequence induction in the open-eye, full-stomach situation.

C.7. How will you perform a rapid-sequence induction and intubation without using succinylcholine?

The safety of the patient always must be the primary concern; the preservation of the injured eye is secondary. Measures must be taken to guarantee adequate anesthetic depth and to blunt the hemodynamic responses to laryngoscopy and endotracheal intubation. Pretreatment measures such as narcotics, β-blockers, calcium channel blockers, lidocaine, or midazolam should be considered. Before induction, the patient should breathe 100% oxygen for several minutes, administered by a gently applied face mask. Anesthesia can then be induced using carefully applied cricoid pressure with intravenous sodium thiopental (5 mg per kg) or propofol (2 to 3 mg per kg) and a nondepolarizing muscle relaxant. Several options exist:

- Pancuronium (0.15 to 0.2 mg per kg) will provide intubation condition in 90 seconds. Tachycardia and prolonged muscle relaxation may be a problem.
- Atracurium (0.5 mg per kg) will allow safe intubation in 3 minutes. A larger bolus (1.5 mg per kg) will allow intubation in 60 to 90 seconds but may cause hypotension, tachycardia, and histamine release.
- Cisatracurium—because of its intermediate onset of action, cisatracurium (0.10 to 0.15 mg per kg) is not recommended for rapid-sequence endotracheal intubations. Cisatracurium (0.4 mg per kg) 8 $\times$ ED95 will allow intubation in 90 seconds without histamine release, but duration of action may exceed for 60 minutes.
- Vecuronium (0.2 mg per kg) should provide adequate intubating conditions after 90 seconds.
- Rocuronium (0.8 to 1.0 mg per kg) gives excellent intubating conditions at 60 to 70 seconds. Time to recovery is variable and may take 45 to 60 minutes.
- An alternative is to pretreat the patient with a small dose of the nondepolarizing relaxant several minutes before induction, which may shorten the onset of action and lessen the dose required of subsequently administered relaxant. This has been referred to as a priming dose. Its use is controversial in that it may lead to diplopia, muscle weakness, respiratory distress, and aspiration while offering no definite advantage over the use of larger initial doses of nondepolarizing muscle relaxants. The doses for rapid tracheal intubation with succinylcholine or various nondepolarizing relaxants are listed in Chapter 14, section C.4, Table 14.4.

Whatever technique is selected, it is essential to monitor the degree of muscle relaxation with a neuromuscular blockade monitor. It is also possible to intubate the patient without any muscle relaxant at all after a deep level of anesthesia has been reached, but this is not a recommended technique. Not only is the airway unprotected for a long period, but also prevention of bucking cannot be guaranteed and positive pressure ventilation by face mask may exert pressure on the eye.

C.8. What are the effects of ketamine on the eye?

Ketamine may cause nystagmus and blepharospasm and is, therefore, not suitable for ophthalmic surgery. Studies with respect to the effect of ketamine on IOP have shown both increased and decreased IOP in children and no change in IOP in adults premedicated with diazepam and meperidine. This may depend on whether ketamine is administered through the IM or IV route.

Yoshikawa K, Murai Y. The effect of ketamine on intraocular pressure in children. *Anesth Analg*. 1971;50:199–202.

C.9. Would you consider the use of etomidate as an induction agent? What about propofol?

Although etomidate has been associated with a decrease in IOP when used as an induction agent, the unpredictable incidence of generalized myoclonus seen with etomidate use and resultant elevation of IOP may preclude its use in open-globe injuries, unless rapid and complete prior muscle relaxation can be guaranteed. Propofol, with its antiemetic properties and ability to decrease IOP, would be an excellent choice for induction.

Berry JM, Merin RG. Etomidate myoclonus and the open globe. *Anesth Analg*. 1989;69:256–259.

Miller RD, ed. *Miller's Anesthesia.* 7th ed. Philadelphia: Churchill Livingstone; 2010:2378–2385.

C.10. How do inhalation agents affect IOP and by what mechanism?

Inhalation agents cause dose-related decreases in IOP as a consequence of the following:

- Reduced aqueous humor production
- Depression of the CNS control center
- Facilitation of aqueous humor outflow
- Decreased extraocular muscle tension
- Lowered arterial blood pressure

The degree of IOP reduction is proportional to the depth of anesthesia.

Cunningham AJ, Barry P. Intraocular pressure: physiology and implications for anaesthetic management. *Can Anaesth Soc J*. 1986;33:195–208.

Miller RD, ed. *Miller's Anesthesia.* 7th ed. Philadelphia: Churchill Livingstone; 2010:2379.

C.11. During the procedure, the patient's pulse suddenly dropped to 40 beats per minute. What do you think was happening? What is the oculocardiac reflex (OCR)?

The OCR may be manifested by bradycardia, bigeminy, ectopy, nodal rhythms, atrioventricular block, and cardiac arrest. It is caused by traction on the extraocular muscles (especially medial rectus), ocular manipulation, or manual pressure on the globe. The OCR is commonly seen during eye muscle surgery, detached retina repair, or enucleation or whenever there is extensive traction or rotation of the eyeball.

Barash PG, Cullen BF, Stoelting RK, eds. *Clinical Anesthesia.* 6th ed. Philadelphia: Lippincott Williams & Wilkins; 2009:1327.

Miller RD, ed. *Miller's Anesthesia.* 7th ed. Philadelphia: Churchill Livingstone; 2010:2379.

C.12. What are the afferent and efferent pathways of the OCR?

The OCR is trigeminovagal. The afferent pathway is by way of the ciliary ganglion to the ophthalmic division of the trigeminal nerve and through the gasserian ganglion to the main sensory nucleus in the fourth ventricle. The efferent pathway is the vagus nerve.

Adams AK, Jones RM. Anaesthesia for eye surgery: general considerations. *Br J Anaesth.* 1980;52:663–669.

Barash PG, Cullen BF, Stoelting RK, eds. *Clinical Anesthesia.* 6th ed. Philadelphia: Lippincott Williams & Wilkins; 2009:1327.

Smith GB. *Ophthalmic Anesthesia.* Baltimore: University Park Press; 1983:66–72.

C.13. What factors contribute to the incidence of the OCR?

Preoperative anxiety, light general anesthesia, hypoxia, hypercarbia, and increased vagal tone because of age or drugs. The reported incidence of cardiac rhythm changes during eye muscle surgery is 32% to 82%. The incidence is higher in children.

Miller RD, ed. *Miller's Anesthesia.* 7th ed. Philadelphia: Churchill Livingstone; 2010:2379.

Smith GB. *Ophthalmic Anesthesia.* Baltimore: University Park Press; 1983:66–72.

C.14. How do you diagnose and treat the OCR?

- Monitor the electrocardiogram intraoperatively and during any eye manipulation.
- Stop the surgical stimulus immediately.
- Ensure that ventilation is adequate.
- Ensure sufficient anesthetic depth.

The OCR may fatigue with repeated stimulation.

Miller RD, ed. *Miller's Anesthesia*. 7th ed. Philadelphia: Churchill Livingstone; 2010:2379.

Smith GB. *Ophthalmic Anesthesia.* Baltimore: University Park Press; 1983:66–72.

C.15. Is atropine useful for the OCR?

Atropine use is controversial. Atropine, 0.4 mg IM, as a premedicant has no vagolytic effect after 60 minutes and is of no value in preventing or treating the OCR. Atropine, 0.4 mg IV, is effective for 30 minutes in preventing bradycardia associated with the OCR. Doses greater than 0.5 mg IV can cause tachycardia, which may be detrimental in certain patients with heart disease. At least 2 to 3 mg is required to ensure a total vagal block.

Blanc VF. Anticholinergic premedication for infants and children on the oculocardiac reflex [Letter]. *Can Anaesth Soc J*. 1983;30:683–684.

Miller RD, ed. *Miller's Anesthesia.* 7th ed. Philadelphia: Churchill Livingstone; 2010: 2378–2386.

Steward DJ. Anticholinergic premedication in infants and children on the oculocardiac reflex [Reply]. *Can Anaesth Soc J*. 1983;30:684.

C.16. Can retrobulbar block prevent the OCR? Is it appropriate in this patient?

Retrobulbar block injection is not only unreliable in preventing the OCR but may, during the injection, cause OCR, cardiac arrest, or retrobulbar hemorrhage.

Local infiltration of the recti muscles and a delicate operating technique may decrease the incidence of OCR. In this patient, retrobulbar block is relatively contraindicated because it may increase IOP.

Allen ED, Elkington AR. Local anesthesia and the eye. *Br J Anaesth.* 1980;52:689–694.

McGoldrick KE. Complications of regional anesthesia for ophthalmic surgery. *Yale J Biol Med*. 1993;66:443–445.

Miller RD, ed. *Miller's Anesthesia.* 7th ed. Philadelphia: Churchill Livingstone; 2010:2379.

D. Postoperative Management

D.1. Would you reverse the neuromuscular blockade in this patient?

There is no contraindication to reversal, provided that efforts are made to minimize coughing or bucking on the endotracheal tube.

D.2. Do reversal doses of atropine affect IOP?

Reversal doses of atropine, when given in conjunction with neostigmine, do not significantly alter IOP and this combination may be safely used, even in patients with glaucoma.

Barash PG, Cullen BF, Stoelting RK, eds. *Clinical Anesthesia.* 6th ed. Philadelphia: Lippincott Williams & Wilkins; 2009;1325.

Cunningham AJ, Barry P. Intraocular pressure: physiology and implications for anaesthetic management. *Can Anaesth Soc J.* 1986;33:195–208.

D.3. What would you do before extubating this patient?

- Empty the stomach with an orogastric tube while the patient is still paralyzed.
- Suction the pharynx with the patient still paralyzed or deeply anesthetized.
- Give an antiemetic, such as droperidol 0.01 mg per kg IV or ondansetron 0.1 mg per kg IV, 20 to 30 minutes before the end of surgery.
- Give lidocaine 1.5 mg per kg IV or remifentanil 0.5 to 0.8 μg per kg IV to prevent coughing during emergence.

Gefke K, Anderson LW, Friesel E. Intravenous lidocaine as a suppressant of cough and laryngospasm with extubation after tonsillectomy. *Acta Anaesthesiol Scand.* 1983;27:111–112.

Miller RD, ed. *Miller's Anesthesia.* 7th ed. Philadelphia: Churchill Livingstone; 2010:2385.

D.4. When would you extubate this patient?

There may be a conflict between the desire to extubate awake because of the full stomach and the desire to extubate deep to prevent coughing and bucking. Because modern techniques of eye repair involve minimal risk of suture disruption with coughing, one may extubate awake, thereby protecting the airway.

D.5. The patient awakened in the recovery room and complained of pain and tearing in the opposite eye. The conjunctiva was inflamed. What was the likely cause?

General anesthesia decreases tear production and reduces normal mechanical eyelid closure. Corneal abrasions are the most common perioperative ocular injury, and this patient's complaints are consistent with that diagnosis.

Barash PG, Cullen BF, Stoelting RK, eds. *Clinical Anesthesia.* 6th ed. Philadelphia: Lippincott Williams & Wilkins; 2009:1340.

Miller RD, ed. *Miller's Anesthesia.* 7th ed. Philadelphia: Churchill Livingstone; 2010:2385.

D.6. Will taping the eyes shut or applying ointment prevent corneal abrasions? Are there any contributing factors?

There is no guarantee that an eye that has been taped shut or lubricated will not sustain a corneal abrasion. Most anesthesiologists protect the eyes in some way; however, abrasions still occur. Corneal abrasions represent the most common ophthalmic complication associated with general anesthesia. The incidence may be as high as 44% when no preventative measures have been taken and the cornea is exposed. The mechanism is thought to be drying of or direct trauma to exposed cornea. Possible contributing factors may be mask anesthesia, prone position, or having the patient's face in the surgical field.

Barash PG, Cullen BF, Stoelting RK, eds. *Clinical Anesthesia*. 6th ed. Philadelphia: Lippincott Williams & Wilkins; 2009:1340.

Bronheim D, Abel M, Neustein S. Corneal abrasions following non-ophthalmic surgery: a retrospective view of 35,253 general anesthetics. *Anesthesiology*. 1995;83:A1071.

Gild WM, Posner KL, Caplan RA, et al. Eye injuries associated with anesthesia. *Anesthesiology*. 1992;76:204–208.

D.7. What should you do when you suspect your patient might have a corneal abrasion?

Prompt consultation with an ophthalmologist should be solicited for precise diagnosis and treatment. The patient should be reassured that corneal abrasions usually heal and that relief of pain occurs within 24 to 48 hours. Possible treatments include eye patching and topical administration of antibiotics, short-acting cycloplegics, or anti-inflammatory agents. The use of eye patches is controversial.

A topical anesthetic for the cornea should never be given to a patient for self-administration. Misuse may cause delayed wound healing and keratopathy.

Hulbert MF. Efficacy of eye pad in corneal healing after corneal foreign body removal. *Lancet*. 1991;337:643.

Jampel HD. Patching for corneal abrasions. *JAMA*. 1995;274:1504.

Kaiser PK. The Corneal Abrasion Patching Study Group. A comparison of pressure patching versus no patching for corneal abrasions sue to trauma or foreign body removal. *Ophthalmology*. 1995;102:1936–1942.

D.8. A month after the surgical repair, the patient complained of impaired vision in the operative eye. He was examined and found to have a detached retina. As part of the surgical treatment, the ophthalmologist injected a gas bubble into the patient's posterior chamber. Why is this important to an anesthesiologist?

If a patient with intraocular gas needs to undergo general anesthesia before the gas bubble resorbs, nitrous oxide must be avoided because the gas will expand thereby increasing IOP. The effects on the eye may be disastrous. Various types of gasses may be injected, with different durations. Patients are usually given bracelets to inform anesthesiologists that they have gas in their eye and nitrous oxide must be avoided.

CHAPTER 35

Laser Treatment for Laryngeal Lesions

MARCUS GUTZLER

A 7-YEAR-OLD GIRL

with a past history of recurrent respiratory papillomatosis (RRP) is scheduled for direct laryngoscopy and possible reexcision. The patient has had 10 papilloma reexcisions over the course of the previous 2 years. Currently, she is undergoing adjuvant treatment with α-interferon, but now presents again with slowly progressive hoarseness.

A. Medical Disease and Differential Diagnosis

1. What is the cause of RRP?
2. Does delivery through cesarean section prevent infection of the neonate with human papilloma virus (HPV)?
3. Is this an unusual presentation for RRP?
4. What are the available treatment options for RRP?
5. What are common adverse effects of α-interferon therapy?
6. What is the differential diagnosis of hoarseness in this child?

B. Preoperative Evaluation and Preparation

1. What are the key points of the preanesthetic history and physical examination in this patient?
2. What preoperative laboratory tests are necessary?
3. How should this child be premedicated before coming to the operating room (OR)?
4. What are the special considerations for anesthetic setup in this case?

C. Intraoperative Management

1. What is a laser and how does it work?
2. What are the characteristics of laser radiation?
3. Discuss some advantages associated with the use of lasers for laryngeal surgery.
4. What are some disadvantages of lasers compared with microdebriders?

5. How would you protect the external surface of a conventional endotracheal tube (ETT) for use during laser microlaryngoscopy?
6. What are the disadvantages of foil-wrapped tubes?
7. What special ETTs are available for laser surgery?
8. How would you manage an airway fire?
9. What is the Venturi effect?
10. What is Venturi jet ventilation?
11. How would you institute and conduct manual jet ventilation?
12. How is anesthesia maintained during jet ventilation?
13. What are the complications of jet ventilation?
14. Are there contraindications for the use of jet ventilation?
15. Discuss airway management options during laryngeal papilloma resection.
16. How would you plan to monitor this patient?
17. How would you induce anesthesia for an intermittent apnea technique?

D. Postoperative Management

1. After uneventful laser microlaryngeal resection using jet ventilation, the patient was extubated in the OR and then transferred to the recovery room. What are the common postoperative complications?

A. Medical Disease and Differential Diagnosis

A.1. What is the cause of RRP?

RRP, a disease of the respiratory mucosa characterized by benign nonkeratinizing squamous papillomata, is caused by the human papilloma virus (HPV). On the basis of shared genetic code homologies, HPV are grouped and numbered. Although there are approximately 100 different HPV types identified to date, with respect to RRP, two types stand out: HPV 6 and 11. They are not only the causative agents for RRP but are also responsible for 90% of genital warts (*Condylomata acuminata*). Recently, there has been evidence implicating infections with non-HPV agents in the pathogenesis of RRP.

Derkay CS, Faust RA. Recurrent respiratory papillomatosis. In: Flint PW, Haughey BH, Lund VJ, et al., eds. *Cummings Otolaryngology: Head & Neck Surgery*. 5th ed. Philadelphia: Mosby; 2010:2884–2895.

Donne A, Hampson L, Homer J, et al. The role of HPV type in recurrent respiratory papillomatosis. *Int J Pediatr Otorhinolaryngol*. 2010;74:1:7–14.

A.2. Does delivery through cesarean section prevent infection of the neonate with human papilloma virus (HPV)?

HPV has been estimated to be present in the genital tract of as many as 25% of all women of childbearing age worldwide. Although RRP is the most common benign neoplasm of the larynx in children, its true incidence and prevalence are uncertain. It is estimated that each year, 1,500 to 2,500 new cases of childhood-onset RRP occur in the United States. Therefore, only a minority of children of virus-carrying mothers will become symptomatic, which is not to say that the number of virus-carrying children is not much higher. Even in parturients with an active genital condyloma lesion, the child's risk of contracting the disease when normal spontaneous vaginal delivery is chosen is only approximately 1 in 400.

The route of transmission (i.e., transplacental, perinatal, or postnatal) is not completely understood, as is the preventive value of cesarean sections in parturients known to carry the virus. Cesarean section with the sole intention of preventing the disease in the newborn is therefore not recommended. It may have a role in preventing excessive maternal bleeding likely to result from normal spontaneous vaginal delivery or in circumventing pelvic outlet obstruction secondary to excessive lesions.

It is hoped that with the wider availability of vaccines effective against HPV 6 and 11 (Gardisil, Merck & Co., Inc., Whitehouse Station, NJ), the incidence of RRP will decrease in the future.

Centers for Disease Control and Prevention. *Sexually transmitted disease guidelines*. 2002. Available from: http://www.cdc.gov/STD/treatment/6-2002 TG.htm.

Derkay CS, Faust RA. Recurrent respiratory papillomatosis. In: Flint PW, Haughey BH, Lund VJ, et al., eds. *Cummings Otolaryngology: Head & Neck Surgery*. 5th ed. Philadelphia: Mosby; 2010:2884–2895.

A.3. Is this an unusual presentation for RRP?

Recurrence of voice changes despite repeated surgical interventions is unfortunately not that rare in patients with respiratory papillomatosis. Hoarseness, stridor, and—if severe enough—the development of respiratory distress from airway obstruction are the most consistent signs and symptoms of patients with RRP. Oral, tracheobronchial, and pulmonary involvements also are known to occur.

At present, there is no cure for RRP and no modality that would lead to eradication of the virus from the respiratory mucosa. Local recurrences are therefore to be expected.

Derkay CS, Faust RA. Recurrent respiratory papillomatosis. In: Flint PW, Haughey BH, Lund VJ, et al., eds. *Cummings Otolaryngology: Head & Neck Surgery*. 5th ed. Philadelphia: Mosby; 2010:2884–2895.

A.4. What are the available treatment options for RRP?

As stated in the preceding text, there is no cure but only disease control for relentless and recurrent papillomatosis. The current standard of care is surgical therapy with the goal of complete removal of papillomata and preservation of normal structures as much as possible.

As scarring from overaggressive laryngeal resections may lead to precisely the adverse clinical effects that surgical therapy seeks to avoid or minimize (dysphonia, airway compromise), most experienced surgeons will accept incomplete papilloma resection, especially when near delicate structures such as the anterior laryngeal commissure. Even with the removal of all clinically evident papilloma, not all latent virus particles will have been eradicated.

With respect to surgical technique, the CO_2 laser used to be the mainstay of therapy since the 1970s. According to a recent survey by the American Society of Pediatric Otolaryngology, this may be changing. Most members participating in this survey seem to rely on the use of the microdebrider as the preferred surgical therapy. The microdebrider is considered to be just as precise a surgical tool as the CO_2 laser, while at the same time being easier to use.

There continues to be an appliction for laser-based resections; certain lesions (sessile ones, those with ventricular involvement, or those in the area of significant scarring) still are best dealt with by CO_2-, potassium titanyl phosphate (KTP), or pulsed-dye laser (PDL).

In addition, there seems to be an increasing role for adjuvant medical therapy: α-interferon and various antiviral agents, of which the most commonly used one is intralesional cidofovir.

Derkay CS, Faust RA. Recurrent respiratory papillomatosis. In: Flint PW, Haughey BH, Lund VJ, et al., eds. *Cummings Otolaryngology: Head & Neck Surgery*. 5th ed. Philadelphia: Mosby; 2010: 2884–2895.

A.5. What are common adverse effects of α-interferon therapy?

Interferons (IFNs) are potent cytokines that possess antiviral, immunomodulating, and antiproliferative activities. Of the three known major classes of IFNs (α, β, and γ), only α-interferon is clinically used in RRP. A common therapeutic regimen entails daily subcutaneous applications for a month, followed by a 6-month period of injections three times a week and then further slow weaning as tolerated. Known adverse effects associated with systemic application are an acute, relatively benign influenza-like syndrome, characterized by fever, chills, headache, myalgia, arthralgia, nausea, vomiting, and diarrhea, as well as more serious dose-limiting comorbidities, namely myelosuppression and neurotoxicity. Neurotoxicity is characterized by somnolence, confusion, behavioral disturbance, and rarely, seizures, debilitating neurasthenia, and depression. Alopecia and personality change are common in IFN-treated children. Cardiovascular toxicity (hypotension and tachycardia) and hepatotoxicity seem to be more rare.

Derkay CS, Faust RA. Recurrent respiratory papillomatosis. In: Flint PW, Haughey BH, Lund VJ, et al., eds. *Cummings Otolaryngology: Head & Neck Surgery*. 5th ed. Philadelphia: Mosby; 2010:2884–2895.

A.6. What is the differential diagnosis of hoarseness in this child?

Hoarseness always indicates some abnormality of laryngeal structure or function. Given the patient's previous history, local papilloma recurrence and/or postoperative scarring of laryngeal structures seem likely causes in this patient. A broader differential diagnosis for hoarseness in children would be as follows:

- Anatomic and congenital causes
  - Cystic lesions (laryngocele, thyroglossal cyst)
  - Vocal fold nodules
  - Glottic webs
- Neoplastic causes
  - Squamous cell carcinoma
  - RRP
- Neurologic causes
  - Central (e.g., intracerebral hemorrhage, hydrocephalus)
  - Peripheral neuropathies

- Inflammatory
  - Gastroesophageal reflux
  - Rheumatoid arthritis
  - Angioneurotic edema
- Infectious
  - Croup syndrome
  - Laryngotracheobronchitis
  - Epiglottitis

McMurray JS. Disorders of phonation in children. *Pediatr Clin North Am.* 2003;50:363–380.

B. Preoperative Evaluation and Preparation

B.1. What are the key points of the preanesthetic history and physical examination in this patient?

Of obvious concern in these patients is to quickly detect and address any serious respiratory compromise; in the absence of severe respiratory distress, a detailed history should be obtained. A review of previous anesthetic experiences with particular emphasis on problems pertaining to airway management would be a good starting point. Weight, general health, associated comorbidities, recent respiratory infections, allergies, medications, and nothing-by-mouth status are all of obvious importance. A search for serious adverse effects as a result of the IFN therapy should be done.

With respect to the voice changes, a more in-depth investigation may offer some clues regarding the suspected location: A low-pitched, coarse, fluttering voice suggests a subglottic lesion, whereas a high-pitched, cracking voice, aphonia, or breathy voice suggests a glottic lesion. Associated high-pitched stridor also suggests a glottic or subglottic lesion. Because of the precision of laryngeal mechanics, hoarseness may result from a remarkably small lesion. On the other hand, if the origin of the lesion is remote from the vocal cords, hoarseness may result from a significantly larger lesion.

The concern here is to recognize the lesion that could potentially result in complete airway obstruction once anesthesia has been induced. When in doubt, a flexible nasopharyngoscopy—if not already done before arrival in the operating room (OR)—should be considered immediately preoperatively.

Derkay CS. Recurrent respiratory papillomatosis. *Laryngoscope*. 2001;111:57–69.

B.2. What preoperative laboratory tests are necessary?

In recent years, the value of routine preoperative laboratory screening has been questioned. For a surgical procedure not associated with significant intraoperative blood loss in a child who is not at increased risk for severe and physiologic important anemia, no laboratory tests are required.

This patient may however no longer fall into this latter category. After all, α-interferon is associated with serious side effects, such as neurotoxicity and myelosuppression. Because effects of myelosuppression may not be diagnosed easily by history and physical examination, one might argue that at least obtaining a hematocrit would be in order in this particular patient.

Steward DJ. Preoperative evaluation and preparation for surgery. In: Gregory GA, ed. *Principles of Pediatric Anesthesia*. 4th ed. New York: Churchill Livingstone; 2002:184.

B.3. How should this child be premedicated before coming to the operating room (OR)?

Children with recurrent RRP are often quite anxious and apprehensive coming back to the OR for yet another reexcision. A reassuring preoperative visit by the anesthesiologist should help allay fears. Sedative premedication should be used very carefully, especially in the child with significant respiratory distress. It should not be administered without close monitoring and the immediate availability of oxygen, suction, and positive pressure ventilation. Anticholinergic premedication may be used to dry up oral secretions.

Brett CM, Zwass MS. Eyes, ears, nose, throat and dental surgery. In: Gregory GA, ed. *Principles of Pediatric Anesthesia*. 4th ed. New York: Churchill Livingstone; 2002: 687–688.

B.4. What are the special considerations for anesthetic setup in this case?

Before the initiation of anesthesia, the anesthesiologist should discuss the case with the surgeon. The anesthesiologist should seek a thorough understanding of the surgical plan and must keep in close communication with the surgeon throughout the procedure. A strategy for maintaining oxygenation and ventilation during the case, while working around surgical needs, must be devised. Special equipment (e.g., laser, jet ventilator, bronchoscopes) must be present and in good working condition.

Preparations for successfully dealing with the difficult pediatric airway should be made by both the anesthesia team (difficult airway cart, senior pediatric anesthesiologist) and the surgical team (open tracheotomy set and experienced otolaryngologist on standby).

Whether a laser will be used greatly impacts on airway management. The biggest concern here is prevention of an airway fire. Also, a plan to deal effectively with such a disaster, should it occur, needs to be firmly established beforehand. Aside from that, all OR staff must wear protective eye gear and laser masks when working around the laser.

Derkay CS. Recurrent respiratory papillomatosis. *Laryngoscope*. 2001;111:57–69.

C. Intraoperative Management

C.1. What is a laser and how does it work?

Electromagnetic radiation consists of photons, and photons have properties consistent with both particles and waves. Like radio waves and Roentgen waves, visible light is another form of electromagnetic radiation.

The characteristic features of these different forms of radiation are their respective wavelengths. Visual light is electromagnetic radiation with wavelengths in the range from 385 to 760 nm, shorter wavelengths are ultraviolet, and longer wavelengths are infrared.

Laser is an acronym for light amplification by stimulated emission of radiation. What makes laser special is the high-energy density that it provides, and the ability to quickly transfer large quantities of energy to remote locations, be it through fiberoptic channels (for example with the potassium titanyl phosphate laser) or through free air, as is usually the case with the CO_2 laser.

Several concepts are important for a basic understanding of the phenomenon of laser:

- *The photoelectric effect*. Light of a certain wavelength (e.g., blue) causes metal to eject electrons at a rate proportional to the brightness of this light. Intense light of different colors (e.g., red, orange, yellow) cannot do that.
- *The orbital model*. Electrons circling the nuclei of atoms are limited to a few specific orbital patterns and radii. Each orbital has its specific energy level. The energy differences between electron orbitals are charceteristic for specific atoms. The only way an electron can move from one orbital to another of higher or lower energy is to either absorb or emit an amount of energy equivalent to the difference in energy between the two orbitals.
- *Stimulated absorption*. The process by which a photon's energy is captured by an electron, thereby lifting the electron into a higher energy orbital (the electrons get "excited").
- *Spontaneous emission*. The opposite phenomenon during which an electron drops to a lower orbital, in the process sending out a photon carrying away the excess energy.
- *Population inversion*. Many (as opposed to one single) electrons achieve a higher energy level (higher orbital). Once initiated by a single photon, a chain reaction of stimulated emission sets in (amplification).

The necessary components of a laser system consist of a laser medium (gaseous or solid) containing the atoms whose electrons create the laser light, resonating mirrors to enhance laser efficiency, and an energy source to excite the atoms of the laser medium into generating laser light. An energy source provides the means for obtaining a population inversion of orbital electrons of the laser medium. A pair of axial mirrors permits repeated passes of collimated photons through the medium, allowing maximum amplification by stimulated emission. One of the mirrors is partially transmitting, finally allowing the laser beam to emerge.

Rampil IJ. Anesthesia for laser surgery. In: Miller RD, ed. *Miller's Anesthesia*. 7th ed. Philadelphia: Churchill Livingstone; 2010:2405–2418.

C.2. What are the characteristics of laser radiation?

The high-energy density of laser is the result of three characteristics:

- There is a high degree of monochromaticity; that is, other than with ordinary light, the range of wavelengths is very limited.
- Electromagnetic fields of all photons in the laser beam oscillate synchronously in identical phase, a phenomenon called *coherence*, again distinct from ordinary light where the electromagnetic fields are phased randomly.
- Whereas ordinary light beams spread out in all directions from a point source, laser light remains in a narrow collimated beam.

These characteristics allow for a very concentrated energy delivery, often producing heating at a rate of many thousand degrees per second with lasers in current clinical application.

Rampil IJ. Anesthesia for laser surgery. In: Miller RD, ed. *Miller's Anesthesia*. 7th ed. Philadelphia: Churchill Livingstone; 2010:2405–2418.

C.3. Discuss some advantages associated with the use of lasers for laryngeal surgery.

With laser light, tissue penetration is mostly a function of wavelength. Long-wavelength laser light, such as that from CO_2 (operating at 10,600 nm), is completely absorbed by water in the first few layers of cells. The thermal effect is therefore largely limited to the point of entry into the target tissue. This results in explosive vaporization of the surface tissue of the target with surprisingly little damage to underlying cells. When coupled to an operating microscope, the laser vaporizes the lesions with precision, causing minimal bleeding and edema, an obvious advantage, especially in small pediatric airways.

As mentioned in section A.4, in certain situations, a laser-based resection technique is the surgical method of choice: Sessile lesions, lesions in scarred areas, and those located near or in the laryngeal ventricle often are treated with PDL. Other than the CO_2 laser, this is a laser with a shorter wavelength that typically *spares* the epithelium, but specifically targets the microvascular supply of the overriding lesion. This has obvious advantages, where the epithelium of one wall is in proximity to epithelium from an opposing wall, such as is the case in the anterior laryngeal commissure. Not denuding the epithelium is beneficial from a functional standpoint, as it should limit fibrotic changes from abutting raw surfaces, that might interfere with the delicate interplay of laryngeal substructures. An added benefit at least in the adult patient population is that the PDL can be used with just topical anesthesia alone (delivery is typically via fiberoptic means), thereby avoiding many of the complicating considerations for laser surgery under general anesthesia.

Derkay CS. Recurrent respiratory papillomatosis. *Laryngoscope*. 2001;111:57–69.

Derkay CS, Gallagher TQ. Recurrent respiratory papillomatosis: update 2008. *Curr Opin Otolaryngol Head Neck Surg*. 2008;16:536–542.

Rampil IJ. Anesthesia for laser surgery. In: Miller RD, ed. *Miller's Anesthesia*. 7th ed. Philadelphia: Churchill Livingstone; 2010:2405–2418.

C.4. What are some disadvantages of lasers compared with microdebriders?

There are significant risks associated with the use of laser for laryngeal surgery.

Extra staff is typically required for the safe operation of the laser equipment, adding to the overall cost of the procedure.

Special eye protection for both patient and staff are indispensable, as the powerful laser beam may otherwise cause serious ocular injury. Other body parts need also to be carefully protected from inadvertent laser exposure in order to prevent tissue injury. Inappropriate and aggressive use of the laser may also cause injury to mucosa primarily not affected by disease and create an environment suitable for implantation of viral particles and thereby may actually promote spread of the disease. Laser-induced pneumothorax has been reported after a laryngeal procedure. Although the thermal effect is largely limited to the point of entry into the target tissue, if not used judiciously especially near delicate structures such as the anterior or posterior laryngeal commissure, laser may cause unacceptable scarring and subsequent abnormal vocal fold function.

Laser smoke contains water vapor and destroyed tissue material. It has been found to contain active viral DNA, a potential source of infection for OR personnel. Smoke may also obstruct the surgeon's view during the resection.

The biggest concern with laser use, however, revolves around the generation of an airway fire through ignition of the endotracheal tube (ETT) by inadvertent laser strike, a potentially fatal complication if not effectively dealt with quickly.

When comparing the microdebrider and the CO_2 laser, there is evidence suggesting that removing papillomas using the microdebrider is associated with better

short-term improvement in voice quality, and shorter procedure time, which may ultimately translate to reduced operative cost. Heat-induced scarring of nearby tissues is not a concern, there is no need for circumstantial protection from inadvertent laser strike, and the risk for an airway fire should be no higher than in a standard case.

Derkay CS, Faust RA. Recurrent respiratory papillomatosis. In: Flint PW, Haughey BH, Lund VJ, et al., eds. *Cummings Otolaryngology: Head & Neck Surgery*. 5th ed. Philadelphia: Mosby; 2010:2884–2895.

Werkhaven JA. Microlaryngoscopy-airway management with anaesthetic techniques for CO_2 laser. *Pediatr Anesth*. 2004;14:90–94.

C.5. How would you protect the external surface of a conventional endotracheal tube (ETT) for use during laser microlaryngoscopy?

Inadvertent laser strike can ignite and burn any hydrocarbon material in the airway, including ETTs. Because of their proximity to the operative field, ETTs pose a serious fire hazard during laser use, especially in the oxygen-enriched environment of a general anesthetic.

All commonly used ETTs are potentially flammable, but to some degree flammability is a function of the material used to manufacture the tube. Unfortunately, the now commonplace clear polyvinylchloride (PVC) plastic tubes seem to catch fire much more easily than older red rubber tubes. Also, red rubber tubes seem to lead to less toxic combustion products once ignited.

In addition to limiting the amount of oxygen used to ventilate the patient to as low as tolerated, one strategy to make the use of conventional PVC tubes safer is to guard it with reflective tape. Conventional aluminum or copper tape is an inexpensive (although not U.S. Food and Drug Administration [FDA]-approved) way to offer some protection against brief laser strike. FDA-approved tape is also available (Merocel Laser Guard, Medtronic USA).

Should a regular cuffed tube be used, the cuff in itself unfortunately cannot be protected from laser strike in this manner, as it is impractical to wrap the cuff with tape. Cuff breakage needs to be recognized immediately as it increases the fire hazard significantly; it will allow access of oxygen-enriched gas mixtures to the hypopharynx. One strategy here to reduce risk is to fill the cuff with an indicator dye (e.g., methylene blue in normal saline) to detect a break early and hopefully douse small fires at the same time. The cuff should also be covered from above with wet gauze or neurosurgical sponges to retard heating.

To wrap a PVC tube with tape, the tube should be clean and fat-free, thereby facilitating tape adhesion. The tube diameter should be chosen 1 to 2 mm smaller than usual. Mastisol will further enhance the stickiness to the ETT. Wrapping should start at the distal end or just proximal to the cuff and be continued up to the level of the uvula. The distal end of the tape should be cut at a 60-degree angle, and the tube should then be wrapped in a spiral with approximately 30% overlap, avoiding sharp edges and leaving no PVC exposed.

Rampil IJ. Anesthesia for laser surgery. In: Miller RD, ed. *Miller's Anesthesia*. 7th ed. Philadelphia: Churchill Livingstone; 2010:2405–2418.

Wöllmer W, Wolfgang W, Schade G, et al. Endotracheal tube fires still happen – a short overview. *Medical Laser Application.* 2010;25:118–125.

C.6. What are the disadvantages of foil-wrapped tubes?

Disadvantages of metallic foil-wrapped tubes include risk of trauma to pharyngeal and laryngeal tissues by sharp edges. The tube will lose elasticity and be more prone to kink. If foil becomes detached, the protective effect is lost and aspirated foil may lead to airway obstruction. The reflective surface enhances the risk of inadvertent laser strike of surrounding tissues.

Brett CM, Zwass MS. Eyes, ears, nose, throat and dental surgery. In: Gregory GA, ed. *Principles of Pediatric Anesthesia.* 4th ed. New York: Churchill Livingstone; 2002:687–688.

Wöllmer W, Wolfgang W, Schade G, et al. Endotracheal tube fires still happen – a short overview. *Med Laser Appl.* 2010;25:118–125.

C.7. What special ETTs are available for laser surgery?

The FDA-approved specialized tubes for laser surgery are commercially available. In essence, there are metal- and silicone-based tubes.

The Xomed Laser Shield and Laser Shield II (Medtronic, USA) are silicone-based tubes with laser-reflective aluminum containing coating or reflective aluminum wrap with smooth fluoroplastic overwrap on the outside (in the case of the Laser Shield II). Although these tubes may withstand laser strikes longer then conventional tubes, they will ignite as well with longer exposure.

Two FDA-approved metal tube models are commercially available for use with CO_2 laser. First, there is the Laser Flex tube (Mallinckrodt, USA), an airtight stainless steel spiral tube with two distal PVC cuffs. If one ruptures, the second unruptured cuff will still limit egress of oxygen-rich gas. Second, the Bivona Fome-Cuf (Bivona, USA) is an aluminum spiral tube with an outer silicone coating. This tube has a specially designed self-inflating foam sponge-filled cuff, which will remain expanded even after laser puncture. Not surprisingly, the rigidity and bulkiness of these tubes are practical disadvantages that discourage from their routine use, especially in pediatric patients. Even with these metal tubes, fire hazard is still a concern.

Wöllmer W, Wolfgang W, Schade G, et al. Endotracheal tube fires still happen – a short overview. *Med Laser Appl.* 2010;25:118–125.

C.8. How would you manage an airway fire?

In case of an airway fire, rapid and effective action is required. When suddenly faced with this frightening situation, the "4 Es" mnemonic may help you to stay focused:

- *E*xtract
- *E*liminate
- *E*xtinguish
- *E*valuate

All combustible materials (ETT, pledgets) must be *e*xtracted from the airway at once. Oxygen supply through the tube must be quickly *e*liminated by disconnection from the circuit. Continued flow through a burning tube would lead to a blowtorch effect. Any residual fires need to be *e*xtinguished with normal saline. Ventilation with 100% oxygen should then be provided by mask, and anesthesia should be continued. *E*valuation of the injury is then in order and should be done with direct laryngoscopy and rigid bronchoscopy, thereby assessing the upper and lower airway. Any apparent airway damage makes reintubation the most prudent approach. For severe injury, a low tracheotomy may be indicated.

Werkhaven JA. Microlaryngoscopy-airway management with anaesthetic techniques for CO_2 laser. *Pediatr Anesth.* 2004;14:90–94.

C.9. What is the Venturi effect?

The Venturi effect originally describes the impact of constricted channels on fluid flow. As fluid passes through a constriction of a Venturi tube (a tube with two open ends and a narrowing in its midsection), it must speed up. At the same time, its hydrostatic pressure drops. This pressure drop is proportional to flow, and can, for example, be used to measure flow in pipes without interfering with flow.

Ihra G, Aloy A. On the use of Venturi's principle to describe entrainment during jet ventilation. Letter to the editor. *J Clin Anesth.* 2000;12:417–419.

C.10. What is Venturi jet ventilation?

The jet injector technique of ventilation for upper airway surgery was introduced by Sanders in 1967.

A high-pressure gas source is connected to a stiff, narrow cannula, positioned at the inlet of the laryngoscope. With a manual switch, gas boluses are delivered. In the lumen of the laryngoscope, the high-velocity stream of gas encounters stationary gas, which it pushes forward. Each jet bolus entrains ambient air through the open laryngoscope entrance, substantially augmenting the volume of the bolus and diluting the oxygen fraction of the jet.

Whether or not truly based on the phenomenon known as the *Venturi effect*, the jet injector provides a simple approach to deliver physiologic tidal volumes in a nongas tight delivery system. Venturi ventilation has become synonymous with jet ventilation in the medical literature.

Ihra G, Aloy A. On the use of Venturi's principle to describe entrainment during jet ventilation. Letter to the editor. *J Clin Anesth.* 2000;12:417–419.

McRae K. Anesthesia for airway surgery. *Anesthesiol Clin North America.* 2001;19(3):497–541.

C.11. How would you institute and conduct manual jet ventilation?

Before effective jet ventilation can begin, the operating laryngoscope must be inserted, the larynx adequately exposed and evaluated for appropriateness for jet ventilation, the suspension system installed, and the jet injector needle attached to the laryngoscope and properly aligned with the axis of the trachea. All of this takes time in an anesthetized

apneic patient. Therefore, it is our preference at the New York Presbyterian Hospital-Weill–Cornell Medical Center to begin with laryngoscopy and intubation using a standard PVC ETT if the airway appears appropriate for jet ventilation. Uninterrupted ventilation can now be performed while the operating laryngoscope and jet injector are positioned. When ready, the ETT is removed and jet ventilation begun. Alternatively, following anesthesia induction and demonstration of an adequate mask airway, the patient is paralyzed and the operating laryngoscope and jet injector are inserted and positioned while the patient is apneic.

Ventilation begins with a jet pressure of 5 to 10 psi in infants and children and 15 to 20 psi in adults. The jet pressure is gradually increased until adequate chest excursions are noted. Jet ventilation should produce good clinical expansion of the chest at a rate appropriate for the patient's age. The inspiratory-to-expiratory (I:E) ratio should allow for complete passive exhalation in between jet applications. Monitoring of peripheral arterial saturation is mandatory as is monitoring ventilation both by auscultation and palpation.

Derkay CS, Faust RA. Recurrent respiratory papillomatosis. In: Flint PW, Haughey BH, Lund VJ, et al., eds. *Cummings Otolaryngology: Head & Neck Surgery*. 5th ed. Philadelphia: Mosby; 2010:2884–2895.

Rampil IJ. Anesthesia for laser surgery. In: Miller RD, ed. *Miller's Anesthesia*. 7th ed. Philadelphia: Churchill Livingstone; 2010:2405–2418.

C.12. How is anesthesia maintained during jet ventilation?

Because the delivery of inhalational anesthetics is impractical with jet ventilation (OR pollution, inability to precisely regulate their concentrations), most authors favor a total intravenous technique. Combining a hypnotic agent such as propofol with a short-acting opioid (ideally remifentanil), hypnosis, amnesia, and analgesia can all be achieved, while allowing for a rapid recovery of the patient at the end of the procedure. Temporary muscle relaxation can be achieved with either a short-acting or intermediate-duration muscle relaxants.

Patel A, Feldman MA. Anesthesia for eye, ear, nose, and throat surgery. In: Miller RD, ed. *Miller's Anesthesia*. 7th ed. Philadelphia: Churchill Livingstone; 2010:2357–2388.

C.13. What are the complications of jet ventilation?

Complications associated with jet ventilation include dehydration of the mucosa, inadequate oxygenation and ventilation, gastric distention, regurgitation, and even rupture. Pneumomediastinum and pneumothorax have been reported, and seem to occur mostly when applying jet ventilation with a (partially) obstructed airway, occurring for example during partial closure of the vocal cords. This is best avoided by using muscle relaxation during jet ventilation.

Jaquet Y, Monnier P, Van Melle G, et al. Complications of different ventilation strategies in endoscopic laryngeal surgery. A 10 year review. *Anesthesiology*. 2006;104:52–59.

C.14. Are there contraindications for the use of jet ventilation?

Jet ventilation is most suited for patients with normal, unobstructed airways and normal lung and chest wall compliance.

The ability to fully exhale in between jet applications is crucial. If this is not possible (glottic lesion, significant interarytenoid scarring, laryngospasm), jet ventilation may not be appropriate. Decreased chest wall compliance such as in obese patients may lead to inadvertent gastric distension, further worsening respiratory compliance. Advanced chronic obstructive disease with its inherent prolonged exhalation phase may again make jet ventilation unpractical and in the presence of pulmonary bullae even hazardous. Significant overbite especially when combined with retrognathia makes orolaryngotracheal alignment challenging and accidental gastric hyperinflation likely.

Borland LM. Airway management for CO_2 laser surgery on the larynx: venturi jet ventilation and alternatives. *Int Anesthesiol Clin.* 1997;35:99–106.

Jaquet Y, Monnier P, Van Melle G, et al. Complications of different ventilation strategies in endoscopic laryngeal surgery. A 10 year review. *Anesthesiology.* 2006;104:52–59.

C.15. Discuss airway management options during laryngeal papilloma resection.

In addition to (manual) Venturi jet ventilation, there are three different widely accepted methods for managing the airway during papilloma resection—controlled mechanical ventilation through a small ETT, spontaneous ventilation, and an apnea technique with intermittent ventilation.

Except for the first option, all methods require an at least temporarily unsecured, unprotected airway during parts of the surgical resection. As reassuring as a secured airway may feel to the anesthesiologist, using an ETT during airway laser surgery entails the aforementioned risk of an airway fire. Also, surgical exposure is often suboptimal in the presence of an ETT, as the tube limits access to parts of the larynx.

Access to all parts of the laryngeal mucosa using spontaneous ventilation without an additional airway device (e.g., tube, laryngeal mask airway) is naturally superior. And, depending on the type of laser used, in the *nonpediatric* population, not rarely all that is required is *topical* anesthesia, making it potentially suitable for office-based treatments. In pediatric patients though, maintenance of spontaneous ventilation under general anesthesia is usually the more successful strategy.

For obvious reasons, muscle relaxation is not an option, and the moving surgical field is somewhat of a drawback of this technique, potentially making the resection more demanding.

Intermittent apnea offers a solution to this problem. During apnea with intermittent ventilation, the patient is repeatedly hyperventilated, either by mask or after reintubation. Use of 100% oxygen will extend the tolerable apnea time to follow. Inadvertent movement is best avoided using muscle relaxants. If a tube is used, it is then removed periodically, respirations are held, and the surgeon allowed to operate for brief periods of time, while the peripheral oxygen saturation is closely monitored. The patient is then either reintubated or just masked, before desaturation sets in, and thereby readied for another period of apnea to follow, allowing for further resection as needed. Spreading the virus to more distal parts of the airway by repeated reintubations is a concern with this technique.

Along with spontaneous ventilation, intermittent apnea techniques seem to be favored by most members of the American Society of Pediatric Otolaryngology.

Derkay CS, Faust RA. Recurrent respiratory papillomatosis. In: Flint PW, Haughey BH, Lund VJ, et al., eds. *Cummings Otolaryngology: Head & Neck Surgery*. 5th ed. Philadelphia: Mosby; 2010:2884–2895.

C.16. How would you plan to monitor this patient?

Routine monitors include a pulse oximeter, noninvasive blood pressure measurements, an electrocardiogram, a precordial stethoscope, a temperature probe, an oxygen analyzer, a CO_2 detector, and a neuromuscular blockade monitor. In this otherwise healthy patient scheduled for relatively minor surgery without the potential for significant blood loss or fluid shifts, no additional monitoring is necessary.

American Society of Anesthesiologists. http://www.asahq.org/publicationsAndServices/standards/02.pdf

C.17. How would you induce anesthesia for an intermittent apnea technique?

The choice of anesthetic induction is critically dependent upon the presence of signs and symptoms, suggesting possible airway compromise on induction. If those are present, the logical choice in an adult patient is an awake fiberoptic intubation, thereby not only allowing to secure the airway but also enabling evaluation of the subglottic airway before tube placement.

In children and uncooperative adults, an inhalation induction using sevoflurane is the next safest option. Maintenance of spontaneous ventilation is again critical. In this scenario, muscle relaxants are unsafe, until it is clear that the patient can be ventilated and/or intubated. If severe compromise is present, an awake tracheotomy under local anesthesia may be the best means of managing the airway.

Blind techniques (lightwand, blind oral or nasal intubation) cannot be recommended in this setting because they carry the risk of bleeding and loss of the airway with an obstructing lesion.

A word of caution here: Papillomas are dynamic lesions in a sense that they may grow rapidly, thereby questioning the validity of any but the most recent endoscopic airway examinations. Also, the absence of suggestive signs and symptoms does not truly guarantee a patent airway once anesthesia has been induced. Hence, extreme caution in managing these patients is essential.

If the patient has truly no airway compromise, any routine induction technique (intravenous or inhalational) can be used safely.

Patel A, Feldman MA. Anesthesia for eye, ear, nose, and throat surgery: In: Miller RD, ed. *Miller's Anesthesia*. 7th ed. Philadelphia: Churchill Livingstone; 2010:2357–2388.

D. Postoperative Management

D.1. After uneventful laser microlaryngeal resection using jet ventilation, the patient was extubated in the OR and then transferred to the recovery room. What are the common postoperative complications?

Laryngeal edema can occur early in the postoperative period and is usually manifested by retractions and inspiratory stridor in the recovery room. After microlaryngeal

surgery, patients may benefit from humidified oxygen, intravenous steroids (e.g., dexamethasone), and racemic epinephrine inhalation. Laryngospasm may develop because of laryngeal hyperactivity. To reduce the incidence of laryngospasm, topical anesthesia to the larynx may be used. If laryngospasm develops postoperatively, it is treated initially with positive pressure ventilation with 100% oxygen. More severe forms of laryngospasm may require the use of small doses of succinylcholine (1/10 of a normal induction dose, i.e., 0.1 mg per kg intravenously). The occurrence of barotrauma with jet ventilation has been described and should be kept in mind. Pulmonary complications as a result of retained secretions and subsequent atelectasis have been reported.

SECTION X

Pediatrics

CHAPTER 36

Tracheoesophageal Fistula

Jacques H. Scharoun

A 12-HOUR-OLD FULL-TERM INFANT weighing 2.5 kg presents with choking and cyanosis during its first feed. Neonatal intensive care unit (NICU) staff is unable to pass a feeding tube into the stomach. The baby also has copious oral secretions. Before birth, polyhydramnios was seen.

A. Pathophysiology and Differential Diagnosis

1. What is the diagnosis? What are the clinical features of this disease?
2. What is the pathophysiology of this disease?
3. How does this lesion occur during development?
4. How are different types of tracheoesophageal fistula (TEF) classified?
5. What other problems may this child have, and when should these be investigated?
6. What should the parents be told regarding perioperative risk? Risk of recurrence?

B. Preoperative Evaluation and Preparation

1. What laboratory workup should be obtained before surgery?
2. What options are there if patient has severe lung disease?
3. Describe management in the NICU before surgery.
4. Should these patients be routinely intubated preoperatively for airway protection?

C. Intraoperative Management

1. What intravenous (IV) access and monitoring are appropriate before induction? After induction?
2. Discuss fluid and temperature management for this baby.
3. What are the options regarding induction and intubation?
4. What is the role of fiberoptic bronchoscopy in this patient?
5. Discuss the surgical technique.
6. Discuss common intraoperative problems for this repair.

D. Postoperative Issues

1. When should the baby be extubated?
2. What pain control options are available?
3. What are early and late complications of TEF repair?

A. Pathophysiology and Differential Diagnosis

A.1. What is the diagnosis? What are the clinical features of this disease?

This patient has esophageal atresia (EA) with TEF. This occurs in 1 per 4,000 live births. The diagnosis is suspected prenatally by the presence of polyhydramnios caused by failure of the fetus to swallow amniotic fluid (secondary to EA). Polyhydramnios can also be caused by other defects, including duodenal atresia, anencephaly, congenital diaphragmatic hernia, and Trisomy 18, and only 10% to 20% of fetuses with polyhydramnios will have other anomalies. There will be an absence of fluid-filled stomach bubble on prenatal ultrasound. After birth, the neonate will have copious drooling. Attempting to feed the baby will result in coughing and cyanosis. An orogastric tube (OGT) will coil up in the upper esophageal pouch rather than pass into the stomach.

A.2. What is the pathophysiology of this disease?

In this abnormality, the distal trachea is connected to the lower esophagus through a fistula. This causes three problems. First, inhaled air can bypass the lungs and distend the stomach, which will eventually impede ventilation and cause atelectasis. Second, acidic stomach contents are at continual risk of leaking back into and damaging lung tissue. Third, oral secretions tend to pool in the proximal esophageal pouch resulting in intermittent aspiration, coughing, and cyanosis.

A.3. How does this lesion occur during development?

The median ventral diverticulum of the foregut differentiates into a separate esophagus and trachea by the end of the fifth week of gestation. New insights into the embryologic origin of TEF came from rat studies wherein fetal rats exposed to

Adriamycin reliably produce TEF closely resembling the most common version seen in humans. In this model, the lung bud was found to trifurcate instead of normal bifurcation. Two branches became normal lungs with pseudostratified columnar epithelium. The third branch grew caudally until it merged with the distal esophagus. Hence, the fistula came from respiratory tissue. Bolstering this conclusion is the finding that the fistula expresses thyroid transcription factor-1, which is found only in respiratory tissue of the foregut. Human studies also corroborate this finding. Sonic hedgehog (SHH) is a secreted signaling glycoprotein involved in directing differentiation of the foregut and lung. Defective SHH signaling is associated with VACTERL type anomalies (including TEF) in SHH-knockout mice studies. The tissue was surgically obtained from the esophageal pouch and fistula in neonates undergoing repair of TEF. This tissue was then stained to detect SHH. The proximal pouch, but not the fistula, stained positive for SHH. This suggests that the fistula is not an esophageal structure, despite superficial resemblance. However, humans with SHH mutation develop holoprosencephaly, which is not associated with TEF.

A.4. How are different types of tracheoesophageal fistula (TEF) classified?

There are five types of TEF according to the classic Gross classification (Fig. 36.1). Type A is pure EA with no involvement of the respiratory tree; this occurs in 8% of cases. Gross type B has esophageal atresia and a fistula connecting the proximal esophageal pouch to the trachea; this occurs in less than 1%. The most common is type C, with esophageal atresia and fistula linking the distal esophagus to the trachea; this occurs in 75% to 80% of cases. Rarely, type D occurs with two fistula connecting both proximal and distal esophagus to the trachea (2%). Type E, known as an H-type

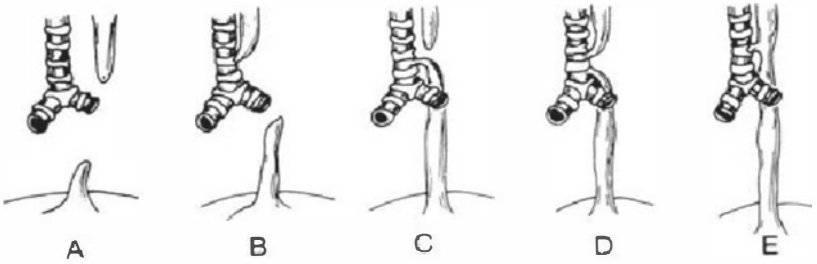

Figure 36.1 Gross's classification of esophageal atresia and tracheoesophageal fistula. (From Gregory GA, ed. *Pediatric Anesthesia*. 2nd ed. New York. Churchill Livingstone, 1989:921, with permission.)

fistula, has no atresia. Instead, an intact esophagus has a linkage with trachea through a fistula, and it occurs in 4%.

Davis PJ, Cladis FP, Motoyama EK, eds. *Smith's Anesthesia for Infants and Children*. 8th ed. Philadelphia: Mosby, Elsevier Science; 2011:575.

A.5. What other problems may this child have, and when should these be investigated?

Unfortunately, TEF often does not occur in isolation. Fifty percent of children with EA/TEF will have additional anomalies. Most often, they occur in the spectrum known as *VACTERL* (formerly known as *VATER*):

V = vertebral anomalies (10%)
A = anal canal defect (anal atresia) (14%)
C = cardiac malformations (29%), including ventricular septal defect, atrial septal defect, tetralogy of Fallot, right sided arch, patent ductus arteriosus)
TE = TEF
R = renal dysplasia
L = limb defect (radial aplasia)

A patient is considered to have VACTERL association with the presence of three or more of these lesions. Nearly one-third of TEF patients will have an additional VACTERL lesion and an additional one-fifth will have two VACTERL problems. Other possible gastrointestinal problems include malrotation of the midgut, and duodenal atresia. Renal problems can include malposition, hydronephrosis, and ureteral abnormalities.

A.6. What should the parents be told regarding perioperative risk? Risk of recurrence?

The survival of TEF babies has improved over the years because of improvements in intensive care unit care, anesthesia, and surgical technique. Waterston developed the first classification of prognosis of TEF in 1962 as follows:

Group A: birth weight greater than 2.5 kg, healthy, survival 95%
Group B: birth weight 1.8 to 2.5 kg and healthy, or greater than 2.5 kg with moderate pneumonia, or other anomalies, survival 68%
Group C: birth weight less than 1.8 kg or greater than 1.8 kg with severe pneumonia or severe congenital anomaly, survival 6%

With improvements in neonatal care, the survival in groups A and B both approach 100%, so new classification systems have been developed to provide more useful information, as birth weight greater than 1.5 kg no longer independently predicts mortality. Of these, perhaps the most useful is the Spitz classification, which is predicated on finding that cardiac disease is the leading risk factor and/or cause of mortality in the TEF group.

Spitz group I: birth weight more than 1.5 kg, no major cardiac disease. Survival 97%
Spitz group II: birth weight less than 1.5 kg, or major cardiac disease. Survival 59%
Spitz group III: birth weight less than 1.5 kg and major cardiac disease. Survival 22%

This date was based on a review of 372 infants from 1980 to 1992. With ongoing improvement in care, a recent review of 188 cases from 1993 to 2004 found Spitz group I survival 99%, group II 82%, and group III 50%.

Most cases of TEF are sporadic, and recurrence rate is 1% in siblings.

B. Preoperative Evaluation and Preparation

B.1. What laboratory workup should be obtained before surgery?

Firstly, one must assess the presence and severity of pulmonary disease, especially looking for aspiration pneumonia, and respiratory distress associated with prematurity. Plain chest x-ray may show infiltrates. It may also show the presence of congestive heart failure in the setting of associated cardiac disease, which may be optimized by administering a diuretic. A radio-opaque OGT will be coiled in the proximal esophageal pouch, whereas an abdominal x-ray may show air in the bowels entering through the fistula. Because of the risk of aspiration, the use of contrast dye to delineate the fistula should be used only when there is diagnostic uncertainty. Ideally, contrast would be given under fluoroscopy, so that any aspiration can be immediately detected. This should only be done if the baby is stable enough to be transported to the fluoroscopy suite. Of note, an OGT that appears to enter the stomach may also reflect esophageal perforation caused by repeated traumatic insertion attempts.

Second, an echocardiogram is *mandatory* as major cardiac defects strongly influence survival and may have an impact on anesthetic management. If the child has severe tetralogy of Fallot, he may require placement of a temporary shunt between the systemic arterial and pulmonary circulation prior to repair of the TEF. In addition, one wants to look for presence of a right-sided aortic arch, because this will require positioning the infant with the opposite side down from usual.

Spinal plain films should be done to exclude vertebral anomalies, especially if epidural pain management is being considered. Renal ultrasound should be done to rule out abnormalities, especially hydronephrosis. In addition, complete blood count

(CBC), arterial blood gas, and electrolytes should be drawn, and at least 1 unit of packed red blood cells should be type and crossed.

B.2. What options are there if patient has severe lung disease?

In the past, most children with TEF were routinely given a gastrostomy (under local anesthesia) followed by a staged repair. Beginning in the 80s, this conservative management began to be questioned, and now primary repair is considered standard of care. However, there remains a subset of neonates with severe pneumonia or respiratory distress syndrome, who are considered poor anesthetic and surgical risk (Waterston type C). If the child is intubated because of respiratory disease, one technique to optimize ventilation while minimizing gastric distension (through the fistula) is to employ high frequency oscillator ventilation to minimize the peak inspiratory pressure.

If this is insufficient, a simple gastrostomy is placed to allow drainage of gastric fluid (to minimize further aspiration) and prevent or relieve gastric distension that can occur with positive pressure ventilation (PPV) in the setting of a type C TEF. This procedure can be performed under local anesthesia and obviates the need for a thoracotomy. The problem with this approach is that by decompressing the stomach, gas from the trachea can now bypass the lungs and exit through the stomach. This is especially a concern if the baby's lungs are noncompliant from pneumonia or respiratory distress syndrome. This can make it difficult or impossible to ventilate the baby adequately. Fortunately, this can be alleviated if the gastrostomy tube is placed underneath a water seal therefore allowing gas to escape when it exceeds a predetermined threshold.

More recently, Ratan et al., describe another salvage technique, which involves occluding the fistula retrograde through a gastrostomy. The child is given local anesthetic over the incision site and a styletted no. 10 French Foley catheter is advanced through a gastrostomy to a position just above the gastroesophageal junction using fluoroscopy. The balloon is then inflated and the catheter is either clamped or placed under water seal. In this way the baby could be ventilated with positive pressure while avoiding gastric distention or inadequate ventilation from gas bypassing the lungs. This technique runs the risk of esophageal rupture and fatal pneumothorax if the catheter is not placed properly.

B.3. Describe management in the NICU before surgery.

After diagnosis of TEF is established and other coexisting anomalies investigated, the baby should be immediately placed on NPO (nothing by mouth). He should be kept in a warmed isolette with the head elevated at least 30 degrees to minimize reflux through the fistula. A nasogastric tube should be placed in the proximal esophageal pouch and kept on intermittent suction to minimize aspiration of oral secretions. Antibiotics to treat aspiration pneumonia should be given when appropriate. Ampicillin and gentamicin should be given in those patients who have coexisting significant cardiac disease as prophylaxis. Ensure that blood is available from the blood bank. Because the patient will require a thoracotomy with lung retraction and intermittent compression of the trachea and great vessels, an arterial line is mandatory for the case. This should ideally be placed in the NICU. An umbilical artery line may be conveniently placed by a qualified neonatologist. Two additional IV lines should also be placed, as the patient will be on NPO. Avoid placing lines in the right arm, as this arm will most likely be elevated during right thoracotomy and access will be limited.

Hammer GB. Pediatric thoracic anesthesia. *Anesth Analg*. 2001;92:1449–1464.

B.4. Should these patients be routinely intubated preoperatively for airway protection?

Unless mandated by severe pulmonary disease, the child is not intubated routinely preoperative to minimize the possibility of gastric distension from PPV through the fistula. It is noted that intubation does not protect the child from aspiration of gastric contents through the fistula.

Hammer GB. Pediatric thoracic anesthesia. *Anesth Analg*. 2001;92:1449–1464.

C. Intraoperative Management

C.1. What intravenous (IV) access and monitoring are appropriate before induction? After induction?

At least one peripheral IV should be in place before induction. A second may be placed after the patient is anesthetized. If the surgeon intends to give the child total parenteral nutrition postoperatively, a central line may be placed. Arterial line placement for blood gas and hemodynamic monitoring should be placed before incision if it has not already been inserted in the NICU. If a peripheral A-line is not feasible, an umbilical arterial line may be placed by someone experienced in this technique. Electrocardiogram, oxygen saturation, end-tidal CO_2, and rectal temperature should be also be monitored. A precordial stethoscope should be placed over the left axilla to assess breath sounds in case of inadvertent movement of the endotracheal tube (ETT) during surgical retraction or positioning. A second precordial stethoscope placed over the stomach may be useful to assess if the fistula is being ventilated.

If a gastrostomy tube is present, the end may be placed underneath a water seal. The presence of bubbling indicates ventilation through the fistula, which will occur if the tip of the ETT is proximal to the opening of the fistula. A capnograph inserted into the gastrostomy tube will indicate the same thing.

Davis PJ, Cladis FP, Motoyama EK, eds. *Smith's Anesthesia for Infants and Children*. 8th ed. Philadelphia: Mosby, Elsevier Science; 2011:577.

C.2. Discuss fluid and temperature management for this baby.

As with all neonates undergoing surgery, meticulous attention to fluid management and temperature is essential. The child should be transported to the operating room (OR) (in a head-up position) in a warmed isolette, with a stocking cap on the head to minimize temperature shifts. The OR should be prewarmed to at least 85°F. Surgical irrigation and IV crystalloid should be warmed, as well as any blood products stored on ice. Using a forced-air convective warming system is strongly recommended. An appropriate size heat-moisture exchanger placed in the airway can be useful. Keep in mind that the neonate is more prone to develop hypothermia for a number of reasons including limited subcutaneous fat. One way the baby compensates is with brown fat nonshivering thermogenesis. When choosing an anesthetic technique, keep in mind that volatile anesthetics including halothane and isoflurane can decrease thermogenesis by up to 70%.

Considering that the patient has been on NPO since birth and whatever was fed probably did not reach the stomach because of esophageal atresia, it is advisable to administer dextrose-containing solution at a controlled rate during the operation. D10/0.2 NS administered IV at maintenance rate using a controlled-infusion pump is an excellent way to avoid hypoglycemia. Insensible losses should be estimated at 3 to 4 mL/kg/hour and replaced with isotonic solution. Urine output (ideally 1 mL/kg/hour) may be difficult to assess accurately in a low–birth weight baby.

Bissonnette B, Dalens B, eds. *Pediatric Anesthesia: Principles and Practice*. 2nd ed. New York: McGraw-Hill; 2002:1003, 1012.

Brunicardi FC, Anderson DK, Billiar TR, et al., eds. *Schwartz's Principles of Surgery*. 9th ed. New York: McGraw-Hill; 2010:1422.

Davis PJ, Cladis FP, Motoyama EK, eds. *Smith's Anesthesia for Infants and Children*. 8th ed. Philadelphia: Mosby, Elsevier Science; 2011:1157.

C.3. What are the options regarding induction and intubation?

The goal is to intubate the baby to allow adequate gas exchange with the lowest possible inspiratory pressure needed to inflate the lungs, avoid atelectasis, and avoid distension of the abdomen. Positive pressure mask ventilation should be avoided. There are several options. First is to keep the child spontaneously ventilating until the fistula is ligated. This requires a deep inhalational technique with gentle assisting of each breath to minimize atelectasis. Intubation can be performed either awake or after inhalation induction. In this way, the lowest inspiratory pressure is required, minimizing distension of the stomach. Awake intubation used to be common, but attention must be paid to the possibility of increased intracranial pressure or intraventricular hemorrhage in the premature infant, as well as the obvious discomfort to the child. Good intubating conditions can be achieved with deep volatile agent, but maintaining adequate ventilation and surgical conditions during a thoracotomy without relaxant may be challenging. Rapid sequence IV induction and intubation (to minimize

face-mask ventilation) is another option provided that attention is paid to minimizing inspiratory pressure.

As important as the intubation is the correct positioning of the ETT. The goal is to have the tip of the ETT distal to the fistula yet proximal to the carina. If the tube is deliberately placed deep (into the right mainstem) with the bevel facing forward, then slowly pulled back just until breath sounds occur on the left equal to the right, the tube is likely to be in good position. If the patient has a preexisting gastrostomy, the ETT should be pulled back almost until gas begins to bubble from the end of the gastric tube (which has been placed under water seal), then readvanced until the bubbling stops. If the tube is in good position, then the child can be paralyzed and normal PPV maintained. The difficulty lies in maintaining good position of the ETT during surgical manipulation and turning the patient lateral.

Davis PJ, Cladis FP, Motoyama EK, eds. *Smith's Anesthesia for Infants and Children.* 8th ed. Philadelphia: Mosby, Elsevier Science; 2011:577.

C.4. What is the role of fiberoptic bronchoscopy in this patient?

Perioperative bronchoscopy before commencing TEF repair has become common. First, the airway can be examined directly to help guide the surgical technique. A cervical level fistula does not require a thoracotomy to repair. Second, if deemed appropriate, the fistula can be occluded using a Fogarty occlusion catheter, thereby allowing unimpeded PPV without distending the abdomen. Bronchoscopy can detect the presence of tracheomalacia, which may assist in planning extubation. Identifying the level of the fistula can assist in correct positioning of the ETT (11% may have it below the carina in one series). Reeves, Burt, and Smith report using a rigid bronchoscope to guide placement of a 2-French Fogarty arterial embolectomy catheter into the TEF and the balloon inflated. The bronchoscope was removed and the patient was then intubated using a 3.0 ETT. Andropoulos, Rowe, and Betts described 61 cases of TEF managed with rigid bronchoscopy. Three babies (those with large fistula) electively had their fistula occluded and all three experience immediate improvement in ventilation. If the fistula was small, it was deemed unlikely to cause ventilatory problems and was left unmodified. Another seven had a catheter placed in the fistula to help the surgeon identify it. This technique of isolating the trachea and esophagus before ligation may be useful in skilled hands. However, there is a real possibility that during positioning or surgical manipulation, the Fogarty balloon may slide back into the trachea. This could precipitate immediate complete airway obstruction if not promptly recognized and treated. Recurrent TEF can be treated endoscopically by placing fibrin glue directly into the fistula, precluding the need for a second thoracotomy.

C.5. Discuss the surgical technique.

First, the patient is positioned in the lateral position, usually left side down. If the patient has a right-sided aortic arch sometimes the surgeon may wish to position him with right side down. A retropleural approach is used which minimizes the danger from an anastomotic leak. The fistula is exposed and ligated (usually occurs within 45 minutes). The upper esophagus is mobilized, then the distal esophagus. The esophagus is joined together. Following this, a feeding tube is placed across the anastomosis to allow feeding (if the patient does not have a gastrostomy). The lung should be carefully reexpanded to eliminate atelectasis before closure.

Spitz L. Oesophageal atresia. *Orphanet J Rare Dis.* 2007;2:24.

C.6. Discuss common intraoperative problems for this repair.

Interference with ventilation is the most common problem and can have many causes. Lung retraction with resulting atelectasis leads to frequent desaturation. It may be difficult if not impossible to maintain normocarbia. The P_{CO_2} may rise to 70 to 80 mm Hg despite all attempts to optimize ventilation. If the patient has a Fogarty catheter in the fistula, it may be displaced into the trachea causing total airway obstruction. Surgical manipulation of the soft trachea makes it vulnerable to kinking or displacement of ETT distal (into right mainstem) or proximally (above the fistula). Frequent compression of vital structures in the mediastinum can lead to profound hemodynamic compromise. Blood and secretions are a constant problem, which risk obstructing the tube. The ETT should be suctioned frequently, more so if blood is seen. (It does not require much blood to clog a 3.0 ETT.) The retracted lung may need to be intermittently reexpanded to avoid severe hypoxia. Severe gastric distension before ligation of the TEF may require emergent gastric needle decompression. It is crucial to maintain close communication with the surgeon. Avoid hypothermia.

Davis PJ, Cladis FP, Motoyama EK, eds. *Smith's Anesthesia for Infants and Children*. 8th ed. Philadelphia: Mosby, Elsevier Science; 2011:577.

D. Postoperative Issues

D.1. When should the baby be extubated?

Although some surgeons prefer to have the baby extubated immediately in the OR to minimize tension on the suture line, this can be risky. Many infants with TEF have a

deficiency of tracheal cartilage at the level of the fistula predisposing to tracheomalacia. This can precipitate airway obstruction requiring immediate reintubation. Many of the children have lung disease from prematurity or aspiration pneumonia; after receiving narcotics for pain they may be prone to hypoventilation. If early extubation is planned an epidural technique might be helpful. However, if the child is to remain intubated, care should be made to limit inspiratory pressure to protect the repair from disruption.

Davis PJ, Cladis FP, Motoyama EK, eds. *Smith's Anesthesia for Infants and Children*. 8th ed. Philadelphia: Mosby, Elsevier Science; 2011:578.

Spitz L. Oesophageal atresia. *Orphanet J Rare Dis*. 2007;2:24.

D.2. What pain control options are available?

If the patient is going to remain intubated postoperative (most likely) then a narcotic technique is advisable. Fentanyl at 10 to 20 μg per kg with muscle relaxant will give hemodynamic stability and allow analgesia to be continued in the postoperative period. For experienced practitioners, epidural can also be placed. An epidural catheter threaded through the caudal space can be threaded up to the thoracic dermatomes. Check the placement of the catheter using fluoroscopy before using it. This technique should only be undertaken by someone highly experienced in regional anesthesia for children, with full awareness of the risks and ability to manage complications.

Bissonnette B, Dalens B, eds. *Pediatric Anesthesia: Principles and Practice*. 2nd ed. New York: McGraw-Hill; 2002:549, 1017.

D.3. What are early and late complications of TEF repair?

Early anastomosis leakage occurs in up to 15%. This may require immediate exploration, or managed expectantly. Esophageal dysmotility and gastroesophageal reflux disease are common; the dysmotility may be from abnormal innervation of the distal esophagus, or may be related to vagal nerve injury during the repair. Stricture of the esophageal anastomosis may require repeated dilatations. Tracheomalacia may be evident postoperative, and vocal cord paresis has been reported.

CHAPTER 37

Congenital Diaphragmatic Hernia

Fun-Sun F. Yao, David Stein, and John J. Savarese

A FULL-TERM MALE BABY

was born with respiratory distress and cyanosis. Physical examination showed barrel chest and scaphoid abdomen. The breath sounds were absent in the left side of the chest; the heart sounds were best heard in the right side of the chest. Labored respiration, nasal flaring, and sternal retraction were found. The baby weighed 2,800 g. Blood pressure was 60/30 mm Hg; heart rate, 160 beats per minute; respiration, 70 breaths per minute; and temperature, 36° C (96.8° F). Arterial blood gas analysis on room air showed the following: pH, 7.20; $Paco_2$, 55 mm Hg; Pao_2, 35 mm Hg; and CO_2 content, 19 mEq per L.

A. Medical Disease and Differential Diagnosis

1. What differential diagnoses are compatible with these signs and symptoms?
2. Describe the incidence and classification of congenital diaphragmatic hernia (CDH).
3. What are the causes of hypoxemia in patients with CDH?
4. How does the diaphragmatic hernia develop in the fetus? Why do varying degrees of pulmonary hypoplasia usually accompany CDH? How do they affect the prognosis?
5. How do you assess the severity of pulmonary hypoplasia?
6. Discuss persistent pulmonary hypertension (PPH) in the patient with CDH.
7. How do you make a diagnosis of right-to-left shunting through the patent ductus arteriosus or patent foramen ovale?
8. What other congenital anomalies are usually associated with CDH?

B. Preoperative Evaluation and Preparation

1. How would you interpret the following arterial blood gas analyses: pH, 7.20; $Paco_2$, 55 mm Hg; Pao_2, 35 mm Hg; and CO_2 content, 19 mEq per L? How would you correct them?
2. What immediate treatment should be given to improve the newborn's respiratory status preoperatively?

3. Should CDH be repaired urgently once the diagnosis is made and confirmed?
4. How would you treat pulmonary hypertension and improve oxygenation?
5. What are the effects of nitric oxide (NO) on pulmonary and systemic circulation?
6. How is extracorporeal membrane oxygenation (ECMO) established?
7. What are the advantages of ECMO?
8. What are the indications and contraindications to ECMO?
9. When is the optimal time to repair CDH?
10. What other measures should you take to prepare the patient for surgery?
11. How would you premedicate this patient?

C. Intraoperative Management

1. What monitors would you use for this neonate during surgery?
2. How would you induce and maintain anesthesia?
3. Would you use nitrous oxide for anesthesia? Why?
4. Would you use 100% oxygen during anesthesia?
5. How would you ventilate the patient?
6. How would you maintain the neonate's body temperature?
7. The surgeon returned the intrathoracic stomach and intestine to the peritoneal cavity and the ipsilateral lung was found to be hypoplastic and collapsed. The resident anesthesiologist tried to expand the collapsed lung manually with positive airway pressure. Five minutes after the abdomen was closed, the blood pressure suddenly dropped from 70/40 to 30/20 mm Hg, the heart rate from 150 to 80 beats per minute, and the pulse oximeter from 95% down to 60% saturation. What would you do immediately?
8. Discuss fluid therapy in this patient.
9. At the conclusion of surgery, would you extubate the patient in the operating room?

D. Postoperative Management

1. What postoperative problems would you expect in this patient? What is the mortality rate in patients with CDH?
2. The neonate's blood gas analyses improved right after surgery. However, 3 hours later, severe hypoxemia recurred in spite of ventilatory support with high inspired oxygen concentration. What are the possible causes? How should this patient be treated?

A. Medical Disease and Differential Diagnosis

A.1. What differential diagnoses are compatible with these signs and symptoms?

Congenital cardiopulmonary anomalies should be considered whenever cyanosis and respiratory distress are present. A scaphoid abdomen is present due to the absence of abdominal contents. The presence of the barrel chest, bowel sounds in the chest, and the shift of heart sounds to the right definitely suggest the diagnosis of CDH. To confirm the diagnosis, a chest radiograph should be performed to demonstrate gas-filled loops of bowel and probably the spleen or liver in the chest. The lung on the side of the hernia is compressed into the hilum, and the mediastinum is shifted to the opposite side of the chest. If in doubt, a radiopaque dye may be injected through a nasogastric tube to delineate the stomach and intestine in the chest.

Kliegman RM, Behrman RE, Jenson HB, et al., eds. *Nelson's Textbook of Pediatrics*. 18th ed. Philadelphia: Saunders; 2007:746–749.

A.2. Describe the incidence and classification of congenital diaphragmatic hernia (CDH).

The incidence of CDH is estimated to be 1 in 2,500 to 5,000 births. The male/female ratio is 2:1, and the left diaphragm is more frequently involved than the right (5:1).

The diaphragm is embryologically formed from the fusion of several components; therefore, a number of developmental defects may occur, resulting in herniation of abdominal contents into the chest. Embryologically, two fundamental types of defects may occur:

- Complete or partial absence of the diaphragm
- Failure of complete muscularization

Embryologic classification is not convenient clinically. A practical classification is used based on the anatomic location of the defects in the diaphragm:

- *Absent diaphragm*.Very rare
- *Diaphragmatic hernia*. (Fig. 37.1)
  - Posterolateral (Bochdalek): 80%
  - Anterior (Morgagni): 2%
  - Paraesophageal: 15% to 20%
- *Eventration*. Very rare

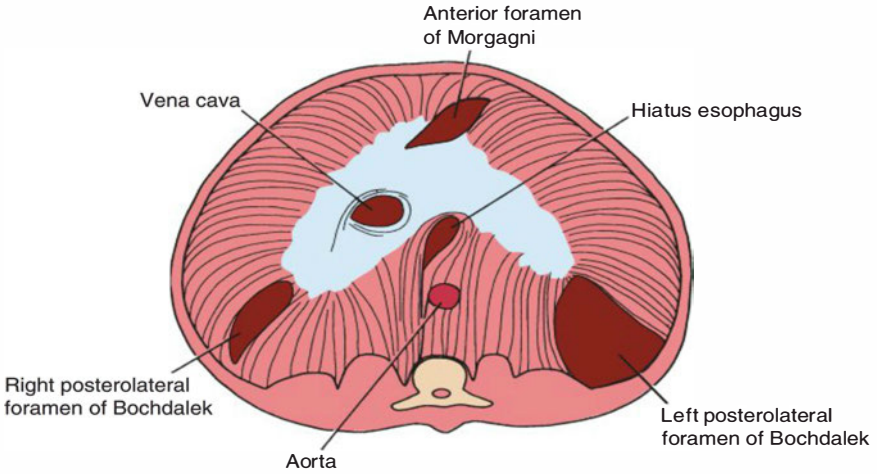

Figure 37.1 Potential sites of congenital diaphragmatic hernia.

Kliegman RM, Behrman RE, Jenson HB, et al., eds. *Nelson's Textbook of Pediatrics*. 18th ed. Philadelphia: Saunders; 2007:746–749.

A.3. What are the causes of hypoxemia in patients with CDH?

The causes of hypoxemia are as follows:

- Atelectasis resulting from compression of the developed lung by the herniated abdominal organs
- Pulmonary hypoplasia with a decrease in the number of alveoli and bronchial generations. The hypoplastic lung will have abnormal pulmonary vasculature resulting from a disruption of normal development of the lung tissue, secondary to the crowding of the herniated abdominal organs in the thorax.
- PPH, causing increased right-to-left shunting through a patent foramen ovale and ductus arteriosus

Gregory GA, ed. *Pediatric Anesthesia*. 4th ed. New York: Churchill Livingstone; 2002:435–436.

Davis PJ, Cladis FP, Motoyama EK, eds. *Smith's Anesthesia for Infants and Children*, 8th ed. Philadelphia: Mosby, Elsevier Science; 2010:567–574.

Kliegman RM, Behrman RE, Jenson HB, et al., eds. *Nelson's Textbook of Pediatrics*. 18th ed. Philadelphia: Saunders; 2007:746–749.

A.4. How does the diaphragmatic hernia develop in the fetus? Why do varying degrees of pulmonary hypoplasia usually accompany CDH? How do they affect the prognosis?

Embryologic development of the diaphragm, gut, heart, and lungs takes place at about the same time, and abnormal development of one organ affects development of the others. Normally, the pleural and peritoneal cavities are separated by the diaphragm from the 8th to the 10th week of gestation. At about the same time, the gut physiologically herniates into the yolk stalk but then returns to the peritoneal cavity. The pleuroperitoneal canals progressively narrow and are finally closed by the 10th week. CDH may result either from the early return of the midgut to the peritoneal cavity or from delayed closure of the pleuroperitoneal canal.

The lung is also undergoing development at this time. Alveolar buds begin to differentiate by the 6th week; airways develop from the 10th to the 12th week. Bronchial branching continues until the 16th week of gestation. Alveolar multiplication continues until 8 years of age.

The degree of pulmonary hypoplasia is related to the timing of the herniation of abdominal organs into the pleural cavity. The earlier the herniation, the more severe the pulmonary hypoplasia. Hypoplasia of the left ventricle may also occur, resulting in cardiac insufficiency. The degree of pulmonary hypoplasia determines the prognosis of CDH. Severe bilateral hypoplasia predicts high mortality. With unilateral hypoplasia, the patient may survive with aggressive therapy. When pulmonary hypoplasia is insignificant, the prognosis is excellent.

Barash PG, Cullen BF, Stoelting RK et al., eds. *Clinical Anesthesia*. 6th ed. Philadelphia: Lippincott Williams & Wilkins; 2009:1193–1194.

Kliegman RM, Behrman RE, Jenson HB, et al., eds. *Nelson's Textbook of Pediatrics*. 18th ed. Philadelphia: Saunders; 2007:746–749.

A.5. How do you assess the severity of pulmonary hypoplasia?

The severity of pulmonary hypoplasia is assessed by the intrapulmonary shunt (Qs/Qt) or the alveolar–arterial difference in oxygen tension (P_{AO_2}–Pa_{O_2}). A (P_{AO_2}–Pa_{O_2}) of more than 500 mm Hg when breathing 100% oxygen is predictive of nonsurvival, and a (P_{AO_2}–Pa_{O_2}) of less than 400 mm Hg is predictive of survival. A (P_{AO_2}–Pa_{O_2}) between 400 and 500 mm Hg represents a zone of uncertain prognosis.

The severity of pulmonary hypoplasia may also be evaluated more aggressively by cardiac catheterization and pulmonary angiogram to define the size and branching pattern of the pulmonary arteries. Patients with severe pulmonary hypoplasia typically will have a fixed right-to-left shunting at the level of the patent ductus arteriosus or patent foramen ovale caused by pulmonary hypertension. Pulmonary angiography demonstrates a small diameter of affected pulmonary artery compared with the main pulmonary artery. The postductal Pa_{O_2} never rises to more than 60 mm Hg in nonsurvivors.

A.6. Discuss persistent pulmonary hypertension (PPH) in the patient with CDH.

Pulmonary hypertension is one of the major causes of hypoxemia in CDH. There are several causes of pulmonary hypertension in these patients:

- Increased pulmonary vascular resistance and pressure result from a hypoplastic lung.
- The pulmonary vasculature is abnormal, with a decrease in volume and marked increase in muscular mass in the arterioles.
- Right-to-left shunting of oxygen depleted venous blood at the patent foremen ovale and the patent ductus arteriosus. This shunting results in varying degrees of hypoxemia, hypercarbia, and acidosis causing high pulmonary vascular resistance and pressure.

When pulmonary artery pressures are higher than systemic pressures, right-to-left shunting occurs across the ductus, resulting in higher Pa_{O_2} in the upper extremities than in the lower extremities. When right ventricular failure (precipitated by pulmonary hypertension, progressive hypoxemia, and acidosis or by closure of the ductus) increases right atrial pressure to a level higher than the left atrial pressure, right-to-left atrial shunting ensues, producing further hypoxemia. Left ventricular failure from hypoxemia and acidosis induces systemic hypotension, resulting in increased ductal shunting and hypoxemia. A vicious cycle is established. Unless pulmonary artery pressure is decreased, progressive hypoxia and death may ensue.

A.7. How do you make a diagnosis of right-to-left shunting through the patent ductus arteriosus or patent foramen ovale?

If right-to-left shunting occurs through the patent ductus arteriosus, the preductal Pao_2 is at least 15 to 20 mm Hg higher than the postductal value. A right-to-left shunt of 20% is considered "normal" for a newborn infant. If shunting occurs through the patent foramen ovale, the preductal Pao_2 is below the value predicted for 20% shunt. When the degree of preductal shunting is severe, detection of ductal shunting is impossible. Echocardiography with color Doppler, cardiac catheterization, and pulmonary angiography will confirm the diagnosis.

Nelson NM, Prod'Hom LS, Cherry RB, et al. Pulmonary function in the newborn infant: the alveolar-arterial oxygen gradient. *J Appl Physiol*. 1963;18:534.

A.8. What other congenital anomalies are usually associated with CDH?

The incidence of other congenital anomalies in newborns with CDH is as follows:

- *Cardiovascular system*. 13% to 23%; for example, atrial septal defect, ventricular septal defect, coarctation of aorta, and tetralogy of Fallot
- *Central nervous system*. 28%; for example, spina bifida, hydrocephalus, and acephalus
- *Gastrointestinal system*. 20%; for example, malrotation and atresia
- *Genitourinary system*. 15%; for example, hypospadias

Gregory GA, ed. *Pediatric Anesthesia*. 4th ed. New York: Churchill Livingstone; 2002:1171–1173.

B. Preoperative Evaluation and Preparation

B.1. How would you interpret the following arterial blood gas analyses: pH, 7.20; $Paco_2$, 55 mm Hg; Pao_2, 35 mm Hg; and CO_2 content, 19 mEq per L? How would you correct them?

The blood gas analyses showed mixed respiratory and metabolic acidosis and severe hypoxemia. Severe hypoxemia is caused by the pulmonary pathologies and PPH.

Hypoxemia stimulates respiratory chemoreceptors and causes hyperventilation, resulting in respiratory alkalosis initially. However, if hypoxemia is not corrected, the patient will become exhausted and CO_2 retention ensues. Severe pulmonary hypoplasia may also cause CO_2 retention. Severe hypoxemia induces anaerobic metabolism, resulting in lactic acidosis.

Hypoxemia and respiratory acidosis should be treated with mechanical ventilation and oxygen therapy. Metabolic acidosis should be corrected by administration of sodium bicarbonate and improvement of circulation with fluid therapy.

Gregory GA, ed. *Pediatric Anesthesia*. 4th ed. New York: Churchill Livingstone; 2002:435–437.

Hines RL, Marschall KE. *Stoelting's Anesthesia and Co-existing Disease*. 5th ed. Philadelphia: Churchill Livingstone/Elsevier; 2008:593–594.

Kliegman RM, Behrman RE, Jenson HB, et al., eds. *Nelson's Textbook of Pediatrics*. 18th ed. Philadelphia: Saunders; 2007:746–749.

B.2. What immediate treatment should be given to improve the newborn's respiratory status preoperatively?

Immediate intervention should include decompression of the stomach with an orogastric or nasogastric tube and administration of supplemental oxygen by mask. Positive pressure ventilation by mask should be avoided to prevent distention of the intrathoracic stomach, which will further compress the lung and compromise respiration. If cyanosis and hypoxemia persist, awake intubation should be done to facilitate mechanical ventilation. Positive airway pressure during mechanical ventilation should not exceed 30 cm H_2O to reduce the risk of tension pneumothorax. Although pneumothorax can happen on either side, it occurs more frequently on the contralateral side of the hernia because the pressure needed to expand the hypoplastic lung is higher than that required to rupture the normal lung.

Gregory GA, ed. *Pediatric Anesthesia*. 4th ed. New York: Churchill Livingstone; 2002:435–437.

Hines RL, Marschall KE. *Stoelting's Anesthesia and Co-existing Disease*. 5th ed. Philadelphia: Churchill Livingstone/Elsevier; 2008:593–594.

Kliegman RM, Behrman RE, Jenson HB, et al., eds. *Nelson's Textbook of Pediatrics*. 18th ed. Philadelphia: Saunders; 2007:746–749.

B.3. Should CDH be repaired urgently once the diagnosis is made and confirmed?

In the past, CDH was considered a surgical emergency, in the belief that the herniated contents caused lung collapse and respiratory failure. However, recognition of the role of pulmonary hypertension, in addition to pulmonary hypoplasia and the effects of surgical repair on pulmonary function, has prompted critical reevaluation of that strategy. It is now clear that lung compression by the herniated viscera is a minor factor in the cardiopulmonary compromise compared with the pulmonary hypertension and hypoplasia. The consensus today is to delay surgery and concentrate on medical stabilization. The goal of preoperative therapy is to reverse the PPH that results in right-to-left shunting across the patent foramen ovale and the ductus arteriosus. Improvement in the infant's status is apparent by improved oxygenation and ventilation. Doppler echocardiography may be used to confirm the decreased pulmonary vascular resistance. The time it takes to stabilize the condition varies from 24 to 48 hours in infants with only mild pulmonary hypertension and hypoplasia up to 7 to 10 days in neonates with severe pulmonary hypertension and hypoplasia.

Kliegman RM, Behrman RE, Jenson HB, et al., eds. *Nelson's Textbook of Pediatrics*. 18th ed. Philadelphia: Saunders; 2007:746–749.

B.4. How would you treat pulmonary hypertension and improve oxygenation?

Pulmonary vascular resistance is greatly increased in the hypoplastic lung, and blood flow is minimal because of medial hyperplasia of pulmonary arterioles. When further aggravated by hypoxemia, acidosis, decreased F_{IO_2}, or sudden changes in pulmonary blood volume, pulmonary vasoconstriction increases and fetal circulation persists. The treatment of pulmonary hypertension includes the following measures in sequence:

- Continue general anesthesia in the intensive care unit, using fentanyl 3 μg/kg/hour, and pancuronium 0.1 mg/kg/hour to blunt the autonomically mediated cardiovascular response (pulmonary vasoconstriction) to stimulation.
- Minimize endotracheal suctioning to avoid transient hypoxemia or decrease in F_{IO_2}.
- Hyperventilate the neonate with low tidal volume and high respiratory rate (60 to 120 breaths/minute) to pH of 7.55 to 7.60. Respiratory alkalosis is the most consistently effective therapeutic modality to achieve pulmonary vasodilation.
- Moderately restrict fluid to 2 to 4 mL/kg/hour.
- Administer pharmacologic vasodilators if the aforementioned measures fail to control pulmonary hypertension. Morphine, prednisolone, chlorpromazine, phentolamine, acetylcholine, bradykinin, tolazoline, prostaglandin E_1, prostaglandin D_2, and inhaled NO have been tried with some success. Milrinone would be helpful if right ventricular failure is apparent.
- Ligate the patent ductus arteriosus to prevent shunting. This is theoretically possible but practically has been associated with sudden right ventricular failure.
- Support with ECMO if pharmacologic intervention fails. ECMO has been associated with a 50% to 65% survival rate.

Vacanti JP, Crone RK, Murphy JD, et al. The pulmonary hemodynamic response to perioperative anesthesia in the treatment of high-risk infants with congenital diaphragmatic hernia. *J Pediatr Surg*. 1984;19:672–679.

B.5. What are the effects of nitric oxide (NO) on pulmonary and systemic circulation?

When produced in vivo, NO is endothelium-derived relaxing factor producing smooth muscle relaxation and vasodilation. Inhaled NO is unique, as it is a selective pulmonary vasodilator and has no effect on systemic circulation because it is

inactivated immediately on exposure to hemoglobin. Clinical studies are limited but have shown some improvement in oxygenation in neonates with PPH exposed to 20 to 80 parts per million (ppm) of NO. NO has been reported to be ineffective before ECMO therapy in those patients with both CDH and pulmonary hypoplasia. After ECMO followed by surgery, NO was effective in improving oxygenation. However, NO has not been shown to improve survival.

B.6. How is extracorporeal membrane oxygenation (ECMO) established?

Venovenous or venoarterial bypass is used. Venovenous bypass is established with a double-lumen catheter through the internal jugular vein, with blood removed from and infused into the right atrium through separate ports. Venoarterial bypass is used preferentially by some centers because it provides the cardiac support that is often needed. The right atrium is cannulated through the internal jugular vein. Blood is allowed to passively flow by gravity into the ECMO circuit, where it is pumped with an occlusive blood pump into the membrane oxygenator. From the oxygenator, blood is returned through a catheter placed through the right common carotid artery into the ascending aorta.

Gregory GA, ed. *Pediatric Anesthesia.* 4th ed. New York: Churchill Livingstone; 2002:436–437.

B.7. What are the advantages of ECMO?

The theoretical advantages are as follows:

- Diversion of as much as 80% of cardiac output from the right atrium into the extracorporeal circuit immediately reduces or eliminates right-to-left shunting through the foramen ovale or ductus arteriosus.
- Right ventricular work is decreased because of reduced pulmonary blood flow and pressure.
- Pulmonary vasoconstriction is reduced because hypoxemia and acidosis are corrected by ECMO. Improved systemic oxygenation and reduced ductal blood flow may lead to spontaneous closure of the ductus arteriosus.
- The hypoplastic lung is allowed to grow rapidly and alveolar size is increased.
- The incidence of bronchopulmonary dysplasia is reduced because F_{IO_2} and airway pressure are lowered by ECMO.

Gregory GA, ed. *Pediatric Anesthesia.* 4th ed. New York: Churchill Livingstone; 2002:437–438.

B.8. What are the indications and contraindications to ECMO?

Patients with severe hypoxemia, hypercarbia, and pulmonary hypertension who do not respond to maximal conventional respiratory and pharmacologic intervention are candidates for ECMO. However, due to the necessity for anticoagulation and the consumption and inactivation of platelets, ECMO is associated with serious complications of intracranial and pulmonary hemorrhage. The entry criteria include a gestational age of 34 weeks or greater, the presence of a reversible disease process, a minimal weight of 2,000 g, and a predicted mortality of greater than 80%. (Predicted mortality is commonly estimated by the oxygenation index [$FIO_2 \times$ mean airway pressure $\times$ 100/PaO_2].) Values of oxygenation index in excess of 40 predict mortality greater than 80%.

The contraindications to ECMO include the following:

- Gestational age less than 34 weeks
- Weight less than 2,000 g
- Preexisting grade II or greater intracranial hemorrhage
- Congenital or neurologic abnormalities incompatible with good outcome
- More than 1 week of aggressive respiratory therapy
- Congenital heart disease

B.9. When is the optimal time to repair CDH?

The newborn should be maintained on ECMO until the pulmonary hypertension is reversed and improvement in lung function is evident. Doppler echocardiography may be used to confirm the reversal of PPH. This is usually seen within 7 to 10 days but in some infants is not apparent for up to 3 weeks. Newborns who do not demonstrate significant improvement over this time have pulmonary hypoplasia that will not benefit from further extracorporeal life support. Timing of repair of the CDH on ECMO is controversial. Some centers prefer early repair to allow a greater duration of postrepair ECMO, whereas many centers defer repair until the infant has demonstrated the ability to tolerate weaning from ECMO support.

Haugen SE, Linker D, Eik-Nes S, et al. Congenital diaphragmatic hernia: determination of the optimal time for operation by echocardiographic monitoring of the pulmonary arterial pressure. *J Pediatr Surg*. 1991;26:560.

Kliegman RM, Behrman RE, Jenson HB, et al., eds. *Nelson's Textbook of Pediatrics*. 18th ed. Philadelphia: Saunders; 2007:746–749.

B.10. What other measures should you take to prepare the patient for surgery?

The patient should be examined carefully for the presence and severity of associated congenital anomalies as described in section A.8. Those patients with congenital heart disease in addition to CDH have significantly increased mortality.

Hypothermia should be prevented and corrected. Hypothermia can aggravate the hypoxemia and acidosis. Hypothermia can also lead to coagulopathy and arrhythmia. The neonate should be maintained in a neutral thermal environment of 36.5° to 37.5° C (97.7° to 99.5° F).

Laboratory studies should include arterial blood gases, complete blood cell count, electrolytes, blood sugar, blood type, and cross-match for blood products.

Venous access should be ready before surgery. Peripheral veins in the upper extremities are preferred because reduction of the hernia often increases abdominal pressure and partially obstructs the inferior vena cava, making lower extremity veins less reliable. Neck veins are avoided in case ECMO is required. Central venous access should be attempted through the umbilical or femoral vein.

B.11. How would you premedicate this patient?

No premedication should be given to the neonate with CDH. The newborn should not have any anxiety, and sedatives will further depress the already compromised cardiopulmonary function.

C. Intraoperative Management

C.1. What monitors would you use for this neonate during surgery?

Respiratory

- Precordial and esophageal stethoscope
- Two pulse oximeters, for preductal and postductal oxygen saturation
- Capnometry
- Inspiratory pressure measurement
- Inspiratory oxygen concentration
- Intraoperative arterial blood gas analysis

Cardiovascular

- Five-lead electrocardiogram
- Blood pressure cuff
- Precordial stethoscope
- Arterial line: right radial artery for preductal Pao_2
- Central venous pressure (CVP) line for evaluating volume status and right ventricular performance

Thermoregulatory

- Esophageal or rectal temperature probe

C.2. How would you induce and maintain anesthesia?

If the neonate has not been intubated, intubation should be performed with spontaneous ventilation. Positive pressure ventilation should be avoided before intubation to prevent gastric distention and further compromise of respiration. An awake intubation can be performed after preoxygenation. However, if the neonate is too vigorous for awake intubation, he can be intubated without a muscle relaxant after breathing sevoflurane and oxygen spontaneously.

The choice of maintenance anesthetics depends on the severity of cardiovascular dysfunction. Patients in shock and severe hypoxemia may tolerate only oxygen and a nondepolarizing relaxant such as rocuronium or vecuronium. If blood pressure is adequate and stable, inhalation agents and narcotics in addition to a muscle relaxant, may be titrated to maintain anesthesia. Narcotics and nondepolarizers may be

continued postoperatively to control ventilation and minimize hormonal response to stress, which may increase pulmonary hypertension.

Barash PG, Cullen BF, Stoelting RK, et al., eds. *Clinical Anesthesia*. 6th ed. Philadelphia: Lippincott Williams & Wilkins; 2009:1193–1194.

Gregory GA, ed. *Pediatric Anesthesia*. 4th ed. New York: Churchill Livingstone; 2002:437.

C.3. Would you use nitrous oxide for anesthesia? Why?

No. Nitrous oxide should not be used in patients with CDH before hernia reduction and abdominal closure. Because nitrous oxide has a higher diffusion capacity than nitrogen (35:1), the amount of nitrous oxide diffused from blood to the gut is much more than the amount of nitrogen diffused from the gut to the blood. Therefore, nitrous oxide may distend the intrathoracic gut and compress the functioning lung tissue, further compromising pulmonary function. Moreover, a distended gut may cause difficulty in abdominal closure and may increase abdominal pressure, compressing the inferior vena cava and resulting in hypotension.

Barash PG. *Clinical Anesthesia*. 6th ed. Philadelphia: Wolters Kluwer/Lippincott Williams & Wilkins; 2009:1193–1194.

Fink R. Diffusion anoxia. *Anesthesiology* 1955;16:511–519.

Gregory GA, ed. *Pediatric Anesthesia*. 4th ed. New York: Churchill Livingstone; 2002:437.

C.4. Would you use 100% oxygen during anesthesia?

Selection of the appropriate inspired concentration of oxygen depends on the severity of pulmonary dysfunction. Retrolental fibroplasia (retinopathy of prematurity) is a potential danger during neonatal anesthesia. Current guidelines suggest that infants are at risk for retrolental fibroplasia until 44 to 50 weeks of gestational age. However, hypoxia causes pulmonary vasoconstriction and pulmonary hypertension, which may increase right-to-left shunting of desaturated blood at preductal or ductal level. Serial arterial blood gases may be used to determine the optimal F_{IO_2}. Air is added to oxygen if the Pa_{O_2} on 100% oxygen is more than 90 to 100 mm Hg. The Pa_{O_2} should be optimally kept at 80 to 100 mm Hg or the arterial oxygen saturation between 95% and 98%.

Gregory GA, ed. *Pediatric Anesthesia*. 4th ed. New York: Churchill Livingstone; 2002:436–437.

C.5. How would you ventilate the patient?

Ventilation is controlled either manually or by a respirator. Small tidal volumes should be used to keep the airway pressure below 30 cm H_2O to prevent contralateral

pneumothorax. High respiratory rates (60 to 120 breaths/minute) should be adjusted to achieve hyperventilation to a $Paco_2$ between 25 and 30 mm Hg to lower pulmonary vascular resistance and minimize right-to-left shunting through the patent ductus arteriosus.

Bray RJ. Congenital diaphragmatic hernia. *Anesthesia.* 1979;34:567.

Gregory GA, ed. *Pediatric Anesthesia.* 4th ed. New York: Churchill Livingstone; 2002:436–437.

C.6. How would you maintain the neonate's body temperature?

The neonate is particularly susceptible to heat loss because of a large surface to volume ratio, lack of insulating fat, and a naturally flaccid and open posture. Body temperature should be monitored carefully and maintained within the normal range. The following steps are used to maintain body temperature:

- Warm the operating room to 80.6° F (27° C).
- Use radiant warming lamps and a heating blanket.
- Use a Heat Moisture Exchanger on the ventilator circuit.
- Warm transfused blood and intravenous fluid to 37° C (99.5° F).

Dierdorf SF, Krishna G. Anesthetic management of neonatal surgical emergencies. *Anesth Analg.* 1981;60:204–214.

Gregory GA, ed. *Pediatric Anesthesia.* 4th ed. New York: Churchill Livingstone; 2002:430–437.

C.7. The surgeon returned the intrathoracic stomach and intestine to the peritoneal cavity and the ipsilateral lung was found to be hypoplastic and collapsed. The resident anesthesiologist tried to expand the collapsed lung manually with positive airway pressure. Five minutes after the abdomen was closed, the blood pressure suddenly dropped from 70/40 to 30/20 mm Hg, the heart rate from 150 to 80 beats per minute, and the pulse oximeter from 95% down to 60% saturation. What would you do immediately?

Any sudden deterioration in blood pressure, heart rate, oxygen saturation, or pulmonary compliance is suggestive of tension pneumothorax. Auscultation of the chest, particularly the contralateral side, should be done immediately. If absent or diminished breath sounds confirm the diagnosis, a chest tube should be inserted immediately. A large-bore intravenous catheter with needle may be inserted to release the tension pneumothorax if a chest tube is not immediately available.

The tension pneumothorax is usually on the contralateral side, because the high airway pressure required to inflate the hypoplastic lung may rupture the normal alveoli on the contralateral side, resulting in pneumothorax. Moreover, the ipsilateral chest usually already has a chest tube after surgery.

If there is no pneumothorax, or if deterioration is not improved after insertion of a chest tube, inferior vena cava compression (causing decreased venous return and decreased cardiac output) should be considered. The peritoneal cavity is often underdeveloped and unable to fully accommodate the returned abdominal organs, which increases the intra-abdominal pressure. In this circumstance, the abdominal wound should be opened to relieve the compression on the vena cava and diaphragm. A Silastic patch may be used to cover the abdominal defect temporarily and the defect will be closed at a later time.

Gregory GA, ed. *Pediatric Anesthesia.* 4th ed. New York: Churchill Livingstone; 2002:437.

C.8. Discuss fluid therapy in this patient.

Fluid therapy should be aimed to correct the preoperative deficit, provide maintenance fluid, and replace intraoperative evaporative, third space, and blood losses.

Kidneys are 80% to 90% mature by 1 month of age. Before that time, the infant cannot tolerate the extremes of renal stress. Neonates are obligate sodium losers; therefore, exogenous sodium should be supplied. In addition, neonates have decreased glycogen storage and are prone to hypoglycemia after brief periods of starvation. Therefore, glucose should also be provided. However, hyperglycemia may predispose the patient to intracranial hemorrhage and should be avoided. The preoperative fluid deficit may be evaluated by careful history taking, signs and symptoms of dehydration, urine output, and CVP monitoring. Maintenance fluids consisting of 5% dextrose in one-fourth to one-half strength saline are given at 4 mL/kg/hour. Intraoperative evaporative and third space losses are replaced with Ringer's lactate or saline at approximately 6 to 8 mL/kg/hour. Each milliliter of blood loss is replaced with 3 mL of Ringer's lactate or 1 mL of 5% albumin. Blood pressure, heart rate, urine output, CVP, hematocrit, and sodium and glucose levels are monitored following the fluid therapy.

Hines RL, Marschall KE. *Stoelting's Anesthesia and Co-existing Disease*. 5th ed. Philadelphia: Churchill Livingstone/Elsevier; 2008:593–594.

C.9. At the conclusion of surgery, would you extubate the patient in the operating room?

No. The patient should not be extubated in the operating room because varying degrees of pulmonary dysfunction are always present postoperatively. The endotracheal tube should be left in place and the baby should be transported to the intensive care unit for further postoperative care.

D. Postoperative Management

D.1. What postoperative problems would you expect in this patient? What is the mortality rate in patients with CDH?

The postoperative course is often characterized by a "honeymoon" period of rapid improvement, followed by sudden deterioration with profound arterial hypoxemia, hypercapnia, and acidosis.

The mortality in patients with CDH varies from 30% to 60%. Factors affecting the mortality include the following:

- Pulmonary hypoplasia
- *Associated congenital defect*. Cardiovascular and central nervous systems
- *Inadequate preoperative preparation*. Hypothermia, acidosis, shock, and tension pneumothorax
- *Ineffective postoperative management*. Hemorrhage, tension pneumothorax, inferior vena cava compression, persistent fetal circulation, excessive suction on chest tube

Waldschmidt J, vonLengerke HG, Berlien P. Causes of death in operated neonates with diaphragmatic defects. *Prog Pediatr Surg*. 1979;13:239.

D.2. The neonate's blood gas analyses improved right after surgery. However, 3 hours later, severe hypoxemia recurred in spite of ventilatory support with high inspired oxygen concentration. What are the possible causes? How should this patient be treated?

As discussed earlier, a tension pneumothorax should be considered and treated if it exists. In the absence of a tension pneumothorax, persistent hypoxemia suggests PPH with right-to-left shunting of venous blood. Recurrent pulmonary hypertension carries a high mortality. ECMO support should be continued or reestablished if already discontinued before surgery. If the infant cannot be weaned from ECMO after repair, options include discontinuing support or therapies such as NO or lung transplantation. High-frequency jet ventilation and oscillatory ventilation have had limited success in patients with CDH.

CHAPTER 38

Tetralogy of Fallot

JAMES A. DINARDO

A 5-MONTH-OLD INFANT

recently adopted from South America is being evaluated for stable persistent cyanosis with arterial oxygen saturation (Sao_2) of 70% to 80% since birth. She feeds well and is in the 70th percentile for weight (6.5 kg). An echocardiogram done before her arrival at your institution suggests that she has tetralogy of Fallot (TOF). Although she has never been noted to have a "Tet spell," her Sao_2 was noted to decrease to 60% during a recent febrile episode. Repeat echocardiogram reveals TOF with severe valvular pulmonary stenosis (PS) and mild subvalvular PS secondary to anterior deviation of the conal septum into the right ventricle outflow tract (RVOT). There is a peak instantaneous gradient of 70 mm Hg across the RVOT as determined by continuous wave Doppler.

A. Medical Disease and Differential Diagnosis

1. What is tetralogy of Fallot (TOF)?
2. What is the pathophysiology of TOF with pulmonary stenosis (TOF/PS)?
3. What is shunting and how is $Q_P : Q_S$ calculated?
4. What is the pathophysiology of TOF with pulmonary atresia?
5. How is the arterial O_2 saturation determined in single ventricle physiology?
6. What is a "pink Tet"?
7. What are hypercyanotic spells? How are they treated?
8. What palliative surgical procedures are available for treating this patient with TOF/PS?
9. What definite surgical procedures are available for treating this patient with TOF/PS?
10. What palliative and definite surgical procedures are available for treating a patient with TOF with pulmonary atresia?

B. Preoperative Evaluation and Preparation

1. What preoperative history and physical examination information do you want?
2. Which other abnormalities need to be considered in this patient?
3. In general, what nothing by mouth (NPO) guidelines will you follow and what premedication will you give to a child with congenital heart disease?

C. Intraoperative Management

1. How will you induce anesthesia in this patient if intravenous (IV) access cannot be obtained?
2. Why would end-tidal carbon dioxide ($ETCO_2$) monitoring be of particular use in a patient with TOF/PS?
3. What is near-infrared spectroscopy (NIRS) and what does it measure?
4. What are the important management issues during creation of a palliative shunt?
5. What is the effect of inhalation anesthetics on airway reflexes, myocardial contractility, systemic vascular resistance (SVR), and pulmonary vascular resistance (PVR) in children?
6. What are the pre–cardiopulmonary bypass (CPB) anesthetic goals for a patient undergoing definitive surgical correction of TOF/PS?
7. What interventions will reliably reduce PVR?
8. How does heparin administration and activated coagulation time (ACT) monitoring differ in children as compared with adults?
9. How is heparin reversed?
10. What is the incidence of protamine reactions in children?
11. What is the role of transesophageal echocardiography (TEE) in this patient?
12. What effect would a residual ventricular septal defect (VSD) have in this patient following separation from CPB?

D. Postoperative Management

1. How should postoperative ventilation be managed in this patient following placement of a transannular patch for TOF/PS?
2. Following complete repair of TOF/PS in an infant, what arterial oxygen saturation (Sao_2) is acceptable?
3. Following placement of a modified Blalock-Taussig shunt (MBTS) for TOF/PS in an infant, what Sao_2 is acceptable?
4. What is junctional ectopic tachycardia (JET)?

A. Medical Disease and Differential Diagnosis

A.1. What is tetralogy of Fallot (TOF)?

In 1888, Fallot described a congenital heart defect composed of four characteristics (1) large VSD, (2) right ventricular (RV) outflow obstruction, (3) overriding aorta, and (4) right ventricle hypertrophy (RVH). Broadly defined, TOF is a complex of anatomic malformations consisting of a large malalignment conoventricular VSD, a rightward and anterior displacement of the aorta such that it overrides the VSD, and a variable degree of subvalvular RVOT obstruction due to anterior, superior, and leftward deviation of the conal (infundibular) ventricular septum. In addition, abnormalities in the septal and parietal bands of the crista supraventricularis further exacerbate infundibular obstruction. RVH is the result of chronic RVOT obstruction. The most common associated lesion is a right aortic arch with mirror image arch vessel branching (innominate artery gives rise to left carotid and left subclavian arteries; right

carotid and right subclavian arise separately) present in 25% of patients. Two broad subsets of TOF exist: TOF with PS (TOF/PS) and TOF with pulmonary atresia. A third much less common type of TOF known as *TOF with absent pulmonary valve* will not be considered here.

Tetralogy of Fallot with pulmonary stenosis

TOF/PS involves the features of TOF in conjunction with varying degrees of valvular PS. At one end of the spectrum of TOF/PS the pulmonary valve may be mildly hypoplastic (reduced annulus size) with minimal fusion of the pulmonary valve leaflets (Fig. 38.1). The pulmonary valve is almost always bileaflet. At the other end of the spectrum, the pulmonary annulus may be very small with near fusion of the valve leaflets. It is important to point out that the valvular obstruction is a *fixed* obstruction while the subvalvular obstruction is *dynamic*. Left uncorrected, RVOT obstruction from both valvular and subvalvular obstruction begets progression of subvalvular obstruction as compensatory RVH increases the mass of the RV and infundibulum. The anatomy of TOF/PS can almost always be definitively delineated (including coronary anatomy) by two-dimensional echocardiography. Cardiac catheterization is rarely necessary or indicated.

Tetralogy of Fallot with pulmonary atresia

TOF with pulmonary atresia involves the features of TOF and infundibular and pulmonary valvular atresia in conjunction with varying degrees of pulmonary arterial atresia. Four groups are said to exist. Group 1 patients have isolated infundibular and pulmonary valve atresia with a main pulmonary artery (PA) and distal PAs of near normal size and architecture. In some of these patients, the main PA may extend to the atretic

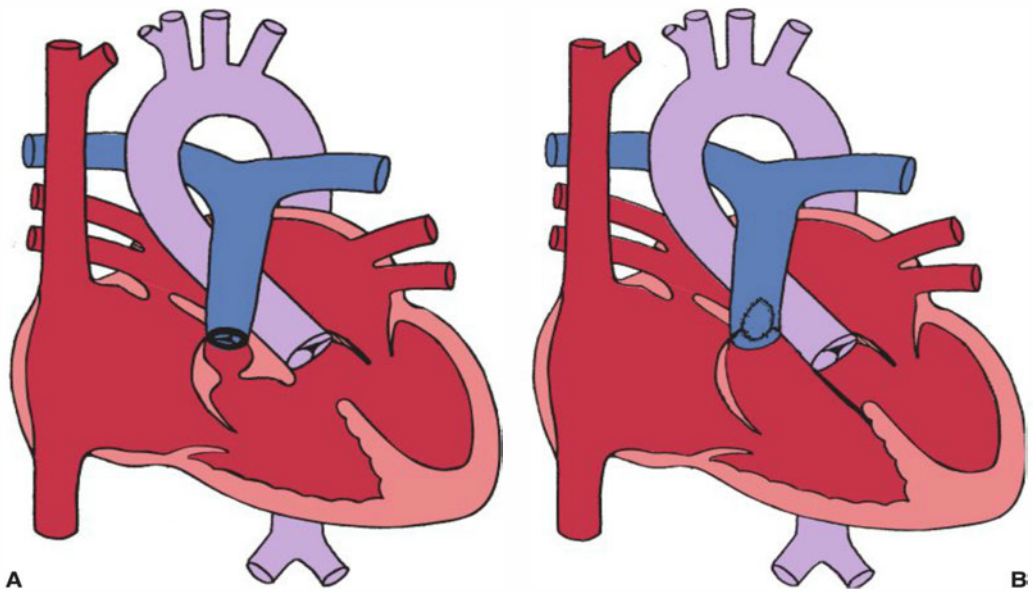

Figure 38.1 **A.** Uncorrected TOF/PS demonstrating malalignment VSD with aortic override, valvar and subvalvar (dynamic) PS. There is a left aortic arch. **B.** Definitively repaired tetralogy of Fallot with pulmonary stenosis (TOF/PS) with ventricular septal defect (VSD) closure creating left ventricle (LV) to aortic continuity, resection of subvalvar muscle bundles and deviated conal septum, and creation of a transannular patch (with pulmonary valvectomy) creating pulmonary insufficiency. A small atrial level communication has been left.

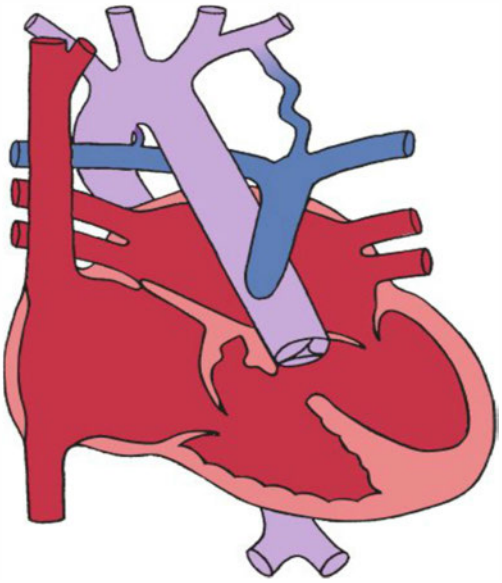

Figure 38.2 Illustration of tetralogy of Fallot with pulmonary atresia group 1 with short segment pulmonary artery, good-sized PAs in continuity supplied by a right-sided patent ductus arteriosus (PDA), and one major aortopulmonary collateral artery (MAPCA) from the left subclavian artery. There is a right aortic arch with mirror image arch vessel branching.

infundibulum. In others, there is short segment atresia of the main PA (Fig. 38.2). Patients in this group have pulmonary blood flow supplied from a patent ductus arteriosus (PDA). Group 2 patients have absence of the main PA, but the PAs are in continuity and supplied by a PDA. Group 3 patients have severely hypoplastic native PAs; the left and right PA may not be in continuity. There are major aortopulmonary collateral arteries (vessels from the aorta to the PA) known as *MAPCAs*. A PDA may be present as well. Some segments of lung may be supplied only by blood from MAPCAs, some only by the native PAs, and others by both sources (Fig. 38.3). Group 4 patients have no native PAs and all pulmonary blood flow is derived entirely from MAPCAs.

The anatomy of MAPCAs in TOF with pulmonary atresia can almost never be clearly delineated by two-dimensional echocardiography alone. Cardiac catheterization and/or magnetic resonance imaging/magnetic resonance angiography are necessary to delineate collateral anatomy and to determine $Q_P : Q_S$.

Jonas RA, ed. Tetralogy of Fallot with pulmonary atresia. In: *Comprehensive Surgical Management of Congenital Heart Disease*. London: Arnold; 2004:440–456.

A.2. What is the pathophysiology of TOF with pulmonary stenosis (TOF/PS)?

TOF/PS is a complex shunt in which a communication (VSD) and a partial obstruction to RV outflow (RV infundibular and valvular stenosis) are present. In

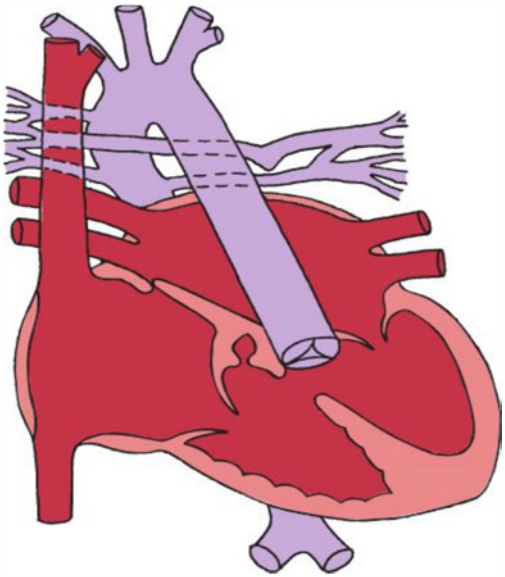

Figure 38.3 Illustration of tetralogy of Fallot with pulmonary atresia group 3 with no main PA, small branch PAs in continuity supplied by major aortopulmonary collateral arteries (MAPCAs). Some lung segments are supplied by the native PAs while others are supplied directly by MAPCAs. There is a right aortic arch with mirror image arch vessel branching.

complex shunts, the resistance to outflow is a combination of the resistance from the obstructive lesions and the vascular resistance. If the resistance from the RV obstructive lesions is high, changes in PVR will have little effect on shunt magnitude and direction. In most patients with TOF/PS, there is a fixed and a dynamic component to RV outflow obstruction. The fixed component is produced by the valvular stenosis. The dynamic component is produced by variations in the caliber of the RV infundibulum. The pathophysiology present in TOF/PS is physiologic right-to-left (R-L) shunting induced by the presence of a VSD and RVOT obstruction. In addition, because the aorta overrides the VSD and the RV, desaturated systemic venous blood tends to stream out the aorta even in the presence of mild RVOT obstruction.

The Sao_2 is determined by the relative volumes and saturations of recirculated systemic venous blood and effective systemic blood flows that have mixed and reached the aorta. This is summarized in the following equation:

$$\text{Aortic } Sao_2 = \frac{\begin{array}{c}([\text{pulmonary venous } O_2 \text{ saturation}]\,[\text{effective systemic blood flow}] \\ +\,[\text{systemic venous } O_2 \text{ saturation}]\,[\text{recirculated systemic venous blood flow}])\end{array}}{(\text{total sytemic blood flow})}$$

This is demonstrated in Figure 38.4 where the $Sao_2 = [(98)(0.5) + (65)(0.5)]/1 = 81$.

A.3. What is shunting and how is Q_P: Q_S calculated?

Shunting is the process whereby venous return into one circulatory system is recirculated through the arterial outflow of the same circulatory system. Flow of blood from the systemic venous atrium (right atrium) to the aorta produces recirculation of

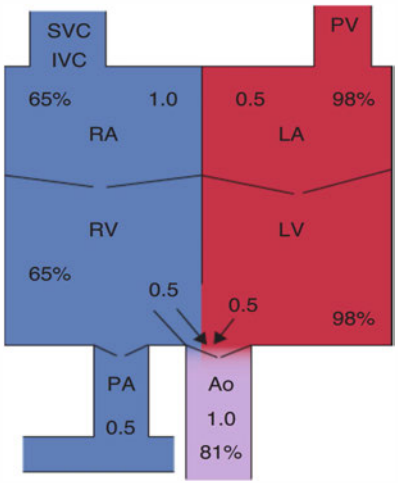

Figure 38.4 Chamber oxygen saturations and relative flows for a patient with uncorrected tetralogy of Fallot with pulmonary stenosis (TOF/PS). Arterial, oxygen saturation (Sao_2) and Q_P : Q_S are illustrated. Ao, aorta; IVC, inferior vena cava; LA, left atrium; LV, left ventricle; PA, pulmonary artery; PV, pulmonary vein; RA, right atrium; RV, right ventricle; SVC, superior vena cava.

systemic venous blood. Flow of blood from the pulmonary venous atrium (left atrium) to the PA produces recirculation of pulmonary venous blood. Recirculation of blood produces a physiologic shunt. Recirculation of pulmonary venous blood produces a physiologic left-to-right (L-R), whereas recirculation of systemic venous blood produces a physiologic R-L shunt. A physiologic R-L or L-R shunt commonly is the result of an anatomic R-L or L-R shunt. In an anatomic shunt, blood moves from one circulatory system to the other through a communication (orifice) at the level of the cardiac chambers or great vessels. Physiologic shunts can exist in the absence of an anatomic shunt; transposition physiology is the best example.

Effective blood flow is the quantity of venous blood from one circulatory system reaching the arterial system of the other circulatory system. Effective pulmonary blood flow is the volume of systemic venous blood reaching the pulmonary circulation, whereas effective systemic blood flow is the volume of pulmonary venous blood reaching the systemic circulation. Effective pulmonary blood flow and effective systemic blood flows are the flows necessary to maintain life. Effective pulmonary blood flow and effective systemic blood flow are always equal, no matter how complex the lesions. Effective blood flow usually is the result of a normal pathway through the heart, but it may occur as the result of an anatomic R-L or L-R shunt.

Total pulmonary blood flow (Q_P) is the sum of effective pulmonary blood flow and recirculated pulmonary blood flow. Total systemic blood flow (Q_S) is the sum of effective systemic blood flow and recirculated systemic blood flow. Total pulmonary blood flow and total systemic blood flow do not have to be equal. Because Q_S (systemic cardiac output) tends to remain constant to supply end organs, a physiologic L-R shunt (pulmonary recirculation) causes volume overload while a physiologic R-L shunt (systemic recirculation) allows Q_S to be maintained at the expense of Sao_2.

Calculation of $Q_P : Q_S$ (the ratio of total pulmonary blood flow to systemic blood flow) is greatly simplified when the determination is made using low inspired concentrations of oxygen. This allows the contribution of oxygen carried in solution ($Po_2 \times 0.003$) to be ignored. Failure to account for this component when determination of $Q_P : Q_S$ is made using a fraction of inspired oxygen (FIO_2) of 1.0 will introduce substantial (100%) error. If the FIO_2 is low, the determination of $Q_P : Q_S$ can be simplified to the following equation using just oxygen saturations:

$$(S_AO_2 - S_{SVC}O_2)/(S_{PV}O_2 - S_{PA}O_2)$$

where A = arterial, SVC = superior vena cava, PV = pulmonary vein that can be assumed to be 98% in the absence of significant pulmonary disease, and PA = pulmonary artery.

DiNardo JA. Anesthesia for congenital heart surgery. In: Jonas RA, ed. *Comprehensive Surgical Management of Congenital Heart Disease*. London: Arnold; 2004:45–65.

A.4. What is the pathophysiology of TOF with pulmonary atresia?

The pathophysiology of TOF with pulmonary atresia is single ventricle physiology. Single ventricle physiology describes the situation wherein complete mixing of pulmonary venous and systemic venous blood occurs at the atrial or ventricular level and the ventricle(s) then distributes output to both the systemic and pulmonary beds. As a result of this physiology the following are observed:

- Ventricular output is the sum of pulmonary blood flow (Q_P) and systemic blood flow (Q_S)
- Distribution of systemic and pulmonary blood flow is dependent on the relative resistances to flow (both intracardiac and extracardiac) into the two parallel circuits
- Oxygen saturations are the same in the aorta and the PA

This physiology can exist in patients with one well-developed ventricle and one hypoplastic ventricle as well as in patients with two well-formed ventricles. In the case of a single anatomic ventricle, there is always obstruction to either pulmonary or systemic blood flow as the result of complete or near complete obstruction to inflow and/or outflow from the hypoplastic ventricle. In this circumstance, there must be a source of both systemic and pulmonary blood flow to ensure postnatal survival. In some instances of a single anatomic ventricle, a direct connection between the aorta and the PA through a PDA is the sole source of systemic blood flow (hypoplastic left heart syndrome) or of pulmonary blood flow (PA with intact ventricular septum). This is known as *ductal dependent circulation*. In other instances of a single anatomic ventricle, intracardiac pathways provide both systemic and pulmonary blood flow without the necessity of a PDA. This is the case in tricuspid atresia with normally related great vessels, a nonrestrictive VSD and minimal or absent PS.

In certain circumstances, single ventricle physiology can exist in the presence of two well-formed anatomic ventricles. This is generally the result of atresia or near atresia of outflow from one of the ventricles. Examples include the following:

- TOF with pulmonary atresia where pulmonary blood flow is supplied through a large PDA or MAPCAs
- Truncus arteriosus
- Severe neonatal aortic stenosis and interrupted aortic arch; in both lesions a substantial portion of systemic blood flow is supplied through a PDA
- Heterotaxy syndrome

DiNardo JA. Anesthesia for congenital heart surgery. In: Jonas RA, ed. *Comprehensive Surgical Management of Congenital Heart Disease.* London: Arnold; 2004:45–65.

A.5. How is arterial O_2 saturation determined in single ventricle physiology?

With single ventricle physiology, the arterial oxygen saturation (Sao_2) will be determined by the relative volumes and saturations of pulmonary venous and systemic venous blood flows that have mixed and reached the aorta. This is summarized in the following equation:

$$\text{Aortic } O_2 \text{ saturation} = \frac{\begin{array}{c}([\text{systemic venous saturation}][\text{total systemic venous blood flow}] \\ +\ [\text{pulmonary venous saturation}][\text{total pulmonary venous blood flow}])\end{array}}{(\text{total systemic blood flow} + \text{total pulmonary venous blood flow})}.$$

The primary goal in the management of patients with single ventricle physiology is optimization of systemic oxygen delivery and perfusion pressure. This is necessary if end-organ (myocardial, renal, hepatic, splanchnic) dysfunction and failure are to be prevented. This goal is achieved by balancing the systemic and pulmonary circulations. The term *balanced circulation* is used because both laboratory and clinical evaluations have demonstrated that maximal systemic oxygen delivery (the product of systemic oxygen content and systemic blood flow) is achieved for single ventricle lesions when $Q_P : Q_S$ is at or just below 1:1. Increases in $Q_P : Q_S$ in excess of 1:1 are associated with a progressive decrease in systemic oxygen delivery because the subsequent increase in systemic oxygen content is more than offset by the progressive decrease in systemic blood flow and by diastolic hypotension due to run-off into the pulmonary circulation. Decreases in $Q_P : Q_S$ just below 1:1 are associated with a precipitous decrease in systemic oxygen delivery because the subsequent increase in systemic blood flow is more than offset by the dramatic decrease in systemic oxygen content.

DiNardo JA. Anesthesia for congenital heart surgery. In: Jonas RA, ed. *Comprehensive Surgical Management of Congenital Heart Disease.* London: Arnold, 2004:45–65.

A.6. What is a "pink Tet"?

The term *pink Tet* refers to any noncyanotic patient with TOF/PS or TOF with pulmonary atresia. In these patients, $Q_P : Q_S$ is sufficiently high ($Q_P : Q_S$ generally greater than 0.8:1 in the presence of a normal mixed venous saturation and pulmonary vein saturation) to maintain a deoxyhemoglobin concentration less than 5 g per dL (Sao_2 generally >80%). The designation of "pink Tet" would apply to TOF/PS patients with minimal valvular and subvalvular PS and to all patients with TOF with pulmonary atresia where pulmonary blood flow is supplied from a large PDA and/or MAPCAs.

DiNardo JA. Anesthesia for congenital heart disease. In: DiNardo JA, Zvara DA, eds. *Anesthesia for Cardiac Surgery.* 3rd ed. Oxford: Blackwell Publishing; 2008:167–251.

A.7. What are hypercyanotic spells? How are they treated?

The occurrence of hypoxic spells in TOF patients may be life threatening and should be anticipated in every patient with TOF/ PS and any infundibular obstruction, even those who are not normally cyanotic. The peak frequency of spells is between 2 and 3 months of age; spells occur more frequently in severely cyanotic patients. The onset of spells usually prompts urgent surgical intervention, so it is not unusual

for the anesthesiologist to care for an infant who is at great risk for spells during the preoperative period. The etiology of spells is not completely understood, but infundibular spasm or constriction plays a role. Crying, defecation, feeding, fever, and awakening all can be precipitating events. Paroxysmal hyperpnea is the initial finding. There is an increase in rate and depth of respiration, leading to increasing cyanosis and potential syncope, convulsions, or death. During a spell, the infant will appear pale and limp secondary to poor cardiac output. Hyperpnea has several deleterious effects in maintaining and worsening a hypoxic spell. Hyperpnea increases oxygen consumption through the increased work of breathing. Hypoxia induces a decrease in systemic vascular resistance (SVR), which further increases the R-L shunt. Hyperpnea also lowers intrathoracic pressure and leads to an increase in systemic venous return. In the face of infundibular obstruction, this results in an increased RV pressure and an increase in the R-L shunt. Treatment of a "Tet spell" includes the following:

- Administration of 100% oxygen
- Compression of the femoral arteries or placing the patient in a knee-chest position transiently increases SVR and reduces the R-L shunt.
- Administration of morphine sulfate (0.05 to 0.1 mg/kg), which sedates the patient and may have a depressant effect on respiratory drive and hyperpnea
- Administration of 15 to 30 mL per kg of a crystalloid solution. Enhancing preload will increase heart size, which may increase the diameter of the RVOT.
- Administration of sodium bicarbonate to treat the severe metabolic acidosis that can be seen during a spell. Correction of the metabolic acidosis will help normalize SVR and reduce hyperpnea. Bicarbonate administration (1 to 2 mEq/kg) in the absence of a blood gas determination is warranted during a spell.
- Phenylephrine (dose 5 to 10 μg/kg IV or 2 to 5 μg/kg/minute as an infusion) can be used to increase SVR and reduce R-L shunting. In the presence of severe RV outflow obstruction, phenylephrine-induced increases of PVR will have little or no effect in increasing RV outflow resistance. It is important to point out that treatment with α-adrenergic agents to increase SVR does nothing to treat the underlying cause of the spell, although the decrease in unstressed venous volume induced by these agents may augment preload.
- β-Adrenergic agonists are absolutely contraindicated. By increasing contractility, they will cause further narrowing of the stenotic infundibulum.
- Administration of propranolol (0.1 mg/kg) or esmolol (0.5 mg/kg followed by an infusion of 50 to 300 μg/kg/minute) may reduce infundibular spasm by depressing contractility. In addition, slowing of heart rate may allow for improved diastolic filling (increased preload), increased heart size, and an increase in the diameter of the RVOT.
- Manual compression of the abdominal aorta will increase SVR; this maneuver is particularly effective for the anesthetized patient. After the chest is open, the surgeon can manually compress the ascending aorta to increase impedance to ejection through the LV. This can be effective in terminating a cyanotic episode.
- Extracorporeal membrane oxygenation resuscitation is another alternative in refractory episodes when immediate operative intervention is not possible.

DiNardo JA. Anesthesia for congenital heart disease. In: DiNardo JA, Zvara DA, eds. *Anesthesia for Cardiac Surgery*. 3rd ed. Oxford: Blackwell Publishing; 2008:167–251.

A.8. What palliative surgical procedures are available for treating this patient with TOF/PS?

Palliative shunt procedures to increase pulmonary blood flow can be used for patients with TOF/PS in whom complicated surgical anatomy precludes definitive repair at

the time of presentation. In addition, some institutions delay elective complete repair until 12 to 18 months of age with placement of a palliative shunt if cyanosis occurs before that time interval. The palliative shunt procedures involve creation of a systemic-to-pulmonary arterial shunt analogous to a PDA. Ideally, these surgical shunts should be mildly restrictive simple shunts. In the presence of a proximal obstruction to pulmonary blood flow, these shunts produce an L-R shunt and an increase in pulmonary blood flow. The volume load imposed on the LV by these shunts parallels the increases in pulmonary flow that they produce. There will be progressive hypertrophy of the body and infundibulum of the RV during the interval from shunt placement to definitive repair as RVOT obstruction will not be relieved. The shunts can be summarized as follows:

Waterston shunt—this shunt results from creation of a side-to-side anastomosis between the ascending aorta and the right PA. This procedure is performed through a right thoracotomy without CPB.

Potts shunt—this shunt results from creation of a side-to-side anastomosis between the descending aorta and the left PA. This procedure is performed through a left thoracotomy without CPB.

Waterston and Potts shunts are of historic interest only. It is difficult to size the orifice of this shunt correctly. Too small an orifice will limit pulmonary blood flow, whereas too large an orifice will create pulmonary overperfusion and congestion and predispose to development of unilateral pulmonary vascular obstructive disease. These shunts may produce distortion of the PA, making subsequent definitive repair difficult. In addition, they are difficult to take down at the time of the definitive procedure.

Central shunt—placing a synthetic tube graft between the ascending aorta and the main or branch PA creates this shunt. This shunt can be performed with or without CPB through a thoracotomy or median sternotomy. It often is used when prior shunt procedures have failed.

Blalock-Taussig shunt (BTS)—as originally described this involved creation of an end-to-side anastomosis of the right or left subclavian artery to the ipsilateral branch PA. Currently, a modification of this procedure known as the *modified Blalock-Taussig shunt* (*MBTS*) is used. It involves interposing a length of Gore-Tex tube graft (3.5 to 4.0 mm in infants) between the subclavian or innominate artery and the branch PA. These shunts usually are performed on the side opposite the aortic arch through a thoracotomy without CPB (Fig. 38.5).

DiNardo JA. Anesthesia for congenital heart disease. In: DiNardo JA, Zvara DA, eds. *Anesthesia for Cardiac Surgery*. 3rd ed. Oxford: Blackwell Publishing; 2008:167–251.

A.9. What definite surgical procedures are available for treating this patient with TOF/PS?

Currently, most patients with TOF/PS have an elective full correction between the ages of 2 and 10 months of age. In some centers, surgery is delayed as long as possible within this time interval, with the precise timing of repair dictated by the onset of cyanotic episodes. Definitive repair for TOF/PS is being accomplished in neonates in some centers if favorable anatomy is present. Surgery is aimed at relieving the outflow obstruction by resection of hypertrophied, obstructing muscle bundles and augmentation and enlargement of the outflow tract with a pericardial patch. Unless the pulmonic annulus is near normal size and the pulmonary valve is only mildly stenotic, enlargement of the outflow tract involves extension of the patch across the pulmonary valve annulus and into the main PA. Because a transannular patch creates pulmonic insufficiency, it is avoided when possible. If stenosis of the PA extends to the bifurcation, the pericardial patch can be extended beyond the bifurcation of the pulmonary arteries.

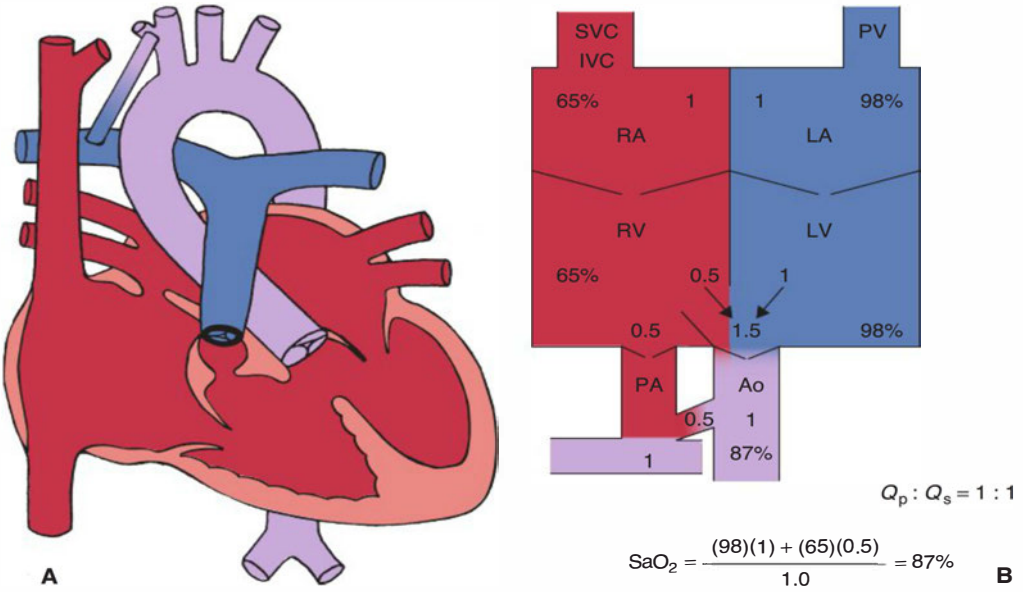

Figure 38.5 **A.** Palliative modified Blalock-Taussig shunt (MBTS) for tetralogy of Fallot with pulmonary stenosis (TOF/PS). Shunt is seen to connect the innominate artery to the right pulmonary artery (PA). This patient has a left aortic arch. **B.** Chamber oxygen saturations and relative flows for a patient with MBTS and TOF/PS. Arterial oxygen saturation (SaO_2) and $Q_P : Q_S$ are illustrated. Ao, aorta; IVC, inferior vena cava; LA, left atrium; LV, left ventricle; PV, pulmonary vein; RA, right atrium; RV, right ventricle; SVC, superior vena cava.

Finally, the VSD is closed. In neonates, this is usually done through the right ventriculotomy created for resection of RVOT obstruction and placement of the transannular patch. In infants and older children, the VSD can be closed through a transtricuspid valve approach.

An important surgical consideration for patients with TOF/PS is the occurrence of coronary artery abnormalities. Approximately 8% of patients have either the left main coronary artery or the left anterior descending artery as a branch of the right coronary artery. In these cases, a right ventriculotomy to enlarge the RVOT will endanger the left coronary artery. In such cases, an extracardiac conduit (RV to main PA) may be necessary to bypass the outflow tract obstruction and avoid injury to the coronary artery.

Jonas RA, ed. Tetralogy of Fallot with pulmonary stenosis. In: *Comprehensive Surgical Management of Congenital Heart Disease*. London: Arnold; 2004:279–300.

A.10. What palliative and definite surgical procedures are available for treating a patient with TOF with pulmonary atresia?

Surgery in group 1 and 2 TOF with pulmonary atresia patients is aimed at establishing a reliable source of pulmonary blood flow in the neonatal period, as these patients

are dependent on prostaglandin E_1 ($PGE1_1$) to maintain a PDA and pulmonary blood flow. These patients may undergo a palliative shunt procedure or a definite procedure. The definite procedure would be creation of continuity between the RV and the main PA through placement of an RV to PA conduit with VSD closure generally performed through the ventriculotomy used for the proximal end of the conduit. Patients in groups 3 and 4 present difficult management problems. As a rule, these patients present with univentricular physiology with a tendency for pulmonary blood flow to become excessive ($Q_P : Q_S > 2$ to 3:1) as the PVR drops following birth. In group 3 patients, neonatal repair with placement of an RV to PA conduit is undertaken to place the PAs in continuity with the RV in an effort to promote native PA growth. In this circumstance, the VSD is left open as a source of R-L shunting and delivery of desaturated blood to the systemic circulation because it would be impossible for the RV to deliver an adequate cardiac output to the left atrium across the hypoplastic pulmonary vascular bed. These infants then undergo multiple cardiac catheterization procedures in order to (1) dilate and stent the hypoplastic native PAs, and (2) to coil embolize MAPCAs, which provide pulmonary blood flow that is competitive with blood flow supplied by native PAs. MAPCAs that provide pulmonary blood flow to segments of lung not supplied by native PAs must be unifocalized to the proximal pulmonary circulation.

Unifocalization may have to be performed and involves removal of the collateral vessel from the aorta with subsequent reanastomosis to the RV to PA conduit or a proximal PA branch. Although the traditional approach has been through a thoracotomy, more recently, most groups have favored a central approach working through a median sternotomy. It is only when 80% to 90% of the pulmonary vascular bed is direct continuity with the RV that closure or fenestrated closure of the VSD can be considered. Usually, this will mean that at least 10 to 12 bronchopulmonary segments are now in direct continuity with the RV.

In group 4 patients, it may be necessary to unifocalize several large collaterals to the distal end of conduit from the RV as the initial intervention. Alternatively, several large collaterals could be unifocalized to an MBTS or central shunt. These procedures serve to promote pulmonary vascular growth, prevent the development of pulmonary vascular obstructive disease, and control the $Q_P : Q_S$.

Jonas RA, ed. Tetralogy of Fallot with pulmonary atresia. In: *Comprehensive Surgical Management of Congenital Heart Disease*. London: Arnold, 2004:440–456.

B. Preoperative Evaluation and Preparation

B.1. What preoperative history and physical examination information do you want?

Clinical history should include medications, allergies, past hospitalizations and operations (including prior anesthetic experiences), and a thorough review of systems. Performance of age-appropriate activities will aid in the evaluation of cardiac function and reserve. The neonate and infant in cardiac failure will manifest symptoms of low cardiac reserve during feeding, which is a strenuous activity, even for a normal newborn. A parent might report that sweating, tiring, dyspnea, and circumoral cyanosis occur during feeding. The observation by a parent that the patient cannot keep the same pace as siblings often is a reliable clinical sign that cyanosis or congestive heart failure is worsening.

Interpretation of vital signs must be age-specific. Growth curves also are useful. Congestive heart failure will inhibit, sequentially, age-appropriate gains

in weight, height, and head circumference. It is not unusual for patients with severe congestive heart failure to weigh less at 3 or 4 months of age than at birth. Interestingly, cyanotic children often do not manifest this failure to thrive. Physical examination will reveal cyanosis, clubbing, or signs of congestive heart failure similar to those seen in adults, such as hepatomegaly, ascites, edema, or tachypnea. Rales may not be heard in infants and children with congestive heart failure, and the degree of heart failure may be determined more reliably by some of the signs and symptoms outlined in the preceding text. The degree of cyanosis is related to the percentage of desaturated hemoglobin. A markedly hypoxemic child with baseline arterial saturations in the 70% range may be anemic and clinically appear less cyanotic than another child with similar arterial saturation and a more appropriate hematocrit of 65%.

Physical examination should include an evaluation of the limitations to vascular access and monitoring sites imposed by previous surgery. A child who has undergone a palliative shunt procedure may have a diminished pulse or unobtainable blood pressure in the arm in which the subclavian artery has been incorporated into the shunt. This obviously has implications for arterial catheter placement, sphygmomanometric blood pressure monitoring, and use of pulse oximetry during surgery. Finally, the child who has undergone multiple palliative procedures may have poor venous access, which may influence the mode of induction.

It often is difficult to differentiate clearly between signs and symptoms of congestive heart failure and a mild upper respiratory tract infection. Because increased pulmonary blood flow seems to predispose multiple respiratory tract infections, the physical examination may show mild tachypnea, wheezing, or upper airway congestion and, in the absence of abnormal laboratory findings or fever, may be impossible to distinguish from congestive heart failure. The decision to proceed to surgery may be necessary even when the differentiation between worsening congestive heart failure and a respiratory tract infection cannot be made with certainty.

DiNardo JA. Anesthesia for congenital heart disease. In: DiNardo JA, Zvara DA, eds. *Anesthesia for Cardiac Surgery*. 3rd ed. Oxford: Blackwell Publishing; 2008:167–251.

B.2. Which other abnormalities need to be considered in this patient?

Because approximately 8% of children with congenital heart disease have other congenital abnormalities, it is prudent to consider and define these defects. For example, patients with TOF/PS and TOF with pulmonary atresia have a higher incidence of 22q11.2 deletion, a defect associated with DiGeorge syndrome, velocardiofacial syndrome, and conotruncal anomaly face syndromes leading to hypocalcemia, immunodeficiency, facial dysmorphia, palate anomalies, velopharyngeal dysfunction, renal anomalies, and speech and feeding disorders as well as neurocognitive, behavioral, and psychiatric disorders. Tracheal stenosis and bronchomalacia may be a serious problem for TOF with pulmonary atresia patients who have undergone tracheoesophageal fistula repair. Needless to say, many of these defects can seriously complicate airway management.

DiNardo JA. Anesthesia for congenital heart disease. In: DiNardo JA, Zvara DA, eds. *Anesthesia for Cardiac Surgery*. 3rd ed. Oxford: Blackwell Publishing; 2008:167–251.

Kobrynski LJ, Sullivan KE. Velocardiofacial syndrome, DiGeorge syndrome: the chromosome 22q11.2 deletion syndromes. *Lancet*. 2007; 370:1443–52.

B.3. In general, what nothing by mouth (NPO) guidelines will you follow and what premedication will you give to a child with congenital heart disease?

Generally speaking, the rule of 2, 4, 6, 8 can be used as the NPO interval for neonates, infants, and children with congenital heart disease:

- 2 hours for clear liquids
- 4 hours for breast milk
- 6 hours for formula
- 8 hours for solid food

Premedication before induction can be used to facilitate a number of objectives. In older children, it can be used to alleviate anxiety before an IV or inhalation induction. In younger children, premedication eases separation of the child from the parents. In infants, judicious premedication alone or in combination with inhaled nitrous oxide can greatly simplify placement of an IV catheter in an otherwise struggling infant. Midazolam 1.0 mg per kg orally in infants and younger children who have not had prior cardiac surgery is useful. In children older than 1 year who have undergone prior operative procedures, oral ketamine 7 to 10 mg per kg in combination with midazolam 1.0 mg per kg works well. These children are remarkably tolerant to midazolam as the result of either heightened anxiety or previous intraoperative and postoperative exposure to benzodiazepines. In circumstances where premedication is deemed important and the child will not take oral medication, the intramuscular route can be used. Ketamine 2 to 3 mg per kg and glycopyrrolate (10 μg/kg) alone or in combination with midazolam 0.1 mg per kg works well.

Ferrari LR, Rooney FM, Rockoff MA. Preoperative fasting practices in pediatrics. *Anesthesiology*. 1999;90:978–980.

C. Intraoperative Management

C.1. How will you induce anesthesia in this patient if intravenous (IV) access cannot be obtained?

An alternative to IV induction in infants and neonates with difficult peripheral IV access is intramuscular induction with ketamine (3 to 5 mg/kg), succinylcholine (5 mg/kg), and glycopyrrolate (10 μg/kg). Glycopyrrolate is recommended to reduce the airway secretions associated with ketamine administration and to prevent the bradycardia, which may accompany succinylcholine administration. This technique provides prompt induction and immediate control of the airway with tracheal intubation and is useful in circumstances where it is anticipated that initial IV access will have to be obtained through the external jugular vein, femoral vein, or internal jugular vein. This technique is hampered by the fact that the short duration of action of succinylcholine limits the period of patient immobility. An alternative technique combines intramuscular ketamine (4 to 5 mg/kg), glycopyrrolate (10 μg/kg), and rocuronium (1.0 mg/kg). This technique is hampered by the longer time interval until attainment of adequate intubating conditions and the longer duration of action of rocuronium as compared to succinylcholine.

DiNardo JA. Anesthesia for congenital heart surgery. In: Jonas RA, ed. *Comprehensive Surgical Management of Congenital Heart Disease*. London: Arnold; 2004:45–65.

C.2. Why would end-tidal carbon dioxide ($ETco_2$) monitoring be of particular use in a patient with TOF/PS?

$ETCO_2$ monitoring is routinely employed in patients with congenital heart disease, with the caveat that the difference between $Paco_2$ and $ETco_2$ will vary as physiologic dead space varies and that, in some circumstances, the difference may be large (>10 to 15 mm Hg). Any acute reduction in pulmonary blood flow (decreased cardiac output, pulmonary embolus, increased intracardiac R-L shunting) will increase this gradient. In a patient with TOF/PS, a gradual reduction in $ETco_2$ will often precede a decrease in Sao_2 as the first manifestation of the increased R-L intracardiac shunting associated with a "Tet spell."

DiNardo JA. Anesthesia for congenital heart surgery. In: Jonas RA, ed. *Comprehensive Surgical Management of Congenital Heart Disease.* London: Arnold; 2004:45–65.

C.3. What is near-infrared spectroscopy (NIRS) and what does it measure?

NIRS is an evolving technology that holds promise as a real-time, online monitor of cerebral tissue oxygenation. This technology is based on the physical principle that light of an appropriate wavelength passing through a solution of a colored compound (chromophore) will be absorbed by the compound. As a result of this absorption, the intensity of the light emerging from the solution will be lower than the intensity of the light projected into the solution. This principle through application of the Beer-Lambert equation "$\log [I_O/I] = c\ \alpha\ d$" allows quantification of the concentration (c) of a chromophore if the emergent light intensity (I) is measured and the following are known:

- Extinction coefficient (α), a constant that describes the absorption characteristics of a particular chromophore at a given wavelength of light
- Thickness of the solution (d)
- Incident light intensity (I_O)

NIRS technology is particularly suited to use in neonates and infants because the thin skull and small head allow light to be transmitted through one side of the head and detected on the other side, a technique known as *transmission spectrometry*.

Cerebral oxygen saturation (Sco_2) as measured by all NIRS technology is the combined oxygen saturation of an uncertain mix of arterioles, capillaries, and venules. Traditional pulse oximetry differs in this respect from NIRS because it is capable of isolating and measuring the arteriole component by gating measurements to pulsatility. It has been previously assumed that Sco_2 represented contributions of cerebral arterial and venous blood in a ratio of 25:75, with the contribution of capillary blood felt to be negligible. More recent data suggest that in children, the average ratio is 15:85. The issue is further complicated by the fact that there is significant variability in the ratio (from 0:100 to 40:60) between patients.

DiNardo JA. Anesthesia for congenital heart surgery. In: Jonas RA, ed. *Comprehensive Surgical Management of Congenital Heart Disease.* London: Arnold; 2004:45–65.

C.4. What are the important management issues during creation of a palliative shunt?

- When a thoracotomy approach is used, unilateral lung retraction will be required for surgical exposure. The resulting atelectasis may severely compromise oxygenation

and CO_2 removal. Intermittent reinflation of the lung may be necessary during the operative procedure. These reinflations should be coordinated with the surgeon. For all the shunts described, the main or branch PA will have to be partially occluded by a clamp to allow creation of the distal anastomosis. The resulting increase in physiologic dead space may compromise oxygenation and CO_2 removal and will increase the arterial $ETCO_2$ gradient.

- Efforts to increase pulmonary blood flow by reducing PVR with ventilatory interventions and by increasing L-R shunting should be initiated before PA occlusion.
- Partial occlusion of the aorta with a clamp will be necessary during creation of Waterston, Potts, and central shunts. The resulting increase in LV afterload may compromise systolic function.
- All of the palliative shunts impose a volume load on the LV. Inotropic support may be necessary to ensure systemic and shunt perfusion after shunt creation.
- Palliative shunts are mildly restrictive simple shunts. It is important to maintain SVR and reduce PVR to maintain pulmonary blood flow in patients with surgical shunts.
- Be prepared to treat an episode of hypercyanosis.

DiNardo JA. Anesthesia for congenital heart disease. In: DiNardo JA, Zvara DA, eds. *Anesthesia for Cardiac Surgery*. 3rd ed. Oxford: Blackwell Publishing; 2008:167–251.

C.5. What is the effect of inhalation anesthetics on airway reflexes, myocardial contractility, systemic vascular resistance (SVR), and pulmonary vascular resistance (PVR) in children?

Sevoflurane, isoflurane, and desflurane all induce dose-related myocardial depression and SVR reduction with mild depression of contractility noted at 1 and 1.5 minimal alveolar concentration (MAC). Halothane induces a greater degree of myocardial depression at 1 and 1.5 MAC than sevoflurane, isoflurane, or desflurane. At these concentrations, neither sevoflurane, isoflurane, nor halothane alters the ratio of PVR to SVR substantially enough to induce any change in $Q_P : Q_S$.

Isoflurane and, particularly, desflurane are not good choices for inhalational induction because their pungency is responsible for a high incidence of airway complications in children. Desflurane has hemodynamic effects similar to isoflurane and may be useful as an adjuvant to narcotic anesthesia or as a primary maintenance agent after the airway has been secured. Sevoflurane has cardiovascular effects similar to isoflurane and is a good agent for inhalational induction in children; the incidence of airway complications is similar to that of halothane. Perhaps more important is the fact that inhalational induction with sevoflurane causes less myocardial depression than halothane in children.

Laird TH, Stayer SA, Rivenes SM, et al. Pulmonary-to-systemic blood flow ratio effects of sevoflurane, isoflurane, halothane, and fentanyl/midazolam with 100% oxygen in children with congenital heart disease. *Anesth Analg*. 2002;95:1200–1206.

C.6. What are the pre–cardiopulmonary bypass (CPB) anesthetic goals for a patient undergoing definitive surgical correction of TOF/PS?

- Maintain heart rate, contractility, and preload to maintain cardiac output. Euvolemia is important to prevent exacerbation of dynamic RVOT obstruction from hypovolemia and reflex increases in heart rate and contractility.

- Avoid increases in the PVR : SVR ratio. The less severe the RV outflow obstructive lesions, the more important this becomes. Increases in PVR relative to SVR, and decreases in SVR relative to PVR, will increase R-L shunting, reduce pulmonary blood flow, and produce or worsen cyanosis.
- Use ventilatory measures to reduce PVR.
- Maintain or increase SVR. This is particularly important when RV outflow obstruction is severe and changes in PVR will have little or no effect on shunt magnitude and direction.
- Aggressively treat episodes of hypercyanosis.
- Maintain contractility. Depression of contractility, particularly in the face of severe RV outflow obstruction, may produce RV afterload mismatch and drastically reduce pulmonary blood flow. The exception to this is a patient in whom the dynamic component of infundibular obstruction is active. Reducing contractility in these patients may reduce RV outflow obstruction through relaxation of the infundibulum.

DiNardo JA. Anesthesia for congenital heart disease. In: DiNardo JA, Zvara DA, eds. *Anesthesia for Cardiac Surgery*. 3rd ed. Oxford: Blackwell Publishing; 2008: 167–251.

C.7. What interventions will reliably reduce PVR?

Po_2. Both alveolar hypoxia and arterial hypoxemia induce pulmonary vasoconstriction. An arterial O_2 tension lower than 50 mm Hg increases PVR over a wide range of arterial pH; however, this effect is enhanced when pH is lower than 7.40. Conversely, high levels of inspired O_2 can reduce an elevated PVR.

Pco_2. Hypercarbia increases PVR, independent of changes in arterial pH. Hypocarbia, on the other hand, reduces PVR only through production of an alkalosis. In fact, reliable reductions in PVR and increases in pulmonary blood flow and Po_2 are seen in children with R-L shunts when hyperventilation to a Pco_2 near 30 mm Hg and a pH near 7.50 is instituted. Similarly, postbypass hyperventilation to a Pco_2 of 30 to 35 mm Hg and a pH of 7.50 to 7.56 in patients with preoperative pulmonary hypertension results in a reduction in PVR when compared with ventilation that produces normocarbia or hypercarbia.

pH. Both respiratory and metabolic alkalosis reduce PVR, whereas both respiratory and metabolic acidosis increase PVR.

Variation in lung volumes. At small lung volumes, atelectasis results in compression of extra-alveolar vessels, whereas at high lung volumes, hyperinflation of alveoli results in compression of intra-alveolar vessels. Therefore, PVR is normally lowest at lung volumes at or near the functional residual capacity. Positive end-expiratory pressure (PEEP) may cause an increase in PVR by increasing alveolar pressure through hyperinflation. However, in situations in which PEEP works to recruit atelectatic alveoli and increase arterial Po_2, a decrease in PVR generally is seen.

Vasodilator agents. There is no IV drug that selectively acts as a pulmonary vasodilator. In general, IV drugs intended to induce pulmonary vasodilation (PGE_1, PGI_2, nitroglycerin, sodium nitroprusside, and tolazoline) induce systemic vasodilation as well. Inhaled nitric oxide, PGE_1, and PGI_2 are the only specific pulmonary vasodilators available.

DiNardo JA. Anesthesia for congenital heart disease. In: DiNardo JA, Zvara DA, eds. *Anesthesia for Cardiac Surgery*. 3rd ed. Oxford: Blackwell Publishing; 2008: 167–251.

C.8. How does heparin administration and activated coagulation time (ACT) monitoring differ in children as compared with adults?

Before use of cardiotomy suction, cannulation, and commencing bypass, it is essential that adequate anticoagulation be obtained. Unfractionated heparin is currently the anticoagulant used for CPB. It generally is acknowledged that an ACT in excess of 400 seconds is necessary to ensure adequate anticoagulation for the safe conduct of CPB.

While there is a large heparin anticoagulation monitoring literature in adults, there is a very small literature in children. The ACT, commonly used to assess CPB anticoagulation, is also prolonged by hypothermia, hemodilution, platelet dysfunction, and low coagulation factor levels. As a result, in children, the ACT will overestimate the antifactor IIa and Xa effects of heparin.

Most institutions use an age- or weight-based protocol to administer the initial pre-CPB dose of heparin such as patients less than 30 kg—200 IU per kg; or patients greater than 30 kg—300 IU per kg. The large circuit prime volume to blood volume ratio would be expected to decrease plasma heparin levels with initiation of CPB unless an appropriate quantity of heparin is added to the CPB prime. Most institutions add heparin to the CPB prime as follows: patients less than 30 kg—2.5 IU per mL of CPB prime; or patients greater than 30 kg—3.0 IU per mL of CPB prime.

Heparin should always be given into a central line through which venous return can be demonstrated easily or as is more common in infants/neonates directly into the heart (usually the right atrium) by the surgeon. This is necessary to ensure that the heparin dose has reached the central circulation. An ACT can be drawn within minutes of heparin administration as peak arterial ACT prolongation occurs within 30 seconds and peak venous ACT prolongation within 60 seconds.

DiNardo JA. Physiology and techniques of extracorporeal circulation in the pediatric patient. In: Lake CL, Booker, PD, eds. *Pediatric Cardiac Anesthesia*. 4th ed. Philadelphia: Lippincott Williams & Wilkins; 2005:228–252.

C.9. How is heparin reversed?

Protamine is a polyvalent cation derived from salmon sperm that is currently used to neutralize systemic heparinization. Protamine normally is given once stable hemodynamics are maintained after termination of CPB. It should not be administered until the likelihood that having to reinstitute CPB is small. After protamine neutralization of heparin begins, the cardiotomy suction should not be used and removal of the arterial and venous cannulas should proceed. This prevents contamination of the heparinized CPB circuit with protamine should prompt reinstitution of CPB be necessary and prevents thrombus formation on the cannulas.

There are several approaches to the neutralization of heparin with protamine, all with reportedly good clinical results. Some centers use 1.0 to 1.3 mg of protamine for each 100 units of heparin determined to exist at the termination of CPB. This ratio is based on the in vitro protamine-heparin neutralization ratio of 1.3:1.0. The amount of heparin present is determined by obtaining an ACT when CPB terminates and using reverse extrapolation of the patient's heparin dose response curve to correlate ACT and heparin dose. This method has been criticized because the ACT obtained at the termination of CPB is prolonged by factors other than heparin, such as CPB-induced platelet dysfunction and hemodilution. This may result in an overestimation of the heparin present at the termination of CPB and a larger than necessary protamine dose.

Some centers simply administer a fixed dose of protamine based on the patient's weight (3 to 4 mg/kg) regardless of the heparin dose administered, whereas others

administer 1.0 to 1.3 mg of protamine for each 100 units of heparin administered. Obviously, these methods do not rely on any post-CPB assessment of residual heparin effect (ACT) to determine the protamine dose. Nonetheless, these methods have been shown to result in adequate heparin reversal. In the case of the fixed dose regimen, heparin reversal is obtained at much lower protamine doses than predicted by the reverse extrapolation method.

The Hepcon automated heparin protamine titration method measures clotting times enhanced by addition of thromboplastin in several channels that contain varying quantities of protamine. The first channel to clot is the channel in which the protamine to heparin ratio is closest to neutralization. The absolute clotting time is not important; only the determination of the channel with the appropriate ratio. Therefore, the determination should be independent of nonheparin factors that prolong the ACT. In theory, this method should allow determination of the appropriate dose of protamine independent of the nonheparin parameters that prolong ACT.

DiNardo JA. Physiology and techniques of extracorporeal circulation in the pediatric patient. In: Lake CL, Booker PD, eds. *Pediatric Cardiac Anesthesia*. 4th ed. Philadelphia: Lippincott Williams & Wilkins; 2005:228–252.

C.10. What is the incidence of protamine reactions in children?

The incidence of protamine reactions in children following cardiac surgery is generally believed to be substantially lower than that in adults. A recent retrospective analysis of 1,249 children revealed the incidence of hypotension (at least 25% decrease in mean arterial pressure) following protamine administration to be 1.76% to 2.88%, depending on the stringency of criteria linking the episode to protamine administration. In this series, no episodes of pulmonary hypertension or RV dysfunction were noted. There is a report of pulmonary hypertension and cardiovascular collapse in 6-week-old infant following protamine administration. Clinical experience indicates that pulmonary hypertensive episodes in children following protamine administration are very rare.

DiNardo JA. Physiology and techniques of extracorporeal circulation in the pediatric patient. In: Lake CL, Booker PD, eds. *Pediatric Cardiac Anesthesia*. 4th ed. Philadelphia: Lippincott Williams & Wilkins; 2005:228–252.

C.11. What is the role of transesophageal echocardiography (TEE) in this patient?

It has been demonstrated that intraoperative TEE has a major impact on post-CPB decision making (such as return to CPB to repair residual lesions) in approximately 15% of cases when it is used nonselectively. In the subset of patients undergoing valve repair and outflow tract reconstruction, TEE provides the best immediate assessment of the adequacy of the operative procedure and, if necessary, directs its revision. While detection of retained intracardiac air is certainly facilitated by the use of intraoperative TEE, it remains to be determined what role the technology will play in improving cardiac de-airing algorithms particularly in neonates/infants.

The role of TEE in the detection of residual VSDs following repair of both simple and complex defects deserves some discussion. Residual defects less than 3 mm are detectable by TEE but generally do not require immediate reoperation because they are hemodynamically insignificant. The majority (75%) of these small defects are not present at the time of hospital discharge as determined by transthoracic echocardiography. Residual defects greater than 3 mm detected by TEE require immediate

reoperation only if they are associated with intraoperative hemodynamic (elevated left atrial pressure and/or pulmonary artery pressure in the presence of good ventricular function) and oximetric ($Q_P : Q_S$ >1.5 : 1 or right atrium to PA oxygen saturation step-up with fraction of inspired oxygen [F_{IO_2}] ≤0.50) evidence that they are significant.

DiNardo JA. Anesthesia for congenital heart surgery. In: Jonas RA, ed. *Comprehensive Surgical Management of Congenital Heart disease*. London: Arnold; 2004:45–65.

Yang SG, Novello R, Nicolson S, et al. Evaluation of ventricular septal defect repair using intraoperative transesophageal echocardiography: frequency and significance of residual defects in infants and children. *Echocardiography*. 2000;17:681–684.

C.12. What effect would a residual ventricular septal defect (VSD) have in this patient following separation from CPB?

A residual VSD is likely to be very poorly tolerated in the patient with TOF/PS. The most likely manifestation is low cardiac output syndrome associated with elevated central venous pressure, left atrial pressure, and pulmonary artery pressure. RVOT obstruction will be completely or near completely eliminated postrepair. PVR is likely to be low and the pulmonary vasculature is likely to be very compliant. As a result there will be potential for a large L-R intracardiac shunt with a residual VSD. This will place a large volume load on the LV and RV. An acute volume load will not be well tolerated by the RV, which is likely to be concentrically hypertrophied and poorly compliant in response to the chronic pressure overload that existed preoperatively. The presence of pulmonary insufficiency will further exacerbate RV dysfunction by imposing an additional volume load.

DiNardo JA. Anesthesia for congenital heart disease. In: DiNardo JA, Zvara DA, eds. *Anesthesia for Cardiac Surgery*. 3rd ed. Oxford: Blackwell Publishing; 2008:167–251.

D. Postoperative Management

D.1. How should postoperative ventilation be managed in this patient following placement of a transannular patch for TOF/PS?

The inspiratory phase of mechanical positive pressure ventilation increases impedance to RV ejection by increasing RV afterload by elevating alveolar pressure and creating more West Zone I and II lung segments. As a result, the extent of this afterload elevation is directly related to the duration of inspiration (respiratory rate and I : E ratio) and to mean airway pressure. Increasing RV afterload will impede antegrade pulmonary blood flow and exacerbate the extent of pulmonary insufficiency induced by the transannular patch. RV afterload will also be increased by elevations in PVR.

As discussed in section C.7, ventilation and gas mixture should be adjusted to minimize PVR. This should be accomplished with a tidal volume of 10 to 15 mL per kg, 3 to 5 mm Hg of PEEP, and a respiratory rate and I : E ratio adjusted to minimize mean airway pressure.

DiNardo JA. Anesthesia for congenital heart disease. In: DiNardo JA, Zvara DA, eds. *Anesthesia for Cardiac Surgery*. 3rd ed. Oxford: Blackwell Publishing; 2008:167–251.

D.2. Following complete repair of TOF/PS in an infant, what arterial oxygen saturation (Sao_2) is acceptable?

Following complete repair of TOF/PS with no residual lesions and minimal intrapulmonary shunt, the Sao_2 should be 100%. In infants and small children, particularly those left with pulmonary insufficiency as the result of a transannular patch and those expected to have restrictive RV function as a result of a ventriculotomy and/or extensive RV hypertrophy, the surgeon may choose to leave a small (3 to 4 mm) atrial level communication or patent foramen ovale. This will allow intracardiac R-L shunting, with the ability to augment systemic cardiac output at the expense of systemic oxygen saturation in the setting of RV dysfunction by allowing direct delivery of desaturated venous blood to the left atrium. In these patients, a Pao_2 of 40 to 50 mm Hg and a Sao_2 of 70% to 80% are acceptable until RV function improves over the course of days.

DiNardo JA. Anesthesia for congenital heart disease. In: DiNardo JA, Zvara DA, eds. *Anesthesia for Cardiac Surgery*. 3rd ed. Oxford: Blackwell Publishing; 2008:167–251.

D.3. Following placement of a modified Blalock-Taussig shunt (MBTS) for TOF/PS in an infant, what Sao_2 is acceptable?

As illustrated in Figure 38.5B in the presence of some antegrade pulmonary blood flow, an appropriate Sao_2 would be 80% to 90%. In the absence of any antegrade pulmonary blood flow, single ventricle physiology would exist and a Sao_2 of 70% to 80% would be more appropriate. Sao_2 is determined by the relative volumes and saturations of recirculated systemic venous blood and effective systemic blood flows that have mixed and reached the aorta. This is summarized in the following equation:

$$\text{Aortic } Sao_2 = \frac{\begin{array}{c}\text{([pulmonary venous saturation] [effective systemic blood flow]}\\ \text{+ [systemic venous saturation] [recirculated systemic venous blood flow])}\end{array}}{\text{(total systemic blood flow)}}.$$

This is demonstrated in Figure 38.5B where the $Sao_2 = [(98)(1) + (65)(0.5)]/1 = 87$
Three variables will ultimately affect Sao_2:

1. *The ratio of total pulmonary to total systemic blood flow ($Q_P : Q_S$).* A greater proportion of the arterial blood will consist of saturated blood (pulmonary venous blood) than of desaturated blood (systemic venous blood) when $Q_P : Q_S \geq 1{:}1$. $Q_P : Q_S$ will be increased when systemic arterial blood pressure is high and PVR is low.
2. *Systemic venous saturation.* For a given $Q_P : Q_S$ and pulmonary venous saturation, a decrease in systemic venous saturation will result in a decreased arterial saturation. Decreases in systemic venous saturation occur as the result of decreases in systemic oxygen delivery or increases in systemic oxygen consumption. Recall that systemic oxygen delivery is the product of systemic blood flow and arterial oxygen content. Arterial oxygen content, in turn, is dependent on the hemoglobin concentration and the arterial saturation. Efforts should be made to increase hematocrit into the range of 35% to 45%, cardiac output should be enhanced with inotropes (dopamine, 5 to 10 μg/kg/minute), and systemic O_2 consumption reduced by appropriate levels of sedation/anesthesia and muscle relaxation if necessary.
3. *Pulmonary venous saturation*. In the absence of large intrapulmonary shunts and/or $\dot{V}/\dot{Q}$ mismatch, pulmonary venous saturation should be close to 100% breathing room air. In the presence of pulmonary parenchymal disease, pulmonary venous saturation may be reduced. The $\dot{V}/\dot{Q}$ mismatch component of pulmonary venous

desaturation will be largely eliminated with a FIO_2 of 1.0, while the intrapulmonary shunt contribution will not be eliminated. For any given systemic venous saturation and $Q_P : Q_S$, a reduction in pulmonary venous saturation will result in a decreased arterial saturation.

DiNardo JA. Anesthesia for congenital heart disease. In: DiNardo JA, Zvara DA, eds. *Anesthesia for Cardiac Surgery*. 3rd ed. Oxford: Blackwell Publishing; 2008:167–251.

D.4. What is junctional ectopic tachycardia (JET)?

Postoperative JET is a transient tachyarrhythmia that occurs immediately following congenital heart surgery. A much rarer form of congenital JET exists as well. JET is due to enhanced automaticity in the area of the atrioventricular (AV) node or proximal His bundle. Associated with JET is a higher than average incidence of AV block. The incidence of JET following TOF/PS repair may be as high as 20% and is felt to be secondary to surgical trauma in the area of the AV node secondary to the retraction necessary to expose the VSD and RVOT from across the tricuspid valve.

JET typically manifests with a junctional rate only slightly faster than the sinus node rate and is the only narrow complex tachycardia in which the atrial rate is less than the ventricular rate (A : V ratio <1:1). Much less commonly (10%), there may be retrograde activation of the atrium with inverted P waves noted and A : V ratio = 1:1. In either case, there is loss of AV synchrony (loss of atrial kick). In many instances, this arrhythmia is well tolerated. However, JET with heart rate greater than 170 bpm is associated with hemodynamic instability and increased postoperative mortality.

Cardioversion is ineffective as is adenosine. The most effective therapy for treatment of JET is atrial pacing at a rate slightly faster than the junctional rate such that A-V synchrony is reinitiated. This therapy is effective unless the junctional rate is very fast (>160 to 170 bpm), at which point atrial pacing at a faster rate is unlikely to improve hemodynamics because the reinitiation of A-V synchrony is offset by the dramatic reduction in diastolic filling time present at these rates. In this circumstance, the most effective therapy is multimodal. JET requiring aggressive treatment prolongs postoperative ventilation times and intensive care unit stay. The goal of aggressive therapy is to terminate JET or reduce the rate to point where atrial pacing can be reinitiated. In order, the following modalities are applied:

- Fever is aggressively treated with antipyretics.
- Sedation and hemodynamics are optimized.
- Reduction of inotrope doses is useful because most agents have chronotrophic activity. This may be difficult in the setting of hemodynamic instability and low cardiac out put syndrome.
- Mild systemic hypothermia is introduced. A cooling blanket and icepacks are used to reduce patient temperature to 32° C (89.6° F) to 35° C (95° F). This usually requires sedation and paralysis to prevent shivering.
- Procainamide or amiodarone therapy is initiated.

Walsh EP. Automatic atrial and junctional tachycardias. In: Walsh EP, Saul JP, Triedman JK, eds. *Cardiac Arrhythmias in Children and Young Adults with Congenital Heart Disease*. Philadelphia: Lippincott Williams & Wilkins; 2001:115–135.

CHAPTER 39

Transposition of the Great Arteries

JAMES A. DINARDO

A 3-DAY-OLD, FULL-TERM, 3.4-KG NEWBORN is scheduled for an arterial switch operation (ASO). Shortly after birth, he demonstrated reverse differential cyanosis with a right arm arterial saturation of 40% and a lower extremity saturation of 60% despite prostaglandin E_1. A bedside balloon atrial septostomy was performed with resolution of reverse differential cyanosis and improvement of arterial saturation to 75%. Prostaglandin E_1 was discontinued 4 hours after the septostomy. He is extubated receiving 0.5 L per minute supplemental O_2 through nasal cannula. His arterial oxygen saturation is 75%; blood pressure, 63/37 mm Hg; pulse, 145 beats per minute; respiration, 46 breaths per minute.

A. Medical Disease and Differential Diagnosis

1. What is transposition of the great arteries (D-TGA)?
2. What additional cardiac lesions are associated with D-TGA?
3. What is the natural history of D-TGA?
4. What is the pathophysiology of D-TGA?
5. What determines the oxygen saturation in patients with D-TGA?
6. Why did this infant have reverse differential cyanosis?
7. What are the preoperative issues pertaining to the coronary arteries in D-TGA?
8. What are the clinical subsets of D-TGA?
9. What is the differential diagnosis of D-TGA and how is the diagnosis made?
10. What preoperative interventions can help stabilize a patient with D-TGA?
11. What are the surgical options for repair? Why is one chosen over the others?

B. Preoperative Evaluation and Preparation

1. What information is important to prepare for this case?
2. What are the anesthetic goals before cardiopulmonary bypass (CPB)?
3. What is the plan for glucose management in this patient?

C. Intraoperative Management

1. How would you monitor this infant?
2. What would be the best method of induction?
3. Is CPB in infants and children different from adults?
4. What is modified ultrafiltration (MUF)?
5. Briefly describe the surgical techniques of the Mustard/Senning, ASO, and Rastelli procedures.
6. What is hypothermia and how is it classified? What is low-flow cardiopulmonary bypass (LFCPB)? What is deep hypothermic circulatory arrest (DHCA)?
7. Why is hypothermia beneficial to the brain during LFCPB and DHCA?
8. Explain the difference between α-stat and pH-stat blood gas management.
9. What are the immediate post-CPB issues following ASO?

D. Postoperative Management

1. How is myocardial ischemia addressed in the intensive care unit (ICU) following the ASO?
2. What immediate postoperative problems would be anticipated following the Rastelli procedure?
3. What intermediate and long-term surgical problems are seen after ASO?
4. What are the long-term outcomes after ASO?
5. What are the long-term outcomes after Rastelli repair for D-TGA with left ventricular outflow tract (LVOT) obstruction?
6. What is long-term neurologic outcome like after ASO?

A. Medical Disease and Differential Diagnosis

A.1. What is transposition of the great arteries (D-TGA)?

D-TGA refers specifically to the anatomic circumstance wherein there is concordance of the atrioventricular (AV) connections associated with discordance of the ventriculoarterial connections. By far the most common manifestation of this anatomy occurs in patients with [S,D,D] segmental anatomy, also known as *D-TGA*. There is atrial situs solitus, D-loop ventricles, and D-loop great arteries. A right-sided right atrium (RA) connects through a right-sided tricuspid valve and right ventricle (RV) to a right-sided and anterior aorta. A left-sided left atrium (LA) connects through a left-sided mitral valve and left ventricle (LV) to a left-sided and posterior pulmonary artery (PA). As a result, there is fibrous continuity between the mitral and pulmonic valves with a lack of fibrous continuity (conus) between the tricuspid and aortic valves. In D-TGA, the combination of AV concordance (RA to RV; LA to LV) and ventriculoarterial discordance (RV to aorta; LV to PA) produces a parallel rather than a normal series circulation.

DiNardo JA. Transposition of the great vessels. In: Lake CL, Booker PD, eds. *Pediatric Cardiac Anesthesia*. 4th ed. Philadelphia: Lippincott Williams & Wilkins; 2005:357–380.

A.2. What additional cardiac lesions are associated with D-TGA?

The most commonly associated cardiac anomalies are a persistent patent foramen ovale (PFO), patent ductus arteriosus (PDA), ventricular septal defect (VSD), and subpulmonic stenosis or LVOT obstruction. Approximately 50% of patients with

D-TGA will present with a PDA before prostaglandin E_1 administration. The foramen ovale is almost always patent, but a true secundum atrial septal defect (ASD) exists in only approximately 5% of patients. Although angiographically detectable VSDs may occur in 30% to 40% of patients, only approximately one-third of these defects are hemodynamically significant. Therefore, for practical purposes, 75% of patients have an intact ventricular septum (IVS). LVOT obstruction is present in approximately 30% of patients with VSD and is most often due to an extensive subpulmonary fibromuscular ring or posterior malposition of the outlet portion of the ventricular septum.

Paul M. Complete transposition of the great arteries. In: Adams FH, Riemenschneider TA, eds. *Fetal and Neonatal Cardiology*. Philadelphia: WB Saunders; 1989:471–423.

A.3. What is the natural history of D-TGA?

D-TGA is a common congenital heart lesion accounting for 5% to 7% of all congenital cardiac defects, second in frequency only to isolated VSDs. Without intervention, D-TGA has a high mortality rate: 45% will die within the first month and 90% will die within the first year of life. This is particularly unfortunate, because infants with D-TGA rarely have extracardiac defects. Advancements in medical and surgical therapy in the last 20 years have greatly improved the outlook for these infants. In fact, following stabilization with prostaglandin E_1 and the Rashkind-Miller balloon septostomy, many of these infants can be offered a definite surgical procedure (arterial switch), giving them a quality of life similar to that of normal children.

Hypoxia and intractable congestive heart failure (CHF) are the two primary causes of death. The early onset and progression of pulmonary vascular occlusive disease (PVOD) plays a major role in the dismal outlook in these patients. Compared with other forms of congenital heart disease, infants with transposition of great vessels (TGV) are at particular risk for accelerated development of PVOD. Systemic hypoxemia, the presence of bronchopulmonary collaterals (which deliver deoxygenated blood to the precapillary pulmonary arterioles), platelet aggregation in the lung, and polycythemia have all been implicated. Infants with TGV and large VSD without LVOT obstruction are at an even higher risk for the early development of PVOD due to exposure of the pulmonary vascular bed to high blood flow and systemic pressures. Advanced, nonreversible pulmonary hypertension reduces the corrective surgical options available to the patient.

DiNardo JA. Transposition of the great vessels. In: Lake CL, Booker, PD, eds. *Pediatric Cardiac Anesthesia*. 4th ed. Philadelphia: Lippincott Williams & Wilkins; 2005:357–380.

A.4. What is the pathophysiology of D-TGA?

In the parallel arrangement of D-TGA, deoxygenated systemic venous blood recirculates through the systemic circulation without reaching the lungs to be oxygenated. This recirculated systemic venous blood represents a physiologic right-to-left shunt. Likewise, oxygenated pulmonary venous blood recirculates uselessly through the pulmonary circulation. This recirculated pulmonary venous blood represents a physiologic left-to-right shunt. Therefore, in a parallel circulation, the physiologic shunt or the percentage of venous blood from one system that recirculates in the arterial outflow of the same system is 100% for both circuits. Unless there are one or more communications between the parallel circuits to allow intercirculatory mixing, this arrangement is not compatible with life.

The sites available for intercirculatory mixing in D-TGA can be intracardiac (PFO, ASD, VSD) or extracardiac (PDA, bronchopulmonary collaterals). Several factors affect the amount of intercirculatory mixing. The number, size, and position of anatomic communications are important. One large, nonrestrictive communication will provide better mixing than two or three restrictive communications. Reduced ventricular compliance and elevated systemic and pulmonary vascular resistance (PVR) tend to reduce intercirculatory mixing by impeding flow across the anatomic communications.

The position of the communication is also important. Poor mixing occurs even with large anterior muscular VSDs due to their unfavorable position. Finally, in the presence of adequate intercirculatory mixing sites, the extent of intercirculatory mixing is directly related to total pulmonary blood flow. Patients with reduced pulmonary blood flow secondary to subpulmonary stenosis or PVOD will have reduced intercirculatory mixing.

DiNardo JA. Anesthesia for congenital heart surgery. In: Jonas RA, ed. *Comprehensive Surgical Management of Congenital Heart Disease*. London: Arnold; 2004:45–65.

DiNardo JA. Transposition of the great vessels. In: Lake CL, Booker PD, eds. *Pediatric Cardiac Anesthesia*. 4th ed. Philadelphia: Lippincott Williams & Wilkins; 2005:357–380.

A.5. What determines the oxygen saturation in patients with D-TGA?

In D-TGA, intercirculatory mixing is the result of anatomic right-to-left and anatomic left-to-right shunts that are equal in magnitude. The anatomic right-to-left shunt produces effective pulmonary blood flow, which is the volume of systemic venous blood reaching the pulmonary circulation. The anatomic left-to-right shunt produces an effective systemic blood flow, which is the volume of pulmonary venous blood reaching the systemic circulation. Effective pulmonary blood flow, effective systemic blood flow, and the volume of intercirculatory mixing are always equal. The systemic blood flow is the sum of recirculated systemic venous blood plus effective systemic blood flow. Likewise, total pulmonary blood flow is the sum of recirculated pulmonary venous blood plus effective pulmonary blood flow. Recirculated blood makes up the largest portion of total pulmonary and systemic blood flow, with effective blood flows contributing only a small portion of the total flows. This is particularly true in the pulmonary circuit where the total pulmonary blood flow (Q_P) and the volume of the pulmonary circuit (LA, LV, PA) is three to four times larger than the total systemic blood flow (Q_S) and the volume of the systemic circuit (RA, RV, aorta). The net result is production of a transposition physiology, where the PA oxygen saturation is greater than the aortic oxygen saturation. Figure 39.1 further elucidates these concepts.

Arterial saturation (Sao_2) is determined by the relative volumes and saturations of the recirculated systemic and effective systemic blood flows reaching the aorta. This is summarized in the following equation:

$$\text{Aortic saturation} = \frac{\begin{array}{c}([\text{systematic venous saturation}]\,[\text{recirculated systemic blood flow}] \\ +\,[\text{pulmonary venous saturation}]\,[\text{effective systemic blood flow}])\end{array}}{(\text{total sytemic blood flow})}$$

This is illustrated in Figure 39.1 where:

$$Sao_2 = ([50][1.2] + [99][1.1])/\,2.3 = 73\%$$

Obviously, the greater the effective systemic blood flow (intercirculatory mixing) relative to the recirculated systemic blood flow, the greater the aortic saturation. For a given amount of intercirculatory mixing and total systemic blood flow, a decrease in systemic venous or pulmonary venous saturation will result in a decrease in arterial saturation.

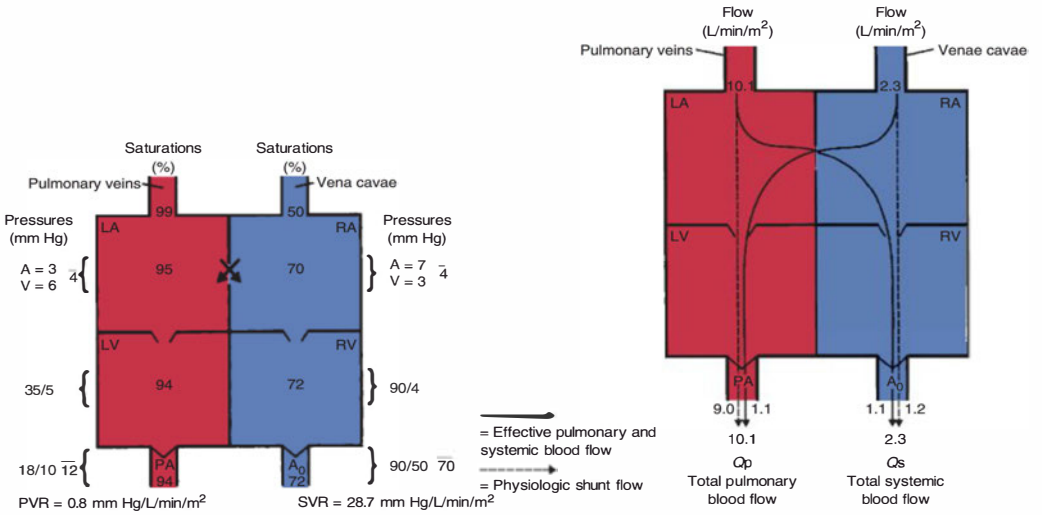

Figure 39.1 Depiction of saturations, pressures, and blood flows in complete transposition of the great vessels with intercirculatory mixing at the atrial level and a small left ventricular outflow tract gradient. It is apparent that total pulmonary blood flow (10.1 L/min/m²) is almost five times the total systemic blood flow (2.3 L/min/m²). Effective (EFF) pulmonary and effective systemic blood flow are equal (1.1 L/min/m²) and are the result of an anatomic shunt at the atrial level. The physiologic left-to-right shunt is 9 L/min/m²; this represents blood recirculated from the pulmonary veins to the pulmonary artery. The physiologic right-to-left shunt is 1.2 L/min/m²; this represents blood recirculated from the systemic veins to the aorta. In this depiction, pulmonary vascular resistance is low (approximately 1/35 of systemic vascular resistance) and there is a small (17 mm peak to peak) gradient from the left ventricle to the pulmonary artery. These findings are compatible with the high pulmonary blood flow depicted. LA, left atrium; LV, left ventricle; PA, pulmonary artery; PVR, pulmonary vascular resistance; *Qp*, total pulmonary blood flow; *Qs*, total systemic blood flow; RA, right atrium; RV, right ventricle; SVR, systemic vascular resistance. A.6. Why did this infant have reverse differential cyanosis?

In D-TGA with IVS, the anatomic mixing sites are usually a PDA and a PFO. The dynamics of intercirculatory mixing in D-TGA with IVS are complex. Anatomic shunting at the atrial level is ultimately determined by the size of the atrial communication and the cyclic pressure variations between the left and right atria. The volume and compliance of the atria, ventricles, and vascular beds in each circuit, as well as heart rate (HR) and phase of respiration all influence this relationship. Shunting is from the RA to the LA during diastole as the result of the reduced ventricular and vascular compliance of the

systemic circuit (RV and systemic arterial circuit). In systole, shunt is from the LA to the RA primarily because of the large volume of blood returning to the LA as a result of the high volume of recirculated pulmonary blood flow.

The direction of shunting across the PDA largely depends on the PVR and the size of the intra-atrial communication. When the PVR is low and the intra-atrial communication is nonrestrictive, shunting is predominantly from the aorta to the PA through the PDA (effective pulmonary blood flow) and predominantly from the LA to RA across the atrial septum (effective systemic blood flow). When PVR is elevated, shunting across the PDA is likely to be bidirectional that in turn encourages bidirectional shunting across the atrial septum. When PVR is high and PA pressure exceeds aortic pressure shunting at the PDA will be predominantly from the PA to the aorta. This will create reverse differential cyanosis—physiology wherein the preductal arterial saturation (right arm) is lower than the postductal arterial saturation (legs). This physiology is usually the result of a restrictive atrial communication producing left atrial hypertension and is associated with low effective blood flows (poor mixing) and hypoxemia. A balloon atrial septostomy can be lifesaving in this setting. Decompression of the LA promotes mixing at the atrial level and also reduces PVR and PA pressure promoting mixing at the PDA. Other causes of reverse differential cyanosis to be considered in D-TGA are the presence of an interrupted aortic arch or severe aortic coarctation.

A.7. What are the preoperative issues pertaining to the coronary arteries in D-TGA?

As in normally related great vessels, the coronary arteries in D-TGA arise from the aortic sinuses that face the PA. In normally related vessels, these sinuses are located on the anterior portion of the aorta, whereas in D-TGA, they are located posteriorly. In most D-TGA patients (70%), the right sinus is the origin of the right coronary artery, whereas the left sinus is the origin of the left main coronary artery. In the remainder of cases, there is considerable variability, with the most common variations being shown in Figure 39.2.

Most patients with D-TGA have a coronary anatomy that is suitable for the coronary reimplantation necessary in the ASO. Patients with certain types of coronary anatomy (intramural coronaries, single coronary artery) are at risk for postoperative myocardial ischemia and early mortality because reimplantation can result in the distortion of the coronary ostia or the narrowing of the artery itself. Patients with intramural coronaries generally require resuspension of the posterior leaflet of neopulmonary valve once the coronaries and a surrounding tissue cuff are excised.

The presence of a single coronary artery or intramural coronary arteries is a risk factor for mortality and this risk has persisted over the last two decades.

DiNardo JA. Transposition of the great vessels. In: Lake CL, Booker PD, eds. *Pediatric Cardiac Anesthesia*. 4th ed. Philadelphia: Lippincott Williams & Wilkins; 2005:357–380.

A.8. What are the clinical subsets of D-TGA?

Four clinical subsets based on anatomy, pulmonary blood flow, and intercirculatory mixing can be used to characterize patients with D-TGA. These are summarized in Table 39.1.

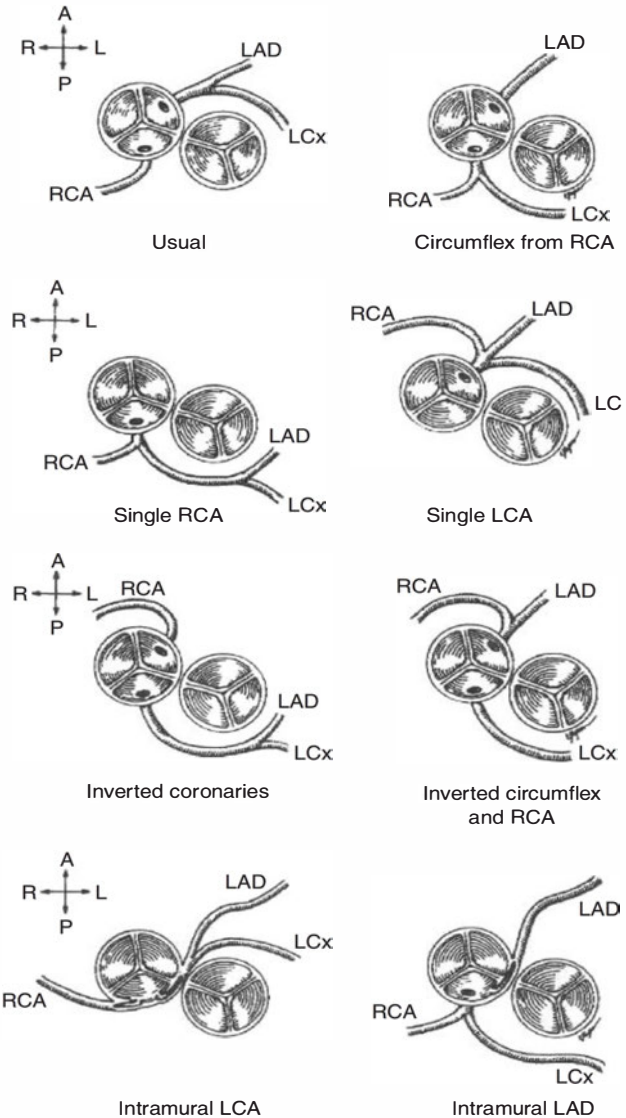

Figure 39.2 Depiction of the most common coronary artery patterns in transposition of the great vessels. The aorta is depicted anterior and to the right of the pulmonary artery. LAD, left anterior descending coronary artery; LCA, left coronary artery; LCx, left circumflex coronary artery; RCA, right coronary artery. (Adapted from Mayer JE, Sanders SP, Jonas RA, et al. Coronary artery pattern and outcome of arterial switch operation for transposition of the great arteries. *Circulation.* 1990:82(suppl III):144, with permission.)

Table 39.1 Clinical Subsets of Transposition of Great Arteries

ANATOMY	PULMONARY BLOOD FLOW	INTERCIRCULATORY MIXING
D-TGA with IVS	Increased	Small
D-TGA with IVS; nonrestrictive atrial septum or PDA	Increased	Large
D-TGA with VSD	Increased	Large
D-TGA with VSD and LVOT obstruction	Reduced	Small
D-TGA with PVOD	Reduced	Small

D-TGA, transposition of great arteries; IVS, intact ventricular septum; PDA, patent ductus arteriosus; VSD, ventricular septal defect; LVOT, left ventricular outflow tract; PVOD, pulmonary vascular occlusive disease.
DiNardo JA. Transposition of the great vessels. In: Lake CL, Booker, PD, eds. *Pediatric Cardiac Anesthesia*. 4th ed. Philadelphia: Lippincott Williams & Wilkins; 2005:357–380.

A.9. What is the differential diagnosis of D-TGA and how is the diagnosis made?

Figure 39.3 delineates the differential diagnosis for D-TGA in the cyanotic newborn.

D-TGA may be associated with either cyanosis or CHF. In patients in whom intercirculatory mixing is limited, cyanosis is severe with little evidence of CHF. CHF is the more common finding in patients with increased pulmonary blood flow, a large quantity of intercirculatory mixing, and mild cyanosis.

Chest radiographs may appear normal in the first few weeks of life in infants with D-TGA and IVS. Eventually, the triad of an enlarged egg-shaped heart (large RA and RV), narrow superior mediastinum, and increased pulmonary vascular markings evolve. In patients with D-TGA and VSD without LVOT obstruction, a large cardiac silhouette and prominent pulmonary vascular markings are seen at birth. Right axis deviation and right ventricular hypertrophy are the electrocardiographic (ECG) findings in D-TGA with IVS, whereas right axis deviation, left ventricular hypertrophy, and right ventricular hypertrophy are seen with D-TGA and VSD.

Two-dimensional echocardiography is the diagnostic modality of choice in the diagnosis and assessment of infants with D-TGA. It accurately establishes the diagnosis of D-TGA and reliably identifies associated abnormalities such as VSD, mitral and tricuspid valve abnormalities, and LVOT obstruction. It also reliably delineates coronary artery anatomy. Echocardiographic analysis of the ventricular septal position or LV geometry is also used to noninvasively assess the LV to RV pressure ratio and IV mass in neonates with D-TGA and IVS who are being evaluated as candidates for an ASO.

In institutions with high-level echocardiography, a comprehensive cardiac catheterization is no longer routinely performed in neonates with D-TGA. A limited catheterization may be performed in conjunction with a balloon atrial septostomy. In the rare instance where coronary anatomy cannot be clearly delineated by echocardiography, coronary angiography may be indicated. During catheterization of infants with PVOD, a trial of ventilation at an FIO_2 of 1.0 may be used to determine whether PVR is fixed or remains responsive to oxygen-induced pulmonary vasodilatation.

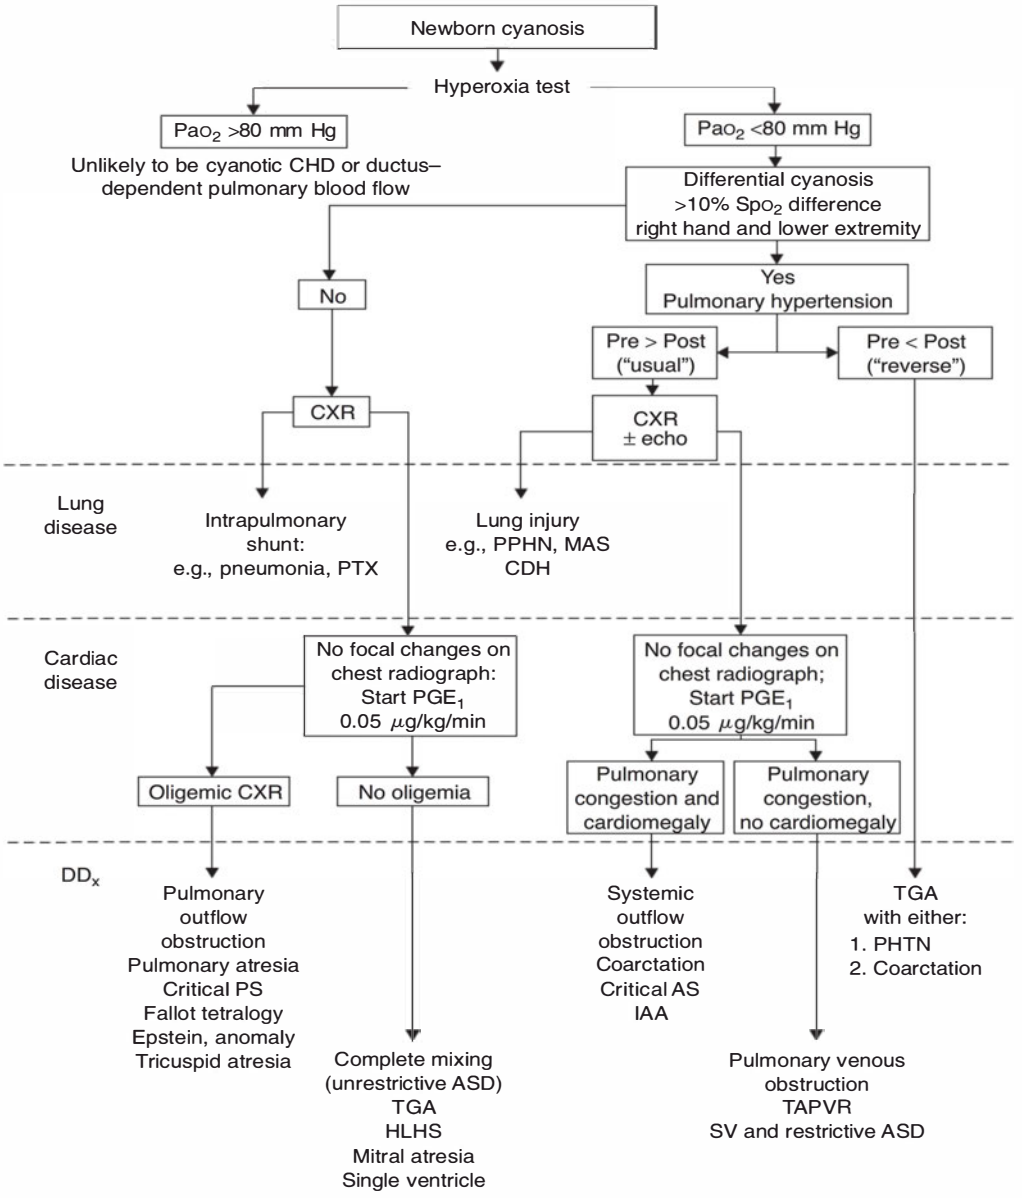

Figure 39.3 The differential diagnosis of transposition of the great arteries. AS, aortic stenosis; ASD, atrial septal defect; CHD, congenital heart disease; CXR, chest radiograph; HLHS, hypoplastic left heart syndrome; IAA, interrupted aortic arch; MAS, meconium aspiration syndrome; PHTN, pulmonary hypertension; PPHN, persistent pulmonary hypertension of the newborn; PS, pulmonary stenosis; PTX, pneumothorax; SV, single ventricle; TAPVR, total anomalous pulmonary venous return; TGA, transposition of great arteries; CDH, congenital diaphragmatic hernia.

A.10. What preoperative interventions can help stabilize a patient with D-TGA?

Intact ventricular septum

Most neonates with D-TGA and IVS will be hypoxemic (arterial saturation ≤60%) within the first day of life. A proportion of these patients will have severely reduced effective pulmonary and systemic blood flow resulting in a Pao_2 less than 20 mm Hg, hypercarbia, and an evolving metabolic acidosis secondary to the poor tissue oxygen delivery. Prostaglandin E_1 (0.01 to 0.05 μg/kg/minute) is administered to dilate and maintain the patency of the ductus arteriosus. This will be effective in increasing effective pulmonary and systemic blood flow, and in improving Pao_2 and tissue oxygen delivery *if* (1) PVR is less than systemic vascular resistance (SVR) and (2) there is a nonrestrictive or minimally restrictive atrial septal communication. In some centers, all neonates stabilized on prostaglandin E_1 alone have a balloon atrial septostomy to enlarge the atrial septal communication so that prostaglandin E_1 can be stopped and surgery scheduled on a semielective basis. Prostaglandin E_1 infusion is associated with apnea, pyrexia, fluid retention, and platelet dysfunction.

If prostaglandin E_1 does not improve tissue oxygen delivery, then an emergent balloon atrial septostomy is performed in the catheterization laboratory utilizing angiography or in the ICU utilizing echocardiography. These patients also require tracheal intubation and mechanical ventilation. This allows reduction of PVR through induction of a respiratory alkalosis and elimination of pulmonary ventilation/pefusion ($\dot{V}/\dot{Q}$) mismatch. Sedation and muscle relaxation reduce oxygen consumption, thereby increasing mixed venous O_2 saturation. Recall that for a given amount of intercirculatory mixing and total systemic blood flow, an increase in systemic venous or pulmonary venous saturation will result in an increase in arterial saturation.

In rare instances, the combination of prostaglandin E_1, an atrial septostomy, and mechanical ventilation with sedation/muscle relaxation may be ineffective. In this circumstance, extracorporeal membrane oxygenation (either venoarterial or venovenous) support to improve tissue oxygenation and to reverse end-organ insult and lactic acidosis before surgery is an alternative approach to emergent surgery in a critically ill neonate.

Ventricular septal defect

Infants in this subset are mildly cyanotic with symptoms of CHF. Pulmonary blood flow is increased, and there is extensive intercirculatory mixing. Reducing PVR to further augment pulmonary blood flow and intercirculatory mixing will not greatly influence the systemic oxygenation. Reducing PVR in these patients may increase the recirculated volume in the pulmonary circuit by increasing circuit compliance. Maintaining systemic blood flow will then necessitate an increase in cardiac output from a failing heart. These patients are commonly stable enough not to require immediate surgical or catheterization laboratory intervention. They are, however, candidates for an ASO before intractable CHF or advanced PVOD occurs.

Ventricular septal defect and left ventricular outflow tract obstruction

The degree of cyanosis in these infants will depend on the extent of LVOT obstruction. LVOT obstruction reduces pulmonary blood flow and intercirculatory mixing, and it protects the pulmonary vasculature from the increased pressures and volumes that accelerate the development of PVOD. The more severe the LVOT obstruction, the less effective will be the efforts to increase pulmonary blood flow by decreasing PVR. When LVOT obstruction is severe, the infant is severely cyanotic and progressively develops polycythemia. These infants may require a palliative aortopulmonary shunt to increase pulmonary blood flow. Ideally, a definitive repair in the form of a Rastelli procedure is performed in the neonatal period.

Pulmonary vascular occlusive disease

The goal of diagnosis and treatment of infants with D-TGA is to intervene surgically before the development of PVOD. As PVOD advances, the child becomes progressively cyanotic and polycythemic. Efforts to reduce PVR will increase pulmonary blood flow and intercirculatory mixing in infants where PVR is not fixed. Infants with advanced PVOD (PVR >10 Wood units; histologic grade 4) are generally candidates only for palliative therapy. In particular, closure of a VSD in the presence of advanced pulmonary hypertension carries a high mortality rate owing to the afterload mismatch and the resultant pulmonary ventricular (LV) dysfunction. These patients are candidates for a palliative intra-atrial physiologic repair (Mustard or Senning procedure) without closure or with fenestrated closure (4- to 5-mm hole in the center of the VSD patch) of the VSD.

A.11. What are the surgical options for repair? Why is one chosen over the others?

Arterial anatomic repair: arterial switch (Jatene) operation

The ASO anatomically corrects the discordant ventriculoarterial connections and is the procedure of choice for patients with D-TGA. Following repair, the RV is connected to the PA and the LV to the aorta. Clinical success with the ASO, summarized in Figure 39.4, was achieved in 1975. In order for the ASO to be successful, the original pulmonary ventricle (LV) must have sufficient mass to be capable of functioning as the systemic ventricle following the switch. Patient selection and the timing of the surgical procedure are, therefore, important variables in determining the success of this procedure. The ASO was originally described in patients with D-TGA and a large VSD or a large PDA. In these patients, the pulmonary ventricle (LV) remains exposed to systemic pressures, and the LV mass remains sufficient to support the systemic circulation. For this subset of patients, the ASO is generally performed within the first 2 to 3 months of life, before intractable CHF or irreversible PVOD intervene.

In patients with D-TGA and IVS, there is a progressive reduction in LV mass as the physiologic pulmonary hypertension present at birth resolves progressively over the first weeks following birth. Adequate LV mass to support the systemic circulation reliably exists in these patients for only the first 3 or 4 weeks following birth. In patients with D-TGA and IVS, the ASO can be performed primarily or as the second

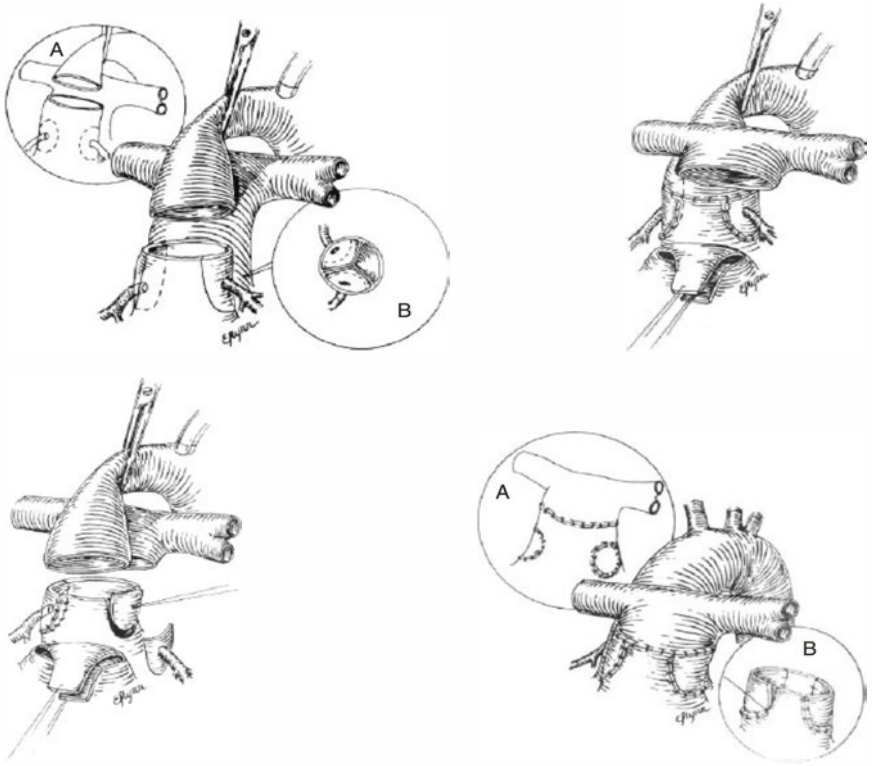

Figure 39.4 Details of the arterial switch procedure. **Upper left.** Aorta is transected and left and right main coronary arteries are excised using **(A)** either button of aortic wall or **(B)** segment of aortic wall extending from rim of aorta. **Lower left.** Equivalent segment of pulmonary arterial wall is excised, and coronary arteries are sutured to pulmonary artery. **Upper right.** Distal pulmonary artery is brought anterior to ascending aorta (LeCompte maneuver), and proximal pulmonary artery is anastomosed to distal aorta. **Lower right.** Sites of coronary explantation are repaired using either **(A)** patch of prosthetic material or **(B)** segment of pericardium. Finally, proximal aorta is sutured to distal pulmonary artery. (Adapted from Castanda AR, Norwood WI, Jonas RA, et al. Transposition of the great arteries and intact ventricular septum: anatomical repair in the neonate. *Ann Thorac Surg.* 1984;38:438–443)

phase of a staged procedure. A successful primary ASO must generally be performed within the first 4 weeks of life; most are performed in the first few days of life. Previously, favorable candidates for the procedure in the neonatal period were shown to have an LV to RV pressure ratio of at least 0.6 by catheterization. Currently, two-dimensional echocardiography is used to noninvasively assess the LV to RV pressure ratio. Three types of ventricular septal geometry have been described. Patients in whom the ventricular septum bulges to the left (type 3), indicating a low pressure in the pulmonary ventricle (LV), are not candidates for a neonatal ASO. Patients with septal bulging to the right (type 1), indicating a high pressure in the pulmonary ventricle (LV), and those patients with an intermediate septal position (type 2) are considered good candidates. Most neonates with D-TGA and IVS who are suitable candidates for an ASO have type 2 septal geometry.

The staged ASO for D-TGA with IVS is used for those neonates in whom surgery cannot be performed in the first month of life secondary to events such as prematurity, sepsis, low birth weight (<1.0 kg), or late referral. The staged procedure retrains the LV to accept the systemic workload. The preparatory surgery involves creation of a nonrestrictive atrial septum (if it does not already exist), placement of a PA band, and creation of an aortopulmonary shunt with entry to the PA distal to the band. The band must be tight enough to increase pressure in the pulmonary ventricle (LV) to approximately one-half to two-thirds of that in the systemic ventricle (RV). This will increase the afterload sufficiently to stimulate an increase in LV mass. Historically, after 3 to 6 months, the PA was debanded, the shunt taken down, and an ASO performed. Currently a rapid two-stage repair is undertaken in which the ASO is performed as early as 1 week after preparatory PA banding, often during the same hospitalization. This approach is based on the fact that a doubling of LV mass is seen after 1 week of PA banding. The staged procedure is complicated by the fact that the adjustment of the PA band to the proper tightness is not an easy task and that the PA band and systemic to PA shunt may result in a distortion of the PA, making the definite ASO difficult. Intraoperative transesophageal echocardiography (TEE) is useful in guiding placement of the PA band. The band is tightened enough to flatten the intraventricular septum by shifting it toward the RV.

Intra-atrial physiologic repairs: Mustard and Senning procedures

Both the Mustard and the Senning procedures are atrial switch procedures that surgically create discordant AV connections in D-TGA. Systemic venous blood is routed to the LV and the PA, whereas pulmonary venous blood is routed to the RV and the aorta. This arrangement results in physiologic but not anatomic correction of D-TGA as the morphologic RV becomes the systemic ventricle. Given the current success with and the almost universal application of the more definitive ASO, these intra-atrial switch procedures are primarily of historic interest in patients with D-TGA.

Rastelli procedure

The Rastelli procedure was described in 1969 as a method of anatomically correcting D-TGA with VSD and LVOT obstruction. This surgery is used when LVOT obstruction in the form of subpulmonic and/or pulmonic stenosis is surgically uncorrectable. Performance of an ASO under these circumstances would leave the infant with residual LVOT obstruction (aortic or subaortic stenosis).

DiNardo JA. Transposition of the great arteries. In: Jonas RA, ed. *Comprehensive Surgical Management Of Congenital Heart Disease*. London: Arnold; 2004:256–278.

B. Preoperative Evaluation and Preparation

B.1. What information is important to prepare for this case?

The preoperative evaluation should begin with a careful history and physical examination. Gestational age, birth complications, family history, and any other medical problems should be noted. A comprehensive airway evaluation should be performed and the previous endotracheal tube size and leak pressure noted. Arterial and intravenous access should be assessed. A type and cross must be sent to the blood bank to ensure adequate red cells and blood component therapies are available in the operating room (OR).

The preoperative ECG and chest radiograph should be reviewed. The preoperative echocardiograms should be reviewed. Particular attention should be paid to septal

geometry, biventricular function, coronary anatomy, and adequacy of mixing at the atrial septal and ductal levels. Prostaglandin E_1 was discontinued in the patient but the ductus arteriosus may remain patent.

Laboratory data should include a complete blood count, electrolytes, platelet count, arterial blood gas, calcium, blood urea nitrogen, creatinine, liver function tests and glucose. Given that this infant presented with severe hypoxemia, end-organ dysfunction must be ruled out. The liver function tests and creatinine should be normal; if they are elevated, consideration should be given to further medical optimization. A head ultrasonographic examination should be performed to rule out intraventricular hemorrhage.

DiNardo JA. Anesthesia for congenital heart surgery. In: Jonas RA, ed. *Comprehensive Surgical Management of Congenital Heart Disease.* London: Arnold; 2004:45–65.

B.2. What are the anesthetic goals before cardiopulmonary bypass (CPB)?

- Maintain HR, contractility, and preload to maintain cardiac output; decreases in cardiac output decrease systemic venous saturation with a resultant fall in arterial saturation.
- Maintain ductal patency with prostaglandin E_1 (0.01 to 0.05 μg/kg/minute) in ductal-dependent patients.
- Avoid increases in PVR relative to SVR; increases in PVR will decrease pulmonary blood flow and reduce intercirculatory mixing; in patients with PVOD, ventilatory interventions should be used to reduce PVR; in patients with LVOT obstruction that is not severe, ventilatory interventions to reduce PVR increase pulmonary blood flow and intercirculatory mixing.
- Reductions in SVR relative to PVR should be avoided; decreased SVR increases recirculation of systemic venous blood and decreases arterial saturation.
- In patients with D-TGA and VSD with symptoms of CHF, ventilatory interventions to reduce PVR are not warranted because they will produce small improvements in arterial saturation at the expense of systemic perfusion.

DiNardo JA. Transposition of the great vessels. In: Lake CL, Booker PD, eds. *Pediatric Cardiac Anesthesia*. 4th ed. Philadelphia: Lippincott Williams & Wilkins; 2005: 357–380.

B.3. What is the plan for glucose management in this patient?

Maintenance for caloric requirements in the awake neonate/infant are 100 kcal/kg/day or 4 kcal/kg/hour. This caloric requirement can be met with glucose 25 g/kg/day or 1 g/kg/hour. From a practical point of view, this glucose requirement can be met with 10% dextrose (100 mg/mL) run at the maintenance volume replacement rate of 4 mL/kg/hour. Ten percent dextrose run at half this rate (2 mL/kg/hour) is usually sufficient to meet the caloric requirements of an anesthetized infant while avoiding both the hyperglycemia and hypoglycemia that can be detrimental to neurologic outcome particularly following deep hypothermic circulatory arrest (DHCA). Dextrose infusions should be discontinued before commencement of CPB because the associated neuroendocrine response to CPB generally produces mild hyperglycemia. Some infants receive nutritional support as part of medical stabilization before surgery. High-calorie total parenteral nutrition and intralipid therapy should be discontinued and replaced with a 10% dextrose infusion several hours before transport to the OR. Continued administration of these high-calorie

infusions makes intraoperative serum glucose management problematic. In these patients, higher dextrose infusion rates may be necessary pre-CPB to avoid rebound hypoglycemia.

DiNardo JA. Anesthesia for congenital heart surgery. In: Jonas RA, ed. *Comprehensive Surgical Management of Congenital Heart Disease*. London: Arnold; 2004:45–65.

C. Intraoperative Management

C.1. How would you monitor this infant?

Ideally, preinduction monitoring should include a blood pressure cuff, ECG, pulse oximeter, and an end-tidal carbon dioxide monitor. In reality, a pulse oximeter and an ECG may be all that is practical in the early stages of induction. The other monitors are then quickly added as induction progresses. Pulse oximeter probes should be placed on an upper and lower extremity (preductal and postductal if relevant). An intra-arterial catheter (radial or femoral) is placed just after induction. Many infants transferred from the ICU will have an umbilical artery or femoral artery catheter in place. A central venous pressure and drug infusion catheter is placed after intubation and stabilization. Double-lumen central venous catheters inserted through the femoral or internal jugular vein are preferred. Nasopharyngeal, tympanic, and rectal temperature probes are also placed following induction. A bladder catheter should be placed. A TEE probe can be inserted following induction and intubation.

DiNardo JA. Anesthesia for congenital heart surgery. In: Jonas RA, ed. *Comprehensive Surgical Management of Congenital Heart Disease*. London: Arnold; 2004:45–65.

C.2. What would be the best method of induction?

This infant would have an IV catheter in place on transfer to the OR. Anesthesia is generally induced and maintained using a synthetic opioid-based (fentanyl or sufentanil) technique. These opioids may be used alone in high doses (25 to 100 μg/kg fentanyl or 2.5 to 10 μg/kg sufentanil) or in low to moderate doses (5 to 25 μg/kg fentanyl or 0.5 to 2.5 μg/kg sufentanil) in combination with an inhalation agent (generally isoflurane or sevoflurane) or a benzodiazepine (generally midazolam). The high-dose technique is particularly useful in neonates and infants. High-dose opioids provide hemodynamic stability, do not depress the myocardium, and blunt reactive pulmonary hypertension. In order to avoid bradycardia, pancuronium (0.1 mg/kg) is administered in conjunction with the opioid; its vagolytic activity offsets the vagotonic activity of the narcotics.

C.3. Is CPB in infants and children different from adults?

The major differences between adult and pediatric CPB are summarized in Table 39.2.

Table 39.2 Major Differences between Adult and Pediatric Cardiopulmonary Bypass

PARAMETER	ADULT	PEDIATRICS
Hypothermic temperature	Rarely below 25° C–32° C	Commonly 15° C–20° C
Use of total circulatory arrest	Rare	Common
Pump prime		
Dilution effects on blood volume	25%–33%	200%–300%
Additional additives in ped primes		Blood, albumin
Perfusion pressures	50–80 mm Hg (some centers accept 30 mm Hg)	20–50 mm Hg
Influence of pH management strategy	Minimal at moderate hypothermia	Marked at deep hypothemia
Measured $Paco_2$ differences	30–45 mm Hg	20–80 mm Hg
Glucose regulation		
Hypoglycemia	Rare—requires significant hepatic injury	Common—reduced hepatic glycogen stores
Hyperglycemia	Frequent—generally easily controlled with insulin	Less common—rebound hypoglycemia may occur

Flows of 2.0 to 2.5 L/minute/m^2 are commonly used for infants, children, and adults during mild to moderate systemic hypothermia. Owing to age-related differences in the relationship of surface area to weight, these flow rates expressed in mL/kg/minute will be substantially higher in the neonate than in the adult. The recommended full flow rates for pediatric CPB are summarized in Table 39.3.

The vast majority of operative procedures in children require the use of either total CPB or DHCA. Venous cannulation for DHCA is usually accomplished with a single large venous cannula in the RA. Once cooling is complete and circulatory

Table 39.3 Recommended Full Flow Rates for Pediatric Cardiopulmonary Bypass

PATIENT WEIGHT (kg)	FULL CPB FLOW RATES (mL/kg/min)
<3	150–200
3–10	125–175
10–15	120–150
15–30	100–120
30–50	75–100
>50	50–75

CPB, cardiopulmonary bypass.

arrest is established, the cannula is removed to allow for maximum exposure. For total CPB, once the cavae (and other sources of systemic venous return) are cannulated, surgical tourniquets or tapes are passed around the external circumference of the vessels. When these tapes are tightened around the cannulae, the right heart can be isolated completely and subsequently opened without entrainment of air into the venous circuit or obscuration of the surgical field by venous blood. During delivery of antegrade cardioplegia, it is essential that at least one tape be left untightened to allow egress of cardioplegia solution from the coronary sinus without distention of the RA. In older children, a larger cannula is used in the inferior vena cava (IVC) as compared with the superior vena cava (SVC), because a larger portion of systemic venous return (two-thirds) is from the IVC.

As with venous cannulation, arterial cannulation in children particularly infants/neonates can be technically challenging. It may be necessary in circumstances where the ascending aorta and aortic arch are hypoplastic and systemic blood flow is ductal dependent (as in hypoplastic left heart syndrome) to obtain systemic perfusion through the ductus arteriosus by cannulating the PA. When the aortic arch is interrupted, cannulation of the aorta both proximal and distal to the interruption is necessary. Because the arterial cannula is relatively large as compared to the aorta in infants/neonates, complete or partial obstruction of the aorta by the cannula itself is possible. Constant vigilance is necessary to avoid this problem. If dampening of the arterial trace, distension of the systemic ventricle, or an increase in CPB line pressure occurs with placement or manipulation of the arterial cannula, the surgeon should immediately be made aware of the situation so the cannula can be repositioned. Some centers utilize near-infrared spectroscopy and transcranial Doppler ultrasonographic technology as adjunctive methods to assess cerebral blood flow during CPB.

C.4. What is modified ultrafiltration (MUF)?

Ultrafiltrators are devices commonly added to the CPB circuit to remove excess fluid and produce hemoconcentration. When used in conjunction with CPB, these devices produce an ultrafiltrate that occurs as the result of a hydrostatic pressure gradient across a semipermeable membrane. These are the same devices that can be used for hemodialysis when they are used in conjunction with a dialysate. When used in conjunction with CPB, they are commonly called *hemoconcentrators* because they produce an increase in hematocrit by removing excess fluid.

These devices consist of a core of microporous hollow fibers made of polysulfone, polyamide, or polyacrylonitrile material arranged in a bundle. The pore size is generally 0.30 to 0.40 μm. Owing to the pressure drop across the device, blood inflow must be obtained from the arterial side of the CPB circuit while blood outflow is diverted to the cardiotomy reservoir or venous reservoir. The ultrafiltrate is collected in a container connected to a vacuum source.

The ultrafiltrate is discarded and has the composition of glomerular filtrate. The rate at which ultrafiltrate is produced is dependent on the transmembrane pressure (TMP) gradient. TMP is determined by the arterial inlet pressure (P_a), the venous

outlet pressure (P_v), the absolute value of applied suction at the outlet (P_n), the oncotic pressure at the inlet (P_i), and the oncotic pressure at the outlet (P_o):

$$\text{TMP} = \frac{P_a + P_v}{2} + P_n - \frac{P_i + P_o}{2}$$

P_n is increased by using the regulated vacuum source connected to the outlet of the device. TMP should not exceed 500 mm Hg.

Continuous ultrafiltration (CUF) refers to ultrafiltration occurring throughout CPB or during those intervals when venous reservoir volume is sufficient to allow it. MUF is a technique that allows ultrafiltration to continue after weaning from CPB. MUF may be performed utilizing either an arteriovenous or venovenous system. In the arteriovenous system, inflow to the ultrafiltrator during MUF is directly from the aortic cannula. Outflow from the ultrafiltrator is to the RA. Blood volume is kept constant as ultrafiltrate is lost by replacing it with blood from the CPB circuit, which passes through the ultrafiltrator before being delivered to the RA. In this way, the CPB circuit can remain primed and the patient's blood, as well as the CPB blood, can be hemoconcentrated. In the venovenous system, the IVC cannula provides inflow to the ultrafiltrator with the aid of a roller pump, whereas outflow from the ultrafiltrator is returned to the SVC cannula. Blood volume is kept constant as ultrafiltrate is lost by replacing it with blood from the CPB circuit, which passes through the ultrafiltrator before being delivered to the SVC. The end point for termination of MUF following CPB varies from institution to institution, with institutions terminating MUF after a set time interval (15 to 20 minutes), a set hematocrit (40%), or a set volume removed (750 mL/m^2). Heparin anticoagulation must be maintained during MUF, with protamine reversal of heparin initiated after termination of MUF.

MUF may be an effective method of attenuating the deleterious consequences of a CPB strategy that involves large asanguinous primes, particularly in neonates and infants. In the studies comparing MUF to no ultrafiltration, a CPB technique consisting of a very large asanginous pump prime (400 to 900 mL) with packed cells added to reach a hematocrit of 15% to 20% has generally been used. This is precisely the group of patients who would need and who would benefit from aggressive removal of excess fluid to reduce total body water and increase hematocrit and coagulation factors. Furthermore, it has been demonstrated that MUF and continuous ultrafiltration during CPB are indistinguishable in their effect on hematocrit, mean arterial pressure, HR, and LV shortening fraction when equal volumes of fluid are removed.

C.5. Briefly describe the surgical techniques of the Mustard/Senning, ASO, and Rastelli procedures.

Intra-atrial physiologic repairs: Mustard and Senning procedures

In both procedures, the interatrial septum is excised, creating a large ASD. In the Mustard procedure, a baffle made of native pericardium or synthetic material is then used to redirect pulmonary and systemic venous blood. In the Senning procedure, autologous tissue from the right atrial wall and interatrial septum is used in place of the pericardium or synthetic material. In either case, pulmonary venous blood flows over the baffle and is directed across the tricuspid valve into the RV and out the aorta.

Systemic venous blood flows on the underside of the baffle to be directed across the mitral valve into the LV and out of the PA. This arrangement results in physiologic but not anatomic correction of D-TGA, as the morphologic RV becomes the systemic ventricle. These procedures are performed with hypothermic CPB, bicaval cannulation, and aortic cross clamping during cardioplegic arrest. Intervals of LFCPB are customarily used.

Arterial anatomic repair: arterial switch (Jatene) operation

The PA and the aorta are transected distal to their respective valves. The coronary arteries are initially explanted from the ascending aorta with 3 to 4 mm of surrounding tissue. The explant sites are repaired either with pericardium or synthetic material. The coronary arteries are reimplanted into the proximal PA (neoaorta). The distal PA is brought anterior to the aorta (LeCompte maneuver) to be reanastomosed to the old proximal aorta (right ventricular outflow) and the distal aorta reanastomosed to the old proximal PA (left ventricular outflow). As a result, the great arteries are switched to create ventriculoarterial concordance with both an anatomic and physiologic repair achieved. The ASO is done using hypothermic CPB with aortic cross clamping and cardioplegic arrest. Intervals of LFCPB are customarily used. A short interval of DHCA may be employed to close the atrial septum or VSD if a single venous cannula rather than bicaval venous cannulation is used. Closure of a VSD is preferentially done transatrially through the tricuspid valve. It is desirable to avoid approaching a VSD through the RV, because an incision in the RV may contribute substantially to postoperative RV dysfunction.

Jatene AD, Fontes VF, Paulista PP, et al. Anatomic correction of transposition of the great vessels. *J Thorac Cardiovasc Surg*. 1976;72:364–370.

Rastelli procedure

The PA is transected and ligated just distal to or at the level of the pulmonary valve. A right ventriculotomy is performed, and the VSD is closed with a patch tunnel such that the LV is in continuity with the aorta. The VSD may have to be enlarged, in some cases, to prevent subaortic stenosis. RV to PA continuity is achieved by placement of valved conduit or valved homograft between the right ventriculotomy site and the proximal main PA. The result is LV to aortic continuity and RV to PA continuity with bypass of the subpulmonic and pulmonic stenosis. This procedure is performed with hypothermic CPB, bicaval cannulation, and aortic cross clamping during cardioplegic arrest. Intervals of LFCPB are customarily used.

Historically, most of these patients had a palliative systemic to PA shunt placed in the newborn period and then returned for the Rastelli procedure and takedown of the shunt at 2 to 3 years of age. The delay was felt necessary to avoid performing a right ventriculotomy in infants with immature myocardium and limited contractile elements and to allow adequate growth of the RV and pulmonary arteries to permit placement of an RV to PA conduit. In the current era with improvements in myocardial protection, CPB technology, and surgical technique, this procedure can be performed as a primary procedure in the neonatal period.

C.6. What is hypothermia and how is it classified? What is low-flow cardiopulmonary bypass (LFCPB)? What is deep hypothermic circulatory arrest (DHCA)?

The levels of systemic hypothermia employed during CPB are generally defined as follows: mild (35° C [95° F] to 32° C [89.6° F]), moderate (31° C [87.8° F] to 26° C [78.8° F]), deep (25° C [77° F] to 20° C [68° F]), and profound (<20° C [68° F]). Unfortunately, it is not uncommon for temperatures less than 20° C (68° F) used in conjunction with pediatric cardiac surgery to be called *deep hypothermia*. Low-flow CPB in neonates/infants conducted in conjunction with temperatures of 18° C (64.4° F) to 25° C (77° F) is generally defined as 50 to 70 mL/kg/minute or approximately 1.0 to 1.5 L/minute/m^2.

Profound hypothermic circulatory arrest, commonly referred to as *DHCA*, is a technique employed to improve exposure of intracardiac defects and to facilitate aortic arch reconstruction in infants and children. DHCA is conducted in conjunction with temperatures of 18° C (64.4° F) to 20° C (68° F) and allows cessation of CPB, venous and arterial cannula removal, and exsanguination of the patient into the venous reservoir of the CPB circuit. There has been substantial refinement of the technique of DHCA since its successful inception in the 1970s. In the current era, DHCA is used selectively and for short intervals. It is utilized primarily for the aortic arch reconstruction component of the Norwood procedure, repair of interrupted aortic arch, neonatal repair of total anomalous pulmonary venous connection, and complicated intracardiac repairs such as complete AV canal defects in small (<2.0 kg) neonates and infants.

C.7. Why is hypothermia beneficial to the brain during LFCPB and DHCA?

Hypothermia is arguably the most important component of LFCPB and DHCA. Hypothermia-induced reduction in cerebral metabolic rate for oxygen ($CMRO_2$) slows the rate of depletion of high-energy phosphates and the development of intracellular acidosis. This in turn delays or prevents the neuronal energy failure that leads to terminal membrane depolarization and subsequent neuronal injury or death during an ischemic episode. Q_{10} defines the ratio of organ O_2 consumption at a defined temperature to the O_2 consumption at a temperature 10° C (18° F) lower. The cerebral Q_{10} is approximately 3.65 in children and 2.3 in adults. Despite this, the cerebral metabolic rate will still be approximately 10% to 15% of its normothermic baseline at 15° C (59° F). If it is assumed that 3 to 5 minutes of cerebral ischemia can be tolerated at 37° C (98.6° F) and the Q_{10} is 3.0, 9 to 15 minutes of ischemia can be tolerated at 27° C (80.6° F) and 27 to 45 minutes can be tolerated at 17° C (62.6° F).

In addition to reducing $CMRO_2$, hypothermia also serves to ameliorate some of the sequalae of neuronal ischemia when instituted *before* the ischemia insult. Specifically, hypothermia markedly reduces release of the excitatory neurotransmitters glutamate, aspartate, and glycine that accompany cerebral ischemia and subsequent reperfusion. In energy-deprived cells, glutamate in particular is neurotoxic in part due to the role it plays in inducing massive calcium influx through N-methyl-D-aspartic acid receptors.

Hypothermia also blunts the inhibitory effect of hypoxia on nitroxidergic (postganglionic parasympathetic nerve where nitric oxide is the neurotransmitter)-induced cerebral vasodilatation. In addition, there is evidence that hypothermia may attenuate neutrophil migration into ischemic tissue.

C.8. Explain the difference between α-stat and pH-stat blood gas management.

pH-stat and α-stat acid–base management are commonly discussed in association with management of CPB. pH-stat and α-stat regulation are acid–base management methods that directly influence blood flow to the brain and other organs. Although pH-stat and α-stat acid–base management are commonly mentioned in association with temperature-corrected and temperature-uncorrected blood gases, it must be emphasized that these are entirely different concepts. The method of blood gas interpretation (corrected or uncorrected) does not dictate the method of acid–base management (pH-stat or α-stat). α-stat or pH-stat management is possible with use of both temperature-corrected and temperature-uncorrected blood gases. In addition, it is important to point out that at a patient temperature of 37° C (98.6° F), there is no difference between pH-stat and α-stat management. The difference between these two strategies becomes more marked as patient temperature progressively decreases below 37° C (98.6° F) and is not clinically relevant until patient temperature is less than 30° C (86° F).

When a blood gas sample is drawn from a patient at 25° C (77° F) and sent to the blood gas laboratory, the sample is warmed to 37° C (98.6° F) before measurement. The values obtained at 37° C (98.6° F) are called the *temperature-uncorrected values*. These values are converted to temperature-corrected values using a nomogram. The nomogram accounts for temperature-induced changes in pH, O_2 solubility, and CO_2 solubility in a closed-blood system. When blood in a closed system is cooled to a lower temperature, the electrochemically neutral pH is higher and the associated P_{CO_2} is lower than in a closed blood system at 37° C (98.6° F). Therefore, electrochemical neutrality is maintained by keeping pH alkalotic in temperature-corrected blood gases and normal in temperature-uncorrected gases. This is known as *α-stat regulation*. For practical purposes, it is easier to use uncorrected gases and keep pH and P_{CO_2} in the range considered normal at 37° C (98.6° F). It has been demonstrated clinically that cerebral blood flow and oxygen consumption are appropriately coupled when α-stat regulation is used. Deep hypothermia in the presence of α-stat regulation produces loss of cerebral autoregulation such that cerebral blood flow varies directly with arterial pressure.

pH-stat regulation refers to maintaining pH and P_{CO_2} at normal values for blood at 37° C (98.6° F) regardless of actual blood temperature. With this strategy, a blood sample will have a normal pH and P_{CO_2} when temperature-corrected gases are used, and acidotic pH and P_{CO_2} values when temperature-uncorrected gases are used. For practical purposes, pH-stat is maintained by adding CO_2 to the ventilating gas during hypothermic CPB to increase P_{CO_2} and decrease the pH. In contrast to α-stat regulation, in which total CO_2 content is kept constant, pH-stat regulation results in an increase in total CO_2 content. The cerebral vasculature maintains vasomotor responses to varying P_{CO_2} during hypothermic CPB. This

response is maintained during both moderate and deep hypothermia despite the fact that deep hypothermia induces loss of cerebral blood flow autoregulation. It has been demonstrated clinically that when pH-stat regulation is used with moderate hypothermic CPB, there is uncoupling of cerebral blood flow and metabolism and loss of cerebral autoregulation. As a result, cerebral blood flow varies linearly with arterial blood pressure, and cerebral hyperperfusion exists with cerebral blood flow far in excess of that dictated by cerebral metabolic rate. This hyperperfusion state is the result of (1) reduced cerebral oxygen consumption induced by hypothermia and (2) cerebral vasodilation resulting from a disproportionately high P_{CO_2} for the degree of hypothermia present. The potential danger of the hyperperfused state is that it may result in increased delivery of microemboli into the cerebral circulation.

C.9. What are the immediate post-CPB issues following ASO?

Bleeding from the extensive suture lines in the post-CPB period may be problematic. Efforts to reduce aortic blood pressure combined with aggressive blood component therapy are often required. In neonates, it may require 1 to 2 units of platelets (0.25 to 0.5 units/kg) to obtain a therapeutic platelet count increase. Because platelets are suspended in fresh frozen plasma, a platelet transfusion of this size usually results in a fresh frozen plasma transfusion of 10 to 15 mL per kg.

Myocardial ischemia following reimplantation of the coronary arteries is a potential problem following the ASO. In some circumstances, the ischemia is transient secondary to coronary air emboli. TEE is very useful to ensure adequate removal of air from the LA and LV before the termination of CPB. It is also useful in assessing the potency of the reimplanted coronary arteries. Maintenance of high perfusion pressures on CPB after aortic cross clamp removal will facilitate the distal migration of air emboli. In other instances, kinking of the reimplanted artery or compromise of the implanted coronary ostia may require immediate surgical intervention. Pharmacologic intervention with traditional therapies to improve the balance of myocardial oxygen demand and delivery such as nitroglycerin and β-blockade are never a long-term alternative to prompt surgical revision of the appropriate anastomosis.

Despite comprehensive preoperative evaluation, the LV of patients undergoing an ASO may be marginal in its ability to support the systemic circulation in the post-CPB period. This may occur as the result of myocardial ischemia, inadequate LV mass, poor protection of the LV during aortic cross clamping, or a combination of these variables. TEE is useful in identifying and continuously evaluating both global and regional LV systolic dysfunction. It also detects mitral regurgitation, which may occur secondary to papillary muscle dysfunction or to dilation of the mitral valve annulus. Inotropic support of the LV and afterload reduction may be necessary to terminate CPB.

DiNardo JA. Transposition of the great vessels. In: Lake CL, Booker PD, eds. *Pediatric Cardiac Anesthesia*. 4th ed. Philadelphia: Lippincott Williams & Wilkins; 2005:357–380.

D. Postoperative Management

D.1. How is myocardial ischemia addressed in the intensive care unit (ICU) following the ASO?

Myocardial ischemia in the ICU following an ASO as heralded by ST-segment/T-wave changes or the development of atrial or ventricular arrhythmias requires immediate attention. Myocardial ischemia should be considered to be mechanical in nature until proved otherwise. Compression of the coronary ostia by swelling of thrombin gelform pads or thrombus formation around the coronary anastomoses must be considered. In this setting, surgical reexploration is likely to be immediately therapeutic.

Another source of mechanically induced myocardial ischemia in the ASO patient occurs as the result of LV dilation. A unique cycle of LV dilation initiating and exacerbating myocardial ischemia exists in patients having undergone the ASO. Myocardial ischemia, afterload mismatch, or overzealous volume infusion can result in LV distension and LA hypertension. This will be particularly likely if there is mitral insufficiency from either papillary muscle dysfunction or dilation of the mitral valve annulus. LV distension may result in tension on and kinking of the coronary reanastomosis sites. LA hypertension produces elevations in PA pressure and distension of the PA. As the LeCompte maneuver brings the distal PA anterior to the ascending aorta, distension of the PA may actually compress or place tension on the coronary ostia. The resulting myocardial ischemia produces further LV dilation, progressive elevations in LA and PA pressures, and continuing compromise of coronary blood flow. Attempts to induce coronary vasodilatation with nitroglycerine are unlikely to be beneficial in this setting, although its preload and afterload reducing may be beneficial. A more rational approach would be initiation of milrinone therapy.

DiNardo JA. Transposition of the great vessels. In: Lake CL, Booker PD, eds. *Pediatric Cardiac Anesthesia*. 4th ed. Philadelphia: Lippincott Williams & Wilkins; 2005:357–380.

DiNardo JA. Transposition of the great arteries. In: Jonas RA, ed. *Comprehensive Surgical Management of Congenital Heart Disease*. London: Arnold; 2004:256–278.

D.2. What immediate postoperative problems would be anticipated following the Rastelli procedure?

Right (pulmonary) ventricular dysfunction may occur in the post-CPB period. These patients are at risk because a right ventriculotomy is used to close the VSD and to create the new pulmonary outflow tract. Heart block may also occur given the proximity of the VSD to the intraventricular conduction pathways. A residual VSD may be present. Because the VSD closure to create LV to aortic continuity is more of a tunnel than a patch closure, LV outflow tract obstruction is also possible.

DiNardo JA. Transposition of the great vessels. In: Lake CL, Booker PD, eds. *Pediatric Cardiac Anesthesia*. 4th ed. Philadelphia: Lippincott Williams & Wilkins; 2005: 357–380.

D.3. What intermediate and long-term surgical problems are seen after ASO?

Supravalvular pulmonary stenosis is probably the most common complication of ASO. This stenosis is due to retraction of the tissue used to replace the tissue excised with the explanted coronaries and, in most patients, is not extensive enough

to result in valvular pulmonary stenosis. Series with long-term follow-up (15 years) confirms that the incidence of supravalvular stenosis severe enough to require reoperation (generally a gradient >50 to 60 mm Hg) is approximately 4% to 8%. Aortic insufficiency occurs in approximately 10% to 15% of patients at long-term follow-up, with the majority (96%) graded as trivial or mild. Time has shown aortic insufficiency to be a rare source of morbidity or indication for reoperation following the ASO.

Early concerns existed regarding the long-term patency and growth potential of the reimplanted coronary arteries. Fortunately these problems have not materialized on a large scale.

DiNardo JA. Transposition of the great vessels. In: Lake CL, Booker PD, eds. *Pediatric Cardiac Anesthesia*. 4th ed. Philadelphia: Lippincott Williams & Wilkins; 2005: 357–380.

Nogi S, McCrindle BW, Boutin C, et al. Fate of the neopulmonary valve after the arterial switch operation in neonates. *J Thorac Cardiovasc Surg*. 1998;115:557–562.

D.4. What are the long-term outcomes after ASO?

The initial result for the arterial switch in experienced institutions is excellent, with an actuarial survival at 1 year of 90% for patients with D-TGA and IVS, and 83% for patients with D-TGA and VSD. Other experienced groups have reported similar results. A recent review of 470 patients from one institution experienced in the ASO, however, revealed a 1-year survival rate of 92% and an 8-year survival rate of 91% for patients with both D-TGA and IVS and D-TGA and VSD. A similar review of 1,200 patients from another experienced institution revealed a 1- and 15-year survival rate of 92% for patients with D-TGA and IVS, and 1- and 15-year survival of 81% and 80% for D-TGA and VSD, respectively. A recent multi-institution review of 631 patients with D-TGA and 167 patients with D-TGA and VSD reviewed similar initial and long-term (15 years) outcomes.

The overwhelming majority (90% to 97%) of patients have normal-sized, patent coronary arteries as assessed by coronary angiography. A recent study of a large cohort demonstrated that survival without coronary events (death from myocardial infarction, sudden death, and reoperation for coronary stenoses) is 92.7% at 1 year and 88.2% at 15 years. The incidence of coronary events is bimodal with a high early and low late event rate. Eighty-nine percent of all coronary events occurred in the first 3 months after ASO. The event rate did not increase again until 6 years after ASO. Two types of coronary anatomy (a single coronary artery origin or two coronaries originating close to each other at a facing commissure) were risk factors for a coronary event.

One of the potential advantages of the ASO over the atrial switch procedure is the use of the native LV as the systemic ventricle. Long-term follow-up indicates that patients who have undergone an ASO have higher systemic ventricular ejection fractions than do patients who have undergone atrial switch procedures. In fact, patients who had D-TGA and IVS repaired in infancy and patients who had D-TGA and VSD repaired later have LV end diastolic dimensions and contractile indices similar to normal patients. Myocardial contractility in patients having undergone a rapid or traditional two-stage arterial switch is mildly depressed as compared to patients having undergone a primary arterial switch. No progression of this ventricular dysfunction has been noted at either intermediate or long-term follow-up.

D.5. What are the long-term outcomes after Rastelli repair for D-TGA with left ventricular outflow tract (LVOT) obstruction?

Outcome following the Rastelli procedure for TGV with VSD and LVOT obstruction is good, with a near 100% early survival rate. One large recent series reports freedom from death or transplantation to be 82% at 5 years, with a progressive decrease to 52% by 20 years. Similar results are reported in another recent series. The need for reintervention (either surgical or catheterization) increases over time. Intervention to relieve RVOT (RV to PA conduit) obstruction accounts for 75% of all interventions, with pacemaker insertion and relief of LVOT obstruction (aortic outflow) accounting for most of the remaining interventions. Freedom from surgical or catheterization intervention for relief of conduit obstruction is 56% at 5 years, decreasing to 21% at 15 years. Patients who had undergone the Rastelli procedure were reported to have increased LV end-diastolic and end-systolic volumes and diminished LV contractile function compared with normal subjects. Despite this, the majority (98%) of these patients were found to be in New York Heart Association functional class 1 or 2 following the Rastelli procedure. It is unclear whether surgery at an earlier age and improvements in construction of the VSD tunnel patch has reduced the incidence of contractile dysfunction following the Rastelli procedure in the current era.

Dearani JA, Danielson DK, Puga FJ, et al. Late follow-up of 1095 patients undergoing operation for complex congenital heart disease utilizing pulmonary ventricle to pulmonary artery conduits. *Ann Thorac Surg*. 2003;75:399–410.

D.6. What is long-term neurologic outcome like after ASO?

The best assessment of neurologic outcome following ASO is data from the Boston Circulatory Arrest Trial. In this trial, infants undergoing ASO for D-TGA with IVS or VSD randomized 171 infants to a strategy of either DHCA or LFCPB using α-stat pH management. Infants in the DHCA group underwent an average of 52 minutes of DHCA, whereas those in the LFCPB group underwent 14 minutes of DHCA.

At age 8 years, parents of children in the trial reported more problems with attention, learning, speech, and the frequency of developmental delay than parents of children in a normative sample. Despite this, children in the cohort had overall physical and psychosocial health status similar to the general population. Furthermore, there was no association between physical and psychosocial scores and the presence or

absence of a VSD or the use of LFCPB versus DHCA. Neurodevelopmental outcome in this cohort was generally not adversely affected unless the duration of DHCA exceeded 41 minutes. Beyond 41 minutes, there was a nonlinear (steadily worsening) outcome with increasing duration of DHCA.

Eight-year data from the trial also demonstrated that neurologic status, IQ, academic achievement, memory, problem solving, and visual–motor integration did not differ between the DHCA and LFCPB groups. Nonetheless, DHCA was associated with greater functional deficiencies (motor function, speech apraxia, visual–motor tracking, phonic awareness) than LFCPB (impulsive behavior, worse behavior as rated by teachers).

CHAPTER 40

Pyloric Stenosis

AARTI SHARMA AND VINOD MALHOTRA

A 3-WEEK-OLD FIRST-BORN MALE INFANT had projectile vomiting, which contained the ingested formula but no bile. His body weight is 2.5 kg. Serum electrolytes: K^+ 2.2 mEq per L, Cl^- 86 mEq per L. Blood pH 7.68. This infant was also noted to have a systolic murmur heard best at the second intercostal space along the left sternal border, which was assessed by a cardiologist and diagnosed as a ventricular septal defect (VSD).

A. Medical Disease and Differential Diagnosis

1. What is the diagnosis in this patient?
2. What is the differential diagnosis of pyloric stenosis?
3. What are the metabolic problems in this newborn secondary to his disease?
4. What are the adverse effects of metabolic alkalosis?
5. How would you treat this infant?
6. How would you determine fluid replacement in a newborn, and what fluids would you use?
7. How would you correct the metabolic alkalosis in this patient?
8. What causes a cardiac murmur?

B. Preoperative Evaluation and Preparation

1. How would you evaluate this patient preoperatively?
2. How would you evaluate a heart murmur?
3. How would you differentiate between functional versus organic murmur?
4. What are the types of VSD? What type of shunt do they cause?
5. What are the risks of surgery and anesthesia in a patient with VSD?
6. How would you prepare this patient rapidly for emergency surgery? Is surgical intervention an acute emergency in this case?
7. How would you prepare this patient for anesthesia?

C. Intraoperative Management

1. What induction–intubation sequence would you use?
2. What are the anatomic characteristics of the airway in the newborn, and how do they differ from those in the adult?
3. How do you determine the size of an endotracheal tube in a pediatric patient?
4. What anesthesia system would you use and why?
5. What are the advantages and disadvantages of commonly employed nonrebreathing systems?
6. How would you monitor this patient intraoperatively?
7. How does the pulse oximeter function?
8. What factors affect the measurement of oxygen saturation by the pulse oximeter?

D. Postoperative Management

1. What are the complications that can occur in the postanesthesia recovery period?
2. How would you treat postextubation "croup" in this infant?

A. Medical Disease and Differential Diagnosis

A.1. What is the diagnosis in this patient?

The most likely diagnosis in this patient is pyloric stenosis. The factors that favor the diagnosis are as follows:

- Age—3 weeks (average age at onset; range 5 days to 5 months)
- Boy child (boy-to-girl ratio = 4:1)
- Projectile vomiting (characteristic)
- Contents—ingested formula, no bile

The resultant biochemical abnormality in this patient is a hypokalemic, hypochloremic, metabolic alkalosis.

Pyloric stenosis occurs in 3 of 1,000 infants born in the United States; its incidence may be increasing. It is more common in whites of Northern European ancestry, less common in blacks, and rare in Asians. Reduced nitric oxide in pyloric tissue may contribute to the pathogenesis of pyloric stenosis.

Behrman RE, Kleigman RM, Jenson HB, et al., eds. *Nelson Textbook of Pediatrics.* 18th ed. Philadelphia: WB Saunders; 2007:1557–1559.

A.2. What is the differential diagnosis of pyloric stenosis?

Pyloric stenosis is distinguished from other congenital anomalies that cause obstruction of the alimentary tract in the newborn. These other anomalies include chalasia of the esophagus, hiatus hernia, duodenal atresia, jejunal atresia, ileal atresia, pancreatic annulus, malrotation of the gut, intra-abdominal hernias, and Meckel's diverticulum. Pathognomonic features of pyloric stenosis include absence of bile staining of the vomitus and visible gastric peristaltic waves on abdominal examination along with the palpable pyloric mass. The diagnosis is commonly made clinically. An "olive" is sometimes palpated in the epigastrium just to the right of the midline. Diagnosis can be confirmed by abdominal ultrasound. Occasionally, an upper gastrointestinal series with barium may be necessary.

Behrman RE, Kleigman RM, Jenson HB, et al., eds. *Nelson Textbook of Pediatrics.* 18th ed. Philadelphia: WB Saunders; 2007:1557–1559.

A.3. What are the metabolic problems in this newborn secondary to his disease?

Metabolic changes occur secondary to protracted vomiting and comprise the characteristic hypokalemic, hypochloremic alkalosis, as evident in this infant. Hyponatremia, although present, may not be manifested in serum value determinations because of severe dehydration. Compensatory respiratory acidosis is a frequent finding; it results from hypoventilation that may be marked and associated with periods of apnea. In severe dehydration leading to circulatory shock, the lack of adequate perfusion coupled with impaired renal and hepatic function may produce an entirely different picture of metabolic acidosis with hyperventilation, resulting in respiratory alkalosis. Therefore, depending on the severity and duration of vomiting and the type of fluid replenishment, one can encounter wide variation in findings on arterial blood gas and electrolyte determinations. However, most frequent findings are hypokalemia, hyponatremia, hypochloremia, and primary metabolic alkalosis with secondary respiratory acidosis. The renal response to vomiting is twofold: serum pH initially is maintained by excretion of alkaline urine with sodium and potassium loss; with depletion of these electrolytes, the kidneys secrete acidic urine (paradoxic acidosis), further increasing the metabolic alkalosis. These findings are summarized in Table 40.1.

Behrman RE, Kleigman RM, Jenson HB, et al., eds. *Nelson Textbook of Pediatrics.* 18th ed. Philadelphia: WB Saunders; 2007:1557–1559.

Coté CJ, Todres ID, Goudsouzian NG, et al., eds. *A Practice of Anesthesia for Infants and Children.* 3rd ed. WB Saunders; 2001:306–307.

Davis PJ, Cladis FP, Motoyama EK, eds. Clinical management of specialized surgical problem. In: *Smith's Anesthesia for Infants and Children.* 8th ed. Philadelphia: Mosby; 2011:750–751.

A.4. What are the adverse effects of metabolic alkalosis?

- An increase in pH results in shifting of the oxygen-dissociation curve to the left, thereby binding more oxygen to the hemoglobin and unloading less oxygen at the tissue level. This phenomenon assumes even more importance in newborns because at 3 weeks they still have up to 70% fetal hemoglobin with an already low value of P50 (i.e., 20 to 22 mm Hg).
- Respiratory compensation is affected by hypoventilation with increased potential for atelectasis, as well as periods of apnea.

Table 40.1 Metabolic Findings in the Newborn Secondary to Pyloric Stenosis

SEVERITY OF DEHYDRATION	ARTERIAL BLOOD GASES				SERUM ELECTROLYTES			
	pH	Pco_2	CO_2	Po_2	NA	K	CL	HCO_3
Mild	↑	↑	↑	↔	↓↔	↓	↓↓	↑
Moderate	↑↑	↑↑	↑↑	↔	↓	↓↓	↓↓↓	↑↑
Severe	↓↓	↓	↓↓	↓	↓	↓↓	↓↓↓	↓↓

(↔), no change; ↑/↓, slight change; ↑↑/↓↓, moderate change; ↑↑↑/↓↓↓, marked change.

- Decrease in ionized calcium.
- Increased potential for seizures.

Behrman RE, Kleigman RM, Jenson HB, et al., eds. *Nelson Textbook of Pediatrics.* 18th ed. Philadelphia: WB Saunders; 2007:1557–1559.

A.5. How would you treat this infant?

Medical management of infant with pyloric stenosis is of acute urgency and should be taken early and vigorously. The principles of management can be grouped under the following three categories: supportive therapy, to stabilize the patient; diagnostic tests, to confirm the diagnosis and to monitor therapy; and surgery as the corrective therapy.

Supportive therapy

- Circulatory support
- Correction of electrolyte imbalance
- Prevention of aspiration

Fluids

The infant with pyloric stenosis is hypovolemic and dehydrated secondary to persistent vomiting. Dehydration severity can vary from mild hypovolemia to circulatory shock. The following parameters are good indicators of dehydration severity:

- Physical appearance—skin turgor, parched mucous membranes, sunken fontanels, sunken eyeballs
- Blood pressure—decreased
- Pulse—increased
- Urine output—decreased
- Weight (birth and present) and weight loss

Quantitative assessment of these parameters gives a fair estimate of the amount of total body fluid depletion. A wide-bore intravenous cannula should be placed and an infusion started immediately to correct the deficits and provide maintenance fluids.

Electrolytes

The patient is alkalotic, hypokalemic, hypochloremic, and hyponatremic and must be provided with necessary ions to replenish the deficit. Albumin or Ringer's lactate may be used to treat the shock first. Next, the deficit should be corrected; 0.45% to 0.9% saline in 5% to 10% dextrose. Potassium (usually 40 mEq per L) must be added to this to correct hypokalemia and aid in the correction of alkalosis. However, potassium infusion should be withheld until satisfactory renal function is established. Fluid therapy should be continued until the infant is rehydrated and serum bicarbonate concentration is <30 mEq per dL, which implies that the alkalosis has been corrected.

Prevention of aspiration

A nasogastric tube should be inserted to thoroughly empty the stomach, and the upper airway reflexes should be preserved.

Diagnostic tests

- To assess the severity of fluid and electrolyte derangement and to monitor therapy, the following should be evaluated: complete blood count, serum electrolytes, blood gases, blood urea nitrogen, electrocardiogram (for marked hypokalemia)
- To confirm the diagnosis—barium swallow, ultrasound imaging

Surgery

Pyloromyotomy is the definitive treatment for these infants. Ramstedt pyloromyotomy through a right upper quadrant transverse incision has been the traditional treatment for hypertrophic pyloric stenosis. Recently, laparoscopic and circumumbilical approaches have been introduced as alternative methods to improve cosmesis, but concerns about greater operative times, costs, and complications remain. Surgery should be carried out early, but only after the patient has been stabilized satisfactorily.

Behrman RE, Kleigman RM, Jenson HB, et al., eds. *Nelson Textbook of Pediatrics*. 18th ed. Philadelphia: WB Saunders; 2007:1557–1559.

Blatnik JA, Ponsky TA. Advances in minimally invasive surgery in pediatrics. *Curr Gastroenterol Rep*. 2010;12(3):211–214.

A.6. How would you determine fluid replacement in a newborn, and what fluids would you use?

The general principles of fluid therapy are based on fluid maintenance, correction of deficits, and replacement of losses.

Maintenance fluids

In the newborn maintenance fluids are as follows:

- First 48 hours of life—75 mL/kg/day or 3 mL/kg/hour
- 2 days to 1 month—150 mL/kg/day or 6 mL/kg/hour
- 1 month onward (up to 10 kg)—100 mL/kg/day or 4 mL/kg/hour

Estimation of the degree of dehydration in a newborn is shown in Table 40.2.

The maintenance fluids take into account the fluid losses occurring normally through the kidney, bowel, skin, and lungs. At birth, the kidney is still undergoing maturation and what may be called "a glomerular imbalance" exists. What it implies is that some mature glomeruli may be connected to the immature tubules and vice versa. Hence, the kidney is functionally limited at birth but undergoes rapid maturation during the first week of life.

Electrolytes

The newborn is an obligate sodium loser as well as a poor tolerator of excessive sodium overload. The maintenance electrolytes are as follows:

- Sodium—3 to 5 mEq/kg/day
- Potassium—2 to 3 mEq/kg/day
- Chloride—1 to 3 mEq/kg/day

Table 40.2 Estimation of the Degree of Dehydration in a Newborn

	MILD	MODERATE	SEVERE
Percent fluid loss	5	10	15–20
Skin turgor	Poor	Very poor	Parched
Mucous membrane and tongue	Dry	Dry	Parched
Fontanelle and eyes	normal	Sunken fontanelle	Sunken eyes
Urine	Concentrated oliguria	Oliguria	Oliguria, anuria
Pulse	Normal	Tachycardia	Marked tachycardia
Blood pressure	Normal	Hypotension	Marked hypotension, shock

Correction of deficits

Deficits take into account the previous unreplaced losses because of a period of no intake by mouth and dehydration resulting from increased losses (e.g., from vomiting, diarrhea, and increased body temperature). The amount of deficit can be assessed by physical examination (see Table 40.2), body weight loss, and hematocrit.

Replacement of losses

Replacing losses covers ongoing abnormal losses not covered by maintenance fluids. Intraoperatively, it covers evaporative losses from the operative site, third spacing, and losses from the lungs if dry gases are used in nonrebreathing circuits (Table 40.3).

The younger and more physically immature the patient, the higher skin permeability, the ratio of body surface area to weight and the metabolic demand. In addition, the use of radiant warmers and phototherapy increases insensible water loss.

Miller RD, ed. *Miller's Anesthesia.* 7th ed. Philadelphia: Churchill Livingstone; 2010:2559–2597.

A.7. How would you correct the metabolic alkalosis in this patient?

To correct the metabolic alkalosis in this patient, the underlying electrolyte derangements (hyponatremia, hypokalemia, and hypochloremia) must be corrected. We correct the deficits by using calculated volumes of 5% dextrose in normal saline or Ringer's lactate solution, which helps to restore sodium and chloride mainly. Dextrose, 5% with one-fourth strength normal saline, may be used to provide maintenance fluids. Once renal function is established, potassium supplements are added to the infusion. Depending on the deficit, this therapy can require anywhere from 12 to 72 hours. In severely alkalotic patients, HCl and NH_4Cl have been used to correct the derangement. However, we have rarely found it necessary.

Barash PG, Cullen BF, Stoelting RK, eds. *Clinical Anesthesia.* 6th ed. Philadelphia: Lippincott Williams & Wilkins; 2009:1193–1205.

A.8. What causes a cardiac murmur?

Cardiac murmurs are caused by turbulent blood flow across cardiac valves or septal defects and are audible sound waves in the range of 20 to 2,000 Hz. Most murmurs in pediatric patients are normal or innocent, occurring in almost 50% of all school-aged children but must be distinguished from those murmurs associated with significant structural heart disease. Auscultation is critically important in diagnosing these murmurs; however, echocardiography remains the gold standard.

Table 40.3 Fluid Requirement to Replace Intraoperative Fluid Losses (Except Blood Loss) in the Newborn

	FLUID REPLACEMENT (mL/kg/hr)
Minor surgery (e.g., herniorrhaphy)	1–3
Moderate surgery (e.g., pyloromyotomy)	3–5
Major surgery (e.g., intestinal)	5–7
Respiratory water loss due to dry gases	2

Allen HD, Driscoll DJ, Shaddy RE, et al. *Moss and Adams' Heart Disease in Infants, Children, and Adolescents*. 7th ed. Philadelphia: Lippincott Williams & Wilkins; 2008:58–65.

Pelech AN. The cardiac murmur. When to refer? *Pediatr Clin North Am*. 1998;45:107–122.

B. Preoperative Evaluation and Preparation

B.1. How would you evaluate this patient preoperatively?

The following information is necessary in evaluating this patient:

History

Onset of illness, frequency and amount of vomiting, last feeding, diarrhea, urine output, activity of the newborn (active or lethargic), and birth weight.

Physical examination

Present body weight (to determine the weight loss), temperature, signs of dehydration (skin turgor, mucous membranes, fontanels, eyeballs, blood pressure, pulse, color, and volume of urine), muscle tone, and level of consciousness.

Laboratory findings

Complete blood count, electrolytes, blood urea nitrogen and blood sugar, urinalysis, and arterial blood gases.

Based on the data available, we can determine the fluid and electrolyte status of the patient and correct these accordingly to stabilize for surgery and anesthesia.

B.2. How would you evaluate a heart murmur?

Heart murmurs can be innocent or organic. By definition, innocent murmurs occur in the absence of structural or physiologic cardiac disease. The clinical diagnosis of a normal or innocent murmur should occur in the setting of an otherwise normal history, physical examination, and appearance. The presence of a family history of hypertrophic cardiomyopathy; congenital cardiac disease; or unexplained infant, childhood, or early adult death is particularly worrisome. Perinatal history of prematurity, maternal diabetes, drug or toxin ingestion, fetal distress, and clearly definable chromosomal disorders have particular cardiorespiratory relevance. The initial approach to the evaluation of the cardiovascular system should include an assessment of the cardiorespiratory system functionality as a pump and delivery system. An index of exercise or play capacity should be sought as a component of assessing growth and development. The author would ask about exercise tolerance, shortness of breath, cyanotic episodes, growth (because congestive heart failure may manifest as failure to thrive), and symptoms of congestive heart failure.

Allen HD, Driscoll DJ, Shaddy RE, et al. *Moss and Adams' Heart Disease in Infants, Children, and Adolescents*. 7th ed. Philadelphia: Lippincott Williams & Wilkins; 2008:58–65.

B.3. How would you differentiate between functional versus organic murmur?

Normal murmurs of childhood are comprised of five systolic and two continuous types but never solely diastolic (Table 40.4). A functional murmur is usually soft, 1/6 or 2/6, and never associated with palpable thrill. Pathologic murmurs are usually louder, 3/6 or greater and are associated with other cardiovascular pathologic features.

Table 40.4 Innocent Murmurs of Childhood

SYSTOLIC MURMURS	CONTINUOUS MURMURS
Vibratory Still's murmur	Venous hum
Pulmonary flow murmur	Mammary arterial souffle
Peripheral pulmonary artery stenosis murmur	
Supraclavicular systolic murmur	
Aortic systolic murmur	

Allen HD, Driscoll DJ, Shaddy RE, et al. *Moss and Adams' Heart Disease in Infants, Children, and Adolescents*. 7th ed. Philadelphia: Lippincott Williams & Wilkins; 2008:58–65.

B.4. What are the types of VSD? What type of shunt do they cause?

One common classification of VSD is based on anatomic location.

- Type I defects, or supracristal defects (5% of all VSDs), are outflow defects located above the crista supraventricularis just under the annulus of aorta.
- Type II defects, or infracristal defects (80% of all VSDs), are lower in membranous septum beneath the crista supraventricularis.
- Type III defects, or canal type (11% incidence), are inlet VSDs that accompany complete atrioventricular canal. They result from partial failure of the endocardial cushions to fuse.
- Type IV, or muscular, defects (2% to 7% incidence), probably results from excessive resorption of septal tissue during the muscular septal formation. They may be located anywhere in the muscular septum and may be multiple (also known as the swiss cheese defect).

VSD is left-to-right shunt. Pathophysiologic effects of VSD include left-to-right shunting, pulmonary hypertension, and heart failure resulting from volume overload.

Allen HD, Driscoll DJ, Shaddy RE, et al. *Moss and Adams' Heart Disease in Infants, Children, and Adolescents*. 7th ed. Philadelphia: Lippincott Williams & Wilkins; 2008: 667–675.

B.5. What are the risks of surgery and anesthesia in a patient with VSD?

Infective endocarditis is a complication of most congenital cardiac anomalies, so the patient requires antibiotic prophylaxis. There is also risk of increasing the flow in the shunt or reversing the flow in the shunt, resulting from acute and persistent increases in systemic vascular resistance or decreases in pulmonary vascular resistance causing hypoxemia and congestive heart failure. Right ventricular infundibular hypertrophy may be present in the patients with a VSD. Normally, this is a beneficial change, because it increases the resistance to right ventricular ejection, leading to decrease in magnitude of the left-to-right shunt. Nevertheless, perioperative events that exaggerate this obstruction to right ventricular outflow, such as increased myocardial contractility or hypovolemia, must be minimized. Therefore, these patients are often

anesthetized with a volatile anesthetic. In addition, intravascular fluid volume should be maintained by prompt replacement of blood loss. During the anesthetic, a normal end-tidal carbon dioxide should be maintained and routine air bubble precautions should be taken.

Hines RL, Marschall KE, eds. *Stoelting's Anesthesia and Co-existing Disease*. 5th ed. Philadelphia: Churchill Livingstone; 2008.

B.6. How would you prepare this patient rapidly for emergency surgery? Is surgical intervention an acute emergency in this case?

Hypertrophic pyloric stenosis is a medical emergency and not a surgical emergency. Therefore, no newborn should be subjected to the additional hazards of anesthesia and surgery until stabilized medically.

Behrman RE, Kleigman RM, Jenson HB, et al., eds. *Nelson Textbook of Pediatrics*. 18th ed. Philadelphia: WB Saunders; 2007:1557–1559.

B.7. How would you prepare this patient for anesthesia?

Fluid and electrolyte replacement should be accomplished satisfactorily; this may take anywhere from 12 to 72 hours depending on the patient's status. The next step is to empty the stomach through a wide-bore nasogastric tube, lavaging out the gastric contents and any leftover barium. Alternatively, an oral-gastric approach allows for passage of a tube with wider lumen that ensures better stomach emptying. Premedication is usually atropine (0.01 to 0.02 mg per kg) intravenous or intramuscular if the patient does not have intravenous line.

Davis PJ, Cladis FP, Motoyama EK, eds. Clinical management of specialized surgical problem. In: *Smith's Anesthesia for Infants and Children*. 8th ed. Philadelphia: Mosby; 2011:750–751.

Gregory GA, ed. *Pediatric Anesthesia*. 4th ed. New York: Churchill Livingstone; 2002:101, 579–580.

C. Intraoperative Management

C.1. What induction–intubation sequence would you use?

These children should arrive to the operating room with an intravenous access. Standard monitors are placed. The stomach is emptied by inserting an orogastric tube after (atropine may be used as premedication). Because the stomach may not be completely emptied, a rapid-sequence induction and intubation with cricoid pressure is highly recommended. Nevertheless, a recent survey of anesthetists in the United Kingdom revealed that 66% of all inductions were performed intravenously with only 56% of cases applying cricoid pressure. There is also some controversy regarding the appropriateness of awake intubations in this situation. A recent study comparing awake, rapid-sequence, or modified rapid-sequence induction demonstrated faster and more successful tracheal intubations in babies whose vocal cords were paralyzed using cisatracurium (0.4 to 0.5 mg per kg), vecuronium (0.1 to 0.2 mg per kg), or rocuronium (0.6 to 1 mg per kg).

The patient can be induced with a mixture of 50% O_2 and 50% N_2O and sevoflurane or halothane, with spontaneous ventilation and gentle assist through the cricoid pressure

as respiration is depressed. The trachea is intubated with muscle relaxant but can be intubated without muscle relaxant if sufficient deeper planes of anesthesia are achieved. Awake intubation may be accomplished in skillful hands in a lethargic neonate or in a critically sick infant. In most cases, however, neonates presenting for this procedure are fit and do not require awake intubation, which can be more traumatic.

Davis PJ, Cladis FP, Motoyama EK, eds. Clinical management of specialized surgical problem. In: *Smith's Anesthesia for Infants and Children*. 8th ed. Philadelphia: Mosby; 2011:750–751.

Zelicof-Paul A, Smith-Lockridge A, Schnadower D, et al. Controversies in rapid sequence intubation in children. *Current Opin Pediatr*. 2005;17:355–362.

Zöhr M. Anesthesia for the child with full stomach. *Current Opin in Anesthesiology*. 2007; 20(3):201–203.

C.2. What are the anatomic characteristics of the airway in the newborn, and how do they differ from those in the adult?

The special characteristics of the upper airway in the newborn are as follows:

- Nasopharynx—narrow nasal passages, obligate nasal breathers
- Oropharynx—large tongue, long and pendulous epiglottis
- Larynx—the distinctive features shown in Table 40.5

It is apparent, therefore, that the newborn who has low respiratory reserve can develop airway obstruction easily. The infant may present problems during intubation and tolerate airway trauma poorly.

Comparative anatomy of the larynx and trachea in the newborn and the adult is shown in Table 40.5.

Davis PJ, Cladis FP, Motoyama EK, eds. Induction, maintenance, and recovery. In: *Smith's Anesthesia for Infants and Children*. 8th ed. Philadelphia: Mosby; 2011:365–394.

C.3. How do you determine the size of an endotracheal tube in a pediatric patient?

The two parameters of endotracheal tube sizes are the tube length and diameter, depending on the age of the child, as shown in Table 40.6. However, these are approximate sizes and one must have one size bigger and one size smaller tube available when selecting

Table 40.5 Comparative Anatomy of the Larynx and Trachea in the Newborn and the Adult

ANATOMIC FEATURES	NEWBORN	ADULT
Size	4 cm	10–13 cm
Shape	Funnel	Cylindrical
Position of the glottis	C3–4	C6
Narrowest point	1 cm below vocal cords	At vocal cords
Vocal cords	Slanting anteriorly	Transverse or slightly slanting posteriorly
Mucous membrane	Loose (swells easily)	More firmly bound

Table 40.6 Endotracheal Tube Size for Pediatric Patient

AGE	LENGTH	INTERNAL DIAMETER (MM)	FRENCH SIZES
Newborn	10	3.0	14
6 mo	12	3.5	16
1 y	14	4.0	18
2 y	15	4.5	20
4 y	16	5.0	22
6 y	17	5.5	24
8 y	18	6.0	26
10 y	19	6.5	28
12 y	20	7.0	30

any tube size. A simple way to remember these numbers is to know the sizes at newborn, 6 months, and 1 year. Between 2 and 12 years the following guide may be used:

- Tube length from tip to incisor teeth (cm) = 11 + age in years
- Tube internal diameter (mm) = 4 + age/4
  French size (French) = 18 + age
  External circumference (French) = ID (mm) × 4 + 2
  (French size means external circumference in millimeters, which equals π times external diameter; π = 3.1416)

Davis PJ, Cladis FP, Motoyama EK, eds. Induction, maintenance, and recovery. In: *Smith's Anesthesia for Infants and Children*. 8th ed. Philadelphia: Mosby; 2011:365–394.

C.4. What anesthesia system would you use and why?

We employ the circle system with alight circuit. The circle system is more advantageous because it maintains heat and humidification better and offers the freedom of choosing varying gas flows. The controversy about the increased resistance in adult system is discounted by the fact that the respiration is assisted or controlled intraoperatively. Newer anesthesia machines use valves with much less resistance than older models. Dead space in these systems is no more than that of the Mapleson circuits.

Dorsch JA, Dorsch SE. *Dorsch & Dorsch Understanding Anesthesia Equipment*. 5th ed. Philadelphia: Lippincott Williams & Wilkins; 2008:209–218.

C.5. What are the advantages and disadvantages of commonly employed nonrebreathing systems?

Commonly used nonrebreathing systems include Bain Breathing circuit (Mapleson D system) and Jackson-Rees modification of Ayre's T-piece. They offer the following advantages and disadvantages:

Advantages

- Minimal dead space
- No valves, low resistance
- Lightweight

- Reservoir bag to assist ventilation
- Good appreciation of patient's respiratory exchange

Disadvantages

- High flow of fresh gases required
- Low flows may allow rebreathing of gases without CO_2 absorption
- Loss of heat and humidity because of high flow of cold, dry gases (Bain's circuit allows some heating of inspired gases by surrounding fresh gas flow tubing with expired gas tubing)
- Scavenging problems of waste gases

Dorsch JA, Dorsch SE. *Dorsch & Dorsch Understanding Anesthesia Equipment*. 5th ed. Philadelphia: Lippincott Williams & Wilkins; 2008:191–208.

C.6. How would you monitor this patient intraoperatively?

Monitoring should include blood pressure, electrocardiogram, rectal temperature, precordial stethoscope, pulse oximeter, and an end-tidal CO_2 monitor.

C.7. How does the pulse oximeter function?

The commonly used pulse oximeter (Nellcor pulse oximeter Model 100) combines the scientific principles of spectrophotometric oximetry and plethysmography. Light of two wavelengths, 660 nm (red) and 925 nm (infrared), is emitted by a pair of light-emitting diodes and is passed through the tissue being measured to a photodetector. Because the saturated hemoglobin absorbs more blue light than unsaturated hemoglobin, the absorption of light for each color is an indication of the ratio of oxygen saturated blood to unsaturated blood. The pulsating vascular bed, by expanding and relaxing, creates a change in light-path length that modifies the amount of light detected. The microprocessor-controlled circuitry in the unit senses the pulsatile waveform, which is solely produced by the arterial blood, thereby allowing measurement of pulse rate and arterial saturation. The oximeter is reliably accurate in 50% to 100% saturation range.

Barash PG, Cullen BF, Stoelting RK, et al. eds. *Clinical Anesthesia*. 6th ed. Philadelphia: Lippincott Williams & Wilkins; 2009:700–702.

Instruction manual. *Nellcor pulse oximeter model N-100, instruction manual*. Hayward, CA: Nellcor Inc; 1984.

Tremper KK, Barker SJ. Pulse oximetry. *Anesthesiology*. 1989;70:98–108.

C.8. What factors affect the measurement of oxygen saturation by the pulse oximeter?

Dysfunctional hemoglobin, as with carboxyhemoglobin and methoxyhemoglobin, can affect the accuracy of the oximeter. Intravascular dyes such as cardiogreen can also interfere with the accuracy of the instrument. Skin color, tissue thickness, venous blood, light intensity, and ambient light do not affect the accuracy of the instrument because they do not pulse.

Barash PG, Cullen BF, Stoelting RK, eds. *Clinical Anesthesia*. 6th ed. Philadelphia: Lippincott Williams & Wilkins; 2009:700–702.

Instruction manual. *Nellcor pulse oximeter model N-100, instruction manual*. Hayward, CA: Nellcor Inc; 1984.

Tremper KK, Barker SJ. Pulse oximetry. *Anesthesiology*. 1989;70:98–108.

D. Postoperative Management

D.1. What are the complications that can occur in the postanesthesia recovery period?

The patient should be carefully observed for signs of respiratory depression and periods of apnea secondary to combination of metabolic alkalosis, general anesthesia, and decreased body temperature. However, these infants do not appear to be at increased risk for postoperative apnea. Hypoventilation predisposes to atelectasis. Patient should be awake and responsive to avoid aspiration. Severe hypoglycemia resulting from depletion of liver glycogen stores has been reported 2 to 3 hours after surgery. Postextubation "croup" is a potentially dangerous complication in this age group.

Davis PJ, Cladis FP, Motoyama EK, eds. Associated problems in pediatric anesthesia. In: *Smith's Anesthesia for Infants and Children*. 8th ed. Philadelphia: Mosby; 2011:1282–1288.

Hammer G, Hall S, Davis PJ. Anesthesia for general abdominal, thoracic, urologic, and bariatric surgery. In: *Smith's Anesthesia for Infants and Children*. 7th ed. Philadelphia: Mosby; 2006:685–722.

D.2. How would you treat postextubation "croup" in this infant?

Treatment of the potentially catastrophic postextubation laryngeal edema should be immediate, vigorous, and carried out under direct observation of the anesthesiologists. It consists of the following:

- Increasing inspired oxygen concentration (50% to 60%)
- Humidification of inspired gases
- Adequate hydration using parenteral fluids
- Light sedation to calm the patient and allow for cooperation in therapy
- Avoidance of any significant respiratory depression
- Epinephrine through hand-held nebulizer and mask, 50 μg/kg/minute of active isomer
  - Racemic epinephrine (2.25%) 0.05 mL per kg diluted in 5-mL saline solution delivered in 10 minutes

Treatment should be given over 10 minutes and may be repeated every 30 minutes, as necessary. Rebound phenomenon may be expected approximately 2 hours after cessation of this therapy.

- Steroids—dexamethasone, 0.5 to 1 mg per kg intravenously
- Reintubation—if signs of deterioration or hypoxia appear
- Tracheostomy, if necessary—rarely, subglottic edema may be so rapid and so severe that tracheostomy is the only choice

The age group most likely to manifest this complication is 1 to 4 years. Infants younger than 1 year are at most risk, mainly because of the size of the airway. Fortunately, an infant of this age is most amenable to early and vigorous intervention and should always be treated as an emergency requiring the continued presence of and evaluation by a physician who is adept at securing an airway for the child.

CHAPTER 41

Inflammatory Airway Disease in Childhood: Laryngotracheobronchitis

MILES DINNER

A 3-YEAR-OLD BOY was brought to the emergency room because of respiratory distress. He was noted to have stridor with substernal retractions and excessive drooling. He complained of a sore throat and had a fever of 39.5° C (103.1° F).

A. Medical Disease and Different Diagnosis

1. What portion of the airway is affected in the croup syndrome and why?
2. What is stridor?
3. How does stridor correlate with anatomic location?
4. Define croup. What is the clinical presentation of laryngotracheitis?
5. What is the differential diagnosis of acute upper airway obstruction in children?
6. What is bacterial tracheitis?
7. What congenital problems can mimic features of croup?
8. How is the severity of croup assessed?
9. What is the medical management of croup? Does this have implications for the anesthesiologist?
10. What is epiglottitis? What are its common causes? What is the incidence?
11. What are the clinical manifestations of epiglottitis?
12. How is the diagnosis of epiglottitis made?
13. What is postextubation croup? How is it managed?
14. What are the nonacute causes of partial airway obstruction in children?

B. Preoperative Evaluation and Preparation

1. Is intubation always required in children with epiglottitis?
2. Why is general anesthesia administered to a child with epiglottitis?
3. How would you prepare the patient for anesthesia?

C. Intraoperative Management

1. How is the airway of the child with epiglottitis best secured?
2. How would you induce anesthesia?
3. Should a child with epiglottitis undergo a rapid-sequence induction?
4. Is awake intubation a practical alternative to secure the patient's airway?
5. What would you do if the airway cannot be secured with intubation?
6. Should this patient have a nasotracheal or orotracheal tube placed?
7. Shortly after intubation, frothy secretions were obtained on suctioning the endotracheal tube. What is the reason for this? How can this be treated?

D. Postoperative Management

1. How long should this patient remain intubated? What criteria determine extubation time?
2. How would you make this patient comfortable during the course of intubation?
3. What outcome can one expect for the child with acute epiglottitis?

A. Medical Disease and Differential Diagnosis

A.1. What portion of the airway is affected in the croup syndrome and why?

The subglottis is typically involved in infants and children presenting with classic croup. The *subglottis* is defined as the segment of the upper airway directly below the vocal cords fusing with the upper trachea. It contains pseudostratified columnar respiratory epithelium, which is loosely adherent and prone to swelling. Because this area is fully cartilagenized in childhood, it lacks the ability to expand and thus can produce early symptoms due to even small degrees of inflammation.

Sobol SE, Zapata S. Epiglottitis and croup. *Otolaryngol Clin North Am*. 2008;41:551.

A.2. What is stridor?

Stridor is the high-pitched adventitious sound produced in the respiratory cycle by the turbulent flow of respiratory gases through a segmental narrowing in the airway. It can be biphasic, inspiratory, or expiratory, depending on the anatomic location.

A.3. How does stridor correlate with anatomic location?

Inspiratory stridor is characteristic of laryngeal or supraglottic obstruction. Such conditions as laryngeal papillomatosis, laryngeal web, laryngomalacia, and vocal cord paresis produce inspiratory stridor. Expiratory stridor is usually typical of intrathoracic processes such as extrinsic tracheal compression by a vascular ring or mass, tracheomalacia, or bronchotracheitis. Biphasic stridor is indicative of lesions or infections involving both the larynx and subglottis such as the croup syndrome, subglottic stenosis, or intralaryngeal masses.

A.4. Define croup. What is the clinical presentation of laryngotracheitis?

Croup is a generalized term referring to infections of the upper respiratory tract with a characteristic cough, inspiratory stridor, and possible respiratory distress. Other terms, namely *laryngotracheobronchitis*, *spasmodic croup*, and *bacterial tracheitis*, are

interwoven within the croup syndrome but have specialized meanings. For instance, spasmodic croup suggests a noninfectious inflammatory process as opposed to the viral etiology of laryngotracheobronchitis. Most cases occur during the colder months. There is a 2:1 male to female prevalence. Also known as *laryngotracheobronchitis* because of the structures involved, croup is usually caused by the *Haemophilus parainfluenzae* virus type 1, although type 2 and 3 may cause disease. Recently, human corona virus has been implicated in croup. It affects children between 1 and 3 years of age, with a median age of 18 months. It manifests subacutely as an exacerbation of cold symptoms with low fever, barking cough, and hoarseness. Exudative inflammation of the upper airway may cause dyspnea and in extreme cases can lead to exhaustion and frank hypoxia. In most cases, it is self-limited and benign.

Rosychuk RJ, Klassen TP, Metes D, et al. Croup presentations to emergency departments in Alberta, Canada: a large population study. *Pediatric Pulmonology.* 2010;45:83–91.

Vander Hook L, Sue K, Ihorst G, et al. Human coronaviaus NL6S infection is associated with croup. *Adv Exp Med Biol.* 2006;581:485–491.

A.5. What is the differential diagnosis of acute upper airway obstruction in children?

A full differential for this condition involves a host of infectious causes. Among the most important are bacterial tracheitis, diphtheria, retropharyngeal abscess, peritonsillar abscess, measles, and Epstein-Barr viral infection. Other causes to be considered are thermal burns, foreign body aspiration, laryngeal fractures, angioneurotic edema, vocal cord paralysis, and uvulitis.

Wald EL. Croup, common syndromes and therapy. *Pediatr Ann.* 2010;39:15–21.

A.6. What is bacterial tracheitis?

This is a severe and potentially fatal disease of an infectious nature occurring as a consequence of infection with *Staphylococcus aureus*, various streptococcal species, and *Haemophilus (H) influenzae*. It occurs in colder weather in young children as a secondary complication of viral laryngotracheitis. Although presenting the same symptoms as epiglottitis, it tends not to evolve as rapidly, and generally does not have odynophagia and drooling, two characteristic signs of epiglottitis. Most of these children require intubation for thick and difficult-to clear-secretions and during endoscopy, subglottic edema with mucosal ulceration is seen.

Wald, EL. Croup: Common syndromes and therapy. *Pediatr Ann.* 2010;39:15–21.

A.7. What congenital problems can mimic features of croup?

A host of anatomic problems can share similar signs and symptoms with the infectious agents causing airway compromise. It is only by the absence of fever and the chronicity of the situation that these are distinguishable. Vocal cord paralysis, laryngeal webs, laryngomalacia, subglottic masses (hemangiomas), and stenosis, as well as vascular anomalies are to be included.

Wald, EL. Croup: Common syndromes and therapy. *Pediatr Ann.* 2010;39:15–21.

A.8. How is the severity of croup assessed?

One evaluates the following parameters in assessing severity of the illness: (1) Work of breathing: Is there tachypnea and or retractions? (2) Chest wall motion: Is the tidal volume adequate with inspiration? (3) Overall appearance: Is the child cyanotic, obtunded, or comfortable? (4) Vocal quality: Is there stridor, diminished voice, or cry? Severe croup unresponsive to the medical therapy may require tracheal intubation. Once the diagnosis of croup has been established, the child is given a croup score, which helps determine therapy (Table 41.1).

Westley CR, Cotton EK, Brooks JG. Nebulized racemic epinephrine by IPPB for the treatment of croup: a double-blind study. *Am J Dis Child.* 1978;132:484.

A.9. What is the medical management of croup? Does this have implications for the anesthesiologist?

Mild croup is treated with inspired gas humidification, hydration, and oxygen to improve the attendant hypoxemia. Croup tents, croupettes, and blow-by oxygen are helpful. Steroids and racemic epinephrine are the prime modalities of therapy. If the patient has moderate retractions and appears dyspneic, 0.5 mL of a 2.25% racemic epinephrine solution in 2.5 mL of normal saline can be administered via nebulizer.

Airway resistance can be high with the reactive transudation and intraluminal narrowing. By vasoconstricting the arterioles of the mucosal vasculature, racemic epinephrine relieves edema. The epinephrine is prepared as a mixture of the L and D isomers to limit cardiac stimulation. Patients improve markedly, but the clinician should be cautioned that the relief may be short lived and rebound airway compromise may occur after the epinephrine wears off. The *Beta* 2 activity will cause bronchial smooth muscle relaxation. Avoid racemic epinephrine in children with glaucoma and ventricular outflow obstruction.

Dexamethasone and budesonide when given early in viral croup can be beneficial in reducing inflammation and alleviating symptoms. This takes time to work, however, requiring hours for effective onset. The pediatric dose of dexamethasone is 0.6 mg per kg orally or intramuscularly. Clinical evaluation of topical steroids

Table 41.1 The Westley Croup Score

	0	1	2	3	4	5
Cyanosis	none	—	—	—	With agitation	At rest
Level of Consciousness	Normal, including sleep	—	—	—	—	Disoriented
Stridor	None	With agitation	At rest	—	—	—
Air entry	Normal	Decreased	Markedly decreased	—	—	—
Retractions	None	Mild	Moderate	Severe	—	—

Mild croup has a score <2, moderate is between 3 and 7, and severe has a score >8.

such as budesonide has shown effective improvement, especially with laryngeal edema. Nebulized budesonide has been shown to be as effective as dexamethasone in treatment.

Behrman RE, Kliegman RM, Jensen HB, et al., eds. *Nelson Textbook of Pediatrics*. 18th ed. Philadelphia: WB Saunders; 2007:1763.

Eboriadov M, Chryssanthopoulou D, Stamodis P, et al. The effectiveness of local corticosteroid therapy in the management of mild to moderate croup. *Minerva Pediatr*. 2010:62:23–28.

A.10. What is epiglottitis? What are its common causes? What is the incidence?

Epiglottitis is an inflammation of the epiglottis usually secondary to an infectious process. It can involve other supraglottic structures such as the arytenoid, false cords, and posterior tongue leading to obstruction of the airway. Progression of swelling can rapidly lead to complete airway occlusion and death. Table 41.2 contrasts epiglottitis with croup. Epiglottitis is most often bacterial in origin. The causative agent used to be *H. influenzae* type B. However the vaccine has resulted in a remarkable decline. *Streptococcus pneumoniae* also has been infrequently associated with epiglottitis, and recently, group A beta-hemolytic streptococci have been on the increase. Burn injury, neoplastic infiltration, caustic ingestion, lymphoproliferative disease, and angioneurotic edema are other causes. The incidence has declined to 1.8 per 10,000 admissions at the Children's Hospital of Philadelphia after the *H. influenzae* B vaccine. In one study, five cases of epiglottitis occurred among children who had been immunized.

A recent retrospective review reaffirms that epiglottitis remains a significant problem in the United States, with nearly 4,000 admissions in 2006. The demographics of the disease have shifted away from that of predominantly pediatric nature to one of adulthood. The mean age in the study period from 1998 to 2006 surprisingly was 45 years old and the mortality was 36%.

Table 41.2 Characteristics of Croup and Epiglottitis

	CROUP	EPIGLOTTITIS
Etiology	Parainfluenza virus	*Haemophilus influenzae*
Age	4 months to 2 years	2 to 5 years
Onset	Subacute exacerbation of preexistent URI	Acute
Temperature	Low-grade fever	High fever
Course	Usually mild, stridor may worsen at night	Rapid progress of symptoms
Symptoms	Barky cough, stridor	Dysphagia, sore throat Dysphonia, respiratory distress

URI, upper respiratory infection

A.11. What are the clinical manifestations of epiglottitis?

This illness presents acutely in the otherwise healthy child between 2 and 5 years of age with fever as high as 40° C. Within a few hours, the epiglottic inflammation progresses and the child becomes dyspneic. The child sits forward to use the accessory muscles of respiration and complains of a fullness and pain in the throat. Speech sounds are muffled, known as a "hot potato voice." Salivation often is characteristic and swallowing is difficult. The child appears anxious and concentrates only on breathing. The barking cough of croup usually is absent. The older child will assume a tripod posture with the neck extended to maximize air entry. As the child fatigues, cyanosis leading to complete asphyxia may ensue without intervention. Inspiratory effort is maximal with severe airway compromise, and negative pressure pulmonary edema can occur. Chest auscultation may reveal decreased breath sounds.

Kliegman RE, Behrman RE, Jensen HB, et al., eds. *Nelson Textbook of Pediatrics*. 18th ed. Philadelphia: WB Saunders; 2007:1763.

A.12. How is the diagnosis of epiglottitis made?

Acute epiglottitis is a dire emergency and any child whose clinical presentation warrants the diagnosis of epiglottitis must be evaluated promptly in a hospital. Pharyngoscopy to visualize an inflamed epiglottis should not be attempted in an office setting, because this can stimulate upper airway reflexes and lead to increasing dyspnea. All medical centers should have in place a management protocol that standardizes the approach to this rapidly progressive and fatal disease and that involves a team of physicians and nurses from the specialties of pediatrics, otolaryngology, and anesthesiology. A logical approach is as follows:

- The child is kept calm with a parent in attendance at all times. Supplementary oxygen, maintenance of a sitting position, and reassurance are essential.
- If the patient clinically conforms to a classical presentation of epiglottitis, the operating room is alerted and the child is taken there immediately for intubation.
- With other diagnostic considerations, such as a foreign body in the upper airway, retropharyngeal abscess, congenital anomalies, and croup, the child may be escorted to radiology. The time taken for the x-ray examination obviously should be avoided in the critically ill child. A physician skilled in airway management should accompany the child with all necessary resuscitation equipment available.
- The classic thumb sign on a lateral x-ray film is an aptly named shape seen with epiglottic enlargement. However, the absence of this sign does not eliminate the diagnosis of epiglottitis. Croup is distinguished by the steeple sign representing a uniform narrowing of the subglottic airway by inflammation. Recently, magnetic resonance imaging has demonstrated the standard measurements for the hypopharyngeal space in various age groups, and it has correlated this measurement with the change produced by epiglottic inflammation. This may be a useful tool in the future to assess the severity of airway involvement.
- Laboratory evidence is nonspecific, although a high white count with bands and polymorphonuclear leukocytes is more suggestive of epiglottitis than of croup.
- Fiber-optic pharyngoscopy can be most effective if performed gently by a skilled examiner; it immediately confirms or eliminates the diagnosis. Do not perform a laryngoscopy if anxiety is increased by the procedure and hence exacerbates airway obstruction.

Kliegman RE, Behrman RE, Jensen HB, et al., eds. *Nelson Textbook of Pediatrics*. 18th ed. Philadelphia: WB Saunders; 2007:1763.

Shorten GD, Opie NJ, Graziotti P, et al. Assessment of upper airway anatomy in awake, sedated and anaesthetized patients using magnetic resonance imaging. *Anaesth Intensive Care*. 1994;22:165.

A.13. What is postextubation croup? How is it managed?

Anesthesiologists are often in the position of treating patients with postextubation airway edema, which resembles croup in its symptomatology.

Pediatric patients undergoing general endotracheal anesthesia may mimic many of the physical signs of the croup syndrome following extubation. The tracheal and subglottic mucosa have become irritated by the plastic tube, which initiates an inflammatory response, causing airway luminal narrowing. Because airway resistance is inversely proportional to the fourth power of the tracheal radius (with turbulent flow, this increases to the fifth power), the pediatric airway is especially compromised by edema. Halving the lumen will increase laminar airflow resistance 16 times.

Postextubation croup may manifest more frequently in a patient who has received large quantities of fluid or transfusions; maintained unusual or strained lateral head positioning; has a history of smoke inhalation, restrictive congenital anomalies such as a tracheoesophageal fistula, or acquired subglottic stenosis secondary to prolonged intubation as a neonate; has a coexistent upper respiratory infection, especially bronchitis; or has a cuffed endotracheal tube with high cuff pressure. The air leak test, which gauges the pressure needed to generate an audible leak in the presence of an endotracheal tube, may be predictive of postextubation stridor in children over 7 years of age.

Management involves reducing airway constriction by administering nebulized racemic epinephrine, steroids, and humidification of inspired gases. On occasion, reintubating with a soft endotracheal tube one-half to one size smaller than previously used is necessary until the inflammation subsides. Note that topical lidocaine ointment can have vasodilatory actions and should not be used in patients with postextubation croup.

A.14. What are the nonacute causes of partial airway obstruction in children?

Several congenital anomalies are associated with respiratory difficulties. These can be subdivided into intrinsic and extrinsic pathologies as follows.

Extrinsic pathologies

- Cystic hygroma—a proliferation or expansion of lymphatic channels, usually in the cervical region, which can compress the airway and lead to enlargement of the tongue.
- Vascular anomalies—abnormalities of the aortic arch usually caused by aberrant vessels lead to compression of the airway. This is often position dependent and may be responsible for coughing and wheezing when the patient is supine.
- Neoplastic compression of the trachea by lymphoma, hemangioma, neurofibromatosis, rhabdomyosarcoma, and other neural tumors in the mediastinum may occur and enlarge or compress airway structures.

Intrinsic pathologies

- Subglottic stenosis—especially as acquired in previously intubated neonates. This form of airway narrowing occurs below the vocal cords, and it can lead to marked airway obstruction with respiratory infections. The congenital form may not be appreciated until an upper respiratory infection is present, when stridor may occur.
- Vocal cord paralysis—considered the second most common laryngeal anomaly in children, it is associated with the Arnold-Chiari malformation.
- Laryngeal structural anomalies—webs, laryngoceles, and cysts.

Perry H. Stridor. In: Fleisher GR, Ludwig S, Henretig FM, eds. *Textbook of Pediatric Emergency Medicine*. 5th ed. Philadelphia: Lippincott Williams & Wilkins; 2006.

B. Preoperative Evaluation and Preparation

B.1. Is intubation always required in children with epiglottitis?

Adult patients often can be managed under very vigilant intubation provided that there is no impending obstructive danger. However, contemporary practice warrants the establishing of an airway with an endotracheal tube in the vast majority of infants and children. Nasotracheal intubation most often is used for ease of maintaining the child's comfort and safety. Endoscopic evaluation using appropriate fiber-optic airway endoscopy is a major advance in the management of epiglottitis.

Acevedo JL, Lander L, Choi S, et al. Airway management in pediatric epiglottis, a national perspective. *Otolaryngol Head Neuro Surg*. 2009;140:548–551.

Damm M, Eckel HE, Jungehulsing M, et al. Airway endoscopy in the interdisciplinary management of acute epiglottitis. *Int J Pediatr Otorhinolaryngol*. 1996;38:41.

B.2. Why is general anesthesia administered to a child with epiglottitis?

General anesthesia facilitates several activities. It gives the examiner a thorough look at the supraglottic area, which would be impossible and dangerous in the awake child. In addition, endotracheal intubation can be accomplished under controlled, relaxed conditions without trauma and laryngospasm. Intubation can be difficult because of the swelling and deformation of the paraepiglottic tissues. Clinicians who have no experience with this unusual appearance will find it easier to visualize landmarks and secure the airway when the patient is in a surgical plane of anesthesia.

Diaz JH. Croup and epiglottitis in children. *Anesthesiology*. 1985;64:628.

Jenkins IA, Saunders M. Infections of the airway. *Pediatric Anesth*. 2009;19:118–130.

B.3. How would you prepare the patient for anesthesia?

Expedience is crucial. Once the diagnosis is made and the operating room alerted, the child is transported accompanied by his or her parents and a physician with airway supportive equipment. It is not necessary to place an intravenous line, because this can be done more easily under anesthesia without upsetting the child. Any maneuver that causes the child to cry will potentially interfere with breathing. The child should, therefore, be kept calm and constantly reassured. Nasal prong or face tent oxygen should be provided and portable pulse oximetry should be used.

Equipment, which is prepared in the operating room, includes a suitable mask and endotracheal tube, sized two gauges (1-mm diameter) smaller than normally expected. Lidocaine, succinylcholine, atropine, and ketamine in convenient dilutions should be readily available. A cricothyrotomy tray should be available as a precaution.

The parent is dressed in operating room attire to accompany the child into the operating room. Before induction, the parent is instructed on his or her role in comforting the child, encouraging complicity with mask breathing, and gently holding the child when the inhalation induction commences. The parent also should be told that as the child begins to fall asleep, he or she will be asked to leave the room. For anesthesiologists unaccustomed to the presence of parents in the operating room, the extra anxiety created by parental presence can be attenuated by having them depart just as the patient begins to get sleepy. When parents can provide their assistance in an emotionally controlled, supportive way, a smooth, safe anesthetic induction usually can be well facilitated. A Hudson mask can also be used if hooked up to the outflow portion of the anesthesia machine to facilitate mask induction.

Berry FA. Management of the pediatric patient with croup or epiglottitis. *ASA Annual Meeting Refresher Course Lectures*. Park Ridge, IL: American Society of Anesthesiologists; 1990:261.

Tan GM. New way to mask induce a child. *Paediatric Anesth*. 2002;12:742.

C. Intraoperative Management

C.1. How is the airway of the child with epiglottitis best secured?

Little debate occurs over the safety and efficacy of endotracheal intubation provided that supportive staff is readily available. The endotracheal tube should be sized down 0.5 mm or 1.0 mm due to the inherent swelling and to protect against postextubation complications. Thick, copious secretions must be cleared frequently to prevent obstruction, and the child must be sedated to tolerate the endotracheal tube and to keep it secure in place. In the smaller hospital without a pediatric intensive care facility or experienced personnel, a tracheotomy may be the safest route.

C.2. How would you induce anesthesia?

Verbal assurance is constantly given. The child is seated on the parent's lap in the operating room and is preoxygenated. Sevoflurane is a good choice of induction agent because it is less pungent than other irritative gases like desflurane and is usually well tolerated without a high incidence of laryngospasm, coughing, or other irritative reflexes. The inhalational agent should be initiated slowly and increased in concentration as tolerated. A flavored mask with a pleasant scent may be helpful to enlist the child's cooperation. As the child tires, the supine position is assumed. If there are any considerations of gastric content regurgitation either due to a recent meal or antecedent history of reflux, cricoid pressure is applied as a safeguard against aspiration. The patient may undergo a brief period of excitement during which care is taken not to be overly zealous with ventilatory assistance. Spontaneous, unassisted ventilation should continue as an intravenous line is started. Glycopyrrolate 0.01 mg per kg is given intravenously as an antisialagogue. Ventilatory assistance but not control can be initiated to limit hypercarbia. End-tidal gas analysis is monitored continually and the airway is adjusted to provide maximal tidal exchange. Sevoflurane concentration is increased as tolerated to 8%, provided cardiovascular stability is maintained to achieve adequate depth of anesthesia. Airway obstruction will decrease ventilation and anesthetic uptake, requiring longer induction time.

When the patient is in a deep plane of anesthesia (remember that the minimal alveolar concentration of sevoflurane in children is higher than in adults), a careful laryngoscopy is carried out. Paralysis is unnecessary in this deep plane of anesthesia. However, if several attempts are required with the possibility of the patient becoming light and reactive, a small dose of a neuromuscular blocker (e.g., rocuronium 0.4 mg per kg) will serve to maintain stable intubating conditions. This should be given only after it has been shown that the patient can be ventilated with a bag and mask.

Spalding MB, Ala-Kokko TI. The use of inhaled sevoflurane for endotracheal intubation in epiglottitis. *Anesthesiology*. 1998;89:1025.

C.3. Should a child with epiglottitis undergo a rapid-sequence induction?

In the child with a full stomach, a mask induction leaves the airway unprotected from aspiration of gastric contents. However, a rapid-sequence induction may predispose the patient to severe hypoxia and hypoventilation should the clinician not be able to intubate expediently. Because the supraglottic landmarks are distorted by erythema and edema, recognition of the glottic inlet is obscured. In the spontaneously breathing patient, small air movements and the resultant secretional bubbling may highlight the glottic opening. In addition, paralysis in no way secures ventilatability.

If the patient must be manually ventilated, it is possible to meet with complete obstruction secondary to invagination of the swollen supraglottic tissues into the laryngeal introitus. In such a case, positive end-expiratory pressure or the jaw-thrust maneuver may fail to correct the airway obstruction.

Should the child be too agitated to cooperate with an inhalational induction, an intramuscular dose of ketamine (2 to 3 mg per kg) will accomplish sedation and preserve ventilation. However, it may accentuate airway reflexes, and the clinician should be wary of laryngospasm. Videolaryngoscopy with the various available modalities has improved laryngeal visualization, but these remain limited in their use.

C.4. Is awake intubation a practical alternative to secure the patient's airway?

Some authors suggest awake intubation with topical anesthesia. In such cases, the anesthesiologist should be alerted to the possibility of adenoidal bleeding, difficult visualization, agitation, trauma, and compromised ventilation. Unless one has acquired great skill at awake pediatric intubation in the child with a normal airway, this technique should be avoided in these patients. In the adult, the awake glidescope intubation has been reported with success.

Diaz JH. Croup and epiglottitis in children. *Anesthesiology.* 1985;64:628.

Sinofsky AH, Milo SP, Scher C. The awake glidescopic intubation: an additional alternative to the difficult intubation. *Middle East Anesth.* 2010;20:743–746.

C.5. What would you do if the airway cannot be secured with intubation?

Preemptive caution is critical and an ENT (ear, nose, and throat) surgeon should be available. In the event that the airway is lost, percutaneous transtracheal ventilation can be performed. This involves inserting a needle through the cricothyroid membrane as follows. Localize the cricothyroid membrane and topically cleanse the area with antiseptic. Anesthetize the skin with lidocaine (if time permitting) and then insert a 16-gauge catheter (attached to needle) in the midline in the inferior portion of the cricothyroid membrane and directed caudally. Attach a 3-mL syringe to the needle barrel applying negative pressure. If the syringe contains a few milliliters of saline, air bubbles will be apparent when the trachea is entered. Following entry, advance the catheter into the trachea. Depending on the hub size, a 3.0-mm or 3.5-mm endotracheal tube adapter can be inserted into the catheter to interface with an Ambu bag. Alternatively, a 6.5-mm or 7.0-mm endotracheal tube adapter can be inserted into a 3-mL syringe without the plunger to interface with an Ambu bag or anesthesia circuit (Fig. 41.1). Jet ventilation can also be applied with high-pressure tubing keeping careful observation of respiratory dynamics and saturation. A tracheotomy in skilled hands also can be performed.

Delaney WA, Kaiser RE. Percutaneous transtracheal jet ventilation made easy. *Anesthesiology.* 1991;74:952.

Deutsch ES. Tracheotomy: pediatric considerations. *Respir Care.* 2010;55:1082–1090.

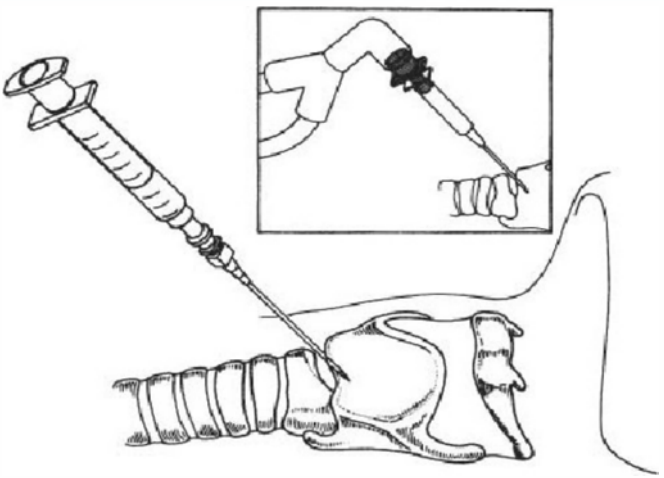

Figure 41.1 An emergency cricothyrotomy may be performed by passing a 14-gauge intravenous catheter through the cricothyroid membrane into the trachea. A 3-mL syringe with the plunger removed will accept a 15-mm endotracheal tube adapter that allows attachment of an oxygen-delivery system. (From Barash PG, Cullen BF, Stoelting RK, eds. *Clinical Anesthesia.* 4th ed. Philadelphia: Lippincott Williams & Wilkins; 2001:1035–1041, with permission.)

C.6. Should this patient have a nasotracheal or orotracheal tube placed?

The patient will better tolerate a nasal endotracheal tube for prolonged intubation. Oropharyngeal toilet also will be easier. However, because the intubation can be difficult with epiglottitis and may predispose the patient to the problems listed in section C.4, the orotracheal route is easier and safer. Once the airway is secured orally, a nasotracheal tube can be inserted with laryngoscopic guidance.

C.7. Shortly after intubation, frothy secretions were obtained on suctioning the endotracheal tube. What is the reason for this? How can this be treated?

Davis et al. describes 7% of these patients as having pulmonary edema after intubation. This phenomenon relates to the transudation into the alveoli during periods of increased transpulmonary pressure. This occurs especially during obstructed inspiration. If the obstruction is complete, it is referred to as the "Müller" maneuver. The high negative pressures are buffered by the decreased venous return during exhalation. However, relief of the airway obstruction facilitates the extravasation of fluid for an increased venous return.

Treatment of this negative pressure pulmonary edema requires positive end-expiratory pressure. Diuretics and fluid restriction are not required because this condition generally is self-correcting. This can be administered by nasal bilevel means, mask continuous pressure, or intubation.

Davis HW, Gartener JC, Galvis AG, et al. Acute upper airway obstruction: croup and epiglottitis. *Pediatr Clin North Am.* 1981;28:859.

D. Postoperative Management

D.1. How long should this patient remain intubated? What criteria determine extubation time?

Earlier studies have shown a mean intubation duration of 36 hours in 23 patients with a range of 19 to 67 hours. These patients were treated with ampicillin or chloramphenicol and the epiglottis was visualized before extubation. The current antibiotic regimen is cefazolin 75 to 100 mg/kg/day in three divided doses or clindamycin 30 to 40 mg/kg/day in three divided doses with the addition of a third-generation cephalosporin such as cefotaxime or ceftriaxone.

Criteria for extubation include an increased air leak around the endotracheal tube as well as decreased erythema and edema. Vernon and Sarnaik, however, feel that instrumentation and examination of the child is unnecessary and extubation at 36 to 48 hours can be accomplished easily in all patients. Hopkins recommended that the flexible fiber-optic laryngoscope be used to visualize the epiglottis and determine extubation time.

Damm M, Eckel HE, Jungehulsing M, et al. Airway endoscopy in the interdisciplinary management of acute epiglottitis. *Int J Pediatr Otorhinolaryngol.* 1996;38:41.

Hopkins RL. Extubation in epiglottitis. *Anesth Analg.* 1984;63:468.

Vernon DD, Sarnaik AP. Extubation in epiglottitis. *Anesth Analg.* 1984;63:469.

D.2. How would you make this patient comfortable during the course of intubation?

The child must be kept sedated to minimize movement, to prevent deliberate extubation, and to provide anxiolysis. Midazolam (0.075 mg per kg) as a starting dose titrated upward to effect followed by a continuous infusion of 0.04 mg/kg/hour will be effective in this regard. If necessary, a fentanyl infusion (1 to 2 μg/kg/hour) can be supplemented. Alternatively, a short course of propofol can be given as a drip. A bilateral superior laryngeal nerve block in experienced hands allows for better endotracheal tube toleration.

Of course, respiratory care, humidification, suctioning, and secretion mobilization must receive attention.

D.3. What outcome can one expect for the child with acute epiglottitis?

Residual airway problems are unusual in the vast majority of children. Most children who are diagnosed in time and intubated go on to a full recovery without sequelae. Complications include associated pneumonia, respiratory failure, hypoxia, and cardiac arrest.

CHAPTER 42

Cleft Palate

AARTI SHARMA

A 3-MONTH-OLD MALE INFANT

was scheduled for repair of a cleft lip and a cleft palate. According to his pediatrician, the infant was born at full term and had no other medical problems.

A. Medical Disease and Differential Diagnosis

1. Describe the anatomic concept of a cleft palate and a cleft lip.
2. What is the cause of a cleft lip or a cleft palate?
3. What is the incidence of a cleft lip and a cleft palate?
4. Discuss the pathophysiology of a cleft lip and palate in the neonate and in the older child (e.g., age >5 years).
5. What other conditions are associated with a cleft lip and a cleft palate?
6. What is Pierre Robin syndrome?
7. What is Treacher Collins syndrome?
8. What kind of specialized team care would these patients need?
9. Discuss indications and timing of closure of a cleft lip and palate.
10. What is velopharyngeal incompetence and how can it be diagnosed?
11. What is the relation of tonsillectomy and adenoidectomy to velopharyngeal incompetence?

B. Preoperative Evaluation and Preparation

1. What information do you need before closure of a cleft lip and palate?
2. What preoperative orders are needed?

C. Intraoperative Management

1. What monitors will you need for cheiloplasty and palatoplasty?
2. Discuss the induction and the anesthetic management for cleft lip and palate.
3. What positioning is recommended for cleft palate repair surgery?
4. What are the reported complications of this type of surgery and anesthesia?
5. Briefly describe the surgical techniques used to repair cleft defects.

6. How does a pharyngeal flap affect anesthetic management or any subsequent anesthetic administered to this patient?
7. What is an Abbe flap? What are its anesthetic implications?
8. What is the crucial problem of anesthesia for cleft palate? What are the unique considerations of this surgical repair?
9. What is laryngospasm? How would you make a diagnosis of laryngospasm?
10. How would you manage the patient with laryngospasm?

D. Postoperative Management

1. What complications of cleft lip and cleft palate surgery may be seen in the recovery room?
2. How do you protect the airway postoperatively?
3. How would you control postoperative pain in patients following a cleft lip and a cleft palate repair?

A. Medical Disease and Differential Diagnosis

A.1. Describe the anatomic concept of a cleft palate and a cleft lip.

Congenital clefts of upper lip occur because of failure of fusion of the maxillary and the medial and the lateral nasal processes. They vary from notch in the upper lip to a cleft through the lip and the floor of the nose involving the alveolar ridge, or they may be complete cleft of the lip and the palate.

The cleft palate is divided into prepalatal and postpalatal clefts. The incisive foramen marks the boundary between the two. They both have different embryologic development. Prepalatal cleft involves anterior palate, alveolus, lip, nostril floor, and ala nasi. Postpalatal clefts may extend anywhere from soft and hard palate to the incisive foramen. The third type is a submucosal cleft in which a bone defect exists without a mucosal defect. The most common cleft of the palate is a left complete cleft of the prepalatal and palatal structures. The second most common is a midline cleft of all the soft palate and part of the hard palate without a cleft in the prepalatal area. Various degrees of the cleft palate and lip are shown in Figure 42.1.

Aston SJ, Bartlett SP, Beasley RW, et al., eds. *Grabb and Smith's Plastic Surgery*. 6th ed. Lippincott Williams & Wilkins; 2007:179–190.

Gregory GA, ed. *Pediatric Anesthesia*. 4th ed. New York: Churchill Livingstone; 2002:731.

A.2. What is the cause of a cleft lip or a cleft palate?

Major components of face develop between 4 and 7 weeks of fetal life. There are three mesodermal islands, one central and two lateral. Prepalatal clefts are caused by the failure of these mesodermal elements to develop and fuse. Palatal clefts are caused when the palatal ridges fail to migrate medially, contact, and fuse (Fig. 42.1).

Aston SJ, Bartlett SP, Beasley RW, et al., eds. *Grabb and Smith's Plastic Surgery*. 6th ed. Lippincott Williams & Wilkins; 2007:179–190.

A.3. What is the incidence of a cleft lip and a cleft palate?

Cleft lip and cleft palate may occur together or separately. A cleft lip with or without a cleft palate occurs in 1:1,000 births. A cleft palate alone occurs in approximately

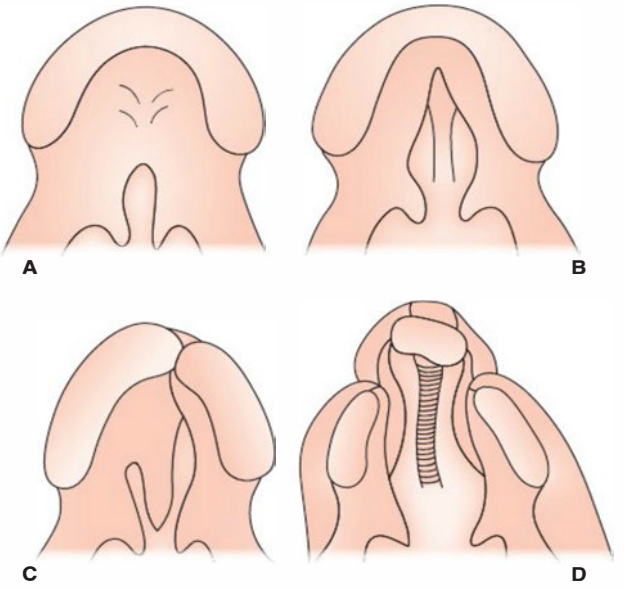

Figure 42.1 Various degrees of cleft palate and lip. **A.** Cleft of the soft palate only. **B.** Cleft of the soft and hard palate as far forward as the incisive foramen. **C.** Complete unilateral alveolar cleft, usually involving the lip. **D.** Complete bilateral alveolar cleft, usually associated with bilateral clefts of the lip. (Adapted from McCarthy JG, ed. Cleft lip and palate and craniofacial abnormalities. In: *Plastic surgery.* Vol 4. Philadelphia: WB Saunders; 1990.)

1:2,500 births. A cleft lip with or without a cleft palate is more common in boys, whereas isolated cleft palate is more common in girls.

The highest incidence of a cleft lip and a cleft palate occurs among Asians (1.61:1,000 births), whereas the lowest incidence is in African Americans (0.3:1,000 births). The incidence in whites is intermediate (0.9:1,000 births).

Samanich J. Cleft palate. *Pediatr Rev.* 2009;30:230–232.

A.4. Discuss the pathophysiology of a cleft lip and palate in the neonate and in the older child (e.g., age >5 years).

Cleft palate is responsible for some major physiologic disorders. The pharynx communicates more extensively with the nasal fossae and the oral cavity. The complex mechanisms of swallowing, breathing, hearing (through the eustachian tube), and speech are, therefore, impaired.

The presence of a cleft lip and palate in a neonate results in feeding difficulties. The neonate cannot suck because the cleft makes the creation of a negative pressure difficult. Breast-feeding is improbable and bottle-feeding is difficult.

Essentially, all children with a cleft palate have middle ear disease because abnormal anatomy of the nasopharynx adversely affects eustachian tube function. Chronic middle ear effusion produces varying degree of conductive hearing loss. Nasal septation between food and air is absent, creating a nonphysiologic mixing chamber in the nasopharynx. Not infrequently, this is associated with chronic rhinorrhea that must be distinguished preoperatively from infection.

Secondary defects of tooth development, growth of the ala nasi, and velopharyngeal function (contact between the soft palate and the posterior pharynx for speech and swallowing) can also occur.

Psychologic problems may be considerable as this youngster approaches school age and peer association. The speech of these children is typically nasal with an inability to sound the so-called plosives (*p*/*k*/*d*/*t*) and fricatives (*s*/*f*).

Malek R, ed. Cleft lip and palate, lesions, pathophysiology and primary treatment. London: Martin Dunitz; 2001:124–130.

A.5. What other conditions are associated with a cleft lip and a cleft palate?

Associated anomalies occur 30 times more frequently in the patient with isolated cleft palate than in the noncleft population.

The most common non–syndrome-related abnormalities are umbilical hernias, clubfoot, and limb and ear deformities.

The most common syndromes associated with a cleft lip and a cleft palate are:

- Velocardiofacial (Shprintzen) syndrome
- Van der Woude syndrome
- Stickler syndrome
- Pierre Robin syndrome
- Fetal alcohol syndrome
- Goldenhar syndrome (facio-auriculo-vertebral syndrome or hemifacial microsomia)
- Treacher Collins syndrome
- Nager syndrome
- Down syndrome

Calzolari E, Pierini A, Astolfi G, et al. Associated anomalies in multimalformed infants with cleftlip and palate: an epidemiologic study of nearly 6 million births in 23 EUROCRAT registeries. *Am J Med Genet*. 2007;143:528–537.

A.6. What is Pierre Robin syndrome?

This syndrome is characterized by retrognathia or micrognathia, glossoptosis, and airway obstruction. For facial cleft surgeons, Pierre Robin syndrome is defined by a triad of clinical criteria:

- Retrognathia
- Severe respiratory and/or digestive disorders in early infancy
- Cleft palate

An incomplete cleft of the palate is associated with the syndrome in approximately 50% of these patients. In patients with micrognathia (small jaw) or retrognathia, the chin is posteriorly displaced, causing the tongue to fall backward toward the posterior pharyngeal wall. This results in obstruction of the airway on inspiration. Crying or straining by these children can often keep the airway open. However, when the child relaxes or sleeps, airway obstruction occurs. Because of these respiratory problems, feeding may become very difficult. This can lead to a sequence of events: glossoptosis, airway obstruction, crying or straining with increased energy expenditure, and decreased oral intake. This vicious cycle of events if untreated can led to exhaustion, cardiac failure, and ultimately death.

Jones KL, ed. *Smith's Recognizable Patterns of Human Malformation*. 7th ed. Philadelphia: WB Saunders; 2006:262.

A.7. What is Treacher Collins syndrome?

It is highly complex disease process consisting of

- Hypoplastic cheeks, zygomatic arches, and mandible
- Microtia with possible hearing loss
- High arched or cleft palate
- Macrostomia (abnormally large mouth)
- Antimongoloid slant to the eyes
- Colobomas (notching of the outer portion of the lower eyelid)
- Increased anterior facial height
- Malocclusion (anterior open bite)
- Small oral cavity and airway with normal-sized tongue
- Pointed nasal prominence

Jones KL, ed. *Smith's Recognizable Patterns of Human Malformation*. 7th ed. Philadelphia: WB Saunders; 2006:280–281.

A.8. What kind of specialized team care would these patients need?

These patients need a pediatrician to maintain their overall health and a surgeon and an anesthesiologist to accomplish the various surgeries. They would need a speech therapist to prevent or overcome the speech deficiencies and an orthodontist for early orthodontic intervention to develop and maintain relatively normal bite and dentition. The care team also includes geneticist, pediatric dentist, prosthodontist, psychologist, medical social worker, and public health nurse.

Nelson WE, Behrman RE, et al. eds. *Nelson Textbook of Pediatrics*. 18th ed. Philadelphia: WB Saunders; 2007:1532–1533.

A.9. Discuss indications and timing of closure of a cleft lip and palate.

Functional goals of cleft palate surgery are normal speech, hearing, and maxillofacial growth. It is thought that speech and hearing are improved by early cleft palate repair (before 24 months of age) and that the delayed closure (after 4 years) is associated with less retardation of midfacial growth. An early two-stage palate repair is advocated in management of these patients. The recommended sequence involves closure of the soft palate at 3 to 6 months of age with secondary closure of the residual hard palate at 15 to 18 months of age. This sequence takes advantage of the early physiology and growth that occurs in the soft palate, which is vital in the development of speech. Furthermore, it avoids the potential pitfalls of the growth disturbance related to early periosteal undermining of palatal and vomerine tissue. This repair sequence also provides total palatal closure before speech evolves. If soft palate is repaired at the time of lip repair, an additional anesthetic is avoided.

Malek R, ed. Cleft lip and palate, lesions, pathophysiology and primary treatment. London: Martin Dunitz; 2001:197–205.

A.10. What is velopharyngeal incompetence and how can it be diagnosed?

Velopharyngeal incompetence is inability of soft palate in fulfilling its role in closing the nasopharynx, thereby affecting the phonation seriously.

To produce plosive sounds, *p*/*k*/*t*/*d*, or the sibilants, *s*/*sh*, the soft palate must touch the posterior pharyngeal wall to close the nose. Failure of closure results in the typical hypernasal speech. The most common cause of this is the cleft palate, but patients with congenitally short palates and no cleft can also have this typical speech. Treatment consists of surgical lengthening of the palate by the pushback operation with or without pharyngeal flap. The diagnosis of velopharyngeal incompetence can be suggested by the child's speech. More objective diagnosis can be obtained by direct vision of the soft palate while the child is pronouncing certain keywords (*kah, kah*), by the fogging of the hand mirror placed under the nose during speech, and from cinefluorographic x-ray films.

In patients with velopharyngeal incompetence, videofluoroscopy and nasopharyngoscopy can provide information that will help select the appropriate procedure, either pharyngoplasty or posterior pharyngeal flap.

Dudas JR, Deleyiannis FW, Ford MD, et al. Diagnosis and treatment of velopharyngeal insufficiency: clinical utility of speech evaluation and videofluoroscopy. *Ann Plast Surg*. 2006;56(5):511–517.

A.11. What is the relation of tonsillectomy and adenoidectomy to velopharyngeal incompetence?

There is often a considerable mass of tonsillar and adenoidal tissue at the age when surgery is usually performed, and, in addition to the latent danger of infection, the flap used in pharyngoplasty creates an obstruction that seriously complicates their subsequent removal. Furthermore, bulky tonsils may hinder retrodisplacement of the soft palate or block the air flow by obstructing cavum, which has already been reduced in volume by the retrodisplacement and the presence of the flap. It is, therefore, preferable to remove the tonsils and adenoids a few months before pharyngoplasty. The parents may wonder why this decision has been made, because they have been repeatedly told that the adenoids should not be removed in case of cleft palate because this might create or aggravate velar insufficiency. However, once velar inadequacy is confirmed, the parents are in a position to understand that these precautions are no longer justified and that the adenoids can represent a source of problems if not treated with radical measures. During tonsillectomy, it is important to leave the tonsillar pillars absolutely intact, because their muscle structure has a vital physiologic role.

Malek R, ed. *Cleft Lip and Palate, Lesions, Pathophysiology and Primary Treatment*. London: Martin Dunitz; 2001:146.

B. Preoperative Evaluation and Preparation

B.1. What information do you need before closure of a cleft lip and palate?

Preoperative anesthetic evaluation is invaluable and includes the history and physical examination and suitable laboratory data. It gives a picture of the patient's general health. Hemoglobin level, which is often low in very young infants, should be obtained. If Treacher Collins or Pierre Robin syndrome is suspected, an x-ray film of the mandible may be helpful. Examination of the mouth may indicate potential intubation problems. The examination also offers a good opportunity to appraise the family environment, because parental cooperation is essential for proper postoperative care.

Most surgeons repair a cleft lip when the baby is 6 to 10 weeks old and opt to repair a cleft palate at 6 to 12 months of age. The exact age of repair will depend on the size and health of the child and the surgeon's preference.

Because periosteoplasty and lip adhesions are carried out as soon as the segments are in alignment and the surgery is less extensive, the rule of 10 can be used with moderate license:

- *Weight*. Approximately 10 lbs.
- *Hemoglobin*. 10 g/dL or more
- *White blood cell count*. Less than 10,000 per μL
- *Age*. Can be less than 10 weeks

With open cleft palate, however, it is common to have crusting and low-grade infection of the nasopharynx because of food and fluid regurgitation through the cleft. It is nearly impossible to eliminate this completely. Unless an acute inflammation process is present, this does not lead to complications.

Barrett BM Jr, ed. *Patient Care in Plastic Surgery*. St. Louis: Mosby; 1996:343–344.

B.2. What preoperative orders are needed?

Preoperative fasting has been a prerequisite for elective surgery. An issue of particular importance to the pediatric patient is the wonderful changes that have taken place regarding preoperative fasting. Recent work has shown that prolonged fasting does not reduce the risk of aspiration pneumonitis during anesthesia. This has led to reduction in the fasting times. Reduced fasting increases patient comfort and there may be less potential for intraoperative hypoglycemia. Fasting guidelines for infants and children are shown in Table 42.1.

Because multiple operations may be required, the emotional trauma of each hospital experience must be minimized. The most common premedication used at Cornell Medical Center in pediatric patients is oral midazolam. Dose can range from 0.25 to 0.5 mg per kg orally. Children younger than 8 months rarely require premedication. In children with anticipated difficulty in airway management and in those with propensity toward airway obstruction, premedication should be avoided. Special orders include antibiotics, if the infant or child has associated congenital heart disease, and the typing and crossmatching of a unit of blood for palatal surgery.

Cote CJ. Preparation, premedication and induction of anesthesia in children. *ASA Annual Meeting Refresher Course Lectures*. Park Ridge, IL: American Society of Anesthesiologists; 2001:243.

Table 42.1 Minimum Fasting Period (Hours) for Pediatric Patients

	CLEAR FLUIDS	BREAST MILK	FORMULA OR COW'S MILK	SOLIDS
Children	2	—	6	6
3–12 mo	2	4	6	6
<3 mo	2	4	4	6

C. Intraoperative Management

C.1. What monitors will you need for cheiloplasty and palatoplasty?

Heart rate, respiration, blood pressure, temperature, and oxygen saturation are monitored at all times. An electrocardiogram provides visual and audible evidence of the electrical activity of the heart. A precordial stethoscope monitors both heart and respiratory sounds. It is particularly important in this patient because once the surgery has begun, the anesthesiologist no longer has easy direct access to the airway. The use of pulse oximetry and an end-tidal CO_2 monitor is indispensable. Temperature should be monitored per rectum or axilla. A warming blanket should be used in these patients to avoid hypothermia. Blood loss determination should be made by a calibrated catchment trap in the suction line and by weighing sponges. Blood loss rarely exceeds 10% of circulating blood volume; however, properly crossmatched and screened blood should be available but used only if absolutely necessary.

C.2. Discuss the induction and the anesthetic management for cleft lip and palate.

After suitable monitors are attached, the infant is induced with oxygen, nitrous oxide, and either sevoflurane or halothane. Because cardiac depressant effects of sevoflurane are less pronounced than that of halothane, sevoflurane is preferred for induction. In addition, the myocardium is more sensitive to exogenous epinephrine with use of halothane. Recommended maximal doses of lidocaine and epinephrine for palate or lip surgery are 5 mg per kg and 10 μg per kg, respectively. This epinephrine dose is for hypocarbic or normocarbic patients.

Once the patient is asleep, an intravenous line is established and appropriate intravenous fluids are started. Intubation can be facilitated with nondepolarizing muscle relaxants such as vecuronium 0.1 mg per kg. Muscle relaxants should be withheld if any possibility of difficulty in intubation exists.

Laryngoscopy in patient with a cleft lip is generally straightforward, but the cleft palate has the capability to trap and immobilize a straight blade. Should this occur, the anesthesiologist must first recognize the problem and then consider inserting a gauze pack or a dental roll in the cleft before laryngoscopy.

To achieve a cosmetic repair, symmetry is essential, so the tube should exit the mouth in the midline without facial distortion from either the tube or the securing tape. Some surgeons prefer to suture the tube to the lower gum.

An orogastric tube should be passed to empty the stomach of gas and secretions, and it should be removed before preparation of the surgical field.

A pharyngeal pack of moistened ribbon gauze is inserted for a cleft lip repairs; as for a cleft palate repair, the surgeon inserts the gag before insertion of the pharyngeal pack. Following the gag and pack insertion, ventilation should be reassessed, because tube compression may have occurred. To avert eye injury, an ocular lubricant is placed in the eyes, and the upper eyelids are splinted shut with tape.

During the surgery, it is necessary to have good communication and cooperation between the surgeon and the anesthesiologist because the surgeon's tools and hands and the anesthesiologist's endotracheal tube and apparatus all occupy the same very small space.

Gregory GA, ed. *Pediatric Anesthesia*. 4th ed. New York: Churchill Livingstone; 2002:731.

C.3. What positioning is recommended for cleft palate repair surgery?

Correct positioning of the child is important for the plastic surgeon, who sits at the head of the operating table. Head extension must be maximal for cleft palate surgery.

The entire body is raised with a thick foam mat or folded blanket, allowing the head to drop back hyperextended into a stockinette head support. Not only does this position provide good exposure, but it also allows blood to flow away from the larynx and toward the nasopharynx, allowing it to be removed by suction.

C.4. What are the reported complications of this type of surgery and anesthesia?

Anesthetic complications include obstruction of the endotracheal tube, inadvertent extubation during the procedure, and cardiac arrest. Postanesthetic complications include airway obstruction, bleeding with or without aspiration, and pneumonia. Complications not related to anesthetic management are wound healing, diarrhea, and otitis media. The mortality rate has been reported to be less than 0.5%.

Gregory GA, ed. *Pediatric Anesthesia.* 4th ed. New York: Churchill Livingstone; 2002:731–732.

C.5. Briefly describe the surgical techniques used to repair cleft defects.

The Furlow procedure is the most common technique for cleft palate closure. It involves opposing z-plasties of the mucosa and the musculature of the soft palate. The goal is to separate the nonfunctioning attachments to the posterior border of the hard palate and to displace the mucosa and the musculature posteriorly.

Other basic surgical techniques include von Langenbeck technique, Schweckendiek technique, two-flap technique, three-flap/V-Y technique.

Although most of the repairs do not involve repairing the muscular sling, doing so allows better palatal and eustachian tube function.

Sadove AM, van Aalst JA, Culp JA. Cleft palate repair: art and issues. *Clin Plast Surg.* 2004;31(2):231–241.

C.6. How does a pharyngeal flap affect anesthetic management or any subsequent anesthetic administered to this patient?

The presence of this flap prohibits nasoendotracheal intubation and makes many nasal techniques difficult (e.g., insertion of nasogastric tube). The degree of obstruction is related to the width of the flap. Traumatic rupture of this flap secondary to attempted nasotracheal intubation could produce bleeding, aspiration, and laryngospasm.

Traumatic rupture of soft palate can occur from placement of laryngeal mask airway.

Knowledge of prior surgery is essential to good anesthetic management. Following the pushback and pharyngeal flap operation (pharyngoplasty), significant airway obstruction has been noted in the early postoperative period. Use of pulse oximetry during sleep state has demonstrated obstruction and desaturation in the first 48 to 72 hours.

Dearlove O, Perkins RJ, Briggs G. Anaesthesia after cleft palate repair. *Anaesthesia.* 2004;59(10):1032.

Somerville NS, Fenlon S, Boorman J, et al. Disruption of cleft palate repair following the use of the laryngeal mask airway. *Anaesthesia.* 2004;59(4):401–403.

C.7. What is an Abbe flap? What are its anesthetic implications?

An Abbe flap is a full-thickness pedicle flap taken from the lower lip and swung on its own artery to a position in the upper lip to replace a tissue deficit resulting from any

cause, such as surgical excision of malignancy or loss of tissue in a bilateral cleft lip. The lips must remain closed until the flap "takes," and then it can be detached from its blood supply. Usually, this operation is performed in children of an older age under local anesthesia, but it occasionally requires general anesthesia if the patient is young. All the problems of a closed mouth, such as the possibility of vomiting and aspiration, are encountered in addition to those associated with preservation of the flap.

Koshy JC, Ellsworth WA, Sharabi SE, et al. Bilateral cleft lip revisions: the Abbe flap. *Plast Reconstr Surg*. 2010;126(1):221–7.

C.8. What is the crucial problem of anesthesia for cleft palate? What are the unique considerations of this surgical repair?

The establishment, maintenance, and protection of the airway comprise the crucial problem of anesthesia for palate surgery. Failure to establish, maintain, and protect the airway results in tachypnea, CO_2 retention, hypoxemia, increased bleeding, hypovolemia, arrhythmia, cardiac arrest, and death. The major cause of cardiac arrest in infants and children is hypoxia.

Positioning of the patient is usually supine with table rotated 90 degrees to 180 degrees with oral RAE or reinforced endotracheal tube extending down the midline of the jaw taped to the chin. The mouth gag that is used for surgical exposure may be released intermittently to allow reperfusion of the tongue. However, each manipulation may affect the endotracheal tube. Blood that collects in the oropharynx should be carefully suctioned at the end of the procedure without disrupting the suture line. Residual blood and secretions in the oropharyngeal cavity may irritate the larynx and cause laryngospasm.

Jaffe RA, Samuels S, eds. *Anesthesiologist's Manual of Surgical Procedures*. 4th ed. Lippincott Williams & Wilkins; 2009:1417–1418.

C.9. What is laryngospasm? How would you make a diagnosis of laryngospasm?

This is defined as glottic closure resulting from a reflex constriction of the laryngeal muscles. It is much more common in pediatric anesthesia than in adults. Incidence is twice that of adults in older children and three times that of adults in younger children. Airway complications are further increased in children with upper respiratory tract infections. In the pediatric patient, the oxygen consumption is greater; thus, the consequences of laryngospasm in children may be more serious. The oxygen consumption is highest in the youngest patients.

Laryngospasm can occur during anesthesia for two reasons: first, a lack of inhibition of glottic reflexes because of central nervous system depression; and, second, increased number of stimuli—such as manipulation of the airway, secretions or blood irritating the cords, and stimulation of visceral nerve endings at an inadequate depth of anesthesia.

Bingham R, Lloyd-Thomas A, Sury M, eds. *Hatch & Sumner's Textbook of Paediatric Anesthesia*. 3rd ed. London: Hodder Arnold; 2008:288–289.

C.10. How would you manage the patient with laryngospasm?

Laryngospasm may be partial or complete. Partial spasm will be diagnosed by a characteristic stridulous noise and a mismatch between the patient's respiratory effort and

the disappointingly small movements of the reservoir bag. Methods of overcoming laryngospasm include applying positive pressure to the airway, deepening anesthesia, and administering muscle relaxants or a bolus of propofol. Recently, it was found that a bolus of propofol works extremely quickly, without the side effects of succinylcholine. The exact mechanism of action of propofol is not clear, but it could be due to increasing the depth of anesthesia or direct effect on the glottis. When there is complete laryngospasm, there will be silence with regard to air movement. The application of positive pressure may not be helpful in these circumstances and indeed may make the situation worse by forcing the false cords against the tightly closed true cords. It is much better to relax the cords before the hypoxia is severe. Succinylcholine can be given intramuscular or intravenous.

Bingham R, Lloyd-Thomas A, Sury M, eds. *Hatch & Sumner's Textbook of Paediatric Anesthesia*, 3rd ed. London: Hodder Arnold; 2008:288–289.

D. Postoperative Management

D.1. What complications of cleft lip and cleft palate surgery may be seen in the recovery room?

Complications include airway obstruction, bleeding, and hypothermia. Airway obstruction is the result of closure of the cleft structures plus some edema secondary to trauma. In case of pushback procedure with or without a pharyngeal flap, the obstruction is due to the new posterior position of the palate and the pharyngeal flap.

Combination of a closed palate, a small mandible pushing the tongue into a small pharynx, edema, blood, and the residual effects of anesthesia make postextubation airway obstruction more likely. There could also be swelling of the tongue due to mouth gag placement during surgery.

Anesthesiologist must be aware of the potential problems such as subglottic edema, flap edema, increased oral secretions, posterior displacement of tongue, mucosal swelling of hypopharynx, and overlooked throat pack.

Blood loss is not an anesthetic complication but its replacement is an anesthesiologist's responsibility, as is prevention of aspiration.

Hypothermia delays emergence and produces metabolic acidosis and respiratory and myocardial depression. The most important problem for the anesthesiologist is maintenance of the airway.

Davis PJ, Cladis FP, Motoyama EK, eds. *Smith's Anesthesia for Infants and Children*. 8th ed. Philadelphia: Mosby, Elsevier Science; 2011:831–836.

D.2. How do you protect the airway postoperatively?

Following palatoplasty, the pharynx and the nasopharynx are suctioned before extubation. Some anesthesiologists advocate that this be done with the aid of the laryngoscope to ensure removal of any mucus, blood, or clots. If suctioning is done before removing the Dingman gag, the laryngoscope may not be necessary. The infant should be as awake as possible. A long traction suture is placed through the tongue and tied loosely. Traction on the suture stimulates respiration and clears the airway. Neither an oral nor a nasal airway should be inserted unless absolutely necessary; either one could disrupt the sutures and undo all the surgical work. The traction suture is removed when the infant leaves the recovery room.

Following palate surgery, the infant is placed in prone or lateral position with the head dependent, turned to the side, and hyperextended. This position can be achieved with a jack placed under the foot of the crib or by placing a bulky bath blanket under the hips of the infant. Any blood or mucus will accumulate in the dependent cheek or roll out of the mouth.

Following cleft lip surgery, a Logan bow is frequently used to take the tension off the newly sutured lip. The infant can still be placed in the lateral position. Elbow restraints are essential, and they are placed on the infant or the child before leaving the operating room. A high-humidity atmosphere is recommended postoperatively to reduce the incidence of tracheitis, but others have failed to show any correlation between the use of humidity and the incidence of tracheitis.

Davis PJ, Cladis FP, Motoyama EK, eds. *Smith's Anesthesia for Infants and Children*. 8th ed. Philadelphia: Mosby, Elsevier Science; 2011:831–836

D.3. How would you control postoperative pain in patients following a cleft lip and a cleft palate repair?

The continuum of pain management continues through to the recovery room, the pediatric intensive care unit, or to an inpatient bed in patients with a cleft lip or a cleft palate repair. No child should be discharged from the recovery room with uncontrolled pain. Cleft palate repair is associated with the risk of postoperative airway obstruction, which may be increased with administration of opioids. Nerve blocks may be used to improve pain relief, to decrease perioperative consumption of opioids, and to favor early feeding resumption after repair.

Infraorbital nerve block can be used for pain control after a cleft lip repair. Nasopalatine and palatine nerve blocks will provide palatal hard and soft tissue anesthesia. Recently, bilateral maxillary nerve blocks using a suprazygomatic approach has been used for effective pain relief.

Opioid analgesics that can be used postoperatively are shown in Table 42.2.

Nonopioid analgesics that can be used postoperatively are shown in Table 42.3.

Table 42.2 Opioid Analgesics for Pediatric Patients

DRUGS	DOSAGE	FORM
Fentanyl	1 μg/kg	IV
Morphine	0.05–0.1 mg/kg	IV
Meperidine	1 mg/kg	IV
Codeine	1.5 mg/kg q4h	PO: 15-mg, 30-mg, 60-mg tablets; syrup 15 mg/mL
Oxycodone	0.15 mg/kg	PO: 5-mg tablets; syrup 5 mg/mL

IV, intravenous; PO, by mouth.

Table 42.3 Nonopioid Analgesics for Pediatric Patients

DRUG	DOSAGE	FORMS AVAILABLE
Acetaminophen (Tylenol)	10–15 mg/kg PO maximum 2,600 mg/d	Tablets: 80 mg
		Syrup: 325 mg/5 mL
		Suppositories: 120, 325, 650 mg
Ibuprofen (Motrin)	10–20 mg/kg PO q6h	Tablets: 300, 400 mg
		Syrup: 100 mg/5 mL
Ketorolac (Toradol)	0.5 mg/kg IV to load (maximum dose 30 mg)	Parenteral form used intramuscularly/intravenously
	0.5 mg/kg q8h intramuscularly or intravenously (limit use to 48 hr)	

IV, intravenous; PO, by mouth.

CHAPTER 43

Congenital Heart Disease with a Cervical Mass in Infancy

Miles Dinner and Marie A. Sankaran Raval

A 1-WEEK-OLD MALE INFANT

was diagnosed shortly after birth with an interrupted aortic arch (IAA). The workup revealed the child to have a 22q11 deletion syndrome (formerly known as *DiGeorge syndrome*). An enlarging cervical mass was noted, and the child was brought to the operating room for exploration.

A. Medical Disease and Differential Diagnosis

1. What is the 22q11 deletion syndrome?
2. What are the associated cardiovascular defects in 22q11 deletion syndrome?
3. What are the endocrinologic consequences of 22q11 deletion syndrome and the attendant manifestations?
4. What are the immunologic findings in 22q11 deletion syndrome?
5. What is the differential diagnosis of cervical masses in infancy?
6. What is a cystic hygroma? What are the complications? What is the treatment?
7. What is the IAA anomaly?
8. What is the pathophysiology of the IAA syndrome?
9. How is ductal patency maintained?
10. What are the side effects of prostaglandin infusion?
11. What is the hyperoxia test?

B. Preoperative Evaluation and Preparation

1. What preoperative studies should be obtained to evaluate the neck mass?
2. How would you categorize the difficult airway in children?
3. What features of the difficult airway can be noted on physical examination?
4. How would you optimize preoperatively the ability to secure the airway in the operating room?
5. What laboratory studies are necessary before surgery?

6. What are the causes of congestive heart failure (CHF) in the infant? How would you assess this infant on your preoperative evaluation for signs of CHF?
7. How would you optimize the preoperative treatment of CHF?
8. How would you premedicate this infant?
9. When is premedication useful in infants and children?
10. Before the planned surgery, the infant is scheduled for a magnetic resonance imaging (MRI) scan. You are asked to ensure that the baby remains immobile for 20 minutes to perform the scan adequately. How would you accomplish this?

C. Intraoperative Management

1. What anesthesia equipment, circuit, and monitors would you use?
2. Describe techniques other than direct laryngoscopy that would be useful for securing the airway in this baby.
3. How would you monitor blood loss in this patient?
4. What anesthetic technique should be used in a patient who may experience severe loss of blood intraoperatively?
5. How would you induce anesthesia in this infant?
6. Intraoperatively, the surgeon must dissect the tumor in the anterior mediastinum and needs to have a quiet surgical field. How would you accomplish this in the infant?

D. Postoperative Management

1. How would you manage this patient postoperatively?

A. Medical Disease and Differential Diagnosis

A.1. What is the 22q11 deletion syndrome?

Formerly known as *DiGeorge syndrome*, this constellation of abnormalities results from an embryogenic disruption in the formation of the third and fourth aortic arches. It occurs in approximately 1 in 4,000 births. The velocardiofacial syndrome with features of facial, palatal, developmental, and cardiac abnormalities is distinct from the DiGeorge syndrome but has the same 22q11 deletion.

The common clinical features are hypocalcemia, immunodeficiency, dysmorphic facial features, palatal and velopharyngeal dysfunction, renal anomalies, and congenital heart disease (CHD). A significant number of patients with tetralogy of Fallot and IAA have a 22q11 deletion.

The DiGeorge anomaly is characterized by thymic and parathyroid aplasia or hypoplasia, cardiovascular defects, and dysmorphic facies. It arises as a consequence of a developmental defect in the embryology of the third and fourth pharyngeal pouches. It is currently thought to be caused by inadequate neural crest migration into the pharyngeal pouches, with the subsequent limitation in growth of the derivative structures. The condition arises from Mendelian disorders, teratogen exposure, or cytogenetic abnormalities. A chromosome 22q11 microdeletion is a constant finding. Depending on the extent of the thymic hypoplasia, clinical manifestations can range from little trouble with infections to severe immunodeficiency that can be corrected with cultured thymic tissue transplant, bone marrow transplant, or peripheral blood transplant.

Goldmuntz E. DiGeorge syndrome: new insights. *Clin Perinatol.* 2005; 32:963–978.

Kliegman RM, Behrman RE, Jenson HB, et al., eds. *Nelson Textbook of Pediatrics*. 18th ed. Philadelphia: Saunders, 2007:884–885.

A.2. What are the associated cardiovascular defects in 22q11 deletion syndrome?

Congenital heart defects are found in 80% of patients with this syndrome. Most patients with DiGeorge syndrome have associated anatomic cardiovascular anomalies involving the aortic arch system. The most common abnormality is tetralogy of Fallot, followed by tetralogy of Fallot with pulmonary atresia, isolated ventricular septal defect (VSD), IAA, and truncus arteriosus. These defects arise during the crucial developmental stages of the truncoconal parts of the heart from the pharyngeal pouch derivatives. Cardiac MRIs are invaluable in defining the aortic arch anatomy in detail

Momma K. Cardiovascular anomalies associated with chromosome 22q11.2 deletion syndrome. *Am J Cardiol*. 2010;105:1617–1624.

A.3. What are the endocrinologic consequences of 22q11 deletion syndrome and the attendant manifestations?

Thymic aplasia occurs in approximately 60% of patients with the 22q11 syndrome. These patients fail to make parathyroid hormone, or they are severely deficient in its production, leading to hypocalcemia. Hypocalcemia in the neonate is often difficult to detect clinically but it can lead to irritability; jitteriness; twitching; or frank seizure activity, failure to thrive, tachycardia, and hypotension. Stridor, syncope, and carpopedal spasm may occur. Trousseau sign (carpopedal spasm elicited by an inflated blood pressure cuff) and Chvostek sign (twitching of facial muscles after tapping the facial nerve) can be seen. Growth hormone and thyroid hormone deficiency have been reported.

Sperling MD, Mark A, eds. *Pediatric Endocrinology*. 3rd ed. Philadelphia: Saunders; 2008:690–696.

A.4. What are the immunologic findings in 22q11 deletion syndrome?

Patients with the 22q11 deletion syndrome demonstrate marked variability in the degree of involvement of the immune system. Total lymphocyte counts, percentage of T cells, and T-lymphocyte function ranges from normal to severely depressed. The most consistent abnormality is a decrease in total T cells, which is seen in approximately 75% to 80% of these patients. Approximately 1% of patients have thymic aplasia requiring transplant and 20% have no evidence of reduced T cells. Spontaneous resolution of immunodeficiency occurs in some patients, but progressive loss of function can be seen in others. Patients with the partial DiGeorge anomaly can be immunized and generate good antibody responses; therefore, humoral immunity is often intact, as is functional cellular immunity.

Markert ML, Alexieff MJ, Li J, et al. Complete DiGeorge syndrome: development of rash, lymphadenopathy, and oligoclonal T cells in 5 cases. *J Allergy Clin Immunol*. 2004;113:734–741.

Sullivan, KE. Chromosome 22q11.2 deletion syndrome: DiGeorge syndrome/velocardiofacial syndrome. *Immunol Allergy Clin North Am*. 2008:28:353–366.

A.5. What is the differential diagnosis of cervical masses in infancy?

Neck masses can originate from a congenital anatomic anomaly, neoplasm, or infection. In the first category are branchial cysts, thyroglossal duct cysts, and failed thymic descent. Branchial cysts arise in the embryo from the thymic stalk or the pharyngeal pouch. They may be present at birth or arise later. They lie beneath the sternomastoid muscle and may bulge out from the anterior border. They can become infected and thereby enlarge with pus. When this occurs, the airway or upper esophagus may be compressed. Thyroglossal duct cysts are spherical, midline masses that may extend back to the base of the tongue and may represent all of the thyroid tissue that the baby has. The thymus gland arises high in the neck and must descend in the embryo to the anterior mediastinum. If this caudad movement becomes arrested, the thymus can appear as a soft, compressible mass along the anterior border of the sternocleidomastoid muscle.

Infectious masses can be due to tuberculosis, Kawasaki disease, Epstein-Barr viral infection, Ludwig angina, and catscratch disease. Neoplastic masses in the cervical region can be teratomas, hemangiomas, neurofibromas, lymphomas, goiters, or cystic hygromas. Teratomas are firm, midline masses arising adjacent to the thyroid isthmus. Hemangiomas may be extensive and compress vital structures. Neurofibromas may arise individually or as a consequence of neurofibromatosis (von Recklinghausen syndrome) and they can be very large. A goiter represents an enlarged thyroid gland that may be hypothyroid, hyperthyroid, or euthyroid.

Ungkamont K, Yellon RF, Weissman JL. Head and neck space infections in infants and children. *Otolaryngol Head Neck Surg*. 1995;112:375–382.

A.6. What is a cystic hygroma? What are the complications? What is the treatment?

Cystic hygroma is a developmental malformation of the lymphatic system found most often in the posterior triangle of the neck and axilla of children. They are divided into suprahyoid and subhyoid masses. They are compressible masses that are most often found in infants younger than 1 year and they intermittently enlarge. Suprahyoid masses can be extremely difficult to manage because of the obstructive symptoms and feeding difficulties, and they may become infected, producing rapid compromise of breathing.

Complete surgical removal of these masses is often impossible, and repeat debulking is sometimes the only treatment. Facial paresis may be a consequence of resection. The mortality of obstructing cystic hygroma diagnosed prenatally exceeds 20% following delivery. Intubation of the neonate during delivery under uninterrupted maternal–fetal circulation has been performed to prevent the fatal consequences of immediate postpartum airway obstruction. Bleomycin or derivatives of *Streptococcus pyogenes* have been used as a sclerosing agents with favorable results.

Burezq H, Williams B, Chitte SA. Management of cystic hygromas: 30 year experience. *J Craniofac Surg*. 2006;17:815–818.

Townsend CM Jr., Beauchamp RD, Evers BM, et al., eds. *Sabiston Textbook of Surgery*. 18th ed. Philadelphia: Saunders; 2008:2052–2053.

A.7. What is the IAA anomaly?

IAA is a group of three anatomic abnormalities in which the aorta has a complete atresia at a site somewhere along the arch. If untreated, it is uniformly lethal within 1 week of life as a consequence of closure of the ductus arteriosus. In type A, which accounts for 43%, the aorta is interrupted between the left subclavian artery and the aortic isthmus. Type B, the most common (53%), has the lack of continuity between the left carotid and the left subclavian arteries. The defect in type C is distal to the brachiocephalic artery and is the least common of three types. A VSD is frequently associated with 22q11.2 syndrome. Approximately 50% of patients with IAA have DiGeorge syndrome. IAA can also coexist with a single ventricle and atrioventricular canal.

Brown JW, Ruzmetov M, Okada Y, et al. Outcomes in patients with interrupted aortic arch and associated anomalies: a 20-year experience. *Eur J Cardiothorac Surg.* 2006;29:666–673.

Goldmunte E, Clark BJ, Mitchell LE, et al. Frequency of 22q11 deletions in patients with conotruncal defects. *J Am Coll Cardiol.* 1998;32:492–498.

Momma K. Cardiovascular anomalies associated with chromosome 22q11.2 deletion syndrome. *Am J Cardiol.* 2010;105:1617–1624.

A.8. What is the pathophysiology of the IAA syndrome?

Because of the discontinuity between the descending aorta and the arch, blood flow to the descending aorta cannot occur unless a patent ductus arteriosus exists. Pulse oximetry will reveal normal saturation in the right arm, with a decreased saturation in the lower extremities. If the ductus is inadequate to provide perfusion to the lower body because of its closure, severe metabolic acidosis, CHF, renal insufficiency, and shock may develop. With a VSD, most of the cardiac output will be directed into the pulmonary vascular bed as the ductus closes. Ductal patency can be maintained with prostaglandins. Symptoms of ductal closure include tachypnea, lethargy, and poor feeding. Two-dimensional echocardiography is diagnostic.

Kliegman RM, Behrman RE, Jenson HB, et al., eds. *Nelson Textbook of Pediatrics*. 18th ed. Philadelphia: Saunders; 2007:1900–1903.

A.9. How is ductal patency maintained?

The ductus arteriosus is kept open by the infusion of prostaglandin E_1 (PGE_1). Both PGE_1 and prostaglandin E_2 are produced endogenously in the ductus, metabolized in the lungs, and achieve high levels in the fetus relative to adults. Among the endogenous prostaglandins, prostaglandin E_2 is the most important. Postnatally, the levels fall associated with increased metabolism resulting from the increase in pulmonary blood flow. An infusion of prostaglandin will delay the natural closure of the ductus and improve systemic arterial oxygenation. Less acidosis will also be seen in arterial blood gases compared to those obtained before PGE_1 infusion administration. In the case of an IAA, circulation to the lower body is totally dependent on the patency of the ductus, and, therefore, continual infusion of PGE_1 is critical to keep the infant alive. The infusion is titrated at a rate of 0.05 to 0.1 μg/kg/min. Because of its relatively long half-life, discontinuation of the drip will not acutely cause ductal closure in the event of inadvertent stoppage.

Freed MD, Heymann MA, Lewis AB, et al. Prostaglandin E_1 in infants with ductus arteriosus-dependent congenital heart disease. *Circulation*. 1981;64:889–905.

Hermes-DeSantis ER, Clyman RI. Patent ductus arteriosus: pathophysiology and management. *J Perinatol*. 2006;26(suppl 1):S14–S18.

Kliegman RM, Behrman RE, Jenson HB, et al., eds. *Nelson Textbook of Pediatrics*. 18th ed. Philadelphia: Saunders; 2007:2956.

A.10. What are the side effects of prostaglandin infusion?

Prostaglandin infusion has a variety of side effects ranging from fever to hypotension, seizure-like activity, flushing, and edema. Platelet aggregation may be reduced. Apnea and bradycardia can also occur, which may require prophylactic intubation and mechanical ventilation. A separate intravenous line must be used.

Kliegman RM, Behrman RE, Jenson HB, et al., eds. *Nelson Textbook of Pediatrics*. 18th ed. Philadelphia: Saunders; 2007:2956.

A.11. What is the hyperoxia test?

This test is performed to distinguish pulmonary and cardiac causes of cyanosis. To perform the test, the patient is first placed on 100% oxygen for 10 minutes. A pre-ductal arterial blood gas is then taken from the patient's right arm. Supplemental oxygen in patients with pulmonary disease significantly augments systemic oxygenation, which is not the case in cyanotic congenital heart defects. Of course, in severe pulmonary conditions, there may be a failure to raise the oxygen tension meaningfully but the chest radiograph would be valuable in affirming the diagnosis of lung pathology. Similarly, in some congenital heart lesions with mixing such as truncus arteriosus, the supplemental o_2 decreases pulmonary vascular resistance resulting in an increase in oxygen tension but rarely more than 150 mm Hg.

Keane JF, Locke JE, Fyler DC, eds. *Nadas' Pediatric Cardiology*. 2nd ed. Philadelphia: Saunders; 2006: 141–142.

B. Preoperative Evaluation and Preparation

B.1. What preoperative studies should be obtained to evaluate the neck mass?

Cervical masses have a variable nature, invasiveness, and potential for airway compression. Thus, MRI studies and a sonogram should be obtained before surgery to better define the nature of the cystic hygroma and highlight the region of airway compression. These cysts are known to invade the anterior mediastinum and can, therefore, cause extrinsic distortion of the lower airway anywhere from the cricoid ring to the carina. Cystic fluid can be aspirated under sonography to reduce the size of the mass and potentially relieve compressive symptoms. On rare occasions, there may be ingrowth of the pericardium and displacement of the lung. For suprahyoid masses, radiologic studies will define the scope of laryngeal compression and retropharyngeal involvement, which will obviously affect the ability to intubate the trachea. A flexible neonatal bronchoscopic examination can define extrinsic compressive deformations of the airway.

B.2. How would you categorize the difficult airway in children?

Children with difficult airways can be grouped into four main groups. The first group includes children who have congenital anomalies affecting the airway such as vascular rings, laryngomalacia, micrognathia, and neurofibromatosis. Second would be children with an acute acquired obstruction such as injury or foreign body. The third group includes infectious causes such as retropharyngeal abscess, croup, diphtheria, and peritonsillar abscess. In the last group are those children who prove to be difficult to visualize on intubation and who do not have known congenital abnormalities.

Hall SC. The child with a difficult airway: recognition and management. *ASA Annual Meeting Refresher Course Lectures*. Park Ridge, IL: American Society of Anesthesiologists; 2006:412.

B.3. What features of the difficult airway can be noted on physical examination?

Starting at the mouth and working caudally, we can examine a host of physical features that can challenge the clinician. Many anatomic abnormalities can be discerned before direct laryngoscopy. Conditions that result in a constricted oral opening, such as scleroderma, epidermolysis bullosa, burn cicatrization, or congenital microstomia prevent insertion of the laryngoscope. A small lower jaw and maxillary protrusion often accompany the anterior larynx, making laryngeal inlet exposure during laryngoscopy impossible. This is seen in children with syndromes such as Pierre Robin, Apert syndrome, Crouzon syndrome, Treacher Collins syndrome, and many other craniofacial syndromes.

Macroglossia as a consequence of certain metabolic storage diseases, cystic abnormalities, and hamartomatous tumors of the tongue (Goltz syndrome) can make effective laryngoscopy impossible.

Temporomandibular ankylosis, as seen in patients with juvenile rheumatoid arthritis and other rheumatic processes, may prevent mouth opening. A narrow, high-arched palate may suggest a problematic intubation. Neck extension problems may accompany some neuromuscular disorders, trauma, arthritis, or Goldenhar syndrome.

Berry FA, ed. *Anesthetic Management of Difficult and Routine Pediatric Patients*. New York: Churchill Livingstone; 1986:167.

Wetmore RF, Muntz HR, McGill TJ. *Pediatric Otolaryngology: Principles and Practical Pathways*. New York: Thieme Medical; 2000:775.

B.4. How would you optimize preoperatively the ability to secure the airway in the operating room?

Because of the risk inherent in inducing anesthesia in this infant, plan for a fiberoptic laryngoscopy. The infant bronchoscope is of such small diameter that it does not have a suction port, and visualization is especially impaired because of secretions. An antisialagogue is a must to permit proper anatomic recognition through the fiberoptic scope. Glycopyrrolate (0.01 mg per kg) given half an hour before anesthesia will limit secretions without the excessive tachycardia that may occur with atropine. In this infant with cardiac compromise, any unnecessary stress on the heart should be avoided. An appropriate laryngeal mask airway (LMA), in this case a no.1, should be readied, as should equipment trays for emergency cricothyrotomy. Adjunctive devices such as a rigid infant bronchoscope with video imaging can be tremendously useful should fiberoptic or classical laryngoscopy prove too difficult. An appropriate-sized

rigid scope can serve to visualize the laryngeal inlet and hold the endotracheal tube as an introducing stylet to facilitate intubation.

An updated report by the American Society of Anesthesiologists Task Force on Management of Difficult Airway. Practice guidelines for management of the difficult airway. *Anesthesiology*. 2003;98:1269–1277.

DeLeo A, Dimmitt P. Pediatric upper airway endoscopy. *ORL Head Neck Nurs*. 2005;23:29–30.

B.5. What laboratory studies are necessary before surgery?

Because of the strong association of 22q11 deletion syndrome with hypocalcemia, serum calcium should be measured. In addition, because of the inherent dysphagia with a cystic hygroma, the infant will not have been feeding. To ensure that adequate parenteral nutrition and hydration were provided, serum glucose and sodium levels should be noted. Because of the potential for severe metabolic acidosis secondary to underperfusion of the lower body through the interrupted descending aorta, a serum pH and bicarbonate concentrations must be obtained. A $Paco_2$ level will indicate the adequacy of ventilation in the face of a potentially obstructing mass, and a baseline Pao_2 level will serve as a guideline to the infant's degree of CHF, pulmonary insufficiency, and central shunting.

Because the surgery can be extensive, with a significant loss of blood, a baseline complete blood count with hematocrit should be obtained. In addition, the prothrombin time and partial thromboplastin time should be obtained before surgery of this magnitude because of the possibility of baseline immaturity in coagulation factor production and the inherent bleeding potential from the large dissection that will be done. Specific gravity of the urine will suggest the diagnosis of dehydration, although urinary concentrating ability does not mature until the infant is 3 months of age. A chest radiograph will define the state of the lungs and indicate whether there is tracheal deviation.

B.6. What are the causes of congestive heart failure (CHF) in the infant? How would you assess this infant on your preoperative evaluation for signs of CHF?

The causes of CHF can be divided into five major areas:

- Cardiac rhythm disturbances (heart block and supraventricular tachycardia)
- Volume overload (anemia, sepsis, and VSD)
- Systolic ventricular dysfunction (myocarditis, malnutrition, and dilated cardiomyopathy)
- Pressure overload (aortic stenosis and coarctation)
- Diastolic ventricular dysfunction (pericardial tamponade and restrictive cardiomyopathy)

CHF occurs either in response to an excessive volume or pressure load or as a consequence of myocardial muscle impairment. Volume overload is due to factors causing a large increase in cardiac output (e.g., large VSD or ductus arteriosus). In these circumstances, there must be a sufficiently large left-to-right shunt to cause a severe strain on the heart. In the normal newborn, these lesions do not usually produce heart failure until 1 to 2 months of age because it takes longer than usual for the pulmonary vascular resistance to fall. The elevated pulmonary vascular resistance protects the left ventricle from the stress of overcirculation. This is not true in premature infants who do not manifest the same degree of pulmonary arteriolar constriction. Therefore, they are susceptible to large left-to-right shunts early and show CHF more easily.

Regurgitant valvular lesions can lead to CHF. In complex CHD, such as truncus arteriosus or tricuspid atresia with transposition, the additional stress of hypoxemia or univentricular overload may herald the early onset of CHF. Large arteriovenous malformations may occur intracranially and cause CHF. Excessive pressure loads are seen in obstruction to cardiac output from aortic stenosis, aortic coarctation, and aortic interruption. In the immediate newborn period, right-sided CHF is seen with greater frequency because of severe pulmonary hypertension. Pulmonary hypertension has many causes: intrinsic lung parenchymal insufficiency or pathology, as in diaphragmatic hernia, meconium aspiration or hyaline membrane disease, chronic hypoxemia, hypervolemia, and polycythemia.

Primary myocardial failure is unusual in the newborn; it occurs with endocardial fibroelastosis and anomalous coronary circulation. However, the myocardium in the infant is susceptible to depression from metabolic derangements such as hypoglycemia, hypocalcemia, or birth asphyxia. Certainly, severe anemia with the associated decrease in systemic and myocardial oxygen supply forces an increase in myocardial work that can lead to CHF.

Infants are different from adults in their manifestations of CHF. Because of possible coexisting lung disease in many premature infants, signs of cardiac dilation may be absent because of the decreased systemic venous return from elevated intrathoracic pressure. Although immature, the carotid baroreceptors still initiate an increase in sympathetic outflow in response to reduced perfusion. The increased α-adrenergic stimulation impairs blood flow to the systemic arteriolar beds, resulting in cold, underperfused extremities, and diminished splanchnic perfusion. Fatigue, loss of appetite, and failure to thrive follow. Tachycardia from β-receptor stimulation occurs. Generalized sweating results from sympathetic cholinergic fiber stimulation. Extracellular water increases because of decreased renal excretion of sodium from a lowered glomerular filtration rate. Peripheral pitting edema is much less common in infants than older children and adults. The venous system in infants is extremely distensible and, therefore, raised right atrial pressure may not show large jugular venous engorgement. The most prominent manifestation of CHF in the infant is tachypnea. Because pulmonary venous pressure is elevated from left ventricular failure, the lung compliance falls because of the augmented interstitial fluid. Breathing becomes rapid and shallow and the resultant increase in oxygen requirement causes a cyclic dependency to maintain both tachycardia and tachypnea. Subcostal retractions are seen because of the increase in respiratory effort.

Infants have a greater lymphatic drainage capacity than adults and, therefore, can clear interstitial accumulations more readily. Therefore, rales are not as frequent a manifestation of CHF in infants as in adults. The bronchial mucosa may be swollen because of the engorgement of the bronchial venous system. The lumen of the airway is narrowed, resulting in wheezing that is often seen in infantile CHF. Hepatomegaly is a cardinal sign of right ventricular failure in infants.

Kliegman RM, Behrman RE, Jenson HB, et al., eds. *Nelson Textbook of Pediatrics*. 18th ed. Philadelphia: Saunders; 2007:1976–1981.

B.7. How would you optimize the preoperative treatment of CHF?

The typical manifestations of CHF in infants, namely tachycardia, tachypnea, subcostal retractions, and rhonchi, are also cardinal signs of pulmonary infection in this age group. They are difficult to distinguish. Often, they coexist and treatment must address both conditions. In this patient, the structural abnormality, the IAA, needs surgical correction; nevertheless, correction must be deferred until the neck mass is resected. In this infant, the CHF is caused by pressure overload from the IAA and the hypocalcemia is due to parathyroid hormone insufficiency. Calcium must be

normalized by intravenous infusion. If glucose is low, as would be expected in undernourishment, glycogen depletion from the stress of illness, or increased utilization, it should be supplemented by slow intravenous administration. Myocardial work is compromised by the presence of metabolic acidosis, which occurs as a consequence of the increased lactic acid production during anaerobic metabolism. The pH should be normalized with sodium bicarbonate. Because of the attendant sodium load, tromethamine may be an alternative.

Myocardial function should be optimized with digitalis in most infants with CHF, although in the IAA syndrome, there may be decreased renal perfusion. As a consequence, the digoxin levels may rise and toxicity may occur. Catecholamine (e.g., dopamine or dobutamine) should be infused to boost contractility. Pulmonary symptoms should be treated with antibiotics and positive pressure ventilation with oxygen carefully adjusted to arterial blood gas measurements. Intubation and mechanical ventilation may be necessary in many infants with CHF. Diuresis with furosemide will promote restoration of pulmonary compliance by decreasing lung water in conjunction with fluid restriction.

McMillan JA, Feigin RD, DeAngelis C, et al., eds. *Oski's Pediatrics: Principles and Practice*. 4th ed. Philadelphia, Lippincott Williams & Wilkins; 2006:357.

B.8. How would you premedicate this infant?

Infants younger than 2 years do not routinely require preoperative anxiolytics or narcotics. Premedicants such as midazolam have no place in this scenario. An infant with a compromised airway and circulation cannot tolerate any degree of respiratory depression. Therefore, no sedatives should be given at all. As mentioned, because a fiberoptic intubation is planned, glycopyrrolate should be given for its antisecretory activity.

B.9. When is premedication useful in infants and children?

Patients with dynamically responsive cyanotic CHD (e.g., tetralogy of Fallot) benefit from premedication before coming to the operating room. In these children, the inherent anxiety of transfer to unfamiliar surroundings, change in temperature, and parental separation may trigger infundibular spasm and reduce pulmonary blood flow, thereby leading to a blue spell. Acute hypoxemia is not an optimal state in which to initiate an anesthetic induction. Therefore, sedation with oral midazolam or rectal pentobarbital is useful to allay the child's impending state of panic and reduce the risk for provoking a hypoxemic spell. Of course, premedication is always helpful to make the overall experience of the operating room less imposing to the young child. In producing variable degrees of amnesia and reducing the potential for physical agitation, premedication offers a real benefit for children intensely frightened of the operating room.

B.10. Before the planned surgery, the infant is scheduled for a magnetic resonance imaging (MRI) scan. You are asked to ensure that the baby remains immobile for 20 minutes to perform the scan adequately. How would you accomplish this?

Given this infant's extreme risk for complete airway occlusion, there is no safe method other than endotracheal intubation, which will guarantee immobility on demand and ensure a patent airway. The routine method of sedating an infant for an MRI scan

(i.e. chloral hydrate, oral midazolam) should not be used here. Establishing an airway emergently in this infant may be impossible even with a LMA, and, therefore, sedation can proceed only after the trachea is intubated. Section C.2 details fiberoptic intubation in infants. If the infant has demonstrated a postprandial sleep cycle and can take oral fluids, it may be well worth the attempt at an MRI by using nothing at all except the inherent feeling of wellness from a full stomach.

C. Intraoperative Management

C.1. What anesthesia equipment, circuit, and monitors would you use?

Because of the depressed cellular immunity, this patient is susceptible to infection. Therefore, particularly strict attention must be paid to sterile technique during line placement and instrumentation of the patient. The anesthesiologist must wear gowns and gloves to protect the infant. Sterility of the disposable circle system, mask, endotracheal tube, fiberoptic bronchoscope, and laryngoscope should be ensured. Routine monitors for all surgery on infants include a precordial stethoscope, rectal temperature probe, electrocardiogram, blood pressure, capnograph, and spirometer. Multiple pulse oximeters should be used to offer flexibility in the event of dysfunction. In this case, the IAA prevents saturation data from the lower body and left arm. End-tidal expired gas concentrations should be recorded for anesthetic gases, nitrogen, and oxygen. Accurate capnography in small infants may be hampered by side-arm gas sampling resulting from the relatively high gas flows relative to the expired gas flow from the infant.

In this procedure, an arterial line should be inserted in the right radial site because the IAA will not allow for pressure determination on the left side. Because of the potential for significant blood loss, a central line should be placed through either the femoral vein or subclavian vein if possible. Keep in mind the distorted anatomy and the potential for difficulty in cannulation with the subclavian site. If the subclavian site is elected, before proceeding with this complicated case, a chest radiograph should be obtained to document the absence of a pneumothorax and good line position. The femoral vein may be chosen as an alternative site. Catheter length is important, and it is easy in an infant to inadvertently place the central line across the tricuspid valve, in which case misleading values of the right ventricular pressure would be obtained. Remember, in setting the transducer height that small variances in the alignment of the zero point can result in relatively large central venous pressure (CVP) value discrepancies. Therefore, the transducer should be placed with great care to approximate the right atrial level and be moved accordingly as the table height is changed.

Cerebral oximetry, described nearly 30 years ago, may be a useful intraoperative monitor to detect intraoperative ischemic events and guide intervention.

Rosen DA, Tobias JD. Cerebral oximetry using near-infrared spectroscopy aids in the diagnosis of interrupted aortic arch. *J Intensive Care Med*. 2008;23:335–337.

C.2. Describe techniques other than direct laryngoscopy that would be useful for securing the airway in this baby.

It is highly unlikely that laryngeal visualization could be accomplished in this infant with direct visualization. On the computed tomography scan, the mass is seen to elevate the tongue and deviate the larynx to the side. Because of this limitation in direct visualization, the clinician should be well acquainted with alternative methods

before emergently instituting them. The following techniques can be useful when laryngoscopy cannot be accomplished easily.

Infant video laryngoscope

This relatively new device allows for excellent glottic visualization and facilitation of intubation and may provide a better visualization than conventional laryngoscopy in some patients.

Intubation through an LMA

Securing the airway with an LMA and then using this as a guide for insertion of a fiberoptic-guided endotracheal tube.

Retrograde cricothyroid wire

Although technically difficult, the retrograde cricothyroid wire technique can be successful and is best for oral intubation. A guidewire is inserted through a large-gauge needle used to puncture the cricothyroid membrane and is threaded cephalad to be retrieved out through the mouth. This wire then serves as a stent for placement of the endotracheal tube.

Blind nasal intubation

Although very successful in the adult patient, the blind nasal intubation technique can be difficult in infants or small children. Certainly, performing an awake, sedated intubation in this manner mandates giving adequate topical anesthesia to a less than cooperative infant. In addition, the smaller endotracheal tubes used in pediatrics are far more compliant than others, especially when warmed with nasopharyngeal respiratory gases, which makes it difficult to maintain the anterior curve on the tube to enter the larynx. Styletted nasal tubes should be used only by clinicians skilled in this specialized technique.

Nasal intubation with laryngoscope and Magill forceps

If the larynx cannot be visualized by laryngoscopy, an anesthetized, spontaneously breathing nasal intubation with laryngoscopic assistance can be carried out in some patients. In this case, great care is taken to ensure that the patient maintains adequate ventilatory exchange during the inhalational induction. Halothane or sevoflurane is initiated because either is less pungent and more easily tolerated than the other halogenated ethers, and the anesthesiologist should be ever mindful that total obstruction is possible in some of these infants because of their airway abnormalities. If spontaneous breathing can be maintained, the intubation should be attempted after a surgical plane of anesthesia is achieved. The laryngoscope is used to visualize the epiglottis, and the tip of the endotracheal tube is aligned with the help of a Magill forceps and then advanced in the subepiglottic region. Capnographic monitoring during this maneuver can help verify the direction of the endotracheal tube tip.

Fiberoptic intubation

Fiberoptic intubation is most successful when carried out as the initial maneuver. It may be impossible to use after several unsuccessful attempts with conventional laryngoscopy because the upper airway is then often traumatized and hypersecretory. Fiberoptic technology is still not widely disseminated to the infant population. Most centers do not have the smallest, "ultrathin" bronchoscopes, which come as small as 2.2 mm in diameter. Limitations are found in their use because of the size and lack of a suction port. The endotracheal tube requires good lubrication before threading over the scope.

In older patients, three specialized fiberoptic methods are available that may be useful in intubating difficult infants. First, the clinician can pass a guidewire through

the suction port of the larger instrument to serve as a stylet for the endotracheal tube. Second, the scope can be used to visualize and guide a nasal endotracheal tube inserted into the opposite nostril. Finally, a 4.5-mm tube can be placed at the laryngeal orifice to be used as a stent for inserting a small guidewire, which can in turn be used to place a smaller endotracheal tube.

Transtracheal jet ventilation can be used when applicable. In this technique, a 16-gauge intravenous catheter is placed through the cricothyroid membrane and jet ventilation with 100% oxygen is provided. A second intravenous catheter is placed through the cricothyroid membrane and a guidewire (0.021 in. diameter J-tip) is introduced with cephalad angulation. Jet ventilation continues as the guidewire is threaded through the nose and connected to the working part of a fiberoptic scope. The scope is then advanced through the laryngeal inlet, and a tube is threaded over the scope when the guidewire is removed. Sedation can be provided with a remifentanil drip (0.1 to 0.2 μg/kg/min). Of course, safety is the foremost consideration in any technique for inserting an artificial airway. If the anesthesiologist cannot perform a cricothyrotomy, personnel capable of an accurate and quick cricothyrotomy should be on hand in case there is a life-threatening loss of airway control. In an emergency cricothyrotomy, a longitudinal incision is made in the skin and fascia above the cricothyroid membrane, after which the cricothyroid membrane is punctured and entered with a small endotracheal tube. Another technique uses a 14-gauge angiocatheter, which is inserted into the cricothyroid membrane. Intratracheal location is verified by the loss of resistance with an attached syringe and the aspiration of air. The catheter is attached to a 3-mL syringe (without plunger), which is then connected to the Y-piece of the anesthesia circuit by an adapter from a 7.0-mm internal diameter endotracheal tube.

C.3. How would you monitor blood loss in this patient?

In many of these procedures, blood loss can be significant, exceeding the patient's calculated blood volume. Often, much of this loss is not measurable because blood is either lost under the drapes or irrigated away. Certainly, meticulous weighing of sponges and observation of suction canisters are important, but blood loss can be continuous from the time of skin incision and may be seemingly relentless for an inexperienced clinician. Absolute changes in the CVP are a relative guide to the volume in the central compartment, but no one isolated value correlates with a known blood volume. A falling CVP in association with a downward trend in blood pressure during periods of surgical intervention known to produce significant bleeding should be treated aggressively with brisk transfusion. If blood loss is allowed to continue, severe hypotension can rapidly ensue.

C.4. What anesthetic technique should be used in a patient who may experience severe loss of blood intraoperatively?

Blood loss should be replaced milliliter for milliliter to prevent falling behind in volume. It is wise to choose an anesthetic technique that produces a relatively stable

blood pressure throughout the surgery, so that new downward trends in blood pressure can be attributable to blood loss and not to pharmacologic action. For instance, if a steady level of desflurane or sevoflurane is given at 1.25 minimal alveolar concentration (MAC) with a resultant mean arterial pressure (MAP) 15% lower than awake, further dips in MAP during surgical intervention can be taken as intravascular volume depletion secondary to bleeding and replaced accordingly. This interpretation would be obscured if there were frequent anesthetic interventions associated with MAP changes, such as intermittent narcotization, relaxant titration, or up and down titration of hypotension-inducing agents.

An important clue to the blood volume loss of the patient is the blood pressure at a MAC of anesthesia. If a stable pressure is established at a given MAC of inhalational agent, a lower than expected blood pressure at this MAC is almost always indicative of hypovolemia and, therefore, calls for fluid or blood replacement. Frequent hematocrit determinations drawn with the arterial blood gases are important. Remember, it is most unusual in an otherwise healthy infant to produce hypotension with intravascular overload.

C.5. How would you induce anesthesia in this infant?

After securing the airway and checking for bilateral breath sounds, narcotic titration with fentanyl should be given in repeated doses of 2 μg per kg. Remember, this infant may behave sensitively to any anesthetic agent because of the cardiovascular anomalies. Therefore, beat-to-beat monitoring of the blood pressure with an arterial line, as the fentanyl is administered, ensures against inadvertent drops in pressure. Because this patient is not going to be extubated, fentanyl can be given in the range of up to 50 μg per kg or higher to allow for dense analgesia. Because this will be a long procedure, cisatracurium or a longer acting relaxant such as pancuronium can be administered. If tolerated, small concentrations of approximately 0.5% to 4% desflurane or sevoflurane 0.25% to 1.5% can be administered to synergize with the narcotic and assist with amnesia and unconsciousness. The prostaglandin infusion should be maintained throughout the entire surgery.

C.6. Intraoperatively, the surgeon must dissect the tumor in the anterior mediastinum and needs to have a quiet surgical field. How would you accomplish this in the infant?

Double-lumen tubes are not used in the neonatal age group because of the exceedingly small lumen and the technical difficulties of securing both lungs. Instead, a single-lumen endotracheal tube can be advanced to the right or left mainstem bronchus to allow for one-lung ventilation. This may be fraught with consequences in this infant with IAA, but it can still be attempted. Keep in mind that hypoxic pulmonary vasoconstriction may not occur readily in the neonate and excessive shunting may be in evidence. In addition, having an infant on one-lung ventilation may lead to an elevated $Paco_2$ from pulmonary insufficiency. During thoracotomies in infants for pulmonary banding or Blalock–Taussig shunts, it is not uncommon to see extremely elevated $Paco_2$ values from retraction of the lung, especially the right side, which has almost 60% of the total lung surface area.

D. Postoperative Management

D.1. How would you manage this patient postoperatively?

This procedure, involving extensive dissection around the neck and upper thorax, warrants that the patient stay intubated or have a tracheostomy placed. A tremendous amount of upper airway and neck edema will surely ensue, which would make extubation life threatening. To facilitate care over the next day, the patient should be well narcotized and paralyzed if necessary to coordinate effective mechanical ventilation. Artificial ventilation and oxygen supplementation should be titrated to arterial blood gas determinations. In addition, the prostaglandin drip must be continued to ensure ductal patency. Generous narcotic supplementation will ensure that the pulmonary vascular resistance stays in a state of relative quiescence. If an endotracheal tube is maintained, fiberoptic visualization of the laryngeal inlet after 24 hours will enable a more educated decision on the suitability of extubation. Anatomic airway factors aside, the IAA and associated CHF will make extubation of this baby more challenging. Assuming all other factors are under control, the following ventilatory parameters should be met before extubation: normal arterial blood gases with satisfactory oxygenation of 28% oxygen, spontaneous tidal volume greater than 5 mL per kg, and inspiratory force greater than 12 cm H_2O. One should always be on the alert for airway obstruction and ready to intercede with reintubation or tracheostomy if prompt deterioration occurs.

CHAPTER 44

Patent Ductus Arteriosus and Prematurity

Isobel Russell, Rajesh Bhat, and Fun-Sun F. Yao

A 2-WEEK-OLD MALE INFANT weighing 900 g was scheduled for ligation of patent ductus arteriosus (PDA). He was born at 27 weeks' gestation as part of a triplet pregnancy complicated by preterm labor. Immediately after delivery, he was intubated because of respiratory distress. He was given indomethacin prophylactically because of his prematurity and presumed PDA. A transthoracic echocardiogram (TTE) confirmed the patency of the ductus arteriosus and demonstrated its closure after one course of indomethacin. His respiratory function was gradually improving with ventilatory support until 2 weeks later when his oxygenation and ventilation suddenly worsened. A murmur was heard over his chest. A repeat TTE demonstrated left-to-right shunting through the ductus arteriosus. Another course of indomethacin was administered, but the ductus remained patent. His blood pressure was 50/20 mm Hg; heart rate, 165 beats per minute. The laboratory data were as follows: white blood cell (WBC) count, 17,000 per mm^3; hemoglobin, 11 g per dL; hematocrit, 34%; urine specific gravity, 1.005; protein, 1 +; sugar, 1 +; serum calcium, 6.0 mg per dL; blood glucose, 60 mg per dL; arterial blood gases: pH, 7.30; $Paco_2$, 60 mm Hg; Pao_2, 49 mm Hg on Fio_2 50%, inspiratory pressure, 19/6 cm H_2O; and ventilation rate, 40 per minute.

A. Medical Disease and Differential Diagnosis

1. How would you classify prematurity? What are the common problems associated with prematurity?
2. What are the survival rates of preterm infants?
3. What are the incidence and survival rates of respiratory distress syndrome (RDS)? Discuss its pathophysiology.
4. What is bronchopulmonary dysplasia (BPD)? How would you treat it?
5. What are apnea spells? What are the possible causes of apneic spells?

6. Discuss the incidence and pathophysiology of PDA in preterm infants.
7. How would you make a diagnosis of PDA? Describe its treatment.
8. Would you give digitalis to treat congestive heart failure in preterm infants? Why?
9. How does indomethacin close the ductus? What are the adverse effects of indomethacin?
10. What is retinopathy of prematurity (ROP) (retrolental fibroplasia [RLF])? Discuss its etiology, pathophysiology, prognosis, and prevention.
11. Define neutral and critical temperatures. What are these values in the preterm neonate, in the term neonate, and in the adult? Discuss temperature regulation in the neonate.

B. Preoperative Evaluation and Preparation

1. How would you evaluate this patient preoperatively?
2. What are the normal values of arterial blood gases and pH in preterm and term pediatric patients?
3. Interpret the arterial blood gases: pH, 7.30; $Paco_2$, 60 mm Hg; Pao_2, 49 mm Hg; HCO_3^-, 20 mEq per L on 50% oxygen; and 6 cm H_2O of positive end-expiratory pressure (PEEP). How would you improve them?
4. What are the normal values of arterial blood pressure, heart rate, and respiratory rate for preterm infants?
5. What are the normal values of WBC, red blood cells (RBC), hemoglobin, glucose, electrolytes, calcium, blood urea nitrogen, and creatinine for preterm infants?
6. Would you transfuse blood to this patient preoperatively?
7. How would you interpret the urinalysis: specific gravity, 1.005; sugar, 1 +; protein, 1 +?
8. Would you correct a serum calcium level of 6.0 mg per dL? What other information would you like to have? Which contains more calcium, 10 mL of 10% calcium chloride or 10 mL of 10% calcium gluconate? Could you hyperventilate this child safely?
9. How would you premedicate this patient?

C. Intraoperative Management

1. What monitors would you use for this child during surgery?
2. How does the oxygen analyzer work?
3. What is the Doppler effect? How does the Doppler transducer measure blood pressure?
4. What is the mechanism of pulse oximetry? Why is it important to monitor arterial oxygen saturation? What levels of arterial oxygen saturation would you like to keep during surgery?
5. How would you maintain the patient's body temperature?
6. How do the anesthetic requirements of the preterm infant differ from those of the adult?
7. What size endotracheal tube would you have used if the patient had not been intubated?
8. How would you have induced anesthesia if the patient had not been intubated?
9. How would you maintain anesthesia?
10. How would you ventilate the patient? What tidal volume, respiratory rates, and FIO_2 would you set for the infant?
11. Discuss blood and fluid therapy in this preterm infant.

12. During dissection of the ductus arteriosus, the arterial oxygen saturation dropped from 92% to 80% and the heart rate decreased from 140 beats per minute to 80 beats per minute. What were the causes? How would you correct this situation?

D. Postoperative Management

1. Would you reverse the muscle relaxants and extubate the patient at the end of surgery?
2. How can one minimize the risk of transporting the patient to the neonatal intensive care unit (ICU) after surgery?
3. The patient's condition deteriorated postoperatively in the ICU. Physical examination revealed persistent cardiac murmur. What was the possible diagnosis?

A. Medical Disease and Differential Diagnosis

A.1. How would you classify prematurity? What are the common problems associated with prematurity?

Live born infants delivered before 37 weeks from the first day of the last mentstrual period are termed premature by the World Health Organization. Preterm infants can be classified into three groups, as shown in Table 44.1. Infants of borderline prematurity usually require no special care, but, because of their susceptibility to RDS, they should be observed closely for 24 to 48 hours in the newborn nursery. Further, those with a poor suck reflex may require gavage feedings. Infants classified as moderately premature require intense neonatal care, and neonatal mortality correlates inversely with gestational age. Neonates of extreme prematurity constitute only

Table 44.1 Classification of Prematurity

	BORDERLINE PREMATURITY	MODERATE PREMATURITY	EXTREME PREMATURITY
Gestational age (wk)	36–37	31–35	24–30
Percentage live births	16%	6%–7%	<1%
Weight (g)	2,500–3,200	1,500–2,500	500–1,500
Associated problems	Poor suck	Poor suck	Poor suck
	RDS	RDS	RDS
	Temperature regulation	Temperature regulation	Temperature regulation
		Sepsis	Sepsis
		Intracranial hemorrhage	Intracranial hemorrhage
			Necrotizing enterocolitis
			Congestive heart failure
			Birth asphyxia
Level of care	Careful observation in newborn nursery	Neonatal ICU	Neonatal ICU

ICU, intensive care unit; RDS, respiratory distress syndrome.

1% of all preterm infants; however, mortality in this group is extremely high, accounting for greater than 70% of all neonatal deaths. Furthermore, morbidity in surviving infants is substantial, often secondary to irreversible neurologic or respiratory insult.

Gregory GA, ed. *Pediatric Anesthesia*. 4th ed. New York: Churchill Livingstone; 2002:369.

A.2. What are the survival rates of preterm infants?

The survival rates of preterm infants depend mainly on their maturity or birth weights. Because of the advancement in neonatal care, survival rates have increased twofold in the last two decades. Recently, the survival rates for infants with birth weights 500 to 750 g, 750 to 1,000 g, 1,000 to 1,250 g, 1,250 to 1,500 g, and 1,500 to 2,000 g have been approximately 53.9%, 86.3%, 94%, 96.8%, and 97%, respectively. Recent reports showed the survival rates for premature infants born at 24, 25, and 26 weeks' gestation to be 43%, 74%, and 83%, respectively.

NICHD Neonatal Research Network. *Very low birth weight outcomes of the National Institute of Child Health and Human Development Neonatal Research Network*, Jan 1995 through Dec. 1996.

A.3. What are the incidence and survival rates of respiratory distress syndrome (RDS)? Discuss its pathophysiology.

RDS, formerly called hyaline membrane disease, is common in preterm infants. RDS is a life-threatening condition associated with 50% to 75% of all deaths of premature infants. It occurs three times more often in those born by cesarean section than in those born vaginally. The incidence of RDS depends on the birth weight. It happens in 86% of preterm infants weighing 501 to 750 g; 79% of preterm infants weighing 751 to 1,000 g; 48% of preterm infants weighing 1,001 to 1,250; and 27% of preterm infants weighing 1,251 to 1,500 g.

The survival rate has increased dramatically over the last 50 years. Survival depends on the infant's size. Ninety percent of those weighing 900 to 1,000 g survive, whereas approximately 70% of those weighing 500 to 700 g survive. Recently, an increase in survival and a decrease in severity of RDS have been associated with maternal steroid administration and routine administration of exogenous surfactant into the lungs of neonates of less than 28 weeks' gestation at birth. This may pose a problem for the anesthesiologist if these patients require surgery. Ventilation with high positive pressures and large volumes increases the likelihood of pulmonary gas leaks, pneumothorax, and lung injury.

Physical examination of the infant with RDS will likely reveal cyanosis, tachypnea, intercostal retractions, and bilateral rales that fail to clear with suctioning. An arterial blood gas sample will demonstrate hypoxemia, metabolic acidosis, and respiratory alkalosis; a chest radiograph will show diffuse, hazy ("ground glass") infiltrates.

Deficiency of the alveolar phospholipid surfactant is thought to be the cause of RDS. The surfactant is produced by the type II alveolar cells and is necessary for the maintenance of alveolar stability. Surfactant production is usually inadequate before 35 weeks of gestational age. In its absence, alveolar collapse and a decrease in functional residual capacity (FRC) occur, with consequent right-to-left shunting, arterial hypoxemia, and metabolic acidosis. Administration of betamethasone to women 48 hours before the delivery of fetuses less than 34-week gestation significantly reduces the incidence, mortality, and morbidity of RDS.

A.4. What is bronchopulmonary dysplasia (BPD)? How would you treat it?

BPD is defined as oxygen dependence at 36 weeks postconceptual age with oxygen requirements to maintain Pao2 > 50 mm Hg beyond 28 days of life in infants with birth weight less than 1,500 g. BPD is a chronic lung disease as a result of mechanical ventilation, oxygen toxicity, infection, or a combination of these factors. It includes interstitial fibrosis, lobar emphysema, and components of reactive airway disease, and may render the baby oxygen, steroid, or ventilator dependent. With progressive disease, it may lead to pulmonary hypertension and right heart failure. It usually progresses through four stages:

Stage I: At 2 to 3 days of age, the chest radiograph shows classic RDS. There are atelectasis, hyaline membrane, hyperemia, lymphatic dilation, metaplasia, and necrosis of bronchiolar mucosa.

Stage II: At 4 to 10 days of age, the chest radiograph shows obscure cardiac borders and nearly complete opacification of lung fields. The pathology reveals necrosis and repair of epithelium, persisting hyaline membrane, emphysematous coalescence of alveoli, and thickening of alveolar and capillary membranes.

Stage III: At 10 to 20 days of age, the chest radiograph shows small rounded areas of sponge-like radiolucency. There are few hyaline membranes, regeneration of clear cells, bronchiolar metaplasia, mucous secretion, emphysematous alveoli, and focal thickening of basement membrane.

Stage IV: After 30 days of age, the radiolucent areas seen in stage III enlarge and alternate with thin strands of radiodensity. The pathology reveals emphysematous alveoli and marked hypertrophy of epithelium.

BPD causes maldistribution of ventilation and perfusion, resulting in hypoxemia and hypercarbia. The treatment is supportive. The goals of treatment are to minimize the F_{IO_2} and mean airway pressure, reduce the amount of lung water with diuretics (furosemide 5 to 10 mg per kg every 6 hours), and to support cardiac contractility with inotropes.

A.5. What are apnea spells? What are the possible causes of apneic spells?

Apnea spells are defined as cessation of breathing lasting more than 20 seconds or more than 10 seconds and produces oxygen desaturatuion and bradycardia. Apneic spells are common in preterm infants, especially after the first week of life and almost universal in infants who are less than 1,000 g at birth. The causes are multiple and include the following:

- Hypothermia or hyperthermia
- Hypoglycemia or hyperglycemia
- Hypocalcemia or hypercalcemia
- Hypovolemia or hypervolemia
- Anemia
- Decreased FRC
- PDA
- Constipation
- Hypothyroidism
- Immature brain stem function
- Lack of type I muscle fibers in diaphragm
- Excessive handling
- Sepsis
- Gastroesophageal reflux disease

Repeated apnea increases the likelihood of central nervous system damage because of repeated episodes of hypoxemia. Infants who have apneic spells do not breathe during anesthesia; therefore, they should be ventilated throughout anesthesia, including the induction phase. Inhaled and intravenous anesthetics affect the control of breathing and contribute to upper airway obstruction, thereby increasing the likelihood of apnea during the postoperative period, especially in preterm infants less than 60 weeks postconception age.

A.6. Discuss the incidence and pathophysiology of PDA in preterm infants.

Fifty percent of infants weighing less than 1,000 g and 20.2% of infants under 1,750 g have hemodynamically significant PDA. In term infants, the ductus arteriosus closes soon after birth in response to the increased arterial oxygen tension. However, in preterm infants, it has a thinner, poorly contractile muscular layer with diminished responsiveness to the increasing oxygen levels after birth. In addition, preterm infants often suffer from hypoxemia because of RDS, so that there are both a reduced

stimulus to and a reduced response to physiologic closure. As many as 20% of neonates with RDS have a PDA. However, on the third to fifth day of life, some resolution of the RDS usually occurs, with a concurrent decrease in pulmonary resistance. This allows blood shunting from the systemic to the pulmonary circulation by way of the PDA, resulting in pulmonary vascular overload and ultimately left heart failure. The pulmonary congestion worsens respiratory failure, resulting in further hypoxemia and CO_2 retention.

A.7. How would you make a diagnosis of PDA? Describe its treatment.

The diagnosis of PDA in preterm infants may be suspected when there is sudden increase in respiratory failure, tachycardia, tachypnea, and a widened pulse pressure. The typical continuous or machinery murmur of PDA is usually not present in this population, but a systolic murmur, sometimes extending into diastole, and a hyperdynamic precordium are nearly always present. The diagnosis is confirmed by echocardiography that demonstrates left atrial enlargement. Two-dimensional echocardiography can identify the aortic end of the ductus. Continuous-wave Doppler can detect abnormal flow in the pulmonary artery. Color Doppler can visualize the jet of abnormal flow.

The initial treatment of PDA is medical. It includes fluid restriction and administration of diuretics and indomethacin. Indomethacin, 0.1 to 0.2 mg per kg, three doses for every 12 hours, usually closes the ductus within 24 hours. If the ductus fails to close with medical treatment, surgical ligation is indicated. There is now the option of percutaneous closure of PDA with an Amplatzer Duct Occluder.

A.8. Would you give digitalis to treat congestive heart failure in preterm infants? Why?

Digitalis should not be given to small preterm infants because it does not effectively improve stroke volume or ventricular emptying. However, it does decrease the heart rate, resulting in detrimental decrease in cardiac output. Meanwhile, digitalis toxicity increases mortality in preterm infants.

Gregory GA, ed. *Pediatric Anesthesia*. 4th ed. New York: Churchill Livingstone; 2002:349.

A.9. How does indomethacin close the ductus? What are the adverse effects of indomethacin?

The ductus arteriosus functionally closes shortly after birth in term infants when the vascular smooth muscle contracts. The muscular contraction of the ductus is initiated by the increased oxygen content and is influenced by other factors, such as release of vasoactive substances, the relative resistances in the aorta and pulmonary artery, and the differences in sensitivity of the vessel to oxygen. The ductus arteriosus produces several prostaglandins, including PGI_2 and PGE_2; both prostaglandins relax the smooth muscle of the ductus and keep the ductus patent. Meanwhile, the ductus of preterm infants is far more sensitive to the vasodilating effects of prostaglandins than is the ductus of term infants. Indomethacin is one of the most potent inhibitors of the prostaglandin-forming cyclooxygenase. Therefore, indomethacin decreases the synthesis of prostaglandins, resulting in closure of the ductus. Adverse effects of indomethacin include decreased mesenteric, renal, and cerebral blood flow. Ibuprofen is another nonselective cyclooxygenase inhibitor that can be used effectively to treat PDA and has less side effects on organ blood than indomethacin, although there is no clinical data to support its use in place of indomethacin.

A.10. What is retinopathy of prematurity (ROP) (retrolental fibroplasia [RLF])? Discuss its etiology, pathophysiology, prognosis, and prevention.

Some degree of ROP occurs in approximately 50% of infants weighing 1,000 to 1,500 g at birth, 78% of those weighing 750 to 999 g, and more than 90% of those weighing less than 750 g. At stage 3, ROP was not noted in infants with birth weight more than 1,500 g. No ROP was noted in infants born more than 32 weeks' gestational age. ROP begins with retinal vascular obliteration, which is followed by increased vascularity, hemorrhage, cicatrization, and finally retinal detachment. ROP refers to all stages of the disease and its sequelae. RLF, the term previously used for this disease, described only the cicatricial stages.

The factors that cause ROP and determine its outcome are not fully known, but prematurity, the degree of retinal immaturity at birth, and days on supplemental oxygen therapy are major factors. Other contributing factors include respiratory distress, apnea, bradycardia, heart disease, infection, hypoxia, hypercarbia, acidosis, anemia, and the need for transfusion. The presence of fetal hemoglobin may protect against ROP, and patients transfused with adult blood may be at great risk for developing ROP. Generally, the lower the birth weight and the sicker the infant, the greater the risk for ROP.

The retinal vasculature in the developing fetus spreads outward from the optic disc, reaching the nasal side of the retinal periphery by 36 weeks' gestational age and the temporal side at 40 weeks. Classically, it was postulated that hyperoxia constricts the retinal arterioles, resulting in swelling and degeneration of the endothelium. This causes paradoxical retinal ischemia in spite of systemic hyperoxia. When normoxic conditions are restored, vascularization resumes in an aberrant manner, leading to retinal detachment and blindness. ROP is divided into five stages:

Stage 1: A thin white line separates the posterior vascularized portion of the retina from the anterior avascular retina.

Stage 2: The demarcation line increases in volume and elevates. At this point, it is known as the "ridge". The changes in stage 1 and 2 regress in 80% of patients. Between 5% and 10% of premature infants with stage 1 and 2 disease progress to stage 3.

Stage 3: Tissue proliferation develops from the ridge, usually posteriorly. Stage 3 can be mild, moderate, or severe, depending on the volume of the extraretinal tissue.

Stage 4: Partial retinal detachment occurs with the macula still attached (stage 4a). The macula is detached in stage 4b.

Stage 5: Total retinal detachment occurs.

Eighty-five percent of ROP cases undergo spontaneous recovery. Mild ROP regresses in 2 to 3 months, and moderate ROP in 6 months. The most severe ROP usually results in blindness or limited vision.

It is unclear what level of Pao_2 causes ROP, but a Pao_2 of 150 mm Hg for as short a time as 1 to 2 hours can do so. Furthermore, the retinal vessels of these neonates certainly constrict maximally with a Pao_2 of 100 mm Hg. In addition, it is also possible that ROP might develop at lower Pao_2 levels because infants of this age are normally exposed to a much lower Pao_2 (30 to 40 mm Hg) in utero than the levels found during the neonatal period. Therefore, in order to reduce the possibility of ROP, it is wise to maintain the Pao_2 levels between 50 and 70 mm Hg or the saturation of oxygen (Sao_2) between 87% and 92% for infants <44 to 50 weeks' gestation. However, prevention of ROP ultimately depends on the prevention of premature birth and its attendant problems. Oxygen alone is neither sufficient nor necessary to produce ROP, and no safe level of oxygen has yet been determined. Each infant must be treated with whatsoever is necessary to sustain life and neurologic function. Some investigations have suggested the use of vitamin E for its antioxidant effects in infants at risk for ROP. However, its efficacy has not been proved.

A.11. Define neutral and critical temperatures. What are these values in the preterm neonate, in the term neonate, and in the adult? Discuss temperature regulation in the neonate.

Neutral temperature is the ambient temperature that results in minimal oxygen consumption. Critical temperature is the ambient temperature below which an unclothed, unanesthetized individual cannot maintain a normal core temperature (see Table 44.2).

Normally, body heat is lost by conduction, convection, radiation, and evaporation. The neonate is particularly susceptible to heat loss owing to a large surface: volume ratio, lack of insulating fat, and naturally flaccid and open posture. When stressed by a cold environment, vasoconstriction occurs, but the neonate is unable to shiver. Further

Table 44.2 Neutral and Critical Temperature

	NEUTRAL TEMPERATURE (°C)	CRITICAL TEMPERATURE (°C)
Preterm neonate	34	28
Term neonate	32	23
Adults	28	1

cold stress stimulates norepinephrine release, promoting the exothermic metabolism of brown fat deposits in an attempt to maintain core temperature. Continued cold stress often results in episodes of bradycardia, apnea, hypoglycemia, and metabolic acidosis.

When the infant's rectal temperature reaches 36.6° C to 37.3° C (97.88° F to 99.14° F), dilation of peripheral vessels occurs. The term neonate will perspire at 37.2° C (98.96° F) in an attempt to maintain a normal core temperature, whereas those infants born before 37 weeks' gestation are unable to sweat.

B. Preoperative Evaluation and Preparation

B.1. How would you evaluate this patient preoperatively?

The preoperative evaluation of preterm infants should be based on a clear understanding of the pathophysiology of prematurity. The preoperative evaluation of this patient should begin with a careful review of the medical record, followed by a systematic physical examination and laboratory evaluation, specifically:

- *History*. Birth trauma, asphyxia, maternal drug history, respiratory, cardiovascular, and fluid status
- *Physical examination*. Evaluation of the airway, cardiopulmonary system, fluid status (skin texture, turgor, mucous membranes, and fontanelles), and abdominal examination
- *Laboratory data*. WBC count; hemoglobin and hematocrit; serum electrolytes; serum coagulation profile, including prothrombin time, partial thromboplastin time, and platelet count; serum calcium and serum protein; arterial blood gases; urinalysis and urine-specific gravity; chest and abdominal radiographs

B.2. What are the normal values of arterial blood gases and pH in preterm and term pediatric patients?

The normal blood gas and pH values for pediatric patients are shown in Table 44.3. The normal pH and $Paco_2$ values for pediatric patients are similar to those for adults, whereas the normal Pao_2 values are lower in pediatric patients than in adult patients.

Gregory GA, ed. *Pediatric Anesthesia*. 4th ed. New York: Churchill Livingstone; 2002:257, 355.

Table 44.3 Normal Values of Arterial Blood Gases and pH in Pediatric Patients

AGE	PRETERM	TERM	1 MONTH	1 YEAR
pH	7.37 ± 0.03	7.40 ± 0.02	7.41 ± 0.04	7.39 ± 0.02
Pao_2 (mm Hg)	60 ± 8	70 ± 11	95 ± 8	93 ± 10
$Paco_2$ (mm Hg)	37 ± 6	39 ± 7	40 ± 6	41 ± 7

B.3. Interpret the arterial blood gases: pH, 7.30; $Paco_2$, 60 mm Hg; Pao_2, 49 mm Hg; HCO_3^-, 20 mEq per L on 50% oxygen; and 6 cm H_2O of positive end-expiratory pressure (PEEP). How would you improve them?

The blood gases show respiratory and metabolic acidosis. The Pao_2 of 49 mm Hg is low, but acceptable for preterm infants with chronic lung disease. In order to prevent ROP, it is wise to keep Pao_2 between 50 and 70 mm Hg. $Paco_2$ of 60 mm Hg indicates hypoventilation, which can be corrected by increasing respiratory rate or tidal volume. In order to avoid the pulmonary oxygen toxicity, FIo_2 should be lowered to less than 40% by increasing levels of PEEP. Mild metabolic acidosis may be corrected by hyperventilation and by improving fluid balance and circulation.

B.4. What are the normal values of arterial blood pressure, heart rate, and respiratory rate for preterm infants?

The blood pressure is related to the size of infants, as shown in Table 44.4. The heavier the birth weight, the higher the blood pressure is. The normal heart rate is 120 to 160 beats per minute. The respiratory rate is normally between 30 and 60 breaths per minute. However, it can increase to 100 to 150 breaths per minute depending on how severely the lung compliance is decreased.

Cote C, Lerman J, Todres I. *Practice of Anesthesia in Infants and Children*. 4th ed. Saunders/Elsevier; 2009:18.

Gregory GA, ed. *Pediatric Anesthesia*. 4th ed. New York: Churchill Livingstone; 2002:251.

B.5. What are the normal values of WBC, red blood cells (RBC), hemoglobin, glucose, electrolytes, calcium, blood urea nitrogen, and creatinine for preterm infants?

The WBC count usually ranges from 9,000 to 30,000 per mm^3 at birth and decreases to 5,000 to 20,000 per mm^3 during the fifth week of life.

Table 44.4 Normal Blood Pressure of Infants Weighing between 1,000 and 4,000 g

	BIRTH WEIGHT (g)			
	1,000	2,000	3,000	4,000
Systolic BP (mm Hg)	50 ± 10	55 ± 10	60 ± 10	70 ± 10
Diastolic BP (mm Hg)	25 ± 10	30 ± 10	35 ± 10	40 ± 10
Mean BP (mm Hg)	35 ± 10	40 ± 10	45 ± 10	50 ± 10

BP, blood pressure.

The normal RBC and hemoglobin are 5.1 ± 1.0 × 10^6 per mm^3 and 19.5 ± 5.0 g per dL, respectively, at birth and decrease to 4.5 ± 0.7 × 10^6 per mm^3 and 12.2 ± 2.3 g per dL, respectively, at 3 months of age. At birth, most of the hemoglobin is fetal hemoglobin, which has a greater affinity for oxygen. Therefore, the oxygen saturation (and content) of blood for a given Pao_2 is higher. By 7 months of age, the circulating hemoglobin is of the adult type.

The normal blood glucose level is between 45 and 90 mg per dL. A glucose level below 40 mg per dL is common in preterm infants. It should be corrected with a bolus of 10% to 20% glucose (2 to 5 g/kg) given over 5 minutes, followed by a continuous infusion of glucose. Severe hypoglycemia (<10 mg/dL) may cause brain damage.

The serum calcium concentration of preterm infants is normally lower than that of term infants because preterm infants have decreased serum proteins. Normal calcium level is over 8.0 mg per dL.

The normal values of sodium, potassium, and chloride are 135 to 145, 3.0 to 5.0, and 105 to 115 mEq per L, respectively.

The creatinine levels of term infants at birth are 0.6 to 1.2 mg per dL, but, within 1 month, fall to levels of 0.1 to 0.2 mg per dL. Preterm infants have relatively high serum creatinine levels compared with term infants. They are 0.8 to 1.8 mg per dL at birth and fall to 0.2 to 0.8 mg per dL in 1 month.

The normal blood urea nitrogen level is 10 to 20 mg per dL in term infants, whereas it is 16 to 28 mg per dL in preterm infants.

Behrman RE, Kliegman RM, Jenson HB, Stanton BF, eds. *Nelson Textbook of Pediatrics*. 18th ed. Philadelphia: WB Saunders; 2007:2944–2949.

Gregory GA, ed. *Pediatric Anesthesia*. 4th ed. New York: Churchill Livingstone; 2002:350–357.

B.6. Would you transfuse blood to this patient preoperatively?

The patient had a hemoglobin of 11 g per dL; we would not transfuse blood to this patient. To ensure oxygen-carrying capacity, most clinicians agree that a hemoglobin of 10 g per dL is the lowest acceptable level if cardiorespiratory disease exists. If infants are well, a hemoglobin level of above 7.0 g per dL is usually tolerable.

Cote C, Lerman J, Todres I. *Practice of Anesthesia in Infants and Children*. 4th ed. Saunders/Elsevier; 2009:739.

Gregory GA, ed. *Pediatric Anesthesia*. 4th ed. New York: Churchill Livingstone; 2002:357.

B.7. How would you interpret the urinalysis: specific gravity, 1.005; sugar, 1 +; protein, 1 +?

In infants weighing 1,000 to 3,300 g, the normal urine-specific gravity is 1.005 to 1.010. A urine specific gravity of greater than 1.020 suggests dehydration.

Glucosuria 1 + normally presents in 13% of preterm infants who are less than 34 weeks' gestational age because the preterm infant has a decreased renal tubular reabsorption for glucose. After 34 weeks of gestational age, glucosuria is usually associated with serum hyperglycemia.

Albumin is normally filtered by the glomerulus and is completely reabsorbed. However, because of tubular immaturity, 16% to 21% of preterm infants have proteinuria.

Cote C, Lerman J, Todres I. *Practice of Anesthesia in Infants and Children*. 4th ed. Saunders/Elsevier; 2009:170.

Grant BS Jr. Developmental patterns of renal functional maturation compared in the human neonate. *J Pediatr*. 1978;92:705.

Jones MD, Gersham EL, Battaglia FC. Urinary flow rates and urea excretion rates in newborn infants. *Biol Neonate*. 1972;21:321.

Rhodes PG, Hammel CL, Berman LB. Urinary constituents of the newborn infant. *J Pediatr*. 1962;60:18.

B.8. Would you correct a serum calcium level of 6.0 mg per dL? What other information would you like to have? Which contains more calcium, 10 mL of 10% calcium chloride or 10 mL of 10% calcium gluconate? Could you hyperventilate this child safely?

Normally, the serum calcium is maintained at 8.0 mg per dL; however, in the preterm infant, a level of 7.0 mg per dL is acceptable. This child's serum calcium is 6.0 mg per dL. Therefore, supplementation with 30 to 100 mg per kg of calcium gluconate or 10 to 20 mg per kg of calcium chloride is appropriate.

Hypocalcemia in neonate is defined as serum calcium less than 3.5 mEq per L or serum ionized calcium less than 1.5 mEq per L. When evaluating the serum calcium levels, it is important to know the serum protein concentration; neonatal hypocalcemia is usually due to hypoproteinemia. It is also important to determine the ionized calcium concentration (usually 45% of the total calcium concentration), because this is the calcium immediately available at the cellular level. The chloride molecule is approximately one-third the weight of the gluconate molecule. For this reason, approximately three times more calcium is given when an equivalent volume of calcium chloride is administered instead of 10% calcium gluconate. Respiratory alkalosis following hyperventilation will reduce serum ionized calcium levels and, for this reason, should be avoided in this infant.

Gregory GA, ed. *Pediatric Anesthesia*. 4th ed. New York: Churchill Livingstone; 2002: 159,351–357.

Hines RL, Marschall KE, eds. *Stoelting's Anesthesia and Coexisting Disease*. 5th ed. New York: Churchill Livingstone; 2008:591–592.

B.9. How would you premedicate this patient?

Children under 1 year of age do not usually need sedation. However, atropine, 0.01 to 0.02 mg per kg, may be given to attenuate the vagal response to a host of different stimuli.

Lake CL, Booker PD, eds. *Pediatric Cardiac Anesthesia*. 4th ed. Philadelphia: Lippincott Williams & Wilkins; 2005:412–416.

C. Intraoperative Management

C.1. What monitors would you use for this child during surgery?

Proper monitoring of this child for safe administration of anesthesia includes the following:

- *Respiratory*. Precordial or esophageal stethoscope, end-tidal CO_2, inspiratory oxygen monitor, pulse oximeter, arterial blood gases, inspiratory pressure gauge
- *Cardiovascular*. Precordial or esophageal stethoscope, electrocardiogram, blood pressure cuff and Doppler transducer, and urinary bag

- *Thermoregulatory*. Esophageal or axillary temperature probe with servoloop overhead heater, and thermal blanket

If the patient has an umbilical artery catheter in place, it is useful for the measurement of blood pressure and arterial blood gases. However, it is probably unnecessary to establish an arterial line for the surgery alone because invasive monitoring in this age group is not without risk.

C.2. How does the oxygen analyzer work?

Oxygen analysis can be done by either parametric or ampometric analysis. Parametric analysis is based on the fact that oxygen is a dipole molecule. When a gas containing oxygen is passed through a magnetic field, the gas is deflected in proportion to the concentration of oxygen. Sensors can detect this deflection and give a readout of oxygen concentration. Ampometric analysis can be done with one of the two devices: the galvanic cell analyzer and the polarographic cell analyzer. In the galvanic or fuel cell analyzer, oxygen diffuses through a membrane of the sensor into an electrolyte solution from which the oxygen absorbs electrons and forms hydroxide ions. The hydroxide ions then diffuse to a lead anode where oxidation to lead oxide and water occurs with the resultant liberation of free electrons. An electron flow (current) is thereby generated between the anode and the cathode, which is proportional to the oxygen level at the sensor. This current is directly displayed by a meter that indicates oxygen percentage. These devices are relatively inexpensive to purchase but carry a high operating cost because the sensor is eventually exhausted and must be replaced.

The polarographic cell, or Clark electrode, uses a battery to induce a negative potential of 0.75 V between the anode and the cathode. As oxygen diffuses across a membrane and into the electrolyte solution separating the anode and cathode, the polarizing voltage at the cathode causes electrons to combine with oxygen molecules, reducing them to hydroxide ions. The hydroxide ions then move to the anode, causing electron flow (current) that is proportional to the initial oxygen concentration. This flow is read by a meter that translates to oxygen percentages. These monitors are initially more expensive than galvanic cell monitors, but they are less expensive to maintain, requiring only inexpensive electrolyte solution and battery replacement.

Saidman LJ, Smith NT, eds. *Monitoring in Anesthesia*. 3rd ed. Boston: Butterworth-Heinemann; 1993:384.

C.3. What is the Doppler effect? How does the Doppler transducer measure blood pressure?

In 1841, Christian Doppler noted the change in observed frequency from a constant frequency sound generator when the source moved with respect to the observer. Ballot confirmed this "Doppler effect" in 1845 with the simple example of the frequency increase in a train's steam whistle as the train approached an observer. In the 1960s, Ware described a practical ultrasonic system for transducing arterial wall motion to obtain blood pressure. The ultrasonic system consists of an occlusive cuff and a dual crystal ultrasonic transducer placed over the artery distal to the occlusion. One crystal transmits the ultrasonic signal, whereas the other receives the signal reflected from the artery. Although the cuff occludes the artery, there is no arterial wall movement and the crystal receives a signal with an unchanged frequency. When the cuff pressure falls below systolic pressure, arterial wall motion

occurs, causing a Doppler frequency shift, indicating systolic blood pressure. When the cuff pressure falls to diastolic pressure, the artery is open throughout the cycle: rhythmic arterial opening and closing does not occur and there is a loss of Doppler frequency shift. Therefore, one can easily and accurately obtain systolic and diastolic blood pressure.

Saidman LJ, Smith NT, eds. *Monitoring in Anesthesia*. 3rd ed. Boston: Butterworth-Heinemann; 1993:121.

C.4. What is the mechanism of pulse oximetry? Why is it important to monitor arterial oxygen saturation? What levels of arterial oxygen saturation would you like to keep during surgery?

The mechanism of pulse oximetry is described in Chapter 2, section C.10 and Chapter 58, section A.5.

Safe anesthesia practice requires the monitoring of arterial oxygen saturation in all patients to prevent hypoxia. However, in infants of less than 44 to 50 weeks, gestation, it is also vital to guard against hyperoxia, which may cause ROP.

The arterial oxygen saturation should be kept between 86% and 92% (some say 85% to 95%).

Wasunna A, Whitlaw AGL. Pulse oximetry in preterm infants. *Arch Dis Child*. 1987;62:957.

C.5. How would you maintain the patient's body temperature?

Hypothermia greatly increases the metabolic rate and oxygen consumption of preterm infants. The preterm infant is particularly susceptible to heat loss because of a large surface-to-volume ratio, lack of insulating fat, and a naturally flaccid and open posture. In addition, the preterm infant often has impaired thermal regulatory ability; therefore, all precautions must be taken to ensure normothermia. The patient may be transported to the operating room in a battery-operated transport incubator if available. Otherwise, the infant should be covered with Saran Wrap and a warm blanket, and a cap should be put on his or her head to prevent heat loss. The operating room should be warmed to 35° C to 37° C (95° F to 98.6° F) and a servo-controlled infrared heater placed over the operating table. A water-circulating heating blanket should be put under the table sheet and kept at 37° C to 38° C (98.6° F to 100.4° F). All extremities should be wrapped in sheet wadding. All intravenous fluids and inspired gases should be warmed and humidified to help maintain the patient's body temperature. If the facility is available, then in the very low birth weight infants, the procedure can be done at the bedside with the appropriate equipment and using the ICU ventilator for airway management. This helps minimize the risks associated with transportation and also minimize the incidence of hypothermia.

Gregory GA, ed. *Pediatric Anesthesia*. 4th ed. New York: Churchill Livingstone; 2002:358, 360.

C.6. How do the anesthetic requirements of the preterm infant differ from those of the adult?

Achieving proper anesthetic depth in the preterm infant presents a unique challenge to the anesthesiologist. Whereas anesthetic requirements (as determined by minimal alveolar concentration) are decreased in the preterm infant as compared with the adult, possibly due to immaturity of the central nervous system and to increase circulating concentrations of progesterone and β-endorphins. Cardiovascular sensitivity is greatly pronounced because of greater myocardial depression and a reduced peripheral response to catecholamines. Further, the baroreceptor reflex, often poorly developed in the preterm infant, is totally ablated by even light levels of inhalation anesthesia. Therefore, the preterm infant is extremely susceptible to anesthetic overdose, which produces cardiovascular depression leading to hypotension or cardiovascular collapse.

Unfortunately, an inadequate depth of anesthesia is also uniquely hazardous in the neonate. Because there is a lack of cerebral autoregulation, any systemic hypertension from inadequate depth of anesthesia may be transmitted directly to the cerebral circulation, resulting in intraventricular hemorrhage.

For these reasons, it is essential to carefully tailor anesthetic depth to surgical conditions, because the therapeutic margin between underdose and overdose is extremely narrow.

Lou HC, Lassen PH, Fris-Hansen B. Impaired autoregulation of cerebral blood flow in the distressed newborn infant. *J Pediatr*. 1979;94:118.

C.7. What size endotracheal tube would you have used if the patient had not been intubated?

The larynx of a full-term neonate usually accommodates a 3.0- or 3.5-mm endotracheal tube, whereas infants weighing less than 3,500 g tolerate a 3.0-mm tube. In infants weighing less than 1,500 g, a 2.5-mm (internal diameter) tube is usually recommended. The endotracheal tube should be large enough to allow easy ventilation but small enough to permit leaking of gas between the tube and trachea when the lung is ventilated with 15 to 20 cm H_2O pressure. However, a higher leak pressure of 25 to 35 cm H_2O may be aimed for when high peak inspiratory pressures may be required during anesthesia, for example, during a thoracotomy or an upper laparotomy, or if the patient has decreased pulmonary compliance.

Cote C, Lerman J, Todres I. *Practice of Anesthesia in Infants and Children*. 4th ed. Saunders/Elsevier; 2009:735.

Gregory GA, ed. *Pediatric Anesthesia*. 4th ed. New York: Churchill Livingstone; 2002:218.

C.8. How would you have induced anesthesia if the patient had not been intubated?

Preterm infants do need anesthesia for surgery. The patient should be preoxygenated with 100% oxygen, and ventilation should be controlled; otherwise, the preterm infant develops apnea and bradycardia. Anesthesia in the ICU is induced with fentanyl, 1 to

3 μg per kg. When the lid reflexes are lost, the infant is intubated after 0.05 to 0.1 mg per kg of pancuronium. After intubation, breath sounds should be checked bilaterally to ensure that the tube is properly positioned.

Alternatively, anesthesia may be induced in the operating room with an inhalation anesthetic such as sevoflurane followed by muscle relaxation with pancuronium or rocuronium before intubation.

Andropolous D, Russell IA, Stayer S, eds. *Anesthesia for Congenital Heart Disease*. 2nd ed. Wiley-Blackwell; 2010:376.

Robinson SR, Gregory GA. Fentanyl-air oxygen anesthesia for ligation of patent ductus arteriosus in preterm infants. *Anesth Analg*. 1981;60:504.

C.9. How would you maintain anesthesia?

Because preterm infants are extremely sensitive to cardiovascular depression from inhalation anesthetics, we prefer to use fentanyl with or without nitrous oxide for maintenance of anesthesia. Increments of fentanyl, 3 to 5 μg per kg, are titrated to maintain hemodynamic stability. A bolus injection of high-dose fentanyl, 30 to 50 μg per kg, often causes hypotension because the infant is usually dehydrated as a result of fluid restriction and diuretic therapy for congestive heart failure from PDA. Ketamine may be used alone or as a supplement to fentanyl-air-oxygen anesthesia.

Pancuronium, 0.1 mg per kg, is an attractive choice for muscle relaxation because it causes mild tachycardia and the infant's blood pressure is dependent on heart rate.

Lake CL, Booker PD, eds. *Pediatric Cardiac Anesthesia*. 4th ed. Philadelphia: Lippincott Williams & Wilkins; 2005:412–416.

Robinson SR, Gregory GA. Fentanyl-air-oxygen anesthesia for ligation of patent ductus arteriosus in preterm infants. *Anesth Analg*. 1981;60:504.

C.10. How would you ventilate the patient? What tidal volume, respiratory rates, and FIO_2 would you set for the infant?

Controlled ventilation should be employed because preterm infants do not breathe well under anesthesia. The patient may be ventilated by hand with a Jackson-Reese device. The technique allows instantaneous compensation for changes in pulmonary compliance and resistance, especially during thoracotomy. It also permits the use of PEEP. If extra hands are not available, mechanical ventilation, preferably with a pediatric bellows, may be used to ventilate the infant.

During spontaneous respiration, normal tidal volume is 7 mL per kg for all ages. However, the ventilator tidal volumes calculated on the basis of body weight for adult patients, such as 10 mL per kg, are not applicable for pediatric patients, especially small infants. A large amount of ventilator-delivered tidal volume is lost through the large compression volume of the anesthesia breathing circuit and the leak around the uncuffed endotracheal tube. For example, if the compression volume of the anesthesia ventilator is 4.5 mL per cm H_2O (a value typical for adult ventilators) and the ventilator is set to deliver a 100 mL tidal volume to a patient at 20 cm H_2O peak inspiratory pressure, 90 mL is lost to compression volume: Only 10 mL is delivered to the patient. In addition, if pulmonary and chest wall compliances change during anesthesia and surgery, the delivered tidal volume to the patient will also be changed. Therefore, it is wise to set tidal volume whatever necessary to achieve the desired inspiratory

pressures, such as those used in the neonatal ICU before surgery. Usually the peak inspiratory pressures are set between 15 and 25 cm H_2O, depending on the patient's respiratory condition, to ensure adequate chest expansion.

The respiratory rates and inspiratory pressures are adjusted as needed to maintain the $Paco_2$ between 35 and 40 mm Hg or the end-tidal CO_2 between 30 and 35 mm Hg. The Fio_2 is adjusted to keep the Pao_2 between 50 and 70 mm Hg or the arterial oxygen saturation between 87% and 92% (practically 90% to 95%).

Gregory GA, ed. *Pediatric Anesthesia*. 4th ed. New York: Churchill Livingstone; 2002:359.

Robins L, Crooker D, Smith RM. Tidal volume losses of volume limited ventilators. *Anesth Analg*. 1967;46:428.

C.11. Discuss blood and fluid therapy in this preterm infant.

Fluid therapy should be aimed at correcting the preoperative deficit, providing maintenance fluid, and replacing intraoperative evaporative, third space, and blood loss.

Intraoperative blood loss must be carefully estimated by weighing the sponges and using small-calibrated suction bottles in plain view of the anesthesiologist. The preterm infant's blood volume is only 80 to 95 mL (85 to 100 mL per kg); therefore, even a 10 mL blood loss can be critical. Despite these precautions, estimation of blood loss is inevitably inaccurate because of the unmeasured loss in the drapes and tissues. For this reason, it is recommended that 125% to 150% of measured blood loss be replaced. Each milliliter of estimated blood loss is replaced with 3 mL of Ringer's lactate or 1 mL of 5% albumin in saline. If the hematocrit is low (<30%) to begin with, blood losses are replaced with packed RBC.

Maintenance fluids consisting of 5% dextrose in one-fourth strength normal saline are given at 4 mL per kg per hour, whereas evaporative and third-space losses are replaced with Ringer's lactate at 8 to 12 mL per kg per hour for abdominal or thoracic procedures. The adequacy of blood and fluid therapy may be ensured by stable blood pressure, normal central venous pressure (over 3 cm H_2O), and an adequate urine output of >0.75 mL per kg per hour and specific gravity of less than 1.010. In addition, the infant's fontanelle should be above the inner table of the skull if there is no volume depletion.

Cote C, Lerman J, Todres I. *Practice of Anesthesia in Infants and Children*. 4th ed. Saunders/Elsevier; 2009:737;743.

Gregory GA, ed. *Pediatric Anesthesia*. 4th ed. New York: Churchill Livingstone; 2002:360.

C.12. During dissection of the ductus arteriosus, the arterial oxygen saturation dropped from 92% to 80% and the heart rate decreased from 140 beats per minute to 80 beats per minute. What were the causes? How would you correct this situation?

Pediatric patients, especially preterm infants, develop hypoxemia quickly after hypoventilation because they have high metabolism (increased oxygen demand) and low FRC (decreased oxygen reserve). During dissection of the ductus arteriosus, the ipsilateral lung is retracted and compressed by the surgeon. Therefore, the pulmonary resistance increases and pulmonary compliance decreases. Consequently, the delivered tidal volume to the patient decreases and the gas leak around the endotracheal tube increases if the inspiratory pressures remain unchanged. Decreasing tidal volume causes hypoventilation, resulting in hypoxemia and CO_2 retention. In addition, compressing the lung tissue increases intrapulmonary shunt, which causes further hypoxemia. In pediatric

patients, bradycardia is most commonly caused by hypoxemia. During dissection of the ductus arteriosus, surgical manipulation of the vagus nerve and lung tissue may initiate vagal reflex, with resultant bradycardia.

The infant should be manually ventilated with 100% oxygen to correct hypoxemia and bradycardia. If bradycardia persists, atropine, 0.01 to 0.02 mg per kg, should be given. The surgical manipulation should be stopped and the collapsed lung reexpanded. Blood loss or hypovolemia should also be corrected.

When the hemodynamic status and oxygenation are stabilized, the F_{IO_2} and respiratory pressures should be adjusted to ensure adequate ventilation and oxygenation.

D. Postoperative Management

D.1. Would you reverse the muscle relaxants and extubate the patient at the end of surgery?

No. Postoperative ventilatory support would be necessary for this preterm infant with RDS; therefore, reversal of muscle relaxation and extubation are not indicated.

Cote C, Lerman J, Todres I. *Practice of Anesthesia in Infants and Children*. 4th ed. Saunders/Elsevier; 2009:744.

D.2. How can one minimize the risk of transporting the patient to the neonatal intensive care unit (ICU) after surgery?

The anesthesiologist's responsibilities do not end with the successful completion of the operative procedure. Removal of the surgical drapes must be done with caution to prevent inadvertent extubation or removal of the arterial or venous cannula. Transportation of the infant to the neonatal ICU is an extremely hazardous transition and requires watchful vigilance. Arrangements must be made in advance so that elevators are waiting and the nursery is ready to accept the patient. The anesthesiologist must accompany the child until satisfied that care has been appropriately transferred to the neonatal nursery staff.

The same monitors that were employed for surgery must be used in transport, including electrocardiogram and monitors for arterial blood pressure and oxygen saturation. Ventilation should be maintained by hand with a Jackson-Reese device or by a battery-operated transport ventilator, and the child should not be transported with 100% oxygen unless it was used for the operative procedure. A precordial stethoscope is especially helpful to monitor the adequacy of respiration and heart sounds. Finally, every effort to ensure thermal stability must be made, including the use of a heated Isolette (if possible), Saran Wrap, warm blankets, and a cap on the infant's head.

Miller RD, Eriksson L, Fleisher L, eds. *Miller's Anesthesia*. 7th ed. Churchill Livingstone/Elsevier; 2010:2637.

D.3. The patient's condition deteriorated postoperatively in the ICU. Physical examination revealed persistent cardiac murmur. What was the possible diagnosis?

It has been reported that a large ductus arteriosus arising from the aortic arch proximal to the subclavian artery creates the illusion of the arch, leading to surgical closure of the distal left pulmonary artery instead of ductus arteriosus (Fig. 44.1). A sign of

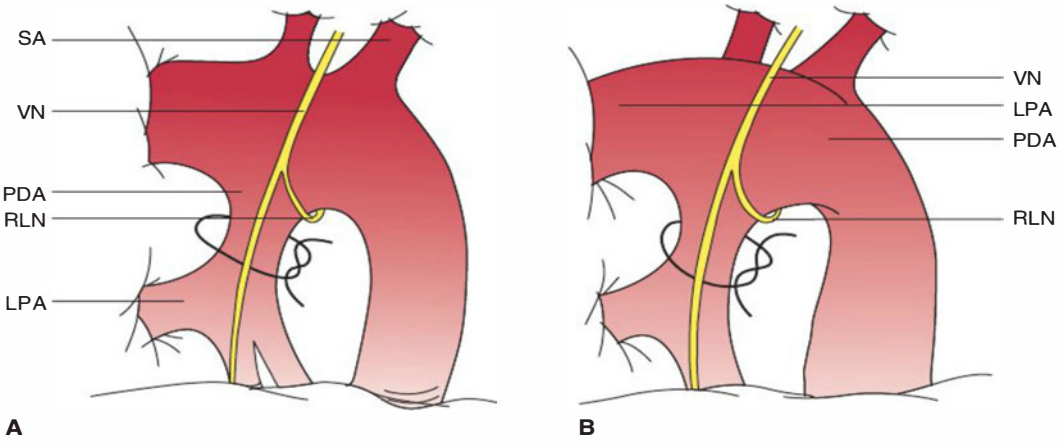

Figure 44.1 **A.** Anatomically atypical patent ductus arteriosus arising proximal to the left subclavian artery. **B.** Large patent ductus arteriosus sweeping into the descending aorta and appearing to be the arch. The ductus overlies the arch and hides it from view. A large distal left pulmonary artery is misinterpreted as the patent ductus (encircled by ligature). LPA, left pulmonary artery; PDA, patent ductus arteriosus; RLN, recurrent laryngeal nerve; SA, subclavian artery; VN, vagus nerve. (Adapted from Pontius RG, Danielson GK, Noonan JA, et al. Illusions leading to surgical closure to the distal left pulmonary artery instead of the ductus arteriosus. *J Thorac Cardiovasc Surg.* 1981;82:103–107.)

successful PDA ligation is an increase in diastolic blood pressure from the elimination of pulmonary runoff during diastole. To help identify the ductus, some surgeons place a temporary clip on the what they believe is the ductus and observe whether the diastolic pressure increases correspondingly.

In this case, the ductus arteriosus was not ligated; therefore, the ductus murmur persisted. Inadvertent ligation of the distal left pulmonary artery resulted in pulmonary ischemia distal to the ligation. Meanwhile, the right lung was further flooded with the shunted blood through the unligated PDA. The resultant ventilation/perfusion maldistribution ($\dot{V}/\dot{Q}$ abnormalities) caused further hypoxemia and CO_2 retention in this infant. The patient should be brought to the operating room for repair of the left pulmonary artery and ligation of the ductus arteriosus.

SECTION XI

Pain Management and Neuraxial Blocks

CHAPTER 45

Brachial Plexus Block

William Urmey

A 62-YEAR-OLD MAN

presents after sustaining a fall and proximal right humeral fracture. The patient's history is remarkable for hypertension and significant chronic obstructive pulmonary disease (COPD). He has a 30 pack-year cigarette smoking history. His only other remarkable history is that he claims to have fainted several times in his life. Recent pulmonary function tests 6 months before admission include a forced vital capacity (FVC) of 1.4 L (33% predicted). The patient's routine medications include atenolol and hydrochlorothiazide. Hydromorphone 1 mg was administered intravenously in the emergency room.

A. Medical Disease and Differential Diagnosis

1. What are the presenting problems in this patient?
2. What additional medical history would you want to obtain?
3. How can testing be done to evaluate severity of the patient's vasovagal syncope (neurocardiogenic bradycardia, asystole)?
4. What implications does the use of atenolol have on the patient's coexisting medical condition?
5. Why is immobilization of the arm important following humeral fracture?
6. What nerve is at particular risk for injury from humeral fracture?

B. Preoperative Evaluation and Preparation

1. What premedication would you order?
2. What are the respiratory effects of benzodiazepines?

C. Intraoperative Management

1. What anesthetic technique would you use?
2. Describe the relevant anatomy of the brachial plexus.
3. What relevant anatomic structures in the neck and below the neck can be injured or injected accidentally during brachial plexus block?
4. What regional technique would you choose to block the brachial plexus in this patient?
5. What are the advantages and disadvantages of the following blocks?
   a. Interscalene block
   b. Subclavian perivascular block
   c. Ultrasound-guided supraclavicular block
   d. Ultrasound-guided infraclavicular block
   e. Axillary block
6. Describe landmarks and procedures for interscalene block with nerve stimulation and ultrasound.
7. Describe landmarks and procedures for ultrasound-guided supraclavicular block.
8. Describe landmarks and procedure for ultrasound-guided infraclavicular block.
9. Describe landmarks and procedure for axillary brachial plexus block using a nerve stimulator.
10. The patient requests to have the interscalene block performed after you administer general anesthesia. Would you agree to this request?
11. What relevant respiratory complications or side effects are you concerned about in this patient?
12. What is the incidence of hemidiaphragmatic paresis following interscalene brachial plexus block? Can this complication be avoided by lowering the volume or concentration of local anesthetic injected? By using ultrasound-guided supraclavicular block?
13. Describe the pulmonary function changes that occur after interscalene brachial plexus block.
14. What would you do if the patient complained of dyspnea after you performed an interscalene block?
15. The surgeon prefers to perform the surgical procedure in the sitting position. What are the advantages and disadvantages of this position compared to the lateral position in this patient?
16. Which nerves are most commonly missed with axillary brachial plexus block? With interscalene block?
17. What is the local anesthetic distribution following brachial plexus block above or below the clavicle?
18. What is the expected duration of brachial plexus block with 40 mL of 1.5% mepivacaine with 5 μg per mL epinephrine?
19. What is the maximum safe dose of local anesthetic for brachial plexus block?

D. Postoperative management

1. In the postanesthesia care unit, the patient complains of dyspnea. How would you evaluate and manage this?
2. On the first postoperative day, the patient complains of persistent numbness and paresthesia in the ulnar nerve distribution. What would you tell the patient? How would you manage neurologic dysfunction after brachial plexus block that persists for 1 week?

A. Medical Disease and Differential Diagnosis

A.1. What are the presenting problems in this patient?

The patient presented for urgent surgery for a proximal humeral fracture and probably has some significant internal bleeding. The patient has significant COPD, most likely secondary to his long cigarette smoking history and has a history of multiple vasovagal episodes in the past. He also has chronic hypertension.

A.2. What additional medical history would you want to obtain?

It is important to know if the patient's fall was precipitated by a vasovagal episode or if the patient simply tripped or lost footing. The patient should be questioned whether any additional trauma occurred at the time of the fall: Has the patient's history of fainting been evaluated in the past? Does the patient have any known cardiac problems?

A.3. How can testing be done to evaluate severity of the patient's vasovagal syncope (neurocardiogenic bradycardia, asystole)?

The patient's syncopal episodes can be evaluated to determine if the cause is cardiac, including electrocardiogram, echocardiogram, and exercise stress test. Electrophysiologic studies and continuous cardiac (Holter) monitoring may be useful in selected patients. Neurocardiogenic syncope can be evaluated by carotid sinus massage (if no contraindications exist) and tilt-table testing with or without addition of a β-agonist. This patient had prior evaluation that documented an abnormal response to head-up tilt-table testing during isoproterenol infusion. After the diagnosis of neurocardiogenic bradycardia, he had been maintained on oral β-blocker therapy for 20 years without further occurrence until the present episode.

Gold BS, Weitz SR, Lurie KG. Intraoperative "syncope": evaluation with tilt-table testing. *Anesthesiology*. 1992;76:635–637.

A.4. What implications does the use of atenolol have on the patient's coexisting medical condition?

The patient's use of atenolol can exacerbate COPD, especially if there is a reversible component of airway disease. However, it can be protective with regard to development of severe bradycardia or sudden asystole if the procedure is to be performed in the "beach chair" or head-up position.

A.5. Why is immobilization of the arm important following humeral fracture?

Immobilization of the arm following humeral fracture is important to avoid injury to the brachial plexus or its terminal branches.

A.6. What nerve is at particular risk for injury from humeral fracture?

The radial nerve is at particular risk, especially with midshaft humeral fracture. Following proximal humeral fracture, the shoulder can be dislocated and malpositioning can cause stretching or pressure on components of the brachial plexus. To this extent, it is important to document any pre-existing neurologic findings on examination, especially if brachial plexus block is being considered.

B. Preoperative Evaluation and Preparation

B.1. What premedication would you order?

No single premedication regimen has been shown to be consistently more effective than others. This patient has already received a recent significant intravenous dose of hydromorphone in the emergency room. If careful history rules out any significant problems or other drug intake, intravenous midazolam can be carefully titrated in the operating room while the patient is monitored with pulse oximetry in the presence of the anesthesia practitioner. Opiates should be avoided because the patient has already received intravenous hydromorphone.

B.2. What are the respiratory effects of benzodiazepines?

Although benzodiazepines almost certainly cause a dose-related, centrally mediated respiratory depression, overall respiratory depression is not nearly as profound as with the administration of intravenous opiates. Use of carefully titrated smaller therapeutic doses of midazolam is usually well tolerated, without significant respiratory depression. Use of benzodiazepines has been shown to elevate the seizure threshold during local anesthetic administration.

Arcangeli A, Antonelli M, Mignani V, Sandroni C. Sedation in PACU: the role of benzodiazepines. *Curr Drug Targets*. 2005;6:745–748.

C. Intraoperative Management

C.1. What anesthetic technique would you use?

Interscalene brachial plexus block provides excellent operating conditions and allows for postoperative analgesia.

C.2. Describe the relevant anatomy of the brachial plexus.

The brachial plexus supplies the nerves to the upper limb. It is formed by the ventral primary divisions of the fifth to the eighth cervical and the first thoracic nerves, with possible contributions from the fourth cervical and second nerve thoracic roots. The roots join to form the superior, middle, and inferior trunks, which divide into anterior and posterior divisions (Fig 45.1.) The three posterior divisions form the posterior cord, whose major branches are the radial and the axillary nerves. The upper two anterior divisions form the lateral cord, whose major branches are the musculocutaneous nerve and the lateral root of the median nerve. The lowest anterior division forms the medial cord, which gives the medial root to the median nerve and terminates as the ulnar nerve. The sympathetic contributions to the brachial plexus are derived from the middle cervical ganglion and the stellate ganglion.

The brachial plexus begins at the level of the nerve roots, usually at C5-T1. It is at this level that the interscalene brachial plexus block, first described by Winnie, is performed. Injections at this level result in a block with central characteristics, much like a one-sided neuraxial block. Resulting sensory block at this level is characterized by a dermatomal pattern. If the block is incomplete, the typical cause is inadequate spread of local anesthetic to certain nerve roots. For example, the C8-T1 nerve roots are often spared during interscalene block anesthesia because local anesthetic distribution fails to include the lower, most caudal, nerve roots of the brachial plexus. As the brachial plexus courses more peripherally from the neck to the axilla, the nerve roots transform to trunks, divisions, cords, and finally form fully differentiated peripheral nerves.

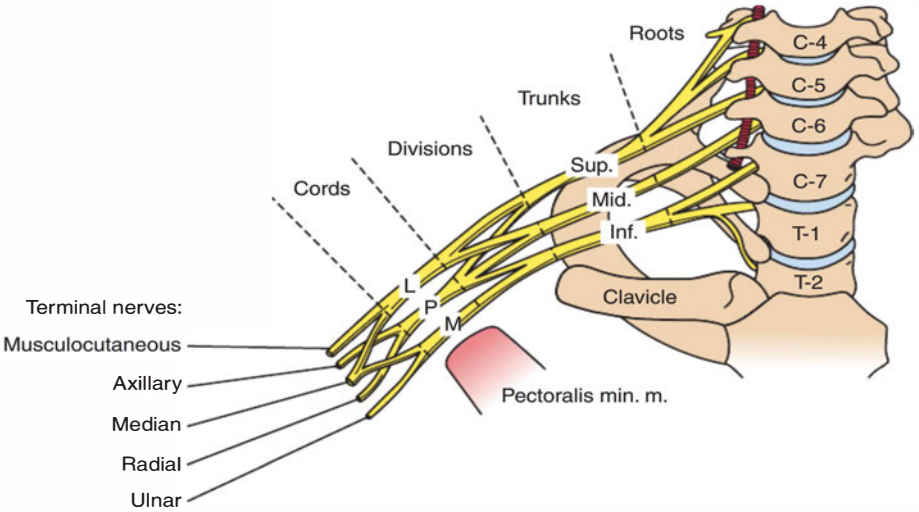

Figure 45.1 The brachial plexus. The roots join to form the superior (Sup), middle (Mid), and inferior (Inf) trunks, which divide into anterior and posterior divisions.

At the level of the axilla, where axillary block is performed, the plexus is composed of terminal nerves that include the median, radial, ulnar, and musculocutaneous nerves. At this level, an incomplete block typically spares sensory or motor blockade in the distribution of a given peripheral nerve, for example, the lateral antebrachial cutaneous nerve (the terminal sensory branch of the musculocutaneous nerve), which exits the surrounding fascia high in the brachial plexus. At this level, the nerves are spread out anatomically around the axillary artery and, depending upon the location of the needle tip during injection and the volume of local anesthetic, any of the four nerves could be spared. This has resulted in the description of multiple injection techniques for axillary block to ensure complete brachial plexus anesthesia.

At the level of the nerve roots or trunks, the brachial plexus is simply a neural plexus, being devoid of major consistently identifiable blood vessels. At this level, brachial plexus identification (i.e., needle tip location) relies on a neural response (paresthesia or motor response to electrical nerve stimulation) or direct imaging (e.g., using ultrasonographic guidance) of the neural tissue itself. At the level of the clavicle and first rib, the plexus picks up the subclavian artery, later to become the axillary artery. At this level or below, one can take advantage of the blood vessels (by palpation, Doppler flow guidance, or ultrasonographic guidance) to assist in the performance of brachial plexus block, and true perivascular techniques of brachial plexus block are the commonly preferred techniques.

C.3. What relevant anatomic structures in the neck and below the neck can be injured or injected accidentally during brachial plexus block?

The brachial plexus in the neck has multiple significant anatomic relationships that include the phrenic nerve, subarachnoid space, epidural space, spinal cord, proximal nerve roots, vertebral artery, jugular veins, and the apex of the lung. Errant needle passes can hit any one of these, and in fact, there are published case reports of complications from needle injury or local anesthetic injection for each of these anatomic structures

Below the neck, the major relevant structures are the blood vessels in the neurovascular plexus, which include the subclavian artery and vein, which more distally become the axillary artery and vein, as well as the parietal pleural, visceral pleural, and lung.

C.4. What regional technique would you choose to block the brachial plexus in this patient?

Interscalene block gives the most complete block for shoulder surgery and facilitates the placement of a catheter that can be used to extend the operative anesthesia or to administer prolonged postoperative analgesia if this is desired.

C.5. What are the advantages and disadvantages of the following blocks?

a. Interscalene block
b. Subclavian perivascular block
c. Ultrasound-guided supraclavicular block
d. Ultrasound-guided infraclavicular block
e. Axillary block

a. Interscalene block

Advantages of interscalene block include a superficial location of the interscalene space that makes it easily accessible by paresthesia, nerve stimulation, or ultrasonographic guidance techniques. Injection of an adequate volume of local anesthetic at the interscalene level results in reliably complete anesthesia or analgesia for surgery on or about the shoulder, including proximal humeral surgery. A single injection results in success rates approaching 100%. A catheter can be easily placed at this site. Finally, the axillary nerve to the deltoid and the musculocutaneous nerve to the biceps brachialis derive from the C5-C6 nerve roots, and therefore reliable relaxation of the deltoid and biceps muscles is guaranteed. This allows optimal surgical exposure and facilitates dislocation of the humeral head from the glenoid socket. If performed properly, it is impossible to cause a pneumothorax with an appropriate needle using this approach.

Disadvantages include the lack of blood vessels in the interscalene space that make perivascular techniques impossible. Close proximity of the phrenic nerve, or perhaps nerve root marginalization of those fibers contributing to phrenic nerve formation, has rarely resulted in injury to these structures and reported cases of permanent phrenic nerve palsy. Interscalene block with a volume of local anesthetic adequate for surgery results in 100% incidence of ipsilateral hemidiaphragmatic paresis.

b. Subclavian perivascular block

Advantages of subclavian perivascular block include the compact plexus at this level and the subclavian artery as a landmark. The major disadvantage is the very real possibility of pneumothorax.

c. Ultrasound-guided supraclavicular block

Advantages of ultrasound-guided supraclavicular block include superficial location of the artery and plexus that allow for easy imaging and perivascular blockade. Also, one is able to visualize two-dimensional local anesthetic distribution and can avoid inadvertent puncture or injection into the vessels. Disadvantages include the intimate

proximity to the apex of the lung, which has resulted in case reports of pneumothorax following this block. In addition, as with all ultrasound-guided blocks, larger gauged needles are often preferred to enhance imaging, which may theoretically cause more trauma than smaller gauge needles used for conventional techniques. Supraclavicular block is associated with a significant incidence of diaphragmatic paresis.

d. Ultrasound-guided infraclavicular block

Advantages of infraclavicular block include the artery, which facilitates imaging for perivascular brachial plexus block. The block does not require positioning of the upper extremity. It is easy to place a catheter at a central location of the plexus via this approach. Disadvantages are related to the depth of the plexus at this level. This may cause more discomfort and is best performed using a curvilinear probe of lower frequency, employing an in-plane technique. The depth results in poor image quality of the distal shaft and tip of the needle.

e. Axillary block

The axillary block is characterized by the major advantage of the superficial location of the individual terminal branches of the brachial plexus. Thus, one can target the fully differentiated terminal nerves by using either nerve stimulation or paresthesia techniques. Disadvantages include the need to locate more than one nerve to guarantee successful brachial plexus block at this level. In addition, as with infraclavicular block, the musculocutaneous nerve is missed with a high frequency.

C.6. Describe landmarks and procedures for interscalene block with nerve stimulation and ultrasound.

For interscalene block by electrical nerve stimulation, the patient's head is turned away from the side of the block at an approximately 45-degree angle with the surface of the bed or table. The interscalene groove (between the anterior and middle scalene muscles) is located by palpation just posterior to the lateral border of the sternocleidomastoid muscle. The electrically shielded stimulating needle is introduced in a dorsal, medial, and caudal direction until an appropriate motor response is elicited. Because of the orientation of the nerve roots in a cephalocaudad plane, a response from C5-C6 nerve roots is most frequently obtained first. C5-C6 motor response is characterized by deltoid, biceps, or brachioradialis muscle contractions. Reduction of electrical current amplitude below 0.5 mAmp at a pulse duration of 0.1 ms results in a success rate with single injection close to 100%.

For interscalene block by ultrasonographic guidance, either an in-plane or out-of-plane approach can be used, depending on the experience and preference of the operator. For an in-plane approach, the needle is inserted in a posterolateral to

anteromedial direction along the long axis of a high-frequency linear array transducer with the needle shaft and tip visualized. The middle and anterior scalene muscles should be visualized, and the hypoechoic nerve roots are usually stacked in a somewhat cephalocaudad arrangement. Injection should be made so that real-time spread of anesthetic can be visualized within the brachial plexus sheath spreading the cross-sectional nerve roots apart.

For an out-of-plane approach (Fig. 45.2), the high-frequency linear array transducer may be placed just caudal to the conventional interscalene block injection point and just above the clavicle. The longitudinal axis of the transducer is oriented in a posterolateral to anteromedial direction, with the center of the probe overlying the interscalene space and the image of the nerve roots, which again will be hypoechoic in cross-section. The needle is introduced in a slightly dorsal, medial, and caudal direction, as originally described in the conventional technique by Winnie. Nerve stimulation can be used to confirm position of the needle tip in the brachial plexus.

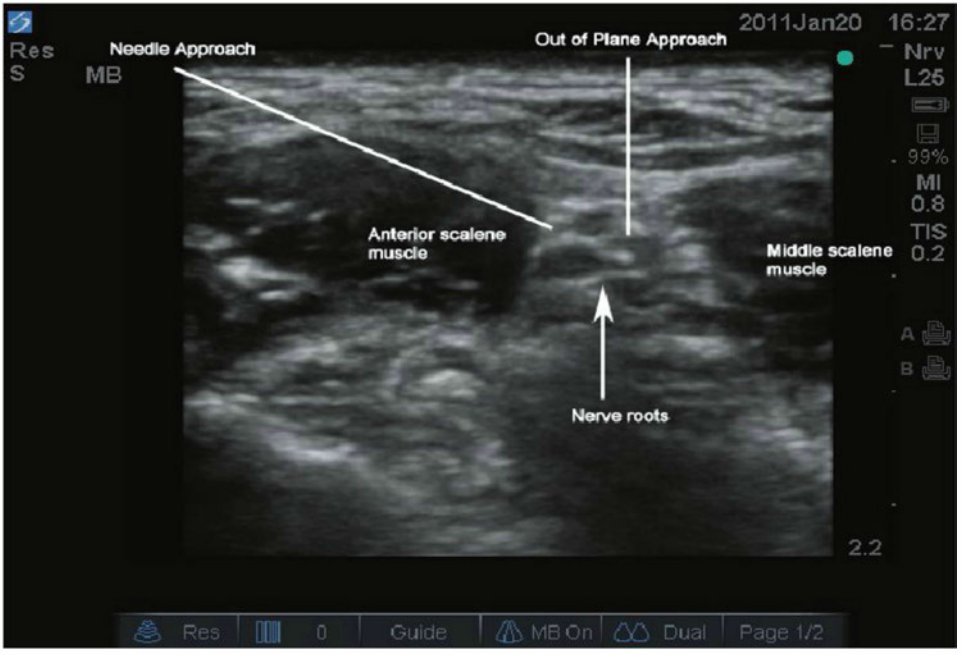

Figure 45.2 Ultrasonograhic (U/S) guidance for interscalene block. Hypoechoic roots can be visualized between the anterior and middle scalene muscles. Plexus may be reached and injected via either A, in-plane approach, or B, out-of-plane approach. Dual guidance utilizing a nerve stimulator in conjunction with U/S is easily applied at this level of the brachial plexus.

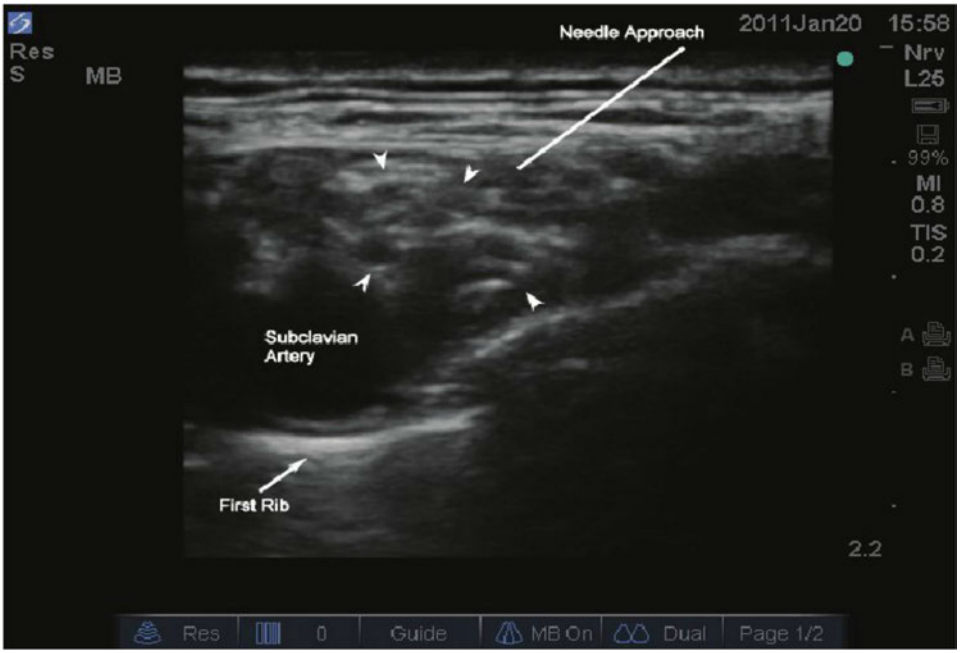

Figure 45.3 Supraclavicular nerve block guided by ultrasound.

C.7. Describe landmarks and procedures for ultrasound-guided supraclavicular block.

The brachial plexus in the supraclavicular area is located posterolateral to the subclavian artery. The plexus is above the first rib, which can be imaged. A high-frequency linear array transducer is placed just above and parallel to the clavicle in the supraclavicular fossa (Fig. 45.3.). An in-plane posterolateral to anteromedial technique is used, making sure that the needle tip and shaft are visualized throughout manipulation of the needle and that the pleura is clearly seen. Local anesthetic is deposited in more than one location among the trunks/divisions of the brachial plexus.

C.8. Describe landmarks and procedure for ultrasound-guided infraclavicular block.

The ultrasound-guided infraclavicular block is usually performed by an in-plane approach with a lower frequency curvilinear transducer that is positioned in the deltopectoral groove. This can be a relatively deep block, and it may require a needle of up to 10 cm in length. The axillary artery and vein and cords of the brachial plexus are visualized (Fig. 45.4). The needle is placed just cephalad to the center of the long axis of the probe and inserted at an angle of 45 degrees until the tip encounters the brachial plexus. This is a perivascular block, and the arterial pulsations greatly facilitate ability to use an out-of-plane approach effectively. One should ensure that local anesthetic spread is visible upon injection. This enhances success and helps to makes certain that accidental intravascular injection is avoided. It is preferable to deposit local anesthetic posterior to the axillary artery close to the posterior cord. It may be necessary to inject in more than one place in the brachial plexus by moving the needle around and dividing doses of local anesthetic injectate.

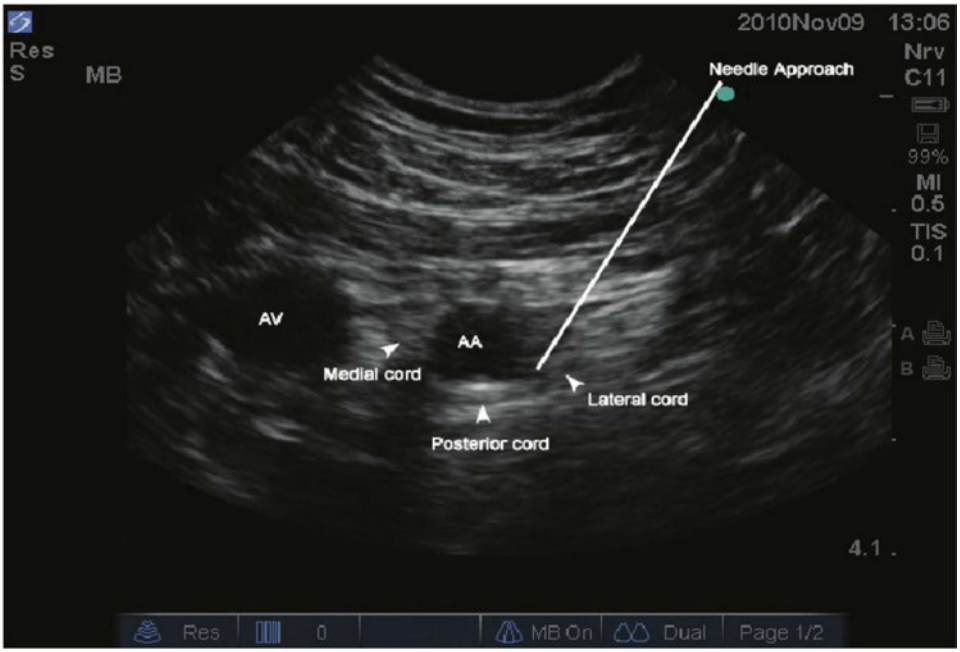

Figure 45.4 Infraclavicular nerve block guided by ultrasound.

C.9. Describe landmarks and procedure for axillary brachial plexus block using a nerve stimulator.

With the patient in a supine position, the arm is elevated to 90 degrees. The patient's artery is palpated, and a small-gauge electrically shielded stimulating needle is introduced just below the artery to elicit motor response from the radial nerve (deep to the artery) or ulnar nerve (medial to the artery; i.e., immediately below with the arm in this position). The needle is re-sited and advanced superficial to the artery for a median nerve motor response. Highest success rate correlates with at least two motor responses in which one response is from radial nerve stimulation. By insisting on current amplitude levels of 0.5 mAmps or below, at short pulse duration (0.1 msec), success rates in the 95% to 100% range can be expected.

C.10. The patient requests to have the interscalene block performed after you administer general anesthesia. Would you agree to this request?

In a landmark publication, Benumof reported four cases of permanent injury to the cervical spinal cord resulting from interscalene block performed during general anesthesia. Imaging of the cervical spinal cord showed vacuolization of the cord or the presence of a syrinx. Intraneural injection of local anesthetic under pressure has been found to spread along the longitudinal axis along the nerve during experimental studies. Thus, theoretically, injection into a proximal nerve root can spread and disrupt the cervical spinal cord.

Performance of interscalene block in the anesthetized patient does not allow the patient to report painful paresthesia or other sensations. Sudden severe pain on injection during peripheral nerve block is a time-honored signal that neural tissue is endangered and that the needle should be promptly withdrawn and re-sited. It has

been shown that needle contact with the nerve is often not associated with the ability to elicit a motor response during electrical stimulation. Reports of accidental intraneural injection during ultrasonographic needle guidance have been published. Therefore, no available modality can ensure against this devastating complication. It is strongly advised that interscalene block not be performed in a patient who is heavily sedated or following induction of general anesthesia.

C.11. What relevant respiratory complications or side effects are you concerned about in this patient?

Ipsilateral hemidiaphragmatic paresis is a consistent side effect associated with interscalene block. It occurs with an incidence of 100%. This expected side effect takes on added importance if the patient has respiratory comorbidities, including contralateral phrenic or diaphragmatic pathology, severe chronic obstructive cardiopulmonary disease, neuromuscular disorders in which a 25% reduction in FVC would not be tolerated, or conditions that restrict ribcage motion such as ankylosing spondylitis. If these conditions are present, significant atelectasis or respiratory failure can occur. With proper technique and needle size, there is no possibility of causing a pneumothorax. Introduction of a catheter, nevertheless, could theoretically reach the apex of the lung.

Urmey W, Talts K, Sharrock N. One hundred percent incidence of hemidiaphragmatic paresis associated with interscalene brachial plexus anesthesia as diagnosed by ultrasonography. *Anesth Analg*. 1991;72:498–503.

C.12. What is the incidence of hemidiaphragmatic paresis following interscalene brachial plexus block? Can this complication be avoided by lowering the volume or concentration of local anesthetic injected? By using ultrasound-guided supraclavicular block?

Hemidiaphragmatic paresis occurs 100% of the time with interscalene block and cannot be avoided by reducing the volume of local anesthetic injected. Volumes as low as 5 mL (which is inadequate for surgical anesthesia) have been associated with a 45% incidence of hemidiaphragmatic paresis. Similarly, reductions in local anesthetic concentration do not avoid this side effect, with concentrations of bupivacaine as low as 0.125% being associated with 100% incidence of hemidiaphragmatic paresis. The use of ultrasound-guided supraclavicular blocks may reduce the incidence of hemidiaphragmatic paresis from 100%, but will still be expected to be associated with a significant incidence. Blocks above the clavicle are associated with spread of local anesthetic into the cervical plexus. The mechanism for phrenic nerve paresis is motor blockade of the C3-C5 nerve roots before forming the phrenic nerve. The main nerve root contributing to formation to the

phrenic nerve is the C4 nerve root. Any block causing sensory blockade of C5, C4, or C3 would be expected to have associated phrenic paresis. A recent publication suggests that with careful deposition of local anesthetic by ultrasonographic guidance, the incidence of hemidiaphragmatic paresis may indeed be avoided during supraclavicular block.

Renes SH, Spoormans HH, Gielen MJ, et al. Hemidiaphragmatic paresis can be avoided in ultrasound-guided supraclavicular brachial plexus block. *Reg Anesth Pain Med*. 2009;34:595–599.

Urmey W, Talts K, Sharrock N. One hundred percent incidence of hemidiaphragmatic paresis associated with interscalene brachial plexus anesthesia as diagnosed by ultrasonography. *Anesth Analg*. 1991;72:498–503.

C.13. Describe the pulmonary function changes that occur after interscalene brachial plexus block.

Pulmonary function (such as FVC and forced expiratory volume in 1 second) reductions of 25% to 30% occur routinely. These changes are usually complete within 15 minutes of completion of the injection. Increased upper rib cage expansion and ipsilateral paradoxical inward motion of the hemiabdomen have been reported (Fig. 45.5). The combined effect of these changes is a reduced ability to cough and clear secretions, which may be poorly tolerated by a patient with severe COPD.

Urmey W, McDonald M. Hemidiaphragmatic paresis during interscalene brachial plexus block: effects on pulmonary function and chest wall mechanics. *Anesth Analg*. 1992;74:352–357.

C.14. What would you do if the patient complained of dyspnea after you performed an interscalene block?

The patient should be reassured and observed. Most patients complaining of dyspnea will have more than adequate pulmonary function for normal respiration. Symptoms of dyspnea may be relieved by placing the patient in the upright or sitting position as tolerated. This position optimizes diaphragmatic geometry and function and increases functional residual capacity. Auscultation often reveals diminished or silent breath sounds on the side of the block. Chest radiography may be obtained if pneumothorax is suspected. Application of a face mask to assess ventilation or end-tidal carbon dioxide may be done, and assisted or controlled ventilation can be used if necessary. Endotracheal intubation should be performed if clinically indicated.

C.15. The surgeon prefers to perform the surgical procedure in the sitting position. What are the advantages and disadvantages of this position compared to the lateral position in this patient?

As discussed earlier, the seated position optimizes chest wall mechanics. However, placing the patient in the seated position may be associated with hypotension or bradycardia. Severe bradycardia or asystole may occur. It is suggested that these events occur as a result of the Bezold-Jarisch reflex (paradoxical cardiac inhibition and bradycardia in response to decreased ventricular volume resulting from venous pooling in sitting position). Use of intravenous β-blockers may help to diminish the incidence

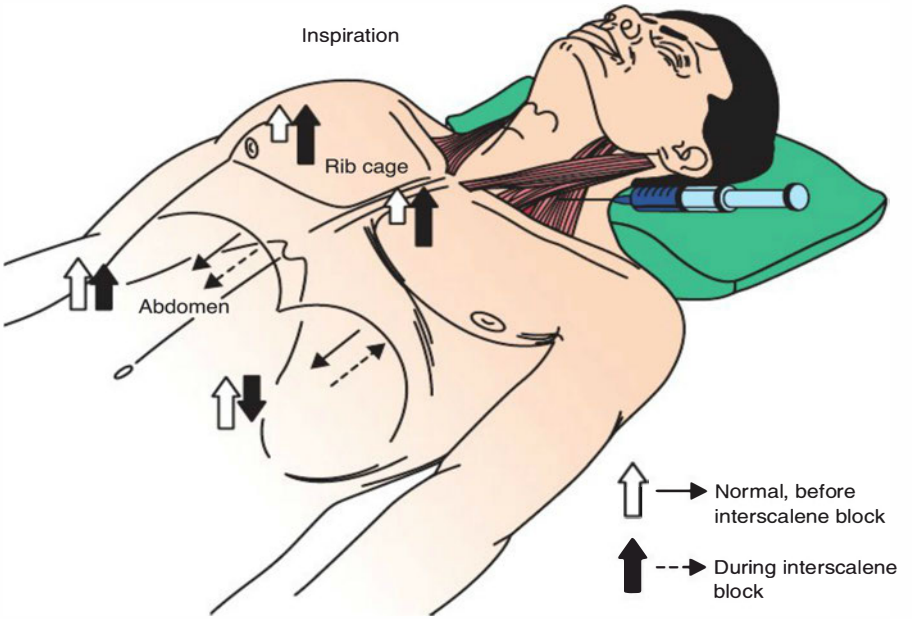

Figure 45.5 Illustration of typical changes in chest wall motion measured by magnetometry during interscalene anesthesia. The ipsilateral hemiabdomen no longer expanded, contracting instead with tidal inspiration 10 minutes after interscalene brachial plexus injection of mepivacaine. (From Urmey WF, McDonald M. Hemidiaphragmatic paresis during interscalene brachial plexus block: effects on pulmonary function and chest wall mechanics. *Anesth Analg*. 1992;74:356, with permission.)

of significant hypotension and bradycardia. The sitting position may be thought of as a variation of the tilt-table test. This patient would be at particular risk for developing intraoperative bradycardia in the sitting position because of the history of syncopal episodes and positive findings on the tilt test. Intraoperative bradycardia can be easily treated with small doses of intravenous epinephrine, ephedrine, atropine, and intravenous fluids. Vigilance and rapid response are of critical importance.

Tarkkila P, Isola J. A regression model for identifying patients at high risk of hypotension, bradycardia and nausea during spinal anesthesia. *Acta Anaesthesiol Scand*. 1992;36:554–558.

C.16. Which nerves are most commonly missed with axillary brachial plexus block? With interscalene block?

Axillary brachial plexus block commonly misses the musculocutaneous nerve, which arises from C5-C6 nerve roots and exits the plexus above the axilla. Interscalene block

commonly spares the ulnar nerve, which is formed by the C8-T1 nerve roots at the lower extent of the brachial plexus.

Lanz E, Theiss D, Jankovic D. The extent of blockade following various techniques of brachial plexus block. *Anesthesia & Analgesia*. 1983;62:55–58.

C.17. What is the local anesthetic distribution following brachial plexus block above or below the clavicle?

The brachial plexus can be thought of as a structure that is enclosed by fascia to form an hourglass-shaped anatomic compartment. The upper chamber of the hourglass is a flattened triangular space containing the nerve roots and trunks of the brachial plexus, which are stacked in a plane. Below the clavicle, a more conventional three-dimensional cylindrical lower hourglass chamber shape applies, widening as the plexus courses distally away from the impingement point, which is at the level of the junction of the clavicle and first rib (where the divisions are located). Clinically, the shape of each compartment, and particularly the high resistance at the middle of the "hourglass" results in very different distributions of local anesthetic when injections are made above versus below the clavicle. Above the clavicle, injections result in central neuraxial block characteristics, with resulting dermatomal patterns of sensory block. Neural structures are relatively compact, and therefore small volumes are adequate to fill the sheath above the clavicle and injectate extends into the cervical plexus. Below the clavicle, the plexus is a neurovascular plexus with fully differentiated cords progressing to terminal nerves that surround the artery in a more three-dimensional anatomy. Typically, larger volumes or multiple injections are required for successful block and injections do not reach the cervical plexus.

Urmey WF. Using the nerve stimulator for peripheral or plexus nerve blocks. *Minerva Anestesiol*. 2006;72:467–471.

C.18. What is the expected duration of brachial plexus block with 40 mL of 1.5% mepivacaine with 5 μg per mL epinephrine?

Such an injection typically lasts 4 to 5 hours for surgical anesthesia.

C.19. What is the maximum safe dose of local anesthetic for brachial plexus block?

There is no absolute maximum safe dose of local anesthetic. The brachial plexus is characterized by relatively low systemic absorption compared to that of other blocks, such as epidural or intercostal. Absorption of local anesthetic following regional anesthetic injection is site specific. The American Society of Regional Anesthesia has published guidelines for local anesthetic toxicity. One should be cognizant of the recent publications demonstrating the efficacy of intravenous infusion of lipid emulsion in reversing local anesthetic–induced cardiac toxicity in animals and in multiple case reports involving human patients. Background information as well as advice concerning resuscitation equipment and procedure, including recommended dosing of lipid emulsion, can be obtained by accessing www.lipidrescue.squarespace.com.

D. Postoperative Management

D.1. In the postanesthesia care unit, the patient complains of dyspnea. How would you evaluate and manage this?

The patient's vital signs should be monitored, including the oxygen saturation. Duration of hemidiaphragmatic paresis following brachial plexus block with mepivacaine or bupivacaine with added epinephrine lasts 3 to 4 hours or 9 to 18 hours, respectively. If a catheter has been placed, it should be checked via imaging to ascertain that it is not in the cervical plexus. Chest radiography should be performed to rule out pneumothorax or significant atelectasis. The patient should be supported by placement into the sitting position and ventilation assisted or controlled if necessary.

Urmey W, Gloeggler P. Effects of bupivacaine 0.5% compared with mepivacaine 1.5% used for interscalene brachial plexus block (abstract). *Reg Anesth*. 1992;17:13.

D.2. On the first postoperative day, the patient complains of persistent numbness and paresthesia in the ulnar nerve distribution. What would you tell the patient? How you would you manage neurologic dysfunction after brachial plexus block that persists for 1 week?

Brachial plexus block via the interscalene approach is characterized by sparing of the C8-T1 nerve roots (ulnar distribution) approximately 50% of the time, even with an injectate volume of 50 mL local anesthetic. The needle does not contact the C8-T1 nerve roots, and therefore direct injury would be exceedingly rare following interscalene block. More commonly, short-term ulnar neuropathy occurs from intraoperative positioning, including pressure at the elbow, flexion at the elbow, or dislocation of the humeral head during open shoulder surgery. Use of a pneumatic tourniquet can also result in such neuropathy. I would tell the patient that this typically goes away after a short period and that if it persists for 1 week, a neurologist would be contacted to evaluate the possibility of ulnar neuropathy or brachial plexopathy. Even persistent neuropathy typically resolves completely in 3 to 6 months. Electromyography can be performed to ascertain the site of any lesion and whether it is at the level of the brachial plexus.

CHAPTER 46

Nerve Blocks of the Lower Extremity

Jeffrey Y. F. Ngeow, David Wang, and Karina Gritsenko

A 67-YEAR-OLD MAN

is scheduled for exploration of a displaced right metatarsal fracture after stumbling on a carpet. His medical history is significant for stage III multiple myeloma, osteoporosis, anemia, increased cholesterol, and chronic back pain related to prior pathologic compression fractures. The patient recently completed a course of chemotherapy and radiation for refractory myeloma. Regular medications include aspirin 81 mg, atorvastatin, OxyContin 10 mg three times daily, oxycodone 15 mg 1 or 2 tablets every 4 to 6 hours as needed, pregabalin 100 mg twice daily, and bisphosphonates. Foot radiographs show spiral fracture of the right fifth metatarsus. Previous magnetic resonance imaging (MRI) showed multiple lumbar compression fractures and degenerative disease without compression of the spinal cord. The patient's hemoglobin is 7.2 g per dL, calcium level is 13.1 mg per dL, and platelets count 79 $\times$ 10^3 per μL. Prior anesthetic records yielded a history of difficult intubations.

A. Medical Disease and Differential Diagnosis

1. What is multiple myeloma?
2. What are concerns associated with multiple myeloma?
3. What is the significance of a pathologic fracture?
4. What is the significance of hypercalcemia and thrombocytopenia in this patient?

B. Preoperative Evaluation and Preparation

1. Will you be concerned with the status of neurologic function in this patient?
2. What is the significance of the abnormal MRI findings?
3. What other investigations should be reviewed in evaluating this patient?
4. Should one proceed with surgery at this time?

5. What anesthetic options should be discussed with the patient preoperatively?
6. What special concerns exist related to neuraxial anesthesia in this patient?

C. Intraoperative Management

1. What special monitoring should be employed intraoperatively?
2. Which peripheral nerve blocks can be used for exploration of the metatarsals? What are the landmarks for an ankle block?
3. What are the advantages and disadvantages of an ankle block?
4. What other peripheral regional anesthetic techniques may be appropriate?
5. How is ultrasound guidance useful in performing peripheral nerve blocks?
6. What are the risks of peripheral nerve block in an immune-compromised patient?

D. Postoperative Management

1. How should the postoperative pain be managed in this patient?
2. Why should the neurovascular status of the foot be followed?

E. Summary

A. Medical Disease and Differential Diagnosis

A.1. What is multiple myeloma?

Multiple myeloma is a disease characterized by proliferation of malignant plasma cells and subsequent overabundance of monoclonal paraprotein. These collections of abnormal cells can accumulate in the bone marrow and interfere with production of normal cells. The monoclonal paraprotein can also interfere with kidney functions and alter the production of normal antibodies. Results of this disease include renal failure, immunodeficiency, infection, hypercalcemia, anemia, weakness, confusion, and fatigue.

Fauci AS, Braunwald E, Kasper DL, et al., eds. *Harrison's Principles of Internal Medicine*. 17th ed. New York: McGraw-Hill; 2008:701–706.

Ross JS, Brant-Zawadzki M, Moore KR, et al. eds. *Diagnostic Imaging Spine*. 1st ed. Salt Lake City: Amirsys; 2005:66–69.

A.2. What are concerns associated with multiple myeloma?

Specific concerns related to multiple myeloma include bone pain, bone metastases, pathologic fractures, spinal cord compression, renal dysfunction, hypercalcemia, leukopenia, anemia, and abnormal bleeding from thrombocytopenia. In addition, the aberrant antibodies may lead to impairment of normal humoral immunity, increasing the patient's susceptibility to encapsulated organisms.

Fauci AS, Braunwald E, Kasper DL, et al., eds. *Harrison's Principles of Internal Medicine*. 17th ed. New York: McGraw-Hill; 2008:701–706.

A.3. What is the significance of a pathologic fracture?

Pathologic fractures are secondary to bone lesions, which include infections and tumor, such as metastases, lymphoma, plasmacytoma, bone cysts, lipoma, and osteoblastoma. These bone lesions can occur in multiple sites of the body. Up to 93% of

myeloma patients have more than one site of bone involvement. A severe bone event is a common presentation in this patient group.

Specifically bone-related pain is the most common symptom of multiple myeloma. It is the most common cancer to metastasize to bone, with up to 90% of patients developing bone lesions and 60% of patients developing a pathologic fracture over the course of their disease. Persistant localized pain is typical of a pathologic fracture in this patient population.

Esteve FR, Roodman GD. Pathophysiology of myeloma bone disease. *Best Pract Res Clin Haematol*. 2007;20:613–624.

Fauci AS, Braunwald E, Kasper DL, et al., eds. *Harrison's Principles of Internal Medicine*. 17th ed. New York: McGraw-Hill; 2008:701–706.

A.4. What is the significance of hypercalcemia and thrombocytopenia in this patient?

Significant laboratory abnormalities in this patient may indicate a patient having lytic lesions, compression fractures, or renal insufficiency. Multiple myeloma can affect the production and inhibition of one or more clotting factors or have an additive effect with other cancers with paraprotein disorders, particularly primary or metastatic liver cancer. The chemotherapy that is used to treat malignancies may also cause such changes. These features may affect the choice of anesthesia technique or anesthetic dosing (renal versus hepatic metabolism of a medication in a patient with an elevated creatinine).

B. Preoperative Evaluation and Preparation

B.1. Will you be concerned with the status of neurologic function in this patient?

In this patient with a history of malignancy and pathologic fractures, one must consider possible nerve injury from compression or invasion. Furthermore, given that the patient is currently thrombocytopenic, the risk for surgery-related hematoma and subsequent nerve damage is increased. As part of the preoperative evaluation, a thorough physical examination including a complete neurologic assessment of strength and sensory testing should be recorded before performing any regional anesthesia.

Hines RL, Greene NM, eds. *Stoelting's Anesthesia and Co-existing Disease*. 5th ed. Philadelphia: Saunders; 2008:516–517.

B.2. What is the significance of the abnormal MRI findings?

Given the patient's history of chronic low back pain and multiple compression fractures, one would expect increased technical difficulty in placing a neuraxial anesthetic.

In addition, trauma from needling may increase the risk for spinal hematoma. Any invasive procedure along the spine might cause additional pain.

Mahnken AH, Wildberger JE, Gehbauer G, et al. Multidetector CT of the spine in multiple myeloma: comparison with MR imaging and radiography. *AJR Am J Roentgenol*. 2002;178:1429–1436.

Ross JS, Brant-Zawadzki M, Moore KR, et al., eds. *Diagnostic Imaging Spine*. 1st ed. Salt Lake City: Amirsys; 2005:66–69.

B.3. What other investigations should be reviewed in evaluating this patient?

Preoperative workup in this patient should include a review of the chest and foot radiographs, laboratory values including biochemistry, electrolytes, and the coagulation profile.

Foot radiography will show the extent of the fracture and guide the type of regional anesthesia selected. For example, if bone grafting seems necessary, it will certainly need to be considered in the anesthetic plan.

A chest radiograph may show lung metastases and even pericardial effusions in a patient with disseminated cancer. Such findings may have a bearing on intraoperative management and postoperative analgesic requirements.

Biochemistry test results will help to rule out systemic conditions that could be expected in a patient with progressive multiple myeloma, including hypercalcemia and renal insufficiency. In addition, one must also be alert to bleeding concerns resulting from thrombocytopenia, platelet dysfunction, and compromised immune status in patients with recent chemotherapy.

Grethlein SJ, Thomas LM. Multiple Myeloma. *EMedicine*. Available at: http://emedicine.medscape.com/article/204369-overview. Accessed December 8, 2010.

B.4. Should one proceed with surgery at this time?

Based on the laboratory values, the patient has a notable hypercalcemia that could be indicative of other abnormalities such as renal dysfunction, hyperviscosity, or hypovolemia. In this scenario, the operation being an elective procedure, it would be appropriate to correct any electrolyte abnormality before proceeding to the operating room.

Hines RL, Greene NM, eds. *Stoelting's Anesthesia and Co-existing Disease*. 5th ed. Philadelphia: Saunders; 2008:516–517.

B.5. What anesthetic options should be discussed with the patient preoperatively?

The most simple and safe anesthetic approach that is compatible with the requirements of the surgery and is acceptable to the patient should be used. In this case study, the history of difficult intubation makes general anesthesia a less desirable option for peripheral surgery. The use of neuraxial techniques is also less desirable given the current thrombocytopenia, history of pathologic fractures, and possible tumor within the spine.

Actual risk for vertebral canal (spinal) hematoma in a patient with thrombocytopenia is unclear. There are even fewer data on the safety of peripheral nerve blocks in the presence of thrombocytopenia. All of the major bleeding complications associated with anticoagulation and nonneuraxial regional techniques that have been reported in the literature occurred after psoas compartment or lumbar sympathetic nerve blocks. Case reports suggest that the major risk of nerve blocks in the presence of anticoagulation relates to blood loss, rather than neurologic complications. If surgery is deemed urgent by the surgeon, a reasonable anesthetic plan may include performing an ankle block for the foot and another peripheral nerve block for the iliac crest, in anticipation of the need for bone graft harvesting.

The mention of nerve blocks may evoke fear of painful needles and anxiety at the possibility of intraoperative pain or awareness. A full discussion of the risks and benefits of any regional anesthetic technique is an important part of the preoperative anesthetic consultation. Irrespective of the anesthetic techniques selected, the patient must be assured of adequate relief from anxiety and pain during the induction of anesthesia, the operation itself, and the postoperative period.

There should also be a discussion of the nature and possible side effects of the drugs involved, including the medications used for intraoperative sedation, as well as the local anesthetic agents. The patient should be informed that regardless of the anesthetic technique used, neither complete anesthesia nor amnesia can be ensured at all stages of the operation.

Spitellie PH. Holmes MA. Domino KB. Awareness during anesthesia. *Anesthesiol Clin North America*. 2002;20:555–570.

B.6. What special concerns exist related to neuraxial anesthesia in this patient?

Issues with coagulopathy can be of significant concern in patients with cancer. Bone marrow replacement by tumor or suppression by chemotherapy can cause thrombocytopenia, hypofibrinogenemia, prolonged prothrombin, thrombin, activated partial thromboplastin times, and elevated fibrinogen degradation products. All of them create higher risks for spinal hematoma. In addition, patients with cancer have a sixfold increase in risk for developing thromboembolism or even disseminated intravascular coagulopathy; thus, pharmacologic prophylaxis with heparin, low molecular weight heparin, or warfarin can be appropriate. If this patient had a history of requiring anticoagulation, the anesthetic technique would be influenced by the timing of the anticoagulant given, especially if a neuraxial anesthetic is chosen.

In patients with a higher likelihood of bone metastases such as cancer of the breast, lung, prostate, or multiple myeloma, the vertebral column is often involved. There has been some concern regarding neuraxial anesthesia and catheter placement, for example, in patients with acute lymphoblastic leukemia. It was thought that traumatic or bloody puncture of the dura may seed the spine with blast cells and thus worsen outcome. At this time, the evidence to support this is sparse and the American Society of Regional Anesthesia (ASRA) guidelines contain no clear recommendation for or against it.

C. Intraoperative Management

C.1. What special monitoring should be employed intraoperatively?

Special monitoring in this case may include a Doppler ultrasound flow detector probe on the operated limb before and after induction of anesthesia. In most cases, an increase in blood flow occurs after successful neural blockade. Any change, or lack of change, in the perfusion status of the foot should be documented. When continuous intraoperative blood flow monitoring is necessary, a sterile probe for pulse oximetry with plethysmographic display may be attached to a nearby digit, if the operating condition permits. If a tourniquet is required, which is usually the case when blood flow is not severely compromised, the tourniquet pressure and acceptable ischemia time must be discussed with the surgeon beforehand and carefully followed. With noncritical cases of vascular insufficiency, a simple preoperative test of noting the reperfusion time following a brief period of ischemia can be used as a guide for acceptability of the tourniquet.

Hines RL, Greene NM, eds. *Stoelting's Anesthesia and Co-existing Disease.* 5th ed. Philadelphia: Saunders; 2008:516–517.

C.2. Which peripheral nerve blocks can be used for exploration of the metatarsals? What are the landmarks for an ankle block?

For complete anesthesia of the foot, each of the five nerves to the foot must be individually blocked. With the exception of the saphenous nerve (which is the extension of the femoral nerve), all of the nerves are derived from the sciatic nerve. Various techniques and landmarks have been described by numerous authors, but essentially, the two major nerves supplying motor function to the foot, the posterior tibial, and the deep peroneal require individual needle insertion, whereas the sensory nerves to the foot (superficial peroneal, saphenous, and sural) can be blocked by a common subcutaneous ring.

To approach the posterior tibial nerve, the foot is dorsiflexed to 90 degrees. The patient is placed either prone with the leg straight or supine with the operated leg flexed and supported by the opposite leg. A fine gauge needle (25G to 27G) is inserted along the medial border of the Achilles tendon at the level of the medial malleolus and advanced to contact the posterior tibia. One must be aware that the posterior tibial artery often lies between the nerve and the tibial periosteum. The local anesthetic solution (without epinephrine) 3 to 5 mL is injected if paresthesia is encountered during needle insertion; otherwise, 5 to 7 mL is injected just superficial to the periosteum (Fig. 46.1).

The deep peroneal nerve at the ankle lies deep between the tendons of the tibialis anterior and the extensor hallucis longus (EHL). These tendons are identified by asking the patient to dorsiflex the big toe (EHL) and the ankle (tibialis anterior). Traditionally, the nerve is blocked here (Fig. 46.2). Because this nerve courses behind

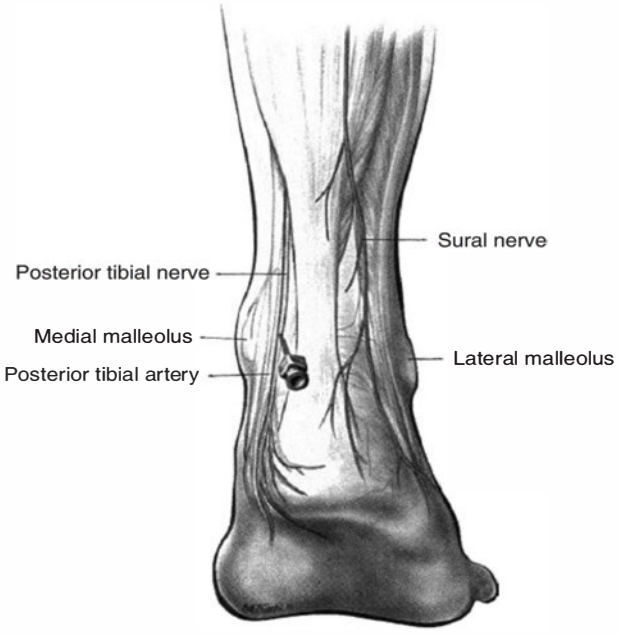

Figure 46.1 The posterior tibial nerve block.

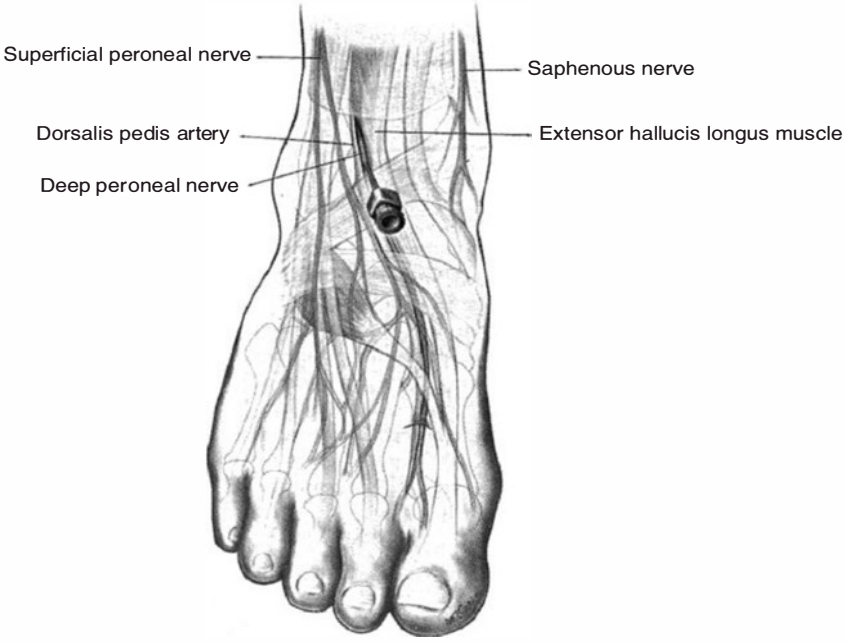

Figure 46.2 The deep peroneal nerve block.

the EHL to emerge just lateral to the EHL tendon on the dorsum of the foot in proximity to the anterior tibial artery, it can be more easily blocked by using the "midtarsal" approach as described by Sharrock et al. (Fig. 46.3, needle B). With this method, the dorsalis pedis pulsation is first located lateral to the EHL tendon at the midfoot, just distal to the extensor retinaculum. A fine-gauge needle is inserted immediately lateral to the arterial pulse until contact is made with periosteum. After withdrawing the needle 2 to 3 mm off the periosteum, 2 to 3 mL of the local anesthetic solution (without epinephrine) should be injected.

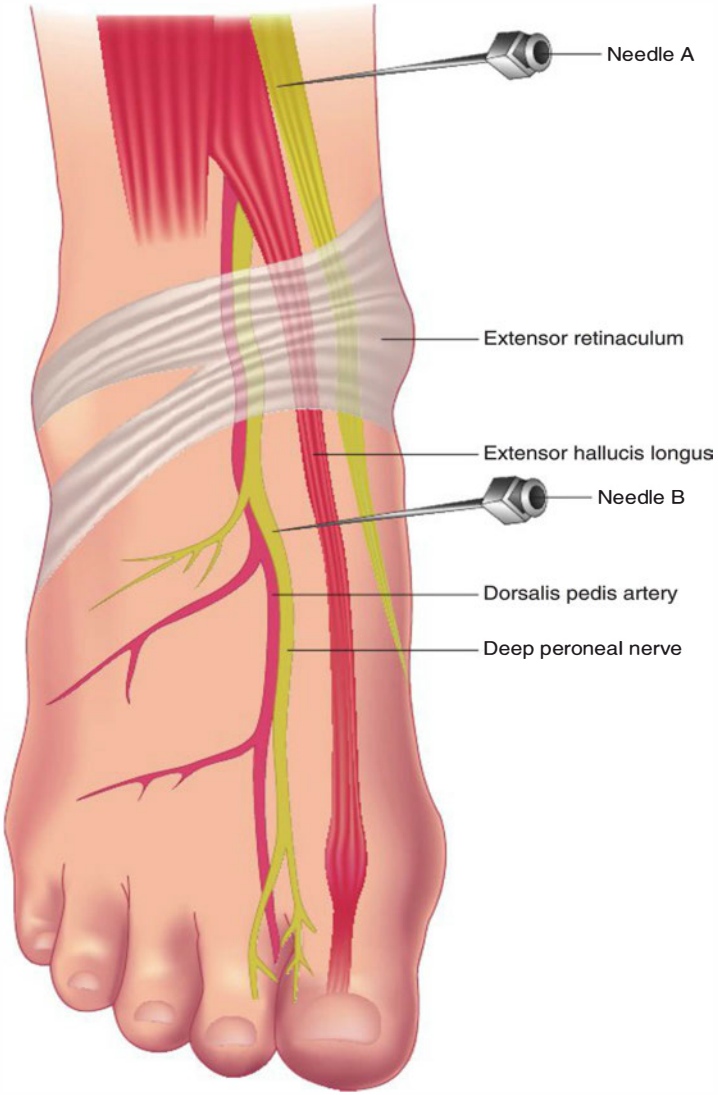

Figure 46.3 Ankle block, Sharrock's midtarsal approach.

From the same needle puncture site as the deep peroneal nerve block, the needle can be redirected to block the branches of the superficial peroneal, saphenous, and sural nerves by making a subcutaneous ring across the dorsum of the foot using 3 to 5 mL of the anesthetic solution (without epinephrine). An alternative to blocking the sural nerve (which is necessary in this patient but may not be necessary for surgery on the great toe, for example), the patient is positioned as for the posterior tibial nerve block, and the needle is inserted immediately lateral to the Achilles tendon at the level of the lateral malleolus in an anterolateral direction. The needle is advanced until contact is made with bone or paresthesia is elicited, and 3 to 5 mL of the local anesthetic is injected.

C.3. What are the advantages and disadvantages of an ankle block?

The main advantages of an ankle block lie in its relative simplicity and safety. The landmarks used in performing this block are readily identified in the majority of patients, and precise localization of each nerve is not necessary with this "field block" technique. Major hemodynamic changes associated with neuraxial techniques are avoided. The main complication of the ankle block is direct intraneural injection of the local anesthetic solution. Short of direct intravascular injections, systemic toxic effect from the usual volume (15 to 20 mL) of local anesthetic agents is unlikely because of slower uptake and distribution of the local anesthetic into the central compartment.

The two main disadvantages of this block are the discomfort associated with the performance of the block and the inability to use a pneumatic tourniquet, unless it is placed just supramalleolarly around the well-padded ankle. The ankle block is uncomfortable for most patients because of the multiple needle insertions involved, as well as the abundance of nerve endings in the foot and ankle region, which makes it extremely sensitive to needle injections. Adequate sedation is recommended before carrying out the block. In addition, the long tendons of the foot continue to work because the muscles have their nerve supply more proximally and the patient must be reminded not to move the foot during surgery.

When prolonged numbness can be tolerated by the patient and is acceptable to the surgeon, the patient can be relieved of postsurgical pain for many hours with long-acting local anesthetic agents such as bupivacaine. Both the patient and the surgical team must be forewarned of the anticipated delay in sensory and motor recovery to allay anxiety during the immediate postoperative period.

C.4. What other peripheral regional anesthetic techniques may be appropriate?

Several other methods may be used to provide regional anesthesia for this patient. Although less common today than other more frequently used and safer techniques, it is possible to use an intravenous regional block when venous access is available. For tourniquets placed on the calf, 30 mL of a 0.5% lidocaine solution injected after exsanguination usually suffices. If the tourniquet is placed on the thigh, 50 to 60 mL will be needed. The downside of this technique is that the exsanguination process may be painful related to tourniquet pain or those patients with a fracture. In addition, accidental loosening of the tourniquet too quickly could result in significant systemic toxicities and complications.

Alternatively, the sciatic nerve (consisting of the tibial and common peroneal nerves) (Fig. 46.4) and saphenous nerve can be blocked separately above the level of the knee joint. At this level, the exact location of the saphenous nerve is variable but it is usually within Hunter canal (Fig. 46.5). If ultrasound imaging is used, the sciatic nerve can be consistently found at the top center of the popliteal fossa just lateral to the popliteal pulse, before its division into the tibial and common peroneal nerves (popliteal block). The sciatic nerve can be blocked at this level with the patient in the prone, lateral, or supine position (with the leg flexed at the hip and the knee).

The classic intertendinous technique involves the identification of the popliteal triangle, which is defined by the tendon of the biceps femoris laterally, the tendons of the semitendinosus and semimembranosus medially, and the popliteal fossa crease. The point of needle insertion varies among different authors, but generally, the nerve can be identified 7 cm above the popliteal crease, at the midpoint between the tendons, or 9 cm above the popliteal crease, 1 cm lateral to the midline of the triangle (Fig. 46.6). Localization of the nerve can be achieved using a paresthesia-seeking technique, a nerve stimulation technique, if ultrasound imaging is not available. Using a nerve stimulation technique, plantar flexion and inversion of the foot (ideally), or dorsiflexion and eversion of the foot, is sought with 0.2- to 0.5-mA current.

Using anesthetic solutions in higher concentrations (such as 2% lidocaine with bicarbonate or 0.75% bupivacaine) with these nerve blocks, the motor nerves to the long tendons of the ankle, as well as the sensory supply to the lower leg and foot, are anesthetized. Patient movement during foot surgery is thus minimized. A major benefit of popliteal over ankle block is that it allows the use of a calf tourniquet. In addition, popliteal catheters are becoming increasingly popular in clinical practice for postoperative pain management.

Combined femoral and sciatic nerve blocks with adequate sedation may provide an alternative to neuraxial techniques for achieving anesthesia below the knee. Although the obturator nerve also innervates the knee, its sensory terminals supply only a small area of skin just medial and superior to the knee joint. The area involved can easily be anesthetized, if necessary, with local infiltration by the surgeon. In this patient, the surgery is in the foot; a femoral and sciatic combination would provide adequate surgical analgesia.

The femoral nerve provides sensory innervation to most of the anterior knee and can be blocked in the supine patient by injection at the femoral triangle (Fig. 46.7). The needle insertion site is immediately lateral to the femoral pulse at the level of the inguinal ligament (classical landmark) or at the level of the femoral crease. The further one moves from the inguinal canal, the more likely the nerve has divided into posterior and anterior divisions. If using a nerve stimulator, a patellar twitch (stimulation of quadriceps contraction) at 0.2- to 0.5-mA current is sought. Otherwise, the nerve can be localized by seeking paresthesia consistent with the distribution of the nerve or by ultrasound guidance (Fig. 46.8). Injection of 0.5% bupivacaine 10 to 25 mL here will usually provide adequate surgical anesthesia. It is also possible to place an indwelling catheter for postoperative infusion. In this patient, because the metatarsal

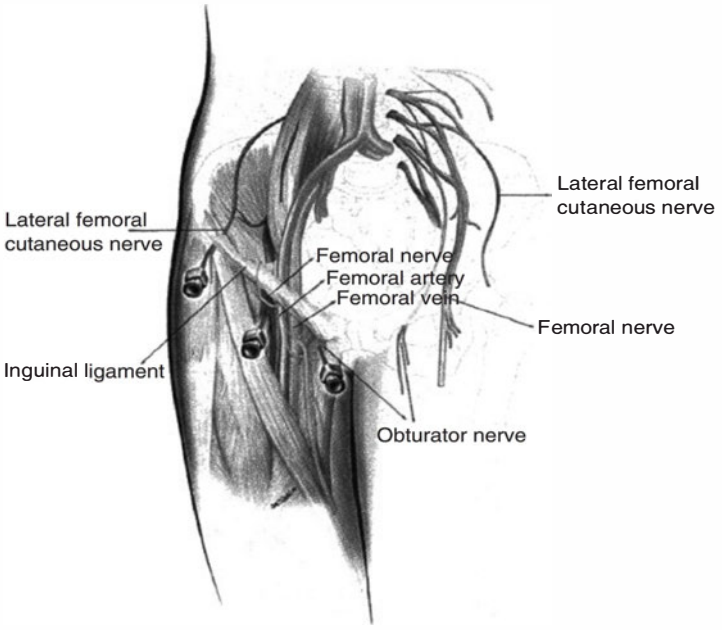

Figure 46.7 The femoral nerve block, lateral femoral cutaneous nerve block, and obturator nerve block.

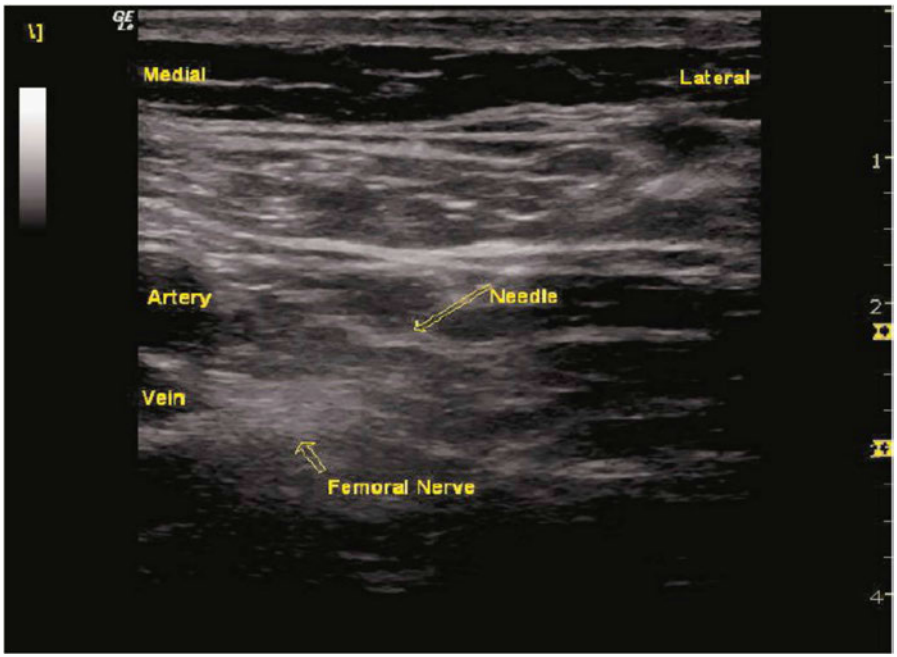

Figure 46.8 Femoral nerve block. (Courtesy Hospital for Special Surgery.)

damage is lateral, the surgical pain would be less in the femoral distribution and more likely in the sciatic distribution, which may lessen the efficacy of a femoral catheter.

A variation of the femoral nerve block is the fascia iliaca block (Fig. 46.9), which was first described by Dalens. This technique does not require a nerve stimulator or the seeking of paresthesia. A line is drawn between the anterior superior iliac spine and the pubic tubercle and divided into thirds. The needle insertion point is made 1 cm caudad to this line, two-thirds of the distance from the pubic tubercle. Two "pops" may be felt as the needle pierces the fascia lata and then the fascia iliaca. The use of a short bevel or pencil-tipped needle may enhance the appreciation of the "pops." The local anesthetic solution (20 to 25 mL) is then injected. Both the fascia iliaca and femoral nerve blocks are effective in providing postoperative analgesia, but the fascia iliaca block is more likely to block the lateral femoral cutaneous nerve as well.

The sciatic nerve can be blocked using several different approaches. The posterior approach (classically described by Labat, with modified approaches described by Winnie, Raj, DiBenedetto, and others) requires placement of the patient with the operative side up and the hip and knee flexed (Sim's position). A description of all the posterior approaches to the sciatic nerve is beyond the scope of this chapter. In essence, these modified approaches use anatomic landmarks that are easier to locate in patients than with the Labat technique and they block the sciatic nerve more distally in the leg, thus avoiding painful needle insertion through the gluteal muscles.

The landmarks for the classical approach by Labat are determined by first drawing a line from the greater trochanter to the posterior superior iliac spine (Fig. 46.10). Winnie modified this approach by adding a second line, drawn from the greater trochanter to the sacral hiatus. From the midpoint of the posterior superior iliac spine line, another line is drawn perpendicularly to meet the sacral hiatus line.

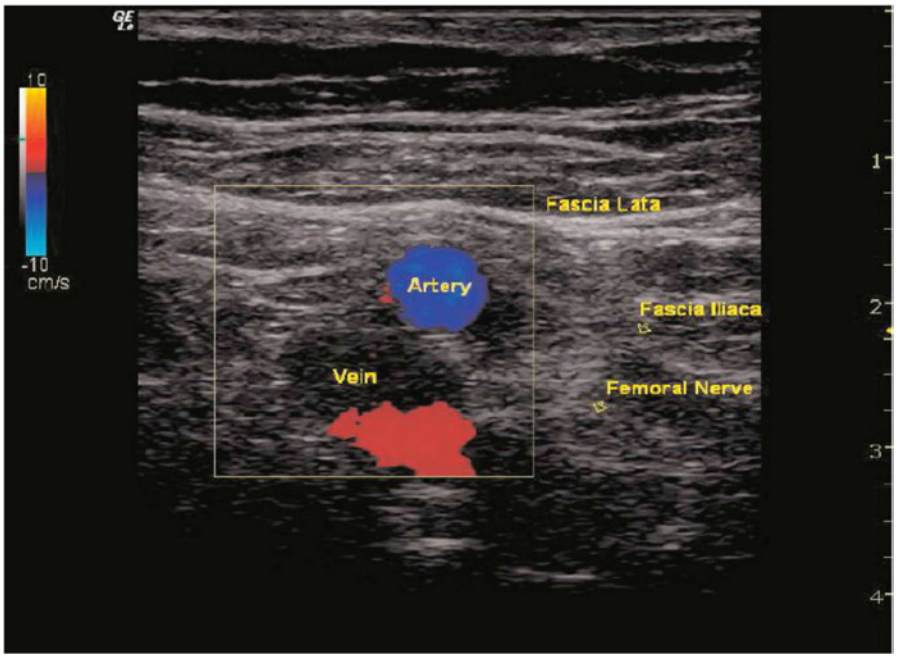

Figure 46.9 Fascia iliaca block. (Courtesy Hospital for Special Surgery.)

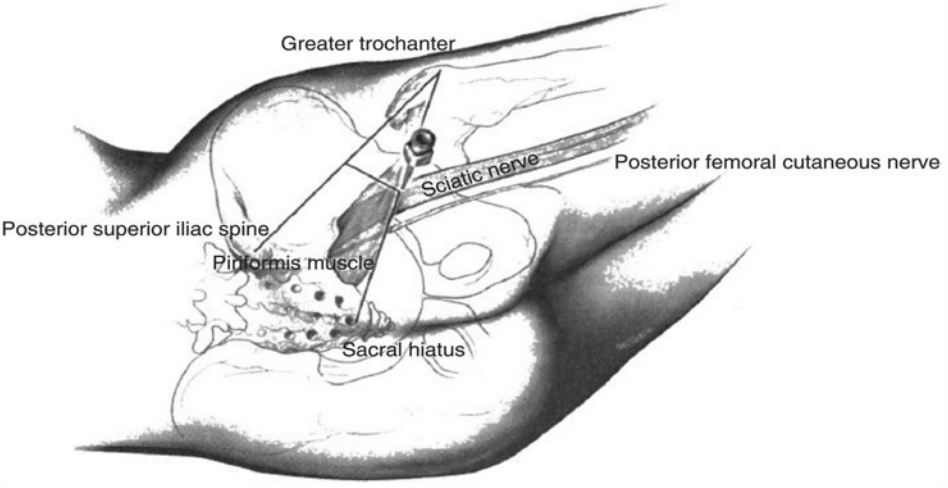

Figure 46.10 Sciatic nerve block; the Labat approach.

The intersection of the perpendicular line and the sacral hiatus line is the needle insertion point. As with the popliteal block (which in essence is a distal sciatic nerve block; see earlier discussion), localization of the nerve can be achieved using a paresthesia-seeking technique or a nerve stimulation technique. Ideally, the paresthesia should be below the knee. Using a nerve stimulation technique, plantar flexion and inversion of the foot (ideally) or dorsiflexion and eversion of the foot are sought at 0.2- to 0.5-mA current. A volume of 20 to 25 mL of the anesthetic solution will be needed to cover the nerve adequately.

If the patient cannot be turned lateral, an anterior approach to the sciatic nerve may be employed. In the supine patient, a line is drawn along the inguinal ligament from the anterior superior iliac spine to the pubic tubercle and is trisected. Another line is drawn from the tip of the greater trochanter inferomedially parallel to the inguinal line. At the junction of the medial and second third of the trisected line, a perpendicular line is drawn to meet the trochanteric line. The intersection is the point of needle entry. A needle inserted here vertically will contact the medial border of the femur at the lesser trochanter. The needle is then directed slightly medially to pass the medial femoral surface. Either muscle stimulation (as described above) or paresthesia should be sought about 5 cm deep to the femur. The posterior femoral cutaneous nerve, which leaves the main trunk early, may be missed by this approach.

C.5. How is ultrasound guidance useful in performing peripheral nerve blocks?

Most peripheral nerve blocks rely on surface anatomic landmarks (bone, vascular, muscular, grooves) to guide initial needle placement. Nevertheless, many studies have demonstrated the unreliability of these landmarks because of wide interpatient variability in nerve location relative to the surface landmarks. Also, in patients with peripheral vascular disease, absent or faint pulse is a poor landmark.

Anatomic landmarks only guide the initial needle placement and ultrasound probe position. Techniques such as electrical nerve stimulation or seeking of paresthesia have been used to more precisely localize the nerve, but neither of these techniques can rule out an intraneural injection. In addition, once the local anesthetic injection has begun, it is impossible to know whether the needle tip position has changed unless there is a form of direct visualization. Ultrasound imaging offers several advantages. First, it provides direct visualization of nerves, which allows selection of the best needle insertion site. Second, it provides real-time guidance for the needle advancing toward the target nerve, thus minimizing "hunting" for the nerve and potential complications such as vascular injury. Finally, direct observation of local anesthetic spread at the time of injection helps the operator to ensure the local anesthetic is deposited completely around the nerves.

Studies by Marhofer and Williams have shown shorter onset time, improved block quality, and reduced arterial puncture (Marhofter's study only) during the performance of femoral blocks and supraclavicular blocks. Despite the purported benefits, there are still proponents of anatomic methods. In our scenario, an ultrasound-guided block may be less critical for conducting the ankle block because surface landmarks are easily identifiable there. In any other nerve block, more proximal within the lower extremity, including femoral nerve, sciatic nerve, saphenous nerve, or popliteal block, ultrasound guidance would offer greater assistance.

C.6. What are the risks of peripheral nerve block in an immune-compromised patient?

Three case reports so far have been written about serious infectious complications of peripheral nerve blocks; two of the three cases occurred in immunocompromised patients, but no recommendations have been developed because data are still sparse to date.

Horlocker TT, Wedel DJ. Regional anesthesia in the immunocompromised patient. *Reg Anesth Pain Med.* 2006;31:334–345.

D. Postoperative Management

D.1. How should the postoperative pain be managed in this patient?

A multimodality approach to postoperative pain management may include nonsteroidal anti-inflammatory drugs, acetaminophen, opioids, anticonvulsants, regional anesthesia, and ketamine. Intraoperative ketorolac or preoperative administration of a COX-2 inhibitor may be useful in reducing opioid requirements. Opioids, whether given via patient-controlled systems or by nurses, should be given before sensations fully recover from the regional anesthetic and pain becomes severe. Specifically in patients with chronic pain, such as this patient, it is important to treat both the chronic baseline of pain as well as the new onset acute surgical pain. Chronic cancer pain, in addition, will have episodes of peaks and troughs outside of the typical pain expected after a procedure and must be addressed with specific care.

Although this patient may have undergone only a comparatively minor foot surgery, he nonetheless has a history of altered regulation of his receptors because of chronic cancer pain. For this reason, options for prolonged postoperative pain control may include intraoperative injection of local anesthetic, morphine, clonidine,

or ketorolac by the surgeon. One can also consider continuous nerve blocks for postoperative analgesia with local anesthetic infusion via an indwelling catheter.

D.2. Why should the neurovascular status of the foot be followed?

It is important to follow the neurovascular function of the lower extremity for a period of 24 to 36 hours because there is a relatively higher incidence of persistent paresthesia following foot and ankle surgery. This may be a result of the nerve blocks or tight surgical dressings. During this period, the patient should be encouraged to report any abnormal sensations and the surgical dressing should be carefully examined to ensure that there is no circulatory compromise or nerve compression. In the longer term, the patient should be followed for possible neuroma formation both at the needle insertion and the surgical sites. The natural history of any pre-existing neurologic dysfunction should be considered when evaluating any reported complications.

E. Summary

Although the surgery may be localized to a distal extremity, the anesthetic requirement may be much more extensive. This is especially crucial in patients who have comorbidities that can affect immune status and coagulation. The preoperative evaluation of the patient must be as comprehensive as with any other operations. The anesthetic techniques outlined in this chapter offer flexibility to cover most demands of the surgery, yet ensure the least physiologic disturbance in a safe and conservative manner.

CHAPTER 47

Complex Regional Pain Syndromes

Sudhir A. Diwan, Vinod Malhotra, and Neel D. Mehta

A 35-YEAR-OLD WOMAN complains of diffuse burning pain in the left arm and hand for the last 6 months. She recalls spraining her left wrist while playing volleyball. Her left hand feels colder than the right, and her fingertips are blue. She is a recently divorced high-profile executive.

A. Medical Disease and Differential Diagnosis

1. What is the differential diagnosis of pain in this patient?
2. What is complex regional pain syndrome (CRPS)?
3. What are the two types of CRPS?
4. What are the diagnostic criteria for CRPS? What is the incidence of this disease?
5. Define allodynia, hyperalgesia, hyperesthesia, and dysesthesia.
6. What are the associated stages of CRPS?
7. What are the possible etiologies of CRPS?
8. Explain the pathophysiology of the development of CRPS.
9. Define sympathetically maintained pain (SMP) and sympathetically independent pain (SIP).
10. How does CRPS differ from neuralgia?
11. What is central pain? How will you differentiate central pain from CRPS?
12. Is the social history of this patient relevant to the development of chronic pain?

B. Pain Management

1. How will you work up CRPS types I and II?
2. Describe the sympathetic nerve supply to the arm.
3. Where is the stellate ganglion located?
4. What are the anatomic landmarks used in the stellate ganglion block?
5. What are the clinical signs of stellate ganglion block?
6. What is Horner syndrome?

7. After a stellate ganglion block, this patient reports no significant change in the degree of pain despite evidence of Horner syndrome. Is the pain psychogenic in this patient?
8. What types of nerve fibers are interrupted in stellate ganglion block?
9. What is a differential block?
10. What are the two major classes of local anesthetics? Describe the major differences in their clinical pharmacology.
11. What factors determine the onset, potency, and duration of a local anesthetic block?
12. How does the addition of epinephrine to commercially available premixed solutions affect the efficacy of local anesthetics?
13. How will you treat this patient?
14. What is the pharmacologic management of CRPS?
15. What is the role of intravenous regional block (Bier method) in diagnosis and treatment of CRPS?
16. Compare and contrast the mechanism of action of ketamine and methadone.
17. What role does ketamine infusion play in the treatment of CRPS?
18. What is the role of spinal cord stimulation (SCS) and surgical sympathectomy?

C. Complications

1. What are the complications of stellate ganglion block?
2. What is the systemic toxicity of local anesthetics?
3. How do you treat the systemic toxicity of local anesthetic drugs?

A. Medical Disease and Differential Diagnosis

A.1. What is the differential diagnosis of pain in this patient?

Pain accompanied by burning and temperature change in this patient is most likely due to CRPS. The differential diagnosis may also include the following:

1. Peripheral neuropathy
2. Soft tissue injury
3. Vascular insufficiency (Raynaud disease)
4. Nerve entrapment syndrome (carpal tunnel syndrome)
5. Brachial plexopathy

Over the years, CRPS has been referred to as *reflex sympathetic dystrophy* (RSD), causalgia, sympathetically maintained pain (SMP), and chronic peripheral pain syndrome. The term CRPS was introduced in 1994 by the International Association for the Study of Pain subcommittee on taxonomy. It is subdivided into CRPS type I (formerly described as RSD) and CRPS type II (formerly described as causalgia).

Ballantyne JC, Rathmell JP, Fishman SM, eds. *Bonica's the Management of Pain*. 4th ed. Philadelphia: Lippincott Williams & Wilkins; 2009:314–331.

Boas RA. Complex regional pain syndromes: symptoms, signs, and differential diagnosis. In: Janig W, Stanton Hicks M, eds. *Reflex Sympathetic Dystrophy: A Reappraisal. Progress in Pain Research and Management*. Seattle: IASP Press; 1996:79–92.

Merskey H, Bogduk N. Classification of chronic pain. In: Task Force on Taxonomy. International Association for the Study of Pain. *Relatively Generalized Syndromes*. 2nd ed. Seattle: IASP Press; 1994:39–56.

Stanton-Hicks M, Janis W, Hassenburch S. Reflex sympathetic dystrophy: changing concepts and taxonomy. *Pain*. 1995;63:127–133.

A.2. What is complex regional pain syndrome (CRPS)?

CRPS is characterized by pain with sudomotor or vasomotor instability. CRPS is triggered by *noxious stimuli* (type I) or by *nerve injury* (type II). It is not limited to the distribution of a single peripheral nerve and is disproportionate to the inciting event.

RSD, causalgia, algodystrophy, Sudeck atrophy, and various other conditions are all grouped under CRPS. This diagnosis is better descriptive of the wide range of clinical signs and symptoms and the complexity of the pathophysiology responsible for the clinical picture.

Ballantyne JC, Rathmell JP, Fishman SM, eds. *Bonica's the Management of Pain*. 4th ed. Philadelphia: Lippincott Williams & Wilkins; 2009:314–331.

Merskey H, Bogduk N. Classification of chronic pain. In: Task Force on Taxonomy. International Association for the Study of Pain. *Relatively Generalized Syndromes*. 2nd ed. Seattle: IASP Press; 1994:39–56.

Stanton-Hicks M, Janis W, Hassenburch S. Reflex sympathetic dystrophy: changing concepts and taxonomy. *Pain*. 1995;63:127–133.

A.3. What are the two types of CRPS?

CRPS-I is defined as a clinical syndrome triggered by a *noxious stimulus* that is not limited to the distribution of a single peripheral nerve. CRPS-II is defined as a clinical syndrome that is due to a *nerve injury* and is mostly limited to the distribution of the injured nerve. The diagnostic criteria are the same for CRPS-I and II.

Ballantyne JC, Rathmell JP, Fishman SM, eds. *Bonica's the Management of Pain*. 4th ed. Philadelphia: Lippincott Williams & Wilkins; 2009:314–331.

Boas RA. Complex regional pain syndromes: symptoms, signs, and differential diagnosis. *Clin J Pain*. 1998;14:48–54.

Janig W, Stanton Hicks M, eds. *Reflex Sympathetic Dystrophy: A Reappraisal. Progress in Pain Research and Management*. Seattle: IASP Press; 1996:79–92.

Stanton-Hicks MD, Burton AW, Bruehl SP, et al. An updated Interdisciplinary clinical pathway for CRPS: report of an expert panel. *Pain Pract*. 2000;2:1–16.

Veldman PH, Reynen HM, Arntz IE, et al. Signs and symptoms of reflex dystrophy: prospective study of 829 patients. *Lancet*. 1993;342:1012–1016.

A.4. What are the diagnostic criteria for CRPS? What is the incidence of this disease?

The diagnosis of CRPS can be made in the following context: A history of trauma to the affected area associated with pain that is disproportionate to the inciting event plus one or more of the following:

- Abnormal function of the sympathetic nervous system
- Swelling
- Movement disorder
- Changes in tissue growth (dystrophy and atrophy)

The main features include pain that is continuous, burning in nature, independent of type and severity of injury, and not limited to a dermatomal distribution. Patients may complain of allodynia, dysesthesia, or hyperalgesia. Movement and stress exacerbate pain. Edema is usually present. Abnormal sudomotor activity, limb discoloration, and local temperature changes are common but inconsistent.

It affects between 200,000 and 1.2 million Americans. This syndrome may follow as many as 5% of all traumatic injuries.

Ballantyne JC, Rathmell JP, Fishman SM, eds. *Bonica's the Management of Pain*. 4th ed. Philadelphia: Lippincott Williams & Wilkins; 2009:314–331.

Merskey H, Bogduk N. Classification of chronic pain. In: Task Force on Taxonomy. International Association for the Study of Pain. *Relatively Generalized Syndromes*. 2nd ed. Seattle: IASP Press; 1994:39–56.

A.5. Define allodynia, hyperalgesia, hyperesthesia, and dysesthesia.

- *Allodynia*. Pain caused by a stimulus that normally does not provoke pain (i.e., touching with a cotton swab).
- *Hyperalgesia*. An increased response to a stimulus that is normally painful (i.e., increased response to pinprick).
- *Hyperesthesia*. Increased sensitivity to a stimulus either due to a diminished threshold or an increased response to stimuli that are normally recognized. Hyperesthesia includes both allodynia and hyperalgesia.
- *Dysesthesia*. An abnormal sensation that is unpleasant to the patient. It may be either spontaneous or evoked (i.e., lumbar radiculopathy).

Ballantyne JC, Rathmell JP, Fishman SM, eds. *Bonica's the Management of Pain*. 4th ed. Philadelphia: Lippincott Williams & Wilkins; 2009:314–331.

A.6. What are the associated stages of CRPS?

Stage I

- Onset of severe pain limited to the site of injury
- Increased sensitivity of skin to touch and light pressure (hyperesthesia)
- Localized swelling
- Muscle cramps
- Stiffness and limited mobility

At onset, skin is usually warm, red, and dry; then it may change to blue (cyanotic) in appearance and become cold and sweaty.

- Increased sweating (hyperhydrosis)
- In mild cases, this stage lasts a few weeks and then subsides spontaneously or responds rapidly to treatment.

Stage II

- Pain becomes even more severe and more diffuse.
- Swelling tends to spread and may change from a soft to hard (brawny) type.
- Hair may become coarse then scant, nails may grow faster and become brittle, cracked, and heavily grooved.
- Spotty wasting of bone (osteoporosis) occurs early but may become severe and diffuse.
- Muscle wasting begins.

Stage III

- Marked wasting of tissue (atrophic) eventually becomes irreversible.
- For many patients, the pain becomes intractable and may involve the entire limb.
- A small percentage of patients have developed generalized *reflex sympathetic dystrophy* (RSD), affecting the entire body.

Ballantyne JC, Rathmell JP, Fishman SM, eds. *Bonica's the Management of Pain*. 4th ed. Philadelphia: Lippincott Williams & Wilkins; 2009:314–331.

A.7. What are the possible etiologies of CRPS?

CRPS may follow relatively minor trauma with or without nerve injury. Causes leading to CRPS include the following:

- Injuries to peripheral tissues (e.g., fractures, dislocations, and postoperative state)
- Inflammatory conditions (e.g., fasciitis, tendonitis, bursitis, and arthritis)
- Immobilization as a result of injury or cast application
- Peripheral nerve injury resulting from direct compression or ischemia (e.g., brachial plexopathy, postherpetic neuralgia, and nerve root injury)
- Central nervous system insults (e.g., head injury, ischemia, and brain tumor)
- Spinal cord lesions
- Idiopathic

Ballantyne JC, Rathmell JP, Fishman SM, eds. *Bonica's the Management of Pain*. 4th ed. Philadelphia: Lippincott Williams & Wilkins; 2009:314–331.

Veldman PH, Reynen HM, Arntz IE, et al. Signs and symptoms of reflex dystrophy: prospective study of 829 patients. *Lancet*. 1993;342:1012–1016.

A.8. Explain the pathophysiology of the development of CRPS.

Several hypotheses have been postulated but none can explain all of the findings and the varying responses to treatment in these patients. These hypotheses include the following:

- Abnormal discharges in sympathetic and nociceptive afferents produced by trauma
- Sensitization of peripheral sensory receptors produced by sympathetic hyperactivity
- Formation of ephapses (artificial synapses) after peripheral nerve injury
- Spontaneous neuronal ectopy at the site of demyelination or axonal injury
- Central reorganization of pain processing (central sensitization)

More than one sequence of events likely take place in a patient, giving rise to a mixed clinical picture. A dynamic change in the physiology and structure of central pain projecting neurons mediated through the N-methyl-D-aspartic acid (NMDA) receptor. Injury initiates and maintains a state of central sensitization in the central pain pathways, resulting in a lower threshold to fire pain transmission neurons and increases their receptive fields. This often leads thermal and mechanical allodynia and spontaneous pain. Finally, the psychologic component and neuromodulation cannot be discernibly separated.

Wall PD, Melzack R, eds. *Textbook of Pain*. 5th ed. New York: Churchill Livingstone; 2005:1011–1027.

A.9. Define sympathetically maintained pain (SMP) and sympathetically independent pain (SIP).

The pain that is maintained by sympathetic innervation or circulating catecholamines is defined as SMP. It describes a pain mechanism, rather than clinical syndrome. Therefore, by definition, patients with CRPS who report pain relief after a sympathetic block (e.g., stellate ganglion block) have SMP. Conversely, pain conditions that show features of sympathetic overactivity, yet fail to respond to sympathetic blocks, are described as SIP.

Ballantyne JC, Rathmell JP, Fishman SM, eds. *Bonica's the Management of Pain*. 4th ed. Philadelphia: Lippincott Williams & Wilkins; 2009:314–331.

Roberts WJ. A hypothesis on the physiologic basis for causalgia and related pains. *Pain*. 1986;24:297–311.

A.10. How does CRPS differ from neuralgia?

The chronic pain seen in neuralgia is usually paroxysmal and follows the distribution of nerve. The pain is sharp and shooting without associated vasomotor or sudomotor changes. The chronic pain syndrome of CRPS is a sustained, diffuse, burning pain independent of nerve distribution and is associated with vasomotor and sudomotor changes.

Benzon H, Rathmell J, eds. *Raj's Practical Management of Pain*. 4th ed. St. Louis: Mosby; 2008:427–431.

A.11. What is central pain? How will you differentiate central pain from CRPS?

Central pain is regional pain initiated or caused by a primary lesion or dysfunction in the central nervous system, usually associated with abnormal sensitivity to temperature and to noxious stimulus. Central pain, also referred to as *deafferentation pain*, is a difficult pain syndrome to treat because the pathophysiology is not well understood. Regional pain not relieved by peripheral nerve blocks, either sympathetic or somatic, is more likely to be central pain. Central pain may be associated with various neurologic symptoms and signs such as monoparesis, hemiparesis, or paraparesis.

Abram SE, Haddox JD, eds. *The Pain Clinic Manual*. 2nd ed. Philadelphia: Lippincott Williams & Wilkins; 2000:253–259.

Ballantyne JC, Rathmell JP, Fishman SM, eds. *Bonica's the Management of Pain*. 4th ed. Philadelphia: Lippincott Williams & Wilkins; 2009:314–331.

A.12. Is the social history of this patient relevant to the development of chronic pain?

In patients with CRPS, the disproportionate pain and dysfunction, and the absence of clear pathogenesis and pathophysiology led to examination of potential psychological etiology. Also noted is the fact that as the CRPS progresses, patients' personality mea-

sures such as Minnesota Multiphasic Personality Inventory profiles tend to resemble those of patients experiencing chronic pain and psychological distress as evidenced by hypochondriasis, depression, and hysteria scales. Certainly, stress has been implicated in increasing sympathetic outflow. The literature suggests that the presence of psychological disorders, particularly anxiety and depression, may predispose the patient to the development of CRPS.

B. Pain Management

B.1. How will you work up CRPS types I and II?

CRPS is diagnosed clinically with a detailed history and physical examination. Because it is a clinical diagnosis of exclusion, other specific conditions that could account for the degree of pain and dysfunction must be ruled out. Objective signs are variable but almost universally include loss of function of the affected part as a result of pain. Allodynia and hyperalgesia are extremely common. Change in temperature and sweating may vary depending on the stage of the disease. Several diagnostic studies may aid in the diagnosis of CRPS but are seldom pathognomonic.

A quantitative sweat test may show excessive sweating, and thermography may demonstrate abnormal heat regulation and disparity in temperature between affected and normal regions. Radiologic studies may reveal patchy osteoporosis in early stages. Triple-phase bone scan using technetium-99m may show increased periarticular uptake in the affected extremity. Nevertheless, negative triple-phase bone scan results do not rule out CRPS. Thermographic, radiologic, or scintigraphic findings can be nonspecific and should be correlated with the clinical findings.

Positive diagnostic sympathetic blocks can confirm the sympathetically mediated component of CRPS.

Ballantyne JC, Rathmell JP, Fishman SM, eds. *Bonica's the Management of Pain*. 4th ed. Philadelphia: Lippincott Williams & Wilkins; 2009:314–331.

Betcher AM, Casten DF. Reflex sympathetic dystrophy: criteria for diagnosis and treatment. *Anesthesiology*. 1955;6:994–1003.

Merskey H, Bogduk N. Classification of chronic pain. In: Task Force on Taxonomy. International Association for the Study of Pain. *Relatively Generalized Syndromes*. 2nd ed. Seattle: IASP Press; 1994:39–56.

B.2. Describe the sympathetic nerve supply to the arm.

The preganglionic sympathetic outflow to the upper extremity is derived from T2-9. These fibers synapse with postganglionic neurons in the stellate ganglion. Therefore, a stellate ganglion block interrupts sympathetic outflow to the upper extremity.

Benzon H, Rathmell J, eds. *Raj's Practical Management of Pain*. 4th ed. St. Louis: Mosby; 2008:845–846.

B.3. Where is the stellate ganglion located?

The stellate ganglion is formed by the fusion of the inferior cervical and the first thoracic ganglia. It usually measures 2.5 cm × 1.5 cm × 0.5 cm and lies between the base of the transverse process of the seventh cervical vertebra and the neck of the first rib. It is situated behind the carotid sheath, ventral to the longus colli muscle, behind the vertebral artery, and lateral to the body of the vertebra. The vertebral, subclavian, inferior thyroid, and first intercostals arteries are in close proximity to the ganglion, as is the recurrent laryngeal nerve. The left pleura is 1 to 2 cm below it, and the right pleura is in closer proximity.

Benzon H, Rathmell J, eds. *Raj's Practical Management of Pain.* 4th ed. St. Louis: Mosby; 2008:845–846.

Miller RD, ed. *Miller's Anesthesia.* 7th ed. New York: Churchill Livingstone, 2010:1639–1675.

B.4. What are the anatomic landmarks used in the stellate ganglion block?

The landmarks used in the stellate ganglion block are the jugular notch of the sternum, the sternocleidomastoid muscle, the cricoid cartilage, and Chassaignac tubercle. In a supine patient with neck extended, a mark placed approximately 3.5 cm from the midline along the jugular notch and the same distance above the clavicle should overlie the transverse process of the seventh vertebra and the medial border of the sternocleidomastoid muscle. This marking is further confirmed by palpating the cricoid cartilage, which lies at the level of the sixth cervical vertebra, and the anterior tubercle on the vertebral transverse process, which is the most prominent tubercle in the neck (Chassaignac tubercle).

Benzon H, Rathmell J, eds. *Raj's Practical Management of Pain*. 4th ed. St. Louis: Mosby; 2008:845–846.

Miller RD, ed. *Miller's Anesthesia.* 7th ed. New York: Churchill Livingstone; 2010: 1639–1675.

B.5. What are the clinical signs of stellate ganglion block?

A stellate ganglion block results in the following ipsilateral signs:

- *Eye*: Ptosis, narrowing of the palpebral fissure, miosis, enophthalmos, conjunctival injection, and lacrimation
- *Face and neck*: Anhidrosis, elevated local temperature, and nasal stuffiness
- *Arm*: Increased temperature and plethysmographic evidence of improved cutaneous blood flow

Benzon H, Rathmell J, eds. *Raj's Practical Management of Pain*. 4th ed. St. Louis: Mosby; 2008:845–846.

Miller RD, ed. *Miller's Anesthesia.* 7th ed. New York: Churchill Livingstone; 2010:1639–1675.

B.6. What is Horner syndrome?

Horner syndrome is a clinical entity characterized by ptosis, miosis, anhidrosis, and enopthalmos, usually seen with a disease process involving the cervical sympathetics and being the classic signs of a stellate ganglion block.

Benzon H, Rathmell J, eds. *Raj's Practical Management of Pain*. 4th ed. St. Louis: Mosby; 2008:845–846.

Miller RD, ed. *Miller's Anesthesia*. 7th ed. New York: Churchill Livingstone; 2010:1639–1675.

B.7. After a stellate ganglion block, this patient reports no significant change in the degree of pain despite evidence of Horner syndrome. Is the pain psychogenic in this patient?

Not necessarily. Horner syndrome indicates only the interruption of sympathetic supply to the head and neck. Unless it is accompanied by objective changes in the arm, it does not indicate sympathetic nerve block of the upper extremity. Further, SMP will respond to sympathectomy, whereas SIP will not.

Benzon H, Rathmell J, eds. *Raj's Practical Management of Pain*. 4th ed. St. Louis: Mosby; 2008:845–846.

Wall PD, Melzack R, eds. *Textbook of Pain*. 5th ed. New York: Churchill Livingstone; 2005:512.

B.8. What types of nerve fibers are interrupted in stellate ganglion block?

The stellate ganglion block results in interruption of the preganglionic, thinly myelinated type B fibers, as well as the postganglionic, unmyelinated type C fibers.

Ballantyne JC, Rathmell JP, Fishman SM, eds. *Bonica's the Management of Pain*. 4th ed. Philadelphia: Lippincott Williams & Wilkins; 2009:314–331.

Casale R, Glynn CJ, Buonocoe M. Autonomic variations after stellate ganglion block: are they evidence of an autonomic afference? *Funct Neurol*. 1990;5:245–246.

B.9. What is a differential block?

The variable effects of local anesthetics on fibers performing different functions are termed *differential block*. The diagnostic distinction can be made by selectively blocking the function of these nerve fibers. The mechanism that results in differential block is best explained by the fiber size and myelination because these factors determine different sensitivities of nerve fibers to local anesthetics. By using different concentrations of local anesthetic, sympathetic and somatic fibers can be selectively blocked. Differential block may be helpful to differentiate somatic versus sympathetic pain and peripheral versus central pain.

Cousins MJ, Bridenbaugh PO, eds. Neural blockade. In: *Clinical Anesthesia and Management of Pain*. 4th ed. Philadelphia: Lippincott Williams & Wilkins; 2009:838–840.

B.10. What are the two major classes of local anesthetics? Describe the major differences in their clinical pharmacology.

The two major classes of clinically employed local anesthetics are esters and amides. The esters are hydrolyzed in the plasma by pseudocholinesterase; the amides are biotransformed in the liver. Although infrequent, local anesthetic toxicity is encountered more commonly in the ester group because of the para-aminobenzoic acid

moiety. True allergic reactions to amides are rare and in most instances are caused by preservatives in the solution. The two groups of local anesthetics contain drugs with varying degrees of rate of onset, duration of neural blockade, potency, and toxicity.

Benzon H, Rathmell J, eds. *Raj's Practical Management of Pain*. 4th ed. St. Louis: Mosby; 2008:811–839.

B.11. What factors determine the onset, potency, and duration of a local anesthetic block?

- Onset correlates with pK_a
- Potency correlates with lipid solubility
- Duration correlates with degree of protein binding

The commonly used local anesthetics are weakly basic tertiary amines that are lipid soluble and unstable in water. They are prepared as acidic salts because the ionized form, which is soluble in water, is stable. Therefore, the aqueous solution contains the ionized (cation) form of the local anesthetic in dissociation equilibrium with the unionized (free base) form, depending on the pH of the medium.

$$\underset{\text{Cation}}{R \equiv NH^+} \rightleftharpoons \underset{\text{Base}}{R \equiv N} + H^+$$

When the local anesthetic is injected into the body, the relative rise in pH will allow the local anesthetic to convert to the uncharged base. The free base, being lipid soluble, will diffuse across the neural membrane and is responsible for neural blockade. With the exception of procaine and chloroprocaine, the commonly employed local anesthetics are highly protein bound, and are therefore longer acting (Table 47.1).

Cousins MJ, Bridenbaugh PO, eds. Neural blockade. In: *Clinical Anesthesia and management of Pain*. 4th ed. Philadelphia: Lippincott Williams & Wilkins; 2009:26–48.

Benzon H, Rathmell J, eds. *Raj's Practical Management of Pain*. 4th ed. St. Louis: Mosby; 2008:811–839.

Table 47.1 Physiochemical Properties of Commonly Used Local Anesthetics

LOCAL ANESTHETIC	pK_A	PROTEIN BINDING (%)
Esters		
Procaine	8.9	5.8
Chloroprocaine	8.7	—
Tetracaine	8.5	75.6
Amides		
Lidocaine	7.9	64.3
Mepivacaine	7.6	77.5
Bupivacaine	8.1	95.6
Etidocaine	7.7	94.0

B.12. How does the addition of epinephrine to commercially available premixed solutions affect the efficacy of local anesthetics?

The addition of epinephrine to a local anesthetic increases the duration and intensity of a block. In commercially available premixed solutions containing epinephrine, antioxidants are added to preserve epinephrine and the result is a lower buffered pH level of the solution. This lowering of the pH level can result in decreased efficacy of the local anesthetic. Best results are achieved by adding the desired concentration of epinephrine to the local anesthetic solution just before injection.

Benzon H, Rathmell J, eds. *Raj's Practical Management of Pain*. 4th ed. St. Louis: Mosby; 2008:811–839.

Mooer DC. The pH of local anesthetic solutions: technical communication. *Anesth Analg*. 1981;60:833–834.

B.13. How will you treat this patient?

Early diagnosis and aggressive physical therapy with pharmacologic control of pain form the basis of the treatment of CRPS. Physical therapy is widely recommended and accepted as a first line of treatment. The treatment of CRPS will differ depending on whether the pain is sympathetically maintained pain (SMP) or SIP. A series of sympathetic blocks has been shown effective in treating SMP of CRPS. A multidisciplinary approach including physiotherapy and symptom-specific psychological treatments (e.g., biofeedback and hypnosis) may be beneficial. Many patients have a component of both SMP and SIP, and a combination of sympathectomy and analgesic treatment is recommended. Nevertheless, no single treatment is consistently successful. Therefore, the treatment plan should be individualized.

Ballantyne JC, Rathmell JP, Fishman SM, eds. *Bonica's the Management of Pain*. 4th ed. Philadelphia: Lippincott Williams & Wilkins; 2009:314–331.

Wall PD, Melzack R, eds. *Textbook of Pain*. 5th ed. New York: Churchill Livingstone; 2005:1011–1027.

B.14. What is the pharmacologic management of CRPS?

SMP of CRPS is treated with the drugs that deplete norepinephrine from the sympathetic nerve terminals. Oral sympatholytic agents include phenoxybenzamine, prazosin, and terazosin. Topical clonidine, a selective α_2-agonist, has been successfully used to treat SMP. Tricyclic antidepressants have been effective in approximately half the number of patients and have been recommended as first-line agents. Other drugs that have been successfully used to treat CRPS are anticonvulsants (e.g., gabapentin, pregabalin, carbamazepine, and topiramate), local anesthetics such as lidocaine and mexiletine, calcitonin, corticosteroids, and high-dose opioids. Anecdotal reports suggest that methadone (opioid with anti-NMDA receptor effect) has been more effective than other opioids. Long-term intrathecal morphine has been reported to produce analgesic effects in CRPS. Nonsteroidal anti-inflammatory drugs have also been used successfully.

Abram SE, Haddox JD, eds. *The Pain Clinic Manual*. Philadelphia: Lippincott Williams & Wilkins; 2001:177–184.

Ballantyne JC, Rathmell JP, Fishman SM, eds. *Bonica's the Management of Pain*. 4th ed. Philadelphia: Lippincott Williams & Wilkins; 2009:314–331.

Becker WJ, Ablett DP, Harris CJ, et al. Long-term treatment of intractable reflex sympathetic dystrophy with intrathecal morphine. *Can J Neurosci*. 1995;22:153–159.

B.15. What is the role of intravenous regional block (Bier method) in diagnosis and treatment of CRPS?

Intravenous regional block (Bier method) with guanethidine, reserpine, bretylium, and phentolamine has been used to achieve temporary sympatholytic effect and relieve sympathetically maintained pain (SMP) of CRPS. Intravenous guanethidine and reserpine have been reported to relieve pain in more than 50% of patients compared with a control group in one study. Nevertheless, guanethidine and reserpine are not commercially available in the United States. The combination of bretylium and lidocaine is more effective than lidocaine alone. α-Adrenergic blockade with intravenous phentolamine is a sensitive test to identify patients with SMP. Phentolamine has been used as a predictor agent before more invasive sympathetic blocks.

Ballantyne JC, Rathmell JP, Fishman SM, eds. *Bonica's the Management of Pain*. 4th ed. Philadelphia: Lippincott Williams & Wilkins; 2009:314–331.

Raja SN, Treede RD, Davis KD, et al. Systemic alpha-adrenergic blockade with phentolamine: a diagnostic test for sympathetically maintained pain. *Anesthesiology*. 1991;74:691–698.

B.16. Compare and contrast the mechanism of action of ketamine and methadone.

Methadone is a strong, long-acting opioid analgesic; ketamine is a dissociative anesthetic. Methadone is used as an opioid, but has mild N-methyl-D-aspartate (NMDA) receptor antagonist properties and is the only strong opioid that has this quality. Ketamine is used in oral preparations, intravenous delivery systems, skin preparations, and other delivery methods, including being compounded in various percentages. These medications can block NMDA receptors and decrease the windup pain and central sensitization typical of chronic intractable pain. Windup causes an amplification of the incoming pain signal at the level of second-degree neurons in the dorsal horn of the spinal cord. By blocking these receptors, not only is windup pain decreased, but tolerance to opioid medications can also be decreased. Ketamine has the added effect of blocking sodium channels.

Benzon H, Rathmell J, eds. *Raj's Practical Management of Pain*. 4th ed. St. Louis: Mosby; 2008:300,605–606.

Chizh, B. Low dose ketamine: a therapeutic and research tool to explore N-methyl-D-aspartate (NMDA) receptor-mediated plasticity in pain pathways. *J Psychopharmacol*. 2007;21:259–271.

B.17. What role does ketamine infusion play in the treatment of CRPS?

Although ketamine may have more than one mechanism of action, the basis for using it to treat CRPS may reside in its strong ability to block NMDA receptors. Ketamine is the only potent NMDA-blocking drug currently available for clinical use. An appropriately prolonged infusion of ketamine appears to maintain a level of ketamine in the

central nervous system long enough to reverse the effects of the sensitization process and associated pain.

Currently, three methods of ketamine administration have been used for treatment, including an outpatient low-dose ketamine administration, a low-dose awake inpatient technique, and a ketamine "coma" technique, a more controversial treatment not currently allowed in the United States. While studies are continuing, intravenous ketamine therapy has been shown to be effective for relief of pain in CRPS-I. There were no adverse cognitive effects of extended treatment with ketamine infusion. Side effects, nevertheless, can occur in the high dose setting, because the infusion can be associated with significant risks, including endotracheal intubation and chronic catheterization with the need for parenteral nutrition. The outpatient therapy requires the patient to return for a 10-day period and often showed loss of effectiveness after 6 to 12 weeks.

Ballantyne JC, Rathmell JP, Fishman SM, eds. *Bonica's the Management of Pain*. 4th ed. Philadelphia: Lippincott Williams & Wilkins; 2009:314–331.

Goldberg ME, Torjman MC, Schwartzman RJ, et al. Pharmacodynamic profiles of ketamine (R)- and (S)- with 5-day inpatient infusion for the treatment of complex regional pain syndrome. *Pain Physician*. 2010;13:379–387.

Kiefer R, Rohr P, Ploppa A, et al. Complete recovery from intractable complex regional pain syndrome, CRPS-type I, following anesthetic ketamine and midazolam. *Pain Pract*. 2007;7:147–150.

B.18. What is the role of spinal cord stimulation (SCS) and surgical sympathectomy?

Surgical, chemical, or radiofrequency sympathectomies produces short-term pain relief, but long-term results are poor and inconsistent. Delayed failure of sympathectomy may be due to regeneration of ipsilateral nerves or reinnervation from the contralateral sympathetic nerves. SCS is an effective treatment for the pain of CRPS, including recurrent pain after surgical or radiofrequency sympatholysis. Epidural SCS is a simple procedure and carries low morbidity.

Ballantyne JC, Rathmell JP, Fishman SM, eds. *Bonica's the Management of Pain*. 4th ed. Philadelphia: Lippincott Williams & Wilkins; 2009:314–331.

Rocco AG. Radiofrequency lumbar sympatholysis: the evolution of a technique for managing sympathetically maintained pain. *Reg Anesth*. 1995;20:3–12.

C. Complications

C.1. What are the complications of stellate ganglion block?

Although complications appear infrequently, the more common complications of stellate ganglion block are as follows:

- Intra-arterial injection: Seizure and hematoma
- Recurrent laryngeal nerve paralysis: Hoarseness of voice
- Brachial plexus block: Motor weakness
- Accidental epidural or subarachnoid injection
- Esophageal injury
- Pneumothorax: Respiratory distress

To avoid complications, aspiration of the needle should be performed before, during, and after administration of local anesthetics to look for (1) air, (2) blood, and (3) cerebrospinal fluid.

Benzon H, Rathmell J, eds. *Raj's Practical Management of Pain*, 4th ed. St. Louis: Mosby; 2008:851–889.

Miller RD, ed. *Anesthesia*. 7th ed. New York: Churchill Livingstone; 2009:1639–1675.

C.2. What is the systemic toxicity of local anesthetics?

The systemic toxic effects of local anesthetics are related to drug levels in blood and are manifested mainly in the central nervous system and the cardiovascular system. As a rule, the central nervous system effects precede the cardiovascular toxic manifestations.

Central nervous system effects

Central nervous system include light-headedness, dizziness, tinnitus, visual disturbances, drowsiness, disorientation, slurred speech, muscle twitching, generalized grand mal seizures, and electroencephalographic changes. Blood levels of local anesthetics associated with central nervous system changes in humans are as follows:

- Procaine: 20 μg per mL
- Lidocaine, mepivacaine, and prilocaine: 5 to 10 μg per mL
- Tetracaine, bupivacaine, and etidocaine: 1.5 to 4 μg per mL
- Lowering the $Paco_2$ by hyperventilation decreases the seizure threshold dose of a local anesthetic drug.

Cardiovascular effects

Ventricular arrhythmias are reported with intravenous bupivacaine only. Cardiac resuscitation is extremely difficult in patients with bupivacaine-induced cardiac arrhythmias. Ropivacaine is less toxic than bupivacaine but more toxic than lidocaine. The mechanism of enhanced cardiotoxicity in pregnant patients is not well understood; nevertheless, 0.75% bupivacaine is no longer recommended in pregnant patients in the United States (Table 47.2).

Table 47.2 Cardiovascular Effects of Lidocaine

BLOOD LEVEL LIDOCAINE (μg/mL)	ELECTROCARDIOGRAPHIC CHANGES	HEMODYNAMIC EFFECTS
<5	–	–
5–10	↑ PR interval	↓ Myocardial contraction
	↑ QRS duration	↓ Cardiac output
	Sinus bradycardia	Vasodilatation
>10	↑ PR interval	↓ Myocardial contraction
	↑ QRS duration	↓ Cardiac output
	Sinus bradycardia	Circulatory collapse
	Atrioventricular block	
	Asystole	

↑, increase; ↓, decrease.

Miller RD, ed. *Anesthesia*. 7th ed. New York: Churchill Livingstone; 2009:913–941.

C.3. How do you treat the systemic toxicity of local anesthetic drugs?

The principles of treatment include the following:

- Secure and maintain the airway.
- Ensure adequate oxygenation and ventilation.
- Treat hypotension and bradycardia promptly.
- Perform immediate cardiopulmonary resuscitation for profound cardiovascular collapse.
- Perform electrical cardioversion for ventricular tachycardia or fibrillation.
- Control seizures with the following:
  - Midazolam 2 to 5 mg intravenously
  - Thiopental sodium 1 to 2 mg per kg intravenously
  - Propofol 1 to 2 mg per kg intravenously
- Administer intravenous lipid to remove bupivacaine from sites of action. Administration of 100 mL of 20% lipid solution has been reported to successfully resuscitate a patient from bupivacaine-induced dysrhythmias refractory to conventional therapy.

CHAPTER 48

Cancer Pain

Sudhir A. Diwan, Shakil Ahmed, and Neel D. Mehta

A 44-YEAR-OLD MAN

was referred to the pain clinic for evaluation and management of abdominal pain. He was recently diagnosed with adenocarcinoma of pancreas with retroperitoneal lymph nodes in the para-aortic region. His pain was localized in the epigastric region and was worse during the night and decreased during the day. He was taking sustained-release morphine sulfate (MS Contin), 100 mg orally every 8 hours, and immediate-release morphine sulfate, 30 mg orally every 3 hours as needed, for breakthrough pain. The patient reported inadequate pain control, nausea, vomiting, and constipation.

A. Medical Disease and Differential Diagnosis

1. What is the definition of pain?
2. How significant is the problem of pain in patients with cancer?
3. What are the components of cancer pain?
4. How does pain contribute to the suffering of patients with cancer?
5. How do psychological factors affect pain in patients with cancer?
6. What are the causes of pain in patients with cancer?
7. How do you classify pain in patients with cancer?
8. What are the characteristics of pancreatic cancer pain?
9. How do you assess pain in patients with cancer?
10. What is the differential diagnosis of abdominal pain?

B. Pharmacologic Treatment of Pain

1. What is the World Health Organization (WHO) stepladder approach for cancer pain management?
2. Which class of drugs does morphine sulfate belong to?
3. What is the difference between morphine and synthetic opioids?
4. How does a mixed opioid agonist/antagonist differ from an opioid agonist?

5. Describe the role of methadone in the management of cancer pain.
6. What are the advantages and disadvantages of methadone?
7. What is the mechanism of action of opioids?
8. What are the side effects of opioid therapy?
9. Define tolerance and physical dependence.
10. How would you treat the side effects of opioid therapy?
11. What is tramadol? Is it an opiate? What is tapentadol and how does it compare to traditional opiates?
12. When would you consider adjuvant analgesics as part of the treatment plan?
13. The patient and his family are worried about addiction. How would you approach this problem?
14. Describe different routes of opioid administration.
15. Describe advantages and complications of patient-controlled analgesia (PCA). What is minimum effective analgesic concentration (MEAC)?
16. What is meperidine? How is it different from other opioids?
17. What is rotation of opioids? When would you consider rotation of opioids?

C. Invasive Therapy

1. Describe the role of peripheral nerve blocks in cancer pain management.
2. Describe the role of a celiac plexus block in cancer pain management.
3. What are the complications of celiac plexus block?
4. Would you consider neuraxial opioid infusion in this patient? Discuss complications of this procedure.
5. Which medications can be used intrathecally? What is ziconotide?
6. What is a Personal Therapy Manager (PTM) and what role does it play in neuraxial pain relief?
7. Would you consider neuraxial neurolysis in this patient to manage his pain? Discuss advantages and disadvantages of these blocks.
8. Which neuroablative procedures can be considered in the terminal stage of pancreatic cancer?
9. Describe the role of radiation therapy in cancer pain.

D. Nonpharmacologic Management

1. What are the various nonpharmacologic techniques of cancer pain management?
2. What physical modalities have been successfully tried in cancer pain management?
3. Describe the role of neuromodulation in cancer pain management.
4. What psychological techniques have been promoted for comfort care and pain relief?
5. What are distraction and reframing techniques? What is the role of hypnosis in cancer pain management?

A. Medical Disease and Differential Diagnosis

A.1. What is the definition of pain?

According to the International Association of the Study of Pain, pain is defined as "an unpleasant, sensory and emotional experience associated with actual or potential tissue damage or described in terms of such damage."

Merskey H, Bogduk N, eds. *Classification of Chronic Pain: Descriptions of Chronic Pain Syndromes and Definitions of Pain Terms*. 2nd ed. Seattle: IASP Press; 1994:210.

A.2. How significant is the problem of pain in patients with cancer?

There are 1,382,400 new patients with cancer annually. Cancer causes 560,000 deaths per year, making it the second leading cause of death in the United States. Thirty percent of the patients with cancer have pain at the time of diagnosis, and 65% to 85% of patients with cancer have pain at advanced stages. Of these, 36% have pain severe enough to impair their ability to function.

Vainio et al. studied 1,840 patients with advanced cancer and found 24% with no pain, 24% with mild pain, 30% with moderate pain, and 21% with severe pain. Daut and Cleeland found pain to be an early symptom of cancer in 48% to 50% of patients with cancer of breasts, ovary, prostate, colon, and rectum, and in 20% of patients with uterus and cervical cancer.

It is estimated that 43,140 men and women (21,370 men and 21,770 women) will be diagnosed with pancreatic cancer and 36,800 men and women will die of the disease in 2010. WHO estimates that 25% of all cancer patients die with unrelieved pain (Table 48.1).

Hewitt D. The management of pain in the oncology patient. *Obstet Gynecol Clin*. 2001; 28:819–846.

A.3. What are the components of cancer pain?

The components of cancer pain are sensory, affective, and psychological. The sensory components could be nociceptive pain elicited by activation of sensory nerve endings by mechanical, chemical, radioactive, or thermal energy. It is often associated with ongoing tissue damage and may be of somatic or visceral origin. Somatic pain may be superficial, well localized, sharp, pricking, burning or deep diffused, dull, and aching. Visceral pain is usually diffuse, referred to body surface, and has a sickening quality to it.

Neuropathic pain is due to pathologic change in the discharge properties of the neurons because of invasion, compression, or damage caused by various cancer treatment modalities. It is typically described as burning, lancinating, painful numbness, or itching sensations. Phantom pain is a pain referred to the amputated part of the body. Psychological pain is usually due to fear, anxiety, depression, existential questions, anger, social and financial issues, social support, and the impact the pain has on the family and caregivers. Most cancer patients report more than one site of pain.

Cancer Facts & Figures – 2010, American Cancer Society (ACS), Atlanta, Georgia, 2010.
Excludes basal and squamous cell skin and in situ carcinomas except urinary bladder.
Incidence projections are based on rates from the North American Association of Central Cancer Registries (NAACCR) from 1995–2006, representing about 89% of the US population.
Estimated deaths are based on data from US Mortality Data, 1969–2007, National Center for Health Statistics, Centers for Disease Control and Prevention, 2010.
[a] Estimated deaths for colon and rectum cancers are combined.
[b] Carcinoma in situ of the breast accounts for about 54,010 new cases annually, and melanoma in situ accounts for about 46,770 new cases annually.
[c] More deaths than cases suggests lack of specificity in recording underlying causes of death on death certificate.

A.4. How does the pain contribute to the suffering of patients with cancer?

Sustained pain on its own can create complex, enduring, unpleasant emotional suffering by its ability to create awareness of the perceived threat to one's life. It causes helplessness in the face of the inevitability of demise as well as exhaustion of hope. Patients with cancer usually identify pain as an indicator of disease progression. Suffering may be attributable to many factors besides physical complaints. Psychological factors include financial issues, lack of social support, loss of job or social position in society, loss of independence, effect on family and friends, social isolation, and fear of death.

Speigel D, Giese-Davis J. Depression and cancer pain: mechanisms and disease progression. *Biol Psychiatry.* 2003;54:269–282.

A.5. How do psychological factors affect pain in patients with cancer?

The ultimate perception of pain depends on the nociceptive stimulus and psychological fear, anger, anxiety, or depression. Twenty-five percent of patients with cancer meet criteria for major depressive syndromes at some point in their illness, with an overall prevalence of 53% in hospitalized patients with cancer. Psychological factors may significantly exacerbate pain. Symptoms usually include anxiety, restlessness, irritability, sleep disorders, obsessive thinking, slowness in motor responses, and hopelessness. These factors affect overall pain behavior and suffering.

Speigel D, Giese-Davis J. Depression and cancer pain: mechanisms and disease progression. *Biol Psychiatry.* 2003;54:269–282.

A.6. What are the causes of pain in patients with cancer?

Pain in patients with cancer may be due to (1) presence and progression of the tumor itself, for example, bone involvement, viscus obstruction, and nerve compression; (2) indirect effect of the tumor, for example, metabolic imbalance, infection, and venous or lymphatic obstruction; (3) consequence of cancer treatment, such as chemotherapy, radiation therapy, or surgery; or (4) unrelated mechanisms such as migraine and myofascial pain.

Localized invasion of peripancreatic structures most commonly causes back pain, which stems from tumor invasion of the splanchnic plexus, common bile duct obstruction, retroperitoneum, or pancreatitis. This pain is described as severe, gnawing, epigastric, upper abdominal radiating to the middle of the back, worse on lying down and improved with upright position.

Grond et al. found in a prospective study of 2,266 patients with cancer that 30% had one pain syndrome, 39% had two pain syndromes, 31% had three pain syndromes, 85% by the cancer itself (bone, 35%; soft tissue, 45%; and visceral, 34%), and 17% by anticancer treatment.

Ballantyne JC, Fishman SM, Rathmell JP, et al., eds. *Bonica's Management of Pain.* 4th ed. Philadelphia: Lippincott Williams & Wilkins; 2009:537–559.

Cherny N. The management of cancer pain. *CA Cancer J Clin.* 2000;50:70–116.

A.7. How do you classify pain in patients with cancer?

Pain, in patients with cancer, may be classified on the basis of the following:

- Chronicity: acute or chronic
- Intensity and severity: visual analog score, numeric pain score, and verbal: mild, moderate, severe, or worst possible pain

- Pathophysiology and mechanism: nociceptive or neuropathic; tumor infiltration of nerves; infiltration of soft tissue or hollow organs, serosa, solid organ necrosis; and destruction of bone
- Individual type and stage of disease: pancreatic, ovarian, prostatic, breast, or lung
- Pattern of pain: incidental pain related to an event or activity; spontaneous pain unrelated to an event or activity and end-of-dose failure
- Pain syndromes: tumor invasion of bone, nerves, spinal cord, viscera, blood vessels, postsurgical, and postchemotherapy and postradiation therapy pain

The pancreatic carcinoma usually presents with vague symptoms of anorexia, weight loss, abdominal discomfort, new-onset diabetes mellitus, or thrombophlebitis. The vague nature of symptoms may result in the delay of diagnosis

Caraceni A, Weinstein S. Classification of cancer pain syndromes. *Oncology*. 2001;15: 1627–1640.

A.8. What are the characteristics of pancreatic cancer pain?

Pancreatic cancer affects 9 or 10 patients per 100,000 in the Western world, men more than women, and blacks more than whites. From 2003 to 2007, the median age at diagnosis for cancer of the pancreas was 72 years of age. The overall 5-year relative survival for 1999 to 2006 from 17 Surveillance, Epidemiology, and End Results geographic areas was 5.6%. Five-year relative survival by race and sex was 5.4% for white men, 5.7% for white women, 4.2% for black men, and 6.0% for black women. Approximately 30% to 60% of patients present with pain, and 80% of the patients with advanced cancer complain of pain. Patients complain of diffuse epigastric pain radiating to the back that is increased on lying down and improved on sitting. About 90% of pancreatic tumors are of the adenocarcinoma type. Cancer in the head of the pancreas usually invades the stomach, duodenum, gallbladder, and peritoneum, whereas tumors in the body spread to liver, spleen, lymph nodes, and left adrenal gland.

Altekruse S, Kosary C, Krapcho M, et al., eds. *SEER Cancer Statistics Review, 1975–2007*. Bethesda, MD: National Cancer Institute. Available at: http://seer.cancer.gov/csr/1975_2007.

Hawes R, Xiong Q, Waxman I, et al. A multispecialty approach to the diagnosis and management of pancreatic cancer. *Am J Gastoenterol*. 2000;95:17–31.

A.9. How do you assess pain in patients with cancer?

A stepwise approach is required for the assessment of pain. It includes history, physical examination, and data collection and ends with clinical diagnosis. It helps the clinician achieve goals of providing pain relief. Assessment involves identifying features of pain, such as location, intensity, quality, timing, exacerbating and relieving factors, response to previous analgesics, and disease-modifying treatments; effects of pain on daily activities and psychological state; associated symptoms; complete physical examination; and laboratory data and imaging.

Ballantyne JC, Fishman SM, Rathmell JP, et al., eds. *Bonica's Management of Pain*. 4th ed. Philadelphia: Lippincott Williams & Wilkins; 2009:559–635.

A.10. What is the differential diagnosis of abdominal pain?

Although abdominal pain could arise from different structures within the peritoneal cavity, the retroperitoneal organs can cause similar pain syndromes. Location and

radiation of the pain can give important clues to make the diagnosis. Retroperitoneal structures present with dull or sharp back pain that is increased on lying down and relieved on sitting hunched up. Abdominal tumors are frequently characterized by colicky pain associated with nausea that is worse after eating. Abdominal pain may be referred to distant areas such as the shoulder, neck, or back, depending on the organ involved. Tumors of the small bowel or large bowel may present with symptoms of obstruction (e.g., abdominal distention, nausea, bilious vomiting) or hematemesis or melena. Other common causes of abdominal pain include omental metastasis, volvulus of intestine, infectious peritonitis, radiation enteritis, and peritoneal carcinomatosis. Mesenteric ischemia presents with diffuse pain that is increased with meals and weight loss.

Nonmalignant causes of abdominal pain such as appendicitis, cholecystitis, and pancreatitis can occur in patients with cancer coincidentally and may complicate the diagnostic process. Opioid analgesics may not be used in these patients because they may exacerbate symptoms of colicky pain (resulting from spasm of sphincter of Oddi), nausea, vomiting, paralytic ileus, and constipation.

Ballantyne JC, Fishman SM, Rathmell JP, et al., eds. *Bonica's Management of Pain*. 4th ed. Philadelphia: Lippincott Williams & Wilkins; 2009:899–925.

B. Pharmacologic Treatment of Pain

B.1. What is the World Health Organization (WHO) stepladder approach for cancer pain management?

The WHO advocated a stepladder approach to manage cancer pain exclusively with oral medications depending on the pain intensity and to some extent the pain mechanism (Fig. 48.1).

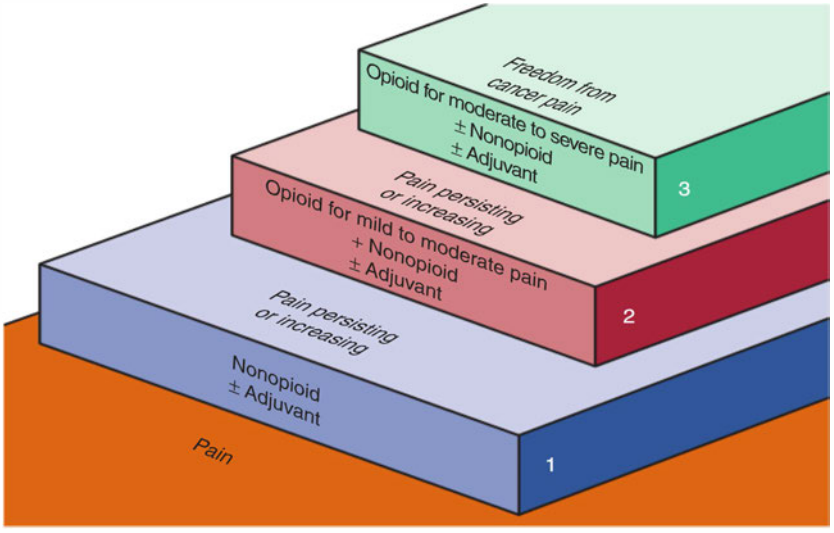

Figure 48.1 World Health Organization–advocated stepladder approach to management of cancer pain.

Step 1. Manage the pain by nonopioid medications with or without adjuvants.
Step 2. If pain is persisting or increasing, add weak opioids to nonopioid analgesics and adjuvants.
Step 3. Strong opioids are used with nonopioid analgesics and adjuvants until the patient achieves complete analgesia.

At this point, if pain still persists, neurolytic or interventional procedures should be employed. Noninvasive routes of drug delivery should be maintained as long as possible, because of its simplicity, convenience, and cost.

Abram S, Haddox J, eds. *The Pain Clinic Manual*. 2nd ed. Philadelphia: Lippincott Williams & Wilkins; 2000:293–351.

Pazdur R, Wagman L , Camphausen KA, et al., eds. *Cancer Management: A Multidisciplinary Approach*. 12th ed. Philadelphia: F.A. Davis Company; 2010:731–746.

B.2. Which class of drugs does morphine sulfate belong to?

Morphine is classified as a μ-receptor opioid agonist because of its high specificity for activation of μ-receptors. An ideal opioid agonist would have a high specificity for receptors producing desirable effects (analgesia and minimal or no specificity for other receptors that cause side effects). Opioids are unique in producing analgesia without loss of consciousness.

Brunton L, Chabner B, Knollman B. *Goodman and Gilman's The Pharmacological Basis of Therapeutics*. 12th ed. New York: McGraw-Hill; 2011:566–578.

B.3. What is the difference between morphine and synthetic opioids?

Morphine is the principal phenanthrene alkaloid present in opium. It is highly ionized and water-soluble. The most active molecule of morphine is the levorotatory isomer of stereochemical structure. The synthetic opiates contain the phenanthrene nucleus of morphine and are manufactured by synthesis, rather than chemical modification. Clinically, histamine release by morphine differentiates it from the synthetic opioids. This may cause urticaria, allergic reactions, and hemodynamic instability, particularly in volume-depleted patients.

Miller RD, ed. *Miller's Anesthesia*. 7th ed. Philadelphia: Churchill Livingstone; 2010:769–824.

B.4. How does a mixed opioid agonist/antagonist differ from an opioid agonist?

The mixed-action opioids bind to μ-receptors, where they are partial agonists or competitive antagonists. Antagonistic properties of these drugs can attenuate the efficacy of subsequently administered opioid agonists and cause withdrawal symptoms in patients already receiving opioid agonists. The advantages of these drugs include low potential for respiratory depression and physical dependence. A dysphoric reaction is very common with mixed-action opioids. Their use is limited because of a ceiling effect, whereby progressive escalation in doses does not increase analgesia as with opioid agonists.

Brunton L, Chabner B, Knollman B. *Goodman and Gilman's The Pharmacological Basis of Therapeutics*. 12th ed. New York: McGraw-Hill; 2011:566–578.

B.5. Describe the role of methadone in the management of cancer pain.

The efficient oral and rectal absorption with prolonged duration of analgesic action of methadone makes it a highly effective and attractive oral drug for cancer pain management. Methadone is a synthetic opiate drug with a unique agonist/antagonist action. Methadone is a μ-receptor agonist and an *N*-methyl-D-aspartate (NMDA) receptor antagonist. Activation of NMDA receptors is involved in the development of hypersensitivity and central sensitization in neuropathic pain and tolerance to opioids. Because of the antagonistic effect at the NMDA receptor site, methadone is very effective in neuropathic pain secondary to cancer-related pathology and therapeutic interventions. The same antagonistic action of methadone minimizes the development of tolerance to opioids.

Brunton L, Chabner B, Knollman B. *Goodman and Gilman's The Pharmacological Basis of Therapeutics*. 12th ed. New York: McGraw-Hill; 2011:566–578.

Manfredi PL, Gonzalez GR, Cheville AL, et al. Methadone analgesia in cancer patients on chronic methadone maintenance therapy. *J Pain Symptom Manage*. 2001;21:169–174.

B.6. What are the advantages and disadvantages of methadone?

Methadone has several advantages, including oral and rectal absorption with bioavailability to 95%, high potency, high lipid solubility, low cost, and no active metabolites. Methadone has a long half-life, and its analgesic effect lasts 6 to 8 hours. Nevertheless, methadone has been used for a long time for heroin abusers as detoxification and maintenance; it carries a social stigma, which can interfere with adequate pain management. Methadone has an irregular elimination half-life with interindividual variation between 20 and 60 hours. Because of that, the cumulative effect of methadone causes sedation, makes titration difficult, and has led to the concept of individualization of methadone dosing.

Ballantyne JC, Fishman SM, Rathmell JP, et al., eds. *Bonica's Management of Pain*. 4th ed. Philadelphia: Lippincott Williams & Wilkins; 2009:1682–1710.

Brunton L, Chabner B, Knollman B. *Goodman and Gilman's The Pharmacological Basis of Therapeutics*. 12th ed. New York: McGraw-Hill; 2011:566–578.

B.7. What is the mechanism of action of opioids?

Opioids act as agonists at stereospecific opioid receptors that are normally activated by endogenous ligands known as endorphins in brainstem and spinal cord. Binding of opioid to the receptor inhibits adenylate cyclase activity and causes hyperpolarization of neurons, which results in suppression of spontaneous discharge and evoked potential. Opioids also interfere with transmembrane transport of calcium ion and interfere with the release of neurotransmitters such as acetylcholine, dopamine, norepinephrine, and substance P. Inhibition of acetylcholine release from nerve endings is the basis of analgesic activity of opioids.

Ballantyne JC, Fishman SM, Rathmell JP, et al., eds. *Bonica's Management of Pain*. 4th ed. Philadelphia: Lippincott Williams & Wilkins; 2009:1682–1710.

Miller RD, ed. *Miller's Anesthesia*. 7th ed. Philadelphia: Churchill Livingstone; 2010:769–825.

B.8. What are the side effects of opioid therapy?

The opioid-related side effects occur because of opioid receptor pharmacodynamics, metabolites, or both. Sedation and respiratory depression are due to μ-receptor

activation. Tolerance to these side effects is developed within a very short period of treatment. The dysphoric reaction is due to activation of κ-receptors. Psychotomimetic and depersonalization reactions are due to activation of σ-receptors. Nausea and vomiting are caused by direct stimulation of the chemoreceptor trigger zone. Increased intrabiliary pressure is due to spasm of the sphincter of Oddi. Other side effects commonly observed are constipation, pruritus, and myoclonus. Almost all side effects diminish with time, except constipation and myoclonus. Patients with cancer who develop constipation secondary to opioid therapy are required to be on a regular bowel regimen to avoid subsequent serious consequences. In patients with compromised renal function, metabolites of morphine (M3G, M6G) cause excessive sedation and metabolites of meperidine (normeperidine) lower the seizure threshold.

Brunton L, Chabner B, Knollman B. *Goodman and Gilman's The Pharmacological Basis of Therapeutics*. 12th ed. New York: McGraw-Hill; 2011:566–578.

Miller RD, ed. *Miller's Anesthesia*. 7th ed. Philadelphia: Churchill Livingstone; 2010:769–825.

B.9. Define tolerance and physical dependence.

Tolerance occurs with the development of the need to gradually escalate the dose to achieve the same pain control, and it can develop in 2 to 3 weeks. Physical dependence develops after chronic use of opioids and it is characterized by development of withdrawal syndrome after administration of an opioid antagonist or abrupt discontinuation of the medication. The potential for tolerance is an agonistic effect of opioids.

Streltzer J, Johansen L. Prescription drug dependence and evolving beliefs about chronic pain management. *Am J Psychiatry*. 2006;163:594–598.

B.10. How would you treat the side effects of opioid therapy?

Oversedation and respiratory depression are treated with a specific μ-receptor antagonist, naloxone, as well as supplemental oxygen. Naloxone, in a 1- to 4-μg per kg intravenous bolus, promptly reverses sedation, respiratory depression, and analgesia. Continuous intravenous infusion at the rate of 2 to 4 μg/kg/hr will reverse only side effects without reversing analgesia. Nausea and vomiting should be managed by antiemetics. Constipation should be treated with a regular bowel regimen of laxatives and stool softener. Methylnaltrexone, a peripheral μ-opioid receptor antagonist with restricted ability to cross the blood–brain barrier, has been shown to improve constipation from opiates without affecting pain relief. Generalized pruritus may respond to one more doses of antihistamine, although pruritus may not be related to histamine release.

Cherny N, Ripamonti C, Pereira J, et al. Strategies to manage the adverse effects of oral morphine: an evidence based report. *J Clin Oncol*. 2001;19:2542–2554.

Slatkin N, Thomas J, Lipman AG, et al. Methylnaltrexone for treatment of opioid-induced constipation in advance illness patients. *J Supp Oncol*. 2009;7:39–46.

B.11. What is tramadol? Is it an opiate? What is tapentadol and how does it compare to traditional opiates?

Tramadol (Ultram) is a nonopioid synthetic analgesic with weak μ-receptor agonistic activity and is thought to exert its analgesic effects by inhibition of reuptake of norepinephrine and serotonin. It should be started at 50 to 100 mg every 6 to

8 hours. It may exhibit μ-receptor–related clinical side effects such as respiratory depression and constipation. Prolonged use may lead to physical and psychological dependence.

Tapentadol is a centrally acting pain reliever, with agonist activity at the μ-receptor, and inhibition of norepinephrine reuptake. Compared to oxycodone IR, tapentadol showed a reduction in gastrointestinal side effects, specifically nausea, constipation, and vomiting. Tapentadol should be administered first in the 50-mg strength and can be increased to 100 mg every 4 to 6 hours as needed. Of note, it too can also cause respiratory depression because it shows μ-opioid agonist activity and is a controlled substance, unlike tramadol.

Both tramadol and tapentadol can cause life-threatening serotonin syndrome with the use of other serotonin–norepinephrine uptake inhibitors, selective serotonin reuptake inhibitors, tricyclic antidepressants, or monoamine oxidase inhibitors and, therefore, should be used with caution in patients on these medications.

Efficacy and tolerability of tapentadol immediate release and oxycodone HCl immediate release in patients awaiting primary joint replacement surgery for end-stage joint disease: a 10-day, phase III, randomized, double-blind, active- and placebo-controlled study. *Clin Therapeut*. 2009;31:260–271.

B.12. When would you consider adjuvant analgesics as part of the treatment plan?

In cancer pain management, adjuvant drugs are considered to enhance pain relief. The adjuvant analgesics are a heterogeneous group of medications originally developed for purposes other than pain relief. These drugs may become necessary in the multimodal approach to treat pain, the adverse effects of analgesic medications, or concomitant psychological disturbances such as insomnia, anxiety, depression, and psychosis. The most useful adjuvants used clinically to manage cancer pain are as follows:

- Corticosteroids
- Tricyclic antidepressants (e.g., amitriptyline)
- Anticonvulsants (e.g., gabapentin)
- Amphetamines
- NMDA receptor antagonists (e.g., methadone, ketamine)
- α_2-Agonists (e.g., clonidine)
- Antihistaminics
- Phenothiazines

Abram S, Haddox J, eds. *The Pain Clinic Manual*. 2nd ed. Philadelphia: Lippincott Williams & Wilkins; 2000:293–351.

Ballantyne JC, Fishman SM, Rathmell JP, et al., eds. *Bonica's Management of Pain*. 4th ed. Philadelphia: Lippincott Williams & Wilkins; 2009:1682–1710.

B.13. The patient and his family are worried about addiction. How would you approach this problem?

Addiction is defined as a persistent pattern of dysfunctional use of opioids that may involve adverse consequences associated with continued use, loss of control over use of opioids, compulsive use of drug, craving for the drug, and typical drug-seeking

behavior. Patients with chronic pain who are using opioids are not at higher risk for addiction than the general population. The goals of treatment, including palliation of pain and improvement in the patient's quality of life, must be clearly defined and explained to the patient and his relatives. At no time should patients with cancer pain be undertreated because of the fear of addiction. The patient and his family should be educated about the common misconception that addiction is a common outcome of opioid therapy.

Heit HA. Addiction, physical dependence and tolerance: precise definitions to help clinicians evaluate and treat chronic pain patients. *J Pain Palliat Care Pharmacother*. 2003;17:15–29.

B.14. Describe different routes of opioid administration.

Oral medications should be used as the first-line approach in most patients with cancer pain who are receiving opioid analgesics. Table 48.2 outlines the routes of opioid administration and available opioid preparations.

The rectal or transdermal route should be chosen before considering invasive therapy for cancer pain. The sublingual route is limited by the inability to deliver large doses.

The intramuscular route is not preferred for long-term administration because it requires repeated painful injections and offers no pharmacodynamic advantages. Intravenous administration provides quick onset and is ideal for painful crises in patients with cancer as patient-controlled analgesia (PCA).

The equianalgesic doses of opioids used orally and parenterally are listed in Table 48.3.

Table 48.2 Routes of Opioid Administration

ROUTE OF ADMINISTRATION	AVAILABLE OPIOID PREPARATION
Oral	Morphine
	Hydromorphone (Dilaudid)
	Methadone (Dolophine)
	Oxycodone, hydrocodone
	Codeine, meperidine
	Levorphanol
Rectal	Suppositories containing morphine
	Hydromorphone, oxycodone
Transdermal	Fentanyl patch
Sublingual	Fentanyl, methadone, buprenorphine
Intramuscular/subcutaneous	Morphine, hydromorphone, methadone
	Meperidine, levorphanol
Intravenous	Morphine, meperidine, methadone, fentanyl
	Hydromorphone, oxymorphone
Epidural/intrathecal	Morphine, methadone, hydromorphone
	Fentanyl, meperidine

Table 48.3 Opioids Used Orally or Parenterally to Treat Cancer Pain

	EQUIANALGESIC DOSE (mg)[a]	
DRUG	**ORAL**	**PARENTERAL**
Morphine	30	10
Hydromorphone	6	2
Oxycodone	20–30	NA
Methadone	10[b]	10[b]
Levorphanol	2–3[b]	2[b]
Codeine	130[c]	75

[a] Suggested doses are guidelines only. Doses are based on chronic opioid use.
[b] Particular care with titration is recommended, because doses may need to be reduced significantly when steady-state levels are reached after 2 to 3 days.
[c] Codeine doses greater than 65 mg may be associated with significant constipation.
NA, not available in the United States.

Mercadante S. Recent progress in the pharmacology of cancer pain. *Expect Rev Anticancer Ther*. 2001;1:487–494.

B.15. Describe advantages and complications of patient-controlled analgesia (PCA). What is minimum effective analgesic concentration (MEAC)?

Intravenous PCA is very advantageous for patients with chronic cancer pain because it allows patients to self-administer medication and find their own comfort zone between side effects and pain control within limits set by the physician. The PCA device is a computerized, programmable, lightweight, battery-operated portable pump with the capability of storage and retrieval of data by the microprocessor. The pump is programmed for three modes of drug delivery: (1) continuous per-hour rate infusion only, which is preset by the physician and over which the patient has no control; (2) continuous with boluses for breakthrough pain, with boluses controlled by the patient; and (3) boluses with lockout time in minutes set by the physician, with the patient controlling his or her own requirement. If necessary, the physician or nurse can deliver extra boluses. Intermittent rescue doses for breakthrough pain, along with continuous infusion, decrease the total requirement of opioids. The rescue-dose delivery mode is safer because patients will not take medication if there is no pain. Nevertheless, the continuous-delivery mode carries risks of oversedation and respiratory depression. The initial cost of the drug-delivery device and training of the health care provider could be expensive. PCA can also be provided by subcutaneous, epidural, or intrathecal route.

MEAC is the minimum effective analgesic concentration of the opioid that is the lower level of the therapeutic window (Fig. 48.2). The upper level of the therapeutic window represents the serum concentration at which adverse side effects will occur. Neither age, sex, body weight, nor rate of drug elimination appeared to be related to the therapeutic concentration.

Ballantyne JC, Fishman SM, Rathmell JP, et al., eds. *Bonica's Management of Pain*. 4th ed. Philadelphia: Lippincott Williams & Wilkins; 2009:1682–1710.

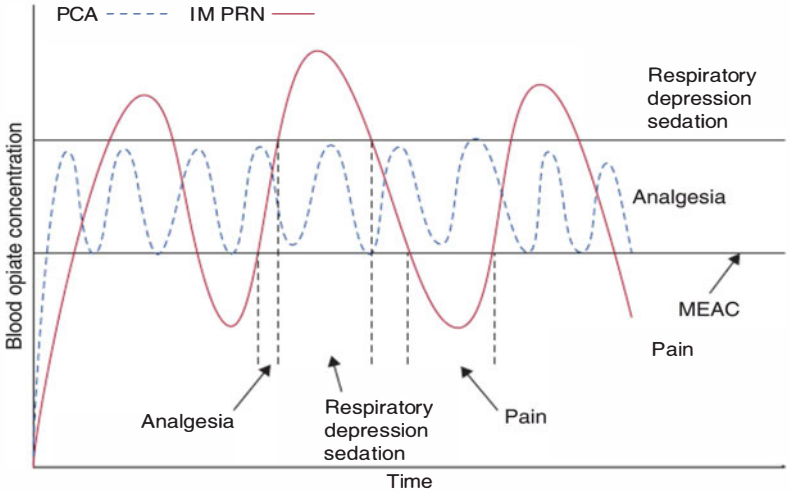

Figure 48.2 The MEAC is the minimum effective analgesic concentration of the opioid that is the lower level of the therapeutic window. IM, intramuscular; MEAC, minimum effective analgesic concentration; PCA, patient-controlled analgesia; PRN, as needed. (Modified from Ashburn M, Smith K. The management of postoperative pain. *Surg Rounds*. 1991;14:129–134.)

B.16. What is meperidine? How is it different from other opioids?

Meperidine is a synthetic opioid that pharmacologically resembles morphine. Meperidine is not an ideal drug for chronic pain because of its short duration of action and its high potential for abuse. The by-product normeperidine is exclusively excreted via the kidney, with an elimination half-life of 36 to 40 hours. In patients with compromised renal function, by-product accumulation has been associated with central nervous system toxicity, including myoclonus, tremulousness, hallucinations, and seizures. Meperidine possesses anticholinergic activity similar to atropine, causing mydriasis, orthostatic hypotension, and tachycardia. Compared with other opioids, meperidine very rarely causes pruritus when given neuraxially. It is extremely effective in the treatment of postoperative shivering. Meperidine also demonstrates local anesthetic actions. It is contraindicated in patients who are receiving monoamine oxidase inhibitors because of the risk of a potentially fatal syndrome characterized by hyperthermia, rigidity, and seizures.

Brunton L, Chabner B, Knollman B. *Goodman and Gilman's The Pharmacological Basis of Therapeutics*. 12th ed. New York: McGraw-Hill; 2011:566–578.

B.17. What is rotation of opioids? When would you consider rotation of opioids?

The sequential trial of changing from one opioid to another when either treatment-limiting toxicity or poor responsiveness develops has become known as *opioid rotation*. The variable response from opioid to opioid in an individual has led to this approach; changing to an alternative opioid may yield a far better balance between side effects and analgesia.

For those patients in whom pain control is inadequate and who have intolerable side effects, different strategies are implemented to improve analgesia. Opioid rotation is a simple strategy that almost all physicians can implement. Depending on equianalgesic potency ratio guidelines, switch is made to other opioids such as methadone or transdermal fentanyl patch. This should be done under close supervision and preferably in an inpatient environment.

Ballantyne JC, Fishman SM, Rathmell JP, et al., eds. *Bonica's Management of Pain*. 4th ed. Philadelphia: Lippincott Williams & Wilkin; 2009:1682–1710.

C. Invasive Therapy

C.1. Describe the role of peripheral nerve blocks in cancer pain management.

The following nerve blocks can be considered depending on the location and distribution of the thoracic or abdominal pain and the involvement of viscera:

- Intercostal nerve blocks
- Interpleural blockade
- Splanchnic nerve blocks
- Celiac plexus block
- Hypogastric plexus block
- Thoracic and lumbar paravertebral somatic nerve blocks
- Rectus abdominis block
- Iliac crest block
- Ilioinguinal and iliohypogastric nerve block
- Cave of Retzius (space between urinary bladder and symphysis pubis) block

Various combinations of peripheral nerve blocks can be performed to aid in the global comfort of the patient by providing better pain control and reducing the total dose of medications and thereby the side effects. The most useful blocks for the upper abdomen and thorax are intercostal nerve blocks and celiac plexus blocks. The splanchnic nerve block and superior hypogastric blocks are the other two that can be considered depending on the location and involvement of the viscera. Thoracic and lumbar paravertebral blocks are performed to obtain spinal nerve segmental analgesia. The intercostal and thoracic paravertebral nerve blocks carry the risk of pneumothorax because of the proximity of the pleura and lung. The peripheral nerve blocks are performed at anatomic sites away from the central neuraxis. More distal blocks have greater chances of incomplete blocks because of spatial distribution, overlap of nerves, and difficulty in blocking multiple branches of arborizing nerve.

DeLeon-Casasola OA. *Pharmacological, Interventional and Palliative Care Approaches*. Philadelphia: Saunders; 2006:531–533.

Waldman SD, ed. *Interventional Pain Management*. 2nd ed. Philadelphia: WB Saunders; 2001:541–553.

C.2. Describe the role of celiac plexus block in cancer pain management.

Diagnostic celiac plexus block with a local anesthetic is performed to precisely differentiate sympathetically maintained pain and localize retroperitoneal or upper abdominal pain. A positive result of the diagnostic block is an indication for more

definitive neurolysis in chronic cancer and nonmalignant pain. Success rates of celiac plexus neurolysis are lower in patients suffering from chronic nonmalignant abdominal pain than in those suffering from abdominal pain of neoplastic origin. Neurolysis of celiac plexus with alcohol or phenol is performed under fluoroscopic guidance or computed tomography–guided technique with strict sterile condition using a single-needle periaortic technique, single-needle transaortic technique, single-needle anterior technique, or endoscopic ultrasound–guided technique. Individual skills of the treating physician, available facilities, patient's general condition, and extent of the spread of tumor should be considered in determining the type of technique to use.

For celiac plexus neurolysis, many pain physicians commonly use 40 to 50 mL of 50% to 70% alcohol or 6% to 10% phenol. Smaller volumes are recommended for absolute alcohol and higher concentration of phenol. Neurolysis with phenol is less painful because of its local anesthetic action, whereas alcohol neurolysis is very painful and should be blocked with pretreatment with local anesthetics.

DeLeon-Casasola OA. *Pharmacological, Interventional and Palliative Care Approaches*. Philadelphia: Saunders; 2006:401–416.

Waldman SD, ed. *Interventional Pain Management*. 2nd ed. Philadelphia: WB Saunders 2001:541–553.

C.3. What are the complications of celiac plexus block?

Serious complications should rarely occur in the hands of a skilled clinician. Hypotension and increased gastrointestinal motility are the most common complications of this block. Neurologic complications include subarachnoid or epidural injection and lumbar nerve root injury, causing long-lasting paresthesia. A potentially severe complication can occur as a result of accidental injection into the nutrient artery of the spinal cord (artery of Adamkiewicz), causing paraplegia. Injury to the kidney may cause temporary hematuria that may not need any treatment. Other complications that have been reported because of the proximity of other vital structures include pneumothorax, chylothorax, intradisc injection, retroperitoneal hematoma, and failure to ejaculate.

Ballantyne JC, Fishman SM, Rathmell JP, et al., eds. *Bonica's Management of Pain*. 4th ed. Philadelphia: Lippincott Williams & Wilkins; 2009:605–618.

C.4. Would you consider neuraxial opioid infusion in this patient? Discuss complications of this procedure.

In properly selected patients, epidural, intrathecal (subarachnoid), or intraventricular infusions of opioids have the advantage of producing profound analgesia without motor, sensory, or autonomic blockade. These routes are considered to deliver preservative-free medications when pain is not well controlled by noninvasive (oral, subcutaneous, or intravenous) routes and escalation of doses is limited by intolerable side effects. The potency ratio of oral to epidural morphine is 1:30 and that from oral to intrathecal morphine is 1:300. The decrease in dose size from oral to intrathecal greatly reduces the side effects and improves pain control and quality of life. The PCA technique can also be employed for epidural routes. Programmable intrathecal pumps can deliver medications at the prescribed dose. Fixed or flexible doses of morphine can deliver via the intrathecal pumps.

Stearns L, Boortz-Mark R, Du Pen S, et al. Intrathecal drug delivery for the management of cancer pain. *J Supp Oncol*. 2005;3:399–408.

C.5. Which medications can be used intrathecally? What is ziconotide?

Morphine is the most commonly used drug; other opiates such as hydromorphone and fentanyl can be used intrathecally. In addition, local anesthetics, α-agonists such as clonidine, and baclofen can be used as recommended by the polyanalgesic consensus panel.

Recently, ziconotide (Prialt), a synthetic equivalent of a naturally occurring peptide found in marine snails, has been shown to be effective in pain relief when used intrathecally. It is a selective voltage-gated calcium channel blocker that inhibits release of pro-glutamate, calcitonin, and substance P in the brain and spinal cord. Side effects include dizziness, nausea, confusion, and psychosis and, therefore, patients trialed on ziconotide should be monitored for cognitive impairment, hallucinations, or changes in mood and consciousness.

Stearns L, Boortz-Mark R, Du Pen S, et al. Intrathecal drug delivery for the management of cancer pain. *J Supp Oncol*. 2005;3:399–408.

Williams J, Day M, Heavner J. Ziconotide: an update and review. *Exp Opin Pharmacother*. 2008;9:1575–1583.

C.6. What is a Personal Therapy Manager (PTM) and what role does it play in neuraxial pain relief?

Increasingly being used is a patient-controlled device that allows patient activated doses via the intrathecal pump (Personal Therapy Manager [PTM], Medtronics Neurological, Minneapolis, MN). The PTM enables the patient to activate delivery of physician-programmed supplemental doses of intrathecal medication. This is especially useful for patients experiencing intermittent pain of varying intensity that cannot be adequately managed with a simple continuous infusion, have an unpredictable need for varying doses of drug, or experience inadequate pain relief or intolerable side effects from supplemental systemic breakthrough pain medications. Nevertheless, risk of sedation, respiratory depression, and other adverse effects are just as possible as when taking oral opiate supplementation and, therefore, caution and careful programming should be ensured.

These routes require a skilled experienced clinician, meticulous technique, and family and facility support in which close monitoring and follow-up can be done. These procedures are reversible but involve expenses for specialized care and operating room costs. Intraspinal opioids may produce the same side effects of nausea, mental clouding, and sedation as in oral and parenteral dosing. Infection (e.g., meningitis and epidural abscess) and hematoma are potentially devastating complications that can cause permanent neurologic deficit if not dealt with in a timely basis. Pruritus and urinary retention are more common than with oral or parenteral administration.

DeLeon-Casasola OA. *Pharmacological, Interventional and Palliative Care Approaches*. 1st ed. Philadelphia: Saunders; 2006:417–429.

Rauck, R, Cherry D, Boyer MF, et al. Long-term intrathecal opioid therapy with a patient-activated, implanted delivery system for the treatment of refractory cancer pain. *J Pain*. 2003;4:441–447.

Stearns L, Boortz-Mark R, Du Pen S, et al. Intrathecal drug delivery for the management of cancer pain. *J Supp Oncol*. 2005;3:399–408.

C.7. Would you consider neuraxial neurolysis in this patient to manage his pain? Discuss advantages and disadvantages of these blocks.

Because of the physical separation of motor and sensory nerve roots in the spinal canal and intrathecal space, chemical neurolytic procedures allow sensory blockade without loss of motor functions. Inadequate pain control with intolerable side effects makes this patient an ideal candidate for neuraxial neurolysis; nevertheless, complications of the procedure should be weighed against benefits. Epidural or intrathecal (subarachnoid) neurolytic blocks are considered for severe intractable pain from advanced cancer as an adjuvant to relieve pain and suffering and improve quality of life. These blocks are primarily effective in relieving pain of somatic origin and less effective for visceral and neuropathic pain.

In selected patients in whom pain relief is not achieved by less invasive measures, these blocks can provide rapid analgesia and allow dosage (and side effects) reduction of systemic drugs. Nevertheless, the risks of postural hypotension, bowel and bladder incontinence, and motor and sensory deficit in the lower extremities cannot be overemphasized. These blocks are irreversible and require a skilled clinician to perform the procedure.

DeLeon-Casasola OA. *Pharmacological, Interventional and Palliative Care Approaches*. 1st ed. Philadelphia: Saunders; 2006:501–507.

C.8. Which neuroablative procedures can be considered in the terminal stage of pancreatic cancer?

Based on the location and type of pain (somatic, visceral, deafferentation), the general condition of the patient, the stage of tumor and metastasis, the life expectancy, and the expertise available, the following neurosurgical procedures could be considered:

- Peripheral neurectomy
- Dorsal rhizotomy
- Anterolateral cordotomy (spinal tractotomy)
- Commissural myelotomy
- Hypophysectomy

Ballantyne JC, Fishman SM, Rathmell JP, et al., eds. *Bonica's Management of Pain*. 4th ed. Philadelphia: Lippincott Williams & Wilkins; 2009:605–618.

C.9. Describe the role of radiation therapy in cancer pain.

Radiation therapy can relieve pain from metastasis and symptoms from local extension of the disease. Radiation therapy is palliative and complementary to analgesic drug therapies to enhance the effectiveness of pain control. Along with therapeutic effectiveness of radiation treatment, the absence of complete specificity for disease may exacerbate or even cause new pain. The radiation dosage should be administered in the fewest fractions possible to promote pain control during and after treatment.

D. Nonpharmacologic Management

D.1. What are the various nonpharmacologic techniques of cancer pain management?

Eisenberg et al. demonstrated that cancer and other chronic pain syndromes such as AIDS and arthritis may receive benefit from alternative modalities. The common therapies offered are as follows:

- Physical therapy and physical modalities
- Relaxation and massage
- Chiropractic manipulation
- Spiritual healing
- Biofeedback and hypnosis
- Magnetic and low-power laser therapy
- Transcutaneous electrical nerve stimulation
- Homeopathy
- Acupuncture
- Prayer

Bradley L, McKendree-Smith N, Cianfrini L. Cognitive-behavioral therapy interventions for pain associated with chronic illness: evidence for their effectiveness. *Semin Pain Med.* 2003;1:44–54.

D.2. What physical modalities have been successfully tried in cancer pain management?

Physical modalities may help decrease stiffness, increase blood flow to the part, help relax the patient, and reduce the dose of analgesics. They include cutaneous stimulation, superficial heat and cold therapy, massage, vibration, and pressure. Cold therapy (cryotherapy) causes vasoconstriction, reduces inflammation, and decreases muscle spasm. Superficial application of heat (thermotherapy) acts through conduction or convection to increase blood flow to the skin and superficial organs. Heat also decreases joint stiffness and increases muscle flexibility. Physical therapy and exercise help to strengthen weak muscles, mobilize stiff joints, and restore coordination. Exercise may reduce pain by 25%. Weight-bearing exercises are avoided if an impending fracture is suspected.

Santiago-Palma J, Payne R. Palliative care and rehabilitation. *Cancer.* 1999;92:1049–1052.

D.3. Describe the role of neuromodulation in cancer pain management.

Neuromodulation techniques such as spinal cord stimulation and deep brain stimulation have not been popular in cancer pain management. Neuromodulation techniques have variable outcome results with success rates between 18% and 80% depending on the study cited. Much of the literature is about chronic nonmalignant pain syndromes. The consensus among most pain physicians is that neuropathic pain syndromes are more effectively treated as spinal cord syndromes than as nociceptive pain syndromes. Thus, spinal cord stimulation and deep brain stimulation should offer relief of neuropathic pain syndromes in patients with cancer.

Transcutaneous electrical nerve stimulation and acupuncture are believed to activate endogenous pain-relieving pathways. Low-voltage stimulation to large myelinated peripheral nerves via cutaneous electrodes may significantly reduce pain.

Acupuncture is a neuromodulatory technique that treats pain with insertion of needles in skin and underlying muscles. Based on various Chinese scientific principles, acupuncture is becoming very popular in Western medical systems. Many intrinsic factors contribute to the success of acupuncture, and in selected patients it does control pain.

D.4. What psychological techniques have been promoted for comfort care and pain relief?

Psychological interventions are an important part of a multimodal approach to pain management in patients with cancer. It helps patients gain a sense of control over pain. Cognitive and behavioral techniques are designed to influence the interpretation of events and bodily sensations. Cognitive techniques help patients think differently about their pain and its management. Behavioral techniques help patients develop skills to cope with pain and help modify their reactions to pain. Patients who undergo psychotherapy report less pain. Relaxation therapy is a well-established modality in managing cancer pain. Several variations of relaxation strategies and techniques have been widely practiced in patients suffering from advanced cancer and have proven effective. Relaxation strategies such as deep breathing, muscle relaxation, and imagery are recommended for the promotion of comfort and relief of pain in hospitalized patients.

Relaxation and imagery are used to achieve a state of mental and physical relaxation, thereby relieving anxiety and muscle tension.

NIH Consensus Conference State of the Science Conference Statement on Symptom Management in Cancer. *Pain, Depression and Fatigue.* Bethesda, MD: National Institute of Health; 2002.

D.5. What are distraction and reframing techniques? What is the role of hypnosis in cancer pain management?

Distraction and reframing techniques encourage focused attention on stimuli other than pain. This involves singing, talking, praying, and watching television. Reframing helps monitor and evaluate negative thoughts and images while encouraging positive thoughts and behavior.

Hypnosis by a skilled person decreases pain and anxiety in patients who have difficulty managing their pain. It also increases coping skills. This technique allows heightened awareness and focused concentration to manipulate perception of pain and has been effective in the management of cancer-related pain syndromes.

CHAPTER 49

Low Back Pain and Sciatica

DAVID Y. WANG AND JEFFREY Y. F. NGEOW

A 57-YEAR-OLD FORMER FACTORY WORKER was injured on the job 8 years ago. He experienced severe low back and right leg pain after lifting a heavy piece of equipment and was found to have a herniated L4-5 intervertebral disc with compression of the right L5 nerve root. He underwent a laminectomy and decompression; nevertheless, he has continued to complain of back pain.

A. Medical Disease and Differential Diagnosis

1. How great an issue is low back pain in the general population?
2. What is the prevalence of low back pain?
3. What is the societal cost of low back pain?
4. What are the risk factors for low back pain?
5. What are the potential sources of pain in the spine?
6. What is the anatomy of the intervertebral discs? What is the mechanism of pain from herniated discs?
7. What is the anatomy of the spinal facets? How do the facet joints cause pain?
8. What are the important findings in the history and physical examination?
9. Which are the appropriate diagnostic studies for low back pain?
10. What is the differential diagnosis of low back pain?
11. What are the causes of multiple spine surgeries and persistent back pain?

B. Management of Low Back Pain and Sciatica

1. What are the noninterventional treatments available?
2. What are the traditional interventional treatments available and how should they be used?
3. What are some of the recent advances in minimally invasive interventions?
4. When should surgery be considered?
5. What new surgical options are now available for treatment of disc disease?

A. Medical Disease and Differential Diagnosis

A.1. How great an issue is low back pain in the general population?

Disorders of the lumbosacral spine cause pain, disability, suffering, public health issues, and socioeconomic issues with far greater impact than disorders of any other part of the body. Most adults will experience several episodes of low back pain during their lifetime. It is estimated that 80% of workers will lose work time because of this complaint. On the basis of primary diagnosis only, a National Ambulatory Medical Care Survey in 1989 to 1990, ranked low back pain as the fifth most frequent reason for adults to visit an office-based medical practice. In surveys employing a wider definition of low back pain, it was found to be the second most frequent symptom prompting physician office visits in the United States.

Hart LG, Deyo RA, Cherkin DC. Physician office visits for low back pain: frequency, clinical evaluation, and treatment patterns from a U.S. national survey. *Spine.* 1995;20:11–19.

Manchikanti L. Epidemiology of low back pain. *Pain Physician.* 2000;3:167–192.

A.2. What is the prevalence of low back pain?

Low back pain usually begins in early life, with the highest frequency of symptoms occurring between ages 35 and 55. Of all adults in industrialized societies, 60% to 80% are affected at some point in their lives. Work absence and symptom duration increase with aging. An acute episode of low back pain usually resolves within 6 weeks. Up to 50% of all adults report having an episode of low back pain during a given year, and approximately 15% of these patients complain of frequent low back pain or pain lasting longer than 2 weeks during a given year. More persistent pain lasting beyond 3 to 6 months occurred in only 5% to 10% of patients with back pain. The U.S. Agency for Health Care Policy and Research reported that 90% of patients with acute low back pain recover their usual activity tolerance within 4 weeks of injury. The remaining 10% of patients who do not recover with time or routine therapy go on to develop chronic symptoms and secondary problems. Using data from the National Health and Nutrition Examinations Survey II, Deyo et al. reported that 1.6% of adults reported symptoms of both back pain and sciatica (lasting for at least 2 weeks). Only 2.1% of respondents had ever been told they had a "ruptured disc" in the lower back. In other clinical studies, it was estimated that as few as 1% to 30% of low back pain can be attributed to nerve root compression. According to the 14-year interval study in North Carolina, the prevalence of chronic, impairing low back pain rose significantly over the 14-year interval, from 3.9% in 1992 to 10.2% in 2006. Recurrences of low back pain are also common, with the percentage of subsequent low back pain episodes ranging from 20% to 44% within 1 year for working populations to lifetime recurrences of up to 85%.

A.3. What is the societal cost of low back pain?

The cost to society of low back pain is enormous. Robertson et al. indicate that the prevalence of back symptoms and objective impairment to function have been unchanged over the last several decades. It appears that the societal perception of disability has changed dramatically over the same period. This has resulted in an increased rate and cost of disability and overutilization of medical care, including surgical treatments. In 1992, the estimates of costs, morbidity, and mortality of occupational injury or illness in the United States were $171 billion, counting direct costs of $65 billion and indirect costs of $106 billion. Injuries accounted for $145 billion spent and illness $26 billion. It is estimated that 75% or more of these costs can be attributed to the 5% of people who become disabled temporarily or permanently from back pain. Occupational low back pain accounts for at least 33% of all healthcare and indemnity costs under workers' compensation. These numbers have been confirmed by recent research supported by the National Institute of Arthritis and Musculoskeletal and Skin Disease.

A.4. What are the risk factors for low back pain?

Traditional beliefs suggested that heavy physical jobs required high energy demand and significant stress and strain on the spine, whereas light jobs required low energy demand. Many low-energy jobs, nevertheless, are static, which is an inherent risk factor for low back pain. Low back pain, degenerative disc disease, and disc herniation are associated with the following:

- Repetitive heavy lifting
- Static work posture (sitting or standing)
- Frequent twisting and bending
- Vibration (operation of motor vehicle or industrial device)
- The common vibration of construction vehicles and industrial devices ranges in frequency from 3.5 to 8.9 Hz.
- Low-frequency vibration, especially around 5 Hz, in conjunction with a prolonged seated position is associated with spine problems.
- The potential for damage to the disc through mechanical resonance is analogous to the high notes of an operatic soprano shattering wine glasses.
- Fatigue of the abdominal and paraspinal muscles has been demonstrated when subjected to 30 minutes of vibration. In the absence of this support, the spine is further susceptible to injury.
- A meta-analysis of 17 studies revealed that whole-body vibration is associated with an increased risk of low back pain, sciatica, and lumbar intervertebral disc disorders.
- Cigarette smoking. Smoking is linked to low back pain, sciatica, and lumbar disc herniation.
  - In an animal model, cigarette smoking significantly affects the vasculature outside the intervertebral disc, where the most pronounced effect is the reduction of solute-exchange capacity, cellular uptake, and metabolism within the disc.

- Cross-country skiing. In a study of skiing and spinal trauma, the diagonal body position required for cross-country skiing was the most common back pain–inducing stance, whereas no skier experienced back pain when only downhill skiing.

The "oxidative stress hypothesis of aging" theory proposed that enhancement of oxygen consumption resulting from increased physical activity may accelerate disc degeneration. On the other hand, strenuous exercises may contribute to positive nutritional effect by facilitating the transport of small solutes into and out of the disc. Generally, it is believed that persons who are physically fit or who maintain a balanced exercise program appear to have a lower risk for chronic low back pain and a more rapid recovery after an episode of acute back pain.

A.5. What are the potential sources of pain in the spine?

In order to more easily identify the various sources of pain, the spine may be divided into three compartments: anterior, middle, and posterior.

The anterior compartment consists of the vertebral body and intervertebral disc. The anterior unit is bound together by cephalocaudal ligaments: anterior longitudinal ligament and posterior longitudinal ligament (PLL). The anterior longitudinal ligament is anatomically much broader and stronger than the PLL. The PLL is intact throughout the length of the vertebral column until it reaches the lumbar vertebrae. From L1, it becomes progressively narrower until at L5-S1 it is only half of its original width. This anatomic feature contributes to an inherent structural weakness in the lumbar spine. Hence, the lower lumbar spine is the region subjected to the greatest static stress and most spinal movement resulting in the greatest kinetic strain.

The middle (neuraxial) compartment contains all of the structures within the bony and ligamentous boundaries of the spinal canal. This includes the PLL, epidural space, meninges, spinal cord, dorsal and ventral nerve roots, root sleeves, dorsal root ganglia, and ligamentum flavum.

The posterior compartment contains the facet joints, laminae, vertebral arches, and structures posterior to the plane of the transverse processes and innervated by the dorsal rami of the spinal nerves. The ligaments are extremely important in stabilizing the vertebral column. The ligamentum flavum (yellow ligament), which connects the

laminae of adjacent vertebrae, is the thickest and strongest ligament in the lumbar region. It can contribute to spinal stenosis by folding inward during upright posture, extension of the back, and hypertrophy.

The sinovertebral nerve originates lateral to the neural foramina and enters the spinal canal anterior to the dorsal root ganglion. It is a branch of the somatic ventral nerve root and the sympathetic grey ramus communicans. This specific nerve, also known as the nerve of Luschka, innervates the outer annulus of the disc, PLL, epidural membranes, and dura at the segmental level of origin and adjacent levels. It is important to note that central low back pain, with or without referred pain to the buttocks, may derive from irritation of the outer part of the annulus fibrosis or the PLL.

In summary, the potential sources of low back and radicular pain include the bony structure of vertebrae, muscles attached to the spine and hips, fasciae, ligaments, discs, facet joints, meninges, vessels, nerve roots, dorsal root ganglia, and nerves in the surrounding areas.

The natural wear and tear on the discs and facet joints results in microtrauma and degeneration. This can induce the release of neurohumoral mediators such as phospholipase A_2, serotonin, H^+, substance P, prostaglandin E_2, and so on, to produce inflammation of the nerve roots or meninges, and sensitize local nociceptors. Furthermore, it has been theorized that material from the nucleus pulposus, sheltered from the immune system by the presence of the annulus fibrosis, might act as a foreign protein and trigger an autoimmune reaction. The recent demonstration of an activated immunocompetent cellular response at the epidural interface of the herniation of the nucleus pulposus supports the concept of the immunogenic capacity of the nucleus pulposus. Tissue injury or inflammation can cause a barrage of nociceptive input into the spinal cord. This may lead to a phenomenon called *central sensitization* or *wind-up* of neurons in the dorsal horn of the spinal cord. The release of excitatory amino acids and neuropeptides in the dorsal horn is thought to be the mechanism underlying the phenomenon of central sensitization. At the cellular level, there is an increase in spontaneous discharge and an expansion of neural receptive fields of wide-dynamic-range neurons located in Rexed lamina V of the spinal cord. Clinically, this is characterized by sensation of pain when exposed to nonnoxious stimuli (allodynia), significantly increased response to painful input (hyperalgesia), and increased response to repetitive stimulation (hyperpathia).

A.6. What is the anatomy of the intervertebral discs? What is the mechanism of pain from herniated discs?

The intervertebral disc is a ring-like structure composed of a centrally located well-hydrated pliable proteoglycan matrix, the nucleus pulposus, which comprises two-thirds of the surface area of the disc. Surrounding the nucleus is a fibrocartilaginous ring composed predominantly of type I collagen, the annulus fibrosus, which makes up the remaining one-third of the surface area of the disc. The annulus fibrosus is stronger anteriorly but often defective posteriorly. As a self-contained fluid system, the disc absorbs shock, permits transient compression, and allows movement. It provides a cushion between the vertebral bodies and allows for greater flexibility.

As the disc ages, the number of viable cells in the nucleus pulposus decreases, and the proportion of cells that exhibit necrosis changes from 2% in infancy to 50% in young adults and 80% in the elderly. The water content in the young disc is 80% to 90% in the nucleus pulposus. With aging, the discs tend to dehydrate, losing up to 70% of their water content. As the nucleus pulposus further dehydrates, it becomes more fibrous and less compliant. A disc will usually herniate under strain and pressure. When overstressed, it will protrude along in the path of least resistance, usually posterolaterally. This can cause direct mechanical pressure on the nerve roots resulting in radiculopathy.

In the healthy back, only the outer third of the annulus fibrosus is innervated. In the degenerative or disrupted disc, small unmyelinated nerve fibers grow into the inner third of the annulus fibrosus and even into the nucleus pulposus. Internal disc disruption is a condition characterized by a degenerated nucleus pulposus with radial fissures extending into the peripheral annulus fibrosus. Upon rupture of the disc, the release of irritative material near the meninges can induce radiculitis and symptoms of radiculopathy without actual herniated disc material compressing the nerve roots. Under such circumstances, significant disc herniation might not be visualized on magnetic resonance imaging (MRI) or computed tomography (CT) scan. In brief, the proposed mechanisms of radiculopathy include direct pressure on nerve fibers as a result of compression injury and indirect impact through impairment of microcirculation, chemical irritation and inflammation, immune reaction, edema formation secondary to permeability changes of the intraneural capillaries, and impairment of the nutritional transport to the nerve root.

Compression of the nerve roots is dependent upon the effective space available within the neural foramina, the osseous structures surrounding the neural foramina, and the tethering effects of the intraspinal and extraspinal ligaments. Posterolateral disc herniations can impinge on the lumbar dorsal root, which then initiates electrical discharges for as long as 25 minutes after the mechanical stimulus has been removed. Radiculopathy can be produced by either biochemical or mechanic stimulation of a swollen, stretched, or compressed nerve root. Approximately 3% to 12% of all lumbar disc herniations occur laterally and extend into or beyond the foraminal zone; in this setting, the patients will complain of sudden and severe radicular pain, often with dysesthesia. On the other hand, discogenic pain resulting from a central disc bulge or herniation stimulates several lumbar tissues such as the outer layer of the annulus fibrosus or PLL. Clinically, this is manifested as central low back pain without any radicular symptoms.

A.7. What is the anatomy of the spinal facets? How do the facet joints cause pain?

The facet, or zygapophysial, joints consist of two arthrodial joints superiorly and inferiorly, each lined with synovium, lubricated by synovial fluid, contained within a joint capsule. These synovial joints enhance spinal stability and flexibility. In the upper part of the lumbar spine (L1–3), the facet planes lie in a generally vertical sagittal plane and permit flexion and extension but prevent lateral flexion or bending in the lordotic curve. The lumbosacral facet joints at the level of L5-S1 depart the farthest from the sagittal plane, allowing some rotation of the lower part of the lumbar spine. With slight forward flexion, the facets of the other lumbar vertebrae separate and permit a modest degree of lateral movement and rotation. Facet loading, if of a repetitive nature, may play a role in the degeneration of the facet joint. After repeated wear and tear, these joints are susceptible to osteoarthritis and associated synovial cyst formation. Hypertrophic facet joints or cysts can encroach on the spinal canal or the intervertebral foramina and contribute to the development of central spinal or foraminal stenosis.

A.8. What are the important findings in the history and physical examination?

A problem-focused pain history should include onset, location, intensity (e.g., pain scale 0 to 10), characteristics (achy, spasmodic, stabbing, burning, shooting, etc.), duration plus aggravating and alleviating factors. The essential purpose in the initial evaluation is to differentiate patients with serious underlying pathology from those with mild problems.

Patients with a disc problem will usually experience an exacerbation of their symptoms with spinal flexion, which increases intradisc pressure. By contrast, in the setting of spinal stenosis, standing or walking exacerbates back and leg pain, whereas forward flexion may alleviate these symptoms. In moderate-to-severe spinal stenosis, extension of the spine may cause radicular pain.

Patients with compression fractures typically present with severe back pain, often intense with minimal lateral rotation or with flexion and relieved by rest. A history of bladder, bowel, or sexual dysfunction may indicate compression of the cauda equina or conus medullaris. Unlike sciatica, often with its unilateral nerve root involvement, patients with cauda equina syndrome usually have bilateral involvement. Although motor function may be normal and pain uncommon in those with conus lesions, patients often demonstrate abnormalities of sensation in a saddle distribution, feeling touch or dysesthesias but neither pain nor temperature. Causes of these symptoms may be a fracture of L1 or L2, tumor, large central disc herniations, or intramedullary cysts affecting the conus. These disorders are considered surgical emergencies and require aggressive evaluation and prompt surgical consultation.

The physical examination should include Lasègue's sign (the straight leg raising test), Braggard's test (dorsiflexion of the ankle with elevation of the leg), and the crossover test. These clinical tests are considered positive when sciatica is reproduced with elevation of the leg between 30 and 60 degrees. If testing the uninvolved leg produces contralateral symptoms, disc disease should be considered. A positive crossover sign occurs when straight leg raising of the patient's contralateral leg elicits pain on the affected side. It is usually a strong indication of nerve root irritation or compression. Extension of the knee while in a seated position, also known as *distracted straight leg raise*, can test sciatic nerve tension too. The patient with significant nerve root irritation tends to complain of increased pain or lean backward to reduce tension on the nerve. The differential diagnosis of spinal shock, upper motor neuron lesions, and lower neuron lesions is shown in Table 49.1. The nerve root signs are shown in Table 49.2.

Table 49.1 Differentiating Spinal Shock, Upper Motor Neuron Lesions, and Lower Motor Neuron Lesions

DISEASE STATE	DEEP TENDON REFLEX	PATHOLOGIC REFLEX/ PLANTAR RESPONSE	SUPERFICIAL REFLEX (NORMAL)
Spinal shock	Absent	Absent	Absent
Upper motor neuron disease	Increased; rarely may be decreased in the acute setting	Positive/extensor Babinski's sign + Oppenheim's sign +	Decreased or absent e.g., Cremasteric reflex −
Lower motor neuron disease	Decreased	Negative/flexor	Present (but L1 L2 lesion will have Cremasteric reflex −)

Table 49.2 Nerve Root Signs

ROOT LEVEL	REFLEX DECREASE	SENSORY DEFECT	MOTOR WEAKNESS
L4	Knee jerk	Anterior thigh, knee, and shin	"Single squat and rise test"; quadriceps (mostly L4)
L5	No easily elicited reflex	Lateral leg and middle dorsal foot	"Heel walk test"; dorsiflexion of foot and toes (L5 and some L4); especially big toe, extensor hallucis longus (EHL)
S1	Ankle jerk	Posterior calf and sole	"Toe walk test"; gastrocnemius/soleus; "toe flexors"

A.9. Which are the appropriate diagnostic studies for low back pain?

In the absence of signs of serious medical disease, there is no need for special studies, because 90% of patients will recover spontaneously within 4 weeks of the onset of pain. Waiting 4 weeks before considering special tests allows these patients to recover spontaneously and avoid unneeded procedures. When pain persists beyond 4 to 6 weeks, plain radiographs of the spine should be considered. Pertinent findings include the height of the intervertebral spaces and vertebral bodies, and bony changes in the endplates. With oblique views, the facet joint space and any spondylolysis can be revealed. The lateral view can help estimate the severity of spondylolisthesis. A CT scan can show a herniated disc or fragment in the spinal canal. It can help to identify early epidural hematoma. With contrast, it can help further differentiate tumors, abscesses, and granuloma in the central nervous system. MRI provides excellent anatomic definition of the disc and its hydration status; it can also show the anatomy of the surrounding soft tissues. MRI with intravenous gadolinium is indicated for distinguishing between a recurrent disc herniation and recent postoperative scar tissue. It is particularly useful when distinguishing intrinsic from extramedullary or epidural spinal cord lesions. When MRI is contraindicated, a myelogram may reveal a filling defect at the level of posterior bulging discs. The myelogram in conjunction with a CT scan enables axial imaging of the spinal cord and subarachnoid space. A bone scan is helpful in the diagnosis of bone or bony fractures that may not be visible by radiography or CT scan, or whenever metastatic disease is suspected.

Discography/discogram/discomanometry (discometry) is a specialized diagnostic test specifically indicated to help diagnose discogenic pain. The presence of pain fibers in the outer third of the annulus fibrosus may explain back pain in some individuals with an annulus tear or internal disc disruption. The test involves an intradiscal puncture and instillation of contrast into the disc nucleus. It provides direct confirmation of nuclear morphology and integrity of the vertebral endplate and annulus.

A.10. What is the differential diagnosis of low back pain?

There are numerous diagnostic labels used to describe low back pain, for example, lumbosacral sprain, lumbar discogenic syndrome, mechanical low back pain, spinal stenosis, spondylosis, spondylolisthesis, osteoarthritis/facet joint syndrome, myofascial pain syndrome, unstable low back, discitis, and failed back surgery syndrome. Each of these labels suggests its own underlying pathology. Acute lumbosacral sprain, by far the most common cause of new-onset low back pain, is often only associated with the presence of postural back pain. It frequently results from reflex muscle spasm secondary to local irritation of structures in the back. When muscle spasm occurs, the normal anatomy may be disturbed and undue force applied to surrounding tissues and structures. In every case, a careful history, physical examination, and the appropriate diagnostic studies will help elucidate the "pain generator."

A.11. What are the causes of multiple spine surgeries and persistent back pain?

Persistent back or leg pain after one or more spinal surgeries is called *failed back surgery syndrome* or *postlaminectomy syndrome*. Usually, the cause is a combination of both nociceptive and neuropathic pain. Over time, a strong psychological component can develop with progressive disability as treatments fail. Approximately 37,500 patients are diagnosed with this syndrome annually in the United States.

When pain persists or recurs in a patient after spinal surgery, the most common neuroradiologic finding is usually that of epidural fibrosis and scarring besides recurrent disc herniations and spinal stenosis. Patients with this condition often report constant dull, aching, poorly localized low back pain with intermittent sharp episodes. They may also report pain or abnormal sensations with neuropathic characteristics such as burning, shooting, throbbing, stabbing, or pulling. The exact source of these complaints is unclear although the scar tissue or arachnoiditis is frequently implicated. When reoperation is performed for the purpose of neurolysis only, a transient improvement of sciatica may be seen, but it usually recurs within the first postoperative year. Success rates for reoperating on patients with failed back surgery syndrome have been highly variable, ranging from 25% to 80%. These patients are perhaps the most challenging of all. They deserve a comprehensive multidisciplinary evaluation, including orthopedic and neurosurgical consultations. Further, surgical intervention should be avoided in the absence of a clear indication.

B. Management of Low Back Pain and Sciatica

B.1. What are the noninterventional treatments available?

The cornerstone of treatment for low back pain and mild sciatica caused by a herniated lumbar disc is conservative care, which includes bed rest, medications, and physical therapy. Patients whose symptoms fail to respond to conservative care may require more invasive treatment.

Both clinical and epidemiologic evidence suggests that the longer the back pain and work loss persist, the less likely there will be improvement of the pain. The chance for return to work is even lower. Improved early management and greater access to primary care services should greatly reduce the number of patients with simple backache who require referral to hospitals. Over the last decades, there has been a paradigm shift in the treatment of low back pain away from focusing care exclusively on the pain in favor of helping patients improve their activity tolerance and function. An early return to activity seems to be associated with a better outcome than does prolonged bed rest (greater than 4 days).

Treatment varies depending on the cause of pain. In December 1994, the Agency for Health Care Policy and Research announced the following guidelines for the care of acute low back problems.

- A brief period of rest
- Over-the-counter pain relievers
- Trunk-strengthening exercises
- A single spinal manipulation

In order to avoid reinjury, an incremental, gradually increasing regimen of aerobic exercise (up to 30 minutes daily) can usually be started within the first 2 weeks of symptom onset. Such activities have been found to stress the back no more than sitting for an equal period on the side of the bed. The combination of aerobics for general fitness with some specific training to improve the strength and endurance of the back muscles is often beneficial.

The role of medications in the treatment of low back pain is to control pain, facilitate rehabilitation, restore normal sleep patterns, and improve mood and motivation. Nonsteroidal anti-inflammatory drugs are an essential part of the treatment of patients with inflammatory back pain, such as that associated with spondylitis. Other medications that have been shown to be useful include tricyclic antidepressants and anticonvulsants. Muscle relaxants are often used to decrease muscle spasm and assist in promoting rest for patients with severe pain. These are usually indicated for short-term treatment and acute relief. Short-term therapy with opioid analgesics may be needed to promote rest as well as maintain activity in the acute phase of low back pain. Long-term use of these medications is generally discouraged, but may be appropriate for carefully selected patients.

When recovery does not occur within 6 weeks and no additional pathology is detected, physical therapy is indicated. Patients should be encouraged to increase activity. Activities and postures that increase stress on the back also tend to aggravate back symptoms. Patients limited by back symptoms can minimize the stress of lifting by keeping any lifted object close to the body at the level of the navel. Activities such as twisting, bending, and reaching while lifting, also increase stress on the back. Prolonged sitting may aggravate back symptoms in discogenic pain patients because of progressive increase in pressure at specific points in the abnormal disc. Body weight optimization and a program that teaches good posture and body mechanics are also important. Neuromuscular reconditioning must be included to ensure a function-specific, task-oriented program. Essential and most importantly, the program must be geared to enhance functional recovery in the affected patient. The exercise training is designed as a step-by-step program to improve patients' function and optimal neutral spine posture. These programs include stabilization training to attain adequate dynamic control of lumbar spine forces and eliminate repetitive injury. Soft tissue flexibility, joint mobility, abdominal muscle strengthening, and aerobic exercise are also important factors.

Spinal manipulation is controversial and is neither recommended in patients with radiculopathy pain, nor is it wise in those for whom a diagnosis has not been established. For appropriately selected patients, if manipulation has not resulted in symptomatic and functional improvement after 4 weeks, it should be stopped and the patient reevaluated.

B.2. What are the traditional interventional treatments available and how should they be used?

Common traditional interventional treatment includes the following:

- Trigger point injection
- Traditional epidural steroid injection (interlaminar approach)
- Transforaminal epidural steroid injection (transforaminal approach)
- Facet joint intra-articular block or medial branch block

Interventional techniques such as trigger point injections and local infiltration are used to provide pain relief of short duration, so other activities and physical therapy that might otherwise be severely limited by pain may be pursued.

Corticosteroids play an important role against inflammation and reduction of edema. Steroids injected into the epidural space have been used for treating low back pain and radiculopathy for many decades. Despite widespread use, the results of epidural steroid injection are still in question because studies evaluating the response to this therapy have been small, poorly controlled, and lacking good long-term follow-up. Published studies of the effectiveness of epidural steroid

injections have varied from 18% to 90%. The addition of hyaluronidase into the epidural injectate is thought to improve the spread of local anesthetic and steroid through tissue planes. Hyaluronidase acts by cleaving hyaluronic acid, which is found within connective tissue, skin, aorta, vitreous humor of the eye, joint cartilage, and the nucleus pulposus of the disc. Epidural steroid injections can be performed through the interlaminar route, the caudal canal, or the intervertebral foramina. The spread of solution in both caudal and interlaminar injection is less controllable because of inconsistent lateral flow into the ventral compartment. This renders the medication less effective as it is diverted away from the compartment, depending on the tightness of the lateral recess and the size of the dural sac. In normal volunteers, the transforaminal method showed good ventral flow, whereas the interlaminar approach showed predominantly dorsal flow, which was far from the usual site of impingement.

Patients who suffer from lumbar facet arthropathy may have symptoms, including band-like low back pain and associated hip, groin, or thigh pain. Pain rarely radiates below the knee in this condition. Blockade of the medial branch of the dorsal ramus of the spinal nerve or intra-articular injections of the lumbar facets are effective in short-term alleviation of this type of pain.

B.3. What are some of the recent advances in minimally invasive interventions?

There are several recent interventional techniques for the management of low back pain and sciatica that can be applied to appropriately selected patients. These include the following:

- Epidural neuroplasty or epidural adhesiolysis
- Epiduroscopy (spinal canal endoscopy)
- Percutaneous radiofrequency denervation of medial branches for facet joint pain
- Automated percutaneous discectomy (APD) or percutaneous automated discectomy (PAD) or percutaneous automated nucleotomy (PAN)
- Percutaneous laser disc decompression (PLDD)
- Intradiscal electrothermal therapy (IDET)
- Percutaneous disc decompression using nucleoplasty
- Percutaneous lumbar discectomy using Dekompressor probe
- Spinal cord stimulation (SCS)
- Intrathecal drug delivery
- Percutaneous vertebroplasty (PV) and percutaneous kyphoplasty (PK)

Epidural neuroplasty or epidural adhesiolysis is done with hypertonic saline and hyaluronidase to lyse epidural adhesions. This technique involves placing a rigid catheter into the epidural space, with manipulation of the catheter to physically breakdown the adhesions and applying local anesthetic, steroid, hypertonic saline (10%), and hyaluronidase over several days.

Epiduroscopy (or spinal canal endoscopy) allows directly visualization of the epidural space using a flexible fiberoptic catheter. Adhesions are lysed with the catheter under direct vision; thereafter, better delivery of medications to the target area can be achieved.

Percutaneous radiofrequency denervation of the medial branches of the dorsal (or posterior) rami of segmental spinal nerves is achieved by applying heat to denature the nerves that innervate the painful facet joints. The success rate has been reported variably in the range of 17% to 90% for facet joint pain of a few weeks' to several months' duration. With this technique, the pain may return several weeks to months after the axons regenerate; repeating the procedure is then indicated.

Percutaneous manual nucleotomy was first presented by Hijikata in 1975. It was proposed as a method of preventing perineural and epidural scar formation by avoidance of entry into the spinal canal. Thereafter, APD or PAD or PAN was designed as a procedure using "nucleotome" (reciprocating suction-cutting probe) for intradiscal decompression by Onik in 1985. The cannula requires a sizable annular incision to reach the nucleus. Its success rate is approximately 70% to 80%.

PLDD is a technique, introduced by Ascher and Choy in 1987, using neodymium:yttrium-aluminum-garnet (Nd:YAGq) laser to "vaporize" a small portion of the nucleus pulposus in an attempt to decompress the involved disc. It has been demonstrated that the inner pressure of the nucleus pulposus drops significantly after the disc ablation. Its success rate is approximately 78%. After 4 to 6 months from this treatment, it was demonstrated that one-third of repeat MRI scans showed modest to moderate decrease in the size of disc herniation. There is concern, nevertheless, that the technique is potentially hazardous to bone and nerve tissue because of the significant rise in temperature resulting from thermal energy transfer.

IDET or annuloplasty, first reported by Saal and Saal in 2000, has been shown to be effective in managing discogenic pain. It is a minimally invasive procedure in which a catheter is inserted into the nucleus pulposus through which an electrode is passed so that a controlled level of heat at a temperature of 90° C (194° F) can be applied to a broad section of the affected disc inner wall. This thermal therapy is postulated to alleviate discogenic pain by shrinking collagen at a target temperature of 65° C (149° F) to 75° C (167° F). Another proposed mechanism is

denervation of exposed nociceptor endings in the outer disc annulus starting at 45° C (113° F).

Percutaneous disc decompression with nucleoplasty is used for those patients whose symptoms are attributed to radiographically contained discs, that is, disc with intact outer annulus.

Since 2000, by combining tissue removal with thermal treatment, disc decompression has been achieved. It applies a focused "coblation" technique, ablating while coagulating (by using bipolar radiofrequency) to reach the level of 40° C (104° F) to 70° C (15° F). At this temperature, molecular dissociation is achieved and thought to minimize the potential for surrounding tissue damage.

Percutaneous disc decompression using a Dekompressor probe is another option for those patients whose symptoms are attributed to radiographically contained discs. It provides objective evidence that disc was removed, the cellular character of that material, and provides a qualitative and quantitative measure.

SCS is a technique in which electrodes are passed into the posterior epidural space. Electrical stimulation of the spinal cord has been shown to be effective in the management of certain neuropathic pain syndromes and postlaminectomy syndromes. The exact mechanism by which pain relief is achieved remains controversial.

Intrathecal drug delivery directly into the cerebrospinal fluid through an implanted catheter and pump can be used to treat intractable pain from a variety of causes, both nociceptive and neuropathic. A variety of medications and combinations thereof can be used depending upon the type and location of symptoms. Among the experts, this is known as *intrathecal polyanalgesia*. This modality is indicated when increasing doses of opioid are required to achieve pain relief but at the expense of disabling side effects. The dose is effectively reduced to approximately 1/300, for example, when converting an oral dose of morphine to its equipotent equivalent delivered intrathecally.

PV and PK are both advanced techniques used in the treatment of painful compression fracture. In the United States, compression fractures occur in approximately 700,000 patients per year, and 80% of these fractures occur in women. The conventional management includes bed rest, analgesics, and bracing. PV was a technique developed in 1984 for the treatment of painful vertebral hemangiomas. It has since become popular for the treatment of osteoporotic vertebral body compression fracture. It involves the application of liquid cement (polymethylmethacrylate), tobramycin, and barium powder (as nonionic contrast) through a special metal needle inserted under fluoroscopy. The cement provides vertebral solidification and buttresses the compressed bone within the vertebral body. The procedure usually takes 45 to 60 minutes, and the patient may be discharged several hours later. Some risks are involved with this procedure, such as leakage of cement into surrounding areas (disc, spinal cord, and nerve roots), infection, bleeding, worsened pain, embolism, and paralysis. Overall, more than 80% of treated patients had moderate to marked pain relief.

PK is a recently developed technique similar to PV, which involves the additional application of an inflatable balloon inside the collapsed vertebral body. The compressed fracture is thus expanded, the lost height of the vertebral body is restored, and an inner space or cavity is created for the cement. This procedure was approved by the U.S. Food and Drug Administration in 1998. A significant reconstitution of the curvature of the spine can be seen following kyphoplasty. According to Lieberman, in 70% of the collapsed vertebral bodies, the kyphoplasty restored 47% of the lost height. This newer technique offers the additional advantage of realigning the spinal column and restoring height to the fractured vertebrae.

PV and PK are associated with pain relief in 67% to 100% of cases. Most patients experience significant pain relief within the first 1 to 2 days. There is also a report of 95% improvement in pain and significant improvement in function following treatment by either of the two techniques.

B.4. When should surgery be considered?

Several surgeries are indicated for low back pain and sciatica. These include laminectomy, macrodiscectomy or microdiscectomy, foraminotomy, intervertebral body insertion, and spinal fusion.

According to Weber's study, the long-term results appear to be no different in the surgery versus nonsurgery group in the case of low back pain. If the following situations occur, surgery should be considered:

- Failure to respond to conservative management for at least 3 months
- A profound or progressing neurologic defect such as a complete foot drop
- Recurring episodes of intractable sciatica involving the same segment—mainly to avoid the cumulative disability of repeated events.

Muscle weakness is a dubious indication for surgery if the paresis is of unknown duration. If the pressure on the nerve root can be relieved immediately after the appearance of the paresis, surgery has been regarded as the therapy of choice. Unfortunately, most patients are unaware of the subtle loss of motor function. The greatest concern and complaints are largely centered on pain, paresthesia, and immobility.

Within the first 3 months of acute low back symptoms, surgery is considered only when serious spinal pathology or nerve root dysfunction, obviously resulting from a herniated lumbar disc, is detected. Nerve root decompression can be considered for a patient if all of the following criteria exist:

- Sciatica is both severe and disabling.
- Symptoms of sciatica persist without improvement for longer than 4 weeks or with extreme progression.
- There is strong physiologic evidence of dysfunction of a specific nerve root with intervertebral disc herniation confirmed ipsilaterally at the corresponding level by imaging.

Patients with acute low back pain alone, without findings of serious conditions or significant nerve root compression, rarely benefit from a surgical consultation. With or without surgery, more than 80% of patients with obvious surgical indications eventually recover.

B.5. What new surgical options are now available for treatment of disc disease?

- Artificial disc replacement (ADR)
- Interspinous process decompression system (X STOP)

In the mid-1980s, Drs. Schellnack and Buttner, German orthopedic surgeons, developed a metal and plastic prosthesis that has been in clinical use for more than 17 years. The prosthesis is known as the *SB CHARITÉ*. The prosthesis design is currently in its third generation. Other prosthetic discs are available, including Prodisc, Maverick, FlexiCore, and Kineflex. In October 2004, the CHARITÉ artificial disc became the first to be approved for disc replacement in the United States. It is composed of two metallic endplates and a polyethylene core that moves between them (Figs. 49.1 to 49.4). Traditional spinal fusion does change the mechanics of the segment that is fused.

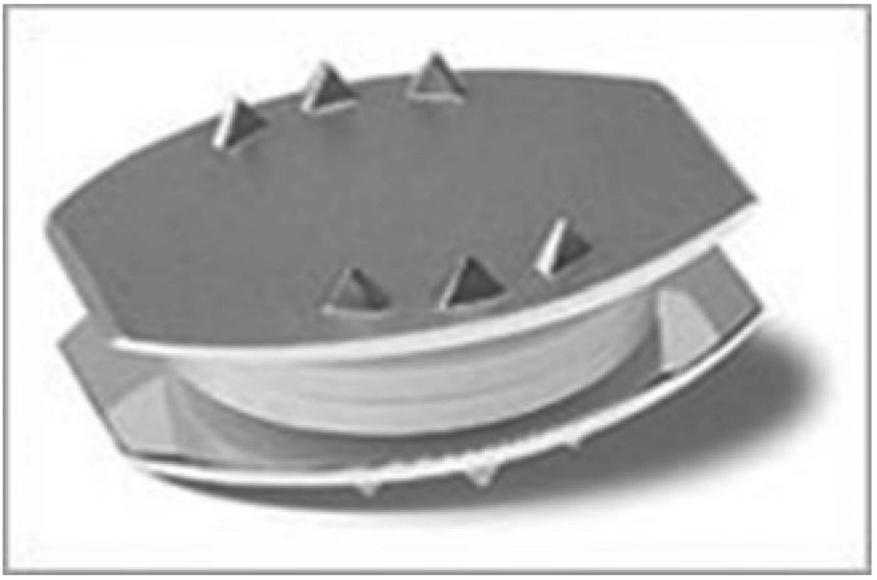

Figure 49.1 Charité disc.

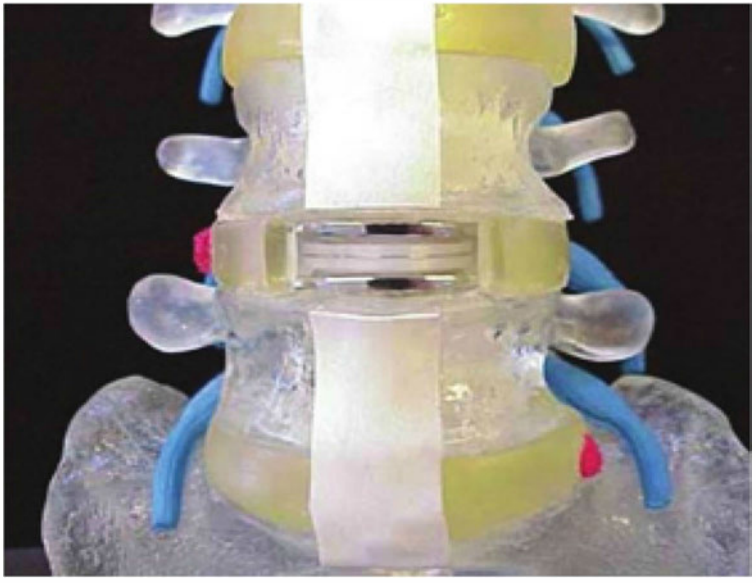

Figure 49.2 Charité disc replacement at L4-5.

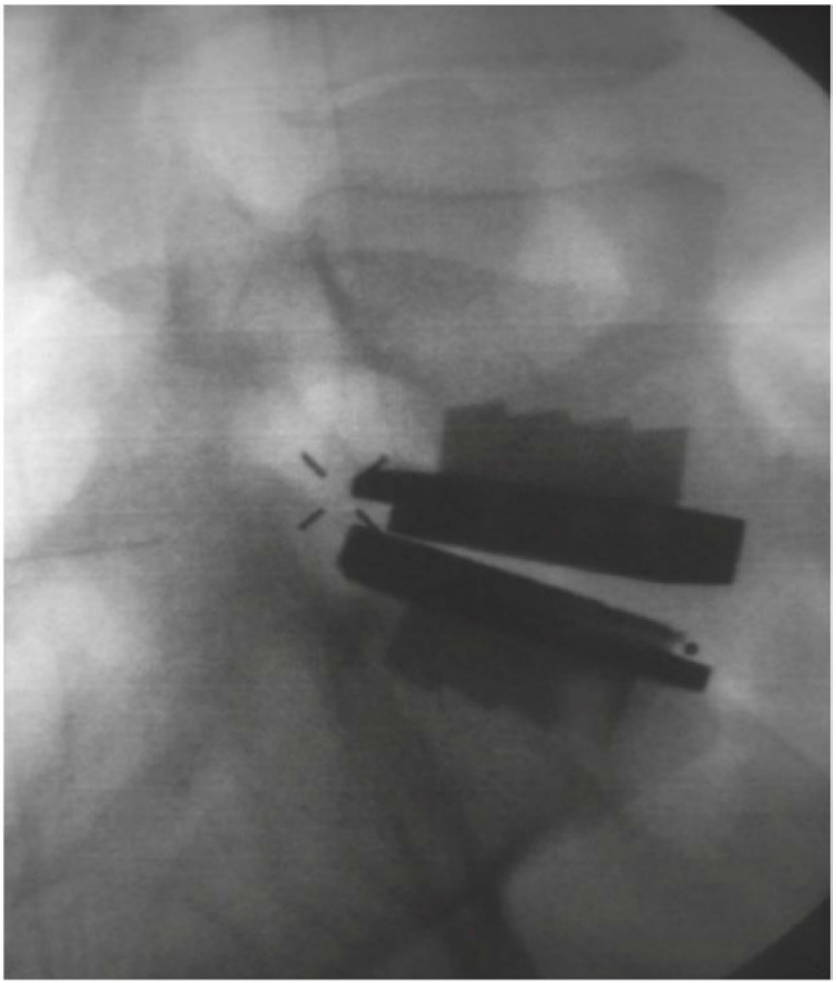

Figure 49.3 L5-S1 artificial disc replacement, lateral fluoroscopic view.

Adjacent segment degeneration can develop at approximately 3% per year (or 16.5% at 5 years, 36.1% at 10 years). One major theoretic advantage of ADR over spine fusion is that it results in no change in the biomechanics of the lower spine, thereby allowing the spine to maintain its normal range of motion and reducing or eliminating the risk for degeneration in the adjacent segments of the spine. The indications for ADR are similar to those for an anterior lumbar interbody fusion using interbody cages. The contraindications for ADR include infection, spinal stenosis, spondylolisthesis (or other types of instability in the spine, such as fracture or tumor), scoliosis, facet joint osteoarthritis, significant radiculopathy, osteoporosis, and pregnancy. Artificial discs are not perfect. The potential disadvantage of ADR is a limited durability. Because disc injury is a common cause of back pain in younger adults, an artificial disc in such patients needs to last for decades. The demands on that disc will be very great, and it may not outlast the lifetime of the patient, who may need revision surgery

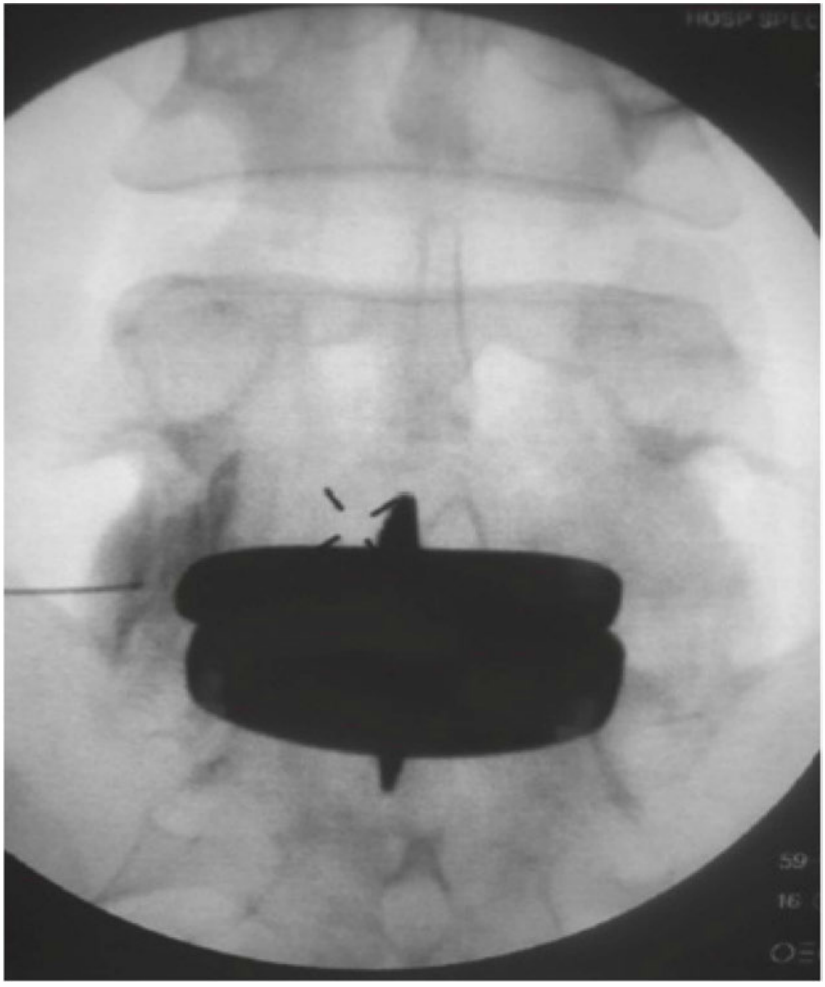

Figure 49.4 Anteroposterior fluoroscopic view of artificial disc replacement.

later. Revision ADR can be very dangerous because of scar tissue from the original surgery in nearby vascular structures. In addition, there is a 1% to 3% of complication of retrograde ejaculation in men. The recent study regarding Canadian cohort of patients demonstrated satisfactory clinical and radiographic results in a carefully selected patient population. The radiographic assessment confirmed preservation and maintenance of motion of the replaced disc (L4-5 or L5-S1) with a follow-up (2 to 7 years) averaging 55 months.

The interspinous process decompression system (X STOP) is a titanium metal implant made to fit between the lumbar spinous processes of the vertebrae (Figs. 49.5 and 49.6). It is designed to relieve narrowing of the spinal canal and neural foramen during extension, thereby reducing the symptoms of neurogenic intermittent claudication. The indications include spinal stenosis and degenerative lumbar spondylolisthesis.

CHAPTER 50

Perioperative Pain Management

Anuj Malhotra, Vinod Malhotra, and Narinder Rawal

A 60-YEAR-OLD-MAN

with a smoking history of a pack of cigarettes a day for approximately 40 years and chronic obstructive pulmonary disease is scheduled for thoracotomy for removal of carcinoma in his right middle lobe.

A. Perioperative Pain Management for Thoracotomy

1. What would be your advice to the patient about the planned thoracotomy and postoperative pain relief?
2. How will you decide about the choice of anesthetic technique?
3. What is chronic postthoracotomy pain syndrome (PTPS)? Does video-assisted thoracic surgery reduce the risk of chronic pain after thoracotomy?
4. What would be your perioperative analgesic strategy?
5. Does the choice of analgesic technique influence postoperative outcome?
6. Does it matter if the epidural catheter is at the thoracic or lumbar level?
7. Does the choice of drugs influence the efficacy or safety of thoracic epidural analgesia (TEA)?
8. What are the usual doses and concentrations of the anesthetic combinations commonly employed in epidural analgesia?
9. If accidental dural puncture occurs during placement of the epidural needle, what steps should be taken?
10. What are the alternatives to TEA?
11. What is the usual clinical regimen for intravenous patient-controlled analgesia (IV-PCA) and is special patient monitoring required during its use?
12. What are the side effects and complications of epidural technique?
13. What recommendations for placement and removal of the epidural catheter will you make if this patient is on antiplatelet or anticoagulant therapy or thromboprophylaxis is planned?

A 70-YEAR-OLD WOMAN

with metastatic breast cancer has been treated for the last 6 months with transdermal fentanyl (Duragesic patch) for her cancer pain. She is currently on a 100-μg per hour patch every 72 hours. She is now scheduled for surgery for hip fracture after a fall. The patient was very dissatisfied with postoperative pain management after her breast surgery 3 months earlier.

B. Chronic Opioid Therapy and Perioperative Pain Management

1. How does chronic opioid therapy influence postoperative pain management?
2. What are the causes for increased postoperative pain and opioid consumption in patients chronically using opioids?
3. What are the main differences between a chronic opioid-consuming patient and a patient who abuses or is addicted to opioids?
4. What issues need to be considered in the opioid-tolerant patient who is scheduled for surgery?
5. What would be your strategy regarding preoperative information and choice of anesthesia technique?
6. What are the choices for perioperative pain management in opioid-tolerant patients?
7. What issues need to be considered before discharging an opioid-tolerant patient?

A 38-YEAR-OLD WOMAN

scheduled for ambulatory laparoscopic cholecystectomy requests to see the anesthesiologist preoperatively to discuss her postoperative analgesia strategy. She experienced severe pain at home for several days after a previous ambulatory laparoscopic gynecologic procedure.

C. Perioperative Pain Management for Ambulatory Surgery

1. What would be your preoperative considerations and advice to the patient?
2. What are the consequences of inadequate pain management after ambulatory surgery?
3. What is the role of premedication or preoperative analgesic?
4. Does the choice of anesthetic technique influence postoperative pain?
5. Are nonsteroidal anti-inflammatory drugs (NSAIDs) effective? If so, does the choice of drug matter?
6. There are three types of pain after laparoscopic cholecystectomy: incisional, subphrenic, and shoulder pain. What is the role of surgical technique in influencing postoperative pain?
7. What would be your strategy for pain control after discharge home?

MANY PATIENTS

continue to experience moderate to severe pain after surgery. What can we do to address this long-standing problem?

D. The Role of an Acute Pain Service

1. What is the extent of the problem and which patients are at the greatest risk of undertreatment?
2. What are the consequences of inadequate postoperative pain relief?
3. What is the role of an acute pain service (APS) in improving postoperative pain management?
4. Does an APS improve postoperative outcome?

A. Perioperative Pain Management for Thoracotomy

A.1. What would be your advice to the patient about the planned thoracotomy and postoperative pain relief?

It is essential that patients undergoing thoracotomy be informed about what to expect after surgery because an understanding of the procedure as well as realistic expectations of pain and rehabilitation can promote recovery and return to normal activity. Patients undergoing thoracotomy may suffer from severe acute postoperative pain if analgesia is not managed appropriately. Pulmonary function is impaired as a result of thoracic surgery, and may be worsened by the effects of pain. Therefore, during the early postoperative period, pain control and maintenance of pulmonary function are the major goals. For preoperative improvement of pulmonary function, patients should be advised to stop smoking and be instructed in deep breathing exercises such as incentive spirometry.

Online educational resources, such as http://www.asahq.org/For-the-Public-and-Media.aspx and http://www.lifelinetomodernmedicine.com/faqs.aspxcan, also help inform patients about their forthcoming anesthetic procedure and provide specific advice about the different anesthetic and pain relief techniques for surgery.

Early postoperative pain may be intense and can delay rehabilitation and mobilization unless appropriately treated. Different techniques may be used to manage different levels of pain immediately following surgery, within the first few postoperative days, and thereafter. Pain management often involves a step-down approach from regional anesthesia or systemic opioids to oral medication. The following issues need to be addressed:

- Information must be given on the hospital policy for pain assessment, for example, the use of visual analog scores.
- Patients require a realistic expectation of the intensity and duration of postoperative pain.
- Pain management techniques that require patient involvement (intravenous patient-controlled analgesia (IV-PCA), patient-controlled epidural analgesia) need to be properly demonstrated.
- Online information resources, such as the PROSPECT (PROcedure SPECific postoperative pain managemenT) guidelines and recommendations by an international panel of anesthesiologists and surgeons available at http://www.postoppain.org, may be of use.

A.2. How will you decide about the choice of anesthetic technique?

The decision about which anesthetic technique to use for an individual patient is based on a review of their overall medical condition and any medications that they are taking. General anesthesia with or without epidural may be selected based on the patient's comorbidities and the planned procedure. Because lung volumes after thoracic surgery may be reduced by up to 50% through a combination of resection and splinting atelectasis, an epidural can have benefit not only for pain relief but also for improving pulmonary function. Other factors such as surgical and anesthetic experience and practice, local ward or institutional protocols for postoperative pain relief, and patient mobilization will also influence the choice of anesthetic technique. If an epidural is included in the anesthetic plan, it may be inactive throughout the case, used as an adjunct to general anesthesia, or bolused at the end of the case prior to a postoperative infusion. Again, this decision is often based on patient and surgical considerations, such as potential blood loss, hypotension, and invasiveness of surgery. Intraoperative epidural use prior to wake up has the benefit of ensuring epidural catheter function and can facilitate a more comfortable transition to the immediate postoperative period.

The use of intraoperative and postoperative thoracic epidural technique has become widely used for management of pain associated with thoracic and major abdominal surgery. Clinical studies have shown that thoracic epidural anesthesia can have effects far beyond pain relief, including decreased opioid consumption, reduced risk of nausea and vomiting, increased lung volumes, reduced risk of pulmonary complications, improved bowel recovery, and a significant reduction in the incidence of myocardial infarction. There is also evidence that neuraxial block decreases the risk of recurrence after cancer resection, likely through an opioid-sparing effect.

Ballantyne JC, Carr DB, DeFerranti S, et al. The comparative effects of postoperative analgesia therapies on pulmonary outcome: cumulative meta-analyses of randomized, controlled trials. *Anesth Analg*. 1998;86(3):598–612.

A.3. What is chronic postthoracotomy pain syndrome (PTPS)? Does video-assisted thoracic surgery reduce the risk of chronic pain after thoracotomy?

Chronic PTPS is defined as pain that recurs or persists along a thoracotomy scar at least 2 months after surgery and is not related to the recurrence of a tumor or an infection. PTPS is generally neuropathic in nature and varies in severity, with a reported incidence of 44% to 80%. Several studies suggest that poor perioperative pain management contributes to chronic PTPS and that aggressive management of early postoperative pain with epidural analgesia can reduce its incidence.

Although used with increasing frequency, thoracoscopic approaches have not had the favorable impact on pain that many had anticipated. Surprisingly, video-assisted thoracic surgery is associated with a prevalence of chronic pain comparable to that of open procedures, with rates of PTPS ranging from 22% to 63%, likely due to intercostal nerve and muscle damage from trocar insertion.

A.4. What would be your perioperative analgesic strategy?

The analgesic plan should consider the entire perioperative period. A multimodal approach would be preferable to account for the multiple pathways by which nociceptive input is conveyed to the central nervous system, the number of pharmacologically distinct mechanisms of modulating this input, the need for effective analgesia throughout the perioperative period and after discharge, and the importance of minimizing side effects, particularly respiratory depression.

Thoracic epidural analgesia (TEA) is the mainstay of recommended therapy for the reasons previously discussed. Contraindications to a thoracic epidural include patient refusal, coagulopathy, thrombocytopenia, therapeutic anticoagulation, previous thoracic spine surgery, and local infection over the entry site. When epidural catheters fail intraoperatively or have patchy coverage, intercostal nerve blocks (ICNBs) or paravertebral blocks may supplement epidural analgesia or serve as a bridge to the immediate postoperative period when an epidural catheter can be safely replaced.

Intravenous nonsteroidal anti-inflammatory drugs (NSAIDs) are useful for treating shoulder pain secondary to referred diaphragmatic pain. This nociceptive input is carried by vagal and phrenic nerves and is often refractory to epidural analgesia. A concern with NSAIDs is platelet dysfunction; however, so long as the bleeding risk is reasonable, their efficacy and lack of respiratory side effects makes them an optimal choice for adjunct analgesia. Cyclooxygenase 2 (COX-2) inhibitors have limited effects on platelets aggregation and comparable efficacy to traditional NSAIDs and thus may be of use in this setting. Adverse cardiac side effects are unlikely with short-term perioperative dosing. Regular administration of paracetamol or acetaminophen may also be useful for treating shoulder pain and can be used in addition to NSAIDs.

When making the transition to oral opioid analgesics from epidural analgesia, the first oral dose should be administered prior to discontinuing the epidural and the epidural dose should be weaned down slowly to ensure adequate coverage with an oral regimen.

Gottchalk A, Cohen SP, Yang S, et al. Preventing and treating pain after thoracic surgery. *Anesthesiology*. 2006;104:594–600.

PROSPECT *(www.postoppain.org)*

A.5. Does the choice of analgesic technique influence postoperative outcome?

Evidence strongly suggests that epidural analgesia is associated with lower rates of perioperative morbidity and, in particular, fewer pulmonary and cardiac complications. Compared with systemic opioids, epidural opioids decreased the incidence of postoperative atelectasis,increased $Pa0_2$, and decreased the incidence of pulmonary infections and pulmonary complications overall. Effective pain control with an epidural technique leads to improved pulmonary function, more effective coughing, earlier mobilization, and improved cooperation with respiratory physiotherapy.

Postoperative myocardial infarction rates are reduced when TEA is incorporated into anesthesia and extended at least 24 hours into the postoperative period. Supraventricular tachyarrhythmias, which are the most common form of cardiac morbidity after pulmonary resection and occur in up to 50% of cases, are reduced by TEA, even when compared with alternative analgesic regimens that confer equivalent pain control. The cardioprotective mechanism of TEA is believed to relate to its sympatholytic effects.

A recent meta-analysis also found that epidural analgesia provided superior postoperative analgesia compared with IV-PCA. As discussed earlier, better postoperative pain relief decreases the likelihood of developing chronic postsurgical pain.

Dworkin RH, McDermott MP, Srinivasa R. Preventing chronic postsurgical pain: how much of a difference makes a difference? *Anesthesiology*. 2010;112(3):516–518.

A.6. Does it matter if the epidural catheter is at the thoracic or lumbar level?

TEA is currently the standard for analgesia for thoracic surgery and, in the absence of contraindications, all patients undergoing major open thoracic surgical procedures should have a thoracic epidural catheter placed preoperatively. The tip of the catheter should reside at the dermatome along which the incision will be made.

Thoracic (versus lumbar) placement of the epidural catheter is dose saving and decreases side effects such as hypotension and bladder dysfunction at equianalgesia. Thoracic placement also reduces motor block of the lower extremities, which allows for improved postoperative ambulation. However, if thoracic epidural placement is contraindicated or cannot be achieved, lumbar epidural anesthesia can be utilized. Lumbar placement can be efficacious, particularly when used with hydrophilic opioids such as morphine; however, local anesthetic volume dosing is significantly higher and may be limited by toxicity.

Grant GJ, Zakowski M, Ramanthan S, et al. Thoracic versus lumbar administration of epidural morphine for postoperative analgesia after thoracotomy. *Reg Anesth*. 1993;18:351–355.

A.7. Does the choice of drugs influence the efficacy or safety of thoracic epidural analgesia (TEA)?

Effective postoperative pain control may be achieved by delivering an opioid, local anesthetic, or a combination of both into the thoracic epidural space. Combinations are the standard because synergy between opioids and local anesthetic agents can enable an optimum balance between analgesia and minimizing blockade of motor function of the thorax and dynamic consequences of sympatholysis. Common components include opioids such as morphine, fentanyl, or sufentanil, and local anesthetic agents such as bupivacaine, levobupivacaine, or ropivacaine. Systemic absorption effects (e.g., sedation) tend to be more common with the lipophilic opioids, such as fentanyl, presumably because of increased absorption into the epidural fat. Hydrophilic opioids, such as morphine, produce a wider dermatomal band of analgesia with less systemic absorption. Of the three commonly used local anesthetic agents, bupivacaine possesses the least favorable cardiac safety profile. In theory, ropivacaine offers the advantage of differential dose-dependent sensory and motor blockade; however, when used in dilute concentrations in combination with opioids, it is unlikely that any advantage of one agent over the other will be apparent.

Rawal N. Intraspinal opioids. In: Rowbotham DJ, Macintyre PE, eds. *Acute Pain*. London: Arnold; 2003:241–266.

A.8. What are the usual doses and concentrations of the anesthetic combinations commonly employed in epidural analgesia?

Before the initiation of patient-controlled epidural analgesia, a test dose of 3 mL of 1.5% lidocaine with epinephrine 1:200,000 is usually employed to rule out intrathecal or intravascular placement of catheter. Once malposition is ruled out, the catheter is usually bolused (as allowed by hemodynamic status) prior to beginning continuous infusion.

Commonly employed combinations of epidural drugs vary from institution to institution. However, in the interest of patient safety, compliance, auditing, and quality assurance, standardization within the institution is recommended. Solutions and volumes can later be titrated to effect or to avoid side effects, for example, increasing or decreasing local anesthetic concentration to change block density, increasing or decreasing volume infused to increase spread, and adding or subtracting opioids to increase analgesia or decrease side effects such as itching, nausea, or vomiting.

At our institution, the following drugs and drug combinations are used at an infusion rate of 4 mL per hour with each demand bolus of 3 mL as needed.

- Bupivacaine 0.0625% with fentanyl 5 μg per mL with a lockout period of 10 minutes between boluses
- Fentanyl 10 μg per mL with a lockout period of 10 minutes

- Bupivacaine 0.0625% with dilaudid 100 μg per mL with a lockout period of 20 minutes
- Morphine sulphate 100 μg per mL with a lockout period of 30 minutes

(See Sample Order Form [Fig. 50.1].)

A.9. If accidental dural puncture occurs during placement of the epidural needle, what steps should be taken?

If accidental dural puncture occurs during placement of epidural needle, the general practice is to remove the needle and place the epidural catheter at adjacent intervertebral spaces. The likelihood of intrathecal spread should be carefully assessed with the test dose. Epidural infusion may be started at the usual rate. Frequent monitoring for sensory and sympathetic block should continue in a controlled setting until the efficacy and safety of the epidural analgesia is established. In addition, the patient should be assessed for any symptoms of neuropathy relevant to the level attempted. The patient should be informed of the dural puncture and the potential for postdural puncture headache.

A.10. What are the alternatives to TEA?

There are times when for technical, medical, or other reasons thoracic epidural catheter placement is unsuccessful, undesirable, or not possible. Alternatives to mid-TEA include lower thoracic and lumbar epidural catheter placement, ICNBs, paravertebral blocks, intrathecal opioids, intrapleural catheters, local anesthetic infiltration, and systemic analgesia with one or more agents.

Lumbar epidural placement can be efficacious, particularly when used with hydrophilic opioids such as morphine to increase dermatomal spread. Lumbar epidurals are most limited by the need for increased local anesthetic dosing and the higher incidence of side effects such as hypotension and urinary retention versus thoracic epidurals.

If epidural placement is ruled out altogether for the reasons previously discussed, ICNBs can be performed percutaneously or under direct vision intraoperatively, using single injections or placement of an intercostal catheter. While often initially effective, unpredictable spread of local anesthetic and rapid local anesthetic absorption by surrounding vessels make this technique less effective than epidural analgesia. Furthermore, indwelling intercostal catheters cannot adequately control pain after posterolateral thoracotomy because posterior primary rami and sympathetic fibers are not blocked. Additionally, percutaneous positioning and securing of intercostal catheters may be technically problematic.

Paravertebral block results in ipsilateral somatic and sympathetic nerve blockade in multiple contiguous thoracic dermatomes above and below the site injection. Paravertebral analgesia has been found to produce good pain relief and preservation of pulmonary function after thoracotomy and is probably the best available alternative to epidural analgesia. Because the concomitant sympathetic blockade is unilateral, the incidence of adverse effects, such as hypotension and urinary retention, is lower. Paravertebral blocks can be performed as single injections or through a paravertebral catheter. Paravertebral catheters can be placed percutaneously or intraoperatively under direct vision and are more suitable than epidural catheters when coagulopathy is of concern. In some studies, paravertebral blocks have been shown to be as effective as TEA with respect to pain control and preservation of pulmonary function after thoracotomy.

A preoperative single bolus of spinal morphine as part of multianalgesic regimen can be considered in order to decrease the need for systemic opioids. Alternatively, pleural catheters may be placed intraoperatively to decrease pleural and visceral pain; however, they do not affect incisional pain and require high volumes of local anesthetic to be effective. Similarly, direct local anesthetic infiltration can be used

EPIDURAL ANALGESIA ORDER SHEET
PAIN MANAGEMENT

IF NO PLATE, PRINT NAME, SEX AND MEDICAL RECORD NO.

DATE: / / TIME: am/pm	ORDER POSTED	CHECKED BY RN
1) Analgesia by epidural infusion (using the PCA infuser).		
2) The patient **MUST NOT** receive any supplemental narcotics, sedatives and/or antiemetics while receiving Epidural Analgesic unless orders are written by the Pain Management Service.		
3) Narcotic (Specify drug, # of mgs, volume, and diluent and concentration):		
4) Initial Bolus given by Pain Service M.D. (Dose given _____)ml		
5) Initial Machine Settings: **Epidural Mode** (circle one) Continuous / Bolus / Both Program in ml. a) **Program in ml.** b) Bolus/Demand Dose _____ ml per attempt. c) Bolus/Demand Lockout _____ minutes. d) Continuous Rate _____ ml per hour. e) Limit _____ ml per four hours.		
6) If pain is not controlled at the above settings (pain ≥ 6), the nurse may administer a PRN rescue / loading dose_____ml every 10 minutes until the patient is comfortable. The maximum rescue / loading dose is_____ml Increase pump settings to: a) Bolus/Demand Dose _____ ml per attempt. b) Bolus/Demand Lockout _____ minutes. c) Continuous Rate _____ ml per hour. d) Limit _____ ml per four hours.		
7) A) For oversedation (sedation scal ≥ 4/R4) and respiratory rates 10–14 minute, notify Acute Pain Service, and decrease pump settings to: a) Bolus/Demand Dose _____ ml per attempt. b) Bolus/Demand Lockout _____ minutes c) Continuous Rate _____ ml per hour. d) Limit _____ ml per four hours B) For respiratory rate less than 10/minute, stop infusion and call the Acute Pain Servive (X-66700, beeper 16664). C) For respiratory rate less than 8/minute, obtain naoxone (0.4 mg/ml and administer 0.1 mg (0.25 ml) IV bolus q2 minutes until respiratry rate is 8/minute or greater, stop Infusion, and notify Pain mangement Service (X-66700, beeper 16664).		
8) Upon initiation and after every loading dose, obtain BP, pulse, respiratory rate, sedation scale and sensory motor function q30 min × 2 hours then q1 h × 2 then q4 hours. Pain analog q4 hours, Temp q12 hours).		
9) If no maintenance IV solution is ordered, IV to med lock.		
10) For Nausea (Specify drug and dosing):		
11) For Sleep (Specify drug and dosing):		
12) Activity level per surgical/medical orders.		
13) For questions or problems, call the Pain Management Service at X-62960 or page: X-66700, beeper 16664.		
14) Please call Unit Coordinator when the pump is discontinued.

Figure 50.1 Epidural analgesia order sheet.

but must be combined with longer-acting strategies to provide adequate pain control. Although systemic opioids have been well documented to reduce postthoracotomy pain, their adverse effects on the respiratory system after general anesthesia, even using patient-controlled delivery systems, and their inability to provide optimal dynamic pain relief favor regional anesthetic techniques, when possible, in thoracotomy patients. Systemic analgesics are best suited as adjuncts to these techniques, and should become the mainstay of analgesic therapy only when invasive approaches are discontinued.

A.11. What is the usual clinical regimen for intravenous patient-controlled analgesia (IV-PCA) and is special patient monitoring required during its use?

Clinical regimens for IV-PCA vary among institutions but the two most commonly used opioids are morphine and dilaudid. Continuous delivery, or basal rate, of the drug is commonly avoided to decrease the likelihood of respiratory depression. Boluses of morphine sulfate 2 mg or dilaudid 0.2 mg are given per demand with a lockout period of 10 minutes. Incremental boluses may be given by the nurse if pain is not controlled. The dose may be decreased or the opioid may be discontinued if respiratory depression occurs. Close monitoring and rescue strategies must be in place to ensure patient safety, particularly for at-risk individuals, including central monitoring of oxygenation and ventilation. (See Sample Order Form [Fig. 50.2].)

A recent workshop of the Anesthesia Patient Safety Foundation (APSF) looked at the issue of dangers of postoperative opioids. The workshop was held in October 2006 and focused on the issue of improved detection of postoperative opioid-induced respiratory depression. The premise of the workshop was that "the available evidence suggests that there is a significant and underappreciated risk of serious injury from PCA and neuraxial opioids in the postoperative period." The observed incidence of respiratory depression in these cases is 0.1% to 1.0% and increases to 3.2% in those older than 80 years. Patients with obstructive sleep apnea and the elderly are understandably at a higher risk of opioid-induced respiratory depression, but there is also a low and unpredictable incidence of life-threatening respiratory depression in young, healthy patients. The workshop highlighted the argument that in the United States, The Joint Commission's emphasis on pain as the "fifth vital sign" has had the unintended consequence of creating an expectation among patients that they will have little to no pain after surgery. As a result, more patients may be receiving inappropriate amounts of analgesics to meet this expectation. The conclusions of the

PATIENT CONTROLLED ANALGESIA (PCA) ADULT ORDER SHEET

IF NO PLATE, NAME, SEX AND MEDICAL RECORD NO.

DATE: / / TIME: am/pm	ORDERED POSTED	CHECKED BY RN
1) Analgesia by Patient Controlled Analgesia (PCA).		
2) The patient **MUST NOT** receive any supplemental narcotics, sedatives and/or antiemetics while receiving PCA unless approved the Pain Management Service or House Officer		
3) Narcotics (Specify drug, # of mgs, volume, and diluent)		
4) Initial Loading: Dose_____mg every 5 minutes until the patient is comfortable. Maximum total load_____mg.		
5) Initial Machine Settings: **PCA Mode** (circle one) Continous / PCA / Both a) **Program in mg.** b) Continous Rate_____mg per hour. c) PCA Dose_____mg per demand. d) PCA Lockout_____minutes. e) Limit_____mg per four hours.		
6) If pain is not controlled at the above settings (pain ≥ 6), the nurse may administer a PRN recue / loading dose_____every 5 minutes until the patient is comfortable. The maximum rescue / loading dose is_____mg. Increase pump settings to: a) PCA Dose_____mg per demand. b) Continous Rate_____mg per hour. c) PCA Lockout_____minutes. d) Limit_____mg per four hours.		
7) For over sedation (sedation ≥ 4/R4) and respiratory rate < 14, decrease pump settings to: a) PCA Dose_____mg per demand. b) Continous Rate_____mg per hour. c) PCA Lockout_____minutes. d) Limit_____mg per four hours. For respiratory rate of 10 or lowrer, stop the pump and call the Pain Management Service (X66700, beeper 16664) or House Officer.		
8) Upon initiation, and after every loading dose given, obtain respiratory rate, heart rate and blood pressure. Repeat qh X 2, q4h X 3, and then heart rate and blood pressure per unit routine or as otherwise ordered. Monitor repiratory rate, pain analog and sedation scale q4h.		
9) Note: For patients who receive intrathecal/Epidural Morphine intraoperatively and have PCA initiated within 12 hours, monitor blood pressure, pulse, respiratory rate, pain analog/sedation q30minutes X 2h, qh X2 and then q4 hours X3, Then, BP per unit routine, Monitor respiratory rate, pain analog/sedation of 4hr.		
10) If no maintenance IV is odered, infuse D5 1/2NS at 40 ml/h via PCA Extension Set.		
11) For Nausea (Specify drug and dosing):		
12) For Sleep (Specify drug and dosing):		
13) For questions or problems, call the Pain Management Service at X62960 or page X66700, beeper 16664		
14) Please call the Unit Coordinator when the pump is discontinued. 15)

Figure 50.2 Patient-controlled analgesia (PCA) adult order sheet.

Anesthesia Patient Safety Foundation committee were that continuous monitoring of oxygenation and ventilation can prevent patient harm; any monitoring system should be centrally linked so that a healthcare professional can be summoned in a timely manner; programs should be instituted to educate providers and patients about the risks of opioid-associated life-threatening respiratory depression; governmental agencies and nongovernmental entities should provide increased support for scientific research in this area; and while treatment of postoperative, opioid-induced depression is an important consideration, prevention may be the more effective strategy.

Weinger MB. Dangers of post operative opioids. APSF workshop and white paper address prevention of postoperative respiratory complications. *APSF Newsl Winter*. 2006–2007;21(4):61–67.

A.12. What are the side effects and complications of epidural technique?

Depending on the extent of blockade, TEA interferes with sympathetic outflow and produces hypotension through cardiodepressant action (blockade of cardiac accelerator fibers) and a reduction in systemic vascular resistance (blockade of sympathetic chain). The use of dilute local anesthetic solutions has led to clinically insignificant motor blockade while maintaining adequate sensory block, though some small-muscle weakness may be observed. Opioid-related side effects include sedation, nausea and vomiting, pruritus, delayed gastrointestinal motility, urinary retention, and respiratory depression. The incidence of delayed respiratory depression after administration of epidural opioids is very low, and epidural opioid analgesia can be used safely on hospital wards. All patients who receive epidural analgesia should have standard orders for the treatment of breakthrough pain and side effects.

The overall catheter-related complication rate is low and includes such complications as dural puncture, unsuccessful catheter placement, paresthesia, and neurologic injury. Paraplegia associated with epidural analgesia may result from epidural hematoma, or less commonly epidural abscess. The potentially catastrophic complications of epidural or intrathecal hematoma are best prevented by realization that motor blockade should not occur with dilute local anesthetic solutions, and postoperative motor weakness should trigger immediate imaging evaluation (MRI) and neurosurgical consultation. Clearly, significant concerns about coagulopathy or local overlying infection should limit epidural catheter placement.

Rawal N. Intraspinal opioids. In: Rowbotham DJ, Macintyre PE, eds. *Acute Pain*. London: Arnold; 2003:241–266.

A.13. What recommendations for placement and removal of epidural catheter will you make if this patient is on antiplatelet or anticoagulant therapy or thromboprophylaxis is planned?

On the basis of current practice and the third consensus statement for Regional Anesthesia in the Patient Receiving Antithrombotic or Thrombolytic Therapy developed by the American Society of Regional Anesthesia, the following guidelines may be helpful.

Prophylactic unfractionated heparin

In the setting of twice-daily subcutaneous prophylaxis with 5,000 U heparin, there is no contraindication to the use of neuraxial techniques. For patients receiving greater than 10,000 U daily or thrice-daily dosing, data are insufficient to determine if there is increased risk of hematoma. These patients should have individual risk/benefit

assessments, and techniques to facilitate detection of hematoma (increased monitoring, dilute local anesthetic solutions) should be implemented. The clinician should keep in mind that subcutaneous heparin reaches peak effect 1 to 2 hours after administration.

Recommendations

- First dose of subcutaneous heparin should ideally be administered *after* block placement. Heparin dosing should be delayed at least 1 hour after epidural catheter placement.
- If the patient is already receiving prophylactic heparin, there is no contraindication to block placement. Some clinicians advocate delaying puncture 2 hours after the last dose.
- Because heparin-induced thrombocytopenia may occur during heparin administration, patients receiving heparin for more than 4 days should have a platelet count checked before neuraxial block placement and prior to catheter removal.
- An epidural catheter may be removed at any time. Some clinicians advocate waiting 2 hours after the last dose.

Therapeutic intravenous unfractionated heparin

Neuraxial techniques combined with intraoperative anticoagulation (excluding the full anticoagulation of cardiac surgery) are acceptable with certain precautions as described in the subsequent text.

Recommendations

- Neuraxial techniques should be avoided in patients with baseline coagulopathies in addition to heparinization.
- Risk/benefit determinations are needed in patients receiving anticoagulant medications such as antiplatelet agents, warfarin, and low-molecular-weight heparin (LMWH). These medications may increase the risk of bleeding complications.
- Heparin administration should be delayed for 1 hour after block placement.
- Epidural catheters may be removed 2 to 4 or more hours after the last heparin dose and once laboratory coagulation values have been evaluated and are normalized.
- Bloody or difficult block placement may increase the risk of epidural hematoma formation in the setting of intraoperative anticoagulation; however, there is insufficient data to warrant canceling a case. Discussion of risks and benefits with the surgeon regarding proceeding is warranted.
- Postoperative care should monitor for signs of hematoma such as motor blockade. Use of weak local anesthetic solutions may facilitate detection.

Preoperative low-molecular-weight heparin

Neuraxial blockade should not be performed if the patient is on other antiplatelet or oral anticoagulant medications in combination with LMWH. This combination increases the risk of spinal and epidural hematoma formation in the setting of neuraxial blockade. In the case of traumatic placement, first dose of LMWH should be at 24 hours postoperatively. LMWH has its peak effect 2 to 4 hours after administration.

- *Prophylactic LMWH*. An example of a prophylactic dose is enoxaparin 40 mg qd or 30 mg q12 hours. Block placement should occur no sooner than 10 to 12 hours after the last dose of LMWH and should be maintained only if single-daily dosing is planned. If LMWH is administered within 2 hours of surgery (prophylactic dose), neuraxial blockade should be avoided.
- *Treatment dose LMWH*. An example of a treatment dose is enoxaparin 1.5 mg per kg qd or 1 mg per kg q12 hours. Block placement should occur no sooner than 24 hours after the last dose of LMWH and only if treatment dosing is being discontinued.

Postoperative low-molecular-weight heparin

- *Prophylactic LMWH, twice-daily dosing*. This dosing regimen may be associated with an increased risk of hematoma. The first dose of LMWH should be administered no sooner than 24 hours postoperatively. Epidural catheters should not be maintained in this situation but may be left in overnight, and should be removed at least 2 hours before the first LMWH dose.
- *Prophylactic LMWH, single-daily dosing*. Epidural catheters may be maintained in this situation, but only after a thorough risk/benefit analysis. The first dose of LMWH should be given 6 to 8 hours postoperatively. The second dose should be given no sooner than 24 hours after the first dose. The epidural catheter should be removed 10 to 12 hours after the last dose of LMWH, and the subsequent dose should be given no sooner than 2 hours after catheter removal.
- *Treatment dose LMWH*. Epidural catheters should not be maintained in this situation. The first dose of LMWH should be given 24 hours after catheter removal.

Oral anticoagulants

- *Aspirin*. There is no contraindication to neuraxial anesthesia in patients taking aspirin alone (81 mg or 325 mg).
- *NSAIDs*. There is no contraindication to neuraxial anesthesia in patients taking NSAIDs alone.
- *Preoperative Coumadin*
  a. Coumadin should be stopped 4 to 5 days before a neuraxial block and the patient should not be on any additional antiplatelet or anticoagulant medications.
  b. The prothrombin time/international normalized ratio (PT/INR) should be measured before the block and should be normalized. Of note, if warfarin is stopped for less than 4 days, INR (determined mainly by factors II and X) may not be reflective of coagulation status (determined mainly by facor VII).
  c. Clinicians' threshold for neuraxial blockade vary. Many suggest an epidural may be placed if the INR is less than or equal to 1.2 and that aspinal may be placed if the INR is less than or equal to 1.3.
  d. For patients receiving an initial preoperative coumadin dose, the PT/INR should be checked before neuraxial block if the first dose was given more than 24 hours earlier or if a second dose has been given.
- *Postoperative Coumadin*
  a. Epidural catheters may be maintained in patients on Coumadin up until the INR is less than 1.5. The PT/INR should be monitored daily and assessed before catheter removal.
  b. Epidural catheters should be removed while the INR is less than 1.5.
  c. If the INR is greater than 1.5, consider discontinuing other medications that may affect coagulation or administration of fresh frozen plasma followed by a repeat coagulation profile prior to epidural catheter removal. These patients should be monitored closely after removal of the catheter for signs of neurologic dysfunction.
- *Preoperative clopidogrel (Plavix) and ticlopidine (Ticlid)*
  a. Plavix must be held for a minimum of 7 days before neuraxial block placement.
  b. Ticlid must be held for a minimum of 14 days before neuraxial block placement.
- *Preoperative abciximab, eptifibatide, and tirofiban*
  a) GPIIb/IIIa inhibitors are profound inhibitors of platelet aggregation. Consider confirming platelet function prior to neuraxial block.
  b) Abciximab must be held for a minimum of 24 to 48 hours prior to neuraxial blockade.
  c) Eptifibatide and tirofiban must be held 4 to 8 hours prior to block placement.

B. Chronic Opioid Therapy and Perioperative Pain Management

B.1. How does chronic opioid therapy influence postoperative pain management?

In recent years, a greater emphasis has been placed on pain as an important health problem, with The Joint Commission even labeling pain as the "fifth vital sign." Consequently, opioids now play a greater role in the treatment of chronic pain of various causes. This has resulted in a rapid increase in the consumption of opioid analgesics. For example, between 1999 and 2003, the annual sales of outpatient opioid analgesics in the United States increased by approximately 130%, more than doubling the sales recorded in the previous decade. Because more patients are treated chronically with opioids, every anesthesiologist is likely to be confronted with acute pain management issues in these patients. Chronic opioid-consuming patients can experience significant postoperative pain given that healthcare professionals are not accustomed to their markedly increased opioid requirements.

Patients on long-term opioid therapy are more likely to require surgery and higher doses of opioids postoperatively. Although the prevalence of chronic opioid-consuming patients who present for surgery is not described, the growing use of opioids is likely to increase the number of such patients. Patients with chronic pain are more likely to have high levels of postoperative pain, and increased postoperative pain has been associated with an increased risk of chronic postsurgical pain. Therefore, the aggressive treatment of postoperative pain is important for patients with chronic pain because they represent a population that is particularly vulnerable to develop chronic postsurgical pain.

Although available data are limited, the management of postoperative pain seems to be more difficult in chronic opioid-consuming patients even when they consume only a modest daily opioid dose. Tolerance to any one opioid preparation results in a clinically measurable increased tolerance to most others.

B.2. What are the causes for increased postoperative pain and opioid consumption in patients chronically using opioids?

Chronic exposure to opioids may result in a need to increase the dose over time to maintain the desired analgesic effect. The need for escalating the dose is often

attributed to the development of tolerance. However, dose escalation can be the result of other factors, such as the progression of the underlying disease.

Recent evidence points to opioid-induced hyperalgesia as an alternative neuropharmacologic phenomenon to explain the need to escalate the opioid dose over time. Paradoxically, administration of opioids may induce an increased sensitivity to pain (hyperalgesia). Further complicating matters, the phenomena of tolerance and hyperalgesia can coexist.

Clinical surveys of long-term opioid use in patients with both cancer and non–malignancy-associated pain have not shown escalating drug dosage to be inevitable; however, some degree of dose increase over time is often observed, particularly in younger patients and with use of short-acting opioids.

Mitra S, Sinatra RS. Perioperative management of acute pain in the opioid-dependent patient. *Anesthesiology*. 2004;101:212–227.

B.3. What are the main differences between a chronic opioid-consuming patient and a patient who abuses or is addicted to opioids?

Patients undergoing surgery may not admit that they are actively abusing pain medications; however, difficulties in achieving adequate postoperative pain control may provide a hint to such abuse.

Many of the issues with respect to chronic opioid-consuming patients also apply to patients who abuse or are addicted to opioids. However, several important differences exist. First, the daily dose of opioid consumed by opioid-abusing patients before surgery is typically larger. Second, opioid-abusing or opioid-addicted patients often suffer from coexisting psychiatric diseases. For example, heroin addicts have an elevated prevalence of depression, anxiety, psychosis, and personality disorders. Depression and anxiety are independent predictors of severe pain after surgery and may complicate the management of postoperative pain. Third, the attitude of healthcare providers toward the use of opioids for controlling pain may be influenced by the abuse history, which makes these patients particularly vulnerable to inadequate postoperative pain control.

Von Limbeek J, Wouters L, Kaplan CD, et al. Prevalence of psychopathology in drug-addicted Dutch. *J Subst Abuse Treat*. 1992;9:43–52.

B.4. What issues need to be considered in the opioid-tolerant patient who is scheduled for surgery?

Tolerance develops at different rates to desired (analgesia) and undesired effects (sedation, nausea, euphoria, respiratory depression, constipation). Long-term use of opioids results in tolerance to some opioid effects such as analgesia, nausea, sedation, and respiratory depression but not to miosis or constipation. Cross-tolerance with other opioids also occurs. Opioid-tolerant patients report higher pain scores at rest and on movement and also remain longer under the care of acute pain services (APSs) than do other patients. The incidence of opioid-induced nausea and vomiting, however, may be lower in opioid-tolerant patients.

de Leon-Casasola OA, Myers DP, Donaparthi S, et al. A comparison of postoperative epidural analgesia between patients with chronic cancer taking high doses of oral opioids versus opioid-naïve patients. *Anesth Analg*. 1993;76:302–307.

Rapp SE, Ready BL, Nessly ML. Acute pain management in paients with prior opioid consumption: a case-controlled retrospective review. *Pain*. 1995;61:195–201.

B.5. What would be your strategy regarding preoperative information and choice of anesthesia technique?

Acute pain management in opioid-dependent patients is a complex issue. There is a tendency among providers to use opioids sparingly, resulting in both poor pain management and withdrawal phenomena. As a result, patients may react with a degree of suspicion, mistrust, or even hostility. Patients need to be reassured that their drug history and dependence will not be an obstacle to the relief of pain. During assessment, care should be exercised to maintain privacy and confidentiality.

Despite the increasing prevalence of opioid dependency, there are few controlled studies available to guide the anesthesiologist in optimizing anesthetic and analgesic care. Because the minimum daily opioid dose that significantly increases postoperative opioid requirements and pain is not known, all patients on chronic opioids should be informed about the potential for severe pain and increased opioid requirements during the postoperative period. Patients should be informed about alternative analgesic techniques that complement opioids.

The selection of anesthesia technique has to be done on an individual basis because there are no data available favoring general, regional, or combined anesthesia for this specific patient population. Although there is no evidence indicating superiority of regional anesthesia for chronic pain patients, individual consideration is likely to favor regional anesthesia. Expert opinion suggests that opioid-tolerant patients should be offered regional anesthesia or analgesia, particularly for procedures performed on the extremities. Advantages of a regional anesthetic and analgesic approach include reduction in opioid requirements and improvement in distal perfusion as a result of sympathetic blockade.

Iocolano CF. Perioperative pain management in the chemically dependent patient. *J Perianesth Nurs*. 2000;15:329–347.

Kopf A, Banzhaf A, Stein C. Perioperative management of the chronic pain patient. *Best Pract Res Clin Anaesthesiol*. 2005;19:59–76.

B.6. What are the choices for perioperative pain management in opioid-tolerant patients?

Management of these patients should focus on two main goals: (1) effective analgesia and (2) prevention of withdrawal. Pre-existing opioid medications must be continued throughout the perioperative period to provide baseline analgesia and to avoid withdrawal. This applies for general anesthesia as well as regional anesthesia. During surgery, the required opioid dose consists of the daily opioid dose taken before surgery and the opioid dose necessary for the surgical intervention. The use of a continuous infusion of opioid may be the best way to provide a steady serum concentration if the oral route is unavailable perioperatively.

Catching up on the opioid dose in the postoperative period can be difficult because of inevitable delays in obtaining and administering opioids at the bedside, the high levels of pain that patients may experience, and a possible reluctance of recovery room staff to administer a sufficiently large opioid dose. Requirements for individual patients are difficult to predict; however, patients who use even modest opioid doses (<50 mg/day oral morphine equivalent) before surgery may often require their baseline opioid dose plus two or more times the amount of opioids typically used for adequate pain control in opioid-naive patients.

Regional anesthesia techniques have many benefits and may be particularly useful in chronic opioid-consuming patients because they provide excellent analgesia to patients prone to severe postoperative pain experiences and avoid the need for high-dose opioids. Neuraxial opioids have also been used effectively in opioid-tolerant patients, and although higher doses are often required, these generally do not result in an increase in adverse effects.

Nevertheless, chronic opioid-consuming patients treated with regional and neuraxial techniques for postoperative pain control should also have access to systemic opioids by the intravenous or oral route for prevention of opioid withdrawal. IV-PCA is a useful modality for pain relief in opioid-tolerant patients, provided that pain intensity and opioid consumption are monitored and background requirements are provided if the patient cannot take their usual opioid. Larger bolus doses will often be needed. Opioid rotation (i.e., using an opioid that is different from their preadmission opioid) may also be of use.

Withdrawal from opioids should be prevented by maintenance of normal preadmission opioid regimens where possible, or appropriate substitutions with another opioid or the same opioid through another route. It may be of benefit to check preadmission opioid doses with the patient's doctor or pharmacist. The use of unauthorized additional opioids (licit or illicit) or diversion may affect both pain relief and the risk of adverse effects.

Ketamine can reduce opioid requirements in opioid-tolerant patients, both intraoperatively and postoperatively. It is an N-methyl-D-aspartic acid receptor antagonist and results in analgesia by inhibiting the processing of nociceptive information. Evidence shows that the addition of N-methyl-D-aspartic acid receptor antagonists with other analgesics or as a sole agent for chronic (e.g., complex regional pain syndrome), ischemic, or neuropathic pain states can reduce the requirement for other analgesic agents. When ketamine is used as a continuous infusion in the postoperative setting, it can have an opioid-sparing effect, although there is no reduction in opioid-related side effects. It can also serve as a bridge until the patient is able to tolerate their home oral regimen. Perioperatively, ketamine is best used as an adjunct to opioid medications.

Multimodal analgesic regimens including combinations of NSAIDs, acetaminophen, gabapentin, and topical local anesthetics are likely to provide benefit as well. Opioid antagonists (naloxone, naltrexone) or mixed agonist–antagonists (e.g., buprenorphine, pentazocine) should be avoided because their use precipitates acute withdrawal reactions.

B.7. What issues need to be considered before discharging an opioid-tolerant patient?

Discharge planning must take into account the potential for prescribed opioids to be abused or misused. Appropriate use of nonopioid analgesics where possible, communication with the primary physician, and patient education and support must all be considered.

Chronic opioid-consuming patients typically require significantly higher postoperative opioid doses for adequate pain control than they received before surgery for their chronic pain symptoms. Attempting to discharge chronic opioid-consuming patients on the same opioid regimen they adhered to before surgery often results in inadequate pain control. Whatever the final oral dose chronic opioid-consuming patients are stabilized on at discharge, a slow tapering from this dose toward the preoperative opioid dose over 2 to 4 weeks is often a reasonable goal. In the case under consideration, the transdermal fentanyl patch should be left in place to provide the patient's pre-existing opioid requirement, and additional short-acting analgesics should be prescribed for postoperative pain.

C. Perioperative Pain Management for Ambulatory Surgery

C.1. What would be your preoperative considerations and advice to the patient?

Adequate postoperative pain management is often the limiting factor when determining whether a patient can have surgery performed as an ambulatory surgical procedure. Ensuring that the patient has appropriate expectations of the outcome of laparoscopic cholecystectomy is critical for a successful conclusion to the procedure, especially with regard to postoperative pain. Unrealistic expectations for no pain at all can be met with anger, disappointment, and the fear and anxiety that something has gone wrong. Failure to meet unrealistic expectations can even lead to litigation.

Planning for postoperative pain management should begin in the preoperative period. Patient education regarding the degree of pain that might be expected and discussion of the pain assessment tools and modalities of pain treatment that might be utilized should reduce the patient's anxiety and the fear of unrelieved pain. Reduced patient anxiety has been shown to reduce the incidence and severity of postoperative pain. In addition, patients have to be made aware of the importance of communicating their analgesic needs. Patients should receive instruction on the importance of coughing, deep breathing, ambulation, and postoperative rehabilitation. Patient information on acute postoperative pain management is available from public sources and patients can be directed to these sources for self-study.

Details of the complications of laparoscopic cholecystectomy given to patients vary between countries and cultures. The most relevant for postoperative pain is to mention the risk of conversion to open laparotomy in a small percentage of cases, which will be associated with a significantly larger incision, more pain, and longer period of hospitalization. Patients need to be informed that there are three types of pain often associated with laparoscopic cholecystectomy: (1) incisional, (2) visceral, and (3) shoulder pain. It is helpful to describe, in particular, the high incidence of referred pain in the shoulders and to reassure the patient that this is related to the laparoscopy and not necessarily their heart or chest. The patient should be informed that there is a relatively high risk of postoperative nausea and vomiting after laparoscopic cholecystectomy (~30% to 50%) and that appropriate prophylaxis will be administered (antiemetic strategies can be tailored based on clinical risk scores for nausea and vomiting).

Predischarge patient information should also include the following: (1) that patients will receive analgesic and/or antiemetic medications (or prescriptions, or both) for management of pain and postoperative nausea and vomiting at home, (2) that the hospital (surgeon or nurse) will make a follow-up call and schedule a follow-up appointment and, (3) that they will get contact telephone numbers in case there are problems or questions.

C.2. What are the consequences of inadequate pain management after ambulatory surgery?

In the ambulatory setting, the type of surgery is a significant predictor of severity of postoperative pain. Even when postoperative pain is effectively treated in the postanesthesia care unit, it often recurs once the patient has returned home. A common example is a peripheral nerve block for orthopedic surgery, which provides excellent analgesia until the block has worn off several hours later. Indeed, Rawal et al. reported that 30% to 35% of patients undergoing ambulatory surgery experienced moderate to severe pain at home.

Uncontrolled pain is associated with an increased incidence of postoperative nausea, agitation, prolonged postanesthesia care unit stay, delayed discharge from an ambulatory facility, and unanticipated hospital admission. Inadequate postoperative pain control is also the most frequent reason for patients to contact their family practitioner after discharge from the hospital. Importantly, the presence of postoperative symptoms including pain contributes to patient dissatisfaction with their surgical experience (see Table 50.1).

Table 50.1 Consequences of Inadequate Pain Management after Ambulatory Surgery

Increased postanesthesia care unit stay
Increased phase II unit stay
Delayed discharge at home
Unanticipated hospital admission
Increased contact with family practitioner
Delayed return to daily living function
Decreased patient satisfaction

C.3. What is the role of premedication or preoperative analgesic?

Preoperative administration of opioid or nonopioid analgesics reduces analgesic requirements and pain scores in the immediate postoperative period. However, opioid premedication is controversial in the ambulatory setting because it may increase the incidence of opioid-related side effects and even delay recovery. Premedication with oral NSAIDs given 60 to 90 minutes before surgery can avoid these concerns and reduce the degree of postoperative pain, analgesic requirements, and time to discharge.

Pre-emptive analgesia refers to the concept that an analgesic medication or intervention administered before surgical tissue injury may produce a greater effect than the same medication or intervention administered following surgical tissue injury. This pre-emptive analgesic effect has been demonstrated for several different medications in animal models, but clinical studies do not support a significant role for pre-emptive analgesia in human patients.

For laparoscopic cholecystectomy, there is no strong evidence that preincisional timing of analgesic administration (pre-emptive analgesia) decreases the intensity or duration of postoperative pain, when compared with intraoperative or postoperative administration. A systematic review (Møiniche et al., 2002) confirms that there is no overall clinical benefit of preoperative analgesia on postoperative pain in a large number of studies examining a variety of analgesic techniques in different surgical procedures.

C.4. Does the choice of anesthetic technique influence postoperative pain?

The choice of anesthetic technique has been shown to have a significant influence on postoperative analgesia in patients undergoing ambulatory surgery. Regional anesthesia techniques offer a number of advantages in outpatient surgery, including prolonged postoperative analgesia.

Opioids remain the primary drugs used to provide intraoperative analgesia. As a result of the faster recovery from ultrashort-acting opioids such as remifentanil, it is necessary to administer longer-acting opioid or nonopioid analgesics to achieve adequate postoperative pain control. However, the role of opioids in ambulatory surgery remains controversial. The use of opioids may be associated with a dose-dependent increase in adverse effects, including nausea, vomiting, sedation, bladder dysfunction, and respiratory depression, all of which may contribute to a delayed recovery.

Only one peer-reviewed study has, to date, prospectively examined the effect of a neuraxial technique on postoperative pain management in patients for laparoscopic cholecystectomy. This study examined combined epidural and general anesthesia (CEGA) versus total intravenous anesthesia (TIVA) and showed a reduction in postoperative pain scores for CEGA versus TIVA. However, an epidural technique is not recommended for routine anesthetic management in patients undergoing laparoscopic cholecystectomy because the majority of patients do not convert to open procedures

and thus the incisions are small and minimally painful. Nevertheless, in certain high-risk pulmonary patients, CEGA can be justified.

TIVA offers an alternative to inhalational anesthesia, and although rapid recovery from anesthesia and reduction in nausea and vomiting are recognized benefits, the analgesic components of TIVA have a very short duration and do not contribute to improved postoperative analgesia.

There is enough evidence in the literature to support the use of incisional local anesthetic infiltration at end of surgery. Infiltration of the surgical wound with local anesthetic can provide excellent analgesia that outlasts the duration of action of the local anesthetics themselves. Another simple and effective method of reducing the intensity of postlaparoscopic pain is intraperitoneal instillation of local anesthetic. Evidence suggests significant pain relief after laparoscopic cholecystectomy when 15 to 20 mL of 0.5% bupivacaine is administered into the hepato-diaphragmatic space.

C.5. Are nonsteroidal anti-inflammatory drugs (NSAIDs) effective? If so, does the choice of drug matter?

The opioid-sparing effects of NSAIDs lower the risk of postoperative nausea and vomiting, pruritus, constipation, and respiratory depression, thereby improving patient comfort and allowing for an earlier discharge.

The introduction of a parenteral preparation of NSAID and the widespread acceptance of the concept of multimodal "balanced" analgesia has increased the popularity of NSAIDs in the management of perioperative pain. NSAIDs available for intravenous use include ketorolac, diclofenac, indomethacin, ketoprofen, tenoxicam, and lornoxicam.

However, NSAIDs have weaker analgesic properties than opioids or local anesthetics and also exhibit a "ceiling effect" with respect to their maximum analgesic

effect. Despite their limitations, NSAIDs may decrease the risk of breakthrough pain because of their more prolonged duration of action and are valuable adjuvants when used in combination with opioids and local anesthetics.

There is no documented evidence of superiority of any particular NSAID for perioperative use. Therefore, the choice of NSAID is dependent upon the route of administration, the duration of the analgesia, propensity for side effects, and the cost.

The oral availability of most NSAIDs is high, whereas that after rectal administration, it is low; therefore NSAIDs should be preferably administered orally. Overall, NSAIDs appear to be safe and well tolerated in patients undergoing ambulatory surgery.

COX-2 inhibitors have been demonstrated in multiple clinical trials to produce analgesic efficacy equal to that of the traditional nonselective NSAIDs without the COX-1 mediated adverse effects of inhibition of platelet aggregation or gastroduodenal ulceration. COX-2 inhibitors used over a short period for postoperative analgesia have not been demonstrated to cause any major adverse events in healthy patients.

C.6. There are three types of pain after laparoscopic cholecystectomy: incisional, subphrenic, and shoulder pain. What is the role of surgical technique in influencing postoperative pain?

The pain after laparoscopic procedures is primarily visceral in origin. Factors responsible for this pain may be related to surgical incisions, carbon dioxide insufflation, and the intra-abdominal pressures maintained during the laparoscopic procedure. Higher insufflation pressures should be avoided, because they can significantly increase the severity of postoperative pain. Subphrenic and shoulder pain after laparoscopic procedures appear to arise from diaphragmatic and phrenic nerve irritation due to insufflated carbon dioxide. This pain tends to be aggravated by ambulation and may persist for several days after surgery. Residual insufflating gas can also increase the intensity of postlaparoscopic pain. Therefore, the abdomen should be actively deflated at the end of the laparoscopic procedure.

Evidence from prospective studies to prevent postoperative pain after laparoscopy includes the following findings:

- Low pressure CO_2 pneumoperitoneum is superior to conventional CO_2 pneumoperitoneum in three out of three controlled studies.
- There is insufficient data to recommend warmed CO_2 pneumoperitoneum for reducing postoperative pain.

- Peritoneal lavage after CO_2 pneumoperitoneum is effective in reducing postoperative pain.
- Helium pneumoperitoneum has no advantage versus CO_2 pneumoperitoneum.

PROSPECT. *Cholecystectomy*. Available at: www.postoppain.org. Accessed March 2007.

C.7. What would be your strategy for pain control after discharge home?

After discharge, acetaminophen, NSAIDs, or opioids, either alone or in combination, are frequently used to provide postoperative pain relief.

Given that acetaminophen has a similar efficacy and a better side effect profile than NSAIDs, it should be considered as an alternative to NSAIDs. Coadministration of acetaminophen and NSAIDs has also been advocated.

Codeine and its derivatives are the most commonly used oral opioid analgesics after ambulatory surgery; however, codeine is a prodrug that must be metabolized to its active form codeine-6-glucuronide and there is a documented large amount of inter-individual variability in codeine metabolism, with 9% of Caucasians complete non-metabolizers. Oxycodone and hydrocodone are orally active derivatives of codeine with higher analgesic potency. Controlled-release preparations of oxycodone have longer duration of action and fewer side effects than the older formulations and have been shown to be highly effective postoperatively. However, there is concern over the misuse of time-release oxycodone in the Oxycontin formulation. The tablet is a nondigestible matrix that is filled with large amounts of oxycodone that are slowly time-released by diffusion out of the matrix. If the matrix is crushed or cut and ingested, the entire drug contained in the preparation is immediately released, which has led to abuse and also to a number of deaths due to accidental overdose. Providers should exercise caution when prescribing this medication. Generally, because postsurgical pain is acute rather than chronic in nature, short-acting opioids for breakthrough pain are sufficient.

D. The Role of an Acute Pain Service

D.1. What is the extent of the problem and which patients are at greatest risk of undertreatment?

Pain relief after surgery continues to be a major medical challenge. Despite a significant improvement over the last decade in our understanding of acute and chronic pain mechanisms and the establishment of APSs, recent studies continue to report that postoperative pain management is not satisfactory for many patients. In addition, publications of guidelines for acute pain management, the introduction of pain as "the fifth vital sign," and the incorporation of the standards advocated by The Joint Commission have not yet translated into improved postoperative analgesia.

More than 30% of patients report moderate to severe pain after surgery. More recent surveys of postdischarge pain put that number even higher. Clinical risk scores to identify patients most at risk for postoperative pain are scarce and not commonly used in practice. Certain patient subpopulations are at greater risk of undertreatment, including infants and children, the elderly, ethnic minorities, and patients with psychiatric illness or those unable to communicate.

D.2. What are the consequences of inadequate postoperative pain relief?

Evidence suggests that inadequate relief of postoperative pain results in harmful physiologic and psychological consequences that lead to significant morbidity, delaying recovery and the return to activities of daily living. Postoperative splinting can lead to atelectasis, and autonomic overactivity associated with pain can result in increased myocardial oxygen demand and increased incidence of perioperative myocardial infarction in at-risk adults. In children, postoperative pain has been found to be an important cause for long-lasting temper tantrums and behavioral changes. In addition, the presence of postoperative pain significantly contributes to patients' dissatisfaction with their anesthesia and surgical experience.

Chronic pain after surgery, also referred to as persistent postsurgical pain, has long been recognized as a major factor in delaying recovery and return to normal daily living. Long-lasting pain is often reported after several common surgical procedures including thoracotomy, mastectomy, hernia repair, and limb amputation. Predisposing risk factors include the severity of preoperative and postoperative pain, intraoperative nerve injury, and psychological vulnerability. Specific early analgesic interventions may reduce the incidence.

D.3. What is the role of an acute pain service (APS) in improving postoperative pain management?

The immediate solution to the problem of inadequate pain relief lies not so much in the development of new analgesic drugs or technologies but in the development of an appropriate organization to utilize existing expertise effectively.

Moreover, effective acute pain management results from education and organizational structure for the delivery of pain relief rather than the specific analgesic techniques themselves. Even simple methods of pain relief can be more effective if proper attention is given to their appropriate, evidence-based use. In many institutions, APSs assume responsibility for managing more advanced methods of pain relief such as patient-controlled analgesia, epidural analgesia, and peripheral nerve catheters to ensure patients receive optimum care from providers well-versed with these analgesic modalities. Additionally, APSs often follow chronic pain patients who are difficult for primary teams to manage and whose complex pain issues are best treated using a multimodal approach.

Werner MU, Søholm L, Rotbøll-Nielsen P, et al. Does an acute pain service improve postoperative outcome? *Anesth Analg.* 2002;95:1361–1372.

D.4. Does an APS improve postoperative outcome?

The introduction of APSs has led to an increase in the appropriate use of specialized analgesic techniques, such as IV-PCA, neuraxial blockade, and peripheral nerve catheters. The implementation of these techniques is an advance in improving analgesia and patient well-being and in reducing postoperative morbidity. In addition, an APS may reduce "analgesic gaps" that can occur during the transition from IV-PCA or epidural analgesia to oral analgesic therapy. Although evaluating the safety of analgesic techniques is an important objective of an APS, its role in preventing and reducing

adverse events has not been well-documented; however, consolidation of decisions regarding pain regimens under one service is likely to have several benefits. First, standardization of protocols decreases prescription or drug administration error. Second, having one service responsible for pain orders decreases the incidence of redundancy and multiple opioid orders. And finally, the availability of a service primarily dedicated to pain is likely to increase the efficacy of interventions and decrease patient pain scores.

In a recent literature review, Werner et al. evaluated the effects of an APS on postoperative outcome in 44 retrospective and 4 prospective clinical trials including 84,097 postoperative patients. The authors found that the implementation of an APS was associated with a significant decrease in pain intensity. In addition, the introduction of an APS was associated with less postoperative nausea and vomiting and urinary retention. However, the authors could not draw clear conclusions about patient satisfaction or postoperative morbidity due to a large variability in the studies regarding composition of the APSs and services provided.

CHAPTER 51

Acupuncture

YUAN-CHI LIN

A 66-YEAR-OLD WOMAN

was scheduled for arthroscopic surgery of her right knee. She experienced severe postoperative nausea and vomiting in the postanesthesia care unit. Despite the use of conventional therapies, her nausea and vomiting persisted. Her past medical history was significant for mastectomy for breast cancer, headache, chronic neck and back pain, osteoarthritis in her knees, peptic ulcer disease, and allergy to Novocain. What role can acupuncture therapy play in her care?

A. Acupuncture as a Complementary Medical Therapy

1. What is acupuncture?
2. How is acupuncture practiced?
3. What are the mechanisms of acupuncture analgesia?
4. What were the conclusions of the National Institutes of Health Consensus Conference about acupuncture?

B. Acupuncture for the Treatment of Chronic Conditions

1. Can acupuncture be used for the treatment of postoperative nausea and vomiting?
2. Can acupuncture be used for the treatment of chemotherapy-induced nausea and vomiting?
3. How effective is acupuncture for the management of chronic headache?
4. Can acupuncture be used for the treatment of chronic neck and back pain?
5. Can acupuncture be used for the treatment of osteoarthritis?
6. What role can acupuncture play in the care of patients with cancer?

C. Complications

1. What are the complications of acupuncture treatment?

A. Acupuncture as a Complementary Medical Therapy

A.1. What is acupuncture?

The word *acupuncture* is derived from the Latin words *acus*, "needle," and *punctura*, "a pricking." The original Chinese term for acupuncture is *Jin Jiao*, which describes the practice of "acupuncture and moxibustion." Moxibustion, which is the burning of moxa (*Artemisia vulgaris*) over the acupuncture points, can also be used for the treatment of various illnesses.

Acupuncture is one of the treatment modalities of comprehensive traditional Chinese medicine. The history of traditional Chinese medicine can be traced back 3000 years. The *Yellow Emperor's Classic of Internal Medicine* from the fourth century BC described the practice of puncturing the body for pain relief. Traditional Chinese medicine is a system of thoughts and practices that are based on the investigations of nature, causes, and effects. It takes the principles of realism and ethics and employs them for the prevention and healing of illnesses.

The theory of *yin and yang* underlies the theoretical framework of acupuncture. Yin and yang are two opposite dynamics that cannot exist in isolation. Rather, they are in a constant state of dynamic balance. If yin and yang are not balanced, illnesses may occur in the body.

The human body is controlled by a vital force called *Qi*. Qi circulates throughout the body and defends its various parts. There are 365 identified acupuncture points in the body, which fall along 12 principal and eight extrameridian systems. Qi was postulated to flow through these meridians in the body.

A.2. How is acupuncture practiced?

Acupuncture utilizes a technique of inserting very fine needles into strategic points in the body called *acupuncture points*. Acupuncture needles vary from 0.5 to 5 inches. in length and from 36 to 42 gauge. There are a wide variety of needles currently available. In *Huang Di Nei Jin* (*The Yellow Emperor's Internal Classic*), Ling Shu described nine shapes of acupuncture needles. Sterile, disposable stainless steel acupuncture needles are the current standard for acupuncture treatment.

After sterilizing the site of the needle entrance on the skin, the acupuncture needle is inserted few millimeters into the epidermis. Following placement of the acupuncture needle, stimulation of the acupuncture point may be achieved manually or by the use of low-voltage electrodes introduced to the needle in a method called *electroacupuncture*.

Each acupuncture point has a prescribed depth of insertion. Manual techniques may involve the lifting and thrusting of the needle or twisting and twirling. *De-Qi* is a typical sensation that is associated with proper acupuncture needle position. Patients describe the sensation as a feeling of soreness, numbness, warmth, heaviness, or pressure around the area where the needle is inserted. The De-Qi sensation is mediated through nonmyelinated C fibers. Many practitioners consider this sensation to be crucial in achieving the effects of acupuncture. Electroacupuncture achieves a similar effect through the use of high- or low-frequency electricity.

Very little pain is associated with the introduction of acupuncture. For various conditions, multiple acupuncture treatment sessions over an extended period may be required to achieve its greatest effectiveness.

Auricular, hand, and scalp acupuncture can be used as microsystems of acupuncture. For example, for the auricular acupuncture (Fig. 51.1) the upper region of the external ear is used to alleviate conditions in the leg and feet. The middle region of the external ear represents chest and back pain. The lower regions are used to relieve headache and neurologic conditions. Auricular acupuncture can also be used for preoperative anxiety control.

Figure 51.1 Auricular acupuncture.
Δ, heart point ; •, shen men; ◆, autonomic point.

The frequency, as well as the number of acupuncture treatments, varies among acupuncture providers. Most practitioners would agree that more than one treatment is necessary to experience the full effect of acupuncture.

Chernyak GV, Sessler DI. Perioperative acupuncture and related techniques. *Anesthesiology*. 2005;102:1031–1049.

A.3. What are the mechanisms of acupuncture analgesia?

Acupuncture inhibits the transmission of pain according to the gate control theory. It may act by stimulating sensory A-β fibers, thereby directly inhibiting the spinal transmission of pain by a smaller A-δ and C fibers.

Acupuncture stimulates the production of endogenous opioid peptides, such as endorphins, enkephalins, and stimulation of the endogenous descending inhibitory pathways. In human studies, analysis of cerebrospinal fluid showed elevated levels of serotonin, endorphins, and enkephalins following acupuncture treatments. Acupuncture analgesia is mainly achieved by the activation of the endogenous antinociceptive system to modulate pain transmission and pain response. Low-frequency (2 Hz) and high-frequency (100 Hz) electrical acupuncture selectively induces the release of enkephalins and dynorphins in both experimental animals and humans. Acupuncture analgesia may be reversed by naloxone.

Functional magnetic resonance imaging has been used to investigate the effect of acupuncture in normal volunteers. Acupuncture needle manipulation on the

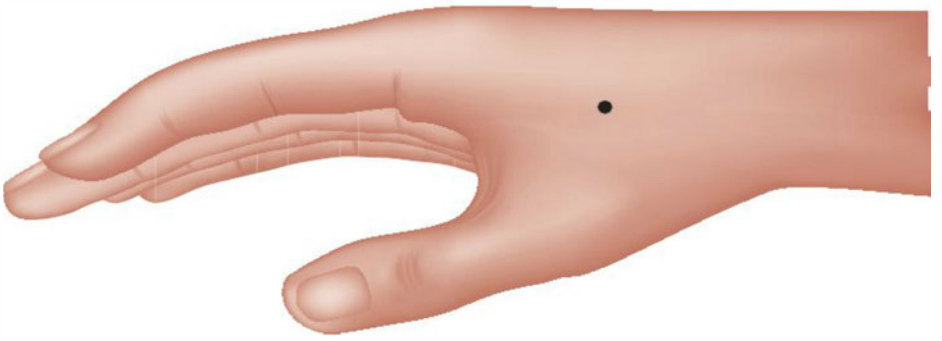

Figure 51.2 LI 4 (Hegu) acupuncture point is on the dorsum of the hand, between the first and second metacarpal bones, radial to the midpoint of the second metacarpal bone.

LI 4 (Hegu) point (Fig. 51.2) modulates the activity of the limbic system and subcortical structure revealed in functional magnetic resonance imaging. Individual variation occurs in the cortical activation patterns elicited by electrical acupuncture stimulation. Real acupuncture elicited significantly higher activation than sham acupuncture over the hypothalamus and primary somatosensorimotor cortex and deactivation over the rostral segment of anterior cingulated cortex.

A.4. What were the conclusions of the National Institutes of Health Consensus Conference about acupuncture?

A National Institutes of Health Consensus Conference concluded that acupuncture is an effective therapeutic intervention that is widely practiced in the United States. Promising results have emerged, for example, supporting the efficacy of acupuncture in adult postoperative and chemotherapy-related nausea and vomiting and in postoperative dental pain. In other conditions, such as addiction, stroke rehabilitation, headache, menstrual cramps, tennis elbow, fibromyalgia, myofascial pain, osteoarthritis, low back pain, carpal tunnel syndrome, and asthma, acupuncture may also be useful as an adjunct treatment, as an acceptable alternative, or when included in a comprehensive management program. Further research is expected to uncover additional areas in which acupuncture interventions will be useful.

B. Acupuncture for the Treatment of Chronic Conditions

B.1. Can acupuncture be used for the treatment of postoperative nausea and vomiting?

Postoperative nausea and vomiting are frequent occurrences following surgery and are best avoided whenever possible. Acupuncture is a commonly used therapy for the treatment of these symptoms. Stimulation of the acupuncture PC-6 (*Nei Guan acupuncture point*; in Chinese this means *gate of the internal organ*) points by acupuncture needles, electrical apparatus, pressure, or magnets is used to achieve relief of nausea and vomiting. The PC-6 acupuncture point is located 2 cun (tsun), approximately 2.6 inches, above the transverse crease of the wrist, between the tendons of the muscle palmaris longus and muscle flexor carpi radialis (Fig. 51.3).

Studies support the use of acupuncture for the treatment of postoperative nausea and vomiting. A systemic review was conducted of 33 randomized controlled trials of acupuncture and acupressure. The results were positive in 27 of these trials. A randomized controlled trial of pediatric patients undergoing tonsillectomy using electroacupuncture in conscious patients showed significant reduction in the occurrence of nausea compared with those in the sham and control groups. The efficacy of acupuncture for postoperative nausea and vomiting prevention is similar to that commonly used pharmacotherapies. A double-blind, randomized, placebo-controlled study revealed that hand acupressure is an effective method for reducing postoperative vomiting in children after strabismus repair.

PC-6 acupressure is a noninvasive method that may have a place as prophylactic antiemetic therapy during gynecologic surgery. Alkaissi et al. did a prospective randomized controlled trial of acupressure in the prevention of postoperative nausea and vomiting for women undergoing general anesthesia for elective gynecologic surgery, with positive results.

Vickers A. Can acupuncture have specific effects on health? A systematic review of acupuncture antiemetic trials. *J R Soc Med.* 1996;89:303–311.

B.2. Can acupuncture be used for the treatment of chemotherapy-induced nausea and vomiting?

Acupressure at the PC-6 acupuncture point has been shown to have a protective effect on people experiencing chemotherapy-induced nausea and vomiting. A review of 11 randomized controlled trials studying the effectiveness of acupuncture point stimulation on chemotherapy-induced nausea and vomiting revealed that electroacupuncture reduced chemotherapy-induced acute vomiting.

Ezzo JM, Richardson MA, Vickers A, et al. Acupuncture-point stimulation for chemotherapy-induced nausea or vomiting. *Cochrane Database Syst Rev.* 2006;(2): CD002285.

B.3. How effective is acupuncture for the management of chronic headache?

Acupuncture therapy for migraine headaches has been reported to be effective in several studies in adults. In a randomized controlled trial of 168 women with migraine, acupuncture was proved to be an adequate migraine prophylaxis. Relative to flunarizine, acupuncture treatment exhibited greater efficiency in the first months of therapy and better patient tolerance. A systemic review of 22 trials including a total of 1,042 patients suggests that acupuncture has a role in the treatment of recurrent headaches. As an added benefit, in a randomized controlled trial of 401 patients with chronic migraine headache, it was also shown that through 12 months of follow-up, acupuncture was relatively cost-effective. Compared with the patients in the control groups, patients receiving acupuncture used 15% less medication, made 25% fewer visits to general practitioners, and took 15% fewer sick days from work.

Cochrane database of systematic reviews of 11 trials with 2,317 participants for patients with episodic or chronic tension-type headache revealed that acupuncture could be a valuable nonpharmacologic tool in patients with frequent episodic or chronic tension-type headaches. In regard to acupuncture for migraine prophylaxis, meta-analysis of 22 trials with 4,419 participants shows acupuncture to be at least as effective as, and possibly more effective than, prophylactic drug treatment and has fewer adverse effects. Acupuncture should be considered a treatment option for patients willing to undergo this treatment.

B.4. Can acupuncture be used for the treatment of chronic neck and back pain?

In a randomized controlled trial of 177 patients with chronic neck pain, the effectiveness of acupuncture, massage, and "sham" laser acupuncture were compared. A study followed 14,161 patients with chronic neck pain for a period of more than 6 months. The patients in the acupuncture group received up to 15 acupuncture sessions over 3 months. The reported neck pain levels and disability scores of the members of the acupuncture group were improved over those of the control group. Treatment success was followed and maintained for 6 months.

A large German clinical study involved 1,162 patients with chronic low back pain indicated that both "real" and "sham" acupuncture treatment were significantly better than conventional therapy for at least 6 months. Another large German study of 1,549 patients with chronic low back pain showed acupuncture plus routine care was associated with marked clinical improvements in patients with chronic low back pain and was relatively cost-effective. A systemic review involve 23 trials of 6,359 patients with low back pain revealed that acupuncture can be a useful supplement to other forms of conventional therapy for nonspecific low back pain.

Haake M, Muller HH, Schade-Brittinger C, et al. German Acupuncture trials (GERAC) for chronic low back pain, randomized, multicenter, blinded, parallel-group trial with 3 groups. *Arch Intern Med.* 2007;167:1892–1898.

B.5. Can acupuncture be used for the treatment of osteoarthritis?

Evidence exists for the efficacy of acupuncture for reducing the pain and dysfunction of osteoarthritis. In a study of 300 patients with chronic osteoarthritis of the knee, participants were randomly assigned to acupuncture, minimal acupuncture, or wait list control group. After 8 weeks of treatment, pain and joint function were improved more with acupuncture than with minimal or no acupuncture.

In another randomized controlled trial of 570 patients with osteoarthritis of the knee, the acupuncture group received 23 true acupuncture sessions over 26 weeks. Acupuncture was shown to provide improvement in function and pain relief as an adjunctive therapy for osteoarthritis of the knee when compared with credible sham acupuncture and education control groups.

In a trial of 30 patients with symptomatic osteoarthritis of the knee, participants were randomized into one of three treatment groups. One group of patients received acupuncture alone; another group of patients received acupuncture, but continued on

their symptomatic medication; and the third group of patients used their symptomatic medication for the first 5 weeks and then had a course of acupuncture added. The patients receiving acupuncture were treated twice weekly over 5 weeks. The results of this study concluded that manual and electroacupuncture causes a significant improvement in the symptoms of osteoarthritis of the knee, either alone or as an adjunct therapy, and with no loss of benefit after 1 month.

B.6. What role can acupuncture play in the care of patients with cancer?

A report of a randomized controlled trial of 90 patients with cancer pain revealed clear benefit from auricular acupuncture for cancer patients experiencing pain, despite stable analgesic treatment. It is reasonable to use acupuncture for the management of chronic cancer-related pain management. Acupuncture can also be used in conjunction with standard antiemetics to control chemotherapy-related nausea and vomiting.

C. Complications

C.1. What are the complications of acupuncture treatment?

Acupuncture is safe. Occasionally, although rarely, a patient may have some bruising at an acupuncture site, which is quickly resolved. The principal risk is infection from the use of improperly sterilized needles. This can be avoided by using disposable sterile acupuncture needles and through the practice of proper insertion of the needles. Extremely rare reports have documented pneumothorax caused by improperly inserted acupuncture needles.

A study of the adverse effects of 34,000 acupuncture consultations in the United Kingdom revealed that the most common adverse events were bleeding, needling pain, and aggravation of symptoms. None of these events were serious. Similarly, a review of nine surveys showed that the most common adverse events were needle pain, tiredness, and bleeding. Feelings of faintness and syncope were uncommon. Feelings of relaxation were reported by as many as 86% of patients. The report of pneumothorax was extremely rare, occurring only twice in nearly a quarter of a million treatments.

A study was conducted involving a prospective postal audit of treatments performed by 1,848 professional acupuncturists in the United Kingdom over a 4-week period. They reported 43 minor adverse events, a rate of 1.3 per 1,000 treatments. The events report included severe nausea and fainting, prolonged aggravation of the symptoms, and pain and bruising. The overall frequency of acupuncture-related adverse events is extremely low, and prospective studies have indicated that even

minor adverse events are uncommon. Acupuncture is considered to be a very safe intervention when applied appropriately, and adverse effects of acupuncture are extremely rare.

SECTION XII

Miscellaneous

CHAPTER 52

Myasthenia Gravis

Cephas P. Swamidoss and Cynthia A. Lien

A 25-YEAR-OLD WOMAN

who was gravida 3, para 2 with a 24-week intrauterine fetal demise, presented for dilation and evacuation in the setting of a history of increasing diplopia and dysphagia. She had a known history of myasthenia gravis (MG), diagnosed previously, and underwent a thymectomy for thymoma during the first trimester of her second pregnancy 2 years ago. Since then, she had been in remission and on no medications. Her vital signs were as follows: pulse rate, 60 beats per minute; blood pressure, 150/80 mm Hg; and respiratory rate, 20 breaths per minute. Her arterial oxygen saturation was 98% on room air. She is 155 cm tall and weighs 65 kg.

A. Medical Disease and Differential Diagnosis

1. What is the clinical course of MG?
2. What is the etiology of MG and how is the diagnosis made?
3. What should be included in this patient's differential diagnosis?
4. What is the difference between MG and Lambert-Eaton syndrome?
5. What is the incidence of MG?
6. Describe the clinical classification of MG.
7. How is myasthenia classified in children?
8. What treatment regimens are available for patients with MG?
9. What are the electrical and humoral events that take place during normal neuromuscular transmission? How are these altered in patients with MG?
10. What is the role of surgery in the treatment of MG?
11. What is the effect of pregnancy on the course of MG?
12. What is the effect of MG on pregnancy?

B. Preoperative Evaluation and Preparation

1. How should you assess these patients preoperatively?
2. What preoperative laboratory data are required?
3. Should this patient be premedicated?

C. Intraoperative Management

1. How should this patient be monitored intraoperatively?
2. What anesthetic regimen would you choose for this patient?
3. Can neuromuscular blocking agents be used in patients with MG?

D. Postoperative Management

1. Would you anticipate that this patient will require prolonged postoperative ventilatory support?
2. How should this patient's postoperative pain be treated?
3. This patient was extubated in the operating room without difficulty, and 40 minutes later, she complained of feeling weak and unable to breathe. Why?

A. Medical Disease and Differential Diagnosis

A.1. What is the clinical course of MG?

The hallmark of the symptoms of MG is fluctuating muscle weakness that worsens with exertion and improves after a period of rest. Patients with MG are strongest after resting and therefore feel energized immediately after waking from sleep. Their weakness worsens as the day progresses.

The presentation of MG is usually insidious, occurring over months to years. The initial symptoms are commonly ocular and consist of ptosis and diplopia. Ptosis can be unilateral or bilateral, symmetric or asymmetric, and typically alternates between eyes. The diplopia is usually intermittent. Extraocular muscle involvement can vary from single muscle paresis to total ophthalmoplegia. Muscle fatigue can result in nystagmus. The pupil is usually spared in MG. Ocular symptoms usually progress to more generalized ones in 80% to 85% of patients with MG. The prognosis is better if the symptoms remain confined to those associated with ocular disturbances for more than 2 years.

Involvement of the bulbar muscles produces dysarthria, dysphagia, and difficulty chewing. Weight loss may occur as a result of decreased oral intake and nasal regurgitation, and a nasal twang in the voice can indicate palatal weakness. Involvement of the facial muscles, particularly the elevators of the angles of the mouth (levator labii superioris and levator anguli oris), results in the characteristic myasthenia "snarl."

Although limb muscle weakness occurs in only 15% to 20% of myasthenics, it can manifest as the inability to do simple everyday tasks such as pulling, reaching, or lifting. Proximal muscles are more commonly involved than distal muscles. Rarely, weakness of the neck extensor muscles (rectus capitis posterior major, rectus capitis posterior minor) may occur. Patients affected in this way are unable to keep their heads upright.

Respiratory muscle weakness presents as dyspnea, particularly in the supine position. If the diaphragm is involved, there is a decreased forcefulness of cough and an inability to project the voice.

Many factors may exacerbate the symptoms of MG. These include physical and emotional stress; infection; exposure to bright sunlight; and, particularly in the case of predominantly ocular symptoms, any increase in temperature associated with infection and hyperthyroidism. Medications, including quinidine, procainamide, aminoglycosides, penicillamine, and calcium channel blockers, can also worsen symptoms.

An infection treated with an offending antibiotic may be enough to exacerbate severe respiratory compromise and may necessitate mechanical ventilation.

A.2. What is the etiology of MG and how is the diagnosis made?

MG is an autoimmune disease caused by an antibody to T cell and blockade of nicotinic acetylcholine receptor (AChR) of the motor endplate. Antibodies are detected in 80% of patients with generalized weakness and 50% of patients with ocular disease only. T-cell stimulation is theorized to occur after sensitization within the thymus to a protein similar or identical to the embryonic AChR. In approximately 85% of patients with MG, pathologic alterations of the thymus gland are found: 10% tumors and 75% hyperplasia of lymphoid follicles within the medullas of the thymus. Blockade of AChR results in abnormally decreased membrane motor endplate potential because of a reduction in the number of functional AChRs at the neuromuscular junction. This decreased neurotransmission at the neuromuscular junction causes the clinical symptoms of muscle fatigue in patients with MG.

A diagnosis of MG is usually made by history and clinical examination. It is then confirmed with several diagnostic tests. Clinical tests of stress endurance include monitoring a prolonged upward gaze, holding an outstretched hand in abduction, and determination of vital capacity. These tests provide objective information about fatigability. Other tests that confirm a diagnosis of MG include the following:

- Electrophysiologic tests
- Pharmacologic tests
- Serologic tests

Electrophysiologic testing involves stimulation of a peripheral nerve with a supramaximal stimulus of 2 Hz four times over 2 seconds in a train-of-four pattern. A decrease in twitch response of more than 10%, when the fourth response is compared with the first, is diagnostic of MG. Patients with MG also show less posttetanic facilitation than their healthy counterparts. The sensitivity of this stimulation test is 50% to 70%.

Single-fiber electromyography is a more sensitive electrophysiologic test. It evaluates the time interval between two muscle fiber action potentials in the same motor unit. Because the same nerve innervates both muscle fibers, the time variation between their action potentials, known as "jitter," is a manifestation of neuromuscular junction transmission. In patients with MG, the "jitter" is increased. The sensitivity of this test is higher than 90%, although it is not specific for MG.

Pharmacologic testing involves the administration of the anticholinesterase edrophonium. For this diagnostic test, the patient is fatigued with a task that can be easily assessed, such as slurred speech or vital capacity, and then is given edrophonium. Patients with myasthenia show dramatic improvement within 2 minutes with intravenous administration of 2.5 to 9 mg of edrophonium.

The curare test may also be used to demonstrate that impulse transmission can be markedly reduced at the neuromuscular junction in patients with MG. This test is rarely used because of the associated morbidity and mortality. Serologic testing

involves identification of AChR antibodies. Antibodies to AChR are a serum marker for the diagnosis of MG and are detected in 80% of patients with generalized MG and 50% of patients with only ocular symptoms. Antibodies to striated muscle are also detected in patients with MG, and their presence in high titers usually is associated with thymoma. Although the antibody level does not correlate with disease severity or the patient's prognosis, the antibody tests are still more specific than any other test for MG.

A.3. What should be included in this patient's differential diagnosis?

A number of disorders mimic MG and should be included in the initial differential diagnosis. Botulism and Lambert-Eaton syndrome (LES) can cause both weakness and ophthalmoplegia. Botulism affects cranial nerves early. A change in pupillary light response and an increased response on repetitive nerve stimulation can differentiate it from MG.

LES causes a distal muscle weakness that improves after exercise. It is associated with oat cell tumor of the lung in 50% of cases. It is also associated with a defect in the autonomic nervous system, which manifests as dry mouth, orthostatic hypotension, and urinary retention.

Thyrotoxicosis can present with generalized weakness and abnormal thyroid function. Patients with neurasthenia characteristically have weakness, which disappears when individual muscle groups are tested. Progressive external ophthalmoplegia, restricted cardiomyopathies, muscular dystrophies, brain tumors, amyotrophic lateral sclerosis, myasthenic polymyopathy with hypersensitivity to neostigmine, and drugs such as D-penicillamine, aminoglycosides, quinine, procainamide, and calcium channel blockers can also cause myasthenia-like symptoms.

Table 52.1 Characteristics of Myasthenia Gravis and Lambert-Eaton Syndrome

	MYASTHENIA GRAVIS	LAMBERT-EATON SYNDROME
Gender most commonly affected	Female	Male
Age at onset	20–40 yr	50–70 yr
Presenting signs	Weakness of ocular, bulbar, and facial muscles; fatigue with activity; muscle pains are uncommon; normal tendon reflexes	Weakness and fatigability of the proximal muscles; transient increase in strength on activity; muscle pains common; tendon reflexes reduced or absent
Pathology	Thymus gland most often abnormal, with 15%–20% of patients having thymoma	Small cell carcinoma of the lung usually present
Electromyographic response	Voltage decrement to repeated stimulation, with a good response to anticholinesterases	Voltage increment to repeated stimulation and a poor response to anticholinesterases
Response to muscle relaxants	Increased sensitivity to non-depolarizing neuromuscular blocking agents and a variable response to succinylcholine	Sensitivity to nondepolarizing neuromuscular blocking agents and a normal to increased response to succinylcholine
Presence of antibodies	Antibodies to the acetylcholine receptor present	Antibodies to calcium channel–associated protein synaptogamin are present
Abnormality of autonomic nervous system	Not present	Present
Treatment	Corticosteroids, plasmapheresis, azathioprine, and thymectomy	Corticosteroids, plasmapheresis, azathioprine, and 3,4-diaminopyridine

A.5. What is the incidence of MG?

MG is relatively rare and has an incidence of approximately 1 in 30,000 people. One and a half times more women than men develop the disease. Men who have this disease have a higher incidence of thymoma. There is a bimodal pattern of incidence, which varies with the sex of the patient. Among women, it occurs within the second and third decade of life—the primary reproductive decades of life. In men, it is seen more commonly in the fifth and sixth decade. Patients younger than 16 years account for less than 10% of cases of myasthenia.

Patients with MG tend to have a higher incidence of autoimmune diseases. These include autoimmune thyroid disease, rheumatoid arthritis, systemic lupus

erythematosus, and diabetes mellitus, suggesting a partial genetic predisposition for myasthenia.

A.6. Describe the clinical classification of MG.

Myasthenia Gravis Foundation of America Clinical Classification

Class I: Any eye muscle weakness, possible ptosis, all other muscle strength is normal
Class II: Mild weakness of other muscles, may have eye muscle weakness of any severity
- IIa: Predominantly limb or axial muscles or both
- IIb: Predominantly oropharyngeal or respiratory muscles or both

Class III: Moderate weakness of other muscles, may have eye muscle weakness of any severity
- IIIa: Predominantly limb or axial muscles or both
- IIIb: Predominantly oropharyngeal or respiratory muscles or both

Class IV: Severe weakness of other muscles, may have eye muscle weakness of any severity
- IVa: Predominantly limb or axial muscles or both
- IVb: Predominantly oropharyngeal or respiratory muscles or both; use of feeding tube without intubation

Class V: Intubation needed to maintain airway

A.7. How is myasthenia classified in children?

In pediatric patients, MG is classified as transient neonatal, neonatal persistent, or juvenile.

Transient neonatal MG occurs in 21% of infants born to mothers with MG. Most of these infants have circulating AChR antibodies that have been passively transferred from mother to baby. The antibodies are transient. The symptoms with which they present include a feeble cry, poor feeding effort, respiratory difficulty, general or facial weakness, and ptosis. These symptoms last an average 18 days.

Neonatal persistent MG is very rare. Onset is at 2 to 3 months of age. These patients have no detectable antibodies to AChR.

Juvenile myasthenia is very similar to the MG in adults.

A.8. What treatment regimens are available for patients with MG?

Multiple forms of treatment for MG are available. They can be broadly classified as follows:

- Pharmacologic
- Surgical
- Plasmapheresis

Pharmacologic treatment with anticholinesterases and immunosuppressants is aimed at manipulation of ACh levels and the immune system.

Anticholinesterases have been used as the initial therapy for symptoms of MG since 1934. By inhibiting the enzymatic metabolism of ACh, these drugs prolong the duration of ACh at the postsynaptic membrane of the neuromuscular junction. Because patient response to these agents is variable, varying from patient to patient and within a patient over the course of a day, patients' education and their involvement in their medical care are required for optimal use of anticholinesterases.

The most common side effects of anticholinesterases are due to the muscarinic effects of ACh and include bradycardia, gastrointestinal cramps, bronchospasm, and an increase in oral and respiratory secretions. The increase in oral secretions can be problematic, particularly for those patients who have bulbar symptoms with already compromised swallowing and in those with respiratory muscle involvement.

Excessive therapy with anticholinergic agents can result in a cholinergic crisis. This will manifest as profound weakness and is due to excess ACh at the neuromuscular junction, which produces a persistent depolarization of the muscle fiber. These symptoms may start a vicious cycle of treating the weakness as myasthenic weakness with anticholinesterases and further exacerbating the cholinergic crisis. In distinguishing clinically between the two, pupillary size may offer some clue to the etiology of the weakness. Hypercarbia in patients with MG causes sympathetic stimulation and dilation of pupils. In a cholinergic crisis, ACh causes constriction of the pupils. It should be noted that patients with primarily ocular symptoms often respond poorly to cholinesterase inhibitors.

Pyridostigmine (Mestinon) is the most commonly used drug for treatment of myasthenia because it causes fewer muscarinic side effects than neostigmine. Its onset of action is 15 to 30 minutes after oral administration, the peak effect is within 1 to 2 hours, and the duration of action is 3 to 4 hours. It is available in three doses (10, 30, and 60 mg), and the typical daily doses range between 30 and 120 mg divided into three to six doses over 24 hours. A long-acting, 180-mg slow-release preparation can be used overnight. A long-acting form of pyridostigmine is also available. Unless the patient has profound morning weakness or nocturnal respiratory distress, it is not commonly used. There is an increased risk for overdosage with the long-acting form of this anticholinesterase.

Edrophonium (Tensilon) 5 to 10 mg intravenously has been used between regularly scheduled doses of anticholinesterases to determine whether the patient is receiving too much or too little medication.

Anticholinesterases do not have an impact on the primary pathology, which is immunologic, and are rarely used alone.

Corticosteroids are used to complement, rather than replace, anticholinesterase therapy. Seventy to eighty percent of patients have complete remission of their disease within weeks to months of treatment with adequate doses of prednisone. Clinical improvement after initiation of corticosteroid therapy is slow and may take weeks. Starting with small doses of corticosteroids can minimize an initial deterioration in a patient's condition. Corticosteroids exert their immunosuppressive effects at many levels of the immune system. They reduce the amount of AChR antibodies and diminish the anti-AChR reactivity of the peripheral blood lymphocytes.

Several different dosing regimens have been suggested. An alternate-day regimen lessens the degree of side effects. The common side effects seen with high-dose corticosteroids are generalized immunosuppression, infection, cataracts, myopathy, osteoporosis, diabetes, and peptic ulcer disease. Most patients require approximately 40 to 60 mg of prednisone per day.

Cytotoxic drugs such as azathioprine and cyclosporine are used in conjunction with corticosteroids and anticholinesterases to reduce the total dose of corticosteroids. Azathioprine acts predominantly on T cells. It is useful in patients in whom corticosteroids are contraindicated. Although it is well tolerated by patients, many months to a year may be required to see its maximal therapeutic effect. Cyclosporine inhibits the production of interleukin-2 by helper T cells. Its efficacy is similar to that of azathioprine, but its maximal therapeutic effect is seen within 1 to 2 months. Its side effects include nephrotoxicity and hypertension.

Adrenocorticotropic hormone (corticotropin) has been used in the treatment of severe MG and is often useful when previous therapy with corticosteroids has failed. This form of treatment, however, is being replaced with plasmapheresis.

Plasmapheresis has been found to effectively remove circulating antibodies and is typically reserved to stabilize patients undergoing myasthenic crisis or preoperatively in patients with severe weakness. After therapy, a patient's condition improves rapidly, but the effects are short lived. When plasmapheresis is used in conjunction with pooled intravenous immunoglobulins in doses of 400 mg/kg/day for 5 days on alternating days, there is a rapid improvement that can last for several weeks.

With an increasing understanding of the immune system, there are some novel potential treatments for MG, such as targeting the specific T and B cells and a nonselective removal of helper T cells, which are responsible for producing the antibodies to AChR. Induction of tolerance to self-antigens by their ingestion has been shown to prevent MG in animal models.

A.9. What are the electrical and humoral events that take place during normal transmission? How are these altered in patients with MG?

Normally, the charge inside a cell is negative relative to the extracellular environment. The potential difference is 70 to 90 mV. During an action potential, the ionic fluxes that occur cause the interior of the cell to become positive by approximately 40 mV. The nerve action potentials cause the release of quanta of ACh from nerve terminals. The ACh crosses the synaptic cleft and attaches to the receptor site on the sarcolemma, causing depolarization. This depolarization is called the *endplate potential*. If the

threshold for excitation is exceeded by the summation of many *endplate potentials*, an action potential invades the muscle cell membrane and spreads along its surface, causing muscle contraction.

In MG, the amount of ACh released from the presynaptic sites is normal or even increased. There are, nevertheless, histologic alterations found at the neuromuscular junctions to which alterations in transmission of impulses can be attributed. These consist of a widening of the synaptic space at the neuromuscular junction and a degeneration of the junctional folds. Most importantly, the concentration of the functional AChRs on the postsynaptic membrane is often reduced by more than 70%. Antibodies to the AChR are responsible for this decrement. These AChR antibodies are directed against various epitopes on the postsynaptic receptor. They decrease the amount of functioning ACh by a number of mechanisms, which include direct blockade, complement-mediated lysis, and increased receptor degradation rate.

A.10. What is the role of surgery in the treatment of MG?

Although the efficacy of thymectomy is based on retrospective data, it is a widely accepted therapy for myasthenic patients, particularly those with thymoma and early-onset generalized MG. Thymectomy has been used as a treatment for MG since 1939, when the removal of a cyst from the thymus of a patient with MG, described by Blalock, resulted in remission of the disease. The goal of thymectomy as a treatment for MG is to induce remission, permitting a reduction in the immunosuppressive medication. From 50% to 80% of patients undergoing thymectomy will demonstrate clinical improvement after thymectomy, and 21% to 38% of patients will go into clinical remission (compared with the 13% of medically treated patients).

The exact role of the thymus in the pathogenesis of MG is likely the T-cell–mediated production of AChR antibodies. Thymic epithelial cells and AChRs share similar epitopes. A thymoma is seen in 15% of patients with MG, and thymic hyperplasia is seen in 80% of patients. That clinical improvement frequently seen after thymectomy is further evidence of an association of the thymus in MG. Therefore, thymectomy may be a logical choice for most patients with MG. It is not done in prepubertal children and in those patients with predominantly ocular symptoms. Furthermore, if the symptoms of the disease respond to medical management, patients are not candidates for surgery.

The surgical approach to thymectomy for MG can be either transsternal or transcervical. The transsternal approach allows for better surgical exposure and a more thorough excision. The main advantage of the transcervical approach is that it is minimally invasive. Mortality with this approach is close to 0%, versus 9% with the transsternal approach. Furthermore, the incidence of requiring postoperative ventilation is 10% after transcervical thymectomy, compared with 50% after the transsternal approach. The rates of remission with the two surgical approaches are comparable. Thymectomy may induce perioperative myasthenic crises. Optimizing medical therapy preoperatively may minimize this risk.

A.11. What is the effect of pregnancy on the course of MG?

The course of MG during pregnancy is unpredictable at best; control at the beginning of the pregnancy does not predict exacerbations or remissions. Worsening symptoms occur in one-third of pregnant women. Although these exacerbations can occur at any time, they are more likely to occur during the first trimester or the first month postpartum. Twenty to forty percent of women experience an improvement in symptoms during the second and third trimesters. Puerperal complications, such as infections, seem to increase the risk of exacerbation of MG symptoms and should be promptly recognized and treated. The mortality risk for mothers with MG is inversely correlated to the duration of the disease, with the highest risk being in the first year and the minimal risk 7 years after the onset of the disease.

A.12. What is the effect of MG on pregnancy?

The effect of MG on pregnancy is relatively small. There is no increase in the rate of spontaneous abortion or low birth weight children. Although MG does not increase the rate of premature birth, there is some suggestion of an increased rate of premature rupture of membranes among women with MG. This etiology is unclear, but some think it is related to the course of medications taken by the mother with MG. Case reports of preeclampsia in the setting of MG have been documented, but no study has proven an increased risk resulting from MG. It is recommended that pregnant patients with MG have frequent follow-up with their obstetricians, every 2 weeks in the first and second trimesters and every week in the third trimester. Ultrasound evaluations are necessary during pregnancy to detect signs of fetal akinesia. Fetal monitoring for signs of hypoxia is also very important during myasthenic exacerbations.

B. Preoperative Evaluation and Preparation

B.1. How should you assess these patients preoperatively?

The preoperative interview should be used to identify factors that may be predictive of the need for postoperative ventilation. These factors include duration and severity of the disease and the total daily requirement of pyridostigmine or other medications. This information can guide the anesthesiologist in formulating the anesthetic plan, choosing preoperative medications, and appropriately arranging for postoperative care. Patients with MG are usually knowledgeable about their medication; they often are able to adjust their own regimen on the basis of their clinical status.

Whether to alter a patient's anticholinesterase medication preoperatively is still much debated. In patients with mild symptoms, discontinuation of anticholinesterase would seem to be preferable because its continued use can complicate anesthesia by rendering patients more susceptible to vagal arrhythmias. Furthermore, anticholinesterase inhibits plasma cholinesterase and acetylcholinesterase. Because of this, the metabolism of ester local anesthetics, succinylcholine, and mivacurium may be slowed. Certainly, patients who are dependent on their medication should continue it. In this case, the anesthesiologist needs to be aware that postoperative requirements may be markedly reduced. Whether the patient is taking or has taken corticosteroids in the past year should also be determined.

Because other autoimmune diseases occur with increased frequency in patients with myasthenia and can have their own anesthetic implications, evidence of hypothyroidism, pernicious anemia, systemic lupus erythematosus, and rheumatoid arthritis should be sought.

Fleisher L, ed. *Anesthesia and Uncommon Diseases.* 5th ed. Philadelphia: WB Saunders; 2006:303–325.

Miller RD, ed. *Miller's Anesthesia.* 7th ed. Philadelphia: Churchill Livingstone; 2010:1032–1033, 1180–1181.

B.2. What preoperative laboratory data are required?

The need for laboratory studies should be tailored to the patient's history. In addition to routine preoperative laboratory data, patients with MG should have electrolyte abnormalities ruled out, particularly hypokalemia, which can exacerbate weakness. Because many of these patients are on corticosteroids, blood glucose levels should be determined. Cyclosporine trough levels should be obtained to adjust dosing and avoid toxic levels. Blood counts and hepatic and renal function should also be checked.

If the patient will require a general anesthetic for the surgical procedure, a preoperative arterial blood gas analysis and pulmonary function tests would serve as baseline for extubation, particularly if it is anticipated that the patient will be mechanically ventilated postoperatively. By definition, patients with thymomas have an anterior mediastinal

mass that should be evaluated for tracheal compression and deviation. This may affect the ease of endotracheal intubation. Patients with MG can have intrathoracic airway or vascular obstruction on anesthetic induction. Flow–volume loops preoperatively can indicate whether the obstruction is intrathoracic or extrathoracic.

B.3. Should this patient be premedicated?

A preoperative visit should include explanation of the anesthetic procedure and the possibility of postoperative ventilation. Often, these measures serve to allay anxiety and decrease the need for preoperative sedation. Medications that cause respiratory depression should be avoided. Glycopyrrolate can be given to reduce the increased secretions resulting from treatment with anticholinesterases. Stress-dose corticosteroids should be given in the perioperative period for patients who are taking corticosteroids preoperatively.

Fleisher L, ed. *Anesthesia and Uncommon Diseases*. 5th ed. Philadelphia: WB Saunders; 2006:303–325.

Miller RD, ed. *Miller's Anesthesia*. 7th ed. Philadelphia: Churchill Livingstone; 2010:1032–1033, 1180–1181.

C. Intraoperative Management

C.1. How should this patient be monitored intraoperatively?

These patients should be monitored with an electrocardiogram, blood pressure cuff, pulse oximeter, esophageal temperature, and end-tidal capnography. Depending on the nature of the procedure and the severity of the patient's myasthenia, an arterial line may be warranted to monitor arterial blood gases during the processes of weaning from mechanical ventilation and extubation of trachea.

A nerve stimulator should be used to monitor muscle strength even if muscle relaxants are not used intraoperatively. Inhalational anesthetics have been shown to cause depression of the twitch response in the absence of a muscle relaxant in patients with MG. They are extremely sensitive to the neuromuscular junction–depressing properties of volatile anesthetics.

Fleisher L, ed. *Anesthesia and Uncommon Diseases*. 5th ed. Philadelphia: WB Saunders; 2006:303–325.

Miller RD, ed. *Miller's Anesthesia*. 7th ed. Philadelphia: Churchill Livingstone; 2010;1032–1033, 1180–1181.

C.2. What anesthetic regimen would you choose for this patient?

Multiple options are available for anesthetizing this patient, ranging from a general endotracheal tube anesthetic to a Proseal laryngeal mask airway to regional anesthesia and even monitored anesthesia care. The decision regarding what is right for this patient in this situation depends on weighing the risks for pregnancy-induced aspiration with the anesthetic risks associated with MG, particularly in the postoperative period. The most conservative anesthesia providers would place the risks for aspiration above those of MG and proceed with a general endotracheal anesthetic. Others would weigh the aspiration risks with those of the difficult airway in a pregnant woman or those of postoperative complications resulting from MG and plan for a regional or monitored care anesthetic. There is no correct answer.

Whatever the chosen course, the anesthetic regimen for this patient should be planned to provide the least and briefest interference with ventilatory and neuromuscular function.

In the setting of a general anesthetic, the patient should be preoxygenated before induction of anesthesia with agents such as thiopental, propofol, or etomidate. Opioids should be used cautiously because these patients are very sensitive to their respiratory depressant effects. Ventilation with 100% oxygen should be assisted, and then controlled as necessary. Once an adequate airway is established, a volatile anesthetic can be added to the oxygen. Muscle relaxants are rarely required for laryngoscopy and intubation if the patient is sufficiently anesthetized. Four percent topical lidocaine may be sprayed onto the vocal cords before intubation. Ventilation should be controlled to ensure adequate gas exchange, and anesthesia should be maintained with oxygen, nitrous oxide, and a volatile anesthetic with or without a continuous infusion of a short-acting intravenous anesthetic. Desflurane and an intermediate-acting muscle relaxant have been reported as an effective combination. Dexmedetomidine or propofol may be considered for total intravenous anesthesia–based techniques. Remifentanil, with its short duration of action, may be an appropriate choice of opioid in these patients. As surgery is completed, the anesthesia is tapered to allow for prompt emergence. The patient should not be extubated until awake and responsive, strong, and able to generate a negative inspiratory force of at least -30 cm H_2O. Additionally, the patient should be able to maintain normal oxygenation and normocapnia before extubation of his trachea.

If a regional anesthetic is chosen, either an epidural or a spinal anesthetic, depending on the dermatomal level achieved, preservation of the thoracic muscles may be desirable in preserving the greatest amount of ventilatory function.

C.3. Can neuromuscular blocking agents be used in patients with MG?

The response of the patient with myasthenia to muscle relaxants is altered because of the inherent disease process and because of treatment with anticholinesterase agents. The depolarizing muscle relaxant succinylcholine has been used to facilitate endotracheal intubation. Nevertheless, patients with myasthenia have a variable response to succinylcholine that depends on their medical treatment. In patients not receiving anticholinesterases, the decreased number of functional receptors makes the endplates "resistant" to the effects of succinylcholine. The dose therefore needs to be increased to reliably facilitate intubation. In patients treated with anticholinesterases, plasma cholinesterase activity is decreased. Therefore, more succinylcholine reaches the motor endplate. As succinylcholine metabolism is decreased in these patients, the neuromuscular block can be prolonged from 4 to 87 minutes. Formation of a phase II block has been reported to occur after a single intubating dose of 0.5 mg per kg of succinylcholine. Although the use of succinylcholine is not contraindicated in patients with MG, some clinicians prefer not to use it because of the risk of prolonged neuromuscular block.

In contrast to what is seen after the administration of succinylcholine, the response of the patient with MG to nondepolarizing drugs is extremely predictable. They are exquisitely sensitive to the nondepolarizing drugs and frequently demonstrate a profound weakness after administration of a precurarizing dose of muscle relaxant. This sensitivity is due to the fact that the number of AChRs is decreased by up to 70% in these patients. The number of available receptors is just sufficient to produce endplate potentials that are above the threshold required for neuromuscular transmission and muscle contraction. This reduced receptor concentration reduces the dose of relaxant required for muscle relaxation. Blockade of 70% of receptors, or an effective decrease in the number of receptors by this same amount, will cause a fade in the mechanomyographic response to a train-of-four stimuli in patients without MG.

Despite this increased sensitivity to nondepolarizing muscle relaxants, they can be safely used in patients with MG. Markedly decreased doses should be used. Pancuronium has been reported to cause 95% neuromuscular blockade with only one-fourth of the usual dose used for maintenance of neuromuscular block (0.005 to 0.01 mg per kg). The intermediate-acting muscle relaxants may be more suitable for patients with MG because of their shorter duration of action. Doses ranging from 10% to 50% of those required in patients without myasthenia were used, and prompt extubation was accomplished after either spontaneous recovery or antagonism of the residual neuromuscular block. Because of the metabolism of mivacurium by plasma cholinesterase, it may not be well suited for patients with MG.

D. Postoperative Management

D.1. Would you anticipate that this patient will require prolonged postoperative ventilatory support?

Predictive criteria for the need for prolonged postoperative ventilatory support have been proposed. Leventhal, Orkin, and Hirsch assigned a scoring system to four factors as follows:

Duration of more than 6 years: 12 points
History of chronic obstructive pulmonary disease: 10 points
Pyridostigmine, more than 750 mg per day: 8 points
Vital capacity less than 2.9 L: 4 points

Patients scoring less than 10 points in their series could be extubated immediately after surgery; those scoring more than 12 points required postoperative ventilatory support. This system of predicting whether a patient will require prolonged intubation and ventilation is not universally applicable. Patients undergoing transsternal

thymectomy require postoperative ventilation more frequently than those undergoing transcervical thymectomy, perhaps because the less invasive procedure has less of an effect on respiratory function.

Similarly, patients with myasthenia undergoing an upper abdominal operation are more likely to require postoperative ventilation than patients undergoing a more peripheral procedure. Obviously, each patient must be considered individually when assessing the need for postoperative ventilatory support.

Miller RD, ed. *Miller's Anesthesia.* 7th ed. Philadelphia: Churchill Livingstone; 2010:1032–1033, 1180–1181.

D.2. How should this patient's postoperative pain be treated?

The patient's postoperative analgesic regimen should be designed to avoid any respiratory compromise. Because these patients are exquisitely sensitive to the respiratory depressant effects of parenteral opioids, these should be used sparingly. Epidural administration of opioids is an alternative to parenteral administration. They may provide better pain relief with smaller doses of medication and therefore cause less ventilatory depression.

Fleisher L, ed. *Anesthesia and Uncommon Diseases.* 5th ed. Philadelphia: WB Saunders; 2006:303–325.

D.3. This patient was extubated in the operating room without difficulty, and 40 minutes later, she complained of feeling weak and unable to breathe. Why?

The anesthesiologist needs to determine whether this exacerbation of weakness is due to a cholinergic crisis or a myasthenic crisis. During myasthenic crisis, patients have a decreased response to anticholinesterases. A cholinergic crisis is caused by an overdose of anticholinesterases. Either can be suspected in the immediate postoperative period, when the stress of surgery can cause an exacerbation of myasthenic weakness and when anticholinergic requirements may be altered. In either case, increased muscle weakness may require ventilatory support.

With either myasthenic or cholinergic crisis, increases in muscle weakness, salivation, and sweating occur. It has been recommended that the two crises be differentiated from each other on the basis of the patient's response to an intravenously administered dose of 10 mg of edrophonium. The patient in a myasthenic crisis should show some improvement in muscle strength. The patient in cholinergic crisis will show either no increase in muscle strength or a worsening of respiratory distress.

Fleisher L, ed. *Anesthesia and Uncommon Diseases.* 5th ed. Philadelphia: WB Saunders; 2006:303–325.

CHAPTER 53

Malignant Hyperthermia

HENRY ROSENBERG AND VINOD MALHOTRA

A 7-YEAR-OLD BOY

with kyphoscoliosis was scheduled for ambulatory surgery for repair of strabismus under general anesthesia. Previous anesthetic history included an uneventful sevoflurane and nitrous oxide anesthesia for bilateral myringotomy. The mother was very nervous because a first cousin of the boy had died under anesthesia in Wisconsin the previous year.

A. Medical Disease and Differential Diagnosis

1. What was the problem of concern in this case?
2. What is malignant hyperthermia (MH)?
3. What are the clinical features of a susceptible patient?
4. Does the history of previous uneventful sevoflurane anesthesia reasonably exclude the patient's susceptibility to MH?
5. What are the clinical features of the syndrome?
6. What are the laboratory findings during an acute crisis of MH?
7. What is the incidence of this syndrome?
8. What is the mode of inheritance of the disease? Does MH skip generations?
9. What genetic disorder results in MH susceptibility?
10. What is the pathophysiology of the syndrome?
11. What laboratory tests can further substantiate the susceptibility of the patient to MH?
12. What is neuroleptic malignant syndrome?

B. Preoperative Evaluation and Preparation

1. How would you prepare this patient for anesthesia and surgery?
2. Is dantrolene prophylaxis indicated?
3. What laboratory tests would you obtain before surgery?
4. Is outpatient surgery appropriate for this patient?
5. In anticipation of general anesthesia, what preparations would you make?

C. Intraoperative Management

1. What anesthetic techniques and agents would you employ?
2. Should body (core) temperature be monitored during general anesthesia lasting more than a short time?
3. What anesthetic agents are contraindicated?
4. If the surgeon wants to use local anesthesia for a procedure, what agents will you recommend?
5. What is the significance of masseter muscle spasm occurring after succinylcholine administration?
6. Twenty minutes into the procedure with sevoflurane anesthesia, the patient developed increasing tachycardia with ventricular premature beats and mottled skin. What emergency measures would you take?
7. What modalities would you monitor closely during management of the crisis?
8. What steps should be taken to avoid major morbidity from MH?

D. Postoperative Management

1. What complications may follow this syndrome?
2. What would be your follow-up in this case?
3. What would you advise the patient and the family?
4. What precautions should an MH susceptible patient take out of the OR?

A. Medical Disease and Differential Diagnosis

A.1. What was the problem of concern in this case?

The patient was a 7-year-old boy with kyphoscoliosis and strabismus and a history of an anesthetic-related death in the family in Wisconsin. Therefore, in addition to the respiratory problems associated with kyphoscoliosis, he presented a likelihood of susceptibility to MH syndrome. The supporting factors for strong suspicion were the family history, kyphoscoliosis, and geographic location. There is a high density of MH–susceptible families in the state of Wisconsin.

A.2. What is malignant hyperthermia (MH)?

MH, first described by Denborough and Lovell in 1960, is an inherited clinical syndrome characterized by elevated core temperature, tachycardia, tachypnea, hypercarbia, rigidity, acidosis, and hyperkalemia. The underlying abnormality relates to an uncontrolled elevation of intracellular calcium in skeletal muscle cells leading to activation of muscle contractile elements and hypermetabolism. These changes are reversed with the administration of dantrolene, but in the absence of timely treatment, death is likely. In almost every instance, the clinical syndrome occurs in a susceptible patient when a "triggering" anesthetic agent is employed. Not all signs appear in all cases. In rare situations, an MH crisis has appeared in humans in the absence of anesthetic drugs.

A.3. What are the clinical features of a susceptible patient?

A family history, if present, particularly in a first-degree relative, is a strong indicator of MH susceptibility. Epidemiologic studies have demonstrated that certain comorbidities such as scoliosis and muscle disorders are more frequent in MH–susceptible individuals. A few myopathic disorders are known to be associated with MH susceptibility. They include central core disease, King-Denborough syndrome, and multiminicore disease (Table 53.1). Nevertheless, most patients susceptible to MH do not have obvious musculoskeletal disorders or a positive family history.

Patients who have Duchenne or Becker muscular dystrophy should not be anesthetized with MH trigger agents because hyperkalemia and rhabdomyolysis may result.

A.4. Does the history of previous uneventful sevoflurane anesthesia reasonably exclude the patient's susceptibility to MH?

No, it does not. Cases may occur during a second or subsequent anesthetic course.

Scoliosis
Hypotonia
Exercise-induced rhabdomyolysis
Central core disease
Multiminicore disease
King syndrome

A.5. What are the clinical features of the syndrome?

The clinical features of malignant hypertension are the result of an uncontrolled, exaggerated, hypermetabolic state triggered by the use of potent inhalation anesthetic agents and succinylcholine. In humans, a few cases of malignant hypertension have been thought to occur as a result of environmental factors other than anesthetic agents. Common manifestations include the following:

Specific for malignant hypertension

- Increase in end-tidal carbon dioxide during constant ventilation (the most sensitive and specific sign)
- Generalized rigidity (extremely high specificity)
- Masseter muscle rigidity
- Increased temperature (not uncommonly higher than 40° C)

Nonspecific

- Tachycardia (the earliest and most consistent clinical sign, though not specific)
- Tachypnea
- Arrhythmias
- Skin mottling
- Profuse sweating
- Altered blood pressure

Hyperkalemic cardiac arrest

Sudden hyperkalemic cardiac arrest has been reported after the administration of MH trigger agents in children with undiagnosed myopathy, especially the dystrophinopathies, Duchenne or Becker muscular dystrophy. This response is not a result of pathophysiologic changes typical for MH, but rather muscle membrane destruction leading to hyperkalemia. The pathways leading to the abnormal response is not clear.

The treatment is similar to treatment for hyperkalemia, that is, glucose and insulin, calcium chloride or gluconate, and hyperventilation.

A.6. What are the laboratory findings during an acute crisis of MH?

The laboratory values reflect changes of a hypermetabolic state and muscle tissue damage (Table 53.2). Hence, hypercarbia, respiratory and metabolic acidosis, hyperkalemia, elevated creatine kinase, and myoglobinemia are common findings. If the hyperthermia is extreme, coagulopathy is common.

Table 53.2 The Laboratory Findings of Acute Malignant Hyperthermia

METABOLIC AND RESPIRATORY ACIDOSIS
Arterial blood gases
↓↓ pH
↑↑↑ P_{CO_2}
Mild decreases in P_{O_2}
Electrolytes
↑ K
↑ Ca or decreased
↑ Mg
Serum
↑ Lactate
↑ Pyruvate
↑ Creatine kinase
↑ Lactate dehydrogenase
↑ Aldolase
↑ Myoglobin
Increased international normalized ratio, increased fibrin split products increased prothrombin time, increased partial thromboplastin time.

A.7. What is the incidence of this syndrome?

The incidence of clinical MH is difficult to measure because many clinical syndromes resemble it, and often the anesthetic management is altered when initial signs suggesting MH are detected. The incidence also depends on the prevalence in a population of genetic mutations causal for MH as well as the prevalence of use of MH trigger agents.

One of the earliest epidemiologic studies of MH was conducted in Denmark, where an estimate of the incidence of fulminant MH was noted to be 1 in 260,000 general anesthetics and 1 in 60,000 anesthetics where succinylcholine was used. The incidence was even higher, that is, 1 in 5,000 anesthetics, when such signs as masseter muscle rigidity, unexplained tachycardia, and unexplained fever were included.

In a province of Quebec, Canada, the prevalence of MH was calculated as 0.2 % of the population based on a detailed genealogic study of families with MH susceptibility.

More recently, genetic studies have suggested that the prevalence of mutations that are causal for MH is 1 in 3,000 in France and in Japan.

The incidence of clinical MH appears to be higher in children and in men. Two recent studies of coded hospital discharge data showed that the prevalence of MH is 1 in 100,000 hospital discharges for adults and 4 per 100,000 discharges for children.

A.8. What is the mode of inheritance of the disease? Does MH skip generations?

MH is inherited in humans in an autosomal dominant fashion with reduced penetrance and variable expressivity. It is heterogenetic with up to seven gene loci implicated, but only two are confirmed.

More than 70% of MH cases are linked to the ryanodine receptor gene located on chromosome 19. Less than 2% are related to mutations in the dihydropyridine receptor (*DHPR*) gene. Over 200 mutations have been found in that gene, with up to 30 documented to be causal for the syndrome.

Because MH is inherited in an autosomal dominant manner, the susceptibility to it does not "skip" generations. Nevertheless, because of the low penetrance, not all of those with MH mutations display the syndrome on exposure to trigger agents.

In MH–susceptible pigs, the inheritance is autosomal recessive with only one DNA change noted to account for all cases.

A.9. What genetic disorder results in MH susceptibility?

In almost all cases, the MH susceptible patient has a defective calcium channel located in the membrane of the sarcoplasmic reticulum of skeletal muscle. This channel is termed the *ryanodine receptor* because it binds the plant alkaloid ryanodine.

The channel is closely associated with other proteins and structures, such as the dihydropyridine calcium channel that mediates transfer of voltage change to the RYR-1 receptor. Other proteins associated with the ryanodine receptor include triadin and FKB-12 binding protein. Mutations in the *RYR-1* gene are associated with MH susceptibility in more than 65% of patients and their families. Nevertheless, only about 30% of patients with MH harbor a mutation *proven* to lead to increased intracellular calcium on exposure to caffeine or MH trigger anesthetics, the critical criteria to confirm the pathophysiology of MH. Over 200 additional mutations have yet to be characterized regarding the effects on calcium movements. One reason for the slow progress in deciphering the

significance of these many mutations is that, unlike many other conditions, there are many private mutations that predispose to MH. No single mutation accounts for more than about 10% of MH cases. The *DHPR* gene, also involved in intracellular calcium control, has been associated with susceptibility in 1% to 2% of MH–susceptible families.

There are probably other genes that may lead to MH susceptibility but are much less common than those associated with the *RYR-1* and the *DHPR* genes.

Of interest is the observation that mutations associated with central core disease and multiminicore disease, two myopathies that also predispose to MH, are located on the *RYR-1* gene as well. In central core disease, the sarcoplasmic reticulum is depleted of calcium to a significant extent because of the increased permeability of the ryanodine receptor. With a depletion of calcium, muscle contraction is weakened when the muscle is activated.

Recently, genetically engineered mice were developed that include one or more of the mutations causal for MH in the mouse genome. The mice display signs typical of MH during exposure to trigger agents and also on exposure to raised environmental temperature.

A.10. What is the pathophysiology of the syndrome?

The MH syndrome results from an abnormal and uncontrolled elevation of intracellular calcium levels in skeletal muscle. The pathophysiology is as follows: The process of calcium release from the sarcoplasmic reticulum normally begins with depolarization of the sarcolemma that is transmitted via the T tubules to the *DHPR*, which in turn activates the calcium channel termed the ryanodine receptor to release calcium.

The elevated calcium removes the inhibition of actin and myosin interaction that leads to mechanical force generation. The calcium release occurs via a channel within the sarcoplasmic reticulum called the ryanodine receptor. Reuptake of calcium returns the intracellular cytoplasmic concentration of calcium to normal and muscle relaxation takes place. Reuptake is mediated via a calcium adenosine triphosphate (ATP)ase pump mechanism.

A variety of intermediate proteins also regulate the intrasarcoplasmic reticulum concentration of calcium, such as calsequestrin, a calcium-binding protein. Genetically engineered mice that do not express calsequestrin have been shown to develop clinical signs of MH on exposure to trigger anesthetics. It is thought that in the absence of the calcium buffer, intracellular calcium levels increase significantly, but only on exposure to MH triggers.

The control of calcium release is highly regulated because when muscle contraction takes place, a variety of energy-consuming steps are required resulting in ATP breakdown and heat production.

During an MH episode, the ryanodine receptor calcium channel is locked in an open position, leading to an uncontrolled release of calcium with elevation of intracytoplasmic calcium levels and continuous muscle activation as well as ATP breakdown. The sarcoplasmic reticulum calcium pump is unable to resequester the calcium. ATP breakdown during this process aggravates heat production further. Dantrolene reverses these changes.

Energy-consuming processes take place through glycolysis as well as oxidative phosphorylation. Eventually, ATP levels are insufficient to maintain sarcolemmal integrity and potassium leaks from the cell resulting in hyperkalemia. Myoglobinemia occurs for the same reason as does an increase of a number of enzymes, including creatine kinase.

A.11. What laboratory tests can further substantiate the susceptibility of the patient to MH?

The most accurate diagnostic test for MH is the exposure of biopsied skeletal muscle to halothane, caffeine, and, more recently, ryanodine or chlorocresol. In this test, approximately 1 g of muscle is harvested from the thigh under regional or, in the case of a child, general anesthesia. Strips or fascicles of muscle weighing 100 to 200 mg are suspended in a water bath at 37° C and exposure is made to halothane, caffeine, ryanodine, or chlorocresol in specific graded concentrations. The isometric contracture, not contraction, response to muscle is measured via strain gauge following specific guidelines. The threshold and height of the contracture is measured, and a diagnosis of MH is made based on the contracture threshold and strength exceeding specific values.

The test is highly sensitive, close to 100%, but as many as 20% of positive results are false-positives. Nevertheless, the value of the test resides in ruling out MH susceptibility with certainty.

Because the test is invasive and costly and requires strict adherence to specific requirements, there are only about six testing centers in North America. There are over 20 in Europe. Two slightly different versions of the test exist, the North American and the European versions. The main difference is in the concentration of drugs used during exposure of the muscle and the threshold for determining a positive response.

The patient and history must be carefully evaluated by the biopsy center director before recommending the test in order to enhance accuracy.

Molecular genetic testing for malignant hyperthermia susceptibility

The era of DNA testing for MH susceptibility began in 1990 when a mutation in the *RYR-1* gene was shown to be causal for MH in pigs. In humans, several genes have been associated with MH, though the *RYR-1* gene is probably responsible for most cases. At present, 30 mutations in the *RYR-1* gene have been found in humans that are causal for MH–based on strict criteria related to in vitro calcium release or clinical MH in several generations and families. Unfortunately, no mutation accounts for more than a small percent of all patients with MH susceptibility. The chief advantage of genetic testing is that all that is required is a blood sample, and the specimen may be shipped to the laboratory. The main limitation of genetic testing is the sensitivity of approximately 30%. Undoubtedly, the sensitivity will improve as more mutations are identified and tested for their ability to alter the structure and function of the ryanodine receptor.

Patients should consider genetic testing if:

1. They have had a positive contracture test.
2. A family member has had a positive contracture test.
3. They have suffered a very likely MH episode but have not had a contracture test.
4. A family member has been found to have a causal mutation.

In those patients who are tested and a causal mutation identified, those with the mutation are MH susceptible (high specificity), but those without the mutation *cannot* be considered MH negative because they may harbor another mutation.

At present, there are two clinical testing laboratories for diagnosing MH susceptibility: PreventionGenetics (www.preventiongenetics.com) and the DNA diagnostic laboratory at the University of Pittsburgh (http://path.upmc.edu/divisions/mdx/diagnostics.html).

The decision to undergo genetic testing is complex because the test, although requiring only a blood sample, costs approximately $900 for the search for the most common mutations. Once a mutation is found, the cost for screening family members is $200 each. This compares to an approximate cost of $6,000 for the contracture test. The pros and cons of testing should be discussed with either a MH expert or a genetic counselor.

A.12. What is neuroleptic malignant syndrome?

The neuroleptic malignant syndrome is also a hypermetabolic syndrome characterized by hyperthermia, rigidity, rhabdomyolysis, acidosis, and tachycardia, features that mimic MH. However, neuroleptic MH is precipitated by a variety of neuroleptic drugs, including haloperidol, the atypical antipsychotics, phenothiazines, and other centrally acting drugs.

This syndrome differs from neuroleptic MH in that central dopamine depletion is responsible for the clinical picture. The mainstays of treatment are benzodiazepines and a dopamine agonist such as bromocriptine. Patients also respond symptomatically to dantrolene therapy. A recent report identified *RYR-1* mutations in a small percentage of patients manifesting neuroleptic MH. Perhaps many more also have these mutations.

A variety of drug-induced hyperthermic syndromes resemble MH such as the serotonin syndrome. The most common situation for the serotonin syndrome is the administration of meperidine in a patient on monoamine oxide inhibitor drugs.

Ecstasy and other methylenedioxymethamphetamine agonists also produce hyperthermia. Again, the signs may resemble MH, but the pathophysiology is very different.

Anesthesiologists may encounter neuroleptic MH in patients who are sedated with haloperidol in the intensive care unit and on infrequent occasions when patients are given dopamine agonist agents such as metoclopramide and promethazine.

B. Preoperative Evaluation and Preparation

B.1. How would you prepare this patient for anesthesia and surgery?

Preoperative preparation should include a detailed medical history, assessment of the patient's physical status, evaluation of laboratory findings including creatine kinase, and specific investigations to determine the susceptibility of the patient to MH. Three possible scenarios are as follows:

- The halothane caffeine contracture test result is normal. The patient should be considered not susceptible to MH, and the anesthetic should be nonrestrictive.
- The halothane caffeine contracture test is abnormal, implying MH susceptibility. Or, a mutation associated with MH is identified. In this case, trigger-free anesthetic agents should be employed and all preparations should be made to quickly treat the syndrome if it develops.
- The halothane caffeine contracture test is not available. This is very frequently the case because this test is done in only a few centers in the country. In such situations, the patient should be treated as MH syndrome and all appropriate steps should be followed.

Islander G, Ranklev-Twetman E. Evaluation of anaesthesia in malignant hyperthermia negative patients. *Acta Anaesthesiol Scand.* 1995;39:819–821.

Rosenberg H, Brandom BW, Sambuughin NK, et al. Malignant hyperthermia and other pharmacogenetic disorders. In: Barash P, Cullen B, Stoelting R, eds. *Clinical Anesthesia*. 6th ed. Philadelphia: Lippincott Williams & Wilkins; 2009:598–613.

B.2. Is dantrolene prophylaxis indicated?

If a nontriggering anesthetic is administered with appropriate monitoring to an MH–susceptible patient, dantrolene prophylaxis is not necessary.

With the judicious use of trigger-free anesthetics, MH is extremely unlikely. A very rare case or two have been reported of MH without trigger agents; nevertheless, because many syndromes may mimic it, it is not at all clear whether any of the cases were really MH.

Dantrolene can cause side effects, such as nausea, vomiting, pain at the injection site, and depression of the twitch response. In patients with pre-existing muscle weakness, dantrolene may cause respiratory insufficiency in the postoperative period.

Brandom BW, Larach GM, Chen Min-Shue A. Complications associated with the administration of Dantrolene 1987 to 2006: A Report from the North American Malignant Hyperthermia Registry of the Malignant Hyperthermia Association of the United States. *Anesth Analg.* 2011;112:1115–1123.

Lichtman AD, Oribabor C. Malignant hyperthermia following systematic warming after hypothermic cardiopulmonary bypass. *Anesth Analg.* 2006;102:372–375

B.3. What laboratory tests would you obtain before surgery?

Chest radiograph and electrocardiogram should be ordered if dictated by his scoliosis or other associated medical illness. Otherwise, there is no routine laboratory testing indicated for strabismus surgery in this child. Serum creatine kinase level is of value as a baseline test and should be obtained.

B.4. Is outpatient surgery appropriate for this patient?

With the use of trigger-free anesthetics and appropriate monitoring, surgery normally performed in an outpatient setting is acceptable. Postoperative admission to the hospital

solely on the basis of MH susceptibility is not warranted. When MH occurs, it is usually in the immediate postoperative period and usually not beyond 2 hours postoperatively. Therefore, it is prudent to keep the patient longer than usual in the postanesthesia care unit in a monitored setting and a little longer in the ambulatory discharge area.

All ambulatory surgery and office-based surgery settings should have a plan for managing MH and transferring the patient to a hospital.

Yentis SM, Levine MF, Hartley EJ. Should all children with suspected or confirmed malignant hyperthermia susceptibility be admitted after surgery? A 10-year review. *Anesth Analg*. 1992;75:345–350.

B.5. In anticipation of general anesthesia, what preparations would you make?

A satisfactory preparation for administering anesthesia to this patient should include measures to prevent and treat an acute crisis of MH. The following should be available:

Equipment

- Drain, remove, or disable vaporizers.
- Fresh circuit, reservoir bag, and soda lime. Flush machine and ventilator by flowing 10 L oxygen per minute for 10 minutes.
  - For newer anesthesia work stations, the washout period may be prolonged up to 60 minutes. The manufacturers' guidelines for machine preparation should be followed.
  - Activated charcoal filter placed on inspiratory and expiratory limb of the machine
- Routine American Society of Anesthesiologists monitors including:
  - Pulse oximeter
  - Capnometer
  - Core temperature monitor
  - electrocardiogram and blood pressure monitors

Items to have available:

Cooling aids

- Hypothermia blanket
- Crushed ice
- Cold saline for irrigation and intravenous infusion
- Nasogastric tube and Foley catheter for cavity cooling

Drugs

- Sodium bicarbonate, mannitol, furosemide, dantrolene (intravenous), sterile water, antiarrhythmics, insulin, 50% dextrose, and calcium chloride
- *Avoid* calcium channel blockers because of interaction with dantrolene, possibly resulting in cardiac arrest

C. Intraoperative Management

C.1. What anesthetic techniques and agents would you employ?

Potent inhalation agents and succinylcholine (excluding nitrous oxide) are to be avoided. If possible, local or regional anesthesia is preferred. Anesthesia may be induced with a barbiturate, benzodiazepine, or hypnotic agent and the patient ventilated with 100% oxygen. Fentanyl or other opioid may be added to ensure adequate depth of anesthesia. Topical anesthesia of the larynx and vocal cords may be achieved with a local anesthetic spray. The trachea is intubated with or without the use of a short-acting or intermediate-acting nondepolarizing muscle relaxant. Anesthetic maintenance is achieved using oxygen and nitrous oxide, an opioid, and a nondepolarizing relaxant as required. Total intravenous anesthesia is a good choice for anesthesia as well. Vital signs are monitored with very close attention to capnography.

C2. Should body (core) temperature be monitored during general anesthesia lasting more than a short time?

Definitely. Although temperature elevation is often not the first sign of MH, it is one of the common early signs of the syndrome. Therefore, core temperature, esophageal, axillary, rectal, urinary bladder, nasopharyngeal temperature should be monitored for all procedures lasting more than 30 minutes. In addition, temperature monitoring is also important in detecting hypothermia.

Larach MG, Gronert GA, Brandom BW, Lehman ED. Clinical Presentation, treatment and complications of malignant hyperthermia in North America from 1987–2006. *Anesth Analg*. 2011;112:1115–1123.

C.3. What anesthetic agents are contraindicated?

In general, the anesthetic agents to be avoided include potent inhalation agents and depolarizing muscle relaxants. Of the agents commonly employed today, the following have been implicated in triggering MH:

- Inhalation agents: halothane, enflurane, isoflurane, desflurane, and sevoflurane
- Muscle relaxants: succinylcholine

Fu ES, Scharf JE, Mangar D, et al. Malignant hyperthermia involving the administration of desflurane. *Can J Anaesth*. 1996;43:687–690.

C.4. If the surgeon wants to use local anesthesia for a procedure, what agents will you recommend?

Both ester and amide local anesthetics are now considered safe for use in patients with MH syndrome.

D'Ambrosia J, Adragna MG. Guidelines for the use of local anesthetics in the dental treatment of patients who are susceptible to malignant hyperthermia. *Spec Care Dentist*. 1988;8:61–63.

Maccani RM, Wedel DJ, Melton A, et al. Femoral and lateral femoral cutaneous nerve block for muscle biopsies in children. *Paediatr Anaesth.* 1995;5:223–227.

C.5. What is the significance of masseter muscle spasm occurring after succinylcholine administration?

Rigidity of the jaw muscles after administration of succinylcholine is referred to as *masseter muscle rigidity* (MMR) or trismus. MMR presages clinical MH in up to 30% of cases. Even in the absence of clinical MH, myoglobinuria following succinylcholine-induced MMR is common postoperatively. MMR probably occurs in individuals of all ages, though MMR is more common in children, particularly following gas anesthesia induction.

MMR has been reported in 1% of children after halothane or succinylcholine induction and in adults after succinylcholine administration. Should MMR occur, elective surgery should be postponed, the patient observed in an intensive care unit setting for 24 hours seeking myoglobinuria specifically. The patient should be followed until creatine kinase levels normalize.

In the case of emergency surgery, the anesthetic should be converted to a "non-trigger" technique and the patient observed for early signs of MH. Dantrolene and other treatment procedures for MH should be made ready.

The patient and/or family should be advised to be evaluated for MH susceptibility.

The incidence of MMR and MH episodes in children have recently decreased as a result of recommendations that the use of succinylcholine in children be reserved for emergency situations.

Other causes of succinylcholine-induced MMR include any form of myotonia or periodic paralysis.

C.6. Twenty minutes into the procedure with sevoflurane anesthesia, the patient developed increasing tachycardia with ventricular premature beats and mottled skin. What emergency measures would you take?

Although tachycardia may arise from other, more common causes, such as a light plane of anesthesia or hypovolemia, its association with dysrhythmia in this patient who has MH syndrome raises the suspicion that a MH crisis may be starting. End-expiratory carbon dioxide should be monitored, and if it is rising despite increasing minute ventilation, the diagnosis of MH should be strongly considered. Time is of the essence and this constitutes a critical emergency, so the following steps should be taken:

- Stop all anesthetics and surgery (if possible).
- Hyperventilate the patient with 100% oxygen.
  - Obtain help and assistance through the MH hotline of the Malignant Hyperthermia Association of the United States (MHAUS; 1-800-MH–HYPER).
- Administer specific drug therapy: Start dantrolene sodium early while muscle perfusion is still present. An initial intravenous dose of 2.5 mg per kg should be

followed by repeated doses of 1 to 2 mg per kg to a total of 10 mg per kg depending on the patient's response. More dantrolene may be administered if clinically indicated.

- Initiate aggressive cooling immediately for rapidly increasing temperatures and for those higher than 40° C. Methods for cooling include surface cooling with the patient on a cooling blanket and packed in ice; gastric, rectal, or peritoneal lavage with iced saline; and iced intravenous fluids (saline). Cooling should be stopped when the patient's temperature falls to lower than 38° C to prevent inadvertent hypothermia.
- Treat acidosis with sodium bicarbonate (2 mEq per kg initial dose and titrate as necessary).
- Treat hyperkalemia with hyperventilation, sodium bicarbonate, insulin, and 50% dextrose.
- Treat arrhythmias with standard antiarrhythmics, and avoid calcium channel blockers if dantrolene has been given.
- An arterial line and Foley catheter should be inserted in all cases of fulminant MH. Central venous catheterization should be considered for unstable patients or where aggressive therapy is needed.
- Maintain urine output with mannitol or furosemide.
- Follow creatine kinase levels every 12 hours.
- Check electrolytes and coagulation parameters.
- Register the patient and the event with the North American Malignant Hyperthermia Registry.

Forms may be obtained through MHAUS. The website for the North American Malignant Hyperthermia Registry is www.mhreg.org.

Ali SZ, Taguchi A, Rosenberg H. Malignant hyperthermia. *Best Pract Res Clin Anesthesiol.* 2003;17:519–533.

C.7. What modalities would you monitor closely during management of the crisis?

The modalities that should be monitored closely include the following:

- End-tidal carbon dioxide
- Arterial blood gases/electrolytes/coagulation
- Core temperature
  - Creatine kinase levels
  - Myoglobin levels: urine and serum
  - Urine output

C.8. What steps should be taken to avoid major morbidity from MH?

All sites where general anesthesia is administered should have 36 vials of dantrolene available within about 10 minutes.

All patients undergoing general anesthesia for more than 30 minutes should have core temperature monitored.

All operating rooms (OR) should have an MH drill each year. This drill should involve all OR personnel, going through the steps of alerting the team, obtaining dantrolene, mixing dantrolene, simulating blood draw, cooling the patient, and discussing the episode with family members.

In addition, nonhospital sites should ensure that a hospital is designated to receive a patient who is experiencing an MH episode. The facility should have a plan regarding who will accompany the patient and what drugs and monitors will accompany the

transport personnel. The local hospital personnel must ensure dantrolene is in stock, as well as be familiar with treating the syndrome.

D. Postoperative Management

D.1. What complications may follow this syndrome?

Disseminated intravascular coagulation syndrome is a major complication of MH, especially when the patient's temperature exceeds 41° C. Other complications include renal failure, hyperkalemia, and compartment syndrome. As a result of massive muscle breakdown, the patient may be weak for days and also complain of muscle cramps and pain.

Rosenberg H, Brandom BW, Sambuughin NK, et al. Malignant hyperthermia and other pharmacogenetic disorders. In: Barash P, Cullen B, Stoelting R, eds. *Clinical Anesthesia.* 6th ed. Philadelphia: Lippincott Williams & Wilkins; 2009:598–613.

D.2. What would be your follow-up in this case?

The vigorous therapy started in the OR should be continued in the immediate postoperative period into the postanesthesia care unit or the intensive care unit. Dantrolene administration should be continued for at least 36 hours after an episode is controlled at a dose of 1 mg per kg every 4 to 6 hours titrated to signs of MH. Serum creatine kinase should be followed until normalized.

Other laboratory values that should be followed until normalized include:

- Arterial blood gases
- Electrolytes
- Coagulation profile

Body temperature should be monitored along with other vital signs. Recrudescence of MH occurs in approximately 25% of treated cases; therefore, the patient should be watched in an intensive care unit setting for at least 36 hours following an episode.

Rosenberg H, Brandom BW, Sambuughin NK, et al. Malignant hyperthermia and other pharmacogenetic disorders. In: Barash P, Cullen B, Stoelting R, eds. *Clinical Anesthesia*. 6th ed. Philadelphia: Lippincott Williams & Wilkins; 2009:598–613.

D.3. What would you advise the patient and the family?

The patient and his family should be warned of the dangerous nature of this syndrome and should be advised to carry an identification band at all times. The pedigree of the family should be prepared, and the members should be investigated for susceptibility to this syndrome and issued medical identification bracelets or pendants accordingly.

The MHAUS has been active since 1981 and offers current information and advice on patient management as well as identification bracelets and a variety of materials for healthcare professionals. The following is some useful contact information:

Emergency hotline: 1-800-MH-HYPER
Address: MHAUS, 39 East State Street, P.O. Box 1609, Sherburne, NY 13815
Phone: 1-800-98-MHAUS
Internet: www.mhaus.org

In addition, the patient and his family should consult with one of the MH diagnostic centers to discuss further evaluation. A complete listing is available through MHAUS.

The patient should be registered with the North American Malignant Hyperthermia Registry.
Forms may be obtained through MHAUS.
The website for the North American MH Registry is www.mhreg.org
The phone number is (888) 274-7899
The Registry is located at the Children's Hospital of the University of Pittsburgh.
The director is Dr. Barbara Brandom.

D4. What precautions should an MH susceptible patient take out of the OR?

In general, MH–susceptible patients should be cognizant of their response to heat and exercise. As for any patient, excess exposure to heat and humidity, especially with exercise, should be limited or avoided. Although it is true that a few cases of what appears to be MH have been reported without anesthesia, these are very rare. At present, there is no way to predict which patients may have an adverse response to environmental conditions.

CHAPTER 54

Postoperative Residual Neuromuscular Weakness and Prolonged Apnea

David Kopman and Aaron F. Kopman

A HEALTHY 35-YEAR-OLD, 65-kg female was scheduled for an elective abdominal hysterectomy. Anesthesia was induced with propofol 2.0 mg/kg, fentanyl 2.0 μg/kg, and rocuronium 1.2 mg/kg. Anesthesia, which lasted 90 minutes, was maintained with desflurane 5.0% end-tidal and supplemented with fentanyl as needed. At the termination of surgery, residual neuromuscular block was not antagonized as the tidal volume was deemed to be adequate, and the train-of-four count (TOFC) using facial nerve stimulation was four with no detectable fade. Upon arrival in the postanesthesia care unit (PACU), the patient was tachypneic, had uncoordinated and floppy arm movements, and appeared to be agitated and in distress. Arterial oxygen saturation on room air was 89%.

A. Medical Diseases and Differential Diagnosis

1. What is the differential diagnosis for postoperative apnea?
2. How is residual neuromuscular block diagnosed?
3. Do all voluntary muscles respond similarly to nondepolarizing relaxants?
4. If this was an emergency surgery, anesthesia was induced with a rapid sequence technique including succinylcholine. The patient remained apneic not only throughout the procedure but also in the PACU. What was the possible diagnosis? How would you confirm it? How would you manage the patient?
5. What are acetylcholinesterase and serum cholinesterase?
6. What is the incidence of atypical cholinesterase activity?
7. What is the significance of the dibucaine number?
8. What are some factors that can lower pseudocholinesterase levels?
9. What are the side effects of succinylcholine?

B. Intraoperative Management

1. How is the choice among muscle relaxants made?
2. How much do individuals vary in their sensitivity to nondepolarizing relaxants?
3. What are the characteristics of nondepolarizing block?
4. What is a train-of-four (TOF) stimulus?
5. Why is the TOF ratio of clinical importance?
6. How do we define adequate recovery of neuromuscular function?
7. Are there useful and/or trustworthy clinical tests of neuromuscular recovery?
8. How accurate are subjective estimates of the TOF ratio?
9. What is double burst stimulation (DBS)?
10. What is a posttetanic count?
11. What function does the conventional peripheral nerve stimulator (PNS) serve?
12. How can the TOF ratio be measured quantitatively?
13. What are the limitations of anticholinesterase antagonists?
14. Is there anything wrong with administering neostigmine when the TOF count (TOFC) is less than 3?
15. Is reversal of residual block always necessary?
16. Is there any way to rapidly antagonize profound nondepolarizing block?

C. Postoperative Management

1. What is the incidence of residual neuromuscular block in the PACU?
2. Does undetected postoperative residual neuromuscular block have clinical consequences?

A. Medical Diseases and Differential Diagnosis

A.1. What is the differential diagnosis for postoperative apnea?

The differential diagnosis for postoperative apnea includes the following:

- Residual anesthetic agent
- Residual narcotic
- Residual muscle relaxant
- Hypocarbia
- Occurrence of some medical complication during anesthesia, such as stroke or embolism

Miller RD, ed. *Miller's Anesthesia.* 7th ed. Philadelphia: Elsevier Churchill Livingstone; 2010:2710–2711.

A.2. How is residual neuromuscular block diagnosed?

This patient showed clear signs of residual neuromuscular weakness upon arrival in the PACU. TOF stimulation at the ulnar nerve showed a TOFC of only 2 at the adductor pollicis (thumb). A provisional diagnosis of residual nondepolarizing block was made and the patient received neostigmine 0.05 mg/kg plus an appropriate dose of glycopyrrolate, 0.01 mg/kg. Seven minutes later, the TOFC was 4 with no evidence of fade on palpation of the thumb, and all signs of residual block had abated.

Miller RD, ed. *Miller's Anesthesia*. 7th ed. Philadelphia: Elsevier Churchill Livingstone; 2010:2710–2711.

A.3. Do all voluntary muscles respond similarly to nondepolarizing relaxants?

Although facial nerve stimulation is widely used by clinicians to judge the adequacy of block and recovery, this practice can be very misleading. At a time when the TOFC at the orbicularis oculi or corrugator supercilii muscles shows good recovery from nondepolarizing block, the response at the hand may be almost nonexistent. Thus, facial nerve stimulation may give the clinician a false sense of security about the adequacy of neuromuscular recovery at the end of a case.

Similarly, in the intubated patient breathing spontaneously, a normal tidal volume and maintenance of an acceptable P_{CO_2} do not necessarily indicate adequate neuromuscular recovery. The diaphragm is the first muscle to recover from nondepolarizing block and requires significantly higher plasma levels of relaxants to maintain paralysis. The muscles that protect the upper airway are far more sensitive to nondepolarizing relaxants.

Thus, a patient who may be able to maintain adequate respiratory exchange while intubated may experience complete airway obstruction when extubated.

Stiffel P, Hameroff SR, Blitt C, et al. Variability in assessment of neuromuscular blockade. *Anesthesiology*. 1980:52:436–437.

A.4. If this was an emergency surgery, anesthesia was induced with a rapid sequence technique including succinylcholine. The patient remained apneic not only throughout the procedure but also in the PACU. What was the possible diagnosis? How would you confirm it? How would you manage the patient?

The easiest possibility to exclude is residual neuromuscular block. In the above patient, stimulation of the ulnar nerve with a PNS resulted in no response of the muscles of the hand. Hence, the diagnosis of a prolonged response to succinylcholine was established. Extreme prolongation in succinylcholine's duration of effect is usually a manifestation of an atypical genotype. Following a 1.0 mg/kg dose of succinylcholine in patients homozygous for the most common atypical butyrylcholinesterase genotypes, apnea generally lasts upwards of an hour and it may take as much as 3 hours for adequate respiratory efforts to return. However, the duration of apnea is highly dependent on the butyrylcholinesterase variant in question and may be shorter or longer than the figures just cited.

Traditionally, identification of the human butyrylcholinesterase (BChE) variant has been performed by biochemical analysis. These tests, which have been used for decades, consist of the measurement of plasma cholinesterase activity with different substrates and of testing the degree of inhibition of this activity with a well-known inhibitor, such as dibucaine, fluoride, or R02-0683. These tests have identified multiple genes, which can reside at the same allelic site such as the atypical, silent, fluoride-resistant, J, K,

H, and Newfoundland variants. However, biochemical testing often leads to equivocal results. More recently, molecular biologic techniques have been applied to identifying a patient's exact genotype.

Once the diagnosis of an atypical response to succinylcholine is ascertained, treatment is entirely supportive and symptomatic. Since the duration of residual block is hard to predict, the patient should remain intubated, artificially ventilated, and sedated. Only after a strong, sustained response to indirect tetanic stimulation at the wrist can be demonstrated should sedation be terminated and an attempt made to wean the patient off controlled ventilation. Patients recovering from prolonged succinylcholine-induced block usually exhibit a "dual" or "phase II" block during recovery (fade on repetitive stimulation). While neostigmine or edrophonium can under certain circumstances antagonize this block, this approach is risky when dealing with prolonged succinylcholine apnea. If significant plasma levels of succinylcholine are still present, the administration of an acetylcholinesterase may be counterproductive.

The patient should obviously be informed that he or she had a prolonged episode of muscular weakness, and that the presumptive cause was an atypical reaction to succinylcholine. The patient should be urged to have this diagnosis confirmed and he or she should be directed to an appropriate laboratory. If an atypical genotype is confirmed, he or she should encourage his or her family members to be tested as well. Finally, the patient should be assured that this diagnosis has no adverse health consequences, but that in the future when surgery is planned, his or her anesthesiologist needs to be informed of this diagnosis.

A.5. What are acetylcholinesterase and serum cholinesterase?

Acetylcholinesterase is a relatively specific enzyme that hydrolyzes acetylcholine (ACh) faster than it does other choline esters. It is found in red blood cells, the central nervous system, and the neuromuscular junction. It is responsible for hydrolyzing and inactivating the ACh produced during normal neuromuscular transmission. It does not hydrolyze succinylcholine and is inhibited by the drug.

Serum cholinesterase, also called *cholinesterase, pseudocholinesterase, butyrylcholinesterase(BChE),* and *nonspecific cholinesterase,* hydrolyzes many choline esters, including succinylcholine. It is found in many human tissues, but not in the red blood cell. It is synthesized in the liver. Its physiologic function is unknown, but it may hydrolyze choline esters, such as propionylcholine and butyrylcholine, which may be formed by bacterial action in the gut and by the enzyme systems responsible for the formation of ACh.

Taylor P, Schumacher M, MacPhee-Quingley K, et al. The structure of acetylcholinesterase: relationship to its function and cellular disposition. *Trends Neurosci*. 1987;10:93.

A.6. What is the incidence of atypical cholinesterase activity?

The incidence of atypical cholinesterase activity varies with the population studied, but it is approximately 1 of 2,800 in the general population of the United States, with a 1:1 male/female ratio.

Kalow W, Genest K. A method for detection of atypical forms of human serum cholinesterase: determination of dibucaine numbers. *Can J Biochem*. 1957;35:339.

Miller RD, ed. *Miller's Anesthesia*. 7th ed. Philadelphia: Elsevier Churchill Livingstone; 2010:863–864.

A.7. What is the significance of the dibucaine number?

The dibucaine number is used to identify the heterozygote. Dibucaine in 10^{-5} mol per L concentration produces the maximum difference in inhibition between the usual and the atypical forms of serum cholinesterase. The term *dibucaine number* has been applied to the percentage of inhibition of serum cholinesterase. The usual homozygote has a dibucaine number of approximately 80, the atypical homozygote has a value less than 30, and the heterozygote has a value between 45 and 69. The relation between the dibucaine number and the duration of succinylcholine neuromuscular blockade is shown in Table 54.1.

A.8. What are some factors that can lower pseudocholinesterase levels?

Reduced pseudocholinesterase activity may be associated with:

- Abnormal genotype
- Normal physiologic variation (e.g., pregnancy). However, until BChE activity is reduced to <30% of normal, only modest increases in the duration of succinylcholine are to be expected.
- Liver disease
- Malnutrition
- End-stage renal disease
- Burns
- Plasmapharesis
- Noncompetitive cholinesterase inhibitors (e.g., pesticides, certain nerve gases)
- Competitive cholinesterase inhibitors (e.g., neostigmine)

Table 54.1 Relation between Dibucaine Number and Duration of Succinylcholine Neuromuscular Blockade

TYPE OF PSEUDOCHOLINESTERASE	GENOTYPE	FREQUENCY	DIBUCAINE NUMBER[a]	RESPONSE TO SUCCINYLCHOLINE OR MIVACURIUM
Homozygous typical	EuEu	Normal	70–80	Normal
Heterozygous	EuEa	1/480	50–60	Slightly prolonged
Homozygous atypical	EaEa	1/3,200	20–30	Markedly prolonged

[a]The dibucaine number indicates the percentage of enzyme inhibited.

These include liver disease, advanced age, malnutrition, pregnancy, burns, oral contraceptives, monoamine oxidase inhibitors, echothiophate, cytotoxic drugs, neoplastic disease, anticholinesterase drugs, tetrahydroaminacrine, hexafluorenium, and metoclopramide.

A.9. What are the side effects of succinylcholine?

The most common untoward side effect seen after succinylcholine administration is muscle pain occurring in the first 24 to 48 hours postoperatively. Women and patients undergoing ambulatory surgery appear most susceptible to this phenomenon. The reported incidence of succinylcholine-induced myalgia is quite variable but probably occurs in 25% to 50% of patients. Discomfort is typically characterized as being similar to the muscle soreness that occurs after heavy or unusual exercise. It has been postulated that the etiology of the phenomenon is related to muscle damage caused by asynchronous contractions during the initial muscle depolarization that precedes paralysis. Defasciculating doses of nondepolarizing relaxants (10% of the ED95) given 2 to 5 minutes prior to succinylcholine have been shown to reduce the incidence of myalgia by as much as 50%. Pretreatment with nonsteroidal anti-inflammatory drugs have also been shown to reduce the incidence of muscle pain following succinylcholine administration.

Succinylcholine may also be associated with various cardiac dysrhythmias including bradycardia, tachycardia, and junctional and ventricular dysrhythmias. Stimulation of nicotinic receptors at sympathetic and parasympathetic ganglion and muscarinic receptors at the sinus node are believed to be involved in this phenomenon. Infants and children may be more likely to manifest clinically significant bradycardia following succinylcholine administration secondary to their relatively high degree of resting vagal tone as compared to adults. Pretreatment with atropine is effective in preventing succinylcholine-induced bradycardia and is recommended when succinylcholine is to be used in this patient population. Sinus bradycardia in adults is more commonly seen when a second dose of succinylcholine is given approximately 5 minutes after the first. Pretreatment with atropine can prevent this as well. Junctional rhythms following succinylcholine administration are also relatively common. The postulated mechanism

of action is muscarinic stimulation of the sinus node that results in diminished sinus activity and the subsequent emergence of the atrioventricular node as the dominant pacemaker. Various mechanisms have been postulated to explain ventricular dysrhythmias that sometimes occur after succinylcholine administration including potassium release from skeletal muscle, succinylcholine-mediated sensitivity to catecholamines, and profound sinus and atrioventricular node slowing.

The most serious complication associated with succinylcholine administration is severe and potentially lethal levels of hyperkalemia in at-risk individuals. When succinylcholine is administered to an otherwise healthy patient during the induction of anesthesia, plasma potassium levels typically increase by <0.5 mEq/L as potassium ions move from the intracellular to extracellular space. The increase is transient and is typically tolerated well by most patients. In at-risk patients, however, the efflux of potassium from the intracellular space can be in excess of 3.5 mEq/L, enough to induce malignant dysrhythmias and cardiac arrest. The list of susceptible patients includes those with congenital muscular dystrophies, upper or lower motor neuron defects, prolonged chemical denervation (e.g., muscle relaxants, magnesium, clostridial toxins), direct muscle trauma or inflammation, extensive burns, and disuse atrophy. In the event that succinylcholine is inadvertently given to an at-risk patient and an exaggerated hyperkalemic response is suspected, prompt treatment with calcium chloride (1 to 2 g), hyperventilation, sodium bicarbonate (1 mEq/kg), regular insulin, and dextrose should be initiated to prevent severe dysrhythmias and cardiac arrest.

Succinylcholine also causes increases in intraocular, intragastric, and intracranial pressures (ICP). The increase in intraocular pressure caused by succinylcholine begins rapidly after drug administration. Peak pressures may rise as much as 5 to 15 mm Hg before returning to baseline levels about 6 minutes after drug dosing. The etiology of this phenomenon is unclear, but detachment of the intraocular muscles from the globe fails to prevent the pressure rise, which is suggestive of an intraocular mechanism. It has been suggested that succinylcholine use should be avoided in the setting of open-eye injuries, although there is scant evidence that its administration has led to extrusion of intraocular contents or blindness.

The increase in intragastric pressure caused by succinylcholine is likely related to fasciculations of the abdominal skeletal musculature. A defasciculating dose of a nondepolarizing muscle relaxant given prior to succinylcholine administration can prevent any increase in intragastric pressure.

Succinylcholine can also cause a transient increase in ICP. The increase in ICP after succinylcholine administration correlates with muscle fasciculations, increased electroencephalogram activity, and elevated cerebral blood flow. Prior administration of a nondepolarizing muscle relaxant can attenuate or even prevent this pressure increase. The use of succinylcholine in the setting of intracranial hypertension is probably best limited to emergency situations where the benefits of rapid airway control outweigh the risks of a transient increase in ICP.

Lastly, it should be remembered that succinylcholine is a potent trigger of malignant hyperthermia. Its use should be restricted to settings where prompt recognition and treatment of malignant hyperthermia are possible.

B. Intraoperative Management

B.1. How is the choice among muscle relaxants made?

A muscle relaxant can be chosen based on onset characteristics, duration of action, and method of metabolism (Table 54.2). Muscle relaxants can be characterized as short, intermediate, and long duration. Metabolism may or may not be dependent on liver and kidney function.

B.2. How much do individuals vary in their sensitivity to nondepolarizing relaxants?

In any group of healthy patients, there exists a wide variability in the sensitivity to the effects of neuromuscular blocking agents (NMBA). The potency of these drugs is expressed as the agent's ED_{50} or ED_{95} (the dose that will produce 50% or 95% depression of a single twitch [T1] in an average individual). The coefficient of variation (the standard deviation as a percentage of the mean value) for the ED_{95} of most agents approximates 20% to 25%. Thus, if the ED_{95} for drug X is 1.0 mg/kg, in 5% of normal individuals, the ED_{95} may be <0.60 mg/kg. Because of the shape of the dose-response curve of nondepolarizing relaxants, this modest difference in drug requirement may have large consequences with regard to the depth of block. In these individuals, a plasma level that produces only 50% block of T1 in the average subject may produce >90% instead.

Similarly, the duration of effect of administered relaxants is quite variable. For example: Following a 1.2 mg/kg dose, the clinical duration of rocuronium (time to 25% T1 recovery) in a sample size of only 12 averaged 67 minutes; however, the range in responses went from 39 to 118 minutes.

Following a dose 2 × the ED_{95} of a blocker of intermediate duration (e.g., vecuronium), 30% of individuals will still need pharmacologic antagonism 2 hours later.

In the aged or in patients with renal or hepatic disease, this variability is even more pronounced. This is especially true of aminosteroid blockers such as vecuronium or rocuronium when compared with atracurium or cisatracurium.

B.3. What are the characteristics of nondepolarizing block?

The distinguishing feature of nondepolarizing block is fade on repetitive stimulation. For example, consider a situation in which the amplitude of twitch height (T1) is

Table 54.2 Characteristics of Commonly Used Muscle Relaxants

DRUG	ED_{95} UNDER N_2O/O_2 (mg/kg)	DOSE FOR INTUBATION (mg/kg)	INTUBATION TIME (sec)	CLINICAL DURATION (min)	METABOLISM (%)	ELIMINATION	
						KIDNEY (%)	LIVER (%)
Ultrashort acting							
Succinylcholine	0.5	1.0	60	5–10	Plasma cholinesterase (98–99)	<2	0
Short acting

From Miller RD, ed. *Miller's Anesthesia.* 7th ed. Philadelphia: Elsevier Churchill Livingstone; 2010:872–880.

reduced by 50% with a nondepolarizing blocker when stimuli are delivered at 0.10 Hz (1 every 10 seconds). If the rate of stimulation is increased to 1 Hz, the height of T1 may fall to <20% of control, and at 2 Hz to about 10% of control. This fade is most easily appreciated subjectively when tetanic stimuli (rates ≥30 Hz) are delivered.

Lee C, Katz RL. Fade of neurally evoked compound electromyogram during neuromuscular block by d-tubocurarine. *Anesth Analg.* 1977;56:271–275.

B.4. What is a train-of-four (TOF) stimulus?

A "train-of-four" consists of four stimuli delivered at half-second intervals (2 Hz). The TOF ratio is the height of the fourth indirectly elicited response divided by the amplitude of the first response. This ratio in unparalyzed individuals normally approximates a value of 1.0 when measured by mechanomyography (MMG), electromyography (EMG), or kinemyography but may exceed a value of 1.10 when measured by acceleromyography (AMG) (see below). As the depth of block increases, this ratio becomes smaller and eventually the fourth, then the third, and so on responses "drop out." If only two responses to a TOF stimulus are present, we speak of a TOFC of 2.

Ali HH, Utting JE, Gray TC. Stimulus frequency in the detection of neuromuscular block in man. *Br J Anaesth.* 1970;42:967–978.

B.5. Why is the TOF ratio of clinical importance?

The TOF fade is a far more sensitive index of residual block than singletwitch depression. In addition, the TOF ratio is useful because each TOF sequence serves as its own control. It is not necessary to know the amplitude of the evoked response prior to relaxant administration, or to worry about baseline drift over time.

Traditionally, the TOF ratio is measured at the hand by noting the response of thumb adduction. While clinicians are much more interested in the neuromuscular function of the diaphragm, masseter, and laryngeal adductors, correlations with adductor pollicis muscle function have over time served as useful clinical surrogates for the muscles we really care about.

Ali HH, Utting JE, Gray TC. Quantitative assessment of residual antidepolarizing block. I. *Br J Anaesth.* 1971;43:473–477.

Kopman AF. Surrogate endpoints and neuromuscular recovery. *Anesthesiology.* 1997;87:1029–1031.

B.6. How do we define adequate recovery of neuromuscular function?

Once the TOF ratio at the adductor pollicis has recovered to a value of 0.70, tests of mechanical respiratory reserve such as vital capacity and peak expiratory flow rate have usually recovered to within 90% of control. At a TOF value of 0.70, recovery of single twitch to control height and a sustained response to tetanic stimulation at 50 Hz for 5 seconds is usually present.

The studies done in the 1970s thus suggested that a TOF ratio of 0.70 was synonymous with adequate neuromuscular recovery and this was the accepted standard for the next two decades. However, by the late 1990s, this assumption was questioned. Work in awake volunteers demonstrated that at a TOF ratio of 0.70, grip strength was decreased by more than 40%. At a TOF ratio of 0.70, the vast majority of subjects had

difficulty apposing their incisor teeth and could not sip water from a straw because they could not make a tight seal around the straw with their lips. All individuals had double vision at TOF ratio <0.90. It was clear that these health volunteers were not "street ready" until their TOF ratios reached or exceeded a value of 0.90. In addition, other volunteer studies revealed even more alarming data. At a TOF ratio of 0.70, there is a decreased response in the ventilatory response to hypoxia (via a mechanism at the carotid body), and the swallowing mechanism becomes disorganized. Partial paralysis (a TOF of 0.70) causes pharyngeal dysfunction and increased risk for aspiration at mechanical adductor pollicis TOF ratios <0.90. Pharyngeal function is not normalized until an adductor pollicis TOF ratio of >0.90 is reached. Thus, the current standard for adequate neuromuscular recovery is a TOF ratio of 0.90 or better.

B.7. Are there useful and/or trustworthy clinical tests of neuromuscular recovery?

The first commercially available PNS did not appear until the mid-1960s, and units capable of delivering TOF stimuli did not arrive for another decade. Even today, devices that can quantify or measure the TOF ratio in real time are not widely distributed. Thus, clinicians have been reluctant to abandon clinical tests of neuromuscular recovery first suggested half a century ago: tidal volume, negative inspiratory force, grip strength, the 5-second head lift, the ability to protrude the tongue and so on. Unfortunately, most of these tests share one fundamental weakness. They require an awake and cooperative patient. Ideally, we would like to know the state of neuromuscular recovery prior to awakening the patient and certainly prior to tracheal extubation.

The most widely cited test (the 5-second head lift) is clearly not a sensitive test of residual block. At a TOF ratio of 0.50, the majority of patients may still pass this test.

Other widely mentioned tests are no better and may actually be very misleading. Traditional "bedside" tests of residual muscle weakness lack sensitivity and must be considered unreliable.

B.8. How accurate are subjective estimates of the TOF ratio?

Unfortunately, visual or tactile estimations of the TOF ratio are notoriously inaccurate. Once the TOF ratio exceeds a value of 0.40 to 0.50, a majority of experienced anesthetists are unable to detect the presence of any fade at all. Thus, failure to detect fade made indicate a true value anywhere from 0.50 to 1.0. Accurate assessment of the TOF ratio requires an objective or quantitative monitor (see later in this chapter).

Viby-Mogensen J, Jensen NH, Engbaek J, et al. Tactile and visual evaluation of the response to train-of-four nerve stimulation. *Anesthesiology.* 1985;63:440–443.

B.9. What is double burst stimulation (DBS)?

Because of the limitations in subjective interpretation of TOF fade, other patterns of stimulation have been investigated. A somewhat more sensitive test is the response to DBS. This sequence consists of a very brief tetanic pulse (3 stimuli at 50 Hz), and a 0.75-second pause followed by another brief tetanus. This is felt by the observer as two strong twitches. Most observers lose the ability to detect DBS fade at a TOF ratio of about 0.60.

Engæk J, Østergaard D, Viby-Mogensen J. Double burst stimulation (DBS): a new pattern of nerve stimulation to identify residual neuromuscular block. *Br J Anaesth.* 1989;62:274–278.

B.10. What is a posttetanic count?

As the level of neuromuscular block is progressively deepened, the TOFC eventually falls to zero. No response to TOF stimulation can be elicited. Because posttetanic potentiation is a prominent feature of nondepolarizing block, it is still possible, however, to get additional information about the depth of block. The following sequence is employed: a 5-sec 50-Hz tetanus, a 3-second pause, then 20 stimuli at 1 Hz. The number of responses elicited is referred to as the posttetanic count. Generally, when the count approximates a value of 10, the first response to TOF stimulation appears.

Viby-Mogensen J, Howardy-Hansen P, Chraemmer-Jørgensen B, et al. Posttetanic Count (PTC): a new method of evaluating an intense nondepolarizing block. *Anesthesiology.* 1981;55:458–461.

B.11. What function does the conventional peripheral nerve stimulator (PNS) serve?

Since subjective estimates of the TOF ratio are so unreliable, one may ask whether intra-operative TOF stimulation serve any purpose. The answer is a resounding yes. The TOFC (the number of evoked responses at the thumb that can be detected) gives a useful estimate of the depth of neuromuscular block. A rough rule of thumb (no pun) follows: A TOFC of 1 equals T1 5% recovery, TOFC of 2 = 15% recovery, TOFC of 3 = 25% recovery, TOFC of 4 (with fade) ≧ 35% recovery. This information allows the clinician to judge the need for additional increments of blocking drug and the point in time when antagonism of residual block with an anticholinesterase is likely to be effective.

Kopman AF. Tactile evaluation of TOF count as an indicator of reliability of antagonism from vecuronium or atracurium-induced neuromuscular blockade. *Anesthesiology*. 1991;75:588–593.

B.12. How can the TOF ratio be measured quantitatively?

Prior to the current decade, the vast bulk of clinical research on neuromuscular function was done by measuring either evoked mechanical force (MMG) or summated electrical action potentials (EMG) at the adductor pollicis. While these techniques represent gold standards for reliability, they are unfortunately cumbersome to use in daily practice. In addition, at present, there are no commercially available MMG or EMG monitors designed for use in the operating room. However, using a different method of measurement (AMG), it is now possible to obtain a real-time display of the TOF ratio using a small handheld device,[1] which is relatively easy to set up and has a user-friendly interface. The rationale for AMG is based on Newton's second law of motion that states that force is equal to mass times acceleration. Presumably, the mass of the thumb remains constant so that the acceleration is directly proportional to force. For measurement of acceleration, a piezoelectric ceramic wafer is fixed to the thumb. When an evoked mechanical response of the thumb is elicited, an electrical signal proportional to the acceleration is generated in the ceramic transducer. This signal can then be digitized, processed, and electronically displayed in real time. Thus, it is now finally possible for the clinician to accurately and easily determine the extent of neuromuscular block (the TOF ratio) in real time. An excellent review of the pros, cons, and limitations of AMG may be found in the following reference:

Claudius C, Viby-Mogensen J. Acceleromyography for use in scientific and clinical practice: a systematic review of the evidence. *Anesthesiology*. 2008;108:1117–1140.

B.13. What are the limitations of anticholinesterase antagonists?

Nondepolarizing neuromuscular block is competitive in nature. Molecules of an NMBA compete with molecules of Ach for access to nicotinic binding sites or receptors at the myoneural junction. The NMBA-receptor or Ach-receptor binding is very evanescent in duration (msec). Thus, the relative concentration of NMBA versus Ach determines which molecule is most likely to succeed in the contest for receptor access. Anticholinesterases such as neostigmine affect antagonism by preventing Ach degradation and thus increasing the concentration of Ach in the synaptic cleft. However, there is a ceiling to this effect. Once the cholinesterase enzyme is completely inhibited, the addition of additional neostigmine or edrophonium will have no further effect. In contrast, there is no limit to the concentration of NMBA that may exist at the receptor if excessive doses of relaxant are administered. In practical terms, the maximum depth of block that can be rapidly antagonized by anticholinesterases approximately corresponds to the reappearance of the fourth response to TOF stimulation. To achieve rapid (within 10 minutes) reversal to a TOF ratio of 0.7 in more than 87% of patients, three or four tactile responses should be present at the time of neostigmine administration. It was not possible within 30 minutes to achieve a TOF ratio of 0.9 in all patients, regardless of the number of tactile responses present at neostigmine administration.

[1]The TOF-Watch Monitor (Organon Teknika B.V., Boxtel, The Netherlands).

Beemer GH, Goonetilleke PH, Bkorksten AR, et al. The maximum depth of an atracurium neuromuscular block antagonized by edrophonium to effect adequate recovery. *Anesthesiology*. 1995;82:852–858.

Kirkegaard H, Heier T, Caldwell JE. Efficacy of tactile-guided reversal from cisatracurium-induced neuromuscular block. *Anesthesiology*. 2002;96:45–50.

B.14. Is there anything wrong with administering neostigmine when the TOF count (TOFC) is less than 3?

As noted previously, when the TOFC is only 1 or 2, anticholinesterases cannot be counted on to achieve satisfactory reversal in a timely manner. The peak effect of the antagonist is followed by a plateau phase that represents the balance between diminishing anticholinesterase activity and spontaneous recovery. The latter becomes the major determinant at profound levels of neuromuscular block. However, even at a TOFC of 1 to 2, it may be possible to achieve a TOF ratio >0.40 within 10 minutes. The problem for the clinician is that further recovery may be quite slow, and unless an objective monitor of neuromuscular function is being used, the clinician is likely to have the false impression that adequate recovery has been achieved.

Kopman AF, Kopman DJ, Ng J, et al. Antagonism of profound cisatracurium and rocuronium block: the role of objective assessment of neuromuscular function. *J Clin Anesth*. 2005;17:30–35.

B.15. Is reversal of residual block always necessary?

If a quantitative monitor of neuromuscular function is used, the answer to this question is simple. If the TOF ratio approximates a value of 0.90 or better, anticholinesterase administration is pointless and is best avoided. Neostigmine, edrophonium, atropine, and so on all have their own side effects and should not be administered unnecessarily. Similarly, if the TOFC is less than 4 or 4 with obvious fade, then anticholinesterase administration is indicated. However, objective monitors are still not widely available. What should be done when the TOFC is 4 with no detectable fade?

Many clinicians base the decision of whether to reverse or not on the time interval since the last dose of relaxant. Unfortunately, this is often an unreliable way to proceed. Two hours after a single dose on an intermediate-duration blocker, 30% of individuals may have TOF ratios <0.90 and 10% will still not have returned to a value of 0.70.

Therefore, in the absence of objective evidence that the TOF ratio is >0.85 to 0.90, an antagonist should be administered. However, when no fade to TOF stimulation can be subjectively detected, the dose of neostigmine can be safely reduced to only 0.02 mg/kg.

Caldwell JE. Reversal of residual neuromuscular block with neotigmine at one to four hours after a single intubating dose of vecuronium. *Anesth Analg*. 1995;80:1168–1174.

Fuchs-Buder T, Meistelman C, Alla F, et al. Antagonism of low degrees of atracurium-induced neuromuscular blockade. Dose-effect relationships for neostigmine. *Anesthesiology*. 2010;112:34–40.

B.16. Is there any way to rapidly antagonize profound nondepolarizing block?

Until recently, the answer to this question was no. A radically new approach to reversal now presents itself with the introduction of sugammadex. At the moment

(July, 2010), this drug is available in Europe and Japan but not yet in North America. Sugammadex is a gamma-cyclodextrin. It acts by strongly binding with monoquaternary amino-steroid blocking agents (rocuronium and vecuronium) and thus lowers the free plasma concentrations of these drugs, allowing the agents to diffuse away from the myoneural junction. (Note: sugammadex is not an effective antagonist of benzylisoquinoliniumbased relaxants such as cisatracurium.) To give just one example of its efficacy, rocuronium is given in a dose of 1.2 mg/kg. Five minutes later, sugammadex 12 mg/kg is administered. In less than 2 minutes, the TOF ratio returned to a value of 0.90.

Another line of attack to the problem of antagonizing deep neuromuscular block is to design a relaxant that can be chemically degraded at will in vivo. A still experimental nondepolarizing blocker of intermediate duration (CW002) is a good example of this approach. The drug is a benzylisoquinolinium fumarate diester and is inactivated by L-cysteine. In dogs, L-cysteine decreased the duration of action from 70 minutes to less than 5 minutes.

C. Postoperative Management

C.1. What is the incidence of residual neuromuscular block in the PACU?

Numerous reports since 2000 make clear that even with agents of intermediate duration, undetected residual weakness in the postoperative period is not a rare event. Large studies from Europe where routine reversal with cholinesterase inhibitors were not administered, 20% to 40% of patients arrived in their PACU with TOF values <0.70.

As might be expected, when a TOF ratio of 0.90 is set as the standard of adequate antagonism, the incidence of post-operative residual neuromuscular block (PORB) approaches 40%. The incidence of PORB is highly variable from institution to institution and very dependent on individual practice patterns. Diligent intraoperative monitoring and routine antagonism of residual block can result in dramatic reductions in the incidence of PORB. In a study from France, between 1995 and 2004, quantitative measurement and reversal of neuromuscular block in the operating room of one institution increased from 2% to 60% and from 6% to 42%, respectively. During the same time, the incidence of residual neuromuscular block defined as a TOF ratio less than 0.9 decreased from 62% to 3%.

Unfortunately, the lessons vividly demonstrated by these authors are far from universally understood or applied. A recent survey of North American and European clinical practices indicates that even in the year 2009, 10% of clinicians rarely or never monitor neuromuscular function with even the simplest of PNS, and the routine administration of antagonists is even less common.

C.2. Does undetected postoperative residual neuromuscular block have clinical consequences?

In North America WNI-YAO in excess of 20 million patients each year receive an anesthetic. The size of the subgroup that receives a nondepolarizing blocking agent is unknown but obviously still numbers in the millions. As indicated previously, the exact incidence of PORB probably varies greatly from institution to institution; nonetheless, even if it is as low as 5% overall (highly optimistic), the number of individuals who arrive in the PACU with suboptimal neuromuscular recovery is substantial. Nevertheless, outcome studies that suggest that this a major public health risk are few and far between, and few clinicians perceive residual block as an important safety issue. In truth, the majority of patients who arrive in the PACU with TOF ratios <0.90 do not experience complications. However, not all individuals are so fortunate. Undetected PORB is clearly associated with potentially adverse respiratory events and increased morbidity. A recent prospective case controlled study of critical respiratory events (episodes of hypoxia, signs of airway obstruction, need for reintubation, etc.) in a university hospital's PACU is instructive. Sixty-one patients with critical respiratory events were identified. Their mean TOF ratio as measured by AMG was 0.62. The TOF value in 42 matched controls was 0.98. The same authors in a separate study were also able to demonstrate a lower frequency of residual neuromuscular blockade in the PACU (4.5%) (TOF ratio ≤ 0.9) in cases where intraoperative AMG was employed compared with the cases where conventional PNS were used (30%). During transport to the PACU, fewer AMG patients developed arterial oxygen saturation values, measured by pulse oximetry, of less than 90% (0%) or airway obstruction (0%) compared with subjective monitoring (21.1% and 11.1%, respectively). The incidence, severity, and duration of hypoxemic events during the first 30 minutes of PACU admission were less in the AMG group (all $P < .0001$). These findings add credence to the hypothesis that incomplete neuromuscular recovery is an important contributing factor in the development of adverse respiratory events in the PACU.

CHAPTER 55

Burns

Michael Tjeuw

A 45-YEAR-OLD MAN

who was smoking in bed sustained 40% second- and third-degree burns over his face, neck, chest, and upper extremities. He had a history of hypertension, angina, and angioplasty of the right coronary artery 1 year ago. He has smoked three packs of cigarettes per day for 20 years and he drinks alcohol daily. He is scheduled for tangential excision of eschar on the third day. Blood pressure, 190/100 mm Hg; heart rate, 120 beats per minute; and weight, 110 kg.

A. Medical Disease and Differential Diagnosis

1. How do you classify the burn injury?
2. How do you express the extent of the burn injury?
3. Should the "rule of nines" be used in children?
4. What is the definition of a major burn according to the American Burn Association?
5. What functions does the skin perform?
6. What pathophysiologic changes accompany major thermal injury?
7. Name some of the known mediators released with thermal injury. What are the responses to those mediators?
8. What is the prognosis for this patient? What major factors affect his prognosis?
9. What are the most common causes of death?
10. Does this patient have a smoke inhalation burn? How do you make the diagnosis?
11. Could you name some of the chemical products of combustion?
12. What is carbon monoxide poisoning? How do you treat carbon monoxide poisoning?
13. What resuscitative measure would you institute immediately in this patient with 40% burns?
14. What fluid formula would you use?
15. What cardiovascular changes typify the burn injury?
16. Is the immune system affected in burn injury? How?

17. What hematologic changes occur in burn injury?
18. What changes occur in liver function? What are the anesthetic implications of such changes?
19. What are Curling ulcers? How can they be prevented?
20. What complications are associated with electrical burns?

B. Preoperative Evaluation and Preparation

1. What preoperative preparations would you order? What are particular concerns in this patient?
2. What are the various operative and management options available for severely burned patients?
3. What is tangential excision split-thickness skin graft (TE/STSG)? What are the principles of this grafting technique?
4. What are the advantages and disadvantages of early TE/STSG?
5. What is this patient's mean arterial blood pressure? How do you calculate it?
6. Are you concerned about this patient's blood pressure? What treatment would you institute?
7. This patient was ventilated with respirator settings of tidal volume 800 mL; respiratory rate, 20 breaths per minute; F_{IO_2}, 60%; and positive end-expiratory pressure, 10 cm H_2O. Arterial blood gas analyses showed the following: pH, 7.25; P_{O_2}, 56 mm Hg; P_{CO_2}, 60 mm Hg; and O_2 saturation, 80%. How would you interpret these arterial blood gas analysis results? What are the possible causes of high P_{CO_2} and low P_{O_2}?
8. How do you calculate oxygen content and oxygen delivery? What factors govern the oxygen delivery to the tissues? What are the causes of tissue hypoxia?
9. What are the symptoms and signs of alcohol withdrawal? Are you concerned that this patient could develop delirium tremens?
10. How would you prevent the adverse effects of alcohol withdrawal?

C. Intraoperative Management

1. What monitors would you use in the operating room?
2. What information can be obtained from an arterial line and a pulmonary artery catheter? How are these calculations performed?
3. If the patient had not been intubated, how would you proceed with the anesthetic induction?
4. Why is awake intubation considered the safest?
5. What anesthetic agents would you use? Discuss inhalation versus intravenous agents.
6. Why are you concerned about the patient's body temperature? What is normothermia for a burned patient?
7. How is temperature best maintained?
8. What derangements occur with hypothermia?
9. What muscle relaxant would you use?
10. Why is succinylcholine contraindicated in burned patients? For how long should it be avoided?
11. What other adverse effects are associated with succinylcholine?
12. How are the doses of nondepolarizing muscle relaxants affected by burn injury?
13. How are the muscle relaxants such as succinylcholine, atracurium, cisatracurium, vecuronium, pancuronium, rocuronium, and curare metabolized and eliminated? Which of them has significant histamine release?
14. What is the difference between metabolism and elimination of drugs?

D. Postoperative Management

1. How would you monitor this patient during transport?
2. What is meant by diffusion hypoxia? How do you prevent it?
3. Why do patients often shiver in the recovery room on emergence from anesthesia?
4. Discuss the causes of oliguria in the recovery room.

A. Medical Disease and Differential Diagnosis

A.1. How do you classify the burn injury?

Burns are classified as first, second, or third degree. First-degree, or superficial, burns are characterized by simple erythema of the skin, with only microscopic destruction of superficial layers of the epidermis. Second-degree, or partial-thickness, burns extend through the epidermis into the dermis. Even when most of the epithelium is destroyed, regeneration may occur from epithelial cells surrounding hair follicles or sweat glands. Third-degree, or full-thickness, burns are characterized by total, irreversible destruction of all the skin, dermal appendages, and epithelial elements. Spontaneous regeneration of epithelium is not possible and the burns are described as full-thickness burns. Such burns require the application of skin grafts if the development of scar tissue is to be avoided. Fourth-degree burns refer to deep thermal injuries involving fascia, muscle, or bone (Table 55.1).

Brunicardi FC, Anderson DK, eds. *Schwartz's Principles of Surgery*. 9th ed. New York: McGraw-Hill; 2010:199–200.

MacLennan N, Heimbach DM, Cullen BF. Anaesthesia for major thermal injury. *Anesthesiology*. 1998;89:749–770.

Table 55.1 Classification of Burn Depth

CLASSIFICATION	BURN DEPTH	OUTCOME
Superficial		
First degree	Confined to epidermis	Heals spontaneously
Partial thickness		
Second degree		
Superficial dermal burn	Epidermis and upper dermis	Heals spontaneously
Deep dermal burn	Epidermis and deep dermis	Requires excision and grafting for rapid return of function
Full thickness		
Third degree	Destruction of epidermis and dermis	Wound excision and grafting required Some limitation of function and scar formation
Fourth degree	Muscle, fascia, bone	Complete excision required, limited function

From MacLennan N, Heimbach DM, Cullen BF. Anesthesia for major thermal injury. *Anesthesiology.* 1998;89:749–779, with permission.

A.2. How do you express the extent of the burn injury?

The extent of the burn injury is expressed as a percentage of the total body surface area (TBSA) displaying either second- or third-degree burns. It is most commonly estimated by the "rule of nines" (Fig. 55.1). The major anatomic portions of the adult may be divided into multiples of 9% of the body surface area. The proportion of each of these areas is estimated and the sum represents the percentage of the TBSA burn. The percentages of body surface are as follows:

- Head and neck 9%
- Right upper extremity 9%
- Left upper extremity 9%
- Right lower extremity 18%
- Left lower extremity 18%
- Anterior trunk 18%
- Posterior trunk 18%
- Perineum 1%

Brunicardi FC, Anderson DK, eds. *Schwartz's Principles of Surgery*. 9th ed. New York: McGraw-Hill; 2010:199–200.

MacLennan N, Heimbach DM, Cullen BF. Anesthesia for major thermal injury. *Anesthesiology*. 1998;89:749–770.

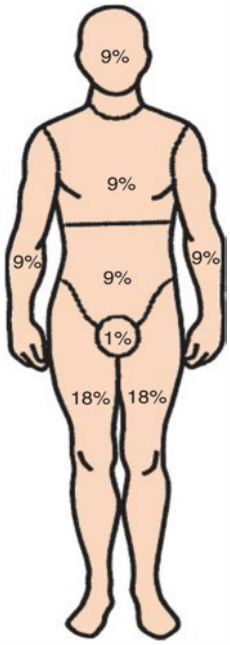

Figure 55.1 The rule of nines for determining the percentage of body surface area burned in adults. (Adapted from MacLennan N, Heimbach DM, Cullen BF. Anesthesia for major thermal injury. *Anesthesiology*. 1998;89:749–770.)

A.3. Should the "rule of nines" be used in children?

The "rule of nines" may not be used to estimate TBSA burns in children because the surface area of the head and neck in children is significantly larger than 9%, and that of the lower extremities is smaller. More precise methods, such as the Lund and Browder chart, may be used to provide greater accuracy by taking into account the changing proportions of the body from infancy to adulthood (Fig. 55.2).

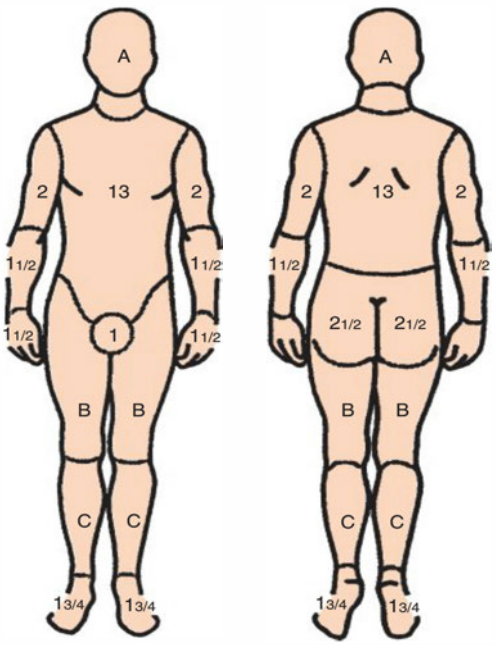
Brunicardi FC, Anderson DK, eds. *Schwartz's Principles of Surgery*. 9th ed. New York: McGraw-Hill; 2010:199–200.

MacLennan N, Heimbach DM, Cullen BF. Anesthesia for major thermal injury. *Anesthesiology*. 1998;89:749–770.

A.4. What is the definition of a major burn according to the American Burn Association?

The American Burn Association defines a major burn as follows:

- Full-thickness burns more than 10% TBSA
- Partial-thickness burns more than 25% in adults or 20% at extremes of age
- Burns involving face, hands, feet, or perineum
- Inhalation, chemical, or electrical burns
- Burns in patients with serious pre-existing medical disorders (adapted from the American Burn Association injury severity grading system)



Relative percentages of areas affected by growth

	AGE IN YEARS					
AREA	0	1	5	10	15	Adult
A: half of head	9½	8½	6½	5½	4½	3½
B: half of thigh	2¾	3¼	4	4¼	4½	4¾
C: half of leg	2½	2½	2¾	3	3¼	3½

Figure 55.2 Diagram and table for determining the percentage of body surface area burned in children. (Adapted from MacLennan N, Heimbach DM, Cullen BF. Anesthesia for major thermal injury. *Anesthesiology*. 1998;89:749–770.)

A.5. What functions does the skin perform?

The skin is the largest organ of the body, with surface area ranging from 1.5 to 2.0 m^2 in the adult. It protects the invasion of microorganisms. It performs other functions in thermal regulation, fluid and electrolytes homeostasis, and sensation (touch, temperature, pain). The skin also has metabolic functions including vitamin D metabolism.

Herndon DN, ed. *Total Burn Care*. 3rd ed. Philadelphia: Saunders-Elsevier; 2007:239–240.

A.6. What pathophysiologic changes accompany major thermal injury?

The pathophysiologic alterations that accompany major thermal injury are complex. When destroyed, skin, which is the largest organ of the body, has a systemic impact. Thermal regulation, fluid and electrolyte homeostasis, and protection against bacterial infection are affected. Immediately after a burn injury, mediators released from the burn wound contribute to local inflammation and edema. A large amount of fluid is lost from the vascular compartment into the burn wound. Sequestration in the extravascular space results in significant hemoconcentration. Increased secretion of antidiuretic hormone may decrease or even completely inhibit urinary output. It has been shown that during the first 4 days after a burn, an amount of albumin equal to twice the total plasma albumin content is lost through the wound. Half of this fluid remains sequestered in the extravascular space for 3 weeks or more before returning to the intravascular compartment.

The metabolic rate is markedly increased after the burn injury. Depending on the size of the burn, the increase in metabolic rate can be doubled or tripled with a proportionate increase in oxygen consumption and carbon dioxide production. This hypermetabolic state will continue for weeks or months until full skin coverage is achieved and the tissue repair processes are complete. Cardiac output (CO) is often decreased in patients with major burns. This decrease is not entirely explained by the rapid reduction in circulating blood volume. It has been shown that a circulating myocardial-depressant factor exists in both humans and laboratory animals.

Changes in vascular integrity occur in other areas remote from the injury site. The entire vascular compartment in the body becomes permeable to circulating macromolecules, such as dextran. This capillary leak syndrome is manifested as edema. In the lung, severe pulmonary edema can be life threatening.

Pulmonary function decreases markedly. Functional residual capacity is reduced. Both lung compliance and chest wall compliance decrease markedly. The alveolar–arterial oxygen gradient (P_{AO_2}–Pa_{O_2}) increases. Minute ventilation is increased; it can be as high as 40 L per minute (normal, 6 L per minute).

Brunicardi FC, Anderson DK, eds. *Schwartz's Principles of Surgery*. 9th ed. New York: McGraw-Hill; 2010:197–205.

Herndon DN, ed. *Total Burn Care*. 3rd ed. Philadelphia: Saunders-Elsevier; 2007:93–97.

MacLennan N, Heimbach DM, Cullen BF. Anesthesia for major thermal injury. *Anesthesiology*. 1998;89:749–770.

A.7. Name some of the known mediators released with thermal injury? What are the responses to those mediators?

After a thermal injury, mediators released from the burn wound contribute to local inflammation and edema. Local mediators include histamine, prostaglandins,

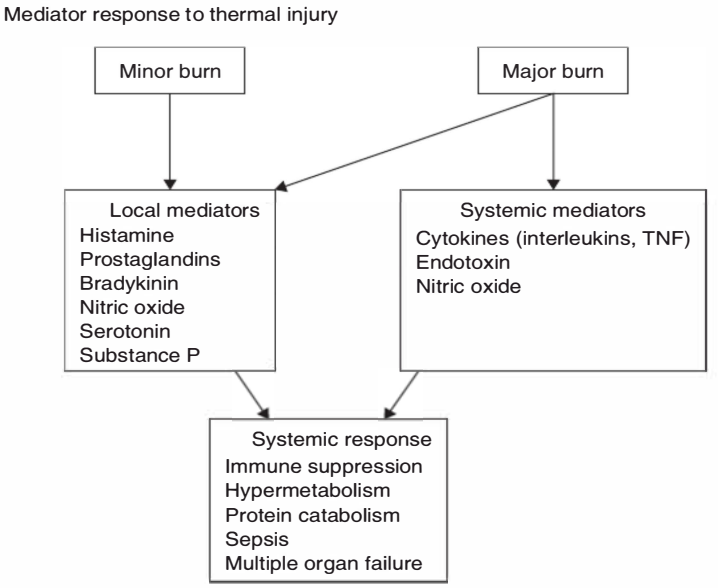


Figure 55.3 Mediators released with thermal injury and the response to their release. TNF, tumor necrosis factor. (From MacLennan N, Heimbach DM, Cullen BF. Anesthesia for major thermal injury. *Anesthesiology.* 1998;89:749–770, with permission.)

thromboxane, bradykinin, nitric oxide, serotonin, catecholamine, and platelet aggregation factor.

In minor burns, the inflammatory process is limited to the wound itself. In major burns, local injury triggers the release of circulating (systemic) mediators, resulting in a systemic response. This is characterized by hypermetabolism, immune suppression, and the systemic inflammatory response syndrome (protein catabolism, sepsis, multiple organ failures).

The systemic mediators are cytokines (interleukins), endotoxin, and nitric oxide (Fig. 55.3).

Brunicardi FC, Anderson DK, eds. *Schwartz's Principles of Surgery*. 9th ed. New York: McGraw-Hill; 2010:197–205.

Herndon DN, ed. *Total Burn Care*. 3rd ed. Philadelphia: Saunders-Elsevier; 2007:97–99.

MacLennan N, Heimbach DM, Cullen BF. Anesthesia for major thermal injury. *Anesthesiology*. 1998;89:749–770.

A.8. What is the prognosis for this patient? What major factors affect his prognosis?

The prognosis for this patient is very poor. Statistical survival based on TBSA alone would predict a less than 50% chance of survival. Other factors that affect his prognosis are age, size and depth of burn, associated pulmonary injury, and pre-existing medical disease. In view of this patient, who had angioplasty for coronary artery disease and hypertension and who is a heavy smoker and obese, the risk of myocardial infarction is greatly increased.

A.9. What are the most common causes of death?

With the understanding of vigorous early fluid resuscitation, hypovolemic shock is not common in United States. The major early cause of death is asphyxia. The most common cause of long-term mortality is septic complications.

A.10. Does this patient have a smoke inhalation burn? How do you make the diagnosis?

The patient probably sustained a smoke inhalation burn. Smoke inhalation should be highly suspected in patients who were burned in an enclosed space, received burns of the face, were burned while under the influence of alcohol or drugs, or lost consciousness at the time of the accident.

A patient with smoke inhalation often exhibits no physical signs or symptoms during the first 24 hours after the burn. Diagnosis is dependent on a high index of suspicion and careful physical and laboratory examination. The early symptoms and signs of respiratory tract injury include singed nasal hair; burned nasal mucosa, lips, and mouth; hoarseness; wheezing; and brassy cough with soot in the sputum. The posterior pharynx may appear red and the larynx may appear edematous. Radiographic findings are usually negative immediately after injury; this is the "clear or lucid period." Laboratory tests include blood gas analysis, carboxyhemoglobin concentration, xenon scans, and fiber-optic bronchoscopy.

Brunicardi FC, Anderson DK, eds. *Schwartz's Principles of Surgery*. 9th ed. New York: McGraw-Hill; 2010:201–202.

Herndon DN, ed. *Total Burn Care*. 3rd ed. Philadelphia: Saunders-Elsevier; 2007:262–265.

A.11. Could you name some of the chemical products of combustion?

Carbon monoxide is produced by incomplete combustion of carbon-containing compounds such as wood, coal, and gasoline. Other chemical products of combustion include ammonia, cyanide, hydrogen chloride, sulfur dioxide, and phosgene. These chemicals combine with water to produce strong acids and alkalines.

Herndon DN, ed. *Total Burn Care*. 3rd ed. Philadelphia: Saunders-Elsevier; 2007:248–250.

A.12. What is carbon monoxide poisoning? How do you treat carbon monoxide poisoning?

Carbon monoxide is the leading cause of hypoxia in survivors of burn injuries. Carbon monoxide has a 200 times greater affinity for hemoglobin than oxygen and therefore displaces oxygen from its hemoglobin-binding sites. Fortunately, this reaction is a competitive, reversible one, so oxygen therapy should be instituted immediately. The half-life for carbon monoxide elimination from hemoglobin can be shortened from 4 hours to 45 minutes with an inspired oxygen concentration of 100%. Although the Pa_{O_2} may be normal, the actual content of oxygen in the blood is markedly reduced.

Brunicardi FC, Anderson DK, eds. *Schwartz's Principles of Surgery*. 9th ed. New York: McGraw-Hill; 2010:201–202.

Herndon DN, ed. *Total Burn Care*. 3rd ed. Philadelphia: Saunders-Elsevier; 2007:250–256.

A.13. What resuscitative measure would you institute immediately in this patient with 40% burns?

Vigorous fluid resuscitation should be instituted immediately to combat the danger of hypovolemia from translocation of intravascular volume into the burn edema, which acts as a "third space." Fluid must be administered adequately to ensure good tissue perfusion and adequate urine output. The airway should be maintained to ensure adequate ventilation. If an upper airway burn is involved, endotracheal intubation is indicated.

A.14. What fluid formula would you use?

Over the last 30 years, many fluid formulas have been developed as guides to initial resuscitation in hypovolemic shock after burn injury. Most use various combinations of crystalloid and colloid solutions, but they differ widely in the colloid/crystalloid ratio and in the rate of fluid administration. Although much controversy still surrounds the use of "the solution" for resuscitation in burn shock, scientific investigation supports the need for both crystalloid and colloid solutions (Table 55.2). Which formula is used to begin such therapy matters little, as long as it is modified according to the patient's changing requirements. The Parkland formula, popularized by Baxter, has been adopted in most burn centers because of its simplicity, reduced cost, and equivalent outcome and is currently the standard against which new formulas must be compared.

Parkland formula

First 24 hours

- *Electrolyte solution (lactated Ringer's)*. 4 mL/kg/percentage of body area with second- and third-degree burn
- *Administration rate*. Half the solution given in the first 8 hours, one-quarter in the second 8 hours, one-quarter in the third 8 hours
- *Urine output*. Maintain at 0.5 to 1.0 mL/kg/hour

Second 24 hours

- *Glucose in water*. To replace evaporated water loss and maintain serum sodium concentration of 140 mEq per L

Table 55.2 Fluid Resuscitation for Adults with Major Burns

Crystalloid Regimens		
Parkland	Lactated Ringer's	4 mL/kg/% burn
Modified Brooke	Lactated Ringer's	2 mL/kg/% burn
Colloid regimens		
Evans	Normal saline	1 mL/kg/% burn
	Colloid	1 mL/kg/% burn
	5% Dextrose	2,000 mL/24 hr
Brooke	Lactated Ringer's	1.5 mL/kg/% burn
	Colloid	0.5 mL/kg/% burn
	5% Dextrose	2,000 mL/24 hr

- *Colloid solutions (e.g., albumin)*. Amount proportional to burn
  - *30% to 50% burn*: 0.3 mL/kg/percentage of burn
  - *50% to 70% burn*: 0.4 mL/kg/percentage of burn
  - *Larger than 70% burn*: 0.5 mL/kg/percentage of burn
- *Urine output*. Maintain at 0.5 to 1.0 mL/kg/hour

Brunicardi FC, Anderson DK, eds. *Schwartz's Principles of Surgery*. 9th ed. New York: McGraw-Hill; 2010:199–201.

Herndon DN, ed. *Total Burn Care*. 3rd ed. Philadelphia: Saunders-Elsevier; 2007:201–204.

A.15. What cardiovascular changes typify the burn injury?

Cardiovascular changes develop in several phases. Acutely, fluid sequestration in the burned area and from capillary leak is caused by direct thermal destruction of the capillary membranes. This results in a massive shift of fluids and proteins from the intravascular compartment to the interstitial spaces. This shift of fluid accounts for the marked decrease in circulating blood volume, resulting in hypotension or the initial burn shock. Decreased blood volume and decreased CO would trigger catecholamine release, resulting in severe vasoconstriction, which may further compromise forward flow and tissue perfusion. Release of myocardial-depressant factors may further depress CO through its direct action on myocardial contractility.

Brunicardi FC, Anderson DK, eds. *Schwartz's Principles of Surgery*. 9th ed. New York: McGraw-Hill; 2010:197–205.

Hendon DN, ed. *Total Burn Care*. 3rd ed. Philadelphia: Saunders-Elsevier; 2007:471–472.

A.16. Is the immune system affected in burn injury? How?

Both the cellular and the humoral components of the immune system are impaired. The presence of devitalized tissue greatly increases the risk of wound infection and systemic sepsis. Endotoxins cause changes in cellular function. Macrophage activity in the alveolar is impaired. Changes in phagocytic and chemotactic properties of neutrophils have been demonstrated. Strict antiseptic precautions must be observed in these patients.

Brunicardi FC, Anderson DK, eds. *Schwartz's Principles of Surgery*. 9th ed. New York: McGraw-Hill; 2010:197–205.

Herndon DN, ed. *Total Burn Care*. 3rd ed. Philadelphia: Saunders-Elsevier; 2007:310–324.

A.17. What hematologic changes occur in burn injury?

Hematologic changes can be seen in erythrocytes (red blood cells [RBCs]), platelets, and the coagulation mechanism.

Erythrocytes (RBCs). Immediately after injury, the hematocrit level increases as noncellular fluid translocates into the interstitium. Anemia is more often the case after fluid resuscitation because of RBC damage and hemolysis during the heating injury. There is shortened RBC half-life and reduction of production due to circulating inhibitory factors.

Platelets. The platelet count usually decreases because of dilutional and consumption by formation of microaggregates in the skin and smoke damaged lung. The platelet level returns to normal by the end of the first week unless sepsis or multiple system organ failure occurs.

Coagulation. Both the thrombotic and the fibrinolytic mechanisms are activated, and clotting factors decrease. Disseminated intravascular coagulopathy is rare but can occur, particularly in fourth-degree burns involving structures deep to the skin.

Brunicardi FC, Anderson DK, eds. *Schwartz's Principles of Surgery*. 9th ed. New York: McGraw-Hill; 2010:197–205.

Herndon DN, ed. *Total Burn Care*. 3rd ed. Philadelphia: Saunders-Elsevier; 2007:325–327.

A.18. What changes occur in liver function? What are the anesthetic implications of such changes?

Hypoperfusion during burn shock can result in decreased hepatic function, severely depressing the detoxification capacity of the liver. Decreased levels of albumin may result in greater free fractions of bound drugs such as benzodiazepines and phenytoin. In contrast, the injury-stimulated rise in the acute-phase reactant α_1-acid-glycoprotein increases the binding of basic drugs such as muscle relaxants, lidocaine, and propranolol.

Brunicardi FC, Anderson DK, eds. *Schwartz's Principles of Surgery*. 9th ed. New York: McGraw-Hill; 2010:197–205.

Herndon DN, ed. *Total Burn Care*. 3rd ed. Philadelphia: Saunders-Elsevier; 2007:361–375.

Martyn JAJ. The use of neuromuscular relaxants in burn patients. In: Rupp SM, ed. *Problems in Anesthesia*. Philadelphia: JB Lippincott; 1989:482.

A.19. What are Curling ulcers? How can they be prevented?

Curling ulcer is a stress ulcer of the duodenum commonly found after a severe burn. Gastric ulceration may occur also. Without treatment, the incidence is as high as 80%. The frequency and severity correlate with the size of the burn. They may present with gastric bleeding. They can be prevented with prophylactic antacids, H_2-antagonists, and early enteral feeding.

Brunicardi FC, Anderson DK, eds. *Schwartz's Principles of Surgery*. 9th ed. New York: McGraw-Hill; 2010:910.

Herndon DN, ed. *Total Burn Care*. 3rd ed. Philadelphia: Saunders-Elsevier; 2007:472.

A.20. What complications are associated with electrical burns?

The burn from electrical current results from the conversion of electrical energy to thermal energy. The damages may vary and are determined by the area of contact, the resistances of the tissues, and the duration of current flow. Often, only the surface entrance and exit sites on the skin show visible injury because of the high current concentrations at these points. Deep tissues such as muscles, tendons, blood vessels, and nerves can be severely injured. Vascular complications such as thrombosis can be late complications. The heart is particularly susceptible to electrical damage. Ectopy and congestive heart failure can be signs of electrical injury.

B. Preoperative Evaluation and Preparation

B.1. What preoperative preparations would you order? What are particular concerns in this patient?

Preoperative preparations should include a medical history, physical examination, and the usual concerns regarding cardiac disease, pulmonary disease, renal function, liver function, anesthetic history, and family history. Of particular concern in this patient are hypertension, ischemic heart disease, angioplasty of left main coronary artery, and the history of heavy smoking and heavy alcohol consumption.

The adequacy of fluid volume resuscitation should be assessed.

Hemodynamic stability should have been achieved.

Laboratory tests should include complete blood cell count, platelet count, electrolytes, blood urea nitrogen, creatinine, coagulation studies, urinalysis, liver function test, electrocardiogram (ECG), chest radiograph, and arterial and venous blood gases.

Other data that may be helpful include central venous pressure (CVP), pulmonary artery occlusion pressure (PAOP), CO, and cardiac index (CI).

In view of this patient's left main coronary artery disease, cardiac enzymes studies in conjunction with cardiologist involvement would be beneficial.

B.2. What are the various operative and management options available for severely burned patients?

Deep partial-thickness and full-thickness burns will not heal spontaneously and require excision and skin graft. The burned skin or eschar is a good culture medium for bacterial growth. Although topical antibiotic creams such as silver sulfadiazine can be applied to control the infection, the definitive treatment is excision of eschar.

The timing and extent of burn wound excision are still debatable; there has been a shift toward earlier excision and grafting. The most widely used approach involves an initial 48-hour period of stabilization, followed by tangential excision split-thickness skin graft (TE/STSG). The extent of excision is limited to 20%. These procedures are repeated every 2 days until the eschar excision is complete. Some favor very early excision (<24 hours from the time of burn).

Brunicardi FC, Anderson DK, eds. *Schwartz's Principles of Surgery*. 9th ed. New York: McGraw-Hill; 2010:197–205.

Herndon DN, ed. *Total Burn Care*. 3rd ed. Philadelphia: Saunders-Elsevier; 2007:177–187.

B.3. What is tangential excision split-thickness skin graft (TE/STSG)? What are the principles of this grafting technique?

TE/STSG is a procedure to debride the dead skin and graft on new layers. The burn eschar is sharply excised from the underlying subcutaneous tissue. Brisk capillary bleeding signifies that adequate excision has been achieved and viable tissue uncovered. Skin grafts may be either full thickness or split (partial) thickness. Full-thickness grafts include all layers of epidermis and dermis in their sample. Therefore, the donor site must be closed primarily. Suitable donor sites are the skinfolds of the axilla and groin. A tissue expander is commonly used to increase the available donor skin. Full-thickness grafts have the advantage of better cosmesis and durability, and they are useful when tissue bulk is desired. More commonly, STSGs are used. These grafts are obtained by slicing the superficial layers of the skin through the level of the dermal pegs. Because maturation of skin cells occurs as they migrate superficially, the graft has many viable layers of dermal cells. When placed on a viable bed of subcutaneous tissue, ingrowth of vessels occurs and the graft remains viable. In addition, because the

excision of donor skin is through the dermis, the deep basement membrane and skin appendages remain intact. Hence, the donor site will heal on its own, architecturally normal, usually with only mild discoloration.

Brunicardi FC, Anderson DK, eds. *Schwartz's Principles of Surgery*. 9th ed. New York: McGraw-Hill; 2010:179–184.

Herndon DN, ed. *Total Burn Care*. 3rd ed. Philadelphia: Saunders-Elsevier; 2007:197–205.

B.4. What are the advantages and disadvantages of early TE/STSG?

By excising the burn eschar early (within 7 to 10 days), one can remove the bacterial load quickly and achieve prompt skin coverage with resultant lessening of septic complications; the hospital and recovery phases are therefore shortened. Very early excision (within 24 hours), however, has the disadvantage of the patient undergoing a major operation during the resuscitative phase of the injury. The patient is not optimally stabilized, and there is an increase in anesthetic risk.

Cultured epithelial autografts are an exacting new technique that can be of great use in patients with large TBSA burns in which donor sites are few in number.

Brunicardi FC, Anderson DK, eds. *Schwartz's Principles of Surgery*. 9th ed. New York: McGraw-Hill; 2010:197–205.

Herndon DN, ed. *Total Burn Care*. 3rd ed. Philadelphia: Saunders-Elsevier; 2007:177–187.

Munster AM, Weiner SH, Spence RJ. Cultured epidermis for the coverage of massive burn wounds: a single center experience. *Ann Surg*. 1990;211:676–680.

B.5. What is this patient's mean arterial blood pressure? How do you calculate it?

The patient's blood pressure is 190/100 mm Hg; therefore, his mean arterial blood pressure is 130 mm Hg (mean arterial pressure = diastolic pressure + one-third of pulse pressure, which is the difference between systolic and diastolic pressure).

B.6. Are you concerned about this patient's blood pressure? What treatment would you institute?

The blood pressure is quite high (190/100 mm Hg). Knowing that this patient has a history of ischemic heart disease with symptoms of angina that required angioplasty of the left main coronary artery 1 year ago, I am very concerned about his hypertension and would like to control the blood pressure to the normal range.

The following intravenous vasodilators may be used:

- Beta-blockers (intravenous labetalol, lopressor)
  - calcium channel blocker (intravenous infusion of nicardipine or clavidipine)
  - angiotensin-converting enzyme inhibitors (intravenous Vasotec)
- Hydralazine

In view of his tachycardia (heart rate, 120 beats per minute), I would prefer an intravenous beta-blocker such as labetalol or lopressor. Increased afterload and tachycardia would increase oxygen demand on the heart and increase the risk of myocardial infarction.

Adequate volume resuscitation should be assessed, so obtaining CVP, PAOP, CO, CI, and systemic vascular resistance would be helpful in instituting treatment.

B.7. This patient was ventilated with respirator settings of tidal volume, 800 mL; respiratory rate, 20 breaths per minute; F_{IO_2}, 60%; and positive end-expiratory pressure, 10 cm H_2O. Arterial blood gas analyses showed the following: pH, 7.25; P_{O_2}, 56 mm Hg; P_{CO_2}, 60 mm Hg; and O_2 saturation, 80%. How would you interpret these arterial blood gas analysis results? What are the possible causes of high P_{CO_2} and low P_{O_2}?

Arterial blood gas analysis results are abnormal. This patient was hypoventilated with high P_{CO_2} of 60 mm Hg (normal P_{CO_2} is 35 to 45 mm Hg); although the minute volume was 16 L (800 mL × 20), the increase in minute volume might not have compensated for his hypermetabolic state with marked increase in CO_2 production.

Ventilation/perfusion mismatch is the most common cause of hypoxemia. Causes of ventilation/perfusion mismatches range from dead space to shunt. The common causes are atelectasis, pneumonia, and pulmonary edema.

This patient had respiratory acidosis and probably mild metabolic acidosis.

Malposition of endotracheal tube with single-lung ventilation is a possible cause that should be ruled out.

B.8. How do you calculate oxygen content and oxygen delivery? What factors govern the oxygen delivery to the tissues? What are the causes of tissue hypoxia?

Oxygen content consists of oxygen in combination with hemoglobin and oxygen dissolved in plasma and can be expressed as:

$$\text{Oxygen content (mL/dL)} = 1.31 \times \text{hemoglobin (g/dL)} \times O_2 \text{ saturation (\%)} + 0.003 \times P_{O_2}$$

Normal arterial oxygen content: $Ca_{O_2} = 20.73$ mL per 100 mL

Normal venous oxygen content: $C_vo_2 = 15.76$ mL per 100 mL

Oxygen delivery is the product of cardiac output (CO) and arterial oxygen content.

$$Do2 = CO \times Ca_{O_2} = CO \times ([1.31 \times \text{hemoglobin} \times O_2 \text{ saturation}] + 0.003 \times P_{O_2})$$

Three main factors govern the oxygen delivery: CO, hemoglobin, and arterial oxygen saturation.

Tissue hypoxia may be due to the following:

- Inadequate CO: "stagnant anoxia"
- Inadequate arterial oxygen saturation: "anoxic anoxia"
- Reduction of hemoglobin concentration: "anemic anoxia"

Lumb AB. *Nunn's Applied Respiratory Physiology*. 6th ed. Philadelphia: Butterworth-Heinemann; 2005:188.

B.9. What are the symptoms and signs of alcohol withdrawal? Are you concerned that this patient could develop delirium tremens?

Minor withdrawal symptoms are anorexia, insomnia, tremors, mild disorientation, hallucination, and convulsion. These symptoms usually peak within 10 to 30 hours of cessation of drinking. Major withdrawal symptoms occur later and are characterized by severe autonomic hyperactivity, which includes anxiety, tachycardia, diaphoresis,

tremors, fever, hallucination, and global convulsion. These major symptoms are also known as *delirium tremens*. There is a real concern that this patient could develop withdrawal syndrome. Early treatment should be instituted.

B.10. How would you prevent the adverse effects of alcohol withdrawal?

Sedatives, such as benzodiazepines, are effective in preventing the withdrawal symptoms. If autonomic hyperactivity symptoms occur, beta-blockers are helpful to attenuate the symptoms, especially tachycardia and dysrhythmias.

C. Intraoperative Management

C.1. What monitors would you use in the operating room?

The routinely used monitors, such as ECG, blood pressure, temperature, inspired oxygen, pulse oximetry, and capnography, should be used in this patient. A urinary catheter is essential to assess urine output. An indwelling arterial line is helpful, because a standard blood pressure cuff would be difficult to apply over the areas to be grafted and harvested. A pulmonary artery catheter or CVP catheter is recommended for the severely burned patient, especially a patient with ischemic heart disease.

C.2. What information can be obtained from an arterial line and a pulmonary artery catheter? How are these calculations performed?

The arterial line can display direct continuous blood pressure, thereby providing continuous real-time monitoring of blood pressure. This is most useful in fluctuating hypotensive or hypertensive situations. In conditions such as atrial fibrillation or ventricular tachycardia, variations in ventricular response or blood pressure can be recognized instantly. The morphology of the waveform can also provide information about arterial resistance (narrow suggestive of both reduced stroke volume and increased systemic vascular resistance) stroke volume (area under the curve), and preload (pulse pressure variation particularly in response to mechanical positive pressure ventilation). In addition, it serves as ready vascular access for blood sampling—for example, arterial blood gas analyses, electrolytes, hematocrit, and blood sugar levels.

Pulmonary artery catheter allows measurement of PAOP. The PAOP is a surrogate of left atrial pressures. Left atrial pressure reflects left ventricular end-diastolic pressure, which is helpful in assessing the preload status of the left ventricle. CVP, although useful as a rough estimate of preload, does not correlate with left ventricular end-diastolic pressure when either isolated right-sided or left-sided cardiac dysfunction occurs.

The multilumen pulmonary artery catheters are capable of measuring CVP and CO through the thermodilution method. It also permits sampling of mixed venous blood. These measurements permit calculation of many hemodynamic variables.

$$\text{Cardiac index (CI)} = \frac{\text{CO}}{\text{Body surface area}} \qquad \text{(normal 2.8 to 4.2 L/min/m}^2\text{)}$$

$$\text{Stroke volume (SV)} = \frac{\text{CO}}{\text{Heart rate}} \qquad \text{(normal 60 – 80 mL/beat)}$$

$$\text{Stroke index (SI)} = \frac{\text{CI}}{\text{Heart rate}} \qquad \text{(normal 40 – 65 mL/beat/m}^2\text{)}$$

$$\text{Systematic vascular resistance (SVR)} = \frac{\text{Mean BP} - \text{CVP}}{\text{CO}} \times 80 \qquad \text{(normal 900 – 1,400 dynes/sec/cm}^5\text{)}$$

$$\text{Pulmonary vascular resistance (PVR)} = \frac{\text{Mean PAP} - \text{PCWP}}{\text{CO}} \times 80 \quad \text{(normal 150 – 250 dynes/sec/cm}^5\text{)}$$

Mixed venous blood samples are needed for shunt calculations:

$$\frac{\dot{Q}_s}{\dot{Q}_t} = \frac{Cc\bar{v}o_2 - Cao_2}{Cc\bar{v}o_2 - C\bar{v}\bar{v}o_2}$$

$Cc\bar{v}o_2$ = pulmonary capillary oxygen content
Cao_2 = artery oxygen content
$C\bar{v}\bar{v}o_2$ = mixed venous oxygen content

A low mixed venous oxygen level (<30 mm Hg) is suggestive of inadequate tissue perfusion.

Miller RD, ed. *Miller's Anesthesia*. 7th ed. Philadelphia: Elsevier/Churchill Livingstone; 2010:1317, 1414.

C.3. If the patient had not been intubated, how would you proceed with the anesthetic induction?

One should anticipate a difficult intubation because this patient has burns over his face and neck. Burns on the face may cause severe edema of the face, pharynx, and larynx, so careful assessment of the mouth opening, pharynx, and larynx should be performed. The safest way to secure the airway is to do an awake intubation with topical anesthesia and mild sedation; it can be achieved with either direct or fiber-optic–guided intubation. If prolonged postoperative intubation is anticipated, the nasotracheal route should be considered. A nasotracheal tube is more easily secured in place, is better tolerated by the patient, and permits better oral hygienic care. Vasoconstriction of the nasal mucosa may be achieved with phenylephrine drops.Alternatively, a tracheostomy should be considered early in those patients with acute lung injury who will require prolonged mechanical ventilation.

C.4. Why is awake intubation considered the safest?

Awake intubation is considered the safest way to secure an airway because when the patient is awake and breathing spontaneously, the patient is less likely to obstruct the upper airway by the tongue and is less likely to have oxygen desaturation. The anesthesiologist does not have to ventilate using a mask and is therefore less likely to distend the stomach.

If the patient is breathing spontaneously and has adequate oxygenation, the anesthesiologist has more time to do a proper laryngoscopy or manipulation of the endotracheal tube. Identifying the passage of air from the glottis may be helpful in blind intubation.

C.5. What anesthetic agents would you use? Discuss inhalation versus intravenous agents.

For the severely burned patient, once the airway is secured, high-dose narcotic-muscle relaxant technique would be preferred, because this technique offers good intraoperative hemodynamic stability in critically ill patients, coupled with excellent postoperative analgesia.

The narcotics such as morphine, meperidine (Demerol), fentanyl, or sufentanil can be used because they do not depress myocardial contractility, whereas potent inhalation agents depress the myocardium. If inhalation agents are chosen, the concentration should be carefully titrated to prevent loss of cardiovascular compensation.

C.6. Why are you concerned about the patient's body temperature? What is normothermia for a burned patient?

Massively burned patients with loss of skin have constant evaporation from open surfaces. They tend to develop severe intraoperative hypothermia. The tendency is exaggerated by the effects of general anesthesia on the temperature-regulating centers, by vasodilation, and by the cool relatively dry environment of the operating room. The infusion of a large amount of intravenous fluids at room temperature also contributes to the development of hypothermia.

Normothermia for a burned patient is approximately 38.5° C because the burned patient develops a resetting of the centrally mediated thermostat.

Brunicardi FC, Anderson DK, eds. *Schwartz's Principles of Surgery*. 9th ed. New York: McGraw-Hill; 2010:197–205.

Herndon DN, ed. *Total Burn Care*. 3rd ed. Philadelphia: Saunders-Elsevier; 2007:205–206.

C.7. How is temperature best maintained?

Hypothermia is an ever-present problem. Burned patients have lost their natural insulation of the skin. Heat loss can occur through convection, conduction, and evaporation. Methods to maintain normothermia should involve active warming and prevention of heat loss. We administer all fluids and blood transfusions through the blood- and/or fluid-warming device. A thermal mattress or a bear-hugger is placed under a single-layer sterile sheet on the operating table and is prewarmed, although this method is not very effective. Warming the operating room to temperatures between 24° C (75.2° F) and 27° C (80.6° F) with a relative humidity higher than 50% is particularly effective. The areas of the patient's body not immediately involved in the surgery must be covered. Heated, humidified circuits are most effective in minimizing the heat loss from ventilation with cold anesthetic gases.

C.8. What derangements occur with hypothermia?

Hypothermia causes many physiologic changes. Hypothermia decreases metabolism, heart rate, CO, and blood pressure. At temperatures less than 28° C (82.4° F), atrial pacing becomes irregular and ventricular ectopic increases. Ventricular fibrillation occurs between 25° C (77° F) and 30° C (86° F) in the human adult.

Decreasing the rate of metabolism can prolong the duration of many anesthetic drugs. Decreased hepatic blood flow could slow the delivery of drugs to the site of metabolism.

Hypothermia shifts the oxygen dissociation curve to the left, resulting in a reduced release of oxygen by hemoglobin. However, the shift to the left is compensated by two factors, namely an increase in dissolved oxygen in the plasma and an increase in dissolved carbon dioxide, which increases acidity and tends to shift the curve to the right.

Miller RD, ed. *Miller's Anesthesia*. 7th ed. Philadelphia: Elsevier/Churchill Livingstone; 2010:1542–1543.

C.9. What muscle relaxant would you use?

A nondepolarizing muscle relaxant should be used. Depolarizing relaxant should be avoided. In general, the choice of muscle relaxant should be based on the duration of the operation and the presence of any coexisting diseases that might affect the elimination of the drug. Muscle relaxants without histamine release would be preferred, such as vecuronium, and rocuronium.

C.10. Why is succinylcholine contraindicated in burned patients? For how long should it be avoided?

Succinylcholine is contraindicated in burned patients because injection of succinylcholine may cause a significant transient increase in serum potassium levels as high as 13 mEq per L, resulting in ventricular fibrillation and cardiac arrest. This hyperkalemic response begins approximately 5 to 15 days after the burn and persists for 2 to 3 months or longer, irrespective of degree and size of burn injury.

The exact mechanism responsible for this response is not known. Gronert and Theye postulated that the abrupt release of potassium is from the hypersensitive muscle membranes. Apparently, extrajunctional acetylcholine receptors are found on the muscle membranes of burned patients. Stimulation of these receptors may mediate the potentially lethal efflux of potassium.

The exact time for this hypersensitivity is unclear. Most authors recommend the avoidance of succinylcholine from 24 to 48 hours after the burn injury and extension of succinylcholine well until complete healing has occurred. A hyperkalemic response has been reported in a patient after 480 days. The recommended limit now is extended to approximately 2 years after the burned skin has healed.

Gronert GA, Theye RA. Pathophysiology of hyperkalemia induced by succinylcholine. *Anesthesiology*. 1975;43:89–99.

Miller RD, ed. *Miller's Anesthesia*. 7th ed. Philadelphia: Elsevier/Churchill Livingstone; 2010:900.

Schaner PJ, Brown RL, Kirksey TD, et al. Succinylcholine-induced hyperkalemia in burned patients. *Anesth Analg*. 1969;48:764–770.

Tolmie JD, Joyce TH, Mitchell GD. Succinylcholine danger in the burned patient. *Anesthesiology*. 1967;28:467–470.

C.11. What other adverse effects are associated with succinylcholine?

Adverse effects of succinylcholine are many. Its side effects are as follows:

- Hyperkalemia, particularly following burns, spinal cord injuries, and generalized major trauma: a single case report of a marked hyperkalemic response to succinylcholine in a patient with a closed head injury without peripheral paralysis
- Increased intracranial and intraocular pressures: the practical importance of which is controversial
- Increased intragastric pressure: counterbalanced by the increase in lower esophageal pressure, which reduces or eliminates the increased risk of regurgitation
- Muscle pains: more likely to concern the patient with minor injuries who ambulates soon after surgery
- Prolonged paralysis in patients with atypical pseudocholinesterase
- Cardiac arrhythmias, particularly bradycardia after repeated doses
- Trigger for malignant hyperthermia

Miller RD, ed. *Miller's anesthesia*. 7th ed. Philadelphia: Elsevier/Churchill Livingstone; 2010:864–866.

C.12. How are the doses of nondepolarizing muscle relaxants affected by burn injury?

In general, burn patients show great resistance to the nondepolarizing relaxants. Martyn et al. first reported that burn patients required a five times higher plasma concentration of d-tubocurarine to attain a given percentage of twitch

depression compared with healthy subjects. The dose of pancuronium is increased by 2.5 times.

Although these patients have altered pharmacokinetics and increased plasma protein binding of the relaxants, most of the increased requirement appears to be due to alterations in the number and affinity of the junctional receptors. This alteration is quite variable.

Martyn JAJ, Liu LMP, Szyfelbein SK, et al. The neuromuscular effects of pancuronium in burned children. *Anesthesiology*. 1983;59:561–564.

Martyn JAJ, Szyfelbein SK, Ali HH, et al. Increased D-tubocurarine requirement following major thermal injury. *Anesthesiology*. 1980;52:352–355.

Miller RD, ed. *Miller's Anesthesia*. 7th ed. Philadelphia: Elsevier/Churchill Livingstone; 2010:900.

C.13. How are the muscle relaxants such as succinylcholine, atracurium, cisatracurium, vecuronium, pancuronium, rocuronium, and curare metabolized and eliminated? Which of them has significant histamine release?

See Table 55.3.

C.14. What is the difference between metabolism and elimination of drugs?

Drug metabolism is the chemical modification of a substance. There are two phases: Phase I metabolism involves chemical reactions of oxidation, reduction, and hydrolysis. Many of these involve catalysis by the cytochrome P450 system in the liver. Phase II metabolism involves *conjugations*, or the combining of endogenous substances with drugs. This is also known as *the synthetic mode of biotransformation*.

Drug elimination involves all processes, which include metabolism, renal and hepatobiliary excretion, and pulmonary excretion such as CO_2 and anesthetic gases.

Miller RD, ed. *Miller's Anesthesia*. 7th ed. Philadelphia: Elsevier/Churchill Livingstone; 2010:482.

Table 55.3 The Metabolism, Elimination, and Histamine Release of Muscle Relaxants

	ELIMINATION			
RELAXANT	KIDNEY (%)	LIVER (%)	PLASMA METABOLISM (%)	HISTAMINE RELEASE
Succinylcholine	<2	0	98	Slight
Atracurium	10–40	0	60–90	Slight
Cisatracurium	16	?	77	None
Vecuronium	40	60	0	None
Pancuronium	85	15	0	None
Rocuronium	25	70	0	None
d-turbocurarine	80	20	0	Moderate

Miller RD, ed. *Miller's Anesthesia*. 7th ed, Philadelphia: Elsevier/Churchill Livingstone; 2010:880,882.

D. Postoperative Management

D.1. How would you monitor this patient during transport?

This patient was most likely intubated, paralyzed, apneic, and still under the influence of general anesthetic. Monitoring should be directed toward respiration, oxygenation, and hemodynamics. These can be achieved by a transport monitor capable of monitoring ECG, blood pressure, CVP, and pulse oximeter. Ventilation should be controlled with an Ambu bag with supplemental oxygen during transport.

D.2. What is meant by diffusion hypoxia? How do you prevent it?

Fink et al. in 1954 first reported diffusion hypoxia during recovery from nitrous oxide–oxygen anesthesia. A mild degree of hypoxia may develop for more than 10 minutes when nitrous oxide–oxygen anesthesia is concluded and the patient is allowed to breathe room air. The arterial oxygen saturation may fall 5% to 10% and often reaches values less than 90% (Pao_2 <60 mm Hg). This occurs at the time when nitrous oxide is eliminated rapidly through the lungs. Nitrous oxide is 35 times more soluble in blood than nitrogen. Therefore, the amount of nitrous oxide diffused from blood to alveoli is much more than the amount of nitrogen diffused from alveoli to blood. Hence, alveolar oxygen is diluted by nitrous oxide. Diffusion hypoxia can be prevented by the inhalation of high concentrations of oxygen for several minutes before the patient is allowed to breathe room air.

Fink R. Diffusion anoxia. *Anesthesiology*. 1955;16:511–519.

Fink R, Carpenter SL, Holiday DA, et al. Diffusion anoxia during recovery from nitrous oxide-oxygen anesthesia. *Fed Proc*. 1954;13:354.

D.3. Why do patients often shiver in the recovery room on emergence from anesthesia?

Postanesthetic shivering is commonly observed in the recovery room. It is more commonly seen after receiving inhalational general anesthetics. It is thought that inhalation agents inhibit the temperature-regulating centers in the hypothalamus, and shivering is a thermoregulatory response to intraoperative hypothermia (the operating room is always cold). Shivering is a mechanism to produce heat to maintain normothermia. However, the precise mechanism of shivering is not fully explained because many patients who shiver are normothermic. It is postulated that the tremor pattern results from anesthetic-induced disinhibition of normal descending control over spinal reflexes. Similar nonthermoregulatory tremor has been seen in women during labor.

Miller RD, ed. *Miller's Anesthesia*. 7th ed. Philadelphia: Elsevier/Churchill Livingstone; 2010:1543–1544.

D.4. Discuss the causes of oliguria in the recovery room.

Oliguria is defined arbitrarily as the production of less than 400 mL of urine in 24 hours. When oliguria occurs, it is a functional manifestation of various clinical entities referred to as *acute renal failure* (ARF). The syndrome of ARF may be classified into the following three groups:

- *Prerenal ARF (hypovolemic)*. There is no structural damage to the kidney. The reduction in renal blood flow results in a reduced filtration rate and a decrease in urinary

flow. It is reversible with volume expansion. However, if untreated, it can progress to the ischemic form of acute tubular necrosis.

- *Renal ARF (acute tubular necrosis)*. There is structural damage to the renal tubules. The damage may be due to ischemia or nephrotoxic substances.
- *Postrenal ARF (obstruction of urinary outflow)*. Pus, tubular debris, clots of blood, and crystalluria can cause bilateral obstruction of the ureters. The flow of urine is completely suppressed in contrast to the low flows found in prerenal and renal disease.

One must determine the cause of the oliguria because the management can vary greatly. To identify the cause of oliguria, one must make a careful assessment of the urinary sediment. Presence of renal tubular cells, renal tubular cell casts, and pigmented granular casts is strong evidence for the diagnosis of acute tubular necrosis. A normal urinary sediment supports a diagnosis of hypovolemic renal failure. Other data, such as CVP, PAOP, and pulmonary artery occlusion pressure can give valuable information about the state of hydration.

CHAPTER 56

Trauma

Danielle Lindenmuth, Jaideep K. Malhotra, and Ralph L. Slepian

A 31-YEAR-OLD MAN

sustained multiple stab wounds to the left upper quadrant of his abdomen and in the left hemithorax. Vital signs were as follows: blood pressure, 85/60 mm Hg; heart rate, 130 beats per minute; respiratory rate, 32 breaths per minute; temperature, 34.5° C (94.1° F). His hematocrit was 27%. He was emergently brought to the operating room for an exploratory laparotomy and possible thoracotomy.

A. Medical Disease and Differential Diagnosis

1. How is trauma classified?
2. What are the injuries associated with thoracic trauma?
3. What are the injuries associated with cardiac trauma?
4. What are the complications of acute pericardial tamponade?
5. What are the anesthetic implications for treating cardiac tamponade?
6. How is the initial assessment and management of the trauma patient performed?
7. What constitutes a primary survey and what is its objective?
8. What constitutes a secondary survey and what is its objective?
9. What are the signs and symptoms of a hemothorax? What is the definition of massive hemothorax?
10. What are the indications for a thoracotomy to treat a hemothorax?
11. How are pneumothoraces categorized?
12. What is an occult pneumothorax?
13. If the patient has a widened mediastinum on chest radiograph, what are your concerns?
14. What are the most commonly injured organs in blunt abdominal trauma?
15. What is a focused abdominal sonography for trauma (FAST) examination?
16. What is diagnostic peritoneal lavage?
17. Why was diagnostic peritoneal lavage not performed for this patient?

18. Define shock.
19. What are the four types of shock?
20. List the signs and symptoms of shock.
21. What is the pathophysiology of hypovolemic shock?
22. How would you classify hemorrhage?
23. What is the initial treatment of hemorrhagic shock?
24. Would you choose crystalloid or colloid therapy to treat hypovolemic shock?
25. Is there a place for dextran or hetastarch (Hespan) in treating hypovolemic shock?
26. Is there a place for hypertonic saline in the treatment of hypovolemic shock?

B. Preoperative Evaluation and Preparation

1. What premedication would you order?
2. What preoperative testing would you order?

C. Intraoperative Management

1. How would you monitor this patient?
2. How would you induce anesthesia?
3. What technique could you use if single-lung ventilation was indicated?
4. What agents would you choose to maintain anesthesia?
5. What muscle relaxant would you choose?
6. What can be done to decrease the incidence of intraoperative awareness?
7. Five minutes after intubation, the peak airway pressure increased from 20 to 40 cm H_2O. What are the possible causes?
8. How would you make a diagnosis of tension pneumothorax?
9. What is the treatment of tension pneumothorax?
10. The patient's blood loss was continuing and the hematocrit was 18%. What type of blood would you give if the type and crossmatch are not completed?
11. What precautions should be taken if more than 2 units of type O Rh-negative uncrossmatched whole blood is given?
12. What are the complications associated with any blood transfusion?
13. What is considered a massive transfusion?
14. What are the complications associated with a massive transfusion?
15. Can the shift of the oxygen–hemoglobin dissociation curve be quantitated?
16. How is hypothermia defined?
17. What are the adverse effects of hypothermia?
18. What is the treatment of hypothermia?
19. What are the effects of blood transfusion on the immune system?
20. What are the guidelines for transfusion of blood products?
21. What are the guidelines for the ratio of plasma/platelet transfusion to packed red blood cells in a massive transfusion?
22. If a patient were a member of the Jehovah's Witness religious sect, would you give a blood transfusion?
23. If a child is a Jehovah's Witness and suffered from hemorrhagic shock, what would you do?

D. Postoperative Management

1. What is acute respiratory distress syndrome (ARDS)? What is transfusion-related acute lung injury (ALI)?
2. How is ARDS treated?

3. In the recovery room, you are called to see this patient because of oliguria. How would you evaluate and treat this patient?
4. If this patient had a crush injury and low urine output, what other concerns might you have? What if the patient has dark or "tea-colored" urine?

A. Medical Disease and Differential Diagnosis

A.1. How is trauma classified?

Trauma is usually separated into two distinct categories: penetrating and blunt trauma. Both can cause havoc on the body's vascular, visceral, musculoskeletal, and nervous systems.

A.2. What are the injuries associated with thoracic trauma?

Penetrating injuries associated with thoracic trauma are typically associated with stabbings and gunshot wounds. The latter causes far more destruction because of the large amount of kinetic energy transferred to the thoracic cavity from the impact of the bullet. As a result, gunshot wounds to the thorax are diffuse and much more likely to be fatal compared to stabbings.

Blunt injuries to the chest are far more common than penetrating injuries. The most common causes of blunt injuries are deceleration injuries (as a result of motor vehicle accidents) and crush injuries. These can range from relatively minor injuries such as rib fractures to more severe ones such as lung contusion, tracheobronchial tears, flail chest, pneumothorax, hemothorax, injuries to the great vessels, and traumatic ruptures of the esophagus or diaphragm.

Kaplan JA, Slinger PD. *Thoracic Anesthesia*. 3rd ed. New York: Churchill Livingstone; 2003:315–326.

A.3. What are the injuries associated with cardiac trauma?

Penetrating cardiac injuries often lead to immediate cardiovascular collapse, and patients rarely survive to reach the operating room. Injuries associated with penetrating cardiac trauma include pericardial tamponade, cardiac perforation, rupture of a chamber, and fistula formation.

Blunt cardiac trauma injuries include cardiac contusion (most common), pericardial ruptures, rupture of a chamber, valvular tears, coronary artery injuries, and ventricular aneurysms.

Barash PG, Cullen BF, Stoelteg RK, et al., eds. *Clinical Anesthesia*. 6th ed. Philadelphia: Lippincott Williams & Wilkins; 2009:904–905.

Kaplan JA, Slinger PD. *Thoracic Anesthesia*. 3rd ed. New York: Churchill Livingstone; 2003:315–326.

A.4. What are the complications of acute pericardial tamponade?

The primary complication of pericardial tamponade is a decrease in cardiac output secondary to pericardial pressure causing severe diastolic dysfunction. Unstable patients with acute pericadial tamponade present with hypotension, tachycardia, and tachypnea. The diagnosis can be made by the presence of Beck triad (hypotension, distended neck veins, and muffled heart sounds) and pulsus paradoxus, though these

signs can be easily missed on a hypovolemic trauma patient. Definitive diagnosis of cardiac tamponade can be made with transthoracic echocardiography. If the diagnosis of acute pericardial tamponade is made and the patient is unstable, immediate evacuation of the pericardium via a pericardiocentesis or a pericardial window is required. (Also see Chapter 11.)

Barash PG, Cullen BF, Stoelteg RK, et al., eds. *Clinical Anesthesia*. 6th ed. Philadelphia: Lippincott Williams & Wilkins; 2009:904–905.

A.5. What are the anesthetic implications for treating cardiac tamponade?

The anesthetic goal for treating acute cardiac tamponade is to maintain intrinsic sympathetic tone. These patients are extremely dependent on intrinsic sympathetic tone, and therefore maintenance of heart rate and preload are of utmost importance. A preinduction intra-arterial catheter and large-bore intravenous access are essential. Ketamine and etomidate are considered appropriate agents for induction. A rapid-sequence induction with succinylcholine or an awake intubation can be performed. If possible, preinduction sedation should be avoided. Inotropes such as epinephrine should be readily available and can be given in small doses to avoid bradycardia and hypotension. Induction should be delayed until after patient preparation and draping is completed. In the event the patient becomes hemodynamically unstable, the effusion can then be drained as quickly as possible. (Also see Chapter 11.)

Barash PG, Cullen BF, Stoelteg RK, et al., eds. *Clinical Anesthesia*. 6th ed. Philadelphia: Lippincott Williams & Wilkins; 2009:904–905.

A.6. How is the initial assessment and management of the trauma patient performed?

A systematic and organized approach to the assessment and management of the trauma patient has been developed by the American College of Surgeons and is taught as Advanced Trauma Life Support. Initial evaluation and management as stated by Advanced Trauma Life Support consists of five components:

1. The primary survey
2. Resuscitation
3. The secondary survey
4. Continued monitoring and reevaluation
5. Definitive care

Kaplan JA, Slinger PD. *Thoracic Anesthesia*. 3rd ed. New York: Churchill Livingstone; 2003:315–326.

A.7. What constitutes a primary survey and what is its objective?

The assessment of the trauma patient consists of the primary and secondary survey. The function of the primary survey is to identify and treat immediately life-threatening injuries. The life-threatening injuries associated with chest trauma are:

- Lost airway
- Tension pneumothorax
- Massive hemothorax
- Open pneumothorax

- Cardiac tamponade
- Flail chest

Kaplan JA, Slinger PD. *Thoracic Anesthesia*. 3rd ed. New York: Churchill Livingstone; 2003:315–326.

Thoracic trauma: Chest trauma initial evaluation. 2010. Available at: www.trauma.org/thoracic

A.8. What constitutes a secondary survey and what is its objective?

The secondary survey is a more detailed examination aimed at identifying other non–life-threatening injuries, planning further laboratory and radiographic studies, and forming a workable differential diagnosis. Examples of chest injuries identified on secondary survey are the following:

- Simple pneumothorax or hemothorax
- Rib fractures
- Pulmonary contusion
- Non–life-threatening blunt myocardial injury

Kaplan JA, Slinger PD. *Thoracic Anesthesia*. 3rd ed. New York: Churchill Livingstone; 2003:315–326.

Thoracic trauma: chest trauma initial evaluation. 2010. Available at: www.trauma.org/thoracic

A.9. What are the signs and symptoms of a hemothorax? What is the definition of massive hemothorax?

The signs and symptoms of a hemothorax include diminished breath sounds on the affected side, hemorrhagic shock, and mediastinal shift. A massive hemothorax is defined as a rapid accumulation of greater than 1,500 mL of blood in the thoracic cavity.

Reed AP, Yudkowitz FS. *Clinical Cases in Anesthesia*. 3rd ed. New York: Churchill Livingstone; 2005:481–493.

A.10. What are the indications for a thoracotomy to treat a hemothorax?

Hemothorax, if severe enough, can lead to hemorrhagic shock. Therefore, timely diagnosis and treatment are of utmost importance. After a chest tube is placed, if drainage of blood is greater than 1,200 mL or if drainage is greater than 200 mL per hour for over 4 hours, a thoracotomy is indicated. Alternatively, if the patient is older than 60 years, then if drainage is greater than 100 mL per hour for over 4 hours, a thoracotomy is also indicated. If the patient does not meet these criteria but is still hemodynamically unstable or if ventilation is difficult, emergent surgery should be performed.

Reed AP, Yudkowitz FS. *Clinical Cases in Anesthesia*. 3rd ed. New York: Churchill Livingstone; 2005:481–493.

A.11. How are pneumothoraces categorized?

Pneumothoraces are categorized into three broad categories: open, closed, and tension pneumothorax. Pneumothoraces, like hemothoraces, can cause severe hypoxemia, impair venous return, and cause a severe mediastinal shift.

Open pneumothoraces are a result of penetrating wounds and allow intrathoracic pressure to equalize with atmospheric pressure. The result is introduction of outside air every time the patient takes a breath. Definitive treatment is to close the wound and placement of a chest tube.

Closed pneumothoraces can result from both blunt and penetrating trauma to the chest. It is defined as the presence of air in the pleural space. Diagnosis can be made radiographically, via a chest radiograph or computed tomography (CT), though in many trauma situations, the patients' condition precludes obtaining a chest radiograph. In such cases, diagnosis can be made by physical examination, that is, by percussion or by diminished or absent breath sounds. In addition, a diagnosis can be made by ultrasound examination of the chest. Recent studies have suggested that using ultrasound detection of a pneumothorax can be a faster and more sensitive test than a supine chest radiograph. Treatment for a pneumothorax is the placement of a chest tube if the patient is unstable or if the pneumothorax is greater than 10% of the pleural cavity.

Tension pneumothorax is the progressive build-up of air within the pleural space that cannot escape. Essentially, it is a "one-way valve" that is exacerbated by positive pressure ventilation. This progressive build-up of air can cause a mediastinal shift, acute rise in airway pressures, and obstruction of venous return. All of these factors can result in a sudden and dramatic cardiovascular collapse.

Kaplan JA, Slinger PD. *Thoracic Anesthesia*. 3rd ed. New York: Churchill Livingstone; 2003:315–326.

Thoracic trauma: chest trauma—pneumothorax. 2010. Available at: www.trauma.org/thoracic

Wilkerson RG, Stone MB. Sensitivity to bedside ultrasound and supine anteroposterior chest for the identification of pneumothorax after blunt trauma. *Acad Emerg Med*. 2010;17:11–17.

A.12. What is an occult pneumothorax?

An occult pneumothorax is a pneumothorax that is diagnosed by CT but was not identified previously on the chest radiograph. In many cases, this type of pneumothorax is managed conservatively and resolves over time, without requiring placement of a chest tube. Frequently, a trauma patient with an occult pneumothorax will require general anesthesia and positive pressure ventilation. Whether these patients should have a chest tube placed pre-emptively is currently debated. For now, the decision should be made on a case-by-case basis.

When any trauma patient is placed on positive pressure ventilation, a history of a negative chest radiograph alone does not rule out the presence of an occult pneumothorax. As many as 50% of all pneumothoraces are occult, with an overall incidence of 5% in all trauma patients.

Ball CG, Kirkpatrick AW, Feliciano DV. The occult pneumothorax: what have we learned? *Can J Surg*. 2009;52:E173–E179.

Ouellet JF, Trottier V, Kmet L, et al. The OPTICC trial: a multi-institutional study of occult pneumothoraces in critical care. *Am J Surg*. 2009;197:581–586.

A.13. If the patient has a widened mediastinum on chest radiograph, what are your concerns?

A chest radiograph revealing a widened mediastinum may indicate the presence of a thoracic aortic injury. These types of injuries are often life threatening, necessitating

immediate identification and intervention. Blunt aortic injury is associated with high-speed deceleration and is the second leading cause of death in trauma patients, accounting for 16% of all trauma-related deaths. Open surgical repair requires a double lumen tube, single-lung ventilation, and clamping of the proximal aorta while taking measures to protect the spinal cord. In patients with coexisting injuries, such as increased intracranial pressure, profound bleeding, or hypoxemia, this procedure may be contraindicated. These patients may be medically managed with blood pressure control until these other issues have resolved. They may also be a candidate to undergo a less invasive endovascular repair, a technique that has been increasingly used over the last 20 years.

Ekah AP, Peterson W, Woods R, et al. Is chest x-ray an adequate screening tool for diagnosis of blunt thoracic aortic injury? *J Trauma*. 2008;65:1088–1092.

Neschis DG, Scalea TM, Flinn WR, et al. Blunt aortic injury. *N Engl J Med*. 2008;359:1708–1716.

A.14. What are the most commonly injured organs in blunt abdominal trauma?

In blunt abdominal trauma, the most commonly injured organs are the spleen, liver, kidneys, and bowel. Generally, blunt abdominal trauma leads to higher mortality rates than penetrating trauma. The reason is multifactorial and includes greater difficulty in diagnosis and frequent association with other injuries, such as head injury, chest trauma, and fractures.

A.15. What is a focused abdominal sonography for trauma (FAST) examination?

FAST is a rapid ultrasonography examination performed in the trauma resuscitation room. It has been used to determine the presence of fluid (blood) within the peritoneum, pericardium, and thorax. Currently, FAST is particularly helpful in the bedside examination of hemodynamically unstable blunt trauma patients. It may also have a role in some patients with penetrating trauma.

Rozycki GS, Root DH. The diagnosis of intraabdominal visceral injury. *J Trauma*. 2010:1019–1022.

Trauma ultrasonography—the FAST and beyond. 2007. Available at: www.trauma.org/radiology/FASTintro.html

A.16. What is diagnostic peritoneal lavage?

In penetrating trauma, diagnostic peritoneal lavage allows for rapid identification of a hemoperitoneum and therefore the discovery of an intraperitoneal injury. Peritoneal lavage is a procedure performed in the emergency room to help determine whether a patient has internal bleeding that requires an exploratory laparotomy. It is done by performing a mini-laparotomy under local anesthesia. A catheter is then placed into the abdomen and is aspirated for gross blood. Aspiration of 10 mL of blood is considered a positive finding. A grossly bloody aspirate is indicative of solid or vascular injury. If less than 10 mL of blood is aspirated, then 1 L of lactated Ringer's solution or normal saline is allowed to drain into the abdomen. The lavage fluid is then allowed to return by gravity and is sent to the laboratory for analysis. Criteria for a positive peritoneal lavage are an erythrocyte count of 100,000 per mm^3, a white blood cell count of 500 per mm^3, the presence of bile or food particles, and

a fluid amylase concentration of 175 units per dL. The white blood cell level itself should not determine the need for laparotomy. The level of white blood cells also does not rise initially, but requires several hours to rise. Alkaline phosphatase and amylase are contained in the small bowel and spill into the abdominal cavity after injury. These levels tend to rise early in injury. Amylase in lavage fluid has been seen as a more accurate marker than alkaline phosphatase. If the peritoneal lavage meets one or more of these criteria, the patient comes to the operating room for an exploratory laparotomy.

Runyan MS, Marx JA. Peritoneal procedures. In: Roberts JR, Hedges JR, eds. *Clinical Procedures in Emergency Medicine*. 5th ed. Philadelphia: WB Saunders; 2009:773–789.

A.17. Why was diagnostic peritoneal lavage not performed for this patient?

Peritoneal lavage was not done for two reasons. First, it is felt that all penetrating wounds to the abdomen need to be surgically explored. Second, this patient was exhibiting signs of shock and obviously needed to be sent to the operating room without delay.

Before CT and ultrasonography technologies, diagnostic peritoneal lavage was the only diagnostic test available to rapidly evaluate the abdomen for injury. Although diagnostic peritoneal lavage is highly sensitive, it can also result in false positive results, leading to unnecessary exploratory laparotomies. CT now allows for evaluation of all intraperitoneal organs, the diaphragm, and the retroperitoneum (an area inaccessible to diagnostic peritoneal lavage), while also allowing for identification of the specific organ injured. CT should be used in the evaluation of hemodynamically stable trauma patients.

Rozycki GS, Root DH. The diagnosis of intraabdominal visceral injury. *J Trauma*. 2010;68:1019–1022.

A.18. Define shock.

Shock is defined as the circumstance of insufficient oxygen delivery to sustain aerobic metabolism in vital cells of essential organs. Shock of all forms appears to be invariably related to inadequate tissue perfusion. The low-flow state in vital organs seems to be the final common denominator in all forms of shock.

Mullins R. Shock, electrolytes and fluid. In: Townsend CM, ed. *Sabiston Textbook of Surgery*. 18th ed. Philadelphia: WB Saunders; 2007:69–112. Available at: MD Consult online database: http://www.mdconsult.com.

A.19. What are the four types of shock?

For a working classification of shock, the following classification offered by Blalock in 1934 is still useful and functional:

- *Hematogenic (hypovolemic, hemorrhagic) shock:* Characterized by a loss of circulatory blood volume.
- *Cardiogenic shock:* Characterized by an inability of the myocardium to pump blood.
- *Vasogenic (septic) shock:* Characterized by an infection that causes a decrease in peripheral vascular resistance.
- *Neurogenic shock:* Characterized by an impairment of the central nervous system–mediated control of vascular tone.

Mullins R. Shock, electrolytes and fluid. In: Townsend CM, ed. *Sabiston Textbook of Surgery*. 18th ed. Philadelphia: WB Saunders; 2007:69–112. Available at: MD Consult online database: http://www.mdconsult.com.

A.20. List the signs and symptoms of shock.

Tachycardia, hypotension, cool extremities, pallor, oliguria, tachypnea, decreased capillary refill, anxiety, restlessness, and loss of consciousness are signs and symptoms of shock.

A.21. What is the pathophysiology of hypovolemic shock?

Cardiovascular derangement

An acute decrease in circulating blood volume leads to an increase in sympathetic activity with an outpouring of epinephrine and norepinephrine from the adrenal gland. The α-adrenergic response causes vasoconstriction, which shunts blood from the skin, viscera, and muscle, thereby preserving the coronary and cerebral circulation. With constriction of both precapillary and postcapillary sphincters, a reduction occurs in hydrostatic pressure of the capillary bed, which allows the osmotic pressure to draw fluid back into the vascular space from the interstitial space. This process of hemodilution tends to expand the patient's blood volume. In addition to the vasoconstriction and hemodilution, a tachycardic response may be noted.

Myocardial-depressant factor is a peptide thought to be released from the pancreas during low-flow states. This peptide is thought to be responsible for some of the decreased cardiac performance seen in trauma patients. Pancreatectomy and various myocardial-depressant factor antagonists demonstrate protective myocardial effects during shock in animals.

Acid–base disturbance

Metabolic acidosis is almost always seen in association with a shock state. As a result of decreased blood flow or a low rate of perfusion, oxygen delivery to vital organs is reduced and consequently a mandatory change occurs from aerobic to anaerobic metabolism. This shift will lead to the production of lactic acid instead of carbon dioxide as the end product of metabolism. The increase in lactic acid leads to a metabolic acidosis.

Jones EA, Kline JA. Shock. In: Marx JA, Hockberger RS, Walls RM, et al., eds. *Rosen's Emergency Medicine: Concepts and Clinical Practice*. 7th ed. St. Louis: Mosby; 2009:34–41.

Mullins R. Shock, electrolytes and fluid. In: Townsend CM, ed. *Sabiston Textbook of Surgery*. 18th ed. Philadelphia: WB Saunders; 2007:69–112. Available at: MD Consult online database: http://www.mdconsult.com.

A.22. How would you classify hemorrhage?

Classification of hemorrhage based on blood loss is as follows:

Class I: Blood loss of up to 15% of the blood volume: normal pulse and blood pressure
Class II: Blood loss of up to 30% of the blood volume: tachycardia, decreased urine output, and anxiety
Class III: Blood loss of up to 40% of the blood volume: marked tachycardia, hypotension, tachypnea, oliguria, and anxiety
Class IV: Blood loss of more than 40% of the blood volume: tachycardia and hypotension, tachypnea, anuria, confusion, and lethargy

Dutton RP. Shock and trauma anesthesia. *Anesthesiol Clin North Am*. 1999;17:83–95.

A.23. What is the initial treatment of hemorrhagic shock?

The initial treatment of hemorrhagic shock is to attempt to stabilize hemodynamics by administering fluids and blood products as required to maintain tissue perfusion and oxygen delivery. Recently, trauma centers have revised the standard approach to resuscitation for major traumatic hemorrhage requiring massive transfusion. Trauma centers have adapted the practice of initial resuscitation with hemostatic components such as plasma and platelets, as well as packed red blood cells. This strategy for treating massive hemorrhage was pioneered from knowledge gained from combat hospitals in Iraq and Afghanistan. This approach involves limiting the total volume of crystalloid and replacing intravascular volume with packed red blood cells and fresh frozen plasma (FFP) in a ratio approaching 1:1. This strategy is geared to avoid the acute coagulopathy associated with major trauma and blood loss and has been shown to decrease mortality rates in combat and civilian injuries requiring massive transfusion.

Barash PG, Cullen BF, Stoelteg RK, et al., eds. *Clinical Anesthesia*. 6th ed. Philadelphia: Lippincott Williams & Wilkins; 2009:904–905.

Griffee MJ, Deloughery TG, Thorborg PA. Coagulation management in massive bleeding. *Curr Opin Anaesthesiol*. 2010;23:263–268.

A.24. Would you choose crystalloid or colloid therapy to treat hypovolemic shock?

Crystalloid solutions can sustain hemodynamics and deliver adequate oxygenation in healthy patients who have lost as much as 30% of their total blood volume. Still, controversy remains over the use of crystalloid versus colloid therapy for the initial therapy of hypovolemic shock.

Proponents of crystalloid therapy believe that both intravascular and interstitial fluid losses occur in hypovolemic shock and that these can be readily replaced with crystalloids. Another benefit of crystalloids is the decrease in blood viscosity, which may enhance perfusion. A particular advantage to lactated Ringer's solution is that lactate is metabolized to bicarbonate, which may help to buffer the patient's acidosis. Finally, in this age of medical economics, the cost of crystalloid is much less than that of colloid. Because crystalloid leaves the intravascular space and enters the interstitial space, large quantities are needed, and some fear that these quantities may lead to both pulmonary and peripheral edema, although studies have not confirmed this fear.

Proponents of colloid therapy, on the other hand, argue that much less volume of fluid is needed to counteract hypovolemic shock and that early colloid therapy can prevent the complications associated with large-volume crystalloid resuscitation such as dilutional coagulopathy, hyperchloremic acidosis, and edema. Colloids maintain the oncotic pressure and hold the interstitial fluids in the intravascular space, which is felt to possibly prevent pulmonary edema. If leaky alveolar capillary membranes are seen within the lung, colloids may worsen pulmonary edema.

A.25. Is there a place for dextran or hetastarch (Hespan) in treating hypovolemic shock?

Dextran and hetastarch are synthetic polysaccharide solutions with varying mean molecular weights. Dextran 40, dextran 70, and hetastarch have all been used as volume expanders. Dextrans are relatively inexpensive, increase effective blood volume, and decrease blood viscosity. Nevertheless, their negative aspects are considerable. They impair coagulation by coating platelets, and they impair typing and crossmatching by coating red blood cells. In addition, anaphylactic reactions have been reported.

A.26. Is there a place for hypertonic saline in the treatment of hypovolemic shock?

Hypertonic saline is now being used for resuscitation at some major centers. Its effects tend to be of short duration, so it is not used alone. It is under investigation as a resuscitative agent, particularly in the prehospital setting, because small volumes may have beneficial cardiovascular effects. If one combines hypertonic saline and dextran, the effective resuscitation will be prolonged. Hypertonic saline is usually supplied as 7.5% NaCl, often combined with a colloid, 6% dextran 70. The optimal dose is thought to be 4 mL per kg.

The potential advantage is that the greater the sodium concentration, the less total volume will be required for resuscitation. A serious potential danger exists in that patients may become hypernatremic, which can lead to brain dehydration. In patients with high intracranial pressure, this brain dehydration may have a potential benefit in lowering it.

Hypertonic saline solutions have been used successfully in hemorrhagic shock resuscitation in animals and humans. This type of fluid resuscitation offers the advantage of requiring smaller volumes for a similar effect (4 to 5 mL per kg), making it especially attractive for use during prehospital resuscitation. Hypertonic saline has been shown to elevate mean arterial pressure and cardiac output and increase renal, mesenteric, total splanchnic, and coronary blood flow. It causes a small and transient rise in circulating volume by transcapillary refill. These beneficial effects after controlled hemorrhage have been established. Its hypertonic nature and small volume usage are particular advantages in traumatic brain injury. Hypertonic saline promotes redistribution of fluid into the vascular compartment and decreases intracranial pressure. It also seems to offer similar advantages to improvement in microcirculatory flow of the spinal cord. Use of these products during uncontrolled hemorrhage, nevertheless, has been strongly questioned.

B. Preoperative Evaluation and Preparation

B.1. What premedication would you order?

None. This is a critically ill patient who is coming to the operating room for emergency surgery. Narcotics and sedatives would be contraindicated because they could worsen his already tenuous hemodynamic state.

B.2. What preoperative testing would you order?

Because of the emergent nature of the trauma setting, preoperative tests and imaging studies are frequently limited. If the patient is hemodynamically unstable, any preoperative evaluation is aborted and the patient is taken directly to the operating room.

If the patient is stable, a portable chest radiograph, arterial blood gas, complete blood count, and FAST can be obtained in a relatively short period in the emergency department or operating room before surgery. Often, these tests can be obtained while the patient is being prepared for emergency surgery. This information can be combined with other monitoring adjuncts such as oxygen saturation, invasive blood pressure, and electrocardiogram to evaluate the patient and formulate an appropriate management strategy. Although it is usually not possible to clinically clear the c-spine before surgery, it is important to know the results of any radiologic studies that have been done, in order to rule out an unstable cervical spine fracture, or adjust anesthetic plan accordingly.

C. Intraoperative Management

C.1. How would you monitor this patient?

Routine noninvasive monitor would include electrocardiogram, blood pressure cuff, oxygen monitor, pulse oximeter, end-tidal carbon dioxide, esophageal stethoscope, temperature probe, and Foley catheter.

Invasive monitors for this patient would include an arterial line and a central venous catheter. An arterial line is useful for blood sampling and direct blood pressure monitoring. The central venous line is helpful for determining the patient's volume status. A pulmonary artery catheter may be indicated if the patient shows signs of heart failure.

C.2. How would you induce anesthesia?

Because all trauma patients are considered to have a full stomach, the best way to protect the patient's airway is to perform a rapid-sequence induction with cricoid pressure while maintaining in-line cervical immobilization of the c-spine for any patient in a c-collar. For the patient with a suspected difficult airway, one could do an awake fiberoptic intubation. Awake fiberoptic intubation in this population can be difficult, because they may be confused, uncooperative, and sometimes even combative. First, if tolerated, the patient should be preoxygenated for 3 to 5 minutes. Next, ketamine 1 to 2.5 mg per kg, might be given followed by succinylcholine 1.5 mg per kg while maintaining cricoid pressure. Ketamine was chosen in this case because of its cardiovascular-stimulating effects and the patient's unstable hemodynamics. Etomidate (0.2 mg per kg) would be another appropriate choice for an induction agent. If the patient was adequately resuscitated in the emergency room and is hemodynamically stable, one could possibly use a small dose of thiopental or midazolam or fentanyl for induction.

If the patient is comatose, in severe shock, or in full arrest on admission to the resuscitation room, no drug other than oxygen and possibly a neuromuscular blocking drug is required until the patient's blood pressure and heart rate sufficiently rebound so anesthetics can be titrated. In awake traumatized patients who are thought to be hypovolemic, etomidate is best tolerated.

Wilson WC, Patel N, Hoyt DB, et al. Perioperative anesthetic management of patients with abdominal trauma. *Anesthesiol Clin North Am.* 1999;17:211–236.

C.3. What technique could you use if single-lung ventilation was indicated?

If the patient does not already have a secure airway, the airway should be secured in the manner described in the previous question. Single-lung ventilation is indicated in this situation if the patient is bleeding from one lung and protection of the other lung is required or to improve the surgical field (lower priority). Once the airway is secured, there are several ways to obtain single-lung ventilation. The easiest and safest technique would be to use an Arndt or Cohen bronchial blocker thorough the endotracheal tube. If those blockers are not available, one could pass an embolectomy catheter (bronchial blocker) in the trachea and then the endotracheal tube. The bronchial blocker could then be positioned under direct vision using fiberoptic bronchoscopy. Alternatively, the bronchial blocker could be placed through a bronchoscopy adapter and endotracheal tube, and its position can be confirmed by fiberoptic bronchoscopy. The point at which the bronchial blocker enters the bronchoscopy adapter can then be sealed with pliable "bone wax" (a form of sterile bees wax that is soft and kneadable).

Another method of obtaining single-lung ventilation would be to change the endotracheal tube to a double-lumen tube through a Cook exchange catheter. The major risks of this option are losing a previously secured airway and aspiration while attempting to change the tube.

C.4. What agents would you choose to maintain anesthesia?

As the patient stabilizes and the hemodynamics improve, other anesthetic agents can be carefully titrated to prevent hypotension, as follows:

- Sedatives or amnestics should be added to the anesthetic as soon as tolerated. Remember to start with small doses and check the patient's reaction to the drugs between doses.
- Opioids should be titrated to control the hemodynamic response to surgery.
- Nitrous oxide must be carefully considered, because it has the capacity to accumulate in closed airspaces or because of the high possibility that this patient has an occult pneumothorax.
- Inhalational anesthetics may be used in low concentrations so the patient's hemodynamics are not compromised.

C.5. What muscle relaxant would you choose?

Vecuronium, rocuronium, and cis-atracurium are free of cardiovascular side effects and have an intermediate duration of action. They are acceptable choices. Pancuronium is a long-acting muscle relaxant with vagolytic properties that may be deleterious to the patient.

Curare, metocurine, atracurium, and mivacurium all have the potential to cause hypotension and therefore would not be chosen for this patient.

C.6. What can be done to decrease the incidence of intraoperative awareness?

The incidence of intraoperative awareness is commonly cited as approximately 0.2%. This is probably an overestimation. In other sources, the incidence of traumatic intraoperative recall associated with pain is less that 0.03%. The American Society of Anesthesiologists Closed Claims database states that claims associated to recall during anesthesia constitute 1.5%. An increased relative risk for recall is seen in certain types of surgery, including cardiac surgery, cesarean sections, and trauma surgery. This most likely represents intentional light anesthesia associated with higher levels of stimulation. Recently, the Bispectral Index by Aspect Medical Systems (Natick, MA) and the PSA 4000 by Physiometrix (Billerica, MA) have been used as monitors of intraoperative awareness. It has been shown that patients with a Bispectral Index value of 50 were able to respond to verbal commands less than 10% of the time. Although

this information may be potentially useful, the application of these monitors during a trauma resuscitation may not be easily accomplished.

Rampil I. Monitoring depth of anesthesia. *Curr Opin Anesthesiol*. 2001;14:649–653.

C.7. Five minutes after intubation, the peak airway pressure increased from 20 to 40 cm H_2O. What are the possible causes?

The possible causes of peak airway pressure increase are as follows:

- Tension pneumothorax
- Bronchospasm
- Endobronchial intubation
- Pulmonary edema
- Secretions
- Kink in the anesthesia circuit or endotracheal tube

C.8. How would you make a diagnosis of tension pneumothorax?

A tension pneumothorax can be diagnosed by the absence of breath sounds on the affected side. The chest movement may be asymmetric. Neck veins will be full, and systemic hypotension can occur if the tension pneumothorax is severe. Any patient who deteriorates under anesthesia and has wounds to the upper abdomen, lower neck, or ribs should be assumed to have a tension pneumothorax until proven otherwise.

Eckstein M, Henderson SO. Thoracic trauma. In: Marx JA, Hockberger RS, Walls RM, et al., eds. *Rosen's Emergency Medicine: Concepts and Clinical Practice*. 7th ed. St. Louis: Mosby; 2009:387–397.

C.9. What is the treatment of tension pneumothorax?

Immediate decompression of the chest is mandatory for tension pneumothorax because a patient's hemodynamics will deteriorate. Diagnosis is made clinically and not by a chest radiograph. An 16 or 18-gauge Angiocath is placed into the second intercostal space at the midclavicular plane. After the air escapes, confirming your diagnosis, and the lung is decompressed, a chest tube should be placed.

Eckstein M, Henderson SO. Thoracic trauma. In: Marx JA, Hockberger RS, Walls RM, et al., eds. *Rosen's Emergency Medicine: Concepts and Clinical Practice*. 7th ed. St. Louis: Mosby; 2009:387–397.

C.10. The patient's blood loss was continuing and the hematocrit was 18%. What type of blood would you give if the type and crossmatch are not completed?

This patient should have blood transfused as soon as possible. Type O Rh-negative packed cells are the universal donor. This should be started while type-specific blood

is being made available. Whenever the type-specific blood is ready, one can switch to it. If the transfusion begins with type O Rh-negative *whole blood* and more than 2 units has been infused, only type O Rh-negative blood should continue to be used. Usually, by the time a patient reaches the operating room from the emergency room, a partial crossmatch can be done. This usually takes 5 to 10 minutes, after which time type-specific blood can be transfused.

Gorgas D. Transfusion therapy. In: Roberts JR, ed. *Clinical Procedures in Emergency Medicine*. 5th ed. Philadelphia: WB Saunders; 2009: 483–80.

Miller R. Transfusion therapy. In: Miller RD, ed. *Miller's Anesthesia*. 7th ed. Philadelphia: Churchill Livingstone; 2010: 1739–1766.

C.11. What precautions should be taken if more than 2 units of type O Rh-negative uncrossmatched whole blood is given?

The plasma from type O Rh-negative *whole blood* contains anti-A and anti-B antibodies, which can cause hemolytic reactions with type A and type B blood cells if given in significant quantities. Therefore, only type O Rh-negative blood should continue to be transfused, although this will lead to minor hemolysis of the patient's own red blood cells. The patient should not receive his type-specific blood until the blood bank determines that the transfused anti-A and anti-B antibody levels have fallen sufficiently low to permit safe transfusion of type-specific blood. This usually requires a 2-week waiting period.

Packed red blood cells have smaller volumes of plasma and are virtually free of anti-A and anti-B antibodies. Therefore, whenever type-specific blood is not yet available, type O Rh-negative uncrossmatched packed red blood cells should be used in preference to type O Rh-negative *whole blood*. Once type-specific blood is available, it can be used safely.

Miller R. Transfusion therapy. In: Miller RD, ed. *Miller's Anesthesia*. 7th ed. Philadelphia: Churchill Livingstone; 2010:1739–1766.

C.12. What are the complications associated with any blood transfusion?

Complications associated with blood transfusion are as follows:

Transfusion reactions

- Febrile reactions occur in approximately 1% of all transfusions. In an awake patient, this is usually no more than an annoyance that requires decreasing the infusion rate.
- Allergic reactions to properly crossmatched blood will manifest as an increase in temperature, pruritus, and urticaria. This may be difficult to diagnose in the anesthetized patient. Treatment consists of administration of antihistamines and discontinuation of the transfusion.
- Hemolytic reactions occur when incompatible blood is administered. Caused by activation of the complement system, they can be life threatening. In the awake patient, fever, chills, dyspnea, substernal, and lumbar pain are seen in addition to hypotension. Under general anesthesia, the only sign that is not masked is hypotension. Also, if free hemoglobin can be documented in the plasma or urine, this too would be indicative of a transfusion reaction. Substances released by the hemolyzed cells can lead to disseminated intravascular

coagulation (DIC) and acute renal failure (ARF). Treatment consists of immediate discontinuation of the transfusion. Hypotension should be treated with hydration, vasopressors, and inotropic agents if needed. Urinary output must be maintained by adequate hydration. Although its value is uncertain, sodium bicarbonate has been used to alkalinize the urine to improve the solubility of the hemoglobin-degradation products. The risk of an ABO-incompatible transfusion is 1:33,500 red blood cell transfusions. Mortality associated with this remains high, at approximately 40%.

Transmission of disease

- Transmission of disease can be a serious problem. HIV, hepatitis B virus, hepatitis C virus, and cytomegalovirus can all be transmitted by transfusion. Because the risk of disease transmission increases with each unit of blood or its components given, they must be carefully scrutinized before they are administered. Currently, the incidence of posttransfusion HIV infection is 1:1,780,000 per transfused unit of blood. The risk of hepatitis B transmission is approximately 1 per 269,000 units. The risk of hepatitis C transmission is 1:1,600,000 per unit transfused. Cytomegalovirus is the most common viral agent transmitted by blood transfusion; it produces clinically important infections only in immunodepressed patients. Malaria, syphilis, Lyme disease, Chagas disease, and other diseases may also be transmitted through transfusion of blood and blood products. The aggregate infection risk is approximately 1 per 34,000. As new nonhemoglobin solutions appear on the market, less blood will be transfused and disease transmission will diminish.

Microembolization

- Microembolization can occur from the transfusion of blood or its components. Stored blood forms microaggregates that are too small to be removed by the standard 170-micron blood filters. Smaller filters have been developed to remove these particles. When using blood filters of the 20- to 40-micron range, the rate of transfusion is dramatically decreased because of the increased resistance of the filters. Some early reports suggested that these microaggregates may lead to pulmonary dysfunction, but this has never been proven.

C.13. What is considered a massive transfusion?

A massive transfusion is defined as the replacement of the patient's total blood volume in a 24-hour period. This is usually between 8 and 10 units of packed red blood cells. Many trauma cases far exceed this amount and may require other blood components in addition to the red blood cells.

Miller RD, ed. Transfusion therapy. In: *Miller's Anesthesia*. 7th ed. New York: Churchill Livingstone; 2010:1739–1766.

C.14. What are the complications associated with a massive transfusion?

Complications of a massive transfusion include hypothermia, acidosis, coagulopathy, DIC, fibrinolysis, citrate toxicity, hyperkalemia, hypokalemia, acid–base imbalance, and impaired hemoglobin function.

- Hypothermia is an obvious consequence of infusing cold banked blood. Therefore, it is recommended that the blood be reconstituted with warm normal saline. In addition, all fluids should pass through a warming device and the operating room should be kept warm, in order to help prevent hypothermia .
- The coagulopathy associated with trauma is multifactorial. It is a combination of thrombocytopenia and dilutional and consumptive factors. Furthermore, the systemic inflammatory response syndrome that is associated with trauma produces activated protein C, an anticoagulant. In addition, hypothermia and acidosis are commonly seen during massive transfusions and this worsens the coagulopathy. Both platelets and coagulation factors are markedly decreased and must be replaced. They should be administered after laboratory documentation of the deficiency. It is no longer accepted practice to give FFP routinely after 5 units of packed red blood cells, and it is not proper to give platelets after 10 units of packed red blood cells. DIC and fibrinolysis may occur after massive transfusions. An important triggering event of DIC and fibrinolysis is shock, with its accompanying tissue ischemia, acidemia, and waste product accumulation. Therefore, early and prompt treatment of hypoperfusion is mandatory.
- Citrate toxicity is frequently discussed, but it is rarely a problem. However, in the pediatric population, citrate toxicity is much more of a problem and should be considered in any child who does not respond to rapid volume administration of blood products. Citrate is added to stored blood to bind calcium and therefore prevent clotting. Citrate binds calcium and decreases the patient's ionized calcium level. Hypocalcemia may present as a prolongation of the QT interval with little effect of cardiac performance. In some cases, ventricular performance may be compromised. Cardiac performance also may be decreased by acidemia, hyperkalemia, and hypothermia, which all accompany the shock state. Citrate is metabolized to bicarbonate, and it can contribute to posttransfusion metabolic alkalosis.
- Hyperkalemia can be a rare occurrence in the massively transfused patient. Plasma potassium levels of stored whole blood range between 12 and 32 mEq per L. The potassium level increases approximately 1 mEq/L/day in stored blood. A unit of whole blood would contain between 4 and 8 mEq of potassium, which is hardly enough to cause hyperkalemia. A unit of packed red blood cells contains insignificant amounts of potassium because most plasma is removed. However, in the shock state with hypoperfusion and acidemia, hyperkalemia may become evident.
- Hypokalemia is also a possibility after a massive transfusion. Citrate is metabolized to bicarbonate, resulting in a metabolic alkalosis that can cause hypokalemia. In addition, the transfused red blood cells take up potassium, which can also result in hypokalemia.
- Acid–base imbalance is a problem after massive transfusion. Banked blood with a pH level of 6.8 is acidotic and may worsen the acidosis that accompanies shock.

This acidosis is easily reversible with the restoration of normal perfusion. No need is seen to give supplemental bicarbonate based on an arbitrary number of units transfused. Nevertheless, if metabolic acidosis persists, sodium bicarbonate is warranted. As stated, citrate from stored blood and lactate from lactated Ringer's solution are metabolized to bicarbonate, and this can cause metabolic alkalosis.

- Impaired hemoglobin function is a theoretic possibility after massive transfusion. The 2,3-diphosphoglycerate level is decreased in banked blood. This will shift the oxygen–hemoglobin dissociation curve to the left, and oxygen will be held more tightly by the hemoglobin molecule. No studies have documented any adverse effects from this.

Goskowicz R. The complications of massive blood transfusion. *Anesthesiol Clin North Am*. 1999;17:959–978.

Miller RD, ed. Transfusion medicine. In: *Miller's Anesthesia*. 7th ed. Philadelphia: Churchill Livingstone; 2010:1739–1766.

C.15. Can the shift of the oxygen–hemoglobin dissociation curve be quantitated?

Yes, the shift of the oxygen–hemoglobin dissociation curve is quantified by means of the P_{50} values (i.e., the partial pressure of oxygen at which hemoglobin is 50% saturated with oxygen). A leftward shift of the curve indicates a low P_{50} value. The normal P_{50} value of blood is 27 mm Hg and the normal level of 2,3-diphosphoglycerate is 4.8 mmol per mL of erythrocytes.

Lumb AB. *Nunn's Applied Respiratory Physiology*. 6th ed. Philadelphia: Butterworth-Heinemann; 2009:463–475.

C.16. How is hypothermia defined?

Hypothermia is defined as a core body temperature of less than 35° C (95° F). A trauma patient brought to the emergency room may already be hypothermic. Prolonged exposure to a cold operating room, evaporative heat loss from the respiratory tract, infusions of cold fluids, and loss of heat production secondary to shock cause decreased core temperature in most patients.

All skin surfaces not in the surgical field should be covered to reduce convective and radiant heat loss. Humidification of inspired gases reduces evaporative heat loss from the lung. All intravenous fluids should be warmed.

Warming the operating room may also lessen heat loss, as will the use of warming blankets.

Sessler D. Temperature regulation and monitoring. In: Miller RD, ed. *Miller's Anesthesia*. 7th ed. Philadelphia: Churchill Livingstone; 2010:1533–1556.

C.17. What are the adverse effects of hypothermia?

- Shivering-induced increase in oxygen consumption by as much as 400%
- A leftward shift in the oxygen–hemoglobin dissociation curve

- Decreased coagulation of blood (10% reduction in coagulation factor activity for every 1° C drop in body temperature)
- Increased epinephrine and norepinephrine levels, causing vasoconstriction
- As hypothermia becomes severe, possible decreases in both heart rate and blood pressure
- Cardiac arrhythmias that can progress to ventricular fibrillation

Tanaka M, Nagasaki G, Nishikawa T. Moderate hypothermia depresses arterial baroreflex control of heart rate during, and delays its recovery after general anesthesia in humans. *Anesthesiology*. 2001;95:51–55.

C.18. What is the treatment of hypothermia?

The normal response to hypothermia is shivering, which is blocked by general anesthesia. Therefore, it is of utmost importance to prevent and treat hypothermia. Recommendations include the following:

- Increase the temperature of the operating room.
- Use a warming blanket.
- Preheat intravenous fluids.
- Pass all fluids through a warming device.
- Use low-flow anesthesia.
- Use a heat moisture exchanger in the anesthesia circuit.

C.19. What are the effects of blood transfusion on the immune system?

Blood transfusion will result in immunologic changes that can be harmful in some patients and helpful in others. This immunomodulation occurs from immune suppression. The blood components crucial to these changes are thought to be the white blood cells or plasma.

An example of a beneficial effect is the increased survival of the renal allograft in patients who had received a prior transfusion. In patients who have cancer, a possible harmful effect of immunosuppression is the increased cancer recurrence rate seen in patients who have had prior transfusion. Finally, clinical studies have demonstrated that perioperative transfusion is associated with an increased incidence of infection and sepsis.

C.20. What are the guidelines for transfusion of blood products?

The New York Presbyterian Hospital Guidelines for blood product usage are as follows:

Red Blood cell transfusion criteria

- Hemoglobin level less than 8 g per dL and mean red cell volume within normal limit (81 to 100 fL, 70 to 125 fL for patients aged 14 years)

- Hemoglobin level less than 8 g per dL and high risk/acute bleed[1]
- Hemoglobin level less than 11 g per dL and clinically symptomatic[2]
- Hemoglobin level less than 11 g per dL and bleed more than 1 unit per 24 hours
- Any Hemoglobin level and high risk[1] and acute bleed
- Any hemoglobin level and symptomatic[2] and acute bleed
- Any hemoglobin level and bleed more than 2 units per 24 hours, or more than 15% of blood volume per 24 hours

Platelet transfusion criteria

- Platelet count less than 10,000 per μL without thrombotic thrombocytopenic purpura, idiopathic thrombocytopenic purpura, posttransfusion purpura, or hemolytic–uremic syndrome
- Platelet count less than 50,000 per μL with minor bleed, preoperative for a minor procedure or prematurity
- Platelet count less than 100,000 per μL with bleed requiring red blood cell transfusion or preoperative for a major procedure
- Bleeding with loss of 1 blood volume
- Bleeding time longer than 10 minutes
- Open heart surgery transfusion of more than mean number of red blood cell units (6 units/case)

FFP transfusion criteria

- Massive transfusion more than 6 units of red blood cells per 24 hours (more than 1 blood volume infants/children)
- Abnormal coagulation test results, with prothrombin time more than 15 seconds or partial thromboplastin time more than 45 seconds during prior 24 hours, or known congenital coagulation factor disorder and bleeding, or prophylaxis for major procedures
- Clinical evidence of abnormal bleeding from venipuncture sites or generalized oozing
- Patients with diagnosis of thrombotic thrombocytopenic purpura
- Open heart surgery transfusion of more than mean number of red blood cell units (6 units/case)

Cryoprecipitate transfusion criteria

- Massive transfusion more than 8 units of red blood cells per 24 hours
- Open heart surgery transfusion of more than mean number of red blood cell units (6 units/case)
- Bleeding or invasive procedure with hypofibrinogemia or DIC
- Deficient factor VIII or von Willebrand factor or abnormal fibrinogen and presurgical or bleed

New York Presbyterian Hospital. *Weill/Cornell Medical Center Protocols*. New York: Weill/Cornell Medical Center; 2011.

Stehling LC, Doherty DC, Faust RJ, et al. Practice guidelines for blood component therapy: a report by the ASA Task Force of Blood Components Therapy. *Anesthesiology*. 1996;84:732–747.

[1] High risk includes patients with coronary artery disease, chronic pulmonary disease, cerebrovascular disease, or congenital or acquired anemia.

[2] Symptomatic includes patients with signs or symptoms of anemia, such as tachycardia, angina, electrocardiographic changes or of neonatal respiratory distress, known hemoglobinopathy, and so forth.

C.21. What are the guidelines for the ratio of plasma/platelet transfusion to packed red blood cells in a massive transfusion?

Coagulopathy is frequently a problem for the trauma patient requiring massive transfusion. The causes are multifactorial. It is due to dilution of platelets and coagulation factors in addition to acidosis and hypothermia. Most trauma centers have implemented massive transfusion protocols that use the strategy of "hemostatic resuscitation." These protocols are highly variable, but the strategy involves minimizing aggressive crystalloid use, early resuscitation with blood products, and early administration of FFP and platelets.

At present, there are no specific guidelines to the transfusion ratio of FFP to packed red blood cells in massive transfusion. Although clearly more studies are required, the early results show an association toward increased survival when a ratio of FFP to packed red blood cells is 1:2 or higher during massive transfusion.

For platelets, in civilian clinical practice, the standard is still to use 1 six-unit pharesis pack for every 5 to 7 units of red blood cells administered. Initial data from the trauma literature suggests that increasing the platelet to packed red blood cell ratio may also potentially be beneficial.

C.22. If a patient were a member of the Jehovah's Witness religious sect, would you give a blood transfusion?

Jehovah's Witnesses are best known for refusing the transfusion of blood and blood products. This belief is based on the Bible (Acts 15:28–29). In the awake and otherwise competent adult, courts have ruled that physicians cannot be held liable if they comply with a patient's directive and withhold life-saving blood administration after specific and detailed informed consent of the consequences of such an omission of treatment. The issue becomes clouded when patients are incompetent, unconscious (most Jehovah's Witnesses carry cards informing medical personnel of their religious beliefs), or minors. They believe all hope of eternal life is forfeited if they accept a transfusion. Therefore, a blood transfusion is considered a physical violation. The right of a Jehovah's Witness to refuse a blood transfusion is absolute. The courts have upheld their rights to refuse a blood transfusion. Most Witnesses take adequate legal steps to relieve the liability of the medical personnel. Most carry a medical alert card that states their wishes and they usually have made arrangements for proxy or surrogate decision makers. In addition, an open and honest avenue of communication must exist between the patient, surgeon, and anesthesiologist.

They will refuse transfusion of whole blood, packed red blood cells, white blood cells, plasma, and platelets, though they will allow the use of cardiopulmonary bypass, dialysis, or similar equipment, as well as intraoperative blood salvage in which the extracorporeal circulation is uninterrupted. Their religious understanding does not absolutely prohibit albumin, immune globulins, or hemophiliac preparations; those products must be decided on an individual basis. They accept all nonblood replacements, including nonblood colloids, crystalloids, dextrans, or oxygen-carrying blood substitutes.

An anesthesiologist may refuse to care for any patient when a procedure is elective. In an emergency situation, legal and ethical requirements apply. Conversely, any

competent adult also has the right to refuse any therapy, and to treat such a patient against that person's will is to commit battery.

Waters JH, Potter PS, Booke M. Cell salvage in the Jehovah's Witness patient. *Anesth Analg*. 2000;90:229–230.

C.23. If a child is a Jehovah's Witness and suffered from hemorrhagic shock, what would you do?

Care of minors presents the greatest concern and often leads to legal action against the parents under child-neglect status. Such actions are questioned by Jehovah's Witnesses who do seek good medical care for their children, while claiming that consideration be given to their families' religious beliefs. Doctors can appeal to the court for permission to transfuse blood to children of this sect who are underage. In an unforeseeable emergency, generally, blood may be given without consulting a court.

D. Postoperative Management

D.1. What is acute respiratory distress syndrome (ARDS)? What is transfusion-related acute lung injury (ALI)?

ARDS is an acute respiratory failure seen in patients with healthy lungs after being exposed to shock, trauma, sepsis, aspiration, transfusion, burns, or toxic inhalation. Initially, when this lung injury was thought to be related to the shock state and its resuscitation, names such as "shock lung" and "traumatic wet lung" were applied to acute respiratory insufficiently following injury. It is now recognized that many types of lung insults will result in damage to the alveolar capillary membrane, resulting in leakage of proteinaceous fluid from the intravascular space into the interstitium and subsequently into the alveolar spaces. This injury with its resulting interstitial and alveolar edema produces a clinical picture ranging from mild to severe pulmonary dysfunction that can be fatal.

ALI is characterized by impaired oxygenation, defined as a ratio of Pao_2/Fio_2 of 300 or less; bilateral pulmonary infiltrates on the frontal chest radiograph; and a pulmonary artery occlusion of 18 mm Hg or more. ARDS is defined as ALI with a Pao_2/Fio_2 ratio of 200 or less. ARDS is characterized by the following:

- Hypoxemia: Is relatively unresponsive to increasing inspired oxygen concentration
- Decreased pulmonary compliance: Clinically appears as stiff lungs
- Initially normal chest radiograph progressing to diffuse infiltrates or even to areas of complete consolidation
- Decrease in resting lung volumes, specifically functional residual capacity

D.2. How is ARDS treated?

The treatment of ARDS is primarily supportive. Currently, mechanical ventilation is the mainstay of supportive therapy for ARDS. The principal goal of mechanical ventilation is to minimize the deleterious effects on gas exchange. Unfortunately, mechanical ventilation has also been associated with further lung injury. Excessive alveolar volumes (volutrauma), high mean and peak airway pressures (barotrauma), and shearing forces caused by frequent collapse and opening of alveolar units are responsible for this further lung injury. Positive end-expiratory pressure is used to increase oxygenation at a fixed F_{IO_2}.

Investigators have looked at lung protection in patients with ARDS. Strategies were used to prevent ventilator-associated lung injury. Amato et al. used a strategy to limit peak inspiratory pressures by using low tidal volumes (less than 6 mL per kg) and the institution of positive end-expiratory pressure. Their strategy was associated with a lower 28-day mortality (38% vs. 71%), higher weaning rate (66% vs. 29%), and lower barotrauma rate (7% vs. 42%).

The National Heart, Lung, and Blood Institute ARDS network reported improved survival in patients using a low tidal volume strategy (6 mL per kg vs. 12 mL per kg). These investigators found a decrease in mortality of approximately 25% in the intervention group compared with the control group.

National Institutes of Health. *National Heart, Lung, and Blood Institute ARDS Network*; 2000.

D.3. In the recovery room, you are called to see this patient because of oliguria. How would you evaluate and treat this patient?

Oliguria is a decrease in urinary output to less than 0.5 mL/kg/hr.

ARF is a syndrome characterized by a rapid (hours to weeks) decline in glomerular filtration rate and retention of nitrogenous waste products such as blood urea nitrogen and creatinine. The kidney is remarkable in its ability to recover from almost complete loss of function. Most ARF is reversible. ARF is associated with major in-hospital morbidity and mortality. The diagnosis of ARF usually hinges on serial analysis of blood urea nitrogen and serum creatinine.

Renal failure can be divided into three categories:

Prerenal

Prerenal failure is the most common cause of ARF and is an appropriate physiologic response to renal hypoperfusion. It is usually caused by a low cardiac output resulting from hypovolemia or cardiac failure. It can be evaluated by checking the patient's heart rate, blood pressure, central venous pressure, pulmonary capillary wedge pressure, and cardiac output. If hypovolemia is the cause, then treatment would consist of a fluid bolus. If the patient is in cardiac failure, then inotropic support and diuretics could be administered. Severe renal hypoperfusion may cause ischemic acute tubular necrosis (ATN). Therefore, prerenal azotemia and ischemic ATN are part of a spectrum of manifestations of renal hypoperfusion.

Renal

Intrinsic renal failure is generally due to toxic injury or ischemia. Ischemic injury is caused by a decrease in perfusion pressure that can lead to renal cellular dysfunction.

Substances that affect renal tubular function in addition to renal blood flow can cause toxic injury. Ischemic ATN, unlike prerenal azotemia, is associated with injury to renal parenchyma and does not resolve immediately on restoration of renal perfusion. In its more extreme form, renal hypoperfusion may result in bilateral renal cortical necrosis and irreversible renal failure. Urinalysis may show cells or casts that are indicative of ARF. Intrinsic renal failure can be minor and short lived, or it can progress to chronic renal failure, depending on the severity of the insult. In the absence of congestive heart failure, use of diuretics should generally be avoided because they can exacerbate ATN. In particular, loop diuretics increase oxygen and ATP consumption at the level of the tubules.

Postrenal

Urinary tract obstruction accounts for less than 5% of cases of ARF. Urinary tract obstruction must be sought and corrected to treat possible causes of postrenal oliguria. This usually requires irrigation or changing of the Foley catheter. Consider the possibility of an intraoperative mishap causing postrenal obstruction.

Saxena R, Toto RD. Approach to the patient with kidney disease. In: Brenner BM, ed. *Brenner and Rector's the Kidney*. 8th ed. Philadelphia: Saunders; 2008:705–723.

D.4. If this patient had a crush injury and low urine output, what other concerns might you have? What if the patient has dark or "tea-colored" urine?

Leakage of myoglobin from muscles and damaged muscle cells secondary to a crush injury can result in rhabdomyolysis. Myoglobin, at high concentrations precipitates in the nephron, appearing pigmented and causing acute renal injury (ARF). The urine may look suspicious for hematuria or have a "tea colored" appearance. Rhabdomyolysis can be diagnosed by the presence of myoglobinuria or elevated serum creatine kinase levels. Preventing ARF in these patients is essential, because the development of ARF is associated with increased mortality. The treatment is hydration with large volumes of crystalloid, resulting in goal urine outputs as high as 100 to 30 mL per hour. In addition, alkinalization of the urine with agents such as bicarbonate may help by decreasing the rate of precipitation. Mannitol has also been used to induce osmotic diuresis and flush the myoglobin through the kidney. Other electrolyte abnormalities that can develop with crush injury and should be monitored for, including hyperkalemia, hyperphosphatemia, hypocalcemia, and metabolic acidosis.

CHAPTER 57

Scoliosis

KATHRYN DELPIZZO AND VICTOR M. ZAYAS

A 14-YEAR-OLD GIRL

with scoliosis is scheduled for posterior spine fusion with segmental instrumentation. She has been told that her scoliosis is idiopathic. Her past medical history is unremarkable, but her mother states that she appears to get short of breath more easily than her friends when she plays basketball.

A. Medical Disease and Differential Diagnosis

1. What is scoliosis?
2. What is the most common type of scoliosis?
3. What are other types of scoliosis?
4. How is the severity of scoliosis assessed and why is the severity important?
5. What abnormalities in pulmonary function tests are most commonly seen in scoliosis? What is the cause of these abnormalities?
6. What is the most common arterial blood gas abnormality seen in scoliosis? What are possible causes for this abnormality?
7. What abnormalities of ventilatory drive may be associated with scoliosis?
8. How may the cardiovascular system be affected in patients with scoliosis?
9. What is the relationship between scoliosis and malignant hyperthermia?

B. Preoperative Evaluation and Preparation

1. What should the anesthesiologist know about the nature of the spinal curve?
2. What aspects of the history are most important?
3. What aspects of the physical examination are most important?
4. Why is a preoperative neurologic assessment important?
5. What tests would you order preoperatively?
6. What preparation should the patient have preoperatively?
7. What should you consider in ordering preoperative medications?
8. How will the surgical procedure influence the anesthetic management?

C. Intraoperative Management

1. What monitoring would you use?
2. What is the incidence of neurologic complications in scoliosis surgery and which patients are at highest risk?
3. What monitoring techniques are used to minimize neurologic complication?
4. What are somatosensory evoked potentials (SSEPs) and how are they used?
5. How reliable are SSEPs for predicting spinal injury?
6. What are motor evoked potentials (MEPs) and how are they used?
7. How is spinal cord monitoring affected by anesthetic agents? What other factors affect spinal cord monitoring?
8. What is the optimal anesthetic technique for scoliosis surgery?
9. What should be done if the SSEPs or MEPs become abnormal during surgery?
10. How is the "wake-up" test performed? What complications can occur during this test?
11. Four hours into the surgical procedure, the surgeon reports some bubbling in the thoracic portion of the wound. Shortly thereafter, end-tidal carbon dioxide decreases abruptly from 35 to 18 mm Hg, heart rate increases from 80 to 120 beats per minute, blood pressure begins to fall, and arterial saturation decreases to 90%. On auscultation through esophageal stethoscope, you hear a loud gurgling murmur. What is your diagnosis?
12. How common is significant air embolism during scoliosis surgery?
13. What should be done if an air embolus is suspected?
14. What complications occur related to positioning the patient?
15. What is transfusion-related acute lung injury (TRALI)?
16. What techniques can be used to minimize transfusion requirements?
17. What techniques would you use to produce deliberate hypotension during scoliosis surgery? What is the major concern of using this technique?

D. Postoperative Management

1. When would you extubate the patient?
2. What should be done to optimize pulmonary status?
3. What laboratory tests should be ordered postoperatively?
4. What fluid therapy would you use postoperatively?
5. What complications may occur following scoliosis surgery?
6. How would you manage this patient's pain postoperatively?

A. Medical Disease and Differential Diagnosis

A.1. What is scoliosis?

The spine normally curves posteriorly in the thoracic region and anteriorly in the lumbar region. These physiologic curves are the thoracic kyphosis and the lumbar lordosis, respectively. The spine is not normally curved when viewed from the front or back. Scoliosis refers to a lateral curvature of the spine. Curves are classified as structural or nonstructural. A nonstructural curve, such as lumbar scoliosis from a leg length discrepancy, will resolve when the patient is supine or uses a shoe lift and does not require surgical correction. In contrast, structural scoliosis lacks normal flexibility and does not correct with bending or lying supine. In addition to the lateral curvature of the spine, the vertebrae are rotated and the rib cage may be markedly deformed (Fig. 57.1). As demonstrated in the computed

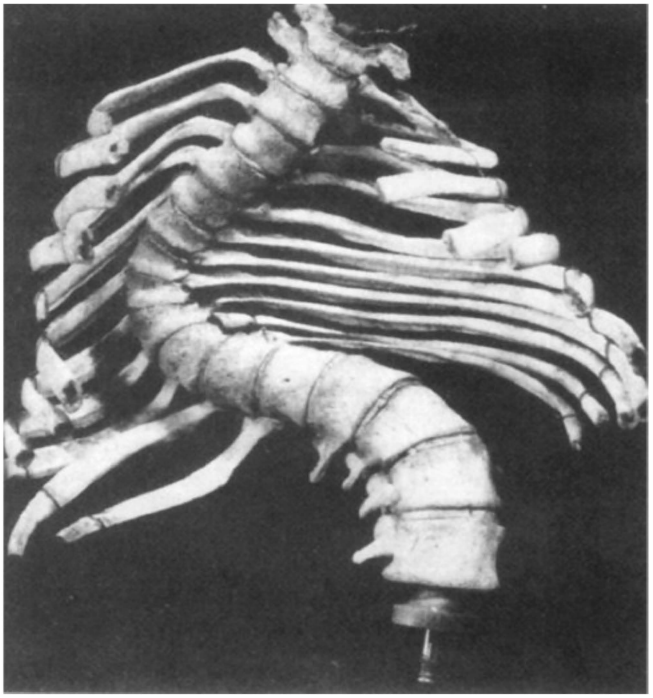

Figure 57.1 In addition to producing a lateral deformity of the spine, scoliosis also results in rotation of the vertebral bodies and significant rib cage deformity.

tomography scan image in Figure 57.2, this thoracic deformity may lead to a significant decrease in total lung volume. Particularly note the decrease in left lung volume relative to the right.

A.2. What is the most common type of scoliosis?

Idiopathic scoliosis is the most common type of scoliosis (70% of all cases) and occurs in infantile, juvenile, and adolescent forms. As the name implies, the cause is unknown, but appears to be multifactorial, including abnormalities of collagen, brainstem function, equilibrium, hormones, and growth. Genetic factors are important in its development, as evidenced by an increased incidence of scoliosis in relatives of affected patients. Recent evidence suggests that pronounced forms of scoliosis (curve greater than 11 degrees) occur only in the carriers of a mutant allele with incomplete penetrance (30% of men, 50% of women).

The prevalence of idiopathic scoliosis in large screening studies depends on the definition of scoliosis and the population screened. The prevalence of spinal curves greater than 10 degrees is 1.5% to 3%, greater than 20 degrees it is 0.3% to 0.5%, and greater than 30 degrees it is 0.2% to 0.3%. The adolescent form of idiopathic scoliosis is by far the most common in the United States. The male-to-female prevalence ratio depends in part on the age of the patient, but scoliosis requiring surgical correction is more common in women. The ratio increases with the severity of the curve, with a ratio of girls to boys at 2:1 for curves of 10 degrees, and increasing to 10:1 for curves over 30 degrees.

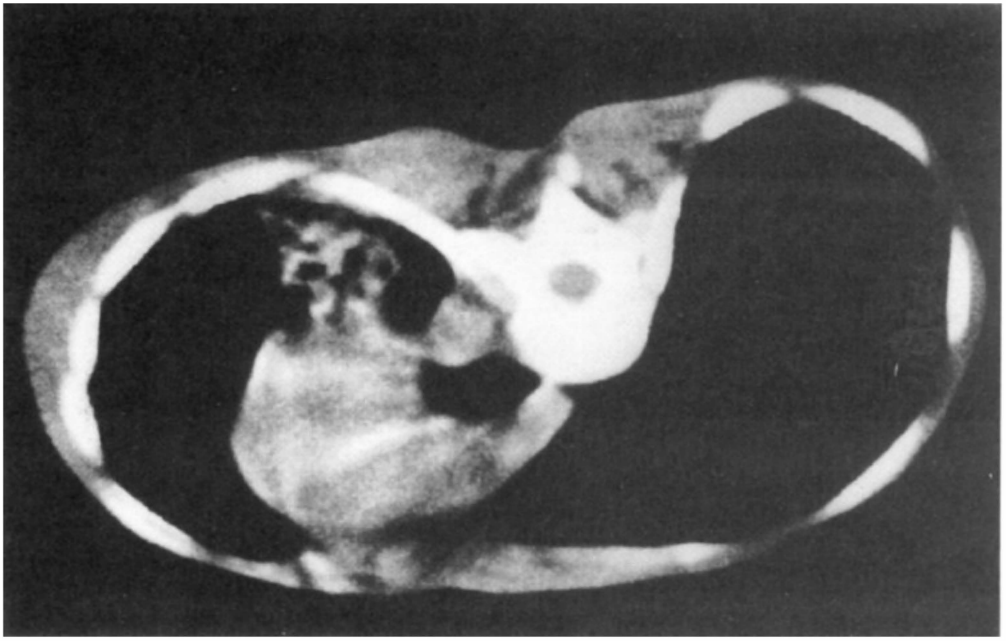

Figure 57.2 A computed tomography scan of the thorax demonstrating significant loss of lung volume resulting from the rib cage deformity.

A.3. What are other types of scoliosis?

Many etiologic classifications exist for structural scoliosis. Neuromuscular scoliosis (paralytic scoliosis) may occur as a result of diseases such as cerebral palsy, muscular dystrophy, poliomyelitis, familial dysautonomia, and so on. This type of scoliosis is associated with significantly increased intraoperative blood loss compared with idiopathic scoliosis. Congenital scoliosis is the result of congenital anomalies such as hemivertebrae and fused vertebrae or ribs. Neurofibromatosis and Marfan syndrome are also associated with scoliosis. These underlying conditions may have a major impact on the anesthetic plan. The classification of structural scoliosis is as follows:

Idiopathic

- Infantile
- Juvenile
- Adolescent

Neuromuscular (Paralytic)

- Neuropathic
  - Upper motor neuron (e.g., cerebral palsy, spinal cord injury)
  - Lower motor neuron (e.g., poliomyelitis, meningomyelocoele)
  - Familial dysautonomia
- Myopathic
  - Muscular dystrophy
  - Myotonic dystrophy

Congenital

- Hemivertebrae
- Congenitally fused ribs

Neurofibromatosis

- Marfan syndrome

Mesenchymal disorders

- Ehlers-Danlos syndrome

Trauma

- Vertebral fracture or surgery
- Postthoracoplasty
- Postradiation

Bradford DS, Lonstein JE, Ogilvie JW, et al., eds. *Moe's Textbook of Scoliosis and Other Spinal Deformities*. 3rd ed. Philadelphia: WB Saunders; 1995:45–86.

A.4. How is the severity of scoliosis assessed and why is the severity important?

In 1966, the Scoliosis Research Society standardized the method for assessing the severity of scoliosis. The most common measure of severity is Cobb angle. Figure 57.3 illustrates how Cobb angle is measured on a spine radiograph. A perpendicular (*2*) is constructed from the bottom of the lowest vertebrae (*1*) whose bottom tilts toward the concavity of the curve, and another perpendicular (*4*) from the top of the highest vertebrae (*3*) whose top tilts toward the concavity. The angle (*5*) at which these perpendiculars intersect is Cobb angle. Numerous studies have documented that the more severe the thoracic curve (greater Cobb angle), the more profound the disturbance in pulmonary function. Surgical treatment is usually recommended for curves greater than 45 to 50 degrees. Curves greater than 60 degrees are usually associated with decreases in pulmonary function.

In a series of 79 patients with thoracic scoliosis, the mean Cobb angle was 45 degrees and vital capacity was decreased by an average of 22%. Figure 57.4 demonstrates that forced vital capacity (FVC) and forced expiratory volume in 1 second (FEV_1) decrease with increasing thoracic curve severity.

Scoliosis severity and impairment of pulmonary function also increase with greater number of vertebrae involved, more cephalad location of the curve, and loss of the normal thoracic kyphosis. Severe curves have a worse prognosis because they tend to progress, and if long standing, can cause permanent damage of the lung parenchyma, respiratory failure, cor pulmonale, and death. It is important to note that patients with neuromuscular types of scoliosis may have a much more profound decrease in pulmonary function for any given curve severity.

A.5. What abnormalities in pulmonary function tests are most commonly seen in scoliosis? What is the cause of these abnormalities?

A decrease in lung volumes, a restrictive pattern, is most commonly seen in thoracic scoliosis. The greatest reduction occurs in vital capacity, which is typically reduced to 60% to 80% of predicted. Total lung capacity, functional residual capacity, inspiratory capacity, and expiratory reserve volume are also decreased. An increase in residual volume has been reported in patients with congenital scoliosis and in patients with idiopathic scoliosis 3 years following corrective spine fusion.

During exercise, ventilation is adequate, but tidal volume is reduced and respiratory rate is increased. Maximal work capacity may also be decreased. Unless there is coexisting obstructive airway disease, the ratio of FEV_1/FVC is normal. Impaired respiratory muscle function also occurs in scoliosis, as evidenced by a decrease in inspiratory force to 70% of normal values. The decrease in inspiratory force is probably due to the inspiratory muscles working at a mechanical disadvantage because of the chest wall deformity.

These abnormalities in pulmonary function are usually the result of abnormal thoracic cage geometry producing a marked decrease in chest wall compliance rather than any abnormality in the lungs or respiratory muscles themselves. In dynamic magnetic resonance imaging, adolescent girls with idiopathic scoliosis and healthy controls showed no difference in diaphragmatic motion. The changes in chest wall compliance can be mimicked in normal volunteers by chest strapping. Exceptions include congenital and infantile scoliosis in which growth of the lungs may be impaired early in development by the thoracic deformity.

A.6. What is the most common arterial blood gas abnormality seen in scoliosis? What are possible causes for this abnormality?

It has been documented that patients with thoracic scoliosis have arterial oxygen desaturation compared to normal controls. Both arterial P_{CO_2} and pH are usually

normal. Several studies have failed to show a correlation between the severity of the spinal curve and the degree of arterial oxygen desaturation.

Arterial hypoxemia is probably caused by ventilation/perfusion ($\dot{V}/\dot{Q}$) inequalities. Decreased diffusing capacity and alveolar hypoventilation may also play a role. Nevertheless, the diffusing capacity is not decreased sufficiently to be the sole cause of the hypoxemia. Similarly, alveolar ventilation at rest and during exercise is usually normal; therefore, arterial P_{CO_2} is usually normal. It has been reported that some patients have a closing capacity higher than functional residual capacity, resulting in premature airway closure during normal tidal breathing. Other studies have failed to demonstrate this finding. Some authors have reported an increase in the ratio of dead space to tidal volume (V_D/V_T), whereas other recent series have found V_D/V_T to be normal. This discrepancy may be related to the patient population studied, the severity of the scoliosis, or both. Severe and long-standing scoliosis can produce severe $\dot{V}/\dot{Q}$ abnormalities, alveolar hypoventilation, carbon dioxide retention, and more severe hypoxemia. If not surgically treated, severe scoliosis increases the risk of premature death from respiratory failure after 40 years of age. A survey of patients with respiratory failure in Sweden found that a vital capacity less than 50% of predicted and a Cobb angle greater than 100 degrees indicated an increased risk of respiratory failure.

A.7. What abnormalities of ventilatory drive may be associated with scoliosis?

The slope of the ventilatory response to carbon dioxide may be decreased in patients with scoliosis. This is probably not specific to scoliosis because this response is known to be reduced in situations in which the work of breathing is increased even in the absence of a chest wall deformity. Patients with mild scoliosis have been reported to exhibit abnormal ventilatory patterns in response to hypoxemia and hypercarbia. This pattern tends to minimize the work of breathing, a higher respiratory rate, and lower tidal volume.

It has also been demonstrated that during maximal exercise, patients with mild-to-moderate scoliosis exhibit a significantly decreased ventilatory capacity, reduced exercise tolerance, and oxygen consumption despite normal pulmonary function testing at rest.

A.8. How may the cardiovascular system be affected in patients with scoliosis?

Patients with scoliosis may develop elevated pulmonary vascular resistance and pulmonary hypertension. This may result in right ventricular hypertrophy and eventually right ventricular failure. A 50-year study of untreated scoliosis demonstrated that the mortality rate of these patients was twice that of the general population and respiratory failure or right heart failure accounted for 60% of the deaths.

The increase in pulmonary vascular resistance is probably due to several factors. Hypoxemia produces pulmonary vasoconstriction, an increase in pulmonary vascular resistance, and hence an increase in pulmonary arterial pressure. Chronic hypoxemia will produce hypertensive vascular changes, and pulmonary hypertension may become irreversible. It has also been proposed that the chest wall deformity compresses some lung regions, increasing vascular resistance in those regions. Finally, if scoliosis develops in the first 6 years of life, the growth of the pulmonary vascular bed may be impaired by the chest wall deformity. Supporting this concept are reports of a decrease in the number of vascular units per lung volume in patients with scoliosis.

The most common cardiovascular abnormality in patients with scoliosis is mitral valve prolapse. Antibiotic prophylaxis should be administered before catheterization of the bladder or laryngoscopy in these patients.

Some conditions that are associated with scoliosis also affect the cardiovascular system. Patients with Duchenne muscular dystrophy develop a cardiomyopathy in the second decade of life that may not be appreciated on the basis of clinical symptoms because these patients are unable to exercise. The electrocardiogram (ECG) may reveal tachycardia, prolonged PR and QRS intervals, ST abnormalities, bundle branch block, Q waves in the left precordial leads, and tall R waves in the right precordial leads. Ejection fraction may be decreased on echocardiogram.

Patients with Marfan syndrome may have mitral and aortic insufficiency, aneurysm of the proximal ascending aorta, and abnormalities of the conduction system.

The association of scoliosis and congenital heart disease has been well established. Although no specific cardiac lesion has been identified, some series have suggested that scoliosis is more common in patients with cyanotic heart disease.

A.9. What is the relationship between scoliosis and malignant hyperthermia?

In 1970, a statistical, retrospective review of 89 patients who developed malignant hyperthermia reported that 6 of these patients had "idiopathic kyphoscoliosis." In the past 40 years, there has been no more supportive evidence of a direct relationship. Certainly, some scoliosis patients do have an increased risk of malignant hyperthermia because of their underlying disease. For example, patients with certain muscle disorders such as central core muscular dystrophy are at increased risk for developing malignant hyperthermia and also develop scoliosis (also see Chapter 53).

Brownell AKW. Malignant hyperthermia: relationship to other diseases. *Br J Anaesth*. 1988;60:303–308.

B. Preoperative Evaluation and Preparation

B.1. What should the anesthesiologist know about the nature of the spinal curve?

It is important to identify the location of the curve, the age of onset, its severity, the direction of the curve, and the etiology of the scoliosis. The location of the curve is important because thoracic scoliosis is associated with pulmonary function abnormalities. Cervical scoliosis may cause difficulties in airway management and may be associated with other congenital anomalies.

The age of onset of scoliosis is of critical importance because the lung continues to grow and develop from birth until 8 years of age. The number of alveoli increases from approximately 20 million at birth to 250 million at 4 years of age. The development of significant thoracic scoliosis during this phase of rapid growth impairs lung development. A significant reduction in alveolar number has been demonstrated in patients with early-onset thoracic scoliosis, predisposing these patients to impaired gas exchange and pulmonary hypertension.

The severity of the curve is important because thoracic curves greater than 60 degrees generally produce significant decreases in pulmonary function. Curves greater than 100 degrees may be associated with significant impairment in gas exchange. Most curves in adolescent idiopathic scoliosis are convex to the right, just as most people are right-handed. A left thoracic convexity should raise the index of suspicion to look for other underlying conditions and congenital anomalies. Finally, an understanding of the etiology of the scoliosis is important because underlying conditions such as muscular dystrophy or cerebral palsy will influence anesthetic management.

Bradford DS, Lonstein JE, Ogilvie JW, et al. eds. *Moe's Textbook of Scoliosis and Other Spinal Deformities*. 3rd ed. Philadelphia: WB Saunders; 1995:585–592.

Weinstein SL, ed. *The Pediatric Spine: Principles and Practice.* 2nd ed. New York: Raven Press; 2001:421–429.

B.2. What aspects of the history are most important?

Cardiopulmonary reserve should be assessed by questioning the patient about shortness of breath, dyspnea on exertion, exercise tolerance, and so on. As a general rule, patients who can exercise normally and "keep up with friends" in vigorous activities will have good cardiopulmonary function. Pulmonary symptoms such as episodes of wheezing or cough may indicate parenchymal lung disease and alter perioperative management. Patients with muscular dystrophy, Marfan syndrome, and neurofibromatosis should be questioned about symptoms suggestive of cardiac conduction abnormalities such as palpitations or syncope.

Weinstein SL, ed. *The Pediatric Spine: Principles and Practice*. 2nd ed. New York: Raven Press; 2001:421–429.

B.3. What aspects of the physical examination are most important?

Particular emphasis in the physical examination should be directed toward the heart and lungs. Auscultation of the lungs may reveal wheezing or rales suggesting obstructive airway disease or parenchymal lung disease. On examination of the heart, in addition to auscultating for murmurs and gallops, signs of pulmonary hypertension, and right ventricular hypertrophy should be sought. Pulmonary hypertension causes

accentuation of the pulmonic component of the second heart sound and a right ventricular lift indicates right ventricular enlargement. Signs of right ventricular failure include engorged neck veins, an enlarged liver resulting from passive liver congestion, and lower extremity edema. If neurofibromatosis is suspected, the skin should be examined for the presence of *café au lait spots* or cutaneous neurofibroma. The airway should be evaluated closely for abnormalities such as cervical scoliosis, neurofibroma, or high arched palate associated with Marfan syndrome that may make endotracheal intubation difficult.

Weinstein SL, ed. *The Pediatric Spine: Principles and Practice*. 2nd ed. New York: Raven Press; 2001:421–429.

B.4. Why is a preoperative neurologic assessment important?

A preoperative neurologic assessment is important because patients who have preexisting neurologic deficits are at increased risk for developing spinal cord injury during scoliosis surgery. Furthermore, it is important to document preoperative neurologic function in order to avoid confusion about postoperative neurologic complications.

If a patient has a ventriculoperitoneal shunt for hydrocephalus, it should be evaluated preoperatively by the patient's neurosurgeon. Although rare, there have been case reports of life-threatening hydrocephalus following posterior spinal fusion in children with cerebral palsy. The shunt can malfunction during correction of the spinal deformity via disconnection, fracture, kinking, or inadequate length.

Abu-Sneineh K, Lipton GE, Gobos PG, et al. Dysfunction of a ventriculoperitoneal shunt after posterior spinal fusion in children with cerebral palsy: a report of two cases. *J Bone Joint Surg Am.* 2003;85:1119–1124.

B.5. What tests would you order preoperatively?

It is probably best to tailor diagnostic testing based on the severity of the scoliosis and underlying conditions rather than ordering a standard battery of diagnostic tests. In the current climate emphasizing medical cost containment, each institution needs to critically reassess preoperative testing. Preoperatively, this healthy 14-year-old may only need a complete blood count and the standard pregnancy test. If the history or physical examination suggests that pulmonary reserve is decreased, then standard pulmonary function testing should be considered. If vital capacity is significantly diminished, an arterial blood gas measurement is indicated. If routine pulmonary function testing reveals evidence of obstructive airway disease (a decrease in the ratio of FEV_1/FVC or a decrease in forced expiratory flow [25% to 75%]), a bronchodilator should be administered to determine if the airway obstruction is reversible.

Patients with onset of scoliosis in the first 8 years of life should have pulmonary function testing, arterial blood gas analysis, and an electrocardiogram. If the electrocardiogram reveals abnormalities such as right ventricular hypertrophy (large R in V_1 and V_2), right atrial enlargement (P_{wave} greater than 2.5 mm) or evidence of a cardiomyopathy, an echocardiogram, or even cardiac catheterization may be indicated, particularly if pulmonary hypertension is suspected.

Kafer ER. Respiratory and cardiovascular functions in scoliosis and the principles of anesthetic management. *Anesthesiology.* 1980;32:339–351.

B.6. What preparation should the patient have preoperatively?

The patient should be prepared both physiologically and psychologically for surgery and the postoperative course. First, preoperative teaching of coughing and incentive spirometry should be emphasized. Patients with evidence of parenchymal lung disease or obstructive airway disease should have aggressive pulmonary toilet or bronchodilator therapy preoperatively. Patients should know that upon awakening, they will be asked to move their extremities and follow basic commands (opening the eyes and mouth, squeezing a hand). Finally, if an intraoperative wake-up test is planned (see subsequent text), the patient should be informed and reassured that he or she will feel no pain or discomfort. It can be helpful to rehearse the wake-up test during the preoperative visit. The patient and family should understand that the wake-up test is often requested by the surgeon.

Some patients may be good candidates for preoperative autologous blood donation, particularly adult-sized patients with a high baseline hemoglobin. There is limited use in many pediatric patients because smaller children do not tolerate the phlebotomy procedure and it may not be beneficial in patients with smaller blood volumes.

B.7. What should you consider in ordering preoperative medications?

Heavy premedication and opioids are probably best avoided in patients with neuromuscular disease, evidence of pulmonary hypertension, impaired gas exchange, or markedly decreased pulmonary function. Use of an antisialagogue may be desirable because many of these surgical procedures are performed in the prone position and copious secretions may wet the tape securing the endotracheal tube and cause it to slip.

B.8. How will the surgical procedure influence the anesthetic management?

A variety of surgical procedures are commonly performed for posterior spine fusion. The blood lost during these procedures may be considerable and varies according to the procedure, the operative time, the number of segments fused, whether deliberate hypotension is used, and other factors. Even when deliberate hypotension is used, blood loss in the range of 15 to 25 mL per kg is not uncommon during uncomplicated spine fusion with Harrington rods or Cotrel-Dubousset instrumentation. This represents a blood loss of 1 to 2 L for a 70-kg patient. Postoperative bleeding may equal or exceed this, emphasizing the need for continued monitoring of these patients in the postoperative period. More extensive procedures such as combined anteroposterior spine fusion, instrumentation into the pelvis, or especially osteotomy of the spine to correct rigid deformities may be associated with blood loss exceeding the patient's own blood volume (75 mL per kg). Patients who require these more extensive procedures are frequently those with neuromuscular scoliosis (Duchenne muscular dystrophy, cerebral palsy) who may already have diminished reserves. Before the patient is taken to the operating room, the anesthesiologist should confirm that the blood bank has the anticipated blood products readily available.

Moderate third-space losses of intravascular fluid occur during scoliosis surgery. These should be replaced with balanced salt solution at a rate of 5 to 7 mL/kg/hour. This is in addition to any deficit or maintenance requirements. Procedures that are more extensive may require higher infusion rates.

The anesthesiologist should speak with the surgeon about the surgical approach and technique. The surgical plan could affect the patient's position during the case. For example, patients undergoing an anterior approach or thoracotomy may need to be positioned laterally. Another consideration is whether the surgeon requires single-lung ventilation in which case the patient may need a double-lumen endotracheal tube.

Guay J, Haig M, Lortie L, et al. Predicting blood loss in surgery for idiopathic scoliosis. *Can J Anaesth.* 1994;41:775–781.

C. Intraoperative management

C.1. What monitoring would you use?

Minimal monitoring for posterior spine fusion should include blood pressure, electrocardiogram, pulse oximetry, end-tidal carbon dioxide, esophageal stethoscope, core temperature, and spinal cord monitoring. A radial artery catheter is used for continuous monitoring of blood pressure, particularly if deliberate hypotension is planned to reduce blood loss. This will also facilitate obtaining blood samples for blood gas and hematocrit determination. All patients should have a urinary catheter placed to document urine output during and particularly after the surgical procedure. Monitoring of central filling pressures may be indicated if the expected blood loss is large, or cardiovascular disease is present or suspected. Although rarely placed in routine scoliosis surgery, a pulmonary artery catheter may be useful in patients with cardiomyopathy from Duchenne muscular dystrophy, and patients with pulmonary hypertension or right ventricular failure, in order to optimize volume replacement therapy. When placing pulmonary artery catheters in patients with pulmonary hypertension, it must be considered that the risk of pulmonary artery rupture, a complication with a mortality rate of 50%, is increased in patients with pulmonary hypertension. Neuromuscular blockade should be monitored if a balanced anesthetic technique is used.

C.2. What is the incidence of neurologic complications in scoliosis surgery and which patients are at highest risk?

In the most recent morbidity report of the Scoliosis Research Society (2006), the rate of complete or partial paraplegia was 0.26%. A study of 6,334 patients undergoing anterior, posterior, or combined anteroposterior spinal fusion reported an overall rate of spinal injury of 0.28%. Of note, combined anteroposterior procedures had a significantly higher rate of spinal cord injuries (1.12%) compared to anterior (0.0%) and posterior (0.21%) procedures.

It has been proposed that distraction of the cord and straightening of the deformity compresses the spinal cord and disrupts the arterial blood supply of the cord. The spinal cord and nerve roots may also be injured directly by hooks or instrumentation.

Prevention of neurologic complications begins with identification of the high-risk group. Patients are at increased risk for developing paraplegia if they have a severe rigid deformity (greater than 120 degrees), kyphosis, neurofibromatosis, congenital or postinfectious scoliosis, a pre-existing neurologic deficit, or more invasive instrumentation. Congenital scoliosis is associated with intraspinal anomalies, including lipomas, tethered cord, cysts, and teratomas that also increase the risk of postoperative neurologic complications. A preoperative myelogram or magnetic resonance imaging is indicated in these patients. Preoperative prophylaxis with high-dose corticosteroids should be considered for patients with a pre-existing neurologic deficit.

Cole JD, Arlet V, Donaldson W, et al. Complications in spinal fusion for adolescent idiopathic scoliosis in the new millennium: a report of the scoliosis society morbidity and mortality committee. *Spine.* 2006;31:345–349.

C.3. What monitoring techniques are used to minimize neurologic complication?

The two monitoring techniques most commonly used in the United States to monitor spinal cord function during scoliosis surgery are SSEPs and MEPs. Some centers continue to use the intraoperative wake-up test, although MEP monitoring has

replaced the routine use of the wake-up test in many centers. The intraoperative wake–up test may still be required if SSEPs or MEPs become abnormal during the surgical procedure.

Weinstein SL, ed. *The Pediatric Spine: Principles and Practice*. 2nd ed. New York: Raven Press; 2001:1764–1765.

C.4. What are somatosensory evoked potentials (SSEPs) and how are they used?

Sensory information from the periphery passes through the posterior columns of the spinal cord on its way to the cerebral cortex. The functional integrity of this pathway can be continually assessed by monitoring SSEPs. This technique involves applying repeated electrical stimuli to a peripheral nerve (e.g., posterior tibial nerve) and measuring the evoked response over the cerebral cortex and subcortical regions using standard electroencephalogram scalp electrodes. These evoked potentials are of very low amplitude, so computer averaging or summation must be used to distinguish these potentials from background noise and the patient's electroencephalogram. A typical evoked potential waveform is shown in Figure 57.5. The time interval between electrical stimulation of peripheral nerve to recording the evoked response over the cortex is defined as the latency. An increase in the latency (slower conduction), a decrease in the amplitude, or a complete loss of the evoked potential should be considered indicative of surgical injury or ischemia until proved otherwise. It is difficult to define standard values for latency and amplitude because of the differences in recording technique among laboratories, and therefore it is important to be familiar with the normal limits for the system that is in use. In general, an increase in latency of 10% to 15% or more and a decrease in amplitude of greater than 50% should be cause for concern.

C.5. How reliable are SSEPs for predicting spinal injury?

Normal intraoperative SSEPs are good predictors of normal postoperative sensory function. Although posterior (sensory) and anterior (motor) spinal injuries tend to occur together during spine surgery or spinal trauma, there have been reports of postoperative paraplegia with normal intraoperative SSEPs. This probably represents selective ischemia in the distribution of the anterior spinal artery. Sensory function and SSEPs are preserved because the posterior columns receive their blood supply from the posterior spinal arteries. For this reason, it is probably best not to rely exclusively on SSEPs to monitor spinal cord function during scoliosis surgery.

In a survey of 173 orthopedic spinal surgeons, it was found that experienced SSEP monitoring teams had fewer neurologic complications per 100 cases than teams with less experience. Neurologic defects with normal SSEPs (false negative) occurred in only 0.063% of cases.

Spielholz NI, Benjamin NV, Engler GL, et al. Somatosensory evoked potentials during decompression and stabilization of the spine: methods and findings. *Spine.* 1979;4:500–505.

C.6. What are motor evoked potentials (MEPs) and how are they used?

MEPs assess the integrity of the spinal motor pathways (anterior columns). MEPs are elicited by transosseous electrical stimulation of the motor cortex using scalp electrodes or by stimulation of the anterior columns using epidural electrodes. Conduction of these stimuli through the motor pathways is monitored as peripheral nerve impulses, electromyographic signals, or actual limb movements.

In a study of 144 patients undergoing spinal deformity correction surgery, the authors report a sensitivity of 1 and a specificity of 0.97 using transcranial MEPs as the sole modality. No patient had any new neurologic deficits.

Hsu B, Cree AK, Lagopoulos J, et al. Transcranial motor-evoked potentials combined with response recording through compound muscle action potential as the sole modality of spinal cord monitoring in spinal deformity surgery. *Spine.* 2008;33:1100–1106.

C.7. How is spinal cord monitoring affected by anesthetic agents? What other factors affect spinal cord monitoring?

All anesthetic agents may affect spinal monitoring to a varying degree. This has been documented for potent inhalation agents, propofol, nitrous oxide, benzodiazepines, droperidol, etomidate, ketamine, barbiturates, and even opioids. Opioids probably have the least effect on SSEPs of all of these agents. Cortical SSEPs and MEPs are very sensitive to nitrous oxide and potent inhalational agents, whereas subcortical SSEPs are more resistant. The addition of nitrous oxide to isoflurane has been shown to have a profound effect on MEPs. MEPs are also profoundly affected by benzodiazepines and thiopental, and ketamine may enhance MEPs.

Nitrous oxide produces a decrease in amplitude in SSEPs without an increase in latency. Isoflurane, sevoflurane, halothane, and so on have similar effects on SSEPs; a dose-dependent increase in latency and decrease in amplitude. The addition of nitrous oxide appears to produce a larger decrease in amplitude than addition of 1% isoflurane or enflurane to a fentanyl-based anesthetic.

Muscle relaxants have no effect on SSEPs or MEP impulses monitored from peripheral nerves. They will affect the intensity of the motor response, which may lead to confusion in interpreting MEPs.

Although it is important to realize that anesthetic agents can affect spinal cord monitoring, excellent results can be obtained if anesthetic depth is stable. For example, it is preferable to administer opioids by continuous infusion rather than by intermittent doses. It is most important to maintain a stable anesthetic before and during periods when monitoring is critical, that is, during spine distraction or instrumentation.

A decrease in arterial pressure below levels of cerebral autoregulation, hypothermia, hematocrits below 15%, and hypoxia will affect both SSEPs and MEPs.

Bernard J, Pereon Y, Fayet G, et al. Effects of isoflurane and desflurane on neurogenic motor and somatosensory-evoked potential monitoring for scoliosis surgery. *Anesthesiology*. 1996;85:1013–1019.

Miller RD, eds. *Miller's Anesthesia*. 7th ed. Philadelphia: Churchill Livingstone; 2010:1502–1509.

C.8. What is the optimal anesthetic technique for scoliosis surgery?

There is no simple answer for the optimal anesthetic technique. Most patients with idiopathic scoliosis are healthy adolescents who tolerate anesthesia and surgery well, and a wide variety of techniques have been used successfully. Many healthy teenagers have a much higher tolerance for opioids and benzodiazepines and will have higher requirements for these agents intraoperatively, compared to adults. The primary concern is the ability to provide an anesthetic that is suitable for spinal cord monitoring while providing amnesia. Before the use of MEP monitoring, anesthetic techniques were tailored to facilitate the wake-up test. Monitoring of MEPs has now replaced routine use of the wake-up test in many centers. Although cortical SSEPs and MEPs may be measurable in most healthy adults receiving 50% to 70% nitrous oxide and 0.5 minimal alveolar concentration isoflurane, this combination is not suitable in small children with immature corticospinal tracts or those with pre-existing neurologic deficits. Furthermore, MEPs may be more sensitive to the combination of nitrous oxide and potent inhalational agents than cortical SSEPs.

Therefore, a typical anesthetic is a combination of a low-dose potent agent (e.g., isoflurane 0.4%) in 50% oxygen per air mixture, with a low-dose propofol infusion and primarily opioid-based intravenous anesthetic. Intravenous midazolam should be given before induction for anxiolysis and amnesia. Small doses may be repeated later if necessary. An infusion of ketamine at a low dose (0.1 to 0.2 mg/kg/hr) may improve MEP monitoring. Many centers use total intravenous anesthesia. Dexmedetomidine has been used as an adjunct in total intravenous anesthesia with minimal effect on MEPs and SSEPs. Muscle relaxants, if used, should be administered by continuous infusion and titrated to a constant train-of-four because the neuromuscular blockade will affect the intensity of the motor response. A baseline set of SSEPs and MEPs should be performed by the neuromonitoring technician as early as possible, ideally before incision, so that changes to the anesthetic or monitoring technique can be made before the most critical part of the operation (i.e., spine distraction and instrumentation).

Succinylcholine should be avoided in patients with muscle disorders. Its administration in patients with Duchenne muscular dystrophy may produce hyperkalemia, cardiac arrhythmias, myoglobinuria, or precipitate malignant hyperthermia. Patients with myotonic muscular dystrophy may exhibit sustained skeletal muscle contractions in response to succinylcholine. This may produce difficulty in ventilation and intubation.

Tobias JD, Goble TJ, Bates G, et al. Effects of dexmedetomidine on intraoperative motor and somatosensory evoked potential monitoring during spinal surgery in adolescents. *Pediatr Anesth*. 2008;18:1082–1088.

C.9. What should be done if the SSEPs or MEPs become abnormal during surgery?

If spinal cord monitoring becomes abnormal, the anesthesiologist should ensure that oxygen delivery and spinal cord perfusion are adequate. Hypovolemia and anemia should be corrected. Arterial oxygen tension should be optimized, and arterial P_{CO_2} should be normalized if the patient is being hyperventilated. It has been reported that normalizing arterial pressure if deliberate hypotension is being used or raising arterial pressure above normal may improve spinal cord perfusion and restore SSEPs to normal. The surgeon should seek a surgical cause such as too much distraction or surgical trespass with instrumentation and correct the problem as quickly as possible. If the abnormality persists despite corrective action, a wake-up test should be performed to determine if the instrumentation should be adjusted or removed. There is evidence that the shorter the interval between detection of injury and removal of instrumentation, the better is the neurologic outcome.

Lyon R, et al. Strategies for managing decreased motor evoked potential signals while distracting the spine during correction of scoliosis. *Journal of Neurosurgical Anesthesiology*. 2004;16(2):167–170.

C.10. How is the "wake-up" test performed? What complications can occur during this test?

The wake-up test is used to assess the integrity of the spinal motor pathways and is performed by "lightening" the depth of anesthesia sufficiently to allow the patient to follow commands. This is usually done as soon as all instrumentation is in place or if an abnormality has been detected with spinal cord monitoring. The patient is first instructed to squeeze the anesthesiologist's hand, confirming that he is responsive, and then asked to move his feet and toes. If the patient is able to squeeze his hands but unable to move his feet, the amount of spine distraction must be reduced until a safe degree of correction is achieved. When the patient moves his feet, anesthesia is quickly deepened with small doses of propofol (0.5 mg per kg). Additional short-acting benzodiazepines may be given. Recall of intraoperative events is very unusual with this technique.

The anesthesiologist should have one or two assistants available in the event the patient moves excessively during the wake-up test. Although this occurs rarely when an adequate amount of opioid has been administered, it is best to be prepared. The authors do not recommend use of opioid antagonists because of the potential for the patient to experience pain and become agitated in the prone position. If naloxone is

deemed necessary to arouse the patient, a small dose (0.3 to 0.5 mcg per kg) should be administered and repeated every 2 to 3 minutes until the respiratory depression of the opioid is reversed. It is not typically necessary to reverse neuromuscular blockade if at least three twitches are present on train-of-four stimulation.

Complications of this technique include extubation in the prone position, recall of intraoperative events, myocardial ischemia, self-injury, and dislodgment of instrumentation or intravenous access. Air embolus from open venous sinuses may occur if the patient is breathing spontaneously and inhales vigorously. It is also important to realize that the wake-up test may be performed too late, after a neurologic insult has already occurred and caused irreversible damage.

C.11. Four hours into the surgical procedure, the surgeon reports some bubbling in the thoracic portion of the wound. Shortly thereafter, end-tidal carbon dioxide decreases abruptly from 35 to 18 mm Hg, heart rate increases from 80 to 120 beats per minute, blood pressure begins to fall, and arterial saturation decreases to 90%. On auscultation through esophageal stethoscope, you hear a loud gurgling murmur. What is your diagnosis?

This constellation of symptoms strongly suggests venous air embolism. There are at least two reports indicating that air bubbling in the wound may be the first clinical sign of an air embolus before cardiovascular collapse. This is thought to occur as a result of retrograde flow of blood containing entrained air through the valveless venous system as a result of an increase in central venous pressure. Central venous pressure rises as a result of an air lock in the right heart. Positive pressure ventilation and pressure on the spine during placement of hardware may also produce bubbling of entrained air.

Adornato DC, Gildenberg PL, Ferrario CM, et al. Pathophysiology of intravenous air embolism in dogs. *Anesthesiology*. 1978;49:120–127.

Will J, Schwend RM, Albin MS, et al. Intraoperative visible bubbling of air may be the first sign of venous air embolism during posterior surgery for scoliosis. *Spine*. 2005;30:629–635.

C.12. How common is significant air embolism during scoliosis surgery?

Fortunately, clinically significant air embolism is uncommon. Nevertheless, cases of fatal air embolism have been reported during scoliosis surgery in children. Most, but not all, cases involve extensive surgical dissection with excessive bleeding. The mortality rate in the reported cases may be 50%.

C.13. What should be done if an air embolus is suspected?

If an air embolus is suspected, the surgical field should be immediately flooded with saline, ventilation begun with 100% oxygen, and intravascular fluid administered to increase central venous pressure. Air is most likely entrained from open epidural and paravertebral veins and venous sinuses in decorticated bone. Flooding the field with saline prevents air entrainment. Ventilation with 100% oxygen reduces the volume of the air embolus, particularly if nitrous oxide was administered. Hypovolemia and low central venous pressure favor air entrainment by increasing the pressure gradient between open veins and the right atrium.

If the patient requires cardiopulmonary resuscitation, placing the patient in the left lateral decubitus position during external cardiac massage may improve blood flow by breaking the air lock of the pulmonary outflow tract. Removing air through either a central catheter or by direct intracardiac aspiration has also been advocated.

Sutherland RW, Winter RJ. Two cases of fatal air embolism in children undergoing scoliosis surgery. *Acta Anaesthesiol Scand.* 1997;41:1073–1076.

C.14. What complications occur related to positioning the patient?

If the head is not positioned carefully, pressure on the eyes may cause thrombosis of the central retinal artery producing loss of vision or blindness. The horseshoe-type head rest (Fig. 57.6) has been implicated in a number of reports of unilateral eye blindness and should be used with great caution if at all. The head should be positioned without excessive flexion or extension and in such a way that the face and eyes can be inspected easily. The position of the head and neck will move during surgical manipulation of the spine and should be inspected frequently during the procedure. It is extremely helpful to have a mirror under the patient's face that can be viewed throughout the case (Fig. 57.7). Patients with Marfan syndrome and neurofibromatosis may have abnormalities of the cervical spine and must be turned and positioned with great caution.

The upper extremities should be positioned at no more than 90 degrees of abduction to the trunk, as illustrated in Figure 57.8A. Figure 57.8B demonstrates

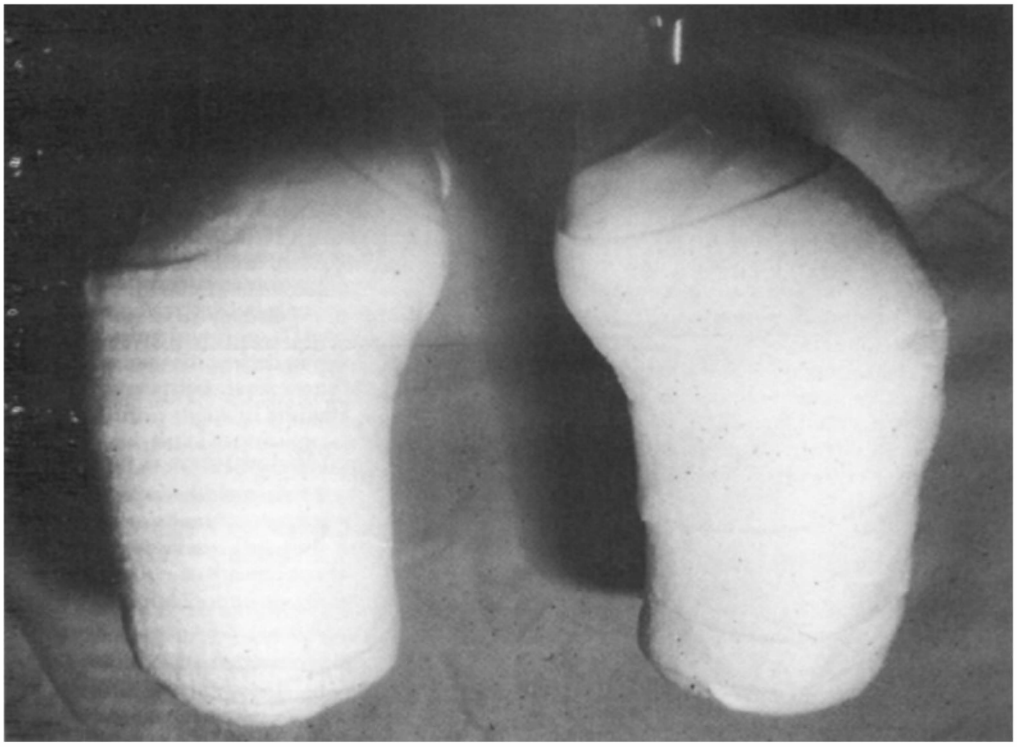

Figure 57.6 This horseshoe-type headrest has been associated with unilateral eye blindness resulting from pressure on the eye during surgery. The forehead rests on the upper portion, with the chin free in the wider, open portion.

Figure 57.7 Foam face rest with mirror.

improper arm positioning because the arms are abducted above the head. This stretches the brachial plexus and may result in a brachial plexus palsy. Both axillae should be inspected to ensure that the frame does not compress the axillary sheath. Proper positioning is shown in Figure 57.9A. Note that there is ample space between the thoracic bolster of the frame and the axilla. Figure 57.9B demonstrates improper positioning on the frame resulting in pressure on the axilla. Care should be taken to pad the ulnar nerves at the elbow. Often, the surgeons will compress or unintentionally move the upper extremities, so the arms and shoulders must be continuously monitored. Impairment of ventilation and increased bleeding from increased venous pressure may occur if the abdomen is compressed by the operating frame.

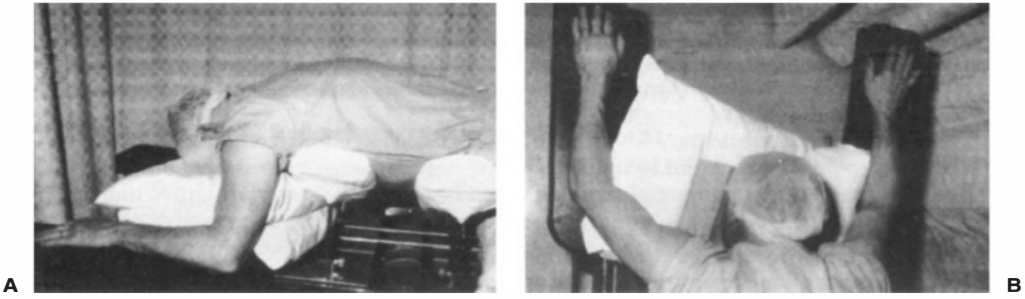

Figure 57.8 Proper arm position and improper arm position during scoliosis surgery. **A.** Degrees of abduction (relative to the trunk). **B.** Improper arm positioning with the arms abducted above the head. This results in stretching of the brachial plexus.

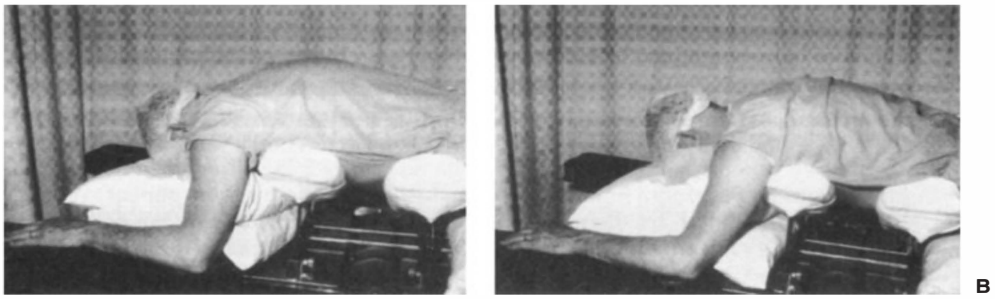

Figure 57.9 Proper and improper positioning on the four poster frame during spine surgery. **A.** Proper positioning on the frame with ample space between the axilla and the thoracic bolster of the frame. **B.** Improper positioning on the frame resulting in compression of the axillary sheath by the thoracic bolster of the frame.

Life-threatening cardiovascular events have occurred due to right ventricular outflow tract obstruction and resultant decreased venous return due to positioning of bolsters.

Neira VM, Gardin L, Ryan G, et al. A transesophageal echocardiography examination clarifies the cause of cardiovascular collapse during scoliosis urgery in a child. *Can J Anesthesia*. 2011:58:451–455.

C.15. What is transfusion-related acute lung injury (TRALI)?

TRALI is noncardiogenic pulmonary edema occurring within 1 to 6 hours of transfusion of a plasma-containing blood product. In intubated patients it presents as copious, pink, and frothy pulmonary edema fluid in the endotracheal tube. Although clinically indistinguishable from adult acute respiratory distress syndrome, TRALI is associated with a much lower mortality rate (5% to 10%). Typically, the chest radiograph and arterial oxygen saturation return to baseline within 72 hours. The exact mechanism of TRALI is unknown, but evidence points to pathologic antibodies in donor plasma causing agglutination of white blood cells on pulmonary endothelial cells. Platelet transfusions have been most commonly implicated. Therapy is supportive, similar to that for acute respiratory distress syndrome.

Silliman CC. Transfusion-related acute lung injury. *Transfus Med Rev*. 1999;13:177–186.

C.16. What techniques can be used to minimize transfusion requirements?

Several techniques can be used to minimize homologous blood transfusion requirements and subsequent risks such as alloimmunization, infections, immunosupression, and graft-versus-host disease. A simple and important way to minimize bleeding is to minimize intra-abdominal pressure, because any increase in abdominal pressure is transmitted to the vertebral venous plexus, increasing venous bleeding. Careful positioning will avoid external pressure on the abdomen, and muscle relaxants or deeper levels of anesthesia have been used to prevent a rise in abdominal wall tension.

Isovolemic hemodilution may also be used to minimize red cell loss during surgery. Before incision, the hematocrit is lowered 20% to 25% by removing blood aseptically and storing it in anticoagulated bags. Intravascular volume is maintained by replacing the blood with three times the volume of a balanced saline solution or an equal volume of colloid. Intraoperatively, the previously withdrawn blood is replaced as needed. Obviously this technique requires careful monitoring of intravascular volume status and hemoglobin level. Most patients will require a central venous catheter to perform this technique. Some patients who are Jehovah's Witnesses and will not accept blood transfusions may accept this type of blood conservation method because the blood can be kept in continuity with the circulation.

Salvaging of blood during the surgical procedure can play an important role as an adjunct to an autologous blood program. In our experience, 50% to 60% of the red blood cells lost can be recovered, concentrated, washed, and returned to the patient using commercially available autotransfusion devices. These red cells are obviously lacking in platelets and plasma. Some Jehovah's Witness patients may also accept this technique if the autotransfusion device is kept in continuity with the circulation.

The use of an antifibrinolytic agent such as aminocaproic acid or tranexamic acid has been shown to decrease blood loss in pediatric patients undergoing scoliosis surgery. These agents may be of particular benefit in patients with neuromuscular scoliosis such as Duchenne muscular dystrophy. These patients have significantly greater intraoperative blood loss compared to patients with idiopathic scoliosis, as much as a twofold to eightfold increased risk. The antifibrinolytic agent is administered as a loading dose followed by a continuous infusion before the activation of the fibrinolytic system, which occurs with surgical incision. It is important to administer the full loading dose before surgical incision for maximum benefit.

Deliberate hypotension has been used to decrease blood loss and improve operating conditions during spine fusion surgery. It has been shown to decrease blood loss 30% to 50% when mean arterial pressure is maintained at 50 to 60 mm Hg. (See also section C.17)

C.17. What techniques would you use to produce deliberate hypotension during scoliosis surgery? What is the major concern of using this technique?

Many techniques have been used to produce deliberate hypotension. These include using high doses of potent inhalation anesthetic agents, vasodilators (sodium nitroprusside, nitroglycerin, adenosine), ganglionic blocking agents (trimethaphan), β-adrenergic blocking agents (propranolol, esmolol), angiotensin-converting enzyme inhibitors (captopril), and combinations of these agents. High doses of potent anesthetics interfere with

spinal cord monitoring and make it more difficult to perform an intraoperative wake-up test; therefore, this technique is not commonly used to produce deliberate hypotension during scoliosis surgery. Animal experiments have suggested that deliberate hypotension with trimethaphan may be associated with a decrease in spinal cord blood flow compared with sodium nitroprusside or nitroglycerin. A commonly used technique employs a short-acting vasodilator such as sodium nitroprusside and a short-acting β-adrenergic blocker such as esmolol. Mean arterial pressure can be rapidly stabilized at 50 to 65 torr and will return to normal within minutes of discontinuing these agents.

The major concern of using deliberate hypotension during scoliosis surgery is the potential for spinal cord blood flow to be compromised with resultant spinal cord injury. This is of particular concern when the spine is distracted because levels of hypotension that are considered safe under normal conditions may compromise spinal cord blood flow after spine distraction. A study in dogs demonstrated that spinal cord blood flow decreases with deliberate hypotension but returns to baseline levels after approximately 35 minutes. Therefore, it has been recommended that the spine should not be distracted for 35 minutes after the start of deliberate hypotension.

In patients at high risk for development of neurologic injury (see section C.2), it is important to balance the potential benefits of deliberate hypotension with the potential risks, and if deliberate hypotension is used, it is probably prudent to maintain mean arterial pressure no lower than 60 or 65 torr. The use of deliberate hypotension can interfere with neuromonitoring signals, particularly the MEPs. With these monitoring techniques becoming standard of care in most centers, the risks and benefits of deliberate hypotension need to be carefully considered.

Miller RD, eds. *Miller's Anesthesia.* 7th ed. Philadelphia: Churchill Livingstone; 2010:2065.

D. Postoperative Management

D.1. When would you extubate the patient?

The decision to continue mechanical ventilation in the postoperative period is usually made preoperatively. Most patients with adolescent idiopathic scoliosis have mild to moderate pulmonary function abnormalities and may be extubated in the operating room after they have moved all extremities to the surgeon's satisfaction. Mechanical ventilation should be continued in patients with severe restrictive lung defects (vital capacity less than 30% of predicted) or severe gas exchange abnormalities such as carbon dioxide retention. Postoperative mechanical ventilation should be considered for patients with Duchenne muscular dystrophy, familial dysautonomia, or severe cerebral palsy. Patients who are mechanically ventilated postoperatively should be managed by nurses and physicians in an intensive care setting. Patients should be sedated to tolerate the endotracheal tube, yet arousable enough to be examined every hour for potential neurologic complications. Dexmedetomidine is a good choice for short-term sedation in this population. It offers potent synergy with opioids for analgesia, and it is easily titrated for frequent wake-ups.

The parameters for extubation given below are the same as for other respiratory disorders:

- Vital capacity greater than 10 mL per kg
- Tidal volume greater than 3–6 mL per kg

- Spontaneous respiratory rate less than 30 per minute
- Negative inspiratory force greater than –30 cm H_2O

Bradford DS, Lonstein JE, Ogilvie JW, et al., eds. *Moe's Textbook of Scoliosis and Other Spinal Deformities*. 3rd ed. Philadelphia: WB Saunders; 1995:590.

Ying Yuen, VM. Dexmedetomidine: perioperative applications in children. *Pediatr Anesth.* 2010;20:256–264.

D.2. What should be done to optimize pulmonary status?

Incentive spirometry should be taught preoperatively and should be used aggressively in the postoperative period. Coughing and deep breathing should be encouraged. Patients with obstructive or reactive airway disease will benefit from bronchodilators. Opioids should be used on a patient-controlled basis with the goal of providing adequate analgesia to allow coughing and incentive spirometry without excessive respiratory depression.

D.3. What laboratory tests should be ordered postoperatively?

Upon the patient's arrival in the recovery room, blood should be sent for analysis of arterial blood gases, hematocrit, electrolytes, blood urea nitrogen, creatinine, and if blood loss has been large, platelet count, prothrombin, and partial thromboplastin time. Determination of arterial blood gases should be repeated if clinically indicated. Hyponatremia with high urinary sodium excretion has been reported following scoliosis surgery and has been attributed to the syndrome of inappropriate antidiuretic hormone secretion. These patients produce small amounts of concentrated urine and excrete large amounts of urinary sodium. Efforts to increase urine output by administration of fluid are unsuccessful and worsen the hyponatremia. Therefore, serum electrolyte concentrations should be measured at least every 12 hours for the first 24 hours and then daily for the first 2 days. Rapid decreases in serum sodium concentration or sodium concentrations less than 125 mEq per L may produce swelling of brain cells (intracellular "edema") and seizures.

Brenner BM, Rector FC, eds. *The Kidney*. 8th ed. Philadelphia: WB Saunders; 2007:494.

Lieh-Lai M, et al. Syndrome of inappropriate antidiuretic hormone secretion in children following spinal fusion. *Crit Care Med.* 1999;27(3):622–627.

D.4. What fluid therapy would you use postoperatively?

Significant losses of intravascular fluid continue to occur in the postoperative period. These should be replaced with balanced salt solution such as lactated Ringer's solution to maintain urine output at a minimum of 0.5 to 1 mL/kg/hr. Hypotonic fluids should be avoided in the first 24 to 36 hours postoperatively. The risk for postoperative hyponatremia is increased if fluid replacement is excessive or if hypotonic fluid is administered. Some authors recommend the use of colloid replacement solutions because serum albumin is often decreased following scoliosis surgery.

Brenner BM, Rector FC, eds. *The Kidney*. 8th ed. Philadelphia: WB Saunders; 2007: 495–498.

Lieh-Lai MW, Stanitski DF, Sarnaik AP, et al. Syndrome of inappropriate antidiuretic hormone secretion in children following spinal fusion. *Crit Care Med.* 1999;27(3): 622–627.

D.5. What complications may occur following scoliosis surgery?

Complications that have been reported in the postoperative period include pneumothorax, atelectasis, pleural effusion, hemothorax, thoracic duct injury, and neurologic injury. Pneumothorax may occur as a result of anterior and posterior surgical dissections, as well as secondary to central venous line placement. A chest radiograph should be obtained upon arrival in the postanesthesia care unit. Atelectasis may occur because of prolonged supine positioning and the use of opioids. Anterior spine fusion by thoracotomy poses the greatest risk of pulmonary complications. Almost 100% of patients undergoing these procedures will develop some degree of atelectasis. Incentive spirometry and deep breathing should be emphasized and may require specialized nursing care.

In addition to intraoperative neurologic complications during instrumentation or distraction of the spine, delayed paraplegia in the first few days postoperatively has been reported. This emphasizes the need for continued monitoring of neurologic status postoperatively.

In the first few postoperative days, adynamic ileus occurs commonly, and some authors recommend placement of nasogastric tubes in all patients. Less commonly, superior mesenteric artery syndrome has been reported to occur in 0.5% of patients. This presents with nausea, vomiting, and abdominal pain after a mean time of 7.2 days. This is probably due to compression of the distal third of the duodenum by the superior mesenteric artery as a result of anatomic changes related to straightening of the spine.

Altiok H, Lubicky JP, DeWald CJ, et al. The superior mesenteric artery syndrome in patients with spinal deformity. *Spine*. 2005;30:2164–2170.

Kahanowitz N, Levine DB. Iatrogenic complications of spinal surgery. *Contemp Orthop*. 1984;9:23–39.

Weinstein SL, ed. *The Pediatric Spine: Principles and Practice*. 2nd ed. New York: Raven Press; 2001:1761–1784.

D.6. How would you manage this patient's pain postoperatively?

Most patients having scoliosis surgery are developmentally mature enough to use intravenous patient-controlled analgesia (PCA). Hydromorphone and morphine are commonly used opioids, and the PCA is usually used until postoperative day 2. Oral analgesics (e.g., oxycodone or hydrocodone with acetaminophen) should be administered once the patient is awake enough to swallow pills or elixir. Antiemetics should be given prophylactically, starting in the operating room. Serotonin receptor antagonists are the first-line treatment, but small doses of dexamethasone may also be used. Histamine-2 receptor blockers can also be helpful the first few days. A transdermal scopolamine patch may be placed preoperatively for patients with risk factors (female of childbearing age, history of motion sickness or postoperative nausea, nonsmokers).

Gan TJ. Risk factors for postoperative nausea and vomiting. *Anesth Analg*. 2006;102:1884–1898.

CHAPTER 58

Hypoxia and Equipment Failure

James B. Eisenkraft and Andrew B. Leibowitz

A 70-YEAR-OLD MAN

is to undergo cystoscopy and transurethral resection of a bladder tumor under general anesthesia through a laryngeal mask airway (LMA). He gives a history of mild asthma and uses an albuterol inhaler when necessary. Breathing room air (F_{IO_2} = 0.21), his pulse oximeter saturation reading (Spo_2) is 94%.

A. Medical Disease and Differential Diagnosis

1. What is hypoxia and what is hypoxemia?
2. Is the partial pressure of oxygen (Pao_2) in arterial blood related to age?
3. Was this patient hypoxemic?
4. What is a pulse oximeter and what is a hemoximeter?
5. How does a pulse oximeter work?
6. How is a two-wavelength pulse oximeter calibrated by the manufacturer?
7. What may affect the accuracy of a two-wavelength pulse oximeter?
8. How do the dyshemoglobins, methemoglobin (metHb) and carboxyhemoglobin (Hbco) affect Spo_2 readings?
9. What is capnometry and what is capnography? Of what value are they in patient monitoring?
10. What is meant by the term *end-tidal carbon dioxide* ($Petco_2$)?
11. What is the appearance of a normal capnogram and what is its significance?
12. What are mainstream and sidestream capnometers?
13. Show some common capnograms and provide a differential diagnosis of each event.
14. What is the arterial–alveolar difference in carbon dioxide?
15. What are some of the important safety features of the contemporary anesthesia workstation?
16. What are common sites for gas leakage?
17. How is the anesthesia machine checked for leaks?

B. Preoperative Evaluations and Preparation

1. What should be included in the equipment checkout in preparation for anesthesia?
2. What emergency equipment should be easily available to the anesthesiologist?
3. How should this patient be premedicated?

C. Intraoperative Management

1. How should this patient be monitored?
2. After uneventful inhalation mask induction, cystoscopy was begun and the Spo_2 was noted to decrease to 81% with the patient breathing an F_{IO_2} of 0.4 (oxygen at 2 L per minute and nitrous oxide at 3 L per minute). The patient developed respiratory distress. The laryngeal mask airway (LMA) was easily maintained and no gross secretions were noted. What acute diagnostic and therapeutic interventions would you perform?
3. The patient was tracheally intubated. Squeezing the reservoir bag in the circle system failed to ventilate the lungs, and a leak was noted. What are the common sites for gas leaks?

D. Postoperative Management

1. What criteria would you use for tracheal extubation?
2. What are the causes of postoperative hypoxemia?
3. What is the difference between shunt, ventilation–perfusion mismatch, and dead space?
4. What is the differential diagnosis of pulmonary edema?
5. How should the ventilator be set if mechanical ventilation is required postoperatively?
6. If this patient had acute lung injury (ALI) secondary to aspiration, beside low-tidal volume ventilation, what other changes in routine therapy should be considered?
7. What therapies that are routinely administered by the anesthesiologist may cause ALI?
8. What methods of oxygen administration may be used postoperatively?

A. Medical Disease and Differential Diagnosis

A.1. What is hypoxia and what is hypoxemia?

Hypoxia is defined as reduction of oxygen supply to tissue below physiologic levels. *Hypoxemia* is defined as deficient oxygenation of the blood. From the anesthesiologist's perspective, hypoxia is usually considered to be decreased oxygen tension (Po_2) inside the body at the tissue level or outside the body (e.g., hypoxic gas mixture), and hypoxemia is decreased oxygen tension in the arterial blood (Pao_2).

Dorland WAN. *Dorland's Illustrated Medical Dictionary*. 31st ed. Philadelphia: WB Saunders; 2007.

Wilson W. Perioperative hypoxia. In: Atlee JL, ed. *Complications in Anesthesia*. Philadelphia: WB Saunders; 1999:175.

A.2. Is partial pressure of oxygen in arterial blood (Pao_2) related to age?

Yes. There is an age-dependent decrease in the Pao_2. In 1972, Marshall and Whyche suggested the following relationship in subjects breathing room air:

$$\text{mean } Pao_2 \text{ in mm Hg} = 102 - 0.33 \text{ (age in years) mm Hg}$$

About this regression line, there are 95% confidence limits (two standard deviations [SDs]) of 10 mm Hg.

Cerveri et al. studied Pao_2 in normal nonsmoking subjects ages 40 to 90 years. They found that Pao_2 was related to age in subjects between 40 and 74 years and constructed the following reference equation:

$$Pao_2 \text{ (mm Hg)} = 143.6 - (0.39 \times \text{age}) - (0.56 \times \text{BMI}) - (0.57 \times Paco_2)$$

For subjects ≥ 75 years old, there was no correlation with age

Marshall BE, Whyche MQ. Hypoxemia during and after anesthesia. *Anesthesiology.* 1972;37:178–209.

Cerveri I, Zoia MC, Fanfulla F, et al. Reference values of arterial oxygen tension in the middle-aged and elderly. *Am J Resp and Crit Care Med.* 1995;152: 934–941.

A.3. Was this patient hypoxemic?

No. An Spo_2 reading of 94% does not signify hypoxemia. This patient is five decades older than a 20-year-old subject; therefore, his mean Pao_2 should be 5 × 5 mm Hg per decade, which is 25 mm Hg less than that (95 mm Hg) expected in a 20-year-old (see section A.2, Sorbini et al.).

$$95 - 25 = 70 \text{ mm Hg}$$

or, using the Marshall and Whyche equation (see section A.2),

$$102 - 0.33\ (70) = 79 \text{ mm Hg}$$

Assuming normal adult hemoglobin, temperature, and pH, this Pao_2 corresponds to a hemoglobin oxygen saturation of approximately 94% on the normal hemoglobin oxygen saturation versus Po_2 curve.

Although the definitions of hypoxemia given in sections A.1 and A.2 must take age into consideration, from a practical point of view, hypoxemia (in the absence of anemia) is generally considered to exist when the Pao_2 is less than 60 mm Hg, which is equivalent to a hemoglobin oxygen saturation of 90%.

A.4. What is a pulse oximeter and what is a hemoximeter?

The pulse oximeter is a noninvasive device that provides a real-time estimate (designated the Spo_2%) of the arterial hemoglobin saturation with oxygen. It is a transmissive oximeter in which the patient's fingertip (or other probe site; e.g., earlobe) serves as an in vivo cuvette through which light at two different wavelengths is transmitted.

If one requires an accurate determination of the arterial hemoglobin saturation with oxygen, an arterial blood sample must be drawn and analyzed in a laboratory co-oximeter, sometimes called a *hemoximeter*. The laboratory co-oximeter is a transmissive oximeter that uses six or more different wavelengths of light to measure total hemoglobin (HbTOT), oxygenated hemoglobin (Hbo_2), deoxygenated ("reduced") hemoglobin (RHb), methemoglobin (metHb), carboxyhemoglobin (HbCO), and other dyshemoglobins, such as sulfhemoglobin. Because each species of hemoglobin has a characteristic absorbance spectrum (i.e., absorbance versus wavelength), examination of a sample of blood using these six or eight wavelengths permits identification and quantification of each hemoglobin species. Conventional pulse oximeters use only two wavelengths of light; therefore, they are unable to determine all of the different hemoglobin species. Fractional saturation (Hbo_2%) is defined as $Hbo_2/(Hbo_2 + RHb + Hbco + metHb)$—that is, Hbo_2 per *total* Hb. Functional saturation (Sao_2) is defined as $Hbo_2/(Hbo_2 + RHb)$. Note that dyshemoglobins are absent from the denominator in the definition of Sao_2.

Kurki TS, Eisenkraft JB. Pulse oximetry. In: Reich DL, Kahn R, Mittnacht A, eds. *Monitoring in Anesthesia and Perioperative Care*. New York: Cambridge University Press; 2011;185–198.

A.5. How does a pulse oximeter work?

The pulse oximeter combines the technologies of spectrophotometry and optical plethysmography. In the pulse oximeter probe, light-emitting diodes transmit red light at wavelength 660 nm and infrared light at wavelength 940 nm through the fingertip or other probe site. Light that passes through the probe site is sensed by a single photodetector and expressed as absorbance at each wavelength. It can be shown that the ratio of absorbances, 660/940 nm, is related to the hemoglobin saturation with oxygen. This is spectrophotometry. Detection of pulsatile flow is by optical plethysmography. With each pulse of arterial blood, the probe site (e.g., fingertip) increases in volume, the path length of the transmitted light increases, and the absorbance of light at 660 nm and 940 nm increases. This *pulse-added* absorbance is considered to be due to the pulsatile flow of arterial blood at the probe site, so that the ratio of pulse-added absorbances, 660/940 nm, can be used to provide an estimate of hemoglobin oxygen saturation in arterial blood.

Kurki TS, Eisenkraft JB. Pulse oximetry. In: Reich DL, Kahn R, Mittnacht A., eds. *Monitoring in Anesthesia and Perioperative Care*. New York: Cambridge University Press; 2011;185–198.

A.6. How is a two-wavelength pulse oximeter calibrated by the manufacturer?

Each pulse oximeter manufacturer creates an empiric calibration algorithm, that is, one based on observations in human volunteers. The algorithm relates the average ratio of pulse-added absorbances, 660/990 nm, to the actual hemoglobin oxygen saturation in arterial blood samples drawn simultaneously and analyzed in a laboratory

hemoximeter. Observations are made with the volunteers breathing varying FIO_2 values so that data for saturations as low as 70% are obtained. The calibration algorithm that is created relates the ratio (R) of pulse-added absorbances, 660/940 nm, to the laboratory hemoximeter readings of HbO_2 or Sao_2%, depending on the pulse oximeter manufacturer. The calibration algorithm is then stored in the software of the pulse oximeter as a "lookup" table. Therefore, the pulse oximeter merely measures R, consults its "lookup" table and displays the corresponding saturation reading as Spo_2. The pulse oximeter does not actually measure saturation; it infers it from the ratio (R), and, therefore, it predicts what the laboratory hemoximeter would read if an arterial sample drawn at that moment were analyzed.

A high value for R corresponds to a low Spo_2 reading; R = 1 corresponds to an Spo_2 reading of 85%, and a low value for R corresponds to a high Spo_2 reading. Whenever the Spo_2 reading is approximately 85%, one should consider the possibility of a spurious reading as a result of the "R = 1" phenomenon. This is commonly due to malpositioning of the probe on the fingertip.

The pulse oximeter (Spo_2) reading is usually specified by the manufacturer to have an SD of ± 2%. Therefore, if the Spo_2 is 96%, there is a 68% likelihood that the true saturation (as measured by a hemoximeter) is 96 ± 2% (i.e., ± 1 SD) and a 95% likelihood that the true saturation is 96 ± 4% (i.e., ± 2 SD).

Guan Z, Baker K, Sandberg WS. Misalignment of disposable pulse oximeter probes results in false saturation readings that influence anesthetic management. *Anesth Analg*. 2009;109:1530–1533.

A.7. What may affect the accuracy of a two-wavelength pulse oximeter?

The two-wavelength pulse oximeter is most accurate when the conditions of its clinical use most closely resemble those of its calibration. Spurious readings or failure may occur during patient movement (e.g., shivering, peripheral nerve stimulation, "twitching"), presence of intense ambient light (low signal/noise ratio), electrocautery use, administration of intravenous dyes with absorbance peaks at 660 nm (e.g., methylene blue), presence of dyshemoglobins (e.g., methemoglobin, carboxyhemoglobin, and sulfhemoglobin), certain colors of nail polish, poor pulsatile flow at the probe site (e.g., hypotension, vasoconstriction, Raynaud disease), and venous pulsations (e.g., tricuspid regurgitation).

Recent improvements in pulse oximetry technology include paradigms to increase the signal/noise ratio, thereby permitting motion artifact reduction and increased sensitivity to pulsatile flow. Such pulse oximeters have significantly lower failure rates during patient movement (such as in the postanesthesia care unit) and during conditions of low flow (e.g., hypothermia).

Barker SJ. "Motion-resistant" pulse oximetry: a comparison of new and old models. *Anesth Analg*. 2002;95:967–972.

A.8. How do the dyshemoglobins, methemoglobin (metHb) and carboxyhemoglobin (Hbco) affect Spo_2 readings?

In methemoglobin, iron in the heme moiety is oxidized (such as by dapsone, benzocaine, nitric oxide, prilocaine) to the Fe^{3+} state rather than being in the normal Fe^{2+} state. Methemoglobin cannot carry oxygen and creates a physiologic anemia.

The absorbance spectrum for metHb shows it to have similar absorbances at 660 nm and 940 nm. Therefore, the more metHb that is present, the more R tends toward 1 and the Spo_2 reading toward 85%. In the presence of metHb, the Spo_2 reading overestimates the fractional saturation and underestimates the functional saturation.

In carbon monoxide (CO) poisoning, CO combines with Hb to create a physiologic hypoxemia. Hbco has a similar absorbance to Hbo_2 at 660 nm, but a very low absorbance at 940 nm. In the presence of Hbco, the Spo_2 overestimates fractional saturation and underestimates functional saturation. Although blood that is poisoned with CO appears "cherry red" to the naked eye, and therefore may look like it is fully saturated with oxygen, it is important to recognize that the ratio of absorbances 660/940 nm will suggest blood with a hemoglobin oxygen saturation in the 90s. In a subject breathing Fio_2 of 1 (when functional saturation is 100%), as the level of Hbco increases, Spo_2 decreases from close to 100% to approximately 91%.

If the presence of dyshemoglobins is suspected, arterial blood must be drawn and analyzed in a laboratory hemoximeter to obtain accurate readings of saturation.

Pulse oximetry technology continues to evolve, and multiwavelength pulse oximeters, called pulse co-oximeters, are now clinically available. One model uses eight wavelengths of light (Masimo Rainbow SET Pulse CO-Oximetry, Masimo Company, Irvine, CA), similar to the laboratory hemoximeter. This technology makes it possible to measure CO (Spco), methemoglobin (SpMet), and total hemoglobin (SpHbt), all noninvasively and in real time.

A.9. What is a capnometer and what is capnography? Of what value are they in patient monitoring?

A capnometer is a device that measures the tension (in units of millimeters of mercury [mm Hg] or kilopascals [kPa]) or concentration (volumes %) of carbon dioxide (CO_2) in the gas near the patient's airway throughout the respiratory cycle. Capnography is the graphic display of the CO_2 concentration on the y-axis against time on the x-axis.

Capnometry may be achieved using different technologies that can monitor CO_2. Most capnometers now use infrared spectroscopy to measure the Pco_2 (i.e., carbon dioxide partial pressure in millimeters of mercury). A built-in barometer measures barometric pressure (P_B) so that CO_2 can also be displayed as a percentage ($Pco_2 \times 100/P_B = \%CO_2$).

Capnography is one of the American Society of Anesthesiologists' standards for basic anesthetic monitoring. ("Continual monitoring for the presence of expired carbon dioxide shall be performed unless invalidated by the nature of the patient, procedure or equipment.") It is the "gold standard" for establishing presence of ventilation.

ASA Standards for Basic Anesthetic Monitoring (approved October 21, 1986 and last amended October 20, 2010). Park Ridge, IL: American Society of Anesthesiologists; 2010.

Gravenstein JS, Jaffe MB, Paulus DA. *Capnography: Clinical Aspects*. New York: Cambridge University Press; 2004.

A.10. What is meant by the term *end-tidal carbon dioxide* (P_{ETCO_2})?

P_{ETCO_2} is the tension of CO_2 in the exhaled gas at the end of an exhalation. Because this gas originates from the alveoli, it is considered to represent the CO_2 tension in the alveolar gas (P_{ACO_2}). The P_{ACO_2} results from the combination of gases coming from ideal alveoli, where ventilation and perfusion are perfectly matched and the CO_2 concentration is the same as arterial (P_{ACO_2}), and alveolar dead space (alveoli that are ventilated but not perfused) where CO_2 concentration is the same as inspired (P_{ICO_2}) and is normally zero.

The presence of a normal capnogram and P_{ETCO_2} depends on (1) production of CO_2 by the tissues, (2) cardiac output and pulmonary blood flow to carry CO_2 to the lungs, and (3) ventilation. Monitoring of P_{ETCO_2} can be used to adjust the setting of a mechanical ventilator and monitor ventilation, as well as detect ventilator malfunctions and breathing system problems such as leaks, incompetent unidirectional valves, exhausted CO_2 absorbent, metabolic problems (e.g., malignant hyperthermia), and gas embolism.

Gravenstein JS, Jaffe MB, Paulus DA. *Capnography: Clinical Aspects*. New York: Cambridge University Press; 2004.

Lumb AB. *Nunn's Applied Respiratory Physiology*. 6th ed. Philadelphia: Elsevier Science; 2005:157–158.

A.11. What is the appearance of a normal capnogram and what is its significance?

A typical normal capnogram (P_{CO_2} versus time) is shown in Figure 58.1. Four phases have been described.

Phase I. This is the expiratory baseline. During exhalation, CO_2–free gas from the mechanical dead space (e.g., flexible or "goose-neck" connector) and anatomic dead space (large conducting airways) flows past the CO_2 sampling port.

Phase II. This is the expiratory upstroke. It is due to CO_2 from alveoli mixed with anatomic dead space gas passing the gas sampling port and is usually a steep upslope.

Phase III. This is the expiratory or alveolar plateau and is due to alveolar CO_2.

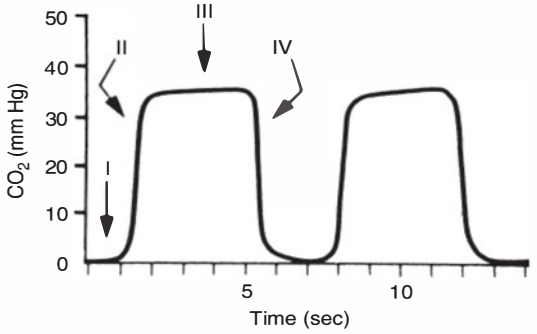

Figure 58.1 Phases of the normal capnogram. *(Phase I)* inspiratory baseline. *(Phase II)* expiratory upstroke. *(Phase III)* expiratory plateau. *(Phase IV)* inspiratory downstroke. (From Good ML. Capnography. Uses, interpretation, and pitfalls. In: *ASA Refresher Courses in Anesthesiology*. Park Ridge, IL: American Society of Anesthesiologists; 1990:179, with permission.)

In patients with healthy lungs, it is nearly horizontal, but in patients with obstructive airway disease, there is a more pronounced upward slope. The maximum expired CO_2 is usually considered as the P_{ETCO_2}.

The angle between the upstroke of phase II and the plateau of phase III is referred to as the *α angle*. The angle between phase III and IV is the *β angle*. An increase in the α angle and slope of phase III is seen commonly in acute bronchospasm. The angle usually decreases with treatment of the bronchospasm.

Phase IV. This is the inspiratory downstroke. During the commencement of inspiration, fresh (i.e., CO_2–free) gas is inhaled past the sensor and the capnogram falls sharply to baseline.

Lumb AB. *Nunn's Applied Respiratory Physiology*. 6th ed. Philadelphia: Elsevier Science; 2005:162.

A.12. What are mainstream and sidestream capnometers?

In a mainstream or nondiverting type of analyzer, the gas analyzer sensor is brought to the airway itself and no gas is removed from the breathing system. A cuvette with a quartz window is placed between the breathing system and the tracheal tube connector. As respired gases flow past the window in the cuvette, a beam of infrared radiation (wavelength 4.3 μm) is directed through the window. Absorbance of infrared radiation at 4.3 μm is used to measure P_{CO_2}. Advantages of the nondiverting analyzer are rapid response time, accurate waveform, and no need to scavenge gases. Disadvantages are that this additional device in the airway can be a site for a disconnect and needs sterilization (or replacement of a disposable single-use cuvette) between cases, need for heating because water vapor condensing on the window causes error, and blocking of the window by secretions or blood. Recently, a mainstream analyzer (IRMA, Phasein, Danderyd, Sweden) capable of measuring oxygen, nitrous oxide, CO_2, and all five potent inhaled anesthetics has become available.

A sidestream or diverting gas analyzer aspirates gas from the breathing circuit through a sampling adapter placed by the airway. The sampled gas passes down a sampling catheter (usually 6 to 10 ft in length) to reach the gas analyzer. Advantages of diverting analyzers are that the breathing circuit adapter is disposable. The analyzer, being remote from the airway, can be more versatile and incorporate several technologies in one "box" to analyze multiple gases (e.g., infrared analysis for CO_2, nitrous oxide, anesthetic agents; paramagnetic sensor or fuel cell for oxygen; or Raman scattering for CO_2, oxygen, agents, nitrous oxide, and nitrogen). Disadvantages of sidestream sampling analysis are slower response times, possibility of sampling leaks, errors resulting from the length of the gas sampling tube, need to scavenge gases from the analyzer after analysis, and susceptibility of the sampling tube to becoming clogged by water or secretions. Because of their versatility in regard to gas monitoring, most anesthetizing locations now use sidestream sampling analyzers.

Eisenkraft JB. Respiratory gas monitoring. In: Reich DL, Kahn R, Mittnacht A., eds. *Monitoring in Anesthesia and Perioperative Care*. New York: Cambridge University Press; 2010;150–170.

A.13. Show some common capnograms and provide a differential diagnosis of each event.

Elevated baseline equals the amount of CO_2 present in inspired gas (Fig. 58.2A).

- Capnometer not properly calibrated to zero
- Delivery of CO_2 to breathing system through fresh gas inflow
- Incompetent unidirectional valves
- Failure of CO_2 absorber (channeling, exhaustion, bypass)

Prolonged expiratory plateau and expiratory upstroke (Fig. 58.2B).

- Mechanical obstruction to exhalation
- Chronic obstructive pulmonary disease
- Bronchospasm

Dips in expiratory plateau (Fig. 58.2C[1]).

- Patient making spontaneous inspiratory effort
- "Curare cleft"

Cardiogenic oscillations if synchronized with electrocardiogram (Fig. 58.2C[2])

- Ventilator pressure relief valve perturbations

Elevated expiratory plateau (Fig. 58.2D).

- Incorrect calibration
- Increased CO_2 production/delivery versus laparoscopic CO_2 gas insufflation

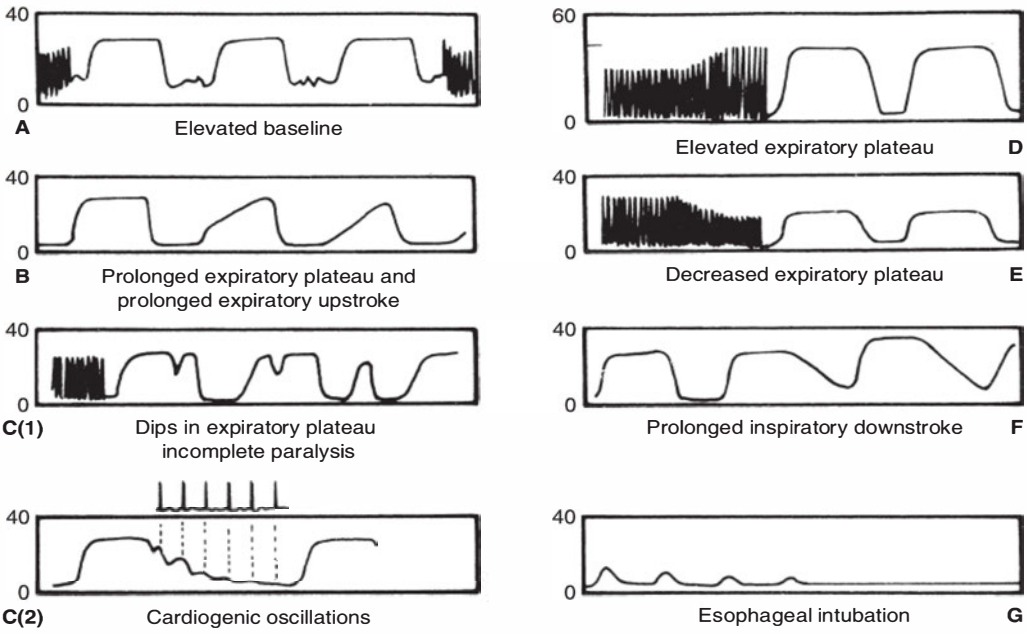

Figure 58.2 Abnormal capnograms.

- Decreased CO_2 removal
- Hypoventilation
- Leak

Decreased expiratory plateau (Fig. 58.2E).

- Incorrect calibration
- Air leak into gas sampling system
- Hyperventilation
- Decreased CO_2 production (hypothermia)
- Increased arterial–alveolar CO_2 gradient (ventilation-perfusion mismatch pulmonary embolus)

Prolonged inspiratory downstroke and raised baseline (Fig. 58.2F).

- Incompetent or missing inspiratory unidirectional valve
- Inspiratory obstruction to gas flow (e.g., kinked tracheal tube)

Esophageal intubation (Fig. 58.2G)

- As CO_2 that has been insufflated into the stomach during bag-mask ventilation, or bag-mask ventilation produced as a result of ingestion of a carbonated beverage, is washed out during esophageal ventilation, the CO_2 waveform disappears within a few breaths.

Eisenkraft JB. Respiratory gas monitoring. In: Reich DL, Kahn R, Mittnacht A., eds. *Monitoring in Anesthesia and Perioperative Care*. New York: Cambridge University Press; 2011;150–170.

A.14. What is the arterial–alveolar difference in carbon dioxide?

The arterial–alveolar difference in CO_2 is usually expressed as the difference between the arterial and P_{ETCO_2} tensions. In an ideal alveolus, the P_{aCO_2} equals P_{ACO_2} and the "P_{aCO_2}–P_{ACO_2}" difference is zero. Ventilation of unperfused alveoli leads to alveolar dead space or wasted alveolar ventilation. Because the P_{ETCO_2} comprises gas from both ideal and dead space alveoli, the "P_{aCO_2}–P_{ACO_2}" difference is a measure of alveolar dead space ventilation. For example,

$$\begin{aligned} &\text{Tidal volume} = 500\ \text{mL, anatomic dead space} = 150\ \text{mL} \\ &P_{aCO_2} = 40\ \text{mm Hg; } P_{ETCO_2} = 36\ \text{mm Hg} \\ &\text{Alveolar tidal volume} = (500 - 150) = 350\ \text{mL} \\ &\text{Ratio of } \frac{\text{Alveolar dead space}}{\text{Alveolar tidal volume}} = \frac{P_{aCO_2} - P_{ETCO_2}}{P_{aCO_2}} = \frac{40 - 36}{40} = 10\% \end{aligned}$$

Therefore, 350 ml × 10% = 35 mL wasted ventilation from each alveolar tidal volume.

$$\begin{aligned} &\text{Ideal alveolar ventilation} = (350 - 35) = 315\ \text{mL per breath} \\ &\text{In this example, physiologic dead space} = \text{anatomic} + \text{alveolar} \\ &\qquad = 150 + 35 = 185\ \text{mL per breath} \\ &\frac{\text{Physiologic dead space}}{\text{Tidal volume}} = \frac{185}{500} = 37\% \end{aligned}$$

Therefore, P_{aCO_2}–P_{ACO_2} measures alveolar dead space ventilation as a percentage of total *alveolar* ventilation. The alveolar dead space is increased by ventilation in excess of perfusion or a decrease in perfusion, such as occurs with pulmonary embolism. Shunt has minimal effect on the P_{aCO_2}–P_{ACO_2} difference.

The $Paco_2$–$Paco_2$ difference is normally 3 to 5 mm Hg in the patient under general anesthesia, but it is not constant. Therefore, although one commonly uses $Petco_2$ to noninvasively estimate $Paco_2$, only analysis of an arterial blood sample in a blood gas analyzer can provide an accurate measure of $Paco_2$, and this should be measured when critical, such as during neurosurgical anesthesia.

Lumb AB. *Nunn's Applied Respiratory Physiology*. 6th ed. Philadelphia: Elsevier Science; 2005:120.

A.15. What are some of the important safety features of the contemporary anesthesia workstation?

Because most problems with anesthesia machines are due to use error, safety design of the contemporary workstation is at four levels.

Features intended to prevent human error

The medical gas pin index and diameter index safety systems ensure that medical gas connections are made correctly. Therefore, one cannot hang a nitrous oxide cylinder in an oxygen hanger yoke or connect a nitrous oxide hose to the oxygen pipeline inlet of the machine.

The "fail-safe" valve is a pressure-sensitive device that interrupts flow of all hypoxic gases on the machine to their flow control valves if the supply pressure of oxygen in the high-pressure system (i.e., components upstream of the oxygen flow control needle valve) falls below a threshold (20 pounds per square inch gauge [psig] in GE-Datex-Ohmeda machines; 12 psig in Dräger Narkomed machines).

When the pressure of oxygen in the high-pressure system falls below 30 psig, an oxygen supply pressure failure alarm is annunciated. The oxygen flow control knob is "touch coded"; that is, it is fluted and larger in diameter than the other gas flow control knobs and is normally located on the right of all other gas flow control valves. In the Dräger Fabius GS workstation, the gas flow controls are arranged vertically, with the oxygen flow control knob as the lowest.

Key-fill systems for anesthesia vaporizers are safety features that also decrease the likelihood of atmospheric contamination during vaporizer filling. The most important of such systems is the Saf-T-Fill system used on desflurane (Suprane) bottles and desflurane vaporizers because the filling with desflurane of a vaporizer specific for another agent could result in a lethal overdose of desflurane.

A pressure relief valve built into the machine common gas outlet, breathing system, or ventilator provides some protection against positive pressure barotrauma.

Features to correct for use error

Gas flow proportioning systems ensure a minimum oxygen concentration of 25% when nitrous oxide and oxygen are being used. Therefore, if the anesthesiologist were to accidentally attempt to increase the flow of nitrous oxide, either the oxygen flow would be increased automatically (GE-Datex-Ohmeda) or the flow of nitrous oxide would be limited according to the flow of oxygen that was set (Dräger Narkomed).

On older machines, during use of the anesthesia ventilator, changes in fresh gas flow, I:E ratio, or respiratory rate cause changes in delivered tidal volume (V_T) that might result in overventilation, underventilation, or even barotrauma. On modern systems (e.g., GE-Datex-OHMEDA S/5 ADU; GE-Datex Aisys workstations that incorporate a 7900 series ventilator with the Smart Vent feature; Dräger Fabius GS and Apollo workstations), once the ventilation parameters have been set, they are maintained because the ventilator or circuit automatically compensates for changes in gas flow settings. In the GE-Datex workstations with Smart Vent, V_T is monitored

continually by a computer. If measured V_T changes from that set to be delivered, the computer adjusts the volume delivered by the ventilator bellows. Dräger and Datascope Anestar workstations use fresh gas decoupling to maintain a constant V_T. In this system, during the inspiratory phase, a decoupling valve closes so that fresh gas entering the breathing system is directed into the reservoir bag and only gas from the ventilator is delivered to the patient. During exhalation, the ventilator chamber refills from the fresh gas flow and the fresh gas that was collected in the reservoir bag during the previous inspiration.

A vaporizer interlock system prevents the unintentional simultaneous use of more than one vaporizer.

Monitoring systems

A monitor of oxygen in the gas delivered to the patient is mandated to be enabled and the low oxygen concentration alarm is activated whenever the anesthesia workstation is capable of delivering an anesthetic gas mixture from the common gas outlet.

Other monitors in the anesthesia workstation include pressure, volume, flow, and gas composition. Some also incorporate airway gas flow monitoring. The breathing system low-pressure monitor alarm is automatically enabled when the ventilator is turned on.

Alarm systems

Contemporary workstations incorporate an integrated prioritized alarm system with visible and audible alerts when set parameter limits are exceeded.

An important safety feature of all modern machines/workstations is the preuse checkout. In 1993, the U.S. Food and Drug Administration (FDA) published anesthesia apparatus checkout recommendations. The machine should be checked by an educated user. Item no. 1 on the FDA checklist is that an alternative means to ventilate the patient's lungs should be present and functioning. Therefore, if a problem arises with the machine, the patient's lungs can be ventilated using a self-inflating resuscitation bag (e.g., Ambu bag). If a machine problem arises and the cause/remedy is not immediately obvious, one should instinctively reach for the resuscitation bag and call for help.

Recognizing that the FDA 1993 checkout recommendations cannot be applied to many of the contemporary workstations, in 2008, the American Society of Anesthesiologists published guidelines applicable to all anesthesia delivery systems so that individual departments can develop a preuse checkout that can be performed consistently and expeditiously. The 2008 guidelines are intended to provide a template for developing checkout procedures that are appropriate for each individual anesthesia machine design and practice setting. They discuss which systems and components should be checked, the checkout interval (e.g., before first case versus before every case), and who may be responsible for performing each checkout procedure—the anesthesiologist or technician (Table 58.1).

A.16. What are common sites for gas leakage?

Because gas can leak from numerous points in the workstation and breathing system, the anesthesiologist must be able to trace the flow of gases from the supply and storage sources through the system components. Most commonly, leaks occur in the breathing system and low-pressure parts of the machine (i.e., components downstream of the gas flow control valves). For the breathing system, trace the flow of gas from the common gas outlet (if accessible), through the antidisconnect fitting and hose, to the breathing circuit fresh gas inlet. Trace the flow of gas past the inspiratory valve, inspiratory limb, gas sampling connector, elbow, to the tracheal tube or airway device. Common sites for leaks include a partially deflated tracheal tube cuff or a disconnection of the sidestream sampling gas analyzer sampling line. Check flow back down the expiratory limb, spirometer, expiratory valve, absorber, pressure gauge, pressure sampling lines, and any user-added components such as filters, humidifiers, and positive end-expiratory pressure (PEEP) valves. Check both the bag and the ventilator circuits for gas leaks.

Leaks in the machine low-pressure system can occur as a result of cracked rotameter flow tubes, incorrectly mounted vaporizers, vaporizer leak around agent filling device, or fracture in the gas piping. Leaks in the high-pressure system usually result from defective valves, connectors, and hanger yokes.

Brockwell RC, Andrews JJ. Inhaled anesthetic delivery systems. In: Miller RD, Erikson LI, Fleisher LA, et al., eds. *Miller's Anesthesia.* 7th ed. New York: Churchill-Livingstone; 2010:667–718.

A.17. How is the anesthesia machine checked for leaks?

Leaks in the machine low-pressure system should be tested for according to the manufacturer's specific recommendations for that particular brand and model.

In general, Dräger Narkomed machines (Narkomed 2B, Narkomed 2C, Narkomed 3, and Narkomed 4) are tested using a positive pressure leak check. In principle, the inspiratory and expiratory connections on the absorber are connected by a short length of 22-mm diameter tubing (i.e., the circle breathing system tubing is removed). The reservoir bag (usually 3 L size) is removed and a test terminal is connected to the bag mount. A short piece of plastic tubing and a sphygmomanometer bulb are connected to the test terminal. With no gases flowing and with the pop-off valve closed, the system is pressurized to 50 cm H_2O by squeezing the sphygmomanometer bulb. Pressure should not decrease by more than 20 cm H_2O in 30 seconds. In this test, the pressure is applied to all of the rigid components of the breathing system and through the fresh gas hose into the machine low-pressure system all the way back to the flow control valves. This test is then repeated with each vaporizer turned on in turn to test for leaks in each vaporizer.

Some anesthesia machines (e.g., GE-Datex-Ohmeda Modulus I, Modulus II, Excel) have a one-way outlet check valve just upstream of the common gas outlet. Other models (e.g., Modulus II Plus, Modulus CD) have no outlet check valve. The presence of an outlet check valve precludes the application of a positive pressure leak check. Whether such a valve is present, a negative pressure leak test can be used to check the low-pressure system. In this test, a suction bulb (negative pressure leak-check device) is connected to the common gas outlet. With all gas flows turned off and vaporizers off, the bulb is squeezed empty (to create a negative pressure of –65 mm Hg) and then connected to the common gas outlet of the workstation. Reexpansion of the bulb should not occur in less than 30 seconds. The test is repeated with each vaporizer turned on in turn to check for leaks in the vaporizers.

The FDA 1993 preuse checkout recommendations describe the use of the negative pressure (bulb) leak-check device and state that the bulb should not refill within 10 seconds. The anesthesiologist must understand how to perform a low-pressure

system leak check and must have the means (i.e., appropriate leak-check device) to check his or her own particular machine.

The newer electronic anesthesia workstations incorporate an automated checkout to test for leaks. The user of the workstation must understand what the automated checkout is designed to check and, more importantly, what it does not check. Even with an automated preuse checkout, some steps must be performed manually as prompted and directed by the checkout screen.

Dorsch JA, Dorsch SE. Equipment checkout and maintenance. In: *Understanding Anesthesia Equipment*. 5th ed. Philadelphia: Lippincott Williams & Wilkins; 2008:931–953.

B. Preoperative Evaluation and Preparation

B.1. What should be included in the equipment checkout in preparation for anesthesia?

In 1993, the FDA published its *14-Step Anesthesia Apparatus Checkout Recommendations*, as follows:

This checkout, or a reasonable equivalent, should be conducted before administration of anesthesia. These recommendations are valid only for an anesthesia system that conforms to current and relevant standards and includes an ascending bellows ventilator and at least the following monitors: capnograph, pulse oximeter, oxygen analyzer, respiratory volume monitor (spirometer), and breathing system pressure monitor with high- and low-pressure alarms. This is a guideline that users are encouraged to modify to accommodate differences in equipment design and variations in local clinical practice. Such local modifications should have appropriate peer review. Users should refer to the operator's manual for the manufacturer's specific procedures and precautions, especially the manufacturer's low-pressure leak test (step no. 5).

Emergency ventilation equipment

Step 1. Verify backup ventilation equipment is available and functioning.

High-pressure system

Step 2. Check oxygen cylinder supply.
- Open oxygen cylinder and verify at least half full (approximately 1,000 psi).
- Close cylinder.

Step 3. Check central pipeline supplies.
- Check that hoses are connected and pipeline gauges read approximately 50 psi.

Low-pressure systems

Step 4. Check initial status of low-pressure system.
- Close flow control valves and turn vaporizers off.
- Check fill level and tighten vaporizer filler caps.

Step 5. Perform leak check of machine low-pressure system.
- Verify that the machine master switch and flow control valves are off.
- Attach "suction bulb" to common fresh gas outlet.
- Squeeze the bulb repeatedly until it is fully collapsed.
- Verify that the bulb stays fully collapsed for at least 10 seconds.

- Open one vaporizer at a time and repeat the tests as discussed earlier.
- Remove suction bulb, and reconnect fresh gas hose.

Step 6. Turn on machine master switch and all other necessary electrical equipment.

Step 7. Test flowmeters.
- Adjust flow of all gases through their full range, checking for smooth operation of floats and undamaged flow tubes.
- Attempt to create a hypoxic oxygen/nitrous oxide mixture and verify correct changes in flow and/or alarm.

Scavenging system

Step 8. Adjust and check scavenging system.
- Ensure proper connections between the scavenging system and both the adjustable-pressure limit (APL, or "pop-off") valve and ventilator relief valve.
- Adjust waste gas vacuum (if possible).
- Fully open APL valve and occlude Y-piece.
- With minimum oxygen flush activated, allow the scavenger reservoir bag to distend fully and then verify that the absorber pressure gauge reads less than 10 cm H_2O.

Breathing system

Step 9. Calibrate oxygen monitor.
- Ensure monitor reads 21% in room air.
- Verify low oxygen alarm is enabled and functioning.
- Reinstall sensor in circuit and flush breathing system with oxygen.
- Verify that monitor now reads more than 90%.

Step 10. Check initial status of breathing system.[1]
- Set selector switch to "bag" mode.
- Check that breathing circuit is complete, undamaged, and unobstructed.
- Verify that CO_2 absorbent is adequate.
- Install breathing circuit accessory equipment (e.g., humidifier, PEEP valve) to be used during the case.

Step 11. Perform leak check of the breathing system.
- Set all gas flows to zero (or minimum).
- Close APL (pop-off) valve and occlude Y-piece.
- Pressurize breathing system to approximately 30 cm H_2O with oxygen flush.
- Ensure that pressure remains fixed for at least 10 seconds.
- Open APL (pop-off) valve and ensure that pressure decreases.

Manual and automatic ventilation systems

Step 12. Test ventilation systems and unidirectional valves.
- Place a second breathing bag on the Y-piece.
- Set appropriate ventilator parameters for the next patient.
- Switch to automatic ventilation ("ventilator") mode.
- Fill bellows and breathing bag with oxygen flush and then turn the ventilator on.
- Set oxygen flow to minimum, and other gas flows to zero.
- Verify that during inspiration, bellows deliver appropriate tidal volume and that during expiration, bellows fill completely.
- Set fresh gas flow to approximately 5 L per minute.
- Verify that the ventilator bellows and simulated lungs fill and empty appropriately without sustained pressure at end expiration.

---

[1] In step no. 10, checking adequacy of the CO_2 absorbent should include changing or hydrating it if there is any possibility that it may have become desiccated. This is because desiccated soda lime can react with desflurane, enflurane, and isoflurane to produce high levels of CO in the breathing system. Baralyme is no longer available for use as an absorbent.

- Check for proper action of unidirectional valves.
- Exercise breathing circuit accessories to ensure proper function.
- Turn ventilator off and switch to manual ventilation ("bag/APL") mode.
- Ventilate manually and ensure inflation and deflation of artificial lungs and appropriate feel of system resistance and compliance.
- Remove second breathing bag from the Y-piece.

Monitors

Step 13. Check, calibrate, and/or set alarm limits of all monitors.

- Capnometer
- Pulse oximeter
- Oxygen analyzer
- Respiratory volume monitor (spirometer)
- Pressure monitor
- High- and low-airway alarms

Final position

Step 14. Check final status of machine.

- Vaporizers off
- APL valve open
- Selector switch to "bag"
- All flowmeters to zero
- Patient suction level adequate
- Breathing system ready to use

The preanesthesia equipment checkout procedures are shown in Table 58.1.

Summary of American Society of Anesthesiologists 2008 Checkout Recommendations by Frequency and Responsible Party. Recommendations for Pre-Anesthesia Checkout Procedures. Park Ridge, IL: ASA. Available at: http://www.asahq.org/clinical/FINALCheckoutDesignguidelines02-08-2008.pdf.

B.2. What emergency equipment should be easily available to the anesthesiologist?

In checking the anesthesia machine, step no. 1 on the FDA 1993 checklist is to verify that backup ventilation equipment is available and functioning. This means a self-inflating resuscitation bag appropriate for patient size (adult versus pediatric) is present and tested. Emergency airway management equipment must be available. The latter may be stored in a "difficult airway cart."

It is also important to have available a means to perform an emergency cricothyrotomy for the "cannot intubate, cannot ventilate" scenario and a means to ventilate and oxygenate through the cricothyroid catheter, once placed. A suitable device is the Sanders injector system.

Other emergency equipment includes a working flashlight, a backup battery for any electricity-dependent workstation, an oxygen tank and regulator, a malignant hyperthermia cart, a "code" cart and defibrillator, a difficult airway cart, a fire extinguisher, knowledge of appropriate response to a fire, and an evacuation plan.

B.3. How should this patient be premedicated?

The goal of premedication must be established preoperatively. Commonly considered objectives listed in order of most to least common are as follows:

- Anxiolysis
- Minimization of gastric volume and acidity when "full stomach" is of concern
- Antibiotic prophylaxis (commonly administered intravenously in the operating room) before surgical incision
- Antisialagogue effect

This patient may require anxiolysis. Premedication for anxiolysis in an ambulatory patient must consider the patient's need to arrive from home and ambulate, as well as the desire for rapid return of clear mental status postoperatively. Most commonly, therefore, no agent is administered preoperatively. Alternatively, for the highly anxious patient, a small dose of a short-acting agent (e.g., lorazepam, 1 to 2 mg orally) may be administered with a few sips of water 30 to 60 minutes preoperatively.

White PF, Eng MR. Ambulatory (outpatient) anesthesia. In: Miller RD, Erikson LI, Fleisher LA, et al., eds. *Miller's Anesthesia.* 7th ed. Philadelphia: Churchill Livingstone; 2010;2419–2460.

C. Intraoperative Management

C.1. How should this patient be monitored?

The "Standards for Basic Anesthetic Monitoring" are established by the American Society of Anesthesiologists and were last amended in October 2010. In summary, they are as follows:

- *Standard I:* Qualified anesthesia personnel shall be present in the room throughout the conduct of all general anesthetics, regional anesthetics, and monitored anesthesia care.
- *Standard II:* During all anesthetics, the patient's oxygenation, ventilation, circulation, and temperature shall be continually evaluated.

Oxygenation

- *Inspired gas:* During every administration of general anesthesia using an anesthesia machine, the concentration of oxygen in the patient breathing system shall be measured by an oxygen analyzer with a low oxygen concentration limit alarm in use.*
- *Blood oxygenation:* During all anesthetics, a quantitative method of assessing oxygenation such as pulse oximetry shall be employed.* When the pulse oximeter is utilized, the variable pitch pulse tone and the low threshold alarm shall be audible to the anesthesiologist or the anesthesia care team personnel.* Adequate illumination and exposure of the patient are necessary to assess color.*

Ventilation

- Every patient receiving general anesthesia shall have the adequacy of ventilation continually evaluated. Qualitative clinical signs such as chest excursion, observation of the reservoir breathing bag, and auscultation of breath sounds are useful. Continual monitoring for the presence of expired CO_2 shall be performed unless invalidated by the nature of the patient, procedure, or equipment. Quantitative monitoring of the volume of expired gas is strongly encouraged.*
- When an endotracheal tube or laryngeal mask is inserted, its correct positioning must be verified by clinical assessment and by identification of CO_2 in the expired gas.

Continual P_{ETCO_2} analysis, in use from the time of endotracheal tube/laryngeal mask placement, until extubation/removal or initiating transfer to a postoperative care location, shall be performed using a quantitative method such as capnography, capnometry, or mass spectroscopy.* When capnography or capnometry is utilized, the P_{ETCO_2} alarm shall be audible to the anesthesiologist or the anesthesia care team personnel.*

- When ventilation is controlled by a mechanical ventilator, there shall be in continuous use a device that is capable of detecting disconnection of components of the breathing system. The device must give an audible signal when its alarm threshold is exceeded.
- During regional anesthesia and monitored anesthesia care, the adequacy of ventilation shall be evaluated by continual observation of qualitative clinical signs and/or monitoring for the presence of exhaled CO_2.

Circulation

- Every patient receiving anesthesia shall have the electrocardiogram continuously displayed from the beginning of anesthesia until preparing to leave the anesthetizing location.*
- Every patient receiving anesthesia shall have arterial blood pressure and heart rate determined and evaluated at least every 5 minutes.*
- Every patient receiving general anesthesia shall have, in addition to the above, circulatory function continually evaluated by at least one of the following: palpation of a pulse, auscultation of heart sounds, monitoring of a tracing of intra-arterial pressure, ultrasound peripheral pulse monitoring, or pulse plethysmography or oximetry.

Body temperature

- Every patient receiving anesthesia shall have temperature monitored when clinically significant changes in body temperature are intended, anticipated, or suspected.

Under extenuating circumstances, the responsible anesthesiologist may waive the requirements marked with an asterisk (*); it is recommended that when this is done, it should be so stated (including the reasons) in a note in the patient's medical record.

The reader should visit the ASA website for the most recent version of the standards: http://www.asahq.org/publicationsAndServices/standards/02.pdf

C.2. After uneventful inhalation mask induction, cystoscopy was begun and the Spo_2 was noted to decrease to 81% with the patient breathing an F_{IO_2} of 0.4 (oxygen at 2 L per minute and nitrous oxide at 3 L per minute). The patient developed respiratory distress. The laryngeal mask airway (LMA) was easily maintained and no gross secretions were noted. What acute diagnostic and therapeutic interventions would you perform?

Immediately, the patient should be examined for airway obstruction. The presence of bilateral breath sounds and the quality of those breath sounds need to be ascertained. The F_{IO_2}, $ETco_2$, heart rate, blood pressure, and Spo_2 also need to be checked. The bladder irrigation fluid intake and output, as well as the intravenous fluid intake, should be reviewed.

Therapeutically, the F_{IO_2} should be increased immediately to 1, and a change to manually assisted ventilation should be considered. If the Spo_2 does not increase rapidly in response to these interventions, tracheal intubation and initiation of positive pressure ventilation should be performed.

Dorotta I, Basali A, Ritchey M, et al. Transurethral resection syndrome after bladder perforation. *Anesth Analg.* 2003;97:1536.

C.3. The patient was tracheally intubated. Squeezing the reservoir bag in the circle system failed to inflate the lungs, and a leak was noted. What are the common sites for gas leaks?

A leak can occur anywhere in the gas circuit. One might logically check for a leak in the circuit starting from the tip of the tracheal tube and working backward toward the gas delivery system, recognizing the following common potential sites:

- Incomplete seal between the tracheal tube cuff and the trachea
- Connection between the tracheal tube and the breathing circuit (e.g., the elbow adapter)
- Spirometric and end-tidal monitoring connections at both the patient end (near the connection between the breathing circuit and tracheal tube) and the monitoring end
- Connection between inspiratory and expiratory gas hoses and the machine
- Within the low-pressure system, including the unidirectional valves, APL valve, reservoir bag or bellows housing, absorber, vaporizers, flowmeters, and scavenging system

Dorsch JA, Dorsch SE. Equipment checkout and maintenance. In: *Understanding Anesthesia Equipment*. 5th ed. Philadelphia: Lippincott Williams & Wilkins; 2008:931–953.

D. Postoperative Management

D.1. What criteria would you use for tracheal extubation?

In the operating room, traditional extubation criteria fall into two categories: global and respiratory. Global criteria include return of consciousness, demonstration of ability to protect the airway, adequate reversal of residual neuromuscular blockade, absence of hypothermia, and presence of a normal metabolic milieu (e.g., no significant anemia, acidosis, and electrolyte abnormality). Commonly applied respiratory criteria are a vital capacity greater than 15 mL per kg, a negative inspiratory force of more than –20 cm H_2O, and an Spo_2 more than 90% while breathing an F_{IO_2} less than 0.40.

Patients with a respiratory insult and the need for postoperative mechanical ventilation in the postanesthesia care unit or intensive care unit may be assessed using additional criteria. The ratio of respiratory rate to tidal volume is now widely used. This is also called the *rapid shallow breathing index* (RSBI). The idea is that slow, deep breathing during minimal respiratory support predicts successful extubation and that rapid, shallow breathing predicts probable failure. To determine this ratio, the patient is observed breathing from a T-bar, or a low level of pressure support (PS) (e.g., less than 10 cm H_2O) and the following is calculated:

$$\text{RSBI} = \text{respiratory rate (breaths per minute)}/\text{tidal volume (in liters)}$$

When the RSBI is more than 100, the implication is that the patient is exhibiting rapid, shallow breathing and will predictably fail an extubation attempt. When the RSBI is less than 100, it is assumed that the patient can breathe at a rate and tidal volume that can be easily maintained after extubation and will be adequate to maintain a normal Pao_2 and $Paco_2$. If during the period of observation while breathing from a T-bar or on PS the patient develops signs of distress such as diaphoresis, agitation, tachycardia, bradycardia, hypertension, or hypotension, the trial is abandoned and the patient is said to have had a weaning failure.

Yang KL, Tobin MJ. A prospective study of indexes predicting the outcome of trials of weaning from mechanical ventilation. *N Engl J Med.* 1991;324:1445–1450.

D.2. What are the causes of postoperative hypoxemia?

The etiology of hypoxemia can be classified physiologically or pathologically. Physiologically, all instances of hypoxemia have only four potential causes:

- Low F_{IO_2}
- Hypoventilation (which will also be associated with an increased P_{aCO_2})
- Ventilation–perfusion mismatch
- Shunt

Pathologically, common etiologies likely to present postoperatively include airway obstruction, atelectasis (especially with upper abdominal retraction and Trendelenburg positioning), right mainstem intubation, aspiration, pulmonary edema, and pulmonary embolus.

Nicholau D. The postoperative care unit. In: Miller RD, Erikson LI, Fleisher LA, et al., eds. *Miller's Anesthesia.* 7th ed. Philadelphia: Churchill Livingstone; 2010:2707–2728.

D.3. What is the difference between shunt, ventilation–perfusion mismatch, and dead space?

The relative quantity of perfusion and ventilation defines these terms. A normal lung has a small portion in which perfusion and ventilation are perfectly matched. Two extreme conditions may exist at either end of the spectrum of perfectly matched perfusion and ventilation; those extremes are shunt and dead space ventilation.

In a shunt, the alveolus is perfused, but it is not ventilated. The physiologic result is hypoxemia. This is characterized by a failure of the P_{aO_2} to rise despite an increase in the F_{IO_2}. Hypoxemia caused by small amounts of shunted blood (i.e., less than 20% of cardiac output) is easily overcome by increasing the F_{IO_2}. This is because the blood that is not shunted will contain enough "extra" dissolved oxygen to make up for the deficit that the shunted blood contributes to the combined total of blood oxygen content. Once the shunt fraction approaches 0.3 (30%), increasing the F_{IO_2} even to 1 will not be effective in preventing hypoxemia. The term *venous admixture* is often used synonymously for shunt.

In dead space, the alveolus is ventilated, but it is not perfused; hence, the alveolar space is essentially "dead." The physiologic result is hypercarbia. This is characterized by a failure to maintain a normal P_{aCO_2} despite an increase in minute ventilation (i.e., tidal volume × respiratory rate).

Ventilation–perfusion mismatch is the term applied to any condition that is not a perfect match—that is, shunt or dead space. The physiologic result is a variable combination of hypoxemia and hypercarbia. The resultant degree of hypoxemia and hypercarbia depends on the relative contribution of partial shunt and dead space.

Lumb AB. *Nunn's Applied Respiratory Physiology.* 6th ed. Philadelphia: Elsevier Science, 2005:122–126.

Petros AJ, Doré CJ, Nunn JF. Modification of the iso-shunt lines for low inspired oxygen concentrations. *Br J Anaesth.* 1994;72:515–522.

D.4. What is the differential diagnosis of pulmonary edema?

Pulmonary edema is usually thought to be either cardiac or noncardiac in etiology. The differential diagnosis of pulmonary edema is shown in Table 58.2.

Conditions that physiologically result from an increase in the pressure within the vessel that cause transudation of fluid from inside the vessel to outside the vessel are traditionally termed *congestive heart failure* (CHF). CHF will be associated with a diminution of cardiac function and an increase in the left ventricular end-diastolic pressure.

A decrease in the pressure outside of the vessel may also result in the net movement of fluid from inside to outside. The classic example of this would be negative pressure pulmonary edema, a condition seen in young patients who are inspiring against a closed glottis.

A change in the permeability of the vessel wall is the major cause of pulmonary edema seen in acute lung injury (ALI) and acute respiratory distress syndrome (ARDS). These conditions require a history of exposure to a risk factor, the development of bilateral infiltrates on chest radiography, and documentation of the absence of heart failure either by echocardiogram or pulmonary artery catheterization. Risk factors for ALI and ARDS include aspiration, long bone fracture, transfusion-related acute lung injury, pancreatitis, inhalational injury, and sepsis (Table 58.2).

In this patient, acute fluid overload from absorption of bladder irrigation fluid should be considered. Physiologically, this picture resembles CHF and will respond to treatment with diuretics.

Bittner EA, Grecu L, George E. Postoperative complications. In: Longnecker DE, Brown D, Newman M, et al., eds. *Anesthesiology*. New York: McGraw Hill; 2007:1700–1715.

Dorotta I, Basali A, Ritchey M, et al. Transurethral resection syndrome after bladder perforation. *Anesth Analg*. 2003;97:1536.

D.5. How should the ventilator be set if mechanical ventilation is required postoperatively?

Parameters that must be set include the mode, respiratory rate, tidal volume, PEEP, and F_{IO_2}.

Patients with an acute need for mechanical ventilation should be given full support with the mode set as volume control, with which all breaths are delivered by the ventilator. Other modes to be considered as the patient improves include synchronized intermittent mandatory ventilation, PS, and combinations of synchronized intermittent mandatory ventilation and PS.

Tidal volume has traditionally been set at 10 mL per kg. Normally, during spontaneous ventilation, the respiratory rate is 12 to 16 breaths per minute and the tidal volume is 6 mL per kg. However, during spontaneous ventilation, there are yawns and sighs that prevent atelectasis. Yawns and sighs are not administered during routine mechanical ventilation. Therefore, standard mechanical ventilation settings use a lower respiratory rate and higher tidal volume than spontaneous values, resulting in the same minute ventilation and no need for sigh (150% of V_T) breaths.

Traditional mechanical ventilation has been recognized as a potential cause of morbidity and mortality when applied to injured lungs. The excessive V_T is thought to cause alveolar injury and worsen lung damage (i.e., volutrauma). This should be distinguished from the more easily recognized concern of pneumothorax, resulting from ventilation of stiff lungs with high inflation pressures, commonly referred to as *barotrauma*. Hence, the current recommendation in ALI and ARDS is that the V_T be set at 6 mL per kg of premorbid weight. Additionally, the peak inspiratory pressure should ideally be less than 35 cm H_2O. This may result in CO_2 retention, but if the

Table 58.2 Differential Diagnosis of Pulmonary Edema

CONDITION	PATHOPHYSIOLOGY	SAMPLE CAUSE
Congestive heart failure	↑ Filling pressure, ↓ cardiac output	Myocardial infarction
Negative pressure pulmonary edema	↑ Outside–inside pressure gradient	Laryngospasm
Acute lung injury and acute respiratory distress syndrome	↑ Permeability	Sepsis, aspiration, fat embolus, TRALI

TRALI, transfusion-related acute lung injury.

pH is more than 7.25, no intervention is necessary. If CO_2 retention is severe and the pH is less than 7.25 after increasing the respiratory rate to as high as 20 breaths per minute, administration of sodium bicarbonate should be considered.

To maximize oxygenation and limit exposure to potentially toxic concentrations of oxygen (i.e., $F_{IO_2} = 1$), usually an end-expiratory pressure of 10 cm H_2O is set.

In addition to standard monitoring, prolonged mechanical ventilation in ALI and ARDS will require arterial line placement to facilitate frequent arterial blood gas determinations. Further, a daily chest radiograph will be required.

The Acute Respiratory Distress Syndrome network. Ventilation with lower tidal volumes as compared with traditional tidal volumes for acute lung injury and the acute respiratory distress syndrome. *N Engl J Med.* 2000;342:1301–1308.

D.6. If this patient had acute lung injury (ALI) secondary to aspiration, beside low-tidal volume ventilation, what other changes in routine therapy should be considered?

The newest "proven" management strategy noted to improve lung function and shorten the duration of mechanical ventilation and intensive care of patients with ALI is conservative administration of intravenous fluids. Although the protocol employed in the National Institutes of Health–sponsored study is too lengthy to expound on in this chapter, suffice it to say, the excessive administration of fluid is harmful, whereas minimizing intravenous fluids appears to be safe and not associated with other organ insufficiency or failure.

Wiedemann HP, Wheeler AP, Bernard GR, et al. National Heart, Lung, and Blood Institute Acute Respiratory Distress Syndrome (ARDS) Clinical Trials Network. Comparison of two fluid-management strategies in acute lung injury. *N Engl J Med.* 2006;354:2564–2575.

D.7. What therapies routinely administered by the anesthesiologist may cause ALI?

Transfusion-related acute lung injury has become the leading cause of transfusion-related morbidity and mortality in the United States. This injury is almost always recognized during or shortly after transfusion and is diagnosed by the absence of cardiac failure and fluid overload. Although any blood product can cause this injury, most recently, the transfusion of fresh frozen plasma and platelets, especially when donated by women who were previously pregnant, seem most responsible. This injury

can be seen even after the transfusion of a single blood product unit and "massive" transfusion is not, as previously thought, a prerequisite.

Triulzi DJ. Transfusion-related acute lung injury: current concepts for the clinician. *Anesth Analg.* 2009;108:770–776.

D.8. What methods of oxygen administration may be used postoperatively?

Most postoperative patients who are prone to develop hypoxemia may be managed with a nasal cannula or face mask. Nasal cannulas are cheap and comfortable, but regardless of flow rates, they cannot achieve an F_{IO_2} of more than 0.30. Face masks have the capability of delivering a wide range of precise F_{IO_2} levels of up to 1.

Occasionally, a patient may require more aggressive oxygen therapy than can be provided by nasal cannula or face mask, but less invasive than tracheal intubation and mechanical ventilation. Noninvasive positive pressure ventilation should be considered. Continuous positive airway pressure and bilevel positive airway pressure may be applied. These modes may be used in patients who either have previously used these devices at home or who are on the verge of requiring tracheal intubation and mechanical ventilation but have conditions thought to be rapidly resolving (e.g., CHF and chronic obstructive pulmonary disease exacerbation). These patients usually do not require an arterial catheter for blood sampling, but do need frequent assessment of their respiratory effort, particularly their respiratory rate and use of accessory muscles, as well as continuous Spo_2 monitoring. Several different types of masks are available. A respiratory therapist should be involved to individually achieve the best mask fit and patient comfort possible. Preparation to emergently tracheally intubate in case noninvasive ventilation fails must always be maintained.

Chanques JS, Jung B. Postoperative noninvasive ventilation. *Anesthesiology.* 2010;112: 453–461.

CHAPTER 59

Electroconvulsive Therapy

PATRICIA FOGARTY MACK

A 72-YEAR-OLD MAN

with major depressive disorder is scheduled for electroconvulsive therapy (ECT). His past medical history reveals significant coronary artery disease, status after three-vessel coronary bypass surgery 5 years ago. He also has chronic atrial fibrillation. He had a transient ischemic attack (TIA) 2 years previously after which he underwent left carotid endarterectomy. In addition, he has sleep apnea and gastroesophageal reflux disease (GERD). The patient weighs 115 kg and is 5 ft 3 in. tall and had a Mallampati class 2 airway. Medications include warfarin, atenolol, and esomeprazole (Nexium).

A. Medical Disease and Differential Diagnosis

1. What are the indications for ECT?
2. Are there any contraindications to ECT?
3. What is the mechanism of action of ECT?

B. Preoperative Evaluation and Preparation

1. How would you assess the cardiac status of this patient?
2. How should his anticoagulation be managed during ECT?
3. What implications do his history of sleep apnea have on management of ECT?
4. How does his history of TIA and carotid endarterectomy impact your preoperative evaluation?
5. Is ECT contraindicated in a patient with a permanent pacemaker or implantable cardiovertor-defibrillator?

C. Intraoperative Management

1. Describe the hemodynamic response to ECT in a typical patient.
2. Is an arterial line warranted in this patient?
3. By what means would you attempt to maximize hemodynamic stability?
4. Describe the cerebral hemodynamic effects of ECT.

5. How would you proceed with an anesthetic induction for this procedure?
6. How do you intend to manage his airway during each treatment?

D. Postoperative Management

1. The patient is extremely agitated upon emergence. Discuss the risk factors for postictal agitation (PIA) as well as the therapeutic options?
2. After three consecutive uneventful inpatient treatments, the psychiatrist asks if the patient may undergo ECT as an outpatient. Would you agree to this plan?

A. Medical Disease and Differential Diagnosis

A.1. What are the indications for ECT?

For centuries, it had been noted that psychosis did not tend to occur in those people with epilepsy. Since the 16th century, patients with severe mental illness were treated with various agents, such as camphor, to induce seizures (pharmacoconvulsive therapy). ECT was first instituted in the late 1930s and gained acceptance in providing a better-controlled seizure. The addition of curare, followed in 1951 by succinylcholine greatly diminished incidence of fracture due to the convulsions. Finally, the advent of methohexital, which ensured unconsciousness without significantly diminishing the seizure, led to the acceptance of ECT as an efficacious and safe treatment.

From the mid-1970s through the 1980s, many new drug treatments for psychiatric illness were developed and found to be efficacious. ECT fell into disfavor as a barbaric treatment when compared to pharmacotherapy.

In the past 15 years, the pendulum has again swung back in favor of ECT as a safe and effective treatment for drug-resistant major depressive disorder and bipolar disorder.

Specific indications for ECT include, but are not limited to major depressive disorder and bipolar disorder, nonchronic schizophrenia (especially with affective or catatonic symptoms) and schizoaffective disorder. Although usually reserved as a second-line therapy for those who are resistant to pharmacologic treatment, ECT has, in some circumstances, been recommended as a first-line therapy, especially if a rapid response is urgently required as in patients with severe suicidal potential, malnutrition/dehydration, and catatonia. Finally, ECT has been recommended in patients who are unable to tolerate pharmacotherapeutic agents for any reason, including during pregnancy.

American Psychiatric Association. *The Practice of Electroconvulsive Therapy: A Task Force Report of American Psychiatric Association*. 2nd ed. Washington, DC: American Psychiatric Association; 2001:5–26.

A.2. Are there any contraindications to ECT?

In the past, the only absolute contraindication was an intracranial mass lesion or vascular malformation; however, ECT has been performed successfully in patients with these diseases. There is considered to be significantly increased risk in patients with intracranial space occupying lesions, any condition associate with intracranial hypertension, recent myocardial infarction with diminished ventricular function, severe hypertension especially associated with pheochromocytoma, evolving stroke, retinal detachment, and any American Society of Anesthesiologists physical status 4 or 5 patient.

American Psychiatric Association. *The Practice of Electroconvulsive Therapy: A Task Force Report of American Psychiatric Association*. 2nd ed. Washington, DC: American Psychiatric Association; 2001:27–30.

EEG, electroencephalography.

A.3. What is the mechanism of action of ECT?

The mechanism of ECT is unknown. There are many neurochemical, neuroendocrine, electrophysiologic, and neuropsychological theories regarding the mechanism of ECT. See Table 59.1.

In addition, although it has been long assumed that a generalized seizure of adequate duration is sufficient for effective treatment, recent research shows that barely suprathreshold stimulation, especially with unilateral ECT is not as efficacious. Current research suggests that something about the process of seizure generalization may be more important than the duration of the seizure.

B. Preoperative Evaluation and Preparation

B.1. How would you assess the cardiac status of this patient?

The cardiac status of the patient needs to be assessed as it would for any other general anesthetic. As there can be periods of significant tachycardia and hypertension following seizure induction, it would be useful to ensure that there is no longer significant myocardium at risk for ischemia and that systolic function is not compromised. If this information cannot be obtained from patient history and assessment of his functional status, it may be useful to obtain a stress test and echocardiogram. Bear in mind that it may be difficult to get an accurate history of functional status from patients who are psychotic or severely depressed.

American Psychiatric Association. *The Practice of Electroconvulsive Therapy: A Task Force Report of American Psychiatric Association*. 2nd ed. Washington, DC: American Psychiatric Association; 2001:77–80.

B.2. How should his anticoagulation be managed during ECT?

The anticoagulation for his atrial fibrillation should be continued throughout his course of therapy, maintaining an international normalized ratio (INR) between 2.0 and 3.0. Although intracerebral hemorrhage is a theoretic concern, a retrospective study from the Mayo Clinic suggests that ECT can be safely performed in patients on warfarin therapy.

American Psychiatric Association. *The Practice of Electroconvulsive Therapy: A Task Force Report of American Psychiatric Association*. 2nd ed. Washington, DC: American Psychiatric Association; 2001:40–41.

Mehta V, Mueller PS, Gonzalez-Arriaza HL, et al. Safety of electroconvulsive therapy in patients receiving long-term warfarin therapy. *Mayo Clin Proc*. 2004;79:1396–1401.

B.3. What implications do his history of sleep apnea have on management of ECT?

His history of sleep apnea is important because suboptimal management of respiratory function may reduce efficacy of treatment and increase complications. Hypocarbia is sometimes required to ensure adequate seizure duration. Additionally, after onset of seizure activity, oxygen consumption is increased dramatically as is CO_2 production. Hypercarbia can exacerbate the tachycardia and hypertensive responses to seizure. Therefore, adequate mask ventilation is required to ensure optimal respiratory status. The use of a laryngeal mask airway (LMA) may be required to ensure adequate ventilation in this patient.

Finally, if the patient uses continuous positive airway pressure (CPAP) or bilevel positive airway pressure (BIPAP) at home, it may be useful to have that machine available to the patient in the postprocedure period when postanesthetic and postictal somnolence may compromise his ability to maintain a patent airway.

Saito S. Anesthesia management for electroconvulsive therapy: hemodynamic and respiratory management. *J Anesth*. 2005;19:142–149.

B.4. How does his history of TIA and carotid endarterectomy impact your preoperative evaluation?

A history of TIA or stroke, is an indication for computed tomography (CT) of the head before their first course of ECT. Another reason for patients to receive a head CT before initiation of ECT is to rule out an organic cause for depression. Although a comprehensive neurologic examination is routinely recommended by the American Psychiatric Association before ECT, it may be that in this patient, more sophisticated neuropsychological testing would be useful in documenting subtle deficits and establishing a true baseline. Finally, if the patient has not had follow-up carotid Doppler examination, it may be useful to ensure that there has not been restenosis or that no new plaques have formed. This is particularly important in view of the fact that the rate pressure product may be increased by as much as 400% in the sympathetic phase of the cardiac response.

American Psychiatric Association. *The Practice of Electroconvulsive Therapy: A Task Force Report of American Psychiatric Association*. 2nd ed. Washington, DC: American Psychiatric Association; 2001:77–80.

B.5. Is ECT contraindicated in a patient with a permanent pacemaker or implantable cardiovertor-defibrillator?

See Chapter 7, section C.11.

C. Intraoperative Management

C.1. Describe the hemodynamic response to ECT in a typical patient.

First, a parasympathetic discharge occurs within a few seconds of application of the electrical stimulus. This may result in bradycardia, which may be profound and even progress to asystole. Because many patients are volume depleted due to poor oral intake or mildly hypotensive secondary to their psychotropic medications, they can be susceptible to further hypotension due to anesthetic induction. Within 1 minute, sympathetic activation due to the seizure results in a tachycardia and at times dysrhythmias as well as hypertension to up to 150% of baseline values. This hypertension usually lasts for between 2 and 5 minutes. If the patient is not adequately ventilated, hypercarbia may add to the hypertension. During the first ECT treatment, the electrical stimulus may often be titrated upward in succession until a generalized seizure occurs. When a generalized seizure does not follow the electrical stimulation, the parasympathetic response predominates and the patient may experience a sustained bradycardia.

With such a dramatic increase in heart rate and blood pressure, the rate pressure product, an indicator of myocardial oxygen demand, is significantly elevated. This can lead to electrocardiographic ischemia as well as regional wall motion abnormalities on echocardiography.

Messina AG, Paranicas M, Katz B, et al. Effect of electroconvulsive therapy on the electrocardiogram and the echocardiogram. *Anesth Analg.* 1992;75:511–514.

Saito S. Anesthesia management for electroconvulsive therapy: hemodynamic and respiratory management. *J Anesth.* 2005;19:142–149.

C.2. Is an arterial line warranted in this patient?

No, in spite of the potential dramatic perturbations in heart rate and blood pressure, these responses are fairy predictable and can be attenuated by judicious use of anticholinergics and antihypertensives. Atropine (0.4 mg) or glycopyrrolate (0.2 mg) are used to prevent the bradycardia associated with the parasympathetic discharge. The tachycardia and hypertension seen as part of the sympathetic response can be prevented with short acting β-blockade, nitroglycerin, or even remifentanil, administered just at the beginning of the sympathetic stimulation.

Severe cardiac complications during ECT are very rare.

Saito S. Anesthesia management for electroconvulsive therapy: hemodynamic and respiratory management. *J Anesth.* 2005;19:142–149.

C.3. By what means would you attempt to maximize hemodynamic stability?

First, one should continue antihypertensive medication on the evening before and the morning of the procedure. Second, a small dose of atropine (0.4 mg) or glycopyrrolate (0.2 mg) may be given several minutes before the electrical stimulation in order to prevent the subsequent bradycardia. At Weill Cornell Medical Center, we

are more likely to use glycopyrrolate as it is a quaternary compound, which will not cross an intact blood–brain barrier. In addition, the tachycardic response from the seizure is not as pronounced when glycopyrrolate is used as compared with atropine. Anticholinergic pretreatment is most important during the first treatment when the electrical stimulation is being titrated and it is likely not to progress into a generalized seizure on the first or second stimulus. If the pretreatment with an anticholinergic leaves a fragile patient with an undesirable tachycardia, we may omit it during subsequent treatments as long as the bradycardia is not too severe or prolonged.

Similarly, medications to attenuate the sympathetic response are typically not administered until it is certain that the seizure will generalize. This results in a requirement for very fast-acting drugs to control heart rate and blood pressure. The drug of choice at Weill Cornell Medical Center is esmolol (0.5 to 1.0 mg per kg) or labetalol (5 to 20 mg). If there is a contraindication to β-blockers, diltiazem, nicardipine, or sodium nitroprusside may be substituted. Nitroglycerin may be particularly useful in patients with ischemic cardiac disease. Remifentanil has also been found to be effective in attenuating the sympathetic response.

A recent study of American Society of Anesthesiologists I and II patients assessed echocardiographic and hemodynamic parameters when the sympathetic response was pretreated with β–blocker, calcium channel blocker, or nitroglycerin prior to the electrical stimulus. No new regional wall motion abnormalities were found, but β–blocker seemed to be the most effective medication at attenuating fractional shortening and the entire sympathetic response.

Kadoi Y, Saito S, Takahashi K-I, et al. Effects of antihypertensive medication on left ventricular function during electroconvulsive therapy: study with transthoracic echocardiography. *J Clin Anesth*. 2006;18:441–445.

Saito S. Anesthesia management for electroconvulsive therapy: hemodynamic and respiratory management. *J Anesth*. 2005;19:142–149.

Van Zijl DH, Gordon PC, James MF. The comparative effects of remifentanil or magnesium sulfate versus placebo on attenuating the hemodynamic responses after electroconvulsive therapy. *Anesth Analg*. 2005;101:1651–1655.

C.4. Describe the cerebral hemodynamic effects of ECT.

Electrically induced seizures lead to cerebral hyperemia (increase in cerebral blood flow) as documented by transcranial Doppler and near-infrared spectroscopy. This response occurs even if the seizure does not generalize, suggesting that they are a result of the electric stimulation itself. The increase in cerebral blood flow has been shown to be related to the degree of systemic hypertension and occurs whether bilateral or unilateral stimulus is applied. Although there is a correlation with systemic hypertension, the systemic antihypertensives do not fully ameliorate the increase in cerebral blood flow. This is due to the fact that these drugs have differing effects on the cerebral and systemic circulations.

Saito S. Anesthesia management for electroconvulsive therapy: hemodynamic and respiratory management. *J Anesth*. 2005;19:142–149.

C.5. How would you proceed with an anesthetic induction for this procedure?

Anesthetic induction may be accomplished with any one of a number of medications. Traditionally methohexital (0.5 to 1.0 mg per kg) has been the induction agent of choice because it has very little effect on seizure duration and has a rapid onset and recovery profile. Unfortunately, methohexital is no longer available in

many areas. At Weill Cornell Medical Center, we now use etomidate (0.2 to 0.3 mg per kg). In research studies, etomidate provides for longer seizure duration when compared to methohexital and propofol; however, postictal hypertension is more severe and myoclonic contractions may be undesirable. In addition, there is a greater incidence of nausea, increased confusion, and prolonged recovery time. Although adrenal suppression has been reported in patients on continuous infusions of etomidate, there are no reports of adrenal suppression in patients receiving multiple bolus doses of etomidate as part of a course of ECT. In patients in whom etomidate is not well tolerated, propofol or thiopental may be used. Studies concur that propofol and thiopental reduce seizure duration; however, there is controversy as to how this reduction in seizure duration impacts the efficacy of therapy.

Ketamine has been noted to have antidepressant effects and potentiate the early reduction of depressive symptoms when given in conjunction with ECT. It appears that ketamine may be useful in some patients in whom a rapid decrease in depressive symptoms is essential, such as those with extreme suicidal ideation or catatonia. Randomized trials addressing the potential long-term benefits and disadvantages versus other induction agents are warranted.

Muscle relaxation is usually achieved with succinylcholine (0.5 to 1.0 mg per kg) unless there is a contraindication. In that case, an appropriate nondepolarizing muscle relaxant may be substituted.

Ding Z, White PF. Anesthesia for electroconvulsive therapy. *Anesth Analg*. 2002;94: 1351–1364.

Okamoto N, Nakai T, Sakamoto K, et al. Rapid antidepressant effect of ketamine anesthesia during electroconvulsive therapy of treatment-resistant depression: comparing ketamine and propofol anesthesia. *J ECT*. 2010;26:223–227.

Saito S. Anesthesia management for electroconvulsive therapy: hemodynamic and respiratory management. *J Anesth*. 2005;19:142–149.

C.6. How do you intend to manage his airway during each treatment?

The diagnosis of sleep apnea and the patient's body habitus raise concerns regarding the ease and effectiveness of mask ventilation. In spite of these concerns, I would proceed with a plan for mask ventilation with a backup plan of LMA or intubation. As ECT is usually administered three times a week, repeated intubations may lead to airway trauma and edema. GERD may also be of concern; however, we do not intubate patients for ECT solely because of GERD. Our plan would include continuation of medication to reduce stomach acid and promote gastric emptying, as well as a dose of preinduction sodium bicitrate.

Effective mask ventilation is important for several reasons. First, hypocapnea may lower seizure threshold and promote more effective therapy. Second, avoidance of hypercapnea postseizure is necessary as hypercapnea will exacerbate hypertension and tachycardia.

In anticipation of potential difficult ventilation during ECT, we proceed with oxygenation for 3 to 5 minutes prior to induction. As soon as induction is accomplished, both an oral and a well-lubricated nasal airway will be placed. A second person ideally is available in case two-person ventilation is required. We find that Jackson-Reese circuits are advantageous for ventilation during ECT. First, they allow you to adjust the amount of positive pressure administered; second, the weight of an Ambu bag can sometimes make maintenance of ideal mask placement difficult; finally, as the patient regains spontaneous ventilation, he or she may breathe comfortably and effectively through the Jackson-Reese circuit. If mask ventilation were not effective, I would place an appropriately sized LMA.

If necessary for adequate ventilation, intubation may be considered. Unfortunately, repeated intubations over several days and weeks may lead to glottic edema and trauma.

Saito S. Anesthesia management for electroconvulsive therapy: hemodynamic and respiratory management. *J Anesth.* 2005;19:142–149.

D. Postoperative Management

D.1. The patient is extremely agitated upon emergence. Discuss the risk factors for postictal agitation (PIA) as well as the therapeutic options?

PIA manifests as disorientation, inability to consistently follow commands, and motor agitation. Risk factors for PIA include prolonged seizure duration, bilateral versus unilateral ECT, and concomitant lithium therapy. In addition, low doses of induction agent as well as very low doses of succinylcholine are considered risk factors. The etiology of low-dose succinylcholine may be related to excess lactate production in those patients who have greater manifestation of clinical seizure activity. Increased lactate levels were noted in patients who experienced PIA versus those who did not.

It is of critical importance to rule out nonconvulsive status epilepticus as an etiology for the PIA. Nonconvulsive status may present as agitation or conversely as mutism.

Treatment of PIA usually consists of benzodiazepine, such as midazolam 1 to 2 mg. If this is not effective, haloperidol may be added. In some circumstances, propofol as a bolus or an infusion have been effective.

Augoustides JG, Greenblatt E, Abbas MA, et al. Clinical approach to agitation after electroconvulsive therapy: a case report and literature review. *J ECT*. 2002;18: 213–217.

D.2. After three consecutive uneventful inpatient treatments, the psychiatrist asks if the patient may undergo ECT as an outpatient. Would you agree to this plan?

Outpatient ECT has become an acceptable therapeutic option in our institution for many patients. Primarily, it is used for maintenance therapy. It may also be used to complete an initial course of ECT provided that the first several treatments are uneventful medically (i.e., no respiratory or cardiovascular problems) and that the patient is demonstrating improvement in psychiatric status. In addition, because psychiatric patients may be unreliable in following preoperative instructions, such as nothing by mouth status, they must have another adult who assumes responsibility for ensuring that those instructions are followed. Of course, they must also have an escort to bring them home.

Finally, there needs to be close communication between the treating psychiatrist and the ECT psychiatrist to keep abreast of any change in psychiatric status or in any medical condition.

CHAPTER 60

Ambulatory Surgery

KATHRYN E. MCGOLDRICK

A 38-YEAR-OLD WOMAN desiring permanent sterility was scheduled for bilateral laparoscopic tubal ligation in the ambulatory surgical suite. Her preoperative outpatient questionnaire indicated a history of glaucoma. Additionally, she had surgery 2 weeks ago under general anesthesia for a detached retina, and her postoperative course was complicated by severe postoperative nausea and vomiting (PONV). She is 5 ft 7 in. tall, weighs 195 lbs, and complains of chronic fatigue. Her only medications consist of "eye drops."

A. Pathophysiology and Differential Diagnosis

1. What are the anesthetic implications of glaucoma?
2. What side effects and important anesthetic interactions are associated with eye drops used to treat glaucoma?
3. Should glaucoma medications be discontinued before elective surgery?
4. Is this patient morbidly obese?
5. What medical conditions may be associated with obesity and morbid obesity?

B. Preoperative Evaluation and Preparation

1. What advantages does outpatient surgery offer?
2. What are the goals of the preoperative evaluation of the surgical outpatient?
3. In order to thoroughly screen for disease, should one put all outpatients through a full battery of laboratory testing?
4. What preoperative laboratory testing is necessary for the surgical outpatient?
5. Which outpatients should receive a preoperative chest radiograph?
6. In which patients is an electrocardiogram (ECG) necessary before outpatient anesthesia and surgery?
7. Would a patient's age or physical status influence the decision to perform outpatient surgery?

8. What patients would be considered inappropriate for ambulatory surgery?
9. What questions are critically important to ask this patient when obtaining her medical history?
10. How would you premedicate this patient?
11. Should every outpatient receive prophylaxis against acid aspiration pneumonitis?
12. Is an overnight fast justified for all outpatients?

C. Intraoperative Management

1. What are the important considerations in choosing an anesthetic technique for outpatient surgery?
2. What are the anesthetic implications of recent retinal detachment surgery?
3. How would you monitor this patient?
4. What is the Bispectral Index (BIS) monitor and what information does it convey?
5. What benefits might be derived from using a BIS monitor?
6. Is BIS monitoring applicable to children?
7. What are the major limitations of BIS monitoring?
8. What does a BIS reading of 56 mean?
9. What are the anesthetic options for laparoscopy?
10. Under what circumstances might spinal anesthesia be appropriate for outpatient laparoscopy?
11. What anesthetic agents would you use to induce and maintain general anesthesia in this patient?
12. Would you avoid the use of nitrous oxide in this ambulatory patient?
13. Discuss the physiologic changes induced by laparoscopy.
14. In addition to the physiologic changes described in the preceding text, what other intraoperative complications are associated with laparoscopy?
15. Why is carbon dioxide the insufflation agent of choice for laparoscopy?
16. What are some alternatives to carbon dioxide for laparoscopy?

D. Postoperative Management

1. What are the common causes of nausea and vomiting in outpatients?
2. How would you pharmacologically prevent PONV in the susceptible ambulatory patient?
3. How is postoperative pain treated?
4. If the patient complained of eye pain postoperatively, how would you manage the situation?
5. What criteria would you use to establish that a patient can be safely discharged after ambulatory surgery?
6. How would you decide when to discharge a patient after regional anesthesia?
7. What instructions should be given to an ambulatory surgical patient upon discharge?

A. Pathophysiology and Differential Diagnosis

A.1. What are the anesthetic implications of glaucoma?

With open-angle glaucoma, elevated intraocular pressure (IOP) exists in conjunction with an anatomically patent anterior chamber angle. It is thought that sclerosis of trabecular tissue produces impaired aqueous filtration and drainage. Treatment consists of medication to produce miosis and trabecular stretching. Commonly used eye

drops include epinephrine, echothiophate iodide, timolol, dipivefrin, and betaxolol. Carbonic anhydrase inhibitors such as acetazolamide can also be administered by various routes to reduce IOP by interfering with the production of aqueous humor. All these drugs are systemically absorbed and can, therefore, have anticipated side effects.

It is important to appreciate that maintenance of IOP is determined primarily by the rate of aqueous formation and the rate of aqueous outflow. The most important influence on formation of aqueous humor is the difference in osmotic pressure between aqueous humor and plasma. This concept is illustrated by the equation:

$$IOP = K\,[(OP_{aq} - OP_{pl}) + CP]$$

where K = coefficient of outflow, OP_{aq} = osmotic pressure of aqueous humor, OP_{pl} = osmotic pressure of plasma, and CP = capillary pressure. The fact that a small change in solute concentration of plasma can dramatically affect the formation of aqueous humor and hence IOP is the rationale for administering hypertonic solutions, such as mannitol, to reduce IOP. Fluctuations in aqueous outflow can also markedly change IOP. The primary factor controlling aqueous humor outflow is the diameter of Fontana's spaces, as illustrated by the equation:

$$A = \frac{r^4 \times (P_{IOP} - P_v)}{8\eta L}$$

where A = volume of aqueous outflow per unit of time, r = radius of Fontana's spaces, P_{IOP} = IOP, P_v = venous pressure, η = viscosity, and L = length of Fontana's spaces. When the pupil dilates, Fontana's spaces narrow, resistance to outflow is increased, and IOP rises. Because mydriasis is undesirable in both closed- and open-angle glaucoma, miotics such as pilocarpine are applied conjunctivally in patients with glaucoma to effect papillary constriction.

The aforementioned equation describing the volume of aqueous outflow per unit of time clearly underscores that outflow is exquisitely sensitive to fluctuations in venous pressure. Because an elevation in venous pressure results in an increased volume of ocular blood as well as decreased aqueous outflow, it is obvious that a considerable increase in IOP occurs with any maneuver that increases venous pressure. Hence, in addition to preoperative instillation of miotics, other anesthetic objectives for the patient with glaucoma include perioperative avoidance of venous congestion and of overhydration. Furthermore, hypotensive episodes are to be avoided because these patients are purportedly vulnerable to retinal vascular thrombosis.

Although glaucoma usually occurs as an isolated disease, it may also be associated with such conditions as Sturge-Weber syndrome, aniridia, mesodermal dysgenesis syndrome, retinopathy of prematurity, Refsum syndrome, mucopolysaccharidosis, Hurler syndrome, Stickler syndrome, Marfan syndrome, and von Reckinghausen disease (neurofibromatosis). Additionally, ocular trauma, steroid therapy, sarcoidosis, some forms of arthritis associated with uveitis, and pseudoexfoliation syndrome can also be associated with secondary glaucoma.

Primary closed-angle glaucoma is characterized by a shallow anterior chamber and a narrow iridocorneal angle that impedes the egress of aqueous humor from the eye because the trabecular meshwork is covered by the iris. Relative pupillary block is common in many angle-closure episodes in which iris–lens apposition or synechiae impede the flow of aqueous from the posterior chamber. In the United States, the prevalence of angle-closure glaucoma (ACG) is one-tenth as common as open-angle glaucoma. In acute ACG, if the pressure is not reduced promptly, permanent visual loss can ensue as a result of optic nerve damage. It is thought that irreversible optic nerve injury can occur within 24 to 48 hours.

McGoldrick KE. Eye, ear, nose, and throat diseases. In: Fleisher LA, ed. *Anesthesia and Uncommon Diseases*. 5th ed. Philadelphia: WB Saunders; 2006:4–5.

McGoldrick KE, Gayer SI. Anesthesia for ophthalmologic surgery. In: Barash PG, Cullen BF, Stoelting RK, et al., eds. *Clinical Anesthesia*. 6th ed. Philadelphia: Lippincott Williams & Wilkins; 2009:1321–1345.

A.2. What side effects and important anesthetic interactions are associated with eye drops used to treat glaucoma?

Echothiophate is a long-acting anticholinesterase miotic that lowers IOP by decreasing resistance to the outflow of aqueous humor. Useful in the treatment of glaucoma, echothiophate is absorbed into the systemic circulation after instillation in the conjunctival sac. Any of the long-acting anticholinesterases may prolong the action of succinylcholine because, after a month or more of therapy, plasma pseudocholinesterase activity may be less than 5% of normal. It is said, moreover, that normal enzyme activity does not return until 4 to 6 weeks after discontinuation of the drug. Hence, the anesthesiologist should anticipate prolonged apnea if these patients are given a customary dose of succinylcholine. In addition, a delay in metabolism of ester local anesthetics should be expected.

Although topical epinephrine has proved useful in some patients with open-angle glaucoma, the 2% solution has been associated with such systemic effects as nervousness, hypertension, angina pectoris, tachycardia, and other dysrhythmias.

Timolol, a nonselective β-adrenergic blocking drug, has historically been a popular antiglaucoma drug. Because significant conjunctival absorption may occur, timolol should be administered with caution to patients with known obstructive airway disease, severe congestive heart failure, or greater than first-degree heart block. Life-threatening asthmatic crises have been reported after the administration of timolol drops to some patients with chronic, stable asthma. Not unexpectedly, the development of severe sinus bradycardia in a patient with cardiac conduction defects (left anterior hemiblock, first-degree atrioventricular block, and incomplete right bundle-branch block) has been reported after timolol. Moreover, timolol has been implicated in the exacerbation of myasthenia gravis and in the production of postoperative apnea in neonates and young infants. Patients may report feelings of fatigue and/or depression in association with the use of timolol drops.

In contrast to timolol, a newer antiglaucoma drug, betaxolol, a β_1-blocker, is said to be more oculospecific and have minimal systemic effects. However, patients receiving an oral β-blocker and betaxolol should be observed for potential additive effects on known systemic effects of β-blockade. Caution should be exercised in patients receiving catecholamine-depleting drugs. Although betaxolol has produced only minimal effects in patients with obstructive airway disease, caution should be exercised in the treatment of patients with excessive restriction of pulmonary function. Moreover, betaxolol is contraindicated in patients with sinus bradycardia, greater than first-degree heart block, cardiogenic shock, and overt myocardial failure.

McGoldrick KE, Gayer SI. Anesthesia for ophthalmologic surgery. In: Barash PG, Cullen BF, Stoelting RK, et al., eds. *Clinical Anesthesia*. 6th ed. Philadelphia: Lippincott Williams & Wilkins; 2009:1321–1345.

A.3. Should glaucoma medications be discontinued before elective surgery?

For all the aforementioned reasons, it is important to continue glaucoma medications in the perioperative period. Moreoever, the anesthesiologist must be aware of

which medications the patient is taking and the effects of these drugs on anesthetic management.

McGoldrick KE, Gayer SI. Anesthesia for ophthalmologic surgery. In: Barash PG, Cullen BF, Stoelting RK, et al., eds. *Clinical Anesthesia*. 6th ed. Philadelphia: Lippincott Williams & Wilkins; 2009:1321–1345.

A.4. Is this patient morbidly obese?

Morbid obesity is defined by a body mass index greater than 40 kg per m^2. This patient has a body mass index of approximately 30 and would, therefore, be considered obese. See Chapter 62, section A.2.

Ogunnnaike BO, Whitten CW. Anesthesia and obesity. In: Barash PG, Cullen BF, Stoelting RK, et al., eds. *Clinical Anesthesia*. 6th ed. Philadelphia: Lippincott Williams & Wilkins; 2009:1230–1246.

A.5. What medical conditions may be associated with obesity and morbid obesity?

A plethora of conditions may be associated with obesity and morbid obesity including diabetes, hyperlipidemia, cholelithiasis, gastroesophageal reflux disease, cirrhosis, degenerative joint and disk disease, venous stasis and thrombotic/embolic disease, sleep disorders including obstructive sleep apnea, several types of cancer, and emotional disorders. Diseases of the cardiopulmonary system are common and concerning. They include, but are not limited to, systemic hypertension, pulmonary hypertension and cor pulmonale, restrictive lung disease, and right and left ventricular hypertrophy.

Neligan PJ, Porter S, Max B, et al. Obstructive sleep apnea is not a risk factor for difficult intubation in morbidly obese patients. *Anesth Analg*. 2009;109:1181–1186.

Qadir N, Smith I. Day surgery: how far can we go and are there still limits? *Curr Opin Anaesthesiol*. 2007;20:503–507.

B. Preoperative Evaluation and Preparation

B.1. What advantages does outpatient surgery offer?

Outpatient surgery typically offers greater convenience to the patient (less time away from home, family, and work), a more pleasant environment with less stress and emotional disturbance, and a reduced risk of infection, particularly for the immunocompromised or the pediatric patient. Additionally, outpatient surgery is more economical and enables more efficient use of operating rooms with greater flexibility in scheduling surgery. Finally, one is not dependent on the availability of hospital beds.

Lichtor JL. Ambulatory anesthesia. In: Barash PG, Cullen BF, Stoelting RK, et al., eds. *Clinical Anesthesia*. 6th ed. Philadelphia: Lippincott Williams & Wilkins; 2009:833–846.

B.2. What are the goals of the preoperative evaluation of the surgical outpatient?

The objectives of the preoperative evaluation are as follows:

- To perform medical assessments, obtain data, arrange for laboratory tests and consultations as indicated, and prescreen for relevant conditions in order to optimize perioperative outcome
- To obtain informed consent
- To provide information and instructions to reduce patient anxiety and improve perioperative management

Organization of the preoperative screening varies among ambulatory surgical facilities throughout the country. The screening process may be organized with an office or facility visit before the day of surgery, by a telephone interview or review of health questionnaire without a visit, or by preoperative screening and visit on the morning of surgery. Each of these systems has its advantages and disadvantages. Nevertheless, the system for preoperative evaluation of ambulatory surgical patients should ensure that screening is performed far enough in advance so that pre-existing disease can be evaluated, treatment optimized, and laboratory data recorded before the patient presents for anesthesia. Written instructions should be supplied to the patient in advance describing the preoperative workup, admission, and recovery periods.

Hata TM, Moyers JR. Preoperative patient assessment and management. In: Barash PG, Cullen BF, Stoelting RK, et al., eds. *Clinical Anesthesia*. 6th ed. Philadelphia: Lippincott Williams & Wilkins; 2009:569–597.

Lichtor JL. Ambulatory anesthesia. In: Barash PG, Cullen BF, Stoelting RK, et al., eds. *Clinical Anesthesia*. 6th ed. Philadelphia: Lippincott Williams & Wilkins; 2009:833–846.

B.3. In order to thoroughly screen for disease, should one put all outpatients through a full battery of laboratory testing?

No. The practice of preoperative "shotgun" laboratory screening for outpatient surgery has received much criticism. In addition to unnecessarily adding several billion dollars annually to the cost of healthcare, laboratory screening tests in asymptomatic patients have been shown to be of dubious value. History and physical examination are a better means of screening for disease and should serve to reduce expensive, potentially harmful, and inappropriate tests.

Pasternak LR. Does reoutine testing affect outcome? In: Fleisher LA, ed. *Evidence-Based Practice of Anesthesiology*. 2nd ed. Philadelphia: Saunders Elsevier; 2009:11–14.

B.4. What preoperative laboratory testing is necessary for the surgical outpatient?

Most outpatient surgical facilities consider the operative procedure and the patient's age, medical condition, medication history, and state and local regulations in determining which preoperative tests are "required." For the healthy ambulatory patient

between the ages of 1 and 40 years having a minor surgical procedure, no laboratory testing may be required. Pregnancy testing is a highly controversial issue. Many believe that pregnancy testing should be offered to all consenting females of childbearing potential. This approach, however, does not substitute for an appropriate pregnancy history and physical examination. Hemoglobin or hematocrit determination is appropriate for surgical procedures associated with substantial blood loss (unlikely in the ambulatory venue), and for patients at risk for anemia or polycythemia, such as children younger than 1 year or with suspected sickle cell disease, patients with a history of anemia, blood dyscrasia or malignancy, patients with congenital heart disease or chronic disease, women with heavy menstrual flow, and patients older than 60 years old. Additional testing depends on an individual's pre-existing condition. For example, serum electrolyte testing would be indicated for a patient with a history of hypertension, diabetes mellitus, renal disease, or for those patients taking diuretics, digoxin, steroids, or angiotension-converting enzyme inhibitors. Likewise, measurement of the partial thromboplastin time and the prothrombin time would be indicated in the presence of a bleeding disorder, anticoagulant use, liver disease, or poor nutritional status. Preoperative urinalysis has not been shown to be useful as a screening test, and is no longer required in a routine anesthetic evaluation.

Finnegan BA, Rashiq S, McAlister FA, et al. Selective ordering of preoperative investigations by anesthesiologists reduces the number and cost of tests. *Can J Anaesth*. 2005;52:575–580.

B.5. Which outpatients should receive a preoperative chest radiograph?

Abnormalities in the chest radiograph in asymptomatic patients are rare, and the risks to the patient probably exceed the benefits. A preoperative chest x-ray is indicated only for patients with a history or clinical findings of active pulmonary disease. Extremes of age, smoking, stable chronic obstructive pulmonary disease, stable cardiac disease, or resolved recent upper respiratory infection should not be considered absolute indications for chest x-ray.

American Society of Anesthesiologists Task Force on Preanesthesia Evaluation. Practice advisory for preanesthesia evaluation: a report by the American Society of Anesthesiologists task force on preanesthesia evaluation. *Anesthesiology*. 2002;96: 485–466; amended on page 492 by the ASA House of Delegates on October 15, 2003.

Joo HS, Wong J, Naik VN, et al. The value of screening preoperative chest x-rays: a systematic review. *Can J Anaesth*. 2005;52:568–574.

B.6. In which patients is an electrocardiogram (ECG) necessary before outpatient anesthesia and surgery?

It has not been established that information obtained from the preoperative ECG affects clinical care. Indeed, the American College of Cardiology/American Heart Association (ACC/AHA) guidelines published in 2007 are silent on the need for a preoperative ECG based on age alone. Nonetheless, Correll and colleagues found that age >65 years is an independent predictor of preoperative ECG abnormalities. The ACC/

AHA guidelines consider ambulatory surgery as one entity, classifying *all* ambulatory procedures as low risk, with reported cardiac mortality <1%. These guidelines reflect the belief that in the absence of active cardiac conditions (defined as unstable coronary syndromes, decompensated heart failure, significant arrhythmias [e.g., high-degree atrioventricular block, symptomatic ventricular arrhythmias, and supraventricular tachycardia with uncontrolled ventricular rate]), cardiovascular testing in stable patients would rarely result in a change in management and it would be a appropriate to proceed with surgery.

In general, a preoperative ECG should be considered in ambulatory patients in whom there is a reasonably high likelihood of cardiac dysfunction and the results of the ECG would have the potential to influence perioperative management. Clearly, the patient's history—including a thorough exploration of activity level and exercise tolerance—the physical examination, and the proposed surgical procedure are vital elements in the assessment of whether an ECG is indicated.

Gold BS. Who should have a preoperative 12-lead electrocardiogram? In: Fleisher LA, ed. *Evidence-Based Practice of Anesthesiology*. 2nd ed. Philadelphia: Saunders Elsevier; 2009:20–23.

B.7. Would a patient's age or physical status influence the decision to perform outpatient surgery?

Even patients at the extremes of age (e.g., younger than 6 months and older than 80 years) have been managed successfully at ambulatory centers throughout the country. With the exception of the former preterm infant and newborns in the first few weeks of life, age alone should not be considered a deterrent in the selection of patients for outpatient surgery. Premature infants (gestational age at birth <37 weeks) who undergo general anesthesia during the first months of life are at increased risk for postoperative apnea for up to 12 hours. This risk is greatest for infants younger than 46 weeks postconceptional age, but some investigators have reported apnea in infants as old as 60 weeks postconceptional age. Unfortunately, the postconceptional age at which the former premature infant no longer represents an increased risk for postoperative apnea, and therefore, would be considered an acceptable candidate for an ambulatory surgical procedure is not absolutely known. Therefore, at the present time, it is safest to admit to a hospital or to a 24-hour recovery unit all former premature infants less than 46 weeks postconceptional age so that they can be monitored for apnea. Many anesthesiologists are more conservative and adhere to cut-offs ranging from 52 to 60 weeks postconceptional age. If anemia, bronchopulmonary dysplasia, or other neonatal problems are present, this period may need to be extended. Likewise, postoperative apneic episodes have been described in otherwise healthy full-term infants who are anesthetized in the first few weeks of life. For this reason, many anesthesiologists are reluctant to proceed with outpatient anesthesia and surgery on a healthy full-term infant of less than 2 to 4 weeks of age.

For the geriatric patient, recent clinical experience has not demonstrated an age-related effect on the duration of recovery or the incidence of postoperative complications after outpatient surgery. However, in determining the acceptability of a geriatric patient for an ambulatory surgical procedure, one must consider the patient's physiologic age and physical status, the surgical procedure, the anesthetic technique, and the quality of care that will be provided at home. Chronologic age per se is not a determinant of suitability for ambulatory surgery.

No longer is outpatient surgery restricted to patients of American Society of Anesthesiologists (ASA) physical status I and II. ASA physical status III and IV patients whose diseases are well controlled preoperatively may be considered acceptable candidates for outpatient surgery.

McGoldrick KE. Anesthesia considerations for the geriatric outpatient. In: Silverstein JH, Rooke GA, Reeves JC, et al., eds. *Geriatric Anesthesiology*. 2nd ed. New York: Springer; 2008:322–337.

B.8. What patients would be considered inappropriate for ambulatory surgery?

An individual may be classified as an inappropriate ambulatory surgery patient for the following reasons:

- The existence of a condition that places an infant at risk
- History of prematurity in an infant less than 46 to 60 weeks postconceptional age
- Apneic episodes, feeding difficulty, or failure to thrive
- Respiratory distress syndrome that has required intubation and ventilatory support (may take up to a year for symptoms to resolve)
- Bronchopulmonary dysplasia with any degree of significant decrease in pulmonary function or requirement for supplemental oxygen
- Acute concurrent illness
- ASA physical status III or IV with poorly controlled disease
- Active cardiac conditions, as defined by ACC/AHA Guidelines
- Acute substance abuse
- Morbid obesity with other serious systemic diseases, such as severe obstructive sleep apnea and ventricular dysfunction
- Placement of a bare metal stent within 4 to 6 weeks of the proposed surgery
- Placement of a drug-eluting stent less than at least 1 year before the date of proposed surgery
- No available adult at home
- Refusal to have surgical procedure done as an outpatient
- Unwilling to follow instructions

The appropriateness of each patient must be evaluated on an individual basis, taking into account a combination of several factors, such as the patient's circumstances, the nature of the surgical procedure, anesthetic technique, anticipated severity of postoperative pain, and comfort level of the anesthesiologist.

Practice alert for the perioperative management of patients with coronary artery stents. A report by the American Society of Anesthesiologists Committee on Standards and Practice Parameters. *Anesthesiology*. 2009;110:22–23.

B.9. What questions are critically important to ask this patient when obtaining her medical history?

It is important to acquire as much information as possible about the patient's eye disease. For example, does she have open- or closed-angle glaucoma? What eye drops is she taking? When she had retinal detachment surgery 2 weeks ago, did the ophthalmic surgeon inject an air or gas bubble to tamponade the retina? If so, which substance was injected and has it been fully resorbed? Additionally, it is important to rule out obstructive sleep apnea in view of the patient's obesity and her complaints of fatigue. Does she snore, have frequent awakenings during the night, and does she fall asleep commonly during the daytime? Obese patients with severe sleep apnea and certain associated conditions (pulmonary hypertension, ventricular dysfunction, etc.) having painful surgery under general anesthesia that may require significant amounts of opioids postoperatively for pain control are typically considered poor candidates for planned outpatient surgery.

American Society of Anesthesiologists Task Force on Perioperative Management. *Practice Guidelines for the Perioperative Management of Patients with Obstructive Sleep Apnea. B.10. How would you premedicate this patient?

Whether the ambulatory surgical patient should receive premedication has been the subject of much interest and debate. Keeping in mind that a prompt recovery is an important consideration in outpatient anesthesia, many authors have recommended that little or no premedication (especially the centrally active depressant premedicants) be given to surgical outpatients so that recovery is not prolonged. Interestingly, most prospective clinical studies have failed to demonstrate a prolonged recovery following premedication with sedative-anxiolytic and analgesic drugs. However, narcotic premedicants have been shown to increase the incidence of postoperative nausea, which could prolong recovery time, and are not recommended unless the patient is in pain preoperatively.

In view of the goals one might want to achieve with outpatient preoperative medication, including anxiety relief, sedation, amnesia, analgesia, vagolysis, prophylaxis against aspiration pneumonia, and prevention of PONV premedicant drugs may be safely used if needed by the patient, provided the drug and the dosage are carefully chosen. Drugs commonly used as premedicants for outpatients include sedative-hypnotics, opioids, anticholinergics, antacids, gastrokinetics, H_2-receptor antagonists, and antiemetics. Most prospective studies have not found recovery to be prolonged after the use of appropriate doses of sedative premedication (e.g., midazolam 1 to 2 mg intravenous). Indeed, proper use of premedication may actually expedite the

discharge process as a result of its ability to reduce postoperative side effects. Clearly, however, lorazepam's very long duration of action makes it unsuitable for use in the ambulatory surgical patient.

Van Vlymen JM, SaRego MM, White PF. Benzodiazepine premedication: can it improve outcome in patients undergoing breast biopsy procedures? *Anesthesiology*. 1999;90:740.

B.11. Should every outpatient receive prophylaxis against acid aspiration pneumonitis?

Despite early studies demonstrating that a large percentage of outpatients are theoretically at risk for gastric aspiration, the actual incidence of pulmonary aspiration is very low (<1/35,000) in surgical patients with no specific risk factors. The possibility that outpatients have a greater potential for acid aspiration than inpatients had prompted several authors in the past to recommend that some form of aspiration prophylaxis be given to all patients scheduled for outpatient surgery. Unfortunately, this is costly and may result in undesired side effects. Although individual ambulatory surgery centers must determine their own policies, pharmacologic prevention of acid aspiration should not be routine, but rather reserved for outpatients with predisposing factors (e.g., pregnancy, symptomatic hiatal hernia, diabetes mellitus with autonomic neuropathy, morbid obesity). When antacids are used, they should be restricted to nonparticulate antacids.

Cohen NH. Aspiration: is there an optimal management strategy? In: Fleisher LA, ed. *Evidence-Based Practice of Anesthesiology*. 2nd ed. Philadelphia: Saunders Elsevier; 2009:327–332.

Lichtor JL. Ambulatory anesthesia. In: Barash PG, Cullen BF, Stoelting RK, et al., eds. *Clinical Anesthesia*. 6th ed. Philadelphia: Lippincott Williams & Wilkins; 2009:833–846.

B.12. Is an overnight fast justified for all outpatients?

Several investigators have questioned the value of the traditional overnight fast for surgical outpatients, particularly pediatric outpatients. Prolonged fasting does not guarantee an empty stomach at the time of induction. It does, however, cause patient discomfort and may produce significant physiologic disturbances in infants and young children. Studies in children and in adults have shown no increase in volume or decrease in pH of gastric fluid when clear liquids were administered as late as 2 hours before induction of anesthesia. Therefore, arbitrary restrictions on the preoperative fast for surgical outpatients without risk factors for pulmonary aspiration, such as "NPO after midnight," appear to be unwarranted. Clear fluids in reasonable amounts (3 mL/kg) may be safely ingested until 2 hours before surgery. Although coffee is not transparent, it is devoid of particulate matter and is accepted as a clear liquid. There is some evidence that briefer periods of preoperative fasting (2 hours) are accompanied by less PONV, as well as a reduced incidence of dizziness, drowsiness, and thirst. Breast milk should be withheld for at least 4 hours in neonates and infants who are being breastfed. Intake of nonclear liquids, nonhuman milk, and solid food should be discontinued at least 6 hours before the induction of anesthesia.

Lichtor JL. Ambulatory anesthesia. In: Barash PG, Cullen BF, Stoelting RK, et al., eds. *Clinical Anesthesia.* 6th ed. Philadelphia: Lippincott Williams & Wilkins; 2009:833–846.

C. Intraoperative Management

C.1. What are the important considerations in choosing an anesthetic technique for outpatient surgery?

- Smooth and rapid onset of action
- Intraoperative amnesia and analgesia
- Hemodynamic stability
- Good operating conditions
- Rapid recovery period without side effects
- Cost-effectiveness

To date, no "ideal" anesthetic drug or technique has been identified for outpatients. No single agent or combination of agents, either inhaled or intravenous, has been clearly demonstrated to reduce recovery time and allow faster discharge of the ambulatory surgical patient. However, with its smooth induction profile and short elimination half-life, propofol may prove to be the induction, if not the maintenance, agent of choice for outpatient anesthesia. The newer halogenated ether compounds, sevoflurane and desflurane, have become increasingly popular in ambulatory anesthesia owing to their rapid onset and quick termination of clinical effects. Currently, desirable anesthetic conditions with an acceptable recovery profile may be produced by a large array of pharmacologically active drugs administered in conjunction with either general, regional, or local anesthesia techniques. It is essential, however, to combine these agents in a rational manner and carefully titrate them to optimal effect.

Gupta A, Fleisher LA. What outcomes are important in ambulatory anesthesia? In: Steele SM, Nielsen KC, Klein SM, eds. *Ambulatory Anesthesia & Perioperative Analgesia.* New York: McGraw-Hill; 2005:83–91.

Lichtor JL. Ambulatory anesthesia. In: Barash PG, Cullen BF, Stoelting RK, et al., eds. *Clinical Anesthesia.* 6th ed. Philadelphia: Lippincott Williams & Wilkins; 2009:833–846.

C.2. What are the anesthetic implications of recent retinal detachment surgery?

Patients who have had vitreoretinal surgery often have a gas bubble deliberately left within the eye to help tamponade and keep the retina attached as adhesions develop. Filtered room air, sulfur hexafluoride (SF_6), and perfluoropropane (C_3F_8) are the most commonly used gases. By varying the concentration, volume, and type of gas used, bubbles can be produced that will last up to 70 days before being completely absorbed. If nitrous oxide is administered during this time, the bubble will rapidly expand with the attendant risk of retinal and optic nerve ischemia secondary to central retinal artery occlusion. Primate models indicate that irreversible retinal damage occurs after 100 minutes of retinal artery obstruction, suggesting that perhaps some recovery might be expected after briefer anesthetics. However, a narrower window may exist in humans. Therefore, nitrous oxide should be avoided in any patient who

has undergone vitreoretinal surgery within the preceding 3 months, unless records are available to confirm that either intraocular gas was not used, or that it has subsequently been completely reabsorbed.

Hart RH, Vote BJ, Borthwick JH, et al. Loss of vision caused by expansion of intraocular perfluoropropane (C_3F_8) gas during nitrous oxide anesthesia. *Am J Ophthalmol*. 2002;134:761–763.

Lee EJK. Use of nitrous oxide causing severe visual loss 37 days after retinal surgery. *Br J Anaesth*. 2004;93:464–466.

C.3. How would you monitor this patient?

The effects of anesthesia during ambulatory procedures should be monitored using the same standards applicable to inpatient procedures. Standard monitoring in this patient would include a blood pressure cuff, ECG, pulse oximeter, precordial or esophageal stethoscope, temperature probe, and measurement of inspired oxygen and end-tidal carbon dioxide. The potential for hypoxia and hypercarbia during laparoscopy requires careful monitoring of oxygen saturation and expired carbon dioxide tension. In addition, intra-abdominal pressure must be measured during gas insufflation into the peritoneal cavity. Although standard intraoperative monitoring is appropriate for most outpatients having laparoscopic surgery, ASA physical status III or IV patients may benefit from invasive hemodynamic monitoring to carefully and continuously determine the cardiovascular response to pneumoperitoneum and position changes.

Muir HA, Olufolabi AJ. Ambulatory anesthesia for laparoscopic surgery. In: Steele SM, Nielsen KC, Klein SM, eds. *Ambulatory Anesthesia & Perioperative Analgesia*. New York: McGraw-Hill; 2005:289–301.

C.4. What is the Bispectral Index (BIS) monitor and what information does it convey?

The BIS monitor is a noninvasive monitoring system that is derived from the electroencephalogram (EEG). Using bispectral analysis of the EEG waveform and other features within the EEG, the BIS monitor is used to detect changes in purported depth of anesthesia or hypnosis. A proprietary algorithm translates the complex data generated from the analysis of the EEG over a 30-second period into a single dimensionless number between 0 (i.e., no brain activity) and 100 (i.e., the patient is fully awake) that is displayed on the BIS monitor. The BIS is one of many brain function monitors that record or process brain electrical activity and convert these signals mathematically into a continuous measure, typically scaled from 0 to 100. It is important to appreciate that intraoperative awareness cannot be measured during the intraoperative phase of general anesthesia, because the recall component of awareness can only be determined postoperatively by obtaining information directly from the patient. Moreover, although clinically important, intraoperative awareness under general anesthesia is a rare occurrence, with a reported incidence of 0.1% to 0.2% in adults.

American Society of Anesthesiologists Task Force on Intraoperative Awareness. *Practice Advisory for Intraoperative Awareness and Brain Function Monitoring. A Report by the American Society of Anesthesiologists Task Force on Intraoperative Awareness*. Approved by the House of Delegates on October 25, 2005

C.5. What benefits might be derived from using a BIS monitor?

Information about the patient's hypnotic state obtained from the BIS, in combination with other monitored parameters and clinical signs, may allow better balancing of hypnotic and analgesic administration. Titration of hypnotic agents based on individual requirements arguably is improved, potentially reducing the incidence of relative underdosing and overdosing. Furthermore, selection of anesthetic interventions (e.g., administration of hypnotics, analgesics, and vasoactive drugs) may be more rational. Reduced drug usage, earlier awakening, and faster recovery have all been associated with using the BIS monitor to help guide anesthesia maintenance. This translates into a higher potential for bypassing the stage 1 postanethesia care unit (PACU) and earlier discharge eligibility from the PACU. It is not known yet whether these benefits will ultimately reduce medical costs significantly. Indeed, a recent meta-analysis based on 1,380 subjects from 11 trials disclosed that BIS monitoring reduced anesthetic consumption by 19%, reduced the incidence of nausea/vomiting, and reduced time in the PACU by 4 minutes. However, these benefits did not lead to a significant reduction in time until patient discharge from the ambulatory surgery unit. Additionally, BIS monitoring actually increased the cost per patient by $5.55 owing to the cost of the BIS electrodes.

Recently, there has been considerable discussion about depth of anesthesia and 1-year mortality. The investigators in the B-Aware Trial reported their secondary analysis of long-term mortality and found that the absence of low BIS values (BIS <40 for >5 minutes) was associated with improved long-term survival and reduced morbidity (myocardial infarction, stroke). However, this putative association does not imply causation. Preoperative comorbidity is an important independent risk factor for postoperative mortality.

C.6. Is BIS monitoring applicable to children?

The BIS was developed and tested on adults. Because the EEG in infants and young children is different from that of an adult and changes as the brain matures, the BIS value may not necessarily apply to the pediatric patient population. Validating the BIS monitor in infants and young children poses significant problems. End points used to confirm BIS in adults, such as assessment of sedation, sleep, or purposeful movement

in response to voice commands, cannot be reliably obtained in young children. Furthermore, there are serious ethical problems in recruiting healthy children as volunteers in studies of general anesthesia. Nevertheless, recent data from numerous authors comparing BIS values between adults and children at various clinical end points during general anesthesia, such as before anesthesia, during maintenance, at emergence, and with increasing concentrations of volatile anesthetic, suggest that BIS generally performs similarly in adults and children with respect to dose response to anesthetic agents. However, a recent study disclosed that in children aged 6 months to 12 years, the BIS increased paradoxically as end-tidal sevoflurane concentration increased from 3% to 4%. BIS values showed a wide variation at the same end-tidal sevoflurane concentration, and the age of the patient was considered to be a factor affecting the BIS values. A consensus seems to be forming that BIS monitoring should be used with caution in infants less than 1 year of age. Clearly, further work in this area is needed. Definitive studies correlating level of sedation, awareness, and anesthetic outcome with BIS in children have not yet been published. Nonetheless, consensus is emerging that the incidence of intraoperative awareness is greater in children than in adults. Children, however, seem to be less disturbed by the experience than adults who appear to be more vulnerable to the development of posttraumatic stress.

C.7. What are the major limitations of BIS monitoring?

The BIS monitor is not a measure of global anesthetic depth. It is only a measure of the patient's level of sedation and hypnotic state. As such, it helps the anesthesiologist assess the potential for patient awareness, but it cannot prevent it. In fact, use of the BIS has not been proved to reduce or eliminate the risk of intraoperative awareness. The BIS will not predict patient movement or hemodynamic response to noxious stimulation, nor will it predict the exact moment when consciousness will return. Sedation produced by both ketamine and nitrous oxide does not produce the expected decrease in BIS. The utility of BIS in patients with neurologic disease has not been adequately studied to validate its use in these patients. Finally, more work is necessary to establish whether BIS is an accurate measure of hypnosis in pediatric patients.

It is important to appreciate that a specific numerical value may not correlate with a specific depth of anesthesia. Moreover, the measured values do not have uniform sensitivity across different anesthetic drugs or types of patients. Artifacts may be introduced by electrocautery, lasers, warming devices, and other devices and circumstances. The BIS cannot be relied upon in all situations, including hypothermia, circulatory arrest, and brain death. Moreover, one small study recently reported that patient position may affect BIS readings, with the head-down position producing an increase in BIS value, and the head-up position being associated with a reduction in BIS value. Clearly, intraoperative monitoring of depth of anesthesia to minimize the

risk of awareness should rely on multiple modalities, including clinical observations of purposeful or reflex movement, ECG tracing, blood pressure, heart rate, end-tidal anesthetic analyzer, and capnography.

The consensus of the ASA Task Force on Intraoperative Awareness is that brain function monitoring is not routinely indicated for patients undergoing general anesthesia, and that the decision to use a brain function monitor should be made on a case-by-case basis by the individual practitioner for selected patients at increased risk.

American Society of Anesthesiologists Task Force on Intraoperative Awareness. *Practice Advisory for Intraoperative Awareness and Brain Function Monitoring. C.8. What does a BIS reading of 56 mean?

The BIS scale is a dimensionless scale from 0 to 100. Typically, BIS values between 40 and 60 correspond with a moderate hypnotic state of general anesthesia, and are associated with a low probability of patient consciousness. Deep sedation with a low probability of explicit recall occurs in the 60 to 70 BIS range, with higher values up to 85 associated with light to moderate sedation. A BIS number below 40 indicates a deep hypnotic state, with brain isoelectricity increasing as BIS approaches 0. As mentioned previously, however, there are multiple exceptions to these generalities, and the BIS is perhaps best thought of as a trend monitor rather than an "absolute" monitor of hypnotic depth.

C.9. What are the anesthetic options for laparoscopy?

In recent years, anesthesiologists have successfully employed local, regional, and general anesthesia for laparoscopy. Local and regional anesthesia offer the potential advantages of faster postoperative recovery and reduced postoperative complications. These techniques also avoid the postoperative discomforts of general anesthesia, such as sore throat, muscle pains, and airway trauma. However, steep Trendelenburg position, pneumoperitoneum, and surgical manipulation often make spontaneous ventilation difficult during local or regional anesthesia. In addition, the potential for postspinal headache and urinary retention may detract from the use of regional

anesthesia in the outpatient. The vast majority of laparoscopic procedures continue to be performed under general endotracheal anesthesia. General anesthesia offers the advantages of elimination of patient anxiety, complete amnesia and analgesia, the ability to control ventilation, muscle relaxation, and a motionless operative field.

Muir HA, Olufolabi AJ. Ambulatory anesthesia for laparoscopic surgery. In: Steele SM, Nielsen KC, Klein SM, eds. *Ambulatory Anesthesia & Perioperative Analgesia.* New York: McGraw-Hill; 2005:289–301.

C.10. Under what circumstances might spinal anesthesia be appropriate for outpatient laparoscopy?

The use of regional anesthesia for laparoscopic surgery is not widely practiced in the United States. However, selective spinal anesthesia has been described in several publications. This method is defined as the practice of using minimal doses of dilute intrathecal agents in order to anesthetize only the nerve roots supplying a specific area and to affect only the modalities that need to be affected. Many of these publications have involved the use of hypobaric solutions of 10 mg lidocaine with the addition of 10 μg fentanyl for gynecologic laparoscopy. This solution purportedly gives good to excellent operating conditions with minimal motor block and a brief recovery period. Typically, dorsal column function, proprioception, and touch remain intact perioperatively. Transient neurologic symptoms have not been reported with the use of 10 mg hypobaric lidocaine with fentanyl, but transient neurologic symptoms have been reported in conjunction with 20 mg intrathecal lidocaine. Recently, low-dose 3 mg levobupivacaine plus 10 μg fentanyl has been used successfully for selective spinal anesthesia in gynecologic outpatient laparoscopy. Clearly, this approach is best used for brief procedures where the surgeon does not require steep Trendelenburg positioning.

C.11 What anesthetic agents would you use to induce and maintain general anesthesia in this patient?

A number of anesthetic agents in a variety of combinations can be used successfully to provide general anesthesia in this patient. A reasonable approach would be to induce anesthesia with propofol or a short-acting barbiturate, such as sodium thiopental, after a preinduction dose of a short-acting benzodiazepine. After intubation, anesthesia is maintained with a volatile anesthetic, such as sevoflurane or desflurane, and an air–oxygen mixture, supplemented with a short-acting narcotic as needed and a muscle relaxant. Alternatively, a total intravenous technique with propofol as the primary agent could be administered.

Muir HA, Olufolabi AJ. Ambulatory anesthesia for laparoscopic surgery. In: Steele SM, Nielsen KC, Klein SM, eds. *Ambulatory Anesthesia & Perioperative Analgesia.* New York: McGraw-Hill; 2005:289–301.

C.12. Would you avoid the use of nitrous oxide in this ambulatory patient?

As mentioned in the preceding text, if the patient has an intraocular gas bubble that is not completely resorbed, nitrous oxide is contraindicated for fear of causing devastating visual damage. In the absence of this contraindication, the use of nitrous oxide, albeit somewhat controversial, could be considered. Traditionally, there had been concerns about its ability to diffuse into bowel lumen causing distension and to increase postoperative nausea/vomiting. It has been shown that surgical conditions during laparoscopic procedures lasting 70 to 80 minutes were identical (bowel distension did not increase over time) regardless of whether nitrous oxide was used. In a laboratory study involving porcine subjects, nitrous oxide was shown to diffuse into a carbon dioxide peritoneum and the nitrous oxide fraction exceeded 29%, a level that can support combustion, within 2 hours. Therefore, the clinical risk associated with prolonged laparoscopy remains unclear. Although it had historically been held that nitrous oxide can contribute to PONV, conclusive evidence is lacking to demonstrate an important effect of nitrous oxide on the incidence of postoperative emesis after laparoscopic cholecystectomy or pelvic laparoscopy. Therefore, any potential benefit from its elimination must be balanced against the potential increased risk of intraoperative awareness.

Taylor E, Feinstein R, White PF. Anesthesia for laparoscopic cholecystectomy: is nitrous oxide contraindicated? *Anesthesiology*. 1992;76:561.

C.13. Discuss the physiologic changes induced by laparoscopy.

Physiologic changes occur as a result of the pneumoperitoneum and the Trendelenburg position that are required during laparoscopy. Carbon dioxide or nitrous oxide can be used to produce the pneumoperitoneum. Insufflation of gas into the peritoneal cavity elevates intra-abdominal pressure and impairs venous return. As intra-abdominal pressure increases above 20 mm Hg, central venous pressure, arterial pressure, pulse pressure, and cardiac output all decrease. Although rare, severe hypotension and cardiac arrest have been reported. The pneumoperitoneum also sequesters blood in the legs, thereby decreasing the circulating blood volume. Vital capacity is significantly reduced as the diaphragm is displaced cephalad by the Trendelenburg position and pneumoperitoneum. Pulmonary compliance is decreased, functional residual capacity is diminished, and aeration of the lower lobes is compromised, predisposing the patient to the development of hypoxia and atelectasis. As the intraperitoneal gas is released and intra-abdominal pressure decreases, all cardiovascular and respiratory parameters should return to normal.

Cunningham AJ, Nolan C. Anesthesia for minimally invasive procedures. In: Barash PG, Cullen BF, Stoelting RK, eds. *Clinical Anesthesia*. 5th ed. Philadelphia: Lippincott Williams & Wilkins; 2006:1062–1065.

Muir HA, Olufolabi AJ. Ambulatory anesthesia for laparoscopic surgery. In: Steele SM, Nielsen KC, Klein SM, eds. *Ambulatory Anesthesia & Perioperative Analgesia*. New York: McGraw-Hill; 2005:289–301.

C.14. In addition to the physiologic changes described in the preceding text, what other intraoperative complications are associated with laparoscopy?

Absorption of carbon dioxide used for peritoneal insufflation may produce hypercarbia, resulting in hypertension, hypotension, catecholamine stimulation, cardiac arrhythmias, and acidosis. Arrhythmias may also be produced by vasovagal reflexes. Hemorrhage accounts for nearly half of the complications from laparoscopy. Bowel injury and ischemia can occur. A cephalad shift of the mediastinum may cause the endotracheal tube to pass into a bronchus after the Trendelenburg position is assumed. Other complications include gas embolization, tension pneumothorax, pneumomediastinum, perforation and electrical injury of organs, and passive regurgitation and aspiration.

Cunningham AJ, Nolan C. Anesthesia for minimally invasive procedures. In: Barash PG, Cullen BF, Stoelting RK, eds. *Clinical Anesthesia*. 5th ed. Philadelphia: Lippincott Williams & Wilkins; 2006:1062–1067.

Muir HA, Olufolabi AJ. Ambulatory anesthesia for laparoscopic surgery. In: Steele SM, Nielsen KC, Klein SM, eds. *Ambulatory Anesthesia & Perioperative Analgesia*. New York: McGraw-Hill; 2005:289–301.

C.15. Why is carbon dioxide the insufflation agent of choice for laparoscopy?

Carbon dioxide is the most commonly used agent for laparoscopy because it is more soluble in blood than air, oxygen, or nitrous oxide. The carbon dioxide–carrying capacity of the blood is high, owing to bicarbonate buffering and combination with hemoglobin and plasma proteins. Rapid elimination also increases the margin of safety in the event of intravenous injection of carbon dioxide. All of these properties contribute to the rapid reversal of the clinical signs of carbon dioxide embolism when treated properly. Therefore, the lethal dose of carbon dioxide is approximately five times greater than that of air.

Muir HA, Olufolabi AJ. Ambulatory anesthesia for laparoscopic surgery. In: Steele SM, Nielsen KC, Klein SM, eds. *Ambulatory Anesthesia & Perioperative Analgesia*. New York: McGraw-Hill; 2005:289–301.

Wolf JS Jr, Carrier S, Stoller ML. Gas embolism: helium is more lethal than carbon dioxide. *J Laparoendosc Surg*. 1994;4:173.

C.16. What are some alternatives to carbon dioxide for laparoscopy?

Insufflation of inert gases, such as helium or argon, instead of carbon dioxide avoids the increase in $Paco_2$ from absorption, thereby avoiding the need for hyperventilation. The ventilatory consequences of the increased intra-abdominal pressure persist, however. Although the hemodynamic consequences of pneumoperitoneum from inert gases are similar to those seen with carbon dioxide, the inert gases blunt the increase in arterial pressure but exacerbate the decrease in cardiac output. Unfortunately, the low blood solubility of the inert gases is concerning in the event of gas embolism.

Gasless laparoscopy, using abdominal wall lift from a fan retractor, is another alternative to carbon dioxide. This technique may be attractive for patients with severe cardiac or pulmonary disease because it avoids the respiratory and hemodynamic consequences

of increased intra-abdominal pressure secondary to insufflation. However, gasless laparoscopy compromises surgical exposure and exacerbates technical difficulty.

D. Postoperative Management

D.1. What are the common causes of nausea and vomiting in outpatients?

Nausea and vomiting are significant problems after ambulatory surgery, causing patient discomfort and delayed recovery and discharge from the ambulatory center. Prolonged vomiting is one of the most frequent causes of unexpected hospital admission from the ambulatory surgical facility and is a major cause of patients' dissatisfaction with their anesthesia care. Patients who have a history of motion sickness and a previous experience of PONV are more likely to develop postoperative emetic symptoms, as are patients who are obese or pregnant or have diabetes mellitus. PONV are common in children; the incidence decreases with age. Men and women are equally affected until puberty, when the incidence becomes considerably higher in women. Excessive anxiety and noncompliance with fasting can increase gastric volume and predispose patients to PONV. Interestingly, smoking has been shown to decrease the incidence of PONV.

The use of narcotic analgesics, particularly morphine and meperidine, as premedication, as part of the anesthetic technique, or postoperatively to control pain, increases the incidence of PONV after outpatient anesthesia. Methohexital is less likely than either thiopental or etomidate to cause postoperative nausea. Consistently, propofol was shown to have a low incidence of emetic symptoms postoperatively.

Although Apfel's scoring system to predict the likelihood of PONV emphasizes female gender, nonsmoking status, history of PONV or motion sickness, and narcotic administration as the major risk factors, Sinclair also identifies surgical issues. Surgical procedures such as breast augmentation, varicose vein stripping, laparoscopy, dilatation and curettage, strabismus correction, myringotomy and tympanostomy tube placement, and orchiopexy are associated with more PONV, with the incidence escalating with increasing surgical and anesthesia time. A recent study by Ruiz et al. found that the type of surgery, when categorized anatomically, was related to the incidence of PONV, with patients having neurologic, head or neck, and abdominal surgery having the greatest likelihood of experiencing emesis in the postanesthesia care unit. In addition, pain, hypotension, and early ambulation are postoperative factors demonstrated to increase nausea and vomiting. Relief of pain often, but not always, relieves concomitant nausea.

Sinclair DR, Chung F, Mezei G. Can postoperative nausea and vomiting be predicted? *Anesthesiology*. 1999;91:109–118.

D.2. How would you pharmacologically prevent PONV in the susceptible ambulatory patient?

Because of concerns about medication cost and potential side effects, routine prophylactic administration of an antiemetic is not considered appropriate for all ambulatory surgical patients. Instead, antiemetic prophylaxis should be reserved for patients who are considered to be susceptible to developing PONV (see preceding text). A large number of medications have been used to prevent postanesthetic nausea and vomiting in the outpatient, some with only limited success. Unfortunately, the ideal medication for each patient is not known. Serotonin antagonists, such as ondansetron 4 to 8 mg intravenous in adults and 0.1 mg per kg intravenous in children, are highly effective, but their use as single agents in high-risk patients may not suffice. Droperidol has been shown to be effective, inexpensive, and without an increase in postoperative sedation when used in low doses, such as 0.625 to 1.25 mg in adults (or as low as 10 to 20 μg per kg). However, the U.S. Food and Drug Administration issued a so-called black box warning on the use of droperidol for antiemetic prophylaxis owing to purported fears about prolongation of the QTc interval and subsequent potentially dangerous ventricular arrhythmias. Nonetheless, Charbit et al. documented that droperidol and ondansetron induce similar clinically relevant QTc prolongation, and concluded that the safety of 5-hydroxytryptamine type 3 (5-HT_3) antagonists may not be superior to that of low-dose droperidol. Although the serotonin antagonists are classically believed to lack efficacy with regard to preventing or treating nausea, the newest 5-HT_3 blocker, palonosetron, appears to reduce its severity, and the extended benefits of palonosetron may last up to 3 days, given its long half-life. In addition, palonosetron purportedly has no QT interval issues.

Prophylactic administration of dexamethasone, 5 to 10 mg intravenous in adults and 0.5 to 1 mg per kg intravenous in children, is effective in the prevention of PONV and appears to offer no evidence of any clinically relevant toxicity. Combining dexamethasone with a serotonin antagonist further decreases the incidence of nausea and vomiting and may prove to be the best prophylactic regimen, although optimal doses of this combination are not currently known. Transdermal scopolamine effectively reduces PONV if given as a premedicant well in advance of the surgery, but the high incidence of anticholinergic side effects and prolonged residual effects on cognitive performance, especially in the elderly, detract from its usefulness in the ambulatory patient.

Aprepitant is a highly selective, brain-penetrating neurokinin_1 receptor antagonist that is effective against centrally induced emesis. A recent study showed that aprepitant was superior to ondansetron for prevention of vomiting in the first 24 to 48 hours, but no notable differences were detected between aprepitant and ondansetron for nausea control, use of rescue drugs, or complete response.

Because the etiology of PONV is multifactorial, there is increasing evidence that a multimodal approach may lead to improved outcomes. Double and triple antiemetic combinations, using drugs with different mechanisms of action, are recommended for patients at high risk of PONV. Moreover, liberal hydration and effective analgesia play an important role in reducing the incidence of PONV. General anesthesia with volatile agents should be avoided, if possible, in high-risk patients. If general anesthesia is necessary, a total intravenous approach with propofol may be advantageous. Moreover, if rescue therapy for PONV is needed within 6 hours of surgery, patients should not receive a repeat dose of the drug that was administered prophylactically. Rather, a rescue drug with a different mechanism of action should be selected.

D.3. How is postoperative pain treated?

Pain control is one of the most important factors in determining when a surgical outpatient can be discharged. Pain should be treated rapidly and effectively to minimize postoperative symptoms so that ambulation and discharge are not delayed. The optimal strategy is to use a preemptive, multimodal approach. Begin controlling postoperative pain intraoperatively by supplementing the anesthetic technique with a short-acting narcotic analgesic or a regional block. Intravenous fentanyl is usually the drug of choice for postoperative pain relief. It may be given in small doses of 12.5 μg at 5-minute intervals and titrated to relief of pain. Ketorolac, a nonsteroidal anti-inflammatory drug, has become increasingly popular in the management of postoperative pain in the ambulatory patient because of its lack of opioid-related side effects (e.g., sedation, nausea, vomiting, respiratory depression). It is available for oral and parental administration, and its use may decrease a patient's requirement for opioid analgesics. Controversy still surrounds the perioperative use of ketorolac because of the potential for bleeding complications and renal dysfunction. Local and regional anesthetic techniques can be used to provide effective postoperative analgesia, and when used to supplement general anesthesia, facilitate a pleasant emergence and minimize the need for opioids. Commonly used techniques include local infiltration of the incision site, intra-articular injection, nerve blockade (e.g., dorsal nerve penile block for circumcision, or ilioinguinal and iliohypogastric nerve blocks for inguinal hernia repair), and caudal blocks. When the patient has resumed intake of oral fluids, oral analgesics (e.g., acetaminophen, nonsteroidal anti-inflammatory drugs, as well as codeine and other opioid analgesics) may be administered for control of pain after discharge.

Lichtor JL. Ambulatory anesthesia. In: Barash PG, Cullen BF, Stoelting RK, et al., eds. *Clinical Anesthesia*. 6th ed. Philadelphia: Lippincott Williams & Wilkins; 2009: 833–846.

D.4. If the patient complained of eye pain postoperatively, how would you manage the situation?

Pain due to corneal abrasion is the most common ocular complication of general anesthesia. Patients with a corneal abrasion usually complain of a foreign body sensation, pain, tearing, and photophobia. The pain is typically exacerbated by blinking and ocular movement. It is wise to have an ophthalmologic consultation immediately. Treatment typically consists of the prophylactic application of antibiotic ointment and patching the injured eye shut. Although permanent sequelae are possible, healing usually occurs within 24 hours.

If the patient complains of intense pain, he or she should be scrupulously observed for signs of red eye, corneal edema, and a fixed mid-dilated pupil, as well as complaints of blurred vision. These are characteristic signs of acute angle-closure glaucoma (ACG), a serious emergency. Ophthalmologic consultation should be secured immediately to acutely decrease intraocular pressure (IOP) with systemic and topical therapy. Topical pilocarpine 2% is administered to cause miosis and pull the iris taut and away from the trabecular meshwork. A topical β-blocker also should be considered. If a prompt reduction in IOP does not ensue, systemic therapy with an agent such as mannitol should be considered, but its potentially adverse hemodynamic effects should be weighed in a patient with cardiovascular disease. If medical therapy is effective in reducing IOP to a safe level and the angle opens, an iridotomy/iridectomy can be performed immediately, or it can be delayed until the corneal edema resolves and the iris becomes less hyperemic. Failure to act effectively and expeditiously in cases of ACG could result in blindness. The excruciating periorbital pain typically described in these patients is an important aid in differential diagnosis.

Patients with open-angle glaucoma can also experience an acute glaucoma attack after surgery, but the IOP tends to be lower than that seen with ACG. The eye characteristically appears pale, dry, and firm, and the patient generally complains of a dull, periorbital headache. Treatment includes topical miotics and 5 to 7 mg per kg of acetazolamide intravenously. If the patient does not respond to medical therapy, laser trabeculoplasty may be necessary. Should laser treatment be ineffective, conventional filtration surgery, placement of a Molteno valve, or a coablative procedure may be indicated.

McGoldrick KE, Gayer SI. Anesthesia for ophthalmologic surgery. In: Barash PG, Cullen BF, Stoelting RK, et al., eds. *Clinical Anesthesia*. 6th ed. Philadelphia: Lippincott Williams & Wilkins; 2009:1321–1345.

McGoldrick KE, Kosarussavadi B. Increased intraocular pressure. In: Atlee JL, ed. *Complications in Anesthesia*. Philadelphia: WB Saunders; 1999:765–768.

D.5. What criteria would you use to establish that a patient can be safely discharged after ambulatory surgery?

For patients to be discharged from an ambulatory facility, they must satisfy specific criteria that are usually summarized on simplified checklists. Although each ambulatory surgical facility must determine its own set of criteria, generally accepted guidelines for safe discharge home after ambulatory surgery include the following:

- Stable vital signs
- No evidence of respiratory depression
- Oriented to person, place, and time
- Able to walk unassisted
- Able to dress unassisted
- Minimal nausea or vomiting
- No active bleeding or oozing
- Pain controllable with oral analgesics
- Responsible adult to escort patient home, and to remain with the patient overnight
- Discharge by both the person who administered anesthesia and the person who performed surgery, or their designees. Written instructions for the postoperative period at home must be supplied to the patient before discharge, as well as a phone number to call in the case of emergency

The requirement for patients to drink and void before discharge is no longer considered mandatory, except in the case of certain patients who had central neuraxial blockade (see subsequent text).

Lichtor JL. Ambulatory anesthesia. In: Barash PG, Cullen BF, Stoelting RK, et al., eds. *Clinical Anesthesia*. 6th ed. Philadelphia: Lippincott Williams & Wilkins; 2009:833–846.

Marshall SI, Chung F. Discharge criteria and complications after ambulatory surgery. *Anesth Analg*. 1999;88:514.

D.6. How would you decide when to discharge a patient after regional anesthesia?

Patients recovering from regional anesthesia must satisfy the discharge criteria listed in the preceding text. In addition, if spinal or epidural anesthesia has been used for outpatients, it is important to ensure recovery from the sympathetic and the motor blocks. Hypotension and syncope on standing may be signs that the sympathetic nervous system is still blocked. An indication that the motor block is no longer functioning is the ability to move the legs and feet freely. A simple test is to have the patient run each heel up and down the opposite leg from the big toe to the knee. A patient's ability to walk to the bathroom and void are excellent recovery tests after epidural or spinal anesthesia, because these abilities reflect recovery of both the motor and the sympathetic functions.

Recently, Mulroy et al. have suggested that delaying discharge for voiding after spinal or epidural anesthesia with *short-acting local anesthetics* is unnecessary in *low-risk* patients (e.g., age younger 70 years; no hernia, rectal, or urologic surgery; no history of voiding problems). Nonetheless, appropriate measures must be in place for bladder catheterization if the inability to void persists after discharge home. The use of ultrasonographic monitoring of bladder volume before discharge may reduce the incidence of urinary retention after the patient returns home.

Pavlin JD, Pavlin EG, Gunn HC, et al. Voiding in patients managed with or without ultrasound monitoring of bladder volume after outpatient surgery. *Anesth Analg*. 1999;89:90–97.

D.7. What instructions should be given to an ambulatory surgical patient upon discharge?

Patients should be discharged to the care of a responsible adult. Additionally, they should be instructed that after surgery, they should not ingest an alcoholic beverage or depressant medication unknown to their surgeon or anesthesiologist, drive a car, or operate complex machinery for at least 24 hours. In addition, the discharge instructions should provide a list of problems that require immediate notification of the surgeon (e.g., bleeding that does not stop, inability to void, and persistent PONV.

Lichtor JL. Ambulatory anesthesia. In: Barash PG, Cullen BF, Stoelting RK, et al., eds. *Clinical Anesthesia*. 6th ed. Philadelphia: Lippincott Williams & Wilkins; 2009:833–846.

CHAPTER 61

Magnetic Resonance Imaging

JUNG HEE HAN

A 2-YEAR-OLD BOY weighing 15 kg is scheduled for a preoperative magnetic resonance imaging (MRI) of his brain for ongoing seizures with possible craniotomy with intraoperative MRI the following week. The technician reports that an attempt to obtain a scan last week was unsuccessful because of patient movement despite adequate sedation by the pediatrician. The child's past medical history is remarkable for partial tonic-clonic seizures since age 1. The child was born full term with no complications at birth and is otherwise healthy. Medications include carbamazepine and valproic acid, both of which were taken the night prior. NPO (nothing orally) status has been maintained for at least 6 hours.

A. Medical Disease and Differential Diagnosis

1. What is magnetic resonance imaging (MRI) and how does it work?
2. What are some advantages of MRI?
3. What are some disadvantages associated with MRI? What are some safety concerns?
4. What are the contraindications to MRI?
5. What are the biologic effects of clinical MRI?
6. What are the anesthetic considerations for this procedure?
7. What is intraoperative MRI?

B. Preoperative Evaluation and Preparation

1. What type of patients may require sedation or general anesthesia for a magnetic resonance examination?
2. What preoperative laboratory testing would you require for this patient?
3. How would you premedicate this patient?

C. Intraoperative Management

1. What are some of the anesthetic options for this patient?
2. How is an MRI conducted?
3. How would you monitor this patient?
4. What special considerations apply to the monitoring equipment used during MRI?
5. How would you induce and maintain general anesthesia in this patient?
6. How would you maintain the airway during the scan?
7. What is the laryngeal mask airway (LMA)?
8. What are the advantages of the LMA compared with the face mask?
9. What are the advantages of the LMA compared with the endotracheal tube (ETT)?
10. What complications are associated with the use of the LMA?
11. What are contraindications to the use of the LMA?
12. What are indications for the use of the LMA?
13. What size LMA is appropriate for this child, and how much air would routinely be required to properly inflate the cuff?
14. How is the LMA prepared?
15. How is the LMA inserted?
16. What additional maneuvers may be attempted if difficulty is encountered when inserting the LMA?
17. Examination of the patient before the table is fed into the MRI scanner reveals wheezing. What most likely is happening, and what do you do?
18. Discuss how the LMA can be used as a conduit for tracheal intubation.
19. Discuss the uses of the LMA in the patient with a difficult airway.

D. Postoperative Management

1. When is the LMA removed?
2. How will you have the patient recover from anesthesia?

A. Medical Disease and Differential Diagnosis

A.1. What is magnetic resonance imaging (MRI), and how does it work?

MRI is a noninvasive diagnostic technique that uses magnetic properties of atomic nuclei to produce high-resolution, multiplanar cross-sectional images of the body. Atoms having an odd number of protons and/or neutrons in their nuclei have an associated electrical charge, and the net rotation of protons or neutrons produces a local magnetic field similar to the electromagnetic field produced by the flow of electrons in a wire loop. Normally, the magnetic fields surrounding these nuclei are randomly oriented. When placed in the powerful static magnetic field of the MRI scanner, the nuclei align themselves longitudinally so they lie parallel or antiparallel to the magnetic field.

Within the MRI, a specific RF pulse of energy (a second magnetic field) is directed toward the patient at right angles to the static magnetic field, thereby displacing the orientation of the aligned nuclei from the longitudinal magnetic field. As the RF pulse is removed, the nuclei return to their original magnetic alignment positions. This is termed *relaxation*. The energy released from the tissue as the nuclei relax is termed an RF signal. It can be detected by the receiver coil of the scanner and used to produce the magnetic resonance image. There are two ways to measure relaxation

time. T1 relaxation represents the time to revert to the resting magnetic state and T2 relaxation represents the time to revert to the resting axial spin. The time it takes for relaxation to occur varies for specific body tissues, especially water and fat. This allows for differentiation of body structures, as well as between normal and pathologic tissue. Different atoms respond to different radiofrequencies, with the response being proportional to the strength of the static magnetic field. Hydrogen is present in high concentrations in biologic tissues and is the atom most often used for imaging. Resolution of the image requires a strong magnetic field. The magnetic field strength used to quantify the scanners is in tesla units. One tesla is equivalent to 10,000 gauss. Most MRI scanners used now have a magnetic field of 0.5 to 3.0 T (the magnetic field of the earth is 5×10^{-5} T). Some research scanners are 8.0 T. Weaker field scanners have the advantage of being an open construction whereas the stronger ones generate better image quality. The magnetic field of an MRI takes several days to establish. Therefore, it is constantly applied even in the absence of a patient, and it is deactivated only in an emergency.

A.2. What are some advantages of MRI?

The advantages of MRI include the lack of ionizing radiation, the capability of using noniodinated intravenous contrast agent, and the production of multiplanar images. MRI also provides excellent resolution of normal tissues (e.g., gray and white matter and soft tissues) without image artifact from bone, and it can differentiate between normal and pathologic tissue. MRI may be used to evaluate blood and cerebrospinal fluid flow, contraction and relaxation of organs such as the heart, and provide images of tissues in proximity to bone; because calcium does not interfere with MRI.

A.3. What are some disadvantages associated with MRI? What are some safety concerns?

There are many hazards associated with an MRI suite. The constant static magnetic field, the pulsed (time-varied) gradient magnetic fields, and the high frequency RF waves all interact and when combined with a ferromagnetic object, can pose significant risk to the patient or operator. Not only can the attraction of these external objects become fatal, but implantable objects can dislodge and malfunction or burn

the patient. Depending on the distance from the core of the magnet, the magnetic field strength diminishes. Distances less than five gauss line can make pacemakers malfunction. Distances less than 50 gauss line can make ferromagnetic gas cylinders become lethal projectile missiles.

Obviously with the growing usage of implantable medical devices (i.e., pacemakers, vascular clips, automatic implantable cardioverter-defibrillators, mechanical heart valves, and implanted infusion pumps,) a potential exists for injury to the patients. Most anesthesiologists agree that magnetic resonance (MR) should not be conducted on patients with an implanted device, but that is not an absolute. Clips used in vascular surgery and neurosurgery need to be verified that they are nonferrous (e.g., titanium) to ensure immobility during the MR scan.

Owing to the potential for catastrophic events, recommendations for MRI safety have been proposed by the American College of Radiology. Briefly, the MRI suite should be separated into four zones: zone I is the public zone immediately outside the MRI suite, zone II is the reception area monitored by MRI personnel, zone III encompasses the control room with access to this area being restricted from the public, and zone IV is the physical MRI scanner room. Entry into zones III and IV should be screened by MRI personnel to ensure everyone's safety. Ferromagnetic objects should not be brought in to zone III but if necessary should be brought in with extreme caution. Items such as credit cards, pens, keys, laryngoscopes, scissors, stethoscopes, paper clips, ferromagnetic gas cylinders should be excluded from zone IV. At the author's institution, all oxygen E-gas cylinders have been replaced by aluminum cylinders to further ensure safety of our patients. Adherence to these zones must be maintained especially during emergent situations for the safety of the patient and personnel.

Safety terminology for devices and implants were devised by the U.S Food and Drug Administration, Center for Devices and Radiologic Health in 1997 to distinguish the safety of the device (MRI safe) and the compatibility of the device (i.e., the lack of artifacts on the exam) in a particular MR environment (MRI compatible). Over the years though, these labels were potentially being misused and due to safety concerns, a set of new terminologies were developed by the American Society for Testing and Materials International. *MR safe* refers to items with no known hazards in any MR environment. *MR conditional* refers to items that pose no known hazards in a specified MR environment (i.e., strength of the magnetic field). *MR unsafe* refers to items that pose definite hazards in all MR environments (i.e., ferromagnetic scissors). Concerns regarding the device and its potential hazards should be addressed by the staff members, on site radiologist, and/or manufacturer to determine whether the exam can be conducted in a safe manner.

Other disadvantages of the MRI include the potential for malfunction of electronic equipment (such as monitors and infusion pumps), as well as limited access to the patient. MRI safe/conditional monitors and machines should be used in the scanner. Thermal injuries have been reported from electrocardiogram (ECG) electrodes and pulse oximeter probes. All cables and monitoring equipments should be placed in a straight manner without coiling to ensure no such injuries. MRI safe/conditional infusion pumps can be used in zone IV, but otherwise pumps can be left in zone III and the tubing passed through a wave guide. The relatively long time necessary to obtain the images (as much as 15 minutes per image, with a total scanning period of 1 to 3 hours), and image degradation from any motion including cardiac contractions, respirations, cerebrospinal fluid flow, and bowel peristalsis are additional disadvantages. Another potential hazard to both the patients and the operators is the high decibels levels of sound emanating from the scanner due to the RF pulses (>90 dB). Hearing protection for both is manadatory even if the patient is under anesthesia. Due to the small bore of most MRI scanners (i.e., 50 to 60 cm in diameter), scanning obese patients may be impossible and a sense of claustrophobia and anxiety can be experienced.

A.4. What are the contraindications to MRI?

Patients with implanted biologic devices, such as pacemakers, automatic implantable cardioverter-defibrillators, and certain pumps, should be excluded from MRI studies because of the possibility of device malfunction, inactivation, or damage in the magnetic field. In an MR environment, the device may be moved, rotated, dislodged or accelerated towards the magnetic core. In the case of certain metallic devices (i.e., leads) they can act as an "antenna" and concentrate the RF energy which can lead to thermal injuries. Fractured leads are absolutely contraindicated due to the high risk of thermal injuries. The safety of various cardiovascular devices for MR examination was reviewed based on ex vivo, animal and in vivo studies and reported by the American Heart Association (AHA) and has been found extremely helpful. Although many coronary stents, peripheral stents, sternal wires, inferior vena cava filters, prostethic heart valves, and annuloplasty rings have been deemed MR safe or conditional, it is important to review each type carefully and decide whether the proposed MR exam is in line with the specified milieu for the particular device. Currently, the American Heart Association and the American Society of Anesthesiologists (ASA) practice advisory task force on the anesthetic care for MRI regard the presence of a pacemaker or an implantable cardioverter-defibrillator (ICD) as a strong relative contraindication to routine MR examination. If the benefits far outweigh the risks of the exam, then the scanning should be performed in an experienced center with expertise in MR imaging and electrophysiology. The care of the patient should be performed in collaboration with the cardiologist, radiologist, device manufacturer, and the technician. Written consent must detail all risks to the patient including death. Full resuscitation equipment must be readily accessible in the MRI suite in case of an arrthymia or equipment malfunction. For a more thorough evaluation of these devices, please refer to the recommendations in the reference article. In contrary to these devices, some others may be better tolerated in the MRI suite. MRI may be performed on a limited basis for patients with certain deep brain stimulators and vagal nerve stimulators. Consultation with the radiologist, neurosurgeon, the referring physician, and perhaps the manufacturer, should be made to ensure the device is MRI safe/conditional for the particular protocol. Orthodontic braces and dentures and tattoos or cosmetics that contain metallic dyes, although safe, can degrade the image quality significantly.

A.5. What are the biologic effects of clinical MRI?

Although an area of controversy and ongoing investigation, most human data to date suggest that there are no significant deleterious effects to patients or health care professionals from exposure to the static magnetic field of an MRI. However, MRI capabilities were developed relatively recently (the 1960s), and epidemiologic evidence of harmful exposure may not yet be apparent. It seems prudent, therefore, to limit repetitive and readily avoidable exposure to the magnetic field. Also controversial is the use of MRI during pregnancy, as the effects of magnetic fields on the human fetus cannot be easily determined. However, current evidence does not support the suggestion that routine clinical exposure of the pregnant patient to MRI can cause developmental abnormalities in the fetus. Pregnant patients have undergone MRI safely during all stages of pregnancy. Nevertheless, caution is advised. Studies have shown that gadolinium-based contrast agents enter the fetal circulation and are filtered in the fetal kidneys into the amniotic fluid. It is unclear the duration of the substance in the fluid, but it can potentially form free gadolinium ions, which can theoretically pose risks to the developing fetus. The appropriateness of MRI examination and the acuteness of the diagnostic need must be considered. Ultrasonography use is preferred if it can provide equivalent diagnostic information, and consideration should be given to postponing the MRI until late in the pregnancy or until after delivery.

A.6. What are the anesthetic considerations for this procedure?

The problems that complicate the anesthetic management of any patient outside the operating room environment exist for patients requiring sedation or general anesthesia for MRI. The MRI suite is often located some distance from the operating

room and the anesthesia department, thus limiting the availability of backup assistance and supplies. As with any remote anesthetizing location, the personnel may not be familiar with the requirements of anesthetized patients, thereby decreasing their ability to provide assistance. Frequently, the MRI suites have been designed without the consideration for anesthetic needs, such as pipeline gases, suction, or an anesthetic exhaust system. Access to a recovery suite for postanesthesia care may not be readily available, thereby necessitating a trip to the main recovery room.

In addition, there are anesthetic challenges unique to the MRI suite. Because of the bulkiness of the unit, the patient is often far removed from the anesthesiologist and access to the airway is limited. Intravenous lines, anesthesia circuits, oxygen tubings, and monitoring cables must be of sufficient length to reach the patient deep within the scanner. The strong magnetic field necessitates the exclusion of all ferromagnetic objects and equipment. The displays of standard monitoring devices can be distorted or displaced by the magnetic field and the monitors themselves can degrade the MRI image by disturbing the signal/noise ratio of the MRI. The ASA Task Force understands that the interpretation of the ECG may be limited due to the superimposed voltages from blood flow in a high magnetic field (i.e., ST-segment interpretation unreliable even with filters). Safe monitoring conditions must be maintained with MR safe/ conditional monitors, remote monitoring and remain in compliance with ASA standards.

A.7. What is intraoperative MRI?

Over the last decade, image-guided surgery systems have been introduced that combine the resources of an operating room with MRI technology and high-performance computing. Several low-, mid-, and high-field strength interventional magnetic resonance systems have been developed that permit access to the patient by surgeons and provide near–real-time imaging during surgical procedures. Intraoperative MRI (iMRI) furnishes the surgeon with the simultaneous combination of direct vision and beyond-the-surface MRI, allowing for more accurate localization and targeting during surgery. In addition, iMRI enables the surgeon to detect the full extent of lesions, to devise a surgical approach that is safe with less potential operative morbidity, and to monitor for unseen hemorrhage. Not surprisingly, iMRI systems are expensive and require the need for MRI-compatible surgical instruments and monitoring equipment. One of the largest challenges anesthesiologists face in this setting is dealing with the high energy iMRI generated electrical noise that can interefere with the ECG signal on the monitor. Unlike in an MRI suite, there are multiple people and objects to account for when the iMRI unit is brought out and engaged around the patient. During the duration of the scan, the anesthesiologist has no access to the patient and visualization of the patient may be limited when enclosed in an electrical noise shield. All ferromagnetic objects such as laryngoscopes, stylets, beepers must be left outside the operating room or placed in a secure area. Lastly, as opposed to an MR exam in a dedicated suite, the anesthetic considerations for iMRI must also include the needs of the ongoing complex surgical procedure.

B. Preoperative Evaluation and Preparation

B.1. What type of patients may require sedation or general anesthesia for a magnetic resonance examination?

Although MRI is painless, patients must remain still throughout the time required to make each scan (as much as 15 minutes) to obtain images free of movement artifacts. Patients who are unable to cooperate adequately (e.g., infants, young children, and adults who are confused, mentally ill, intellectually subnormal) usually require an anesthesiologist to help reduce movement during the examination. Small infants may tolerate the procedure well if fed before the examination and swaddled in a blanket. Oral chloral hydrate is an excellent agent for sedation by nonanesthesiologists and is dosed 80 mg per kg to 100 mg per kg. Especially with computer tomography scans, chloral hydrate has been shown to be effective in children younger than 3 years. Side effects of this drug may include excessive sedation, agitation, or respiratory depression. Most children younger than 5 years of age and as old as 11 years of age require some form of sedation or general anesthesia. Not only are children needing anesthesia, but 30% of adult patients experience some form of anxiety during MR scanning. Anesthesiologists are frequently managing claustrophobic or anxious adults, as well as those requiring either airway protection (unconscious or critically ill patients) or mechanical ventilation (patients with head injuries or elevated intracranial pressure) to ensure that an adequate examination is obtained safely and efficiently.

B.2. What preoperative laboratory testing would you require for this patient?

For a routine MRI examination in this child, no preoperative laboratory tests would be required as long as anticonvulsant medications have been stable with documented adequate serum levels.

Cote CJ, Lerman J, Todres ID. *A Practice of Anesthesia for Infants and Children*, 4th ed. Philadelphia: Saunders Elsevier, 2009:527.

B.3. How would you premedicate this patient?

The goals of premedication for this child would be to provide anxiolysis and facilitate the induction of anesthesia without exacerbating a seizure. At the author's institution, ambulatory pediatric patients are not routinely given pharmacologic premedicants; rather, it is our practice to allow a parent to be present at the time of induction, in order to help allay the child's anxiety and ease the induction. If one elects to administer a sedative drug to this child, a logical choice would be oral midazolam (0.5 mg/kg, maximum 10 mg) in a small amount of cherry or strawberry syrup. It is also the practice at the author's institution that oral chloral hydrate is effective in children less than 12 months of age due to the longer duration of the MR scans in comparision to CT scans.

Cote CJ, Lerman J, Todres ID. *A Practice of Anesthesia for Infants and Children*, 4th ed. Philadelphia: Saunders Elsevier, 2009:506–7 and 513.

C. Intraoperative Management

C.1. What are some of the anesthetic options for this patient?

Many different anesthetic techniques have been used for anesthetizing children undergoing MRI or other painless radiologic procedures. These range from simple sedation with orally administered chloral hydrate, or rectally administered barbiturates, to intramuscularly administered meperidine/promethazine/Thorazine, to general anesthesia with ketamine, propofol, or inhaled anesthetics. Because conscious sedation of children is frequently insufficient to prevent patient movement, deeper levels of sedation or general anesthesia are required to successfully anesthetize the pediatric patient for MRI. The ideal anesthetic should allow the anesthesiologist the ability to titrate and maintain stable drug concentrations in order to prevent undesired patient movement during the scan and to provide rapid rates of induction and recovery with a minimal requirement for special MRI-compatible equipment.

Intravenous anesthesia with propofol meets several of the aforementioned criteria and is therefore an excellent technique for MRI. Continuous intravenous infusion of propofol allows for a precise, rapid titration to the desired effect and provides for a rapid recovery. Propofol use eliminates the need for a nonferromagnetic, MRI-compatible anesthesia machine and for a scavenger of waste anesthetic gases, both of which are the major drawbacks of an inhalational technique. Ketamine, although considered a potent bronchodilator with minimal respiratory depression, can increase salivation. This, especially in children, can cause upper airway obstruction, laryngospasm and microaspiration even in the presence of relatively intact upper airway reflexes. In addition, ketamine may elicit undesirable myoclonic movements, increased intracranial pressure, and emergence delirium.

Miller RD, ed. *Miller's Anesthesia*. 7th ed. Philadelphia: Elsevier, Churchill Livingstone; 2010:2469.

C.2. How is an MRI conducted?

The patient is placed on a long, thin table outside the scanner. After obtaining an adequate level of anesthesia, the patient is positioned. If the head is to be examined, it is often enclosed within a small coil or tube. Next, the table with the patient is fed into the long tube of the MRI magnet. The portion of the body to be examined is usually centered in the magnet approximately 1 m from the end of the tube. During the examination, the delivery of the RF pulses produces a loud thumping noise, which can average 95 dB in a 1.5-T scanner. To obtain a high-quality scan, the patient must refrain from moving during the acquisition of an individual cut or from changing position at any time during the entire examination. An individual scan can take several minutes, and the total scanning time may be from 1 to 3 hours. Body surfaces can absorb some of the RF energy during the sequence but is unlikely to increase the patient's core temperature by more than one degree celsius. Nevertheless, the specific absorption rate of energy in the body as measured in watt per kilogram (W/kg) is monitored and depending on the patient, if too high, the sequence may need to be aborted and adjusted.

Peden CJ, Menon DK, Hall AS, et al. Magnetic resonance for the anaesthetist. Part II. Anaesthesia and monitoring in MR units. *Anaesthesia*. 1992;47:508.

C.3. How would you monitor this patient?

Reliable and accurate monitoring of an unconscious individual during an MRI is essential because the patient cannot be seen adequately nor easily accessed by the anesthesiologist. During sedation, the ASA standard monitors including blood pressure, pulse oximetry, and ECG need to be monitored. During general anesthesia, capnography and temperature should also be monitored. The assessment of ventilation in a spontaneously breathing patient may be difficult especially when the patient is within the magnet and far from view. Monitoring end-tidal carbon dioxide from one limb of the nasal oxygen prongs or through a nasal catheter is frequently successful. Monitoring pulse oximetry is a marker for oxygenation and should not be used as a marker for ventilation. Use of a precordial stethoscope may be unsatisfactory due to the length of tubing required and the loud noise of the MRI scanner. Hypothermia can be problematic, especially in the pediatric patient, because of the high airflow through the scanner cavity. The patient should be covered in blankets. Hyperthermia can also occur and if suspected based on specific absorption rate, the sequence may need to be temporarily stopped. Temperature monitoring can be accomplished by using nonferromagnetic temperature strips or probes with RF filters when feasible. It is currently not mandatory for the anesthesiologist to remain in the scanner room during the examination as long as remote monitoring with direct vision of the patient is possible.

C.4. What special considerations apply to the monitoring equipment used during MRI?

Unshielded ferromagnetic materials within monitors and cables can interfere with imaging signals, causing a distortion of MRI results. Similarly, the radiofrequency RF signals of the scanner can induce currents in ferromagnetic elements of the monitors, causing a distortion of the monitoring signal, and making the monitor unusable. Fortunately, MR safe/conditional monitors and equipment (e.g., ECG electrodes) that use shielding nonferromagnetic components and filters to produce satisfactory functioning without a distortion of signal are readily available. Their use is preferred. In addition, to avoid magnetic pull, monitors should be placed at least 5 to 8 ft from the magnet bore or be permanently mounted.

The ECG may show significant changes within a static magnetic field. In particular the T waves and the late ST segments can mimic the ECG changes associated with conditions such as hyperkalemia and pericarditis. This is due to an induced voltage in blood (a conducting fluid) flowing through the magnetic field. These changes are directly related to field strength, but they do not appear to represent any significant physiologic alteration.

The high RF power used in MRI poses the risk of excessive heat at the monitoring sites and therefore the risk of thermal injury. To minimize the risk of burns from monitoring cables, one should do the following:

- Inspect the insulation on all monitoring wires to ensure that it is intact.
- Place cables and lead wires in straight alignment (do not allow monitoring wires to form loops).
- Remove all leads or wires not in use.
- Separate cables from patient's skin.
- Keep the cable and sensor out of the scanning area (e.g., place a pulse oximeter probe on the toe of a patient whose chest is being examined).
- Avoid excessive power.

C.5. How would you induce and maintain general anesthesia in this patient?

There are many different ways anesthesia can be induced in this child. Since this child does not have aspirational risk, inhalational induction can be performed safely. With a parent present, induction of anesthesia may be accomplished with an inhalation agent (e.g., sevoflurane) in nitrous oxide and oxygen through face mask in a room adjacent to the MRI scanner or at the greatest possible distance from the magnetic field within

the scanner room. After the child has lost consciousness, the parent is escorted back to the waiting room. Intravenous access is then established and all monitors are placed. The anesthetic level is deepened with a loading dose of propofol (e.g., 1 to 2 mg/kg), and if needed the airway is secured. Once the child is under general anesthesia, the child is then moved into the scanner room and placed on the MRI table. The patient and monitors are carefully positioned before attempting to advance the table into the magnet bore. Anesthesia is maintained with either a continuous intravenous infusion of propofol or inhalation agent, combined with nitrous oxide in oxygen.

Alternatively, an intravenous catheter may be inserted first and anesthesia induced with intravenous propofol 3 mg per kg or with any other intravenous induction agent.

Frankville DD, Spear RM, Dyck JB. The dose of propofol required to prevent children from moving during magnetic resonance imaging. *Anesthesiology*. 1993;79:954.

C.6. How would you maintain the airway during the scan?

Limited access to the patient's airway is one of the greatest challenges for the anesthesiologist during an MR scan. In light of this, it has been proposed by many, that securing the airway with either an endotracheal tube or laryngeal mask airway and ventilation be controlled, especially in those whose airway might potentially be problematic. Respiration can be spontaneous or controlled depending on personal preference and the needs of the patient. According to the ASA Task Force, the literature is silent in regards to the management of airway problems (i.e., obstruction, hypoventilation, larygnospasm) during an MR scan. As long as a plan is prepared should emergencies occur, any type of anesthetic can be used to accomplish the scan. Alternatively, total intravenous anesthestic with nasal cannula can be accomplished in lieu of an intubation. This should be considered in only patients with good natural airways whose ventilation is being monitored adequately. Placing a shoulder roll under the patient with the chin taped up may help prevent future airway obstruction during the MR scan. This should only be performed when there are no contraindications to potential spinal injuries with head and neck manipulations.

C.7. What is the laryngeal mask airway (LMA)?

The LMA is a device introduced by a British anesthesiologist, Dr. Archie Brain. It fills the gap in airway management between use of the face mask and tracheal intubation. Constructed of soft medical-grade silicone rubber, the LMA consists of an elliptical spoon-shaped mask with an inflatable rim fused at a 30-degree angle to an internally ridged tube with a standard 15-mm proximal connector. On the concavity of the laryngeal mask is a fenestrated aperture with three orifices through which

the distal end of the tube opens. The cuff of the mask is inflated through a pilot balloon. On the posterior curvature of the tube is a black line running longitudinally to assist in orientating the tube in situ. The standard LMA is latex free and contains no ferromagnetic components except a small metal spring in the pilot-tube valve mechanism. It is nondisposable, and can be autoclaved and reused numerous times (as many as 40). Alternatively, disposable LMAs are available which can be safely used as well.

The small amount of metal in the spring valve is not sufficient to be attracted by the magnetic field and dislodge the LMA. However, if the valve lies near the area being scanned, the scan's image can be distorted. There are flexible LMAs reinforced with a stainless steel wire coil, which should not be used during MRI.

In addition to these classic LMAs, there are a variety of other supraglottic airway devices which can be used in lieu of the classic LMA. Please refer to the individual device to determine whether or not ferromagnetic parts exist.

Landsman IS. The laryngeal mask airway. *Int Anesthesiol Clin*. 1997;35(3):50–51.

C.8. What are the advantages of the LMA compared with the face mask?

When used as an alternative to the face mask, the LMA gives the anesthesiologist more freedom to perform other tasks (e.g., record keeping, monitoring, and drug administration) and decreases the incidence of operator hand fatigue. The LMA allows for more reliable capnography and is capable of maintaining higher hemoglobin oxygen saturations. The contamination of the MRI scanner room environment with inhalational anesthetics is reduced and less manipulation of the airway is required with an LMA. Furthermore, injury to the eyes and facial nerves may be reduced by the avoidance of a face mask and head strap.

Miller RD, ed. *Miller's Anesthesia*. 7th ed. Philadelphia: Elsevier, Churchill Livingstone; 2010:2468–2469.

C.9. What are the advantages of the LMA compared with the endotracheal tube (ETT)?

Although the LMA does not replace the ETT (especially in longer cases and when protection from aspiration is important), it has some advantages. The ease of LMA placement and provoking less stimulation (i.e., less coughing, gagging, swallowing, breath holding, bronchospasm, and cardiovascular response) are two advantages over the ETT. Lighter levels of anesthesia can therefore be better tolerated with an LMA than with an ETT. In inexperienced hands, the LMA can be more rapidly and reliably placed than an ETT, suggesting a potential role in resuscitation. Trauma to the vocal cords is limited because the LMA does not pass through this area. In adults, the incidence of sore throat after LMA usage is reduced when compared with the tracheal tube.

Landsman IS. The laryngeal mask airway. *Int Anesthesiol Clin.* 1997;35(3):51–52.

C.10. What complications are associated with the use of the LMA?

The most serious potential problem of the LMA device is the lack of tracheal protection from aspiration of gastric contents. In patients at low risk of regurgitation, the rate of aspiration during general anesthesia using an LMA is similar to that in all non-LMA general anesthetics (2/10,000 cases). Most authors recommend that it not be used in patients at high risk of regurgitation. Conversely, aspiration of pharyngeal contents has not been shown to be a problem with the LMA, and the use of the device has been reported to be suitable during ear, nose, and throat procedures and dental procedures. Odynophagia occurs in 4% to 12% of patients after LMA use, an incidence that is comparable to the use of a face mask with an oropharyngeal airway. This is still less than that associated with tracheal intubation, which occurs in 30% of the patients. Hoarseness, dysphagia, and several cases of recurrent, hypoglossal and lingual nerve injury have been reported with LMA use. Cuff overinflation, unmonitored increases in cuff pressure secondary to nitrous oxide diffusion, light anesthesia with constriction of pharyngeal musculature, venous engorgement and tissue edema associated with the head-down position, and lidocaine gel lubricant have all been cited as causes of nerve injury. One fatal case has been implicated with the use of an intubating LMA. An unrecognized esophageal tear from an accidental blind esophageal intubation resulted in septic shock and death 9 weeks postintubation. Although this complication was a result of the blind intubation, it nevertheless was associated with an LMA device.

Landsman IS. The laryngeal mask airway. *Int Anesthesiol Clin.* 1997;35(3):51.

C.11. What are contraindications to the use of the LMA?

The following conditions contraindicate the use of the LMA:

- Increased risk of gastric regurgitation (i.e., full stomach, hiatal hernia, bowel obstrucion, delayed gastric emptying)
- Limited ability to open the mouth or extend the neck (e.g., severe rheumatoid arthritis and ankylosing spondylitis), making advancement of the LMA into the hypopharynx difficult
- Low pulmonary compliance or high airway resistance
- Airway obstruction at or below the level of the larynx
- Oropharyngeal pathology (e.g., hematoma, abscess, and tissue disruption)
- Single-lung ventilation

Pennant JH. The laryngeal mask airway. Its uses in anesthesiology. *Anesthesiology.* 1993;79:158–159.

C.12. What are indications for the use of the LMA?

The LMA is best suited for use in any patient in whom anesthesia can be safely maintained through a face mask (except in a patient with oropharynx pathology). It has been used routinely in various surgical procedures including minor gynecologic, urologic, orthopedic, bronchoscopic, and endoscopic diagnostic procedures. In addition, the device may be useful in surgery around the face in which the trachea is intubated solely due to the physical interference imposed by the face mask. Other types of surgery in which the LMA has been used successfully include dental extraction, adenotonsillectomy, repair of cleft palate, myringotomy and placement of tympanostomy tubes, and eye surgery. Furthermore, use of the LMA in the management of the difficult airway is increasing.

C.13. What size LMA is appropriate for this child, and how much air would routinely be required to properly inflate the cuff?

In this 15-kg patient, a size 2.0 LMA with a cuff volume of 5 to 10 mL would be appropriate. A guide to selecting the appropriate LMA based on patient weight, as well as the cuff volumes of the different LMAs, is shown in Table 61.1.

Boehringer LA, Bennie RE. Laryngeal mask airway and the pediatric patient. *Int Anesthesiol Clin*. 1998;36(2):48.

C.14. How is the LMA prepared?

Before insertion, the cuff of the LMA should be carefully inspected, tested for leaks, completely deflated, and lubricated. Only nonsilicone, water-based gels are used for

Table 61.1 The Selection of Laryngeal Mask Airway Size and Cuff Volume According to Patient's Weight

LARYNGEAL MASK AIRWAY SIZE	PATIENT WEIGHT (kg)	MAXIMUM CUFF VOLUME (mL)
1	<5	4
1.5	5–10	7
2	10–20	10
2.5	20–30	14
3	30–50	20
4	50–70	30
5	>70	40

lubrication and are applied only to the posterior surface of the mask. Care should be taken to avoid lubricating the anterior surface because the lubricant may obstruct the distal aperture or be accidentally aspirated into the larynx. Lubricants containing local anesthetics have been implicated in postoperative numbness, allergic reactions, and nerve damage and are not recommended for use with the LMA.

C.15. How is the LMA inserted?

According to the insertion technique described by the device's inventor, Dr. Brain, the operator places his nondominant hand under the patient's occiput and extends the patient's head at the atlantooccipital joint after induction of general anesthesia. This maneuver tends to open the mouth. The device, which has been lubricated and deflated appropriately, should be held like a pen with the index finger of the dominant hand positioned at the junction of the tube and the mask. It is firmly applied against the hard palate as the LMA is guided over the back of the tongue. Force is applied by the index finger in an upward direction toward the top of the patient's head as the device is directed along the palate and slid into the pharynx and hypopharynx, until the resistance of the upper esophageal sphincter is felt. The LMA is then stabilized with the nondominant hand as the inserting hand is removed from the patient's mouth. The cuff is then inflated with just enough air to form an effective seal. One should be able to observe a rising of the cricoid and thyroid cartilages and the lifting of the tube out of the mouth as the cuff is inflated. The longitudinal black line on the surface of the tube is oriented superiorly and should lie against the upper lip in the midline. Tape is used to secure the LMA in position in a manner similar to that used to secure an ETT. A major pitfall in the placement of the LMA is when posteriorly directed pressure is applied, resulting in the tip to be malpositioned, which can lead to trauma and a leak. A bite block may be inserted between the teeth to prevent biting and occlusion of the LMA barrel.

When correctly positioned, the bowl of the LMA mask lies over the laryngeal inlet with the tip of the LMA cuff resting against the upper esophageal sphincter in the hypopharynx, and the sides of the cuff resting in the pyriform fossae. Although the epiglottis often lies within the bowl of the LMA mask, the device usually creates a satisfactory airway even when the epiglottis assumes an awkward position (e.g., downfolded).

Ferson DZ. Laryngeal mask airway: preanesthetic evaluation and insertion techniques in adults. *Int Anesthesiol Clin*. 1998;2(36):34–35.

C.16. What additional maneuvers may be attempted if difficulty is encountered when inserting the LMA?

For the experienced user, the standard insertion technique is successful in most patients (>98%) on the first two attempts. Common reasons for difficult insertion include poor

technique, inadequate depth of anesthesia (with resulting cough, retching, and laryngospasm), user inexperience, inability to negotiate the 90-degree turn from the posterior pharynx to the hypopharynx, a large tongue or tonsils, and use of an incorrectly sized LMA. Numerous maneuvers have been described to overcome insertion difficulties, including physically pulling the tongue forward, thrusting the jaw, and using a laryngoscope, a tongue blade, or a Magill forceps to lift the tongue. Inserting the LMA with the mask facing backward and rotating the device 180 degrees after meeting posterior pharyngeal wall resistance has also been advocated. Partially or completely inflating the cuff before insertion has been suggested to ease insertion. Although this maneuver may offer some advantages for an inexperienced user, it has the potential to cause partial airway obstruction if the tip of the LMA travels in front of the arytenoids toward the larynx. Furthermore, it may increase coughing or laryngospasm because of stimulation of protective airway reflexes or result in a high LMA position in the pharynx. In the patient with a high arched palate, approaching the hard palate slightly diagonally from the side with the LMA situated 15 to 20 degrees lateral from the midline may be useful.

Landsman IS. The laryngeal mask airway. *Int Anesthesiol Clin*. 1997;35(3):55–56.

C.17. Examination of the patient before the table is fed into the MRI scanner reveals wheezing. What most likely is happening, and what do you do?

Wheezing in the setting of an LMA can be caused by light anesthesia resulting in partial laryngospasm, bronchospasm, or malposition of the device with the tip of the mask encroaching on the glottis. One should deepen the anesthetic in the spontaneously breathing patient or administer muscle relaxant in the mechanically ventilated patient as an initial treatment. If the problem is not relieved, despite an adequate level of anesthesia and/or paralysis, the device should be removed and repositioned.

Brimacombe JR. Problems with the laryngeal mask airway: prevention and management. *Int Anesthesiol Clin*. 1998;36(2):141.

C.18. Discuss how the LMA can be used as a conduit for tracheal intubation.

Outside of the zone IV MRI suite, the LMA has been used successfully as a conduit for blind tracheal intubation with an ETT, intubating tracheal stylet or fiber-optic bronchoscope (FOB)–guided ETT. Blind techniques at intubation through the LMA have the greatest chance of success when the LMA has a perfect central position around the larynx (45% to 60%) versus a noncentral location. The ability to effectively pass an ETT blindly through the LMA into the trachea can be further enhanced with the use of concomitant cricoid pressure. With any blind technique, care must be taken because laryngopharyngeal injury can result.

As opposed to these aforementioned blind techniques, the passage of an FOB through the LMA is approximately 100% successful and often less traumatizing.

Table 61.2 The Laryngeal Mask Airway Size That Can Accommodate the Size of Endotracheal Tube and Fiber-optic Bronchoscope

LARYNGEAL MASK AIRWAY SIZE	LARGEST ENDOTRACHEAL TUBE (ID, MM)	FIBER-OPTIC BRONCHOSCOPE SIZE (MM)
1	3.5	2.7
2	4.5	3.5
2.5	5.0	4.0
3	6.0 cuffed	5.0
4	6.0 cuffed	5.0
5	7.0 cuffed	6.0

With an appropriately sized ETT (see later discussion) threaded on the proximal end of the FOB, the scope is passed through the lumen of the LMA and under direct visualization into the trachea. The ETT is then passed over the shaft of the FOB and into the trachea. Unfortunately there are three major disadvantages associated with this technique. First, the ETT needs to be long enough to ensure that the cuff is situated below the vocal cords when the LMA is left in situ, especially in patients with long incisor-to-glottis distances. Second, the internal diameter of the LMA limits the size of the ETT that can be used, which can potentially hinder one's ability to provide effective ventilation. Third, the removal of the LMA over the ETT may risk extubation, which may be difficult to replace. Various solutions to these problems have been proposed, including the use of a tube exchanger to replace the LMA and ETT or deflating the LMA cuff to gain another 1.0 to 1.5 cm of depth in which to advance the LMA and ETT together. However, if the ETT that has been passed through the LMA is of adequate size, the LMA should be left in place with its cuff deflated. Table 61.2 lists the LMA size that can accommodate the size of ETT and FOB.

In addition, a specialized LMA designed to provide a superior conduit for blind or fiber-optically guided tracheal intubations was introduced into clinical practice in 1997. The intubating LMA (LMA-Fastrach) permits single-handed insertion from any position without moving the head and neck from a neutral position and without placing the operator's fingers in the patient's mouth. It consists of an anatomically curved, rigid airway tube constructed of stainless steel and covered with a rubberized material that is wide enough to accept an 8-mm cuffed ETT and is short enough to ensure passage of the ETT cuff beyond the level of the vocal cords. A rigid handle is attached to the distal end of the airway tube to facilitate one-handed insertion, removal, and adjustment of the device's position. The mask aperture bars found on the standard LMA are replaced by a hinged epiglottic elevating bar on the LMA-Fastrach. During intubation with the LMA-Fastrach, the epiglottic elevating bar serves to lift the epiglottis as the ETT emerges from the mask aperture, providing the ETT with an unobstructed path through the vocal cords into the trachea. A special 8-mm, straight, silicone, wire-reinforced ETT is available and should be used for intubation through the LMA-Fastrach, rather than with a standard plastic ETT, to decrease the likelihood of laryngeal trauma.

Landsman IS. The laryngeal mask airway. *Int Anesthesiol Clin.* 1997;35(3):52–59.

C.19. Discuss the uses of the LMA in the patient with a difficult airway.

In addition to serving as a routine airway during general anesthesia, the LMA has proved to be valuable in supporting airways that are difficult to manage and useful as a conduit for tracheal intubation. Uses of the LMA in the patient with a difficult airway include the following:

- *As a conduit for fiber-optic tracheal intubation in the awake patient*. When the preoperative evaluation indicates that the patient should be tracheally intubated awake, the LMA can be placed in the properly prepared awake patient and used as a conduit for fiber-optic intubation. Insertion of an LMA is a relatively moderate stimulus that may be better tolerated by the awake patient than the very stimulating methods of conventional rigid laryngoscopy and bronchoscopy. Visualization of the laryngeal inlet with an FOB is usually easy through the shaft of a properly positioned LMA. In patients whose airways are potentially difficult but who do not require endotracheal intubation, an LMA can be placed when they are awake and used as the primary means of airway control.
- *As an airway in the anesthetized patient who cannot be tracheally intubated*. The LMA is an alternative to the face mask in the patient under general anesthesia who cannot be tracheally intubated but whose lungs can be ventilated using a mask. An exception to this is the patient in whom cricoid pressure must be continuously applied (e.g., the patient at risk of regurgitation). In this situation, placement of the LMA does not protect the airway from regurgitation and would have little benefit over a conventional mask. As noted in section C.8, the LMA has several advantages over the face mask. An additional advantage of the LMA is that it can be used as a conduit for FOB intubation.
- *As a conduit for FOB tracheal intubation in the anesthetized patient who cannot be intubated, but whose lungs can be ventilated.* Refer to section C.18.
- *As an emergency airway in the patient who cannot be ventilated or intubated*. Insertion of the LMA has provided a life-saving emergency airway in this situation and is a reasonable maneuver to try before the tracheal esophageal Combitube or transtracheal jet ventilation, provided that there is no known periglottic pathology. The LMA works well as a routine airway device in most patients, and it is usually easily placed in patients whose airways are Mallampati class 3 or 4 and/or grade III or IV laryngoscopic view. Most anesthesiologists are familiar with the placement of an LMA and can effectively insert one with little trauma.
- *As a conduit for tracheal intubation in the patient who cannot be ventilated or intubated*. If the airway is successfully established with an LMA in this situation, precious time has been obtained to subsequently use the LMA as a conduit for tracheal intubation. If the LMA provides for adequate ventilation, it is likely that the glottic opening lies within the bowl of the LMA, and FOB-guided intubation through the LMA will be successful. If ventilation is poor after LMA insertion, the LMA may not be adequately aligned with the laryngeal inlet or there may be periglottic pathology. In both situations, FOB-guided tracheal intubation may be difficult and may necessitate insertion of a tracheal esophageal Combitube, initiation of transtracheal jet ventilation, or creation of a surgical airway.

D. Postoperative Management

D.1. When is the LMA removed?

The removal of an LMA during excitation stages of emergence may cause coughing and/or laryngospasm; therefore, it should be removed either when the patient is deeply anesthetized or awake. Suctioning of secretions from the pharynx is usually not necessary before removal of the LMA. If suctioning is to be performed, it is important to ensure that an adequate level of anesthesia is maintained to avoid unnecessary airway stimulation. The cuff of the LMA may be deflated before removal or alternatively it may be left fully inflated to scoop out the secretions collected above the mask as it is withdrawn. As with extubation of the trachea, equipment for managing airway emergencies must be immediately available.

Barash PG, Cullen BF, Stoelting RK, eds. *Clinical Anesthesia*. 6th ed. Philadelphia: Lippincott Williams & Wilkins; 2009:760.

D.2. How will you have the patient recover from anesthesia?

Postanesthesia recovery care after an MRI is the same as that required after an anesthetic in the operating room. This can be accomplished in a designated area of the MRI suite provided that adequate facilities and trained personnel are available. For most, such a facility may not be available and the patient will require transport to the main recovery room. To transport the patient quickly and safely, one must ensure that adequate personnel and the proper equipment are organized in advance. It is useful to have the location of recovery and logistics of transport (if necessary) planned before the procedure begins.

CHAPTER 62

Morbid Obesity and Obstructive Sleep Apnea

Jon D. Samuels and Fun-Sun F. Yao

A 46-YEAR-OLD WOMAN

was scheduled for elective laparoscopic sleeve gastrectomy. She had a past medical history significant for morbid obesity (MO) (height, 5 ft 4 in.; weight, 176 kg; body mass index [BMI], 66.6 kg per m^2), Pickwickian habitus, mild rheumatoid arthritis, osteoarthritis, mild asthma, hypertension, adult-onset diabetes mellitus, peptic ulcer disease with severe gastroesophageal reflux, and obstructive sleep apnea (OSA). She experienced daytime somnolence, heavy nighttime snoring, and had slept in a seated position for the previous 2 years. She was able to walk around the house with a cane, but was unable to climb any stairs. A preoperative diagnostic polysomnogram (PSG) was performed, and an apnea–hypopnea index (AHI) of 42 was calculated. Two weeks before surgery, home oxygen therapy with bilevel positive airway pressure (BIPAP) settings had been started at the following settings, with symptomatic improvement: FIO_2 of 0.35, respiratory rate 10 breaths per minute, inspired positive airway pressure of +11 cm H_2O, expired positive airway pressure of +4 cm H_2O, spontaneous mode. Cardiology clearance was obtained as a high-risk candidate, after an echocardiogram revealed mild right-sided cardiomegaly and mild pulmonary hypertension. The patient's blood pressure was 155/82 mm Hg, pulse was 60 beats per minute, and respiration was 20 breaths per minute.

A. Medical Disease and Differential Diagnosis

1. What problems exist with this patient?
2. Define the terms overweight, obesity, MO, super obesity (SO), normal weight, and ideal body weight (IBW). What is the BMI, and how is it measured?
3. What is OSA? What is the significance of OSA in the surgical population? What are the risk factors for OSA?

4. How is OSA diagnosed? Are there any validated questionnaires that have been endorsed by the American Society of Anesthesiologists (ASA)? Are any commonly observed physical findings associated with OSA? What is a sleep study or PSG? How are results obtained from a PSG used to grade the severity of OSA? What are the criteria for ordering a preoperative screening PSG?
5. What are the different types of OSA?
6. What is the Pickwickian syndrome (PS)? What is the pathogenesis of severe OSA?
7. What is the association between obesity and OSA? What is the etiology of pharyngeal pathology in severe obesity? Are all of the changes in the airway confined to the upper airway in obese patients with OSA?
8. What are the anesthetic implications of OSA?
9. What kind of metabolic problems would you expect to find in morbidly obese patients?
10. Describe the changes that occur in the following respiratory parameters in morbidly obese patients:
    - *Pulmonary mechanics:* tidal volume (V_T), functional residual capacity (FRC), residual volume (RV), vital capacity (VC), inspiratory reserve volume (IRV), expiratory reserve volume (ERV), and total lung capacity (TLC)
    - Flow volume loops
    - Pressure volume loops
    - Diffusing capacity for carbon monoxide (DLCO)
    - *Compliances:* lung, chest wall, and total
    - *Resistance:* airway, and total respiratory system
    - Closing capacity
    - Work of breathing
11. What changes occur in Pa_{O_2} and Pa_{CO_2} in morbidly obese patients?
12. What changes occur in intrapulmonary shunt (Q_S/Q_T) and dead space (V_D/V_T) in morbidly obese patients? Describe the equations.
13. What is the impact of pneumoperitoneum (PNP) on the respiratory and cardiovascular system of the bariatric surgical patient? Are there any other effects?
14. What changes occur in the cardiovascular system of the obese patient? Discuss cardiac output (CO), blood volume, blood pressure, and pulmonary arterial pressure.
15. Are there any other disease entities commonly associated with obesity?
16. What anatomic changes that affect the airway are associated with MO?
17. What derangements of the gastrointestinal system are associated with MO?

B. Preoperative Evaluation and Preparation

1. How would you evaluate this patient preoperatively?
2. Interpret the following arterial blood gases: pH 7.25; Pa_{CO_2} 50 mm Hg; Pa_{O_2} 58 mm Hg; and HCO_3^- 25 mEq/L on room air.
3. What is the equation for blood pH?
4. What are the normal values for blood pK_a, dCO_2, HCO_3^-, and H_2CO_3?
5. Interpret the following spirometry screening test: VC 2.36 L (expected 3.375 L); forced expiratory volume in 1 second (FEV_1) per forced vital capacity (FVC) 82%; and VC 70% of expected value.

6. How would you premedicate this patient? Why?
7. Describe weight-based dosing.

C. Intraoperative Management

1. How would you monitor this patient?
2. The ASA's Difficult Airway Algorithm provides a guideline for management of the difficult airway. How do the comorbidities of MO and OSA modify implementation of the algorithm?
3. How would you induce anesthesia? Describe the intubation technique.
4. Why is it important to preoxygenate the obese patient? How would you do it? Compare the effectiveness of the four-maximum-breath and 3-minute techniques.
5. There are many new airway devices on the marketplace. Which of these devices have been particularly successful on the morbidly obese or OSA patient?
6. How would you maintain general anesthesia? What agents would you choose?
7. Which muscle relaxants would you use?
8. Can regional anesthesia be used intraoperatively and postoperatively to decrease opioid requirements? What are the advantages and disadvantages of regional anesthesia? What are some of the newer techniques available?
9. What is the effect of narcotics on the sphincter of Oddi? Is pharmacologic treatment indicated?
10. During surgery, arterial blood gases showed pH 7.35; Pa_{O_2}, 57 mm Hg; Pa_{CO_2}, 52 mm Hg; F_{IO_2}, 0.6; mechanical ventilator V_T, 1.0 L; and ventilatory rate, 15 breaths per minute. The following changes were made to the ventilatory parameters: 10 cm H_2O positive end-expiratory pressure (PEEP) was added, and the V_T was increased to 1.2 L. Twenty minutes later, an arterial blood gas showed pH 7.32; Pa_{O_2}, 55 mm Hg; and Pa_{CO_2}, 55 mm Hg. What is the explanation for these changes?
11. What is apneic oxygenation? Who did the pioneer study?
12. What is diffusion hypoxia? How do you prevent it?

D. Postoperative Management

1. When will you extubate this patient? What are the extubation criteria?
2. What are the major early postoperative complications in the morbidly obese patient? How do health-related risks correlate with obesity? What factors correlated statistically with perioperative mortality?
3. How does position affect respiratory function in the obese patient?
4. How would you prevent postoperative atelectasis?
5. How long would you prescribe supplementary oxygen postoperatively?
6. How would you control postoperative pain?

A. Medical Disease and Differential Diagnosis

A.1. What problems exist with this patient?

Preoperative significant past medical history in this patient consists of MO, OSA, possible PS, right ventricular hypertrophy, mild pulmonary hypertension, systemic hypertension, adult-onset diabetes mellitus, osteoarthritis, mild rheumatoid arthritis, and severe gastroesophageal reflux disease. Epidemiologically, this patient is at increased

risk for coronary artery disease, cardiac arrhythmias, left- and right-sided congestive heart failure, peripheral vascular disease, venous thrombosis and pulmonary emboli, cerebrovascular disease, biliohepatic disease, hepatic steatosis, hepatic cirrhosis, degenerative joint disease, and socioeconomic and psychosocial impairment.

This is a high-risk patient, with increased risk of both perioperative morbidity and mortality. Major anesthetic concerns include risk of difficult airway, DMV, decreased apneic threshold to trace amount of anesthetics, sedatives and narcotics, prolonged anesthesia emergence, postemergence resedation, positional ventilatory collapse, restrictive and obstructive lung disease, ventilation–perfusion mismatch, and worsening of reactive pulmonary hypertension and cor pulmonale. This patient must receive continuation of her preoperative oxygen therapy with continuous positive airway pressure (CPAP) in the immediate recovery period, at the values determined by her sleep study (PSG), or greater. Minor anesthetic concerns include difficult monitoring, difficult vascular access, and positioning issues. Additionally, there is a rare risk of postoperative massive pharyngeal collapse, rhabdomyomysis with renal failure, increased risk of infection including pneumonia, positional injuries. Meticulous attention to acute pain management is essential.

Safe perioperative care for this patient requires triage to a specialized facility, additional personnel, surgeons with advanced laparoscopic training, and anesthesiologists with advanced airway skills and optimal equipment.

A.2. Define the terms overweight, obesity, MO, super obesity (SO), normal weight, and ideal body weight (IBW). What is the BMI, and how is it measured?

Obesity is a multifactorial chronic disease involving social, cultural, physiologic, psychologic, metabolic, endocrine, genetic, and behavioral components, resulting in excess adipose and tissue mass. The modern basis for the determination of demographics is the BMI, or Quetelet's Index, after the Belgian statistician, Adolphe Quetelet, published in 1842, and is measured in body weight in kilograms divided by the height in meters squared (kg per m^2). The standard for IBW, the sex-specific desirable weight for persons with small, middle, and large frames, is published in the Metropolitan Life insurance tables.

- *Anorexia* is defined as a BMI of less than 17.5 in men or women.
- *Underweight* is defined as a BMI of 17.6 to 19.0 in women, or 17.6 to 20.6 in men.
- *Ideal (normal) weight* is defined as a BMI of 19.1 to 25.8 in women, and 20.7 to 26.4 in men.

- *Marginally overweight* is defined as a BMI of 25.9 to 27.2 in women, and 26.5 to 27.8 in men.
- *Overweight* is defined as a BMI of 27.3 to 32.3 in women, and 27.9 to 31.1 in men.
- *Obesity* is defined as a BMI of 32.4 to 34.9 in women, and 31.2 to 34.9 in men.
- *Severe obesity* is defined as a BMI of 35.0 to 39.9 in both sexes.
- *Morbid Obesity* is defined as a BMI of greater than 40.
- *Super Obesity*, a relatively new term, is defined as a BMI greater than 50.

There exist imperial and metric system BMI tables and web-based calculators.

Occasionally, an approximate, non–sex-specific system is used. In this system, a *healthy* (*normal*) *weight* is a BMI of 18.6 to 24.9, *overweight* is a BMI of 25 to 29.9, *obesity* is a BMI of 30 to 34.9, *severe obesity* is a BMI of 35 to 39.9, *MO* is a BMI of more than 40.0.

The older definitions of obesity may occasionally suffice. Overweight was formerly defined as a body weight of up to 20% greater than the predicted ideal weight, and obesity of more than 20%. MO was formerly defined as a body weight of 100 lb above the IBW, or alternatively, of twice the IBW. These definitions involved value judgments and inaccuracies, and were later abandoned, in favor of more objective terminology.

Alternative systems for the determination of obesity exist. In the triceps skinfold thickness test, for example, obesity is defined as a value of greater than 23 mm in men or greater than 30 mm in women. In the Broca Index (height in centimeters minus 100 for men and minus 105 forwomen), the IBW is calculated in kilograms.

- *Men*: ideal body weight (kg) = height (cm) – 100
- *Women*: ideal body weight (kg) = height (cm) – 105

There are different patterns of distribution of obesity. In *peripheral obesity* (e.g., gynoid or gluteal pattern), the individual has a pear shape, and adipose tissue deposition is predominantly in the lower body. In *central obesity* (e.g., android, or cushingoid), and especially upper body obesity, the individual has an apple shape, and adipose tissue deposition occurs predominantly in the upper body. Central obesity has greater associations with perioperative risk and OSA.

A.3. What is OSA? What is the significance of OSA in the surgical population? What are the risk factors for OSA?

OSA is a sleep disorder. Sleep disorders may be grouped into the following types: conditions with excessive daytime somnolence (e.g., OSA), conditions with disorders initiating and maintaining sleep (e.g., insomnia), and circadian rhythm disorders (e.g., jet lag).

In the older terminology, OSA referred to both OSA proper, and to obstructive sleep hypopnea (OSH) syndrome, a milder variant. Currently, it is more precise to refer to obstructive sleep apnea and hypopnea syndrome (OSAHS) when naming the general condition. OSA is the most prevalent sleep disorder, affecting 2% to 26% of the general population. OSA is a major risk factor for perioperative adverse events, as shown in the literature. The prevalence of OSA is higher in the surgical population than in the general population. It is estimated that 70% of the bariatric surgical candidates have moderate-to-severe OSA. In most cases, there is no screening, and diagnosis preoperatively.

OSA is defined as cessation of airflow for more than 10 seconds despite continuing ventilatory effort, five or more times per hour of sleep, associated with a decrease in arterial oxygen saturation (Spo_2) of greater than 4%. *OSH* is defined as a decrease in airflow of more than 50% for more than 10 seconds, 15 or more times per hour of sleep, associated with a decrease in Spo_2 of greater than 4%. Both forms of OSAHS are usually associated with snoring, sleep disruption from increased ventilatory effort–induced arousal, hypersomnolence (daytime sleepiness), altered cardiovascular function, and pathophysiologic alterations, of which hypoxemia and hypercarbia are primary events, and polycythemia, systemic and pulmonary hypertension, various cardiac arrhythmias, myocardial ischemia, right and left ventricular hypertrophy, and eventually, failure are secondary events.

Severe obesity is an independent risk factor for OSAHS. However, not all forms of obesity are linked to OSA. Peripheral obesity and gynecoid obesity have little association with OSA. Central obesity, on the other hand, is associated with OSA, particularly in patients who possess an increased waist circumference or increased neck circumference. Of all risk factors, the strongest correlation is with waist circumference, in particular if the waist-to-hip ratio was >1 in men and >0.85 in women. Craniofacial markers for OSA include increased neck circumference, jowls, poor Mallampati class (3 or 4), and short cricomental space (defined as the perpendicular distance from the cricoid cartilage to the inner mentum of the skin of the neck). In nonobese individuals, risk factors are craniofacial dysostoses, particularly micrognathia (absolute or relative), cartilaginous abnormalities (e.g., lingual tonsillar hyperplasia), chronic nasal obstruction, and tonsillar hypertrophy. Other risk factors include male gender, middle age, evening ingestion of alcohol, and drug-induced sleep.

A.4. How is OSA diagnosed? Are there any validated questionnaires that have been endorsed by the American Society of Anesthesiologists (ASA)? Are any commonly observed physical findings associated with OSA? What is a sleep study or PSG? How are results obtained from a PSG used to grade the severity of OSA? What are the criteria for ordering a preoperative screening PSG?

OSA may be suspected by history, physical examination, or comorbidities, but definitive diagnosis requires a sleep study.

A concise and easy-to-use screening tool for OSA has been developed and validated at preoperative clinics. The STOP questionnaire, stands for habitual Snoring, Tiredness or daytime sleepiness, Observed apnea, and high blood Pressure. When combined with BMI, age, gender, and neck size, the STOP questionnaire has a high sensitivity, especially for moderate to severe OSA. The Berlin questionnaire, which is commonly utilized in preoperative clinics, also efficiently screen for OSA.

Most adults with OSA have upper body obesity, increased neck circumference, micrognathia, and poor Mallampati scores on physical examination. Patient characteristics typically associated with OSA are a higher BMI, hypertension, and certain cephalometric measurements. In 90% of cases, the patient has a BMI in excess of 28 kg per m^2. OSA, however, may result from any condition that predisposes to upper airway obstruction. Some examples are pregnancy, upper airway abnormalities (e.g., deviated nasal septum, hypertrophic tonsils, and adenoids), cartilaginous abnormalities (e.g., lingual tonsillar hyperplasia), craniofacial dysostoses, and certain congenital conditions (e.g., Down syndrome, muscular dystrophy). The absence of a typical or compelling presentation, however, does not rule out the possibility of OSAHS.

Definitive diagnosis of OSA is made by sleep specialists with a formal sleep study or a *PSG*. A PSG is an involved study, performed at sleep study centers, that examines nocturnal sleeping patterns by monitoring physiologic parameters. In its most comprehensive form, the following parameters are studied: two to six electroencephalographic (EEG) channels to measure electrical activity of the brain and to document sleep cycles; two electrooculogram (EOG) channels to distinguish rapid eye movement (REM) from non-REM sleep; chin electromyogram (EMG) to monitor arousal and activity of the upper airway (genioglossus and digastric muscles); an airway microphone to monitor airflow from the nose and mouth; elastic belts placed on the chest and abdomen to monitor respiratory effort; an infrared video camera to monitor body position; one channel of electrocardiogram (ECG) to monitor cardiac activity; a pulse oximeter to monitor oxygen saturation; and two-leg EMG channels to monitor leg movements. A PSG may be ordered to definitively diagnose a sleep disorder, as part of medical management, or in the surgical workup of a high-risk population (e.g., preoperative screening of bariatric surgical candidates).

A PSG will diagnose the presence of OSAHS, type (central, peripheral, or mixed), and grade severity. Results are reported in as the total number of apneas and hypopneas per hour of sleep or the *AHI*. Values of 6 to 20, 21 to 40, and greater than 40 represent mild, moderate, and severe OSA, respectively.

- Mild OSA = AHI of 6 to 20
- Moderate OSA = AHI of 21 to 40
- Severe OSA = AHI of > 40

The total number of arousals hourly is the *Arousal Index* (AI).

- AI = arousals/hour.

The sum of the AHI and the AI is the Respiratory Disturbance Index (RDI).

- RDI = AHI + AI

A.5. What are the different types of OSA?

Sleep-disordered breathing in children and adults is distinct in pathophysiology, clinical presentation, and therapy.

Childhood obstructive sleep apnea (COSA) consists of a continuum from snoring, to upper airway resistance syndrome, to the fully expressed syndrome. The pathophysiology of COSA is most commonly peripheral in origin, due to nocturnal airway blockage from nasal pathophysiology, hypertrophic tonsils and adenoids, or craniofacial dysostoses. The symptomatology in COSA consists of snoring (usually continuous), rare daytime sleepiness, and frequent behavioral disturbances (e.g., attention deficit hyperactivity disorder [ADHD]). It is distinguished from adult OSA by the following: snoring is more continuous, there is no sex predilection, and surgery (commonly adenotonsillectomy, rarely uvulopalatopharyngoplasty) is curative. There is no gold standard for the PSG diagnosis in children.

Adult OSA or OSAHS consists of a continuum from asymptomatic, to paraoxysmal snoring, to severe nocturnal airway closure, requiring the patient to sleep in a sitting position, and daytime somnolence. The pathophysiology of OSAHS is central, peripheral, or mixed. Peripheral disease is caused by redundant adipose tissue in the upper airway, in the setting of severe obesity, sometimes with a superimposed craniofacial dysostosis. The symptomatology of OSAHS consists of intermittent snoring, apneic episodes, with daytime somnolence. OSH syndrome, a milder form of OSA, may be clinically indistinguishable. *Obesity–hypoventilation syndrome* (*OHS*) is severe OSA with chronic daytime hypoventilation, SO, and hypercapnia not related to pulmonary disease. *PS* is OHS with cor pulmonale.

Patients presenting to the operating room commonly have not received a sleep study, or even a clinical diagnosis, so it is incumbant on the anesthesiologist to ask provocative questions (e.g., solicit a history of snoring, daytime somnolence, and obligate mouth breathing), and perform a targeted physical examination (e.g., check for poor Mallampati score, increased neck circumference, relative or absolute micrognathia, increased abdominal girth). So that appropriate modifications in the perioperative plan may be instituted, as will be outlined in the next sections.

A.6. What is the Pickwickian syndrome (PS)? What is the pathogenesis of severe OSA?

The PS was so named by Burwell in 1956, as a reference to Joe, an obese, somnolent boy in the *Posthumous Papers of the Pickwick Club*, written in 1837 by Charles Dickens. With Joe, Dickins had provided the first accurate description of the most severe type of OSA, consisting of a BMI more than 50 kg per m^2 or SO, alveolar hypoventilation (hypoxemia and hypercarbia), heavy nighttime snoring with periodic respiration, hypersomnolence (daytime somnolence), secondary polycythmia, right and left ventricular hypertrophy, and right heart failure. This syndrome may occur with or without pulmonary hypertension.

The complete PS, rarely seen, consists of massive obesity, daytime somnolence, alveolar hypoventilation, periodic nighttime respiration, secondary polycythemia, right ventricular hypertrophy, and failure. In these individuals, there are repeated cycles of sleep, arousal, sleep, accompanied by obstructed breathing, with snoring and restlessness. Hypoxemia and hypercarbia result from disruption of a normal sleep pattern; with loss of REM sleep and cardiovascular changes. Loss of REM sleep induces hypersomnolence, personality, behavior, and cognitive changes, and predisposes these individuals to be accident prone. Eventually severe OSA leads to OHS, with nocturnal, and later diurnal alterations in the control of breathing, manifested as central apneic events, or apnea without ventilatory efforts. They also develop an alveolar–arterial oxygen gradient by ventilation–perfusion mismatch. The major factor in the pathogenesis of this syndrome is unknown, but may be due to decreased hypoxic and hypercarbic ventilatory drive. Later in the disease process, there is progressive daytime hypoxia and hypercarbia. When cor pulmonale supervenes, the PS is complete.

There are several cardiovascular changes in severe OSA, all related to the episodic airway closure, with hypoxemia and hypercarbia. Hypoxemia and alterations in autonomic tone may induce bradycardia during apneic episodes; in half of these patients long sinus pauses, second-degree heart block, and ventricular ectopy may result. These arrhythmias may lead to nocturnal angina and myocardial infarction in susceptible individuals. Pulmonary hypertension may be caused directly by hypoxic pulmonary vasoconstriction, or indirectly by either increased transmural pulmonary artery pressures from negative thoracic pressure created by a sustained ventilatory effort against the upper airway obstruction, or by increases in pulmonary artery tone from increased sympathetic tone created by episodic hypoxemia. Pulmonary hypertension initially causes right ventricular hypertrophy, resulting in a higher right ventricular end-diastolic pressure (RVEDP), and later culminates in right ventricular failure, or cor pulmonale. The systemic circulation is also affected by episodic increases in sympathetic tone, with systemic hypertension presenting early, and left ventricular hypertrophy, followed by left ventricular

failure presenting much later. Systemic hypertension may also lead to increased stroke rate.

A.7. What is the association between obesity and OSA? What is the etiology of pharyngeal pathology in severe obesity? Are all of the changes in the airway confined to the upper airway in obese patients with OSA?

Obesity and OSAHS are both common and coexisting diseases. Obesity has reached epidemic proportions in the industrialized world, and currently poses a greater worldwide health risk than does malnourishment. In the United States alone, obesity is annually responsible for 300,000 premature deaths and an annual healthcare cost of $100 billion. Sixty-five percent of the US population, or 127 million adults, are obese. The prevalence of severe obesity, a strong risk factor for OSAHS, is 3.15% in men and 6.70% in women (according to US population data).

Sixty percent to 90% of patients with OSAHS are obese, and it has been estimated that 9% of women and 24% of men in the United States suffer from the syndrome, a total of 18 million individuals, of which 2% of women and 4% of men are symptomatic. These figures will almost certainly increase, as the demographics shift toward an older and more obese population. Many of these patients are undiagnosed at the time of surgery, representing potential perioperative complications.

There are two reasons why severe obesity per se may cause or exacerbate OSAHS. First, there is an inverse relation between obesity and pharyngeal volume. The pharyngeal area decreases in obesity from deposition of adipose tissue into pharyngeal structures: (colon) in particular, the uvula, the tonsils, the tonsillar pillars, the tongue, the aryepiglottic folds, and, most importantly, the lateral pharyngeal walls. The volume of adipose in the lateral pharyngeal walls correlates with the clinical severity of airway obstruction. Increased deposition of pharyngeal adipose increases the likelihood that relaxation of the upper airway muscles will result in collapse of the soft-walled retroglossal space, or the oropharynx, between the uvula and the epiglottis. The shape of the pharynx remodels from an ellipse with the long axis transverse, to an ellipse with the long axis anterior–posterior. The muscles that open the collapsible pharynx on expiration during sleep (e.g., tensor palatini, genioglossus, and hyoid muscles) in response to stretch receptors in the pharynx are located in the anterior pharynx, and do not function well with a remodeled pharynx.

Second, the patency of the collapsible pharynx is determined by the transmural pressure (the difference between the extraluminal and intraluminal pressure) and the compliance of the wall. If the compliance of the wall and intraluminal pressure (inspiratory pressure) are constant, then the remaining important determinant of upper airway patency is extraluminal pressure. In obese patients, extraluminal pressure is increased by superficially located fat masses; that is, the upper airway is compressed externally. Therefore, neck circumference is greater in obese patients with OSAHS compared with obese non-OSAHS patients. The incidence and severity of OSAHS correlates better with neck circumference than does BMI. Neural control of the more than twenty pairs of muscles (especially the pharyngeal dilator muscles)

is under the control of mechanoceptors and neural signals to the hypoglossal motor neurons through the superior laryngeal or glossopharyngeal nerves to the nucleus of the solitary tract.

There are also lower airway changes in obese individuals with OSAHS. Obesity, particularly central obesity, increases visceral fat volume, resulting in decreased lung volume. According to the lung volume hypothesis, lung volume reduction decreases longitudinal tracheal wall traction, causing increased pharyngeal wall collapsibility. The trachea moves caudally during spontaneous inspiratory breathing and causes longitudinal traction on the pharyngeal wall, subsequently unfolding the mucosa and stiffening the airway.

A.8. What are the anesthetic implications of OSA?

Management of anesthesia in patients with severe OSAHS poses significant risks. These patients are extremely sensitive to minimal doses of central nervous system depressant drugs, such as anesthetics, sedatives, and analgesics, and may exhibit prolonged sedation, resedation, or apnea, as well as upper airway obstruction or, rarely, massive pharyngeal collapse. For these reasons, premedication with benzodiazepines or narcotics is used sparingly if at all, and sedation is generally reserved for painful or unpleasant situations (e.g., placement of invasive lines) where the patient is under the direct observation of a trained clinician.

Difficult tracheal intubation is expected in 13% to 24% of obese patients with OSAHS. In this particular case, the patient presents for laparoscopic bariatric surgery. Although the "ideal general anesthetic" regimen for these patients is a matter of some discussion, the literature does support the following: a safe induction, a deep maintenance anesthetic with muscle relaxants, and a smooth emergence with rapid offset devoid of active metabolites or trace anesthetic. Anesthetic gases should be insoluble, resistant to metabolic degradation, and without lipid depot compartmentalization, combined with rapid return of airway reflexes. The only weak inhalation anesthetic, nitrous oxide (N_2O), has the advantage of being relatively insoluble, as measured by blood–gas solubility coefficient (0.46), but it causes intestinal inflation, may be emetic, and is not recommended in the presence of pulmonary hypertension, a condition that is more common in MO. Of the available potent inhalation anesthetics (desflurane, sevoflurane, and isoflurane), desflurane combines the quickest wake-up, fastest return of airway reflexes, lowest solubility, as measured by the blood–gas solubility coefficient (desflurane, 0.45; sevoflurane, 0.65; and isoflurane, 1.4), and lowest percentage of hepatometabolization (desflurane, 0.02%; isoflurane, 0.2%; sevoflurane, 4% to 5%). Intravenous agents should be either lipophobic (hydrophilic), spontaneously degrade in vivo, or be ultrashort acting.

Sedation or awake fiberoptic intubation: ketamine and dexmedetomidine are optimal agents. *Induction of general anesthesia:* all agents have been utilized. *Maintenance agents:* air/oxygen mixtures, desflurane, cisatracurium, and remifentanil. *Last hour of general anesthesia and emergence:* nitrous oxide (except in the presence of pulmonary hypertension), remifentanil, and morphine sulfate.

When feasible, regional anesthesia is useful. Tracheal extubation is considered only when patients are fully awake with intact upper airway reflexes. Episodic arterial hypoxemia may occur early, in the first 24 hours, or late, from the second to the fifth day, postoperatively.

Discharge from the postanesthetic care unit (PACU) may be made in the morbidly obese OSA, per protocol, after they have been started on CPAP or bilevel positive airway pressure (BIPAP), and have been observed for at least 30 minutes, without stimulation, and found to be free of respiratory arrests. If they have even one respiratory arrest, PACU stay is extended for an additional 3 hours, and consideration is made to transfer the patient to a monitored bed.

Intravenous patient-controlled analgesia (PCA) appears to be well tolerated in the morbidly obese, without deleterious effects on oxygen saturation, respiratory function, blood pressure, or heart rate. Dosing is based on IBW, without continuous rate. Although the gold standard in acute pain management is still morphine sulfate (starting at 20 μg per kg every 10 minutes with a 4 hour dose of 80% of the calculated.maximum dose), hydromorphone has largely supplanted morphine, due to its "one size fits virtually all" profile (starting at 0.2 mg every 10 minutes, progressing to 0.3 mg every 10 minutes, down to 0.1 mg every 15 minutes if excessive). Hydromorphone has less histamine release and nausea and vomit than morphine sulfate. Morphine sulfate and rarely fentanyl are emerging as second line IV PCA agents. Of course, it is important to individualize therapy. It is never appropriate to add a continuous rate in this patient population.There is a paucity of literature on the safety and efficacy of intravenous PCA in the morbidly obese severe OSAHS patient. There are case reports of respiratory complications in this population; postoperative pain management must take into account the exquisite sensitivity of these patients to the ventilatory-depressant effects of opioids.

A.9. What kind of metabolic problems would you expect to find in morbidly obese patients?

In MO, there is an increase in both low metabolically active tissue (e.g., adipose) and normally active tissue (e.g., muscle). In general, lean body weight (LBW) is equal to IBW plus 20% to 40% IBW. IBW is a value, based on population demographics, which could never be realized through weight reduction in a severely obese individual.

Morbidly obese individuals have an increase in total oxygen consumption and carbon dioxide production due to an increased tissue mass. Increased metabolism demonstrates a linear relation with body weight and body surface area. Basal metabolic rate, however, remains normal in obese individuals.

Leptin is a hormone that is derived from adipose tissue, and is involved in lipid metabolism. Leptin serves a key role in metabolism, It signals the appetite center in the hypothalamus to promote satiety when the individual has eaten an adequate portion. Obese patients have a higher serum leptin level, possibly as a result of leptin resistance, and consequently have an abberant satiety response. OSA patients have an even higher serum leptin level than BMI-matched non-OSA patients. Short-term CPAP therapy decreases serum leptin levels. Leptin appears to have a role in respiratory control in obese patients. It prevents respiratory depression. Excessive visceral adipose tissue has been implicated in metabolic syndrome, via the secretion of hormones and proinflammatory cytokines.

A.10. Describe the changes that occur in the following respiratory parameters in morbidly obese patients:

- *Pulmonary mechanics* : tidal volume (V_T), functional residual capacity (FRC), residual volume (RV), vital capacity (VC), inspiratory reserve volume (IRV), expiratory reserve volume (IRV), and total lung capacity (TLC)
- Flow volume loops
- Pressure volume loops
- Diffusing capacity for carbon monoxide (DLCO)
- *Compliances*: lung, chest wall, and total
- *Resistance*: airway and total respiratory system
- Closing capacity
- Work of breathing

Morbidly obese patients have reduced lung volumes, increased work of breathing, and alterations in control of breathing and gas exchange. Body fat distribution, as well as BMI, determines the effect of obesity on pulmonary function.

Pulmonary mechanics. Pulmonary function tests (PFTs), or lung volumes, are uniformly altered in obesity. V_T is normal or increased in the obese, and is decreased in Pickwickian obesity. IRV is decreased. ERV is markedly decreased, because the increased weight of the torso decreases the normal expansive tendency of the rib cage and pulmonary parenchyma. RV is normal. FRC or ERV plus RV, is markedly decreased, because of the decrease in ERV. VC or ERV + V_T + IRV, is decreased because of decreased ERV. TLC or RV + ERV + V_T + IRV, is decreased for the same reason as VC. Individuals with central, as opposed to peripheral fat distribution, have greater decreases in the FVC, forced expiratory volume (FEV), and TLC. The maximum voluntary ventilation (MVV) may also be reduced.

Diffusing capacity for carbon monoxide. The DLCO is usually normal in individuals with obesity and mildly reduced in those with OHS, because the lung parenchyma is normal, and changes in PFTs are due to abnormal chest wall mechanics and lower lung volumes. DLCO is a useful test to separate intrinsic lung pathology from obesity.

Compliance. There is a decrease in the total respiratory system compliance ($1/C_T = 1/C_L + 1/C_{CW}$), where C_T is the total compliance, C_L is the compliance of the lung, and C_{CW} is the compliance of the chest wall. Total compliance is always decreased because of the weight of the torso and abdominal contents pressing against the diaphragm creating a restrictive component, markedly decreasing the chest wall compliance. Lung compliance is often normal, but is decreased when pulmonary and circulatory comorbidities are present (e.g., pulmonary hypertension).

Resistance. There are increases both in the airway resistance (reduced elastic tension of the lung) and in the total respiratory system resistance (increased elastic tension of chest wall) at lower lung volumes, which leads to reduction in the caliber of the smaller airways. The increase in total resistance is approximately 30% in simple obesity, and 100% in OHS. Resistance increases further in the supine position, possibly due to extrinsic adipose pressure of the supralaryngeal airway, and a decreased FRC.

Closing capacity. FRC is reduced in the morbidly obese patient, and may be below the closing capacity, resulting in small airway closure, ventilation–perfusion mismatch, right-to-left shunting, and possibly hypoxemia, the so-called positional ventilatory collapse. This may be worsened in the supine position, Trendelenberg position, by general anesthesia and muscle relaxants, and improved by the use of lung recruitment strategies (e.g., PEEP), and reverse Trendelenberg position.

Increased work of breathing. MO is associated with a 70% increase in the work of breathing, and a fourfold increase in the oxygen cost of breathing (oxygen consumed by the respiratory muscles per liter of ventilation, used as a surrogate for the energy cost of breathing). This is due to decreased lung compliance, increased respiratory resistance, and threshold inspiratory load from adipose tissue mass. Obese individuals with obstructive sleep apnea syndrome (MO-OSAHS) have elevated pharyngeal and nasopharyngeal resistance, raising the work of breathing 60% above the obese, and 250% above the nonobese.

A.11. What changes occur in Pao_2 and $Paco_2$ in morbidly obese patients?

Hypoxemia is the most common blood gas abnormality in the severely obese patient. The etiology is most commonly due to a low ventilation/perfusion ratio, and less commonly as a result of hypoventilation. Pulmonary perfusion is increased in the obese as a result of increased CO, increased circulating blood volume, and, occasionally, pulmonary hypertension. Alveolar ventilation is decreased in the obese as a

result of upper airway closure, and spirometric changes (decreased ERV, and FRC). In addition, the closing volume is often greater than the expiratory reserve volume, particularly in the supine position, causing airway closure, resulting in right-to-left shunt and hypoxemia.

The second most common blood gas abnormality in the severely obese is a variable change in the carbon dioxide tension ($Paco_2$), not related to lung disease, and dependent on the alveolar ventilation. There are three patterns of ventilatory derangement described in the following:

- *Alveolar hyperventilation* in response to a hypoxic drive. This occurs in young, active subjects. $Paco_2$ is approximately 35 mm Hg.
- *Periodic, nocturnal, alveolar hypoventilation* with normal daytime values. This is the hallmark of OSAHS.
- *Daytime, or constant, alveolar hypoventilation*. This occurs in OHS, and PS.

A.12. What changes occur in intrapulmonary shunt (Q_S/Q_T) and dead space (V_D/V_T) in morbidly obese patients? Describe the equations.

Q_S/Q_T is normally less than 5%. In the morbidly obese, this is increased, because of the following:

- Lower ventilation/perfusion ($\dot{V}/\dot{Q}$) ratio
- Upper airway closure (e.g., OSAHS)
- Decreased FRC, from abdominal compression
- Hypoventilation (e.g., OSAHS)
- Increased pulmonary circulation, from increased CO, increased blood volume, and occasionally pulmonary hypertension

$$\text{Shunt equation} = Q_S/Q_T = (Cc_{O_2} - Cao_2)/(Cc_{O_2} - Cv_{O_2})$$

where Cc_{O_2} is pulmonary capillary oxygen content; Cao_2 is arterial oxygen content; Cv_{O_2} is mixed venous oxygen content.

Dead space is anatomic, alveolar, or physiologic. *Anatomic dead space* is the volume of the lung and upper airway that is not involved in gas exchange. Ventilation of this area does not result in gas exchange. The volume of the anatomic dead space in milliliters is approximately equal to the IBW in pounds. Fowler's method of measuring anatomic dead space is by analyzing nitrogen concentration after single breath 100% oxygen. *Alveolar dead space* is the area of alveoli with ventilation and no perfusion, which has a $\dot{V}/\dot{Q}$ equal to infinity, or West Zone 1. *Physiologic dead space*, the sum of anatomic and alveolar dead space, is the total area of lung plus airways not involved in gas exchange. Physiologic dead space is approximately 30% of the V_T. It is decreased in the supine position, and increased with disease states that alter $\dot{V}/\dot{Q}$, and in OHS, because the latter individuals adopt a shallow ventilatory pattern. Physiologic dead space is decreased in the obese, due to increased V_T ventilation and unchanged anatomic dead space. Physiologic dead space, or V_D/V_T, is measured by the Bohr equation.

$$\text{Bohr equation: } V_D/V_T = (Paco_2 - P_{E}co_2)/Paco_2$$

where $P_{E}co_2$ is mixed expired CO_2 tension.

A.13. What is the impact of pneumoperitoneum (PNP) on the respiratory and cardiovascular system of the bariatric surgical patient? Are there any other effects?

Currently, many surgical procedures, including bariatric surgery, are performed by laparoscopy. The peritoneal cavity is inflated through a trocar with carbon dioxide at a pressure of approximately +15 cm H_2O to displace the abdominal wall, and improve working and visualization conditions for the surgeons. Oxygenation, lung, and chest wall compliance decrease, and peak inspiratory and mean airway pressures increase as a result. These values are further decreased by Trendelenburg position, but may not be improved by reverse Trendelenburg, although this is controversial. Respiratory mechanics are worsened by PNP, due to decreased compliance and increased airway resistance. Increased V_T ventilation or ventilatory rate does not improve oxygenation, as long as closing capacity has been exceeded by FRC. Large V_T ventilation has been associated with volutrauma and low lung water pulmonary edema. Although otherwise healthy morbidly obese patients tolerate these changes relatively well, some patients may require lung recruitment strategies, such as the use of pressure mode ventilation, inspiration/expiration ratio of 1:1, and PEEP. Settings should be carefully adjusted to maintain normocarbia, as judged by end-tidal carbon dioxide, and readjusted as conditions change.

PNP effects on the cardiovascular system occur through increases in the systemic vascular resistance and the mean arterial pressure (MAP). There is a biphasic pattern: When inflation pressure is below 10 mm Hg, increased venous return, by splanchnic sequestration, raises MAP and CO. When inflation pressure is above 20 mm Hg, the inferior vena cava is compressed, resulting in decreased venous return, decreasing MAP and CO. PNP and reverse Trendelenburg position may decrease femoral venous blood flow, resulting in venous stasis in a patient population already predisposed to venous thromboembolism.

Increased sympathetic output from from PNP may result in decreased urine output by a 30% to 50% decreased glomerular filtration rate; postoperative renal function is normal. PNP and Trendelenburg position cause cephalad migration of the tracheal tube, and may precipitate endobronchial intubation.

A.14. What changes occur in the cardiovascular system of the obese patient? Discuss cardiac output (CO), blood volume, blood pressure, and pulmonary arterial pressure.

MO produces changes in cardiac morphology and ventricular function.

As BMI increases, both total and circulating blood volume increase. Although absolute blood volume is expanded, relative blood volume is decreased. Increase in circulating blood volume and decrease in systemic vascular resistance results in augmentation in CO. CO increases by increased stroke volume, and heart rate remains unchanged. CO and stroke volume increase in proportion to oxygen consumption and the degree of obesity, but more closely to the LBW. Left ventricular (LV) wall stress increases according to the law of Laplace ($P_2 - P_1 = 2T/R$), where P is the change in pressure produced by the increased volume, T is the LV wall stress, and R is the radius. Increase in afterload from hypertension produces eccentric LV hypertrophy, and eventually LV dysfunction. They are therefore sensitive to acute changes in preload and afterload. Morbidly obese patients presenting to the operating room require an ECG, chest radiographs, and an echocardiogram. Seventy percent of the echocardiograms in morbidly obese patients contain abnormalities.

Hypertension is more prevalent because of increased CO and increased blood volume. Hypertension is more commonly systolic than diastolic in the obese. Obese patients without comorbidity have normal pulmonary artery filling pressures. Those individuals with OHS and PS, however, commonly have pulmonary hypertension, as a result of hypoxic pulmonary vasoconstriction and increased CO. Hypertension and increased CO lead to congestive heart failure in approximately 10% of obese individuals. There are two mechanisms in the pathogenesis of heart failure. In the first, pulmonary and systemic vascular congestion develops as a consequence of chronic volume overload superimposed on diminished diastolic compliance, caused by long-standing ventricular hypertrophy. In the second, chronic volume overload and high CO results in LV hypertrophy. The ventricular wall/cavity ratio decreases, and LV systolic dysfunction results. Echocardiography demonstrates LV hypertrophy in these patients, often in the absence of electrocardiographic evidence. Obesity leads to fatty infiltration of the cardiac conduction system, predisposing to sudden death. Obesity is not a direct predictor of coronary artery disease. As an indirect predictor, obesity is linked to coronary artery disease through hyperlipidemia and systolic hypertension.

A.15. Are there any other disease entities commonly associated with obesity?

Secondary obesity may be associated with hypothyroidism, Cushing disease, insulinoma, hypogonadism, and hypothalamic disorders. Although most obese patients are not diabetic, 80% to 90% of nonketotic diabetics are obese. Increased insulin secretion and insulin resistance resulting from peripheral tissue insensitivity are well-characterized features of obesity. Obesity exacerbates the diabetic state. Furthermore, malignancies of breast, prostate, cervix, uterus, colon, and rectum are more common in the obese.

In addition, there is a disproportionate increase in health-related risks from obesity. Above a BMI of 25, the risk of coronary artery disease more than doubles. Above a BMI of 29, there is an increased perioperative risk of pulmonary embolus. Above a BMI of 35, there is more than a 40-fold increase in adult-onset diabetes mellitus, respiratory disease, osteoarthritis, and OSAHS. Perioperative mortality during weight reduction surgery is statistically correlated with BMI, preoperative hypertension, anastomotic leak, and pulmonary embolus. A combination of central obesity, hypertension, dyslipidemia, and impaired glucose tolerance is termed *metabolic syndrome* and increases risk for morbidity and death.

A.16. What anatomic changes that affect the airway are associated with MO?

Patient-specific anatomic changes in the MO are related to the BMI, type of obesity (peripheral vs. central), and presence or absence of OSAHS. Not all morbidly obese patients have airway involvement. The anatomic changes affecting the airway are not always easily diagnosed on routine physical examination. At a given BMI, there is more airway involvement in central obesity compared with peripheral obesity, and the most severe involvement airway involvement occurs in patients with OSAHS.

Significant anatomic alterations in the airway of the morbidly obese include the following:

- Deposit of adipose tissue in the lateral pharyngeal walls, and to a lesser extent in the uvula, the tonsillar pillars, the tongue, and the aryepiglottic folds, causing a

decreased in the pharyngeal area. Adipose deposition in the false vocal folds may render the glottic opening difficult to recognize, even with the vocal cords abducted.
- Deposit of adipose tissue external to the upper airway (lateral parapharyngeal fat pads, or jowls), extrinsically compressing the airway.
- Presence of hypopharyngeal adipose tissue not evident on external examination that acts as a ball valve, obstructing the upper airway and interfering with the line-of-sight at direct laryngoscopy.
- Presense of pretracheal adipose tissue, which pushes the hyoid bone posteriorly into a less favorable position, causing the epiglottis to partially override the glottic entrance, worsening the laryngoscopic view.
- Alteration in shape of the pharynx from an ellipse with the long axis lateral transverse to an ellipse with the long axis anterior–posterior.
- Decreased efficiency of the anterior pharyngeal dilator muscles (tensor palatini [nasopharynx], genioglossus [oropharynx], hyoid muscles [laryngopharynx]), which promotes snoring.

The anatomic changes that occur with MO are important for three reasons. First, these patients may obstruct their airway with light to moderate sedation (peripheral OSAHS). Various surgical procedures have been developed to improve this problem, such as the uvulopalatopharyngoplasty. Second, these patients may be difficult to mask ventilate, both because of external adipose tissue, and internal collapse of redundant upper airway adipose. Third, there is a higher incidence of difficult intubation (DI) and failed intubation in MO. When coupled with the precipitous desaturation, there is a need to revise the ASA's Difficult Airway Algorithm.

The literature is inconclusive on the relation between obesity and DI. According to some authorities, obesity is an independent risk factor for DI, due to a disproportionately large tongue base, or a short, thick neck. Other authors found that a higher BMI is not an indicator of DI, but that increased neck circumference and poor Mallampati scores (classes 3 and 4) are. MO-OSAHS patients with other risk factors for DI (e.g., micrognathia) develop worsening of airway closure to an even greater degree than their counterparts.

A.17. What derangements of the gastrointestinal system are associated with MO?

There are several changes in the upper gastrointestinal tract that place severely obese individuals at risk for acid aspiration pneumonitis upon induction and emergence

of general anesthesia: prolonged gastric emptying time, decreased gastric pH, increased incidence of hiatal hernia, linear increase in intra-abdominal pressure with increasing body weight, and impaired gastroesophageal antireflux mechanism. Ninety percent of fasting morbidly obese patients exceed Mendelson's criteria, a gastric volume of greater than 0.35 mL per kg total body weight (TBW), with a pH less than 2.5.

There is a substantially higher incidence of hepatobiliary disease in the morbidly obese, such as cholelithiasis, hepatitis, intrahepatic and extrahepatic cholestasis, hepatic steatosis, and cirrhosis. Seventy-five percent of the morbidly obese have hepatic steatosis. Although there is a 25% incidence of severe hepatic dysfunction in the morbidly obese, there is no clear correlation between LFTs and hepatic dysfunction, complicating medical and anesthetic management. Pancreatic disease is also more common in this population, specifically gallstone pancreatitis, adult-onset diabetes mellitus, and insulinoma. There is a higher incidence of colorectal malignancies in the morbidly obese.

B. Preoperative Evaluation and Preparation

B.1. How would you evaluate this patient preoperatively?

Preoperative evaluation should include a detailed history, review of systems, physical examination, and laboratory tests. Special attention should be paid to circulatory, pulmonary, and hepatic functions. Circulatory evaluation includes signs and symptoms of left or right ventricular failure, history of hypertension, and electrocardiographic abnormalities. Respiratory evaluation includes smoking history, exercise tolerance, history of hypoventilation and somnolence, pulmonary function tests with spirometry and baseline arterial blood gases, and chest x-ray results. Hepatic function tests include serum albumin and globulin, serum aspartate aminotransferase, serum alanine aminotransferase, direct and total bilirubin, alkaline phosphatase, prothrombin time, and cholesterol levels.

A cardiology consultation is needed, with a noninvasive assessment of function by echocardiogram. Patients without an adequate echocardiographic window require radionucleotide ventriculography to assess ventricular function and morphology. It is important to obtain a full assessment by the cardiologist, to determine whether this patient is optimized, and which invasive lines, if any, are appropriate. This patient was found to have mild right ventricular hypertrophy and mild pulmonary artery hypertension. Pertinent negatives were the absence of demon-

strated coronary artery disease, and left or right ventricular failure. In this case, it was determined that the patient was optimized, and that an arterial line would be helpful.

Physical examination focuses on the cardiovascular, pulmonary, and the upper airway. The upper airway assessment, in particular, should be thorough. In addition to the routine parameters, atlanto-occipital joint extension, Mallampati classification, temporomandibular joint assessment with interincisor distance, mentohyoid distance, and dentition, the following parameters should be checked: pretracheal adipose thickness, neck circumference, and hypertrophic tonsils and adenoids. Nonreassuring findings related to the latter three variables are a large neck, an abundance of anterior neck soft tissue, and obligate mouth breathing. Neck circumference is an independent predictor of DI; the odds ratio is 1:13. At 40 cm (15.75 in.), there is a 5% chance of DI; at 60 cm (23.62 in.), this increases to 35%. Pretracheal adipose greater than 1 in. (2.5 cm) at the level of the vocal cords, determined by ultrasonography, may be an even better independent predictor of DI. Obligate mouth breathing may be a clue that the patient has adenotonsillar hypertrophy, nasal septal blockage, or a craniofacial dysostosis.

Factors that render difficult mask ventilation (DMV) should be noted. According to Langeron, DMV risk factors are age over 55 years, BMI greater than 26 kg per m^2, history of snoring, presence of a beard, and incomplete dentition. According to Kheterpal, DMV and DI risk factors are limited mandibular protrusion, increased neck circumference, OSA, history of snoring, and BMI over 30 kg per m^2. Redundant adipose tissue may hide physical findings suggestive of a DI (e.g., increased submandibular angle).

Prior anesthetic records should be obtained. Patients with a history of heavy snoring should have a formal sleep study or PSG. Severity of OSAHS, AHI, home oxygen therapy with CPAP or BIPAP, response and compliance should be noted.

The incidence of claims for severe morbidity and death has significantly decreased since release of the practice guideline for management of the difficult airway by the ASA.

B.2. Interpret the following arterial blood gas: pH 7.25; $Paco_2$ 50 mm Hg; Pao_2 58 mm Hg; and HCO_3^- 25 mEq/L on room air.

This blood gas indicates respiratory acidosis and metabolic acidosis with hypoxemia. HCO_3^- 25 mEq per L is a laboratory error. A pH level of 7.25 is acidosis, which may be respiratory, metabolic, or both. If no metabolic abnormality is present, a Pco_2 of 50 mm Hg should produce a pH level of 7.35 (Table 62.1). The difference in pH (7.35 − 7.25 = 0.10) is due to metabolic acidosis. For each 7 mEq per L of acid or base increase, pH changes 0.10 unit in the appropriate direction. A metabolic acidosis of 0.1 unit pH is equivalent to a 7-mEq per L base deficit. The HCO_3^- is expected to be 17 mEq per L (24 − 7 = 17), but a change in $Paco_2$ itself will change the HCO_3^- from chemical equilibrium. Each 10-mm Hg increase in $Paco_2$ from normal increases the HCO_3^- by 1 mEq in acute CO_2 retention and by 4 mEq in chromic retention. Therefore, expect the HCO_3^- to be 17 + 1 = 18 mEq in acute CO_2 retention or 17 + 4 = 21 mEq in chronic CO_2 retention. The blood gas machine provides direct measurement of the pH, $Paco_2$, and Pao_2.

The HCO_3^- is usually derived from an equation or from a nomogram. If a discrepancy is found between the pH, $Paco_2$, and the HCO_3^-, the technical error is usually in the HCO_3^-. It is important to recheck the blood gases according to clinical conditions. A $Paco_2$ of 50 mm Hg indicates alveolar hypoventilation due to decreased minute volume or increased dead space. To interpret the Pao_2, the FIO_2 must be known. A Pao_2 less than 200 Hg may indicate ventilatory failure if the FIO_2 is 1.0. Hypoxia in obese patients is usually caused by increased venous admixture from a decreased ventilation/perfusion ratio as a result of low FRC and hypoventilation. Metabolic acidosis with hypoxemia indicates lactic acidosis from anaerobic metabolism.

Dripps RD, Eckenhoff JE, Vandam LD, eds. *Introduction to Anesthesia: The Principles of Safe Practice*. 7th ed. Philadelphia: WB Saunders; 1988:267–268.

B.3. What is the equation for blood pH?

The Henderson–Hasselbalch equation is:

$$pH = pK + \log \frac{HCO_3^-}{H_2CO_3}$$

The H_2CO_3 concentration is low and cannot be directly measured. Normal blood H_2CO_3 concentration is 0.0017 mmol per L. H_2CO_3 is proportional and not equal to

Table 62.1 Predicted pH at Different $Paco_2$ Levels in the Absence of Metabolic Acid–Base Abnormality.

$Paco_2$	pH (APPROXIMATE)
80	7.20
60	7.30
40	7.40
30	7.50
20	7.60

Each 10-mm Hg decrease in $Paco_2$ from normal increases the pH 0.1 unit. Each 20-mm Hg increase in $Paco_2$ from normal decreases the pH 0.1 unit.

dissolved CO_2. Clinically dissolved CO_2 is used to replace H_2CO_3. Therefore, pK is changed to K_a. Dissolved CO_2 is calculated as αPCO_2; α being the solubility coefficient for carbon dioxide in body fluids, or 0.031 mmol/L/mm Hg PCO_2. For a normal PCO_2 of 40 mm Hg, dissolved CO_2 is calculated to be $40 \times 0.031 = 1.2$ mmol per L. The pK_a is 6.1, but this is variable with temperature and pH. The modified Henderson–Hasselbalch equation is as follows:

$$pH = pK_a + \log \frac{HCO_3^-}{dCO_2} \text{ or } pH = pK_a + \log \frac{HCO_3^-}{0.031 \times PCO_2}$$

Lumb AB. *Nunn's Applied Respiratory Physiology*, 6th ed. Philadelphia, PA: Butterworth-Heinemann; 2005:150–151.

B.4. What are the normal values for blood pK_a, dCO_2, HCO_3^-, and H_2CO_3?

The normal values are pK_a, 6.1; dCO_2,1.2 mmol/L; HCO_3^-, 24 mEq/L; and H_2CO_3, 0.0017 mmol/L.

Lumb AB. *Nunn's Applied Respiratory Physiology*. 6th ed. Philadelphia: Elsevier Butterworth-Heinemann; 2005:149.

B.5. Interpret the following spirometry screening test: VC 2.36 L (expected 3.375 L); forced expiratory volume in 1 second (FEV_1) per forced vital capacity (FVC) 82%; and VC 70% of expected value.

Preoperative spirometric screening reveals mild restrictive lung disease, with no evidence of obstructive lung disease. *VC* is dependent on sex, age, and height. In restrictive lung disease, the VC is less than 75% of the expected value; a value of 70% is consistent with mild restrictive lung disease. The normal *ratio of FEV_1 to FVC (FEV_1/FVC)* is more than 80%; a value of 82% is normal. In obstructive lung disease, the FEV_1/FVC is less than 75%.

Here are some useful approximations: The expected VC in liters of healthy adult males is approximately equal to the height in meters squared. VC is approximately equal to 65 mL per in. or 25 mL per cm height for men, or 52 mL per in. or 20 mL per cm height for women. The *RV* is approximately equal to 30% of the VC.

Flier J, Maratos-Flier E. Biology of obesity. In: Fauci AS, Braunwald E, Kasper DL, et al., eds., *Harrison's Principles of Internal Medicine*. 17th ed. New York: McGraw Hill; 2008:462–468.

B.6. How would you premedicate this patient? Why?

No sedatives or narcotics should be given to an obese, Pickwickian patient as premedication. Light sedation may be administered to an otherwise healthy obese patient, if appropriate monitoring and qualified personnel are available to ensure vigilence. Once respiratory depressants have been administered, supplementary oxygen should be administered to prevent hypoxia from respiratory depression. Current practice is not to give sedatives or hypnotics until these patients are on the operating room table, as part of preparation for painful procedures (e.g., arterial line placement), or airway management (e.g., airway topicalization and cranial nerve blocks V, IX, and X). Even then, emphasis should be on minimal respiratory depression. We believe that a

well-conducted preoperative visit is more important than is sedation. This patient was not sedated before surgery.

When premedication is used, it should be given orally or intravenously, and not intramuscularly, as it may be inadvertently administered into adipose tissue, leading to unpredictable absorption.

B.7. Describe weight-based dosing.

Drugs are dosed in the morbidly obese on the basis of their lipophilicity. *Highly lipophilic drugs* have increased VD for obese individuals relative to normal-weight individuals. Drug doses are calculated on the basis of the patient's TBW. Examples of this group are thiopental, propofol, benzodiazepines, fentanyl, sufentanil, dexmedetomidine, and succinylcholine. *Weakly lipophilic or lipophobic drugs* have unchanged VD. Drug doses are calculated on the basis of the patient's LBW, which is IBW plus 20% to 40% IBW. Examples of this group are alfentanil, ketamine, vecuronium, rocuronium, atracurium, cisatracurium, and morphine sulfate. *Exceptions* are lipophilic drugs with unchanged VD. Drug doses are calculated on the basis of the patient's LBW. An example of this group is remifentanil. In the calculation of weight-based dosing, it is helpful to use Internet calculators. Here is a sample calculation of appropriate dosages in our patient (in bolds are the drugs used).

Demographics: height, 5 ft 4 in. (162.6 cm); weight, 387.2 lb (176 kg); BMI, 66.6 kg per m^2. *IBW*, assuming a large frame, is 134 to 151 lb (60.9 to 68.6 kg). *LBW*, or 120% to 140% IBW is 174 to 196.6 lb (79.2 to 89.2 kg).

Note: IBW can also be derived from Broca's Index (see section A.2).

- *Highly lipophilic drugs (use TBW)*
  - **Midazolam** 2 to 6 mg background sedation for fiberoptic bronchoscopy (FOB)
  - **Dexmedetomidine** 1 μg/kg over 10 minute, followed by 0.2 to 0.7 μg/kg/hour = 176 μg over 10 minute, 35.2 to 123.2 μg/kg/hour for FOB
  - **Thiopental** 4 to 5 mg/kg × 176 kg = 704 to 880 mg bolus for induction
  - **Propofol** 1 to 2 mg/kg × 176 kg = 176 to 352 mg bolus for induction
  - **Fentanyl** 1 to 2 μg/kg = 176 to 352 μg bolus after intubation
  - **Succinylcholine** 1 to 1.5 mg/kg = 176 to 264 mg for intubation
- *Weekly lipophilic or lipophobic drugs (use LBW = 120% to 140% IBW)*
  - **Ketamine** 10 mg/dose for FOB
  - **Morphine sulfate** 10 to 20 mg in divided doses 1 hour before end of surgery
  - **Cisatracurium** 1.5 to 2 μg/kg/minute = 264 to 352 μg/minute infusion
- *Exceptions (use LBW)*
  - **Remifentanil** 0.2 μg/kg/minute = 17 μg/minute

C. Intraoperative Management

C.1. How would you monitor this patient?

In addition to the routine mandated monitors of ECG, noninvasive blood pressure, pulse oximetry, end-tidal carbon dioxide, and temperature, an arterial line is inserted for frequent assessment of blood gases and for continuous blood pressure tracing. An esophageal stethoscope with thermistor is placed in the axilla to monitor temperature, because any device placed in the esophagus may be inadvertently included in the surgical anastomosis. Hourly urine output is evaluated to assess fluid balance. A peripheral nerve stimulator is used to monitor the effects of muscle relaxants. A processed electroencephalogram, such as the bispectral index (Aspect Medical Systems, Inc., Newton, MA), was used to monitor depth of anesthesia.

The advantages of invasive monitoring have to be weighed against the possible complications. Laparoscopic bariatric surgeries have minimal blood loss (typically <100 to 200 mL) and fluid shifts. These are elective cases, and patients are optimized preoperatively. Invasive arterial monitoring is used for the super obese with severe cardiopulmonary disease or poor fit of the noninvasive blood pressure cuff because of the conical shape of the upper arms or unavailability of appropriately sized cuffs. Accurate blood pressure readings may be obtained from the wrist, as it was in this case, or the ankle. Central venous access is typically used when there are difficulties obtaining peripheral access, and was not used here. A pulmonary artery catheter is reserved for patients with documented pulmonary hypertension, cor pulmonale, or left ventricular failure.

C.2. The ASA's Difficult Airway Algorithm provides a guideline for management of the difficult airway. How do the comorbidities of MO and OSA modify implementation of the algorithm?

The ASA's Difficult Airway Algorithm provides a guideline for management of the difficult airway. It was created by a panel of experts under the direction of the ASA in 1993 and modified in 2003. Implementation of the Algorithm will be altered in different patient populations, according to factors such as patient demographics, comorbidities, surgical requirements, equipment availability, presence of additional personnel, and probably most importantly, the skill set of the anesthesiologist.

In the severely obese patient population, with demonstrated or suspected OSA, the following considerations are relevant: patients are "full stomach" by demographics, they are vulnerable to precipitous apneic deoxygenation, the standard airway assessment may not be sufficient, there is a higher incidence of DMV and DI, and redundant adipose tissue may obstruct the line of sight on laryngoscopy.

In this patient population, the Difficult Airway Algorithm is biased toward awake techniques, traditional preoxygenation is preferable to fast track (4 breaths), and extra precautions should be taken prior to induction of anesthesia. These include recruitment of additional experienced personnel during the induction of anesthesia, immediate availability of the full complement of noninvasive and invasive airway management devices, including an unopened tracheostomy set.

C.3. How would you induce anesthesia? Describe the intubation technique.

This patient should be seen before arriving in the operative suite to ascertain nothing by mouth status, and a large bore intravenous access inserted. Nonsedative premedication, such as glycopryollate (0.4 mg), an anticholinergic used to dry the upper airway, and metoclopramide, a prokinetic, may be given in the operative suite to increase gastric emptying, because peak effects occur in approximately 45 minutes. The full complement of alternate airway, noninvasive and invasive (e.g., cricothyriodotomy set and surgical tracheotomy set) airway devices should be available.

On arrival in the operating room, the patient is placed on monitors, and given supplemental oxygen. Sedation is administered with very small doses of midazolam (4 mg), dexmedetomidine, a centrally acting α_2 agonist at the usual dosage range (1 μg per kg over 10 minutes, followed by 0.2 to 0.7 μg/kg/hour TBW), and incremental ketamine (10 mg per dose) as needed, titrated to have an awake, sedated cooperative patient. Dexmedetomidine appears to completely

override the sympathomimetic effects of the other medications. The decision is made to proceed with fiberoptic intubation via an oral route. Extensive oropharyngeal topicalization with 2% lidocaine, hypopharyngeal instillation with lidocaine using a mucosal atomization device, and airway blocks (glossopharyngeal, superior laryngeal, or translaryngeal) would provide excellent conditions. Five percent lidocaine ointment placed on the distal surface of an oral airway with a dollop of lidocaine ointment will come into contact with the mucosa adjacent to the superior laryngeal nerves, providing a suitable alternative to a peripheral block, if the external anatomy is unfavorable. The patient is ready for bronchoscopy when they will tolerate an intubating airway (Williams or Ovassapian) without coughing with a preloaded tracheal tube. Rarely, when anatomic features are unfavorable (e.g., poor mouth opening). fiberoptic intubation is performed via a nasal route. When the vocal cords are visualized, the vocal cords are sprayed with 4% lidocaine prior to entering the trachea. A tracheal tube is carefully passed, the position confirmed via auscultation and capnography. The patient is first anesthetized with high concentration sevoflurane, then switched to desflurane. After confirmation of acceptable chest wall mechanics, cisatracurium (0.2 mg per kg LBW) is given, and mechanical ventilation is initiated.

If the physical examination and past anesthetic record demonstrated easy orotracheal intubation, a rapid sequence intubation could be contemplated using either thiopental (3 to 5 mg per kg TBW) or propofol (2 mg/kg TBW) with succinylcholine (1 to 1.5 mg per kg TBW), with the patient positioned on a ramp.

If the intubating conditions are suboptimal, a noninvasive alternative airway management device is utilized. Both the C-Mac Videolaryngoscope (Karl Storz Endoscopy-America, Inc, Culver City), and the Airtraq Disposable Optical Laryngoscope (Prodol Systems, Spain) are excellent first-line, as well as back-up devices for the MO-OSA patient. They are described in greater detail in section C.5.

The key to success is extensive operator experience, thorough preparation, a helpful assistant, and willingness to return to a direct laryngoscopy when indicated.

C.4. Why is it important to preoxygenate the obese patient? How would you do it? Compare the effectiveness of the four-maximum-breath and 3-minute techniques.

Thorough preoxygenation is important because intubation may take longer in morbidly obese than nonobese patients; moreover, because obese patients have a small intrapulmonary store of oxygen (low FRC), which is rapidly depleted (high oxygen consumption), they are at particularly high risk of hypoxemia.

Maximal total body preoxygenation, or denitrogenation, requires that the patient breathe 100% oxygen for at least 3 minutes in a well-sealed system, to fill the alveolar,

arterial, venous, and tissue spaces, and to obtain a pulse oximeter saturation (SpO_2) of 99% to 100%. This is superior to fast-track preoxygenation, or four-maximum vital capacity breaths. Farmery has created a model to describe the rate of oxyhemoglobin desaturation during apnea. Various preapnea arterial oxygen tensions produce a parallel family of apneic desaturation curves. Not all patients will deoxygenate at the same rate during apnea. In general, the morbidly obese adult desaturates the fastest. The child desaturates next fastest, followed by the moderately ill adult. Only the healthy adult, who desaturates the slowest, recovers from an intubating dose of succinylcholine just as hypoxia ensues.

Drummond et al. have shown that the rate of apneic desaturation after induction of anesthesia is related to the BMI. They suggest that three vital capacity VC breaths of 100% oxygen will allow for 3 minutes of apnea before the onset of hypoxemia. In their study, without preoxygenation, only 1 minute elapsed before significant desaturation occurred. Valentine et al. compared the effectiveness of the four-maximum-breath and 3-minute techniques in elderly patients. They found similar peak oxygen saturation values after preoxygenation with these two techniques. However, a significantly shorter time to all levels of desaturation was associated with the four-maximum-breath method when the patients were kept apneic and exposed to room air. The average times to 90% saturation were $3\frac{1}{2}$ minutes in the four-breath group and $6\frac{1}{2}$ minutes in the 3-minute group. Nakatsuka et al. recommend using pulse oximetry to achieve an Spo_2 of 99% to 100% during induction to ensure maximal oxygen availability and safe duration of apnea (159 ± 60 seconds) in morbidly obese patients. Benumof et al. recommend oxygen insufflation into the pharynx during laryngoscopy through a nasopharyngeal catheter.

Pre-induction CPAP has been advocated both to improve oxygenation, and to decrease atelectasis. Since apnea tolerance time is decreased in both morbidly obese and OSA patients, the triple airway maneuver (mandibular advancement, neck extension, and mouth opening) should be performed if mask ventilation is contemplated.

C.5. There are many new airway devices on the marketplace. Which of these devices have been particularly successful on the morbidly obese or OSA patient?

In the 2003 iteration of the Difficult Airway Algorithm, the Laryngeal Mask Airway (LMA North America, San Diego, CA), the most commonly used supraglottic airway at

the time, was added. Inclusion of the LMA into the Algorithm emphasized that being able to ventilate through a temporary airway: 1) returns the patient to the elective branch of the algorithm, since they are being ventilated and oxygenated, 2) may often is all that was required for patient management, 3) provides a bridge for insertion of a definitive airway. As used in the Algorithm, the "LMA" should not be interpreted as endorsement of any particular manufacturer or product. Since implementation of the first Difficult Airway Algorithm, new and improved Laryngeal Mask Airway products have been developed. There has also been development of new airway devices, and new classes of product lines of other devices.

Many of the devices mentioned in the Algorithm either have fallen into disuse (e.g., retrograde intubation), have been supplanted by newer devices (e.g., tracheoesophageal combitube), or are not commonly utilized by the clinicians (e.g., rigid laryngoscopy). The Algorithm is in need of an update. In addition, there are no large scale studies comparing the performance of the newer devices on either the morbidly obese or OSA populations.

In the intervening period since 2003, there have been several advances in airway management. The first is the advent of affordable, high quality video laryngoscopes. The most promising of these for the severely obese or obstructive sleep apnea (MO/OSA) patient appears to be the C-Mac. The C-Mac is a videolaryngoscope based upon CMOS (complementory metal oxide semiconductor) technology, similar to a cell phone camera. The C-Mac is an unchannelled device, with high quality optical resolution, and may be used either for direct laryngoscopy, like a traditional laryngoscope, or indirect laryngoscopy. Digital photographs or videclips may be easily taken by the laryngoscopist with the C-Mac. Other unchannelled videolaryngoscopic devices, which have been used for this population include the GlideScope and the McGrath videoscope (Shippey). Although glottic visualization is frequently successful, intubation may be problematic, and right palatopharyngeal arch perforation has been reported secondary to blind insertion of the tracheal tube from the back of the pharynx to resurfacing within the camera's visual field at the laryngeal inlet. This complication is more likely to occur when lateral pharyngeal wall crowding occurs, as in MO with jowls, or severe OSA.

The second advance in airway management is the development of a new class of airway device: the channeled, disposable optical laryngoscope. The Airtraq (Prodol Systems, Spain) is the only device in this category. This device has been very successful in the MO/OSA patient. Advantages include portability, being able to intubate in a semi Fowler position "face-to-face", high retention success rate for the novice or infrequent practitioner, and being an excellent conduit for FOB. Intubating may be accomplished in a neutral neck position with little mouth opening.

The third advance in airway management is the development of better airway "bridges" and short-term ventilatory support devices. The LMA Fastrach, or intubating LMA (LMA North America, San Diego, CA), provides a method of oxygenating and ventilating while obtaining a definitive airway. The I-Gel (Intersurgical Complete Respiratory Systems, Berkshire, UK) provides cuffless, high quality perilaryngeal airway with a gastric decompression lumen. The LMA Supreme (LMA North America, San Diego, CA) is a supraglottic airway salvage device with a gastric decompression port that incorporates features of the LMA Unique, ProSeal and Fastrach.

Older propriety rigid laryngoscopes (e.g., Bullard Elite Laryngoscopes [Circon ACMI, Racine, WI], UpsherScope Ultra [Mercury Medical, Clearwater, FL] Wu Scope [Achi Corp, Fremont, CA] have been used effectively on morbidly obese patients. Of the rigid laryngoscopes, the Bonfils Retromolar Intubating Fiberscope [Karl Storz Endoscopy-America, Inc, Culver City]) has the best optical resolution, and is particularly helpful in cases with limited mouth opening. A tracheoesophageal Combitube (Tyco, Bermuda) is a useful airway salvage device in the morbidly obese patient.

The final advance in airway management is the development of high quality, single-use metal laryngoscope blades, which appear to have superior success rates compared with reusable metal laryngoscope blades in rapid sequence induction (RSI) of anesthesia (Amour). For the MO/OSA patient with a challenging airway, FOB remains the gold standard. FOB has substantial limitations, however, such as limited availability, a long learning curve, a low retention rate, equipment fragility, longer set up time, longer intubation time, and few absolute indications (mostly lower airway pathology). As the advanced airway management devices improve, and clinician experience grows, the need for FOB should continue to decline.

C.6. How would you maintain general anesthesia? What agents would you choose?

Although the ideal maintenance anesthetic for morbidly obese patients undergoing laparoscopic surgical procedures is a matter of some discussion, there is support in the literature for a technique comprising insoluble anesthetic gases resistant to metabolic degradation and without lipid depot compartmentalization, combined with rapid return of airway reflexes, plus intravenous agents that are either hydrophilic, spontaneously degrade in vivo, or are ultrashort acting.

Of the potent inhalation agents, desflurane has several advantages; it is insolubile, has a faster wake-up, a faster return of airway reflexes, and a decreased amount of hepatometabolism. Obesity increases the biotransformation of the inhalation

anesthetics, resulting in increased serum toxic products of metabolism. Because of the frequent presence of coexisting liver dysfunction in the morbidly obese (75% have hepatic steatosis, and 25% have severe hepatic dysfunction), and the absence of a clear correlation between liver function tests and hepatic dysfunction, it would seem logical to use the agent with the lowest percentage of hepatometabolism, desflurane (0.02%), compared with isoflurane (0.2%), and sevoflurane (4% to 5%). An agent with a low blood–gas solubility coefficient is better because there will be a smaller body reservoir available for metabolism, and a faster time to steady state at the target organ, the brain. Of the inhaled agents, desflurane has the fastest wake-up, which is followed by sevoflurane, then by isoflurane. Desflurane also has the fastest return of airway reflexes, followed by sevoflurane.

Although nitrous oxide, a weak inhalation anesthetic, has certain advantages, such as a low blood–gas solubility coefficient (0.46), it is not recommended for maintenance use, because it causes intestinal inflation and is emetogenic. Nitrous oxide use is contraindicated with preexisting severe pulmonary hypertension, a condition more common in the severely obese. Short duration use of nitrous oxide, particularly during the surgical closure facilitates offset of relatively lipid soluble agents.

Remifentanil is the intraoperative narcotic of choice because of its rapid onset, consistent profile, and rapid offset. Although it is lipophilic, it has a half-life of 5 minutes, and therefore never enters the lipid compartment. Remifentanil has an equal volume of distribution (VD) calculated as LBW, relative to normal-weight individuals. It is dosed by infusion, starting at 0.2 μg/kg/minute LBW. The lipophilic opioids, fentanyl and sufentanil, that are dosed by TBW, and may cause delayed respiratory depression in the high-risk patient, especially OSAHS, are less than ideal.

C.7. Which muscle relaxants would you use?

Severe obesity, per se, does not increase the risk of "full stomach." Although peak gastric volume is increased, the rate of gastric emptying is identical to that of the non-obese. Hence fasted obese patients should not be at increased risk of aspiration. Co-morbidities such as gastroesophageal reflux, hiatal hernia, peptic ulcer disease, esophageal pathology, and gastroparesis, however, may increase risk of aspiration.

The risk of aspiration must be weighed against the risk of loss of airway. MO/OSA increases the risk of DMV. Modified RSI has the advantage over RSI of allowing confirmation of ability to mask ventilate, prior to administration of muscle relaxant. Once a muscle relaxant is administered to a severely obese patient, there should be the expectation that should mask ventilation be difficult, the airway must be secured, and adequate spontaneous recovery may not occur prior to the onset of severe hypoxemia. This includes succinylcholine, with a wake up time of approximately 10 minutes, following an intubating dose. Smaller than ideal doses may lead to suboptimal intubating conditions, with attendant risks, such as laryngospasm. If a patient who has received a muscle relaxant cannot be intubated, and can only be marginally ventilated, succinylcholine is a better choice than rocuronium, since adequate spontaneous recovery is much faster.

Succinylcholine and rocuronium are the choices for RSI and modified RSI. Succinylcholine is dosed by TBW, because the plasma cholinesterase activity increases in proportion to the BMI. Rocuronium is dosed according to the LBW. Once the neuromuscular reversal agent sugammadex becomes available, a fast-acting nondepolarizing agent such as rocuronium will become a safe alternative to succinylcholine. Rocuronium has a poor dose response curve, and, like vecuronium, undergoes enterohepatic recirculation, and is metaqbolized by the liver. In a patient population with a high incidence of hepatic steatosis, rocuronium is not an ideal choice.

When an awake technique is chosen for securing the airway, a nondepolarizing muscle relaxant may be administered once tracheal intubation has been confirmed. For maintenance of anesthesia, cisatracurium is the preferred muscle relaxant. It is dosed by IBW plus 20% to 25%, or LBW. It has a predictable dose–response curve, and no prolongation of recovery due to organ-independent recovery or Hoffman elimination.

Dense muscle relaxation is required for laparoscopic bariatric surgical procedures, to facilate ventilation, to maintain adequate space for visualization and manipulation of the surgical instruments, and to permit the introduction of surgical instruments and the removal of excised tissues. Intraoperative contracture of the abdominal musculature, due to inadequate muscle relaxants, may increase intra-abdominal pressure during pneumoperitoneum, driving carbon dioxide out from the inflated abdominal cavity through the trocar sites. The adequacy of intraoperative neuromuscular blockade may therefore be assessed by the anesthesiologist, by following both the train-of-four and the inflation pressures necessary for excellent surgical conditions.

A peripheral nerve stimulator should be used to monitor the extent of relaxation and to avoid underdosing or overdosing of nondepolarizing neuromuscular blocking agents. Extubation should only occur after documentation of full baseline train-of-four ($T_4/T_1 > 0.9$), and return of extubation criteria. Reversal agents should be given in appropriate doses.

C.8. Can regional anesthesia be used intraoperatively and postoperatively to decrease opioid requirements? What are the advantages and disadvantages of regional anesthesia? What are some of the newer techniques available?

Several regional anesthetic techniques may be used intraoperatively and postoperatively to decrease opioid requirements. Thoracic epidural anesthesia and analgesia (TEAA), the best studied of these, has been combined with light general anesthesia, and found by some authors to have a good side effect profile, and to offer advantages over general anesthesia, such as decreased postoperative drowsiness, nausea, and respiratory depression, improved cardiovascular function (decreased left ventricular stroke work index), decreased oxygen consumption, earlier return of lung function, less pulmonary complications, earlier return of gastrointestinal function, and shorter hospitalization times than PCA. Regional anesthesia/analgesia remains underutilized (PCA is >90%) in this patient population, because of the following disadvantages: technical difficulties, logistics (slows operating room case flow), increased incidence of epidural failure and catheter dislodgment, decreased epidural space from intra-abdominal pressure causing unpredictable spread of local anesthetics, variable block level, and increased incidence of wound infection, possibly from microdehiscence. Both patient-controlled epidural analgesia (PCEA) and PCA offer excellent pain reduction scores without respiratory depression when properly used. It is recommended that epidurals be inserted in the sitting position, using ultrasonic guidance. Laparoscopic cases currently comprise approximately 75% of bariatric surgical volume, reducing the need for postoperative analgesic services.

Other regional anesthesia techniques in the morbidly obese, that have been less studied include continuous spinal anesthesia and analgesia (CSAA), and intrathecal opioids (ITO). CSAA may be used with or without general anesthesia. The advantages are the same as for TEAA, except that technique is technically easier, there is a denser block, motor component, and more predictable and controllable dermatomal spread. With all of these techniques, local anesthetic dose is typically 75% to 80% of the dose for the nonobese patient. Local anesthetics and opioids act synergistically at decreased dosages. Respiratory depression is more common using hydrophilic agents (e.g., morphine) than lipophilic agents (e.g., fentanyl). Respiratory depression induced by morphine follows a longer time course (1 to 18 hours) than with fentanyl (minutes to 2 hours). It is important to identify those individuals with risk factors for neuraxial respiratory depression risk factors: excessive or repeated doses, concomittent sedatives or hypnotics, advanced age, demonstrated lack of opioid tolerance, increased intra-abdominal pressure (e.g., pneumoperitoneum), and severe OSAHS patients, who may be at risk for massive pharyngeal collapse. Our patient was not a candidate for regional anesthesia/analgesia for this reason.

Some of the newer techniques available include multimodal perioperative analgesia, nonopioid analgesia, and dexmedetomidine. Multimodal perioperative analgesia, a combination of preincisional local anesthetics, nonsteroidal antiinflammatory drugs and PCA, uses preemptive analgesia. Nonopioid analgesia uses a combination of methylprednisolone, ketorolac, clonidine, lidocaine, ketamine infusion, and magnesium sulfate infusion to decrease side effect profile, and speed recovery. Dexmedetomidine, a centrally acting α_2 agonist, may be used intraoperatively and postoperatively to decrease opioid requirements.

For peripheral surgical procedures, the use of peripheral nerve blocks is advocated in the morbidly obese, provided that adequate landmarks exist.

Relatively few studies exist on the use of regional anesthesia to facilitate postoperative pain management following bariatric surgery. The current emphasis is on fast tracking these patients, by using ultra-short acting agents and agents that minimize postoperative respiratory depression, such as remifentanil and dexmetomidine. Early extubation and ambulation are preferable for all but the highest risk candidates.

C.9. What is the effect of narcotics on the sphincter of Oddi? Is pharmacologic treatment indicated?

Subcutaneously administered morphine, 10 mg, increases the pressure in the common bile duct more than 10-fold within 15 minutes; this effect can be present for 2 hours or longer. Opioids can cause sphincter of Oddi spasm, which can interfere with intraoperative cholangiography. At equianalgesic doses, fentanyl, and morphine cause larger increases in biliary pressure than meperidine or pentazocine. Butorphanol and nalbuphine probably do not cause sphincter of Oddi spasm. Morphine is not a good analgesic choice for biliary tract surgery. Atropine partially prevents opioid-induced biliary spasm. Glucagon, nalbuphine, nitroglycerine, volatile anesthetics, and opioid antagonists, such as naloxone, effectively prevent or prophylax opioid-induced biliary spasm. Glucagon, 1 or 2 mg intravenously, is the drug of choice, and is also used to decrease upper gastrointestinal tract motility (e.g., for endoscopic procedures). The only common side effects are slight increase in heart rate, and transient hyperglycemia.

C.10. During surgery, arterial blood gases showed pH 7.35; Pao_2, 57 mm Hg; $Paco_2$, 52 mm Hg; FIo_2, 0.6; mechanical ventilator V_T, 1.0 L; and ventilatory rate, 15 breaths per minute. The following changes were made to the ventilatory parameters: 10 cm H_2O positive end-expiratory pressure (PEEP) was added, and the V_T was increased to 1.2 L. Twenty minutes later, an arterial blood gas showed pH 7.32; Pao_2, 55 mm Hg; and $Paco_2$, 55 mm Hg. What is the explanation for these changes?

Both blood gases are significant for respiratory acidosis and hypoxemia. It is important to look at the surgical field, examine the patient, auscultate the chest, and check the position of the tracheal tube to rule out endobronchial intubation, kinking of the

tube, or mucous plugging. While performing a differential diagnosis, it is advisable to increase the FIO_2, ascertain that the level of pneumoperitoneum is less than 20 cm Hg, note the peak airway pressure, hand bag the patient, and consider a bronchial dilator. FOB inspection of the airway through the tracheal tube may be helpful in certain cases. If the patient remains hypoxic despite these efforts, it may be necessary to inform the surgeon, halt the surgical procedure, and remove the pneumoperitoneum while searching for an etiology.

In the absence of life-threatening events, there are several pathophysiologic explanations for these blood gases. Endotracheal tube movement is more common in severely obese patients. Usually, PEEP increases Pao_2, and increased V_T decreases the $Paco_2$. Occasionally, PEEP and increased V_T may paradoxically decrease Pao_2, and increase the $Paco_2$, especially in morbidly obese patients. There are several reasons for this. First, high airway pressure can interrupt pulmonary capillary blood flow at the uppermost portions of the lung at peak inspiration. Since these areas already have high ventilation/perfusion, further decreases in perfusion result in an increase in physiologic dead space (V_D/V_T) and increased $Paco_2$. The impeded blood flow will be redistributed to areas of lung that are not affected by the high airway pressure, resulting in an increase in intrapulmonary shunt (Q_S/Q_T) and a decrease in PaO_2. Second, high airway pressures decrease venous return and CO, which may decrease Pao_2 and increase $Paco_2$. Third, high V_T and high airway pressures may create low lung water pulmonary edema from volutrauma and barotrauma. Fourth, overdistension of the pleura and turbulent airflow may result from excessive ventilator settings. This may precipitate bronchospasm in susceptible patients, such as asthmatics, especially when associated with light anesthesia. Fifth, at excessive airway pressures, there may be rupture of a preexisting bleb or bulla, possibly necessitating chest tube insertion.

C.11. What is apneic oxygenation? Who did the pioneer study?

Draper and Whitehead conducted the pioneer study on apneic oxygenation in 1944. Apneic oxygenation (formerly known as diffusion respiration) is actually caused by mass movement oxygenation. When the lungs are completely denitrogenized with oxygen and the airway is connected to an oxygen source, continuous oxygenation takes place by mass movement. Normally, every minute, 230 mL of oxygen is removed from the alveoli for metabolism and 200 mL of CO_2 is produced and eliminated from the lungs. When a person is apneic, only 10% of CO_2 accumulates in the alveoli,

and 90% of CO_2 stays in the blood as bicarbonate. Consequently, 250 mL of oxygen is removed from the lungs and 20 mL of CO_2 accumulates in the lungs, creating a 230-mL vacuum effect and sucking in oxygen. Carbon dioxide tension continues to rise because no elimination occurs during apnea. The total pressure in the alveoli is constant, so the decrease in PO_2 equals the rise in Pco_2, ranging from 3 to 6 mm Hg per minute. If the patient had been breathing 100% oxygen before respiratory arrest, the starting alveolar PO_2 would be about 650 mm Hg, and therefore, the patient could theoretically maintain Pao_2 above 100 mm Hg for about 100 minutes of apnea provided that the airway remained clear and connected to 100% oxygen. However, patients will die of severe respiratory acidosis (pH <6.80) before hypoxemia occurs. Moreover, as seen in suffocation, gross hypoxia supervenes after about 90 seconds if apnea with airway occlusion follows air breathing at the FRC. When the airway is patent and the ambient gas is air, gross hypoxia supervenes after about 2 minutes of apnea, as seen during intubation without preoxygenation. However, if the patient is preoxygenated for 3 minutes, gross hypoxia will not occur until 6 minutes of apnea for normal-weight patients and until about 3 minutes of apnea for morbidly obese patients. Apneic oxygenation is an older technique that is not recommended for morbidly obese patients. Aside from hypoxia and hypecarbia, it may lead to atelectasis, or derecruitment of West Zone 3.

A much more useful maneuver in severely obese patients is to utilize one hundred per cent oxygen and PEEP, during both induction and emergence from general anesthesia.

C.12. What is diffusion hypoxia? How do you prevent it?

Fink and colleagues in 1954 first reported diffusion hypoxia during recovery from nitrous oxide-oxygen anesthesia. A mild degree of hypoxia can develop for more than 10 minutes when nitrous oxide-oxygen anesthesia is concluded and the patient is allowed to breathe room air. The arterial oxygen saturation can fall 5% to 10% and often reaches values less than 90% (Pao_2 <60 mm Hg). This occurs at the times when nitrous oxide is eliminated rapidly through the lungs. Nitrous oxide is 35 times more soluble in blood than nitrogen. Therefore, the amount of nitrous oxide diffused from blood to alveoli is much more than the amount of nitrogen diffused from alveoli to blood. Hence, alveolar oxygen is diluted by nitrous oxide. Diffusion hypoxia can be prevented by the inhalation of high concentrations of oxygen for several minutes before the patient is allowed to breathe room air.

Diffusion hypoxia should not be allowed to occur in obese patients. There is no room for deep extubations in the MO/OSA patient. Patients should be fully awake, with baseline respiratory function. All anesthetics and analgesics, with the possible exception of dexmedetomidine, should be stopped. Many of the newer anesthesia

ventilators allow the use of pressure support ventilation during the emergence phase, which minimizes atelectasis. One hundred percent oxygen prior to, and during, extubation followed by a tight fitting face mask with pressure support, aids the patient in re-establishing ventilatory function, and assists in removal of trace anesthetic gas, until the patient is fully recovered.

D. Postoperative Management

D.1. When will you extubate this patient? What are the extubation criteria?

In the past, prophylactic ventilatory support throughout the first postoperative night was occasionally utilized for the morbidly obese OSAHS or OHS patient having an open abdominal weight reduction procedure. Currently, this is rarely the case; due to the huge yearly increases in the number of bariatric surgeries in the United States (16,000 in the early 1990s, to 200,000 in 2010), advanced laparoscopic experience of the surgeons, and advances in the anesthetic care of the morbidly obese, most patients are extubated in the operating room at the conclusion of surgery as soon as the following extubation criteria are met:

- Intact neurologic status, fully awake and alert, with head lift greater than 5 seconds
- Hemodynamic stability
- Normothermia. The core temperature is above 36° C.
- Train-of-four (TOF) reversal documented by peripheral nerve stimulator (T_4/T_1 >0.9). Full reversal of neuromuscular blocking agents.
- Respiratory rate (>10 and <30 breaths per minute)
- Baseline peripheral oxygenation, as judged by pulse oximeter (SpO_2 >95% on FIO_2 of 0.4).
- Rarely, if an arterial line is present, an arterial blood gas may be checked. Acceptable blood–gas results (FIO_2 of 0.4; pH, 7.35 to 7.45; PaO_2, >80 mm Hg; $PaCO_2$, <50 mm Hg).
- Acceptable respiratory mechanics: negative inspiratory force (NIF) (>25 to 30 cm H_2O; vital capacity (VC) >10 mL/kg IBW; V_T >5 mL/kg IBW).
- Acceptable pain control
- No demonstrated or suspected laboratory abnormalities

Extubation criteria should be used systematically in obese patients. In all cases, an attending anesthesiologist with advanced airway skills must be in attendance for extubation. Emergency tracheal reintubation may be necessary. Patients with documented difficult airway should be extubated per protocol. Patients with OSAHS, OHS, and the PS have higher incidence of postoperative respiratory dysfunction. They require special attention before and after extubation, and occasionally warrant a monitored bed for observation.

D.2. What are the major early postoperative complications in the morbidly obese patient? How do health-related risks correlate with obesity? What factors correlated statistically with perioperative mortality?

The major early postoperative complications in the morbidly obese are mostly related to the pulmonary and cardiovascular systems. Postanesthetic hypoxemia, respiratory depression, early ventilatory failure with need for reintubation, positional ventilatory collapse, hemodynamic instability, postoperative nausea and vomiting, and venous thromboembolism are some common examples. Early surgical complications include anastomotic closure with bowel obstruction, anastomotic leak, surgical bleeding, internal hernias with incarcerated bowel and wound infection.

At any given weight, the perioperative risk is greater for central obesity than for peripheral obesity, and for patients with preexisting severe comorbidity, especially OSAHS.

The major perioperative risk of death correlates statistically with BMI, preexisting hypertension, pulmonary embolus, and anastomotic leak.

D.3. How does position affect respiratory function in the obese patient?

In the supine position, intra-abdominal contents shift the diaphragm rostrally resulting in diaphragmatic dysfunction, decreased FRC, airway closure, increase in venous admixture (Q_S/Q_T), decreased Pao_2, and possibly positional ventilatory collapse. The FRC increases 30% in obese patients by changing from the supine position to the sitting position, both in nonsurgical and postlaparotomy patients. Recovery should take place in a semi-Fowler position (head up at an angle of 30 to 45 degrees) as soon as these patients are hemodynamically stable. Other benefits of a semisitting position are decreased superior vena cava pressure, decreased incidence of positional injuries, which are more common in the morbidly obese. Patients recovered in the semi-Fowler position, who are in need of eventual emergent mask ventilation or tracheal reintubation, present better conditions for the laryngoscopist. There is a higher incidence of tracheal tube misplacement in the morbidly obese; care should be taken when positioning these patients in a semi-Fowler position.

Brodsky JB, Lemmons HJ, Brock-Utne, et al. Anesthetic considerations for bariatric surgery: proper positioning is important for laryngoscopy. *Anesth Analg.* 2003;96:1841–1842.

D.4. How would you prevent postoperative atelectasis?

In the past, bariatric surgical procedures were often performed open, with an incidence of postoperative atelectasis of 45%. Approximately 75% are now performed laparoscopically, so the incidence would be expected to decline substantially.

Early ambulation, chest physical ambulation with incentive spirometry, and effective coughing are encouraged to improve respiratory function. Prolonged recumbency is avoided whenever because of its adverse effects on the ventilation/perfusion ratio. Careful titration of postoperative analgesics is emphasized to prevent splinting from pain and hypoventilation from excessive sedation.

Schumann R, Jones SB, Cooper R, et al. Update on best practice recommendations for anesthetic perioperative care and pain management in weight loss surgery 2004–2007. *Obesity (Silver Spring).* 2009;17:889–894.

D.5. How long would you prescribe supplementary oxygen postoperatively?

The incidence of postanesthetic hypoxemia (Pao_2 <60 mm Hg) is increased from a baseline of 25% to 30% in the nonobese to 75% in the obese. For a routine case on an otherwise healthy patient with simple obesity, supplemental oxygen in the PACU is probably sufficient. In most morbidly obese patients with comorbidities, oxygen should be prescribed for 24 to 72 hours. The morbidly obese patient with severe OSAHS on CPAP or BIPAP will usually have continuation of their therapy overnight, be recovered in a semi-Fowler position (at an angle of 30 to 45 degrees) and should have individualized care, with continuous pulse oximetry, and respiratory monitoring. At The New York-Presbyterian Hospital, most of these patients are discharged to home on the third or fourth postsurgical day.

D.6. How would you control postoperative pain?

In more than 90% of bariatric surgical procedures, analgesia is provided postoperatively by parenteral narcotics using patient-controlled analgesia (PCA), as it was for our patient. PCA has been shown to be safe and effective in the morbidly obese patient population. It has many advantages: PCA is simple to use, saves nursing time, involves minimal time delay between patient perception of pain and therapy. There is less splinting and PFTs return early. PCA also facilitates early ambulation and shortens hospital stay. Dosing of morphine, the gold standard, needs to be individualized. Hydromorphone is also frequently used. Dose regimens need to be individualized, according to pain control and side effect profile. There have been some cases of respiratory complications in the MO-OSAHS patient, so extra viligence is needed in this group. PCA dosages for the morbidly obese in the opioid naïve, based on IBW, are as follows:

- Morphine sulfate 20 μg/kg IBW
- Hydromorphone 4 to 5 μg/kg IBW
- Fentanyl 1 μg/kg IBW
- Methadone 20 μg/kg IBW

All settings are every 10 minutes, without continuous rate, at 80% of the calculated maximum doses. Although the opioids have different lipid solubilities, PCA doses were originally formulated using IBW, and this practice has not changed. As we are titrating to individual patient satisfaction, there is room for post-treatment dose modification.

Intravenous infusions of opioids may also be administered in a monitored setting. In the past, opioids have been administered intramuscularly. Although this route has been shown to be effective, intramuscular injection is not advisable in the morbidly obese, because of unpredictable pharmacodynamics, arising from inadvertent injection into lipid tissue.

There are three regional anesthetic/analgesic options: TEAA/PCEA, ITO, and continuous spinal anesthesia/patient-controlled intrathecal analgesia (CSA/PCIA). All of these may be used intraoperatively with or without light general anesthesia (GA). They offer similar side effect profiles and will be described together. *PCEA*, the most commonly used of these, has numerous theoretical advantages. At a lower dose compared with parenteral opioids, there are few side effects and serious complications, effective analgesia, faster recovery, less respiratory complications, decreased total body oxygen consumption, improved cardiac function (decreased left ventricular stroke work index [LVSWI]), and shorter hospitalization times compared with PCA. PCEA dosages in the morbidly obese should be decreased 75% to 80%, due to decreased volume of the epidural space from increased intra-abdominal pressure. PCEA is strongly recommended when feasible, yet remains underutilized. Patients should be positioned in a sitting position for epidural catheter insertion, and ultrasonography guidance is recommended. Disadvantages include a higher rate of wound infection, possibly because of microdehiscence from faster return of gastrointestinal function, and the risk of neural injury. There is frequent technical difficulty with catheter insertion, which slows operating room case flow. There is a higher rate of inadequate function, catheter migration and replacement, and variable block height. Side effects include excessive drowsiness, postoperative nausea and vomiting, pruritis, and urinary retention. Respiratory depression occurs rarely, and is more common with hydrophilic (e.g., preservative-free morphine sulfate [PFMS]) than with hydrophilic agents. With PFMS it may occur from 1 hour until 18 hours. With fentanyl or sufentanil it may occur from minutes until 2 hours. Neuraxial opioid respiratory depression risk factors include advanced age, excessive or repeated doses, lack of opioid tolerance, use of concomitant sedatives or hypnotics, increased intra-abdominal pressure (e.g., pneumoperitoneum), and severe OSAHS, which may precipitate massive pha-

ryngeal collapse. *CSA/PCIA* with light GA has been used for gastroplastic surgery. It is technically easier to perform than TEAA/PCEA, and produces a denser block with motor component, which is more predictable and controllable. *IT* opioids, with or without local anesthetics, are technically easier to administer, and offer an excellent alternative for appropriate surgical procedures. Other methods of controlling postoperative pain in bariatric surgery include preemptive analgesia through local anesthetic wound infiltration before and after surgery, pre- and intraoperative nonopioid drug combination (ketorolac, clonidine, lidocaine, ketamine, magnesium sulfate, and methylprednisolone), and perioperative dexmedetomidine.

hyperammonemia in, 641f, 642, 643f
hyponatremia in, 634, 637–638
on cardiovascular system, 638
neurologic symptoms of, 638
rapid correction of, 640
saline for, 640
hypotension in, 646
hysteroscopy symptoms *vs.*, 644
intravenous fluid in, 629
irrigation solution in
absorption mechanisms in, 634, 635f
absorption of, on cardiopulmonary, renal, and central nervous systems, 636, 637f
distilled water as, 631
estimating absorption of, 634–635

Transurethral resection of the prostate (TURP), after MI *(continued)*
sodium ions in, 637–638
types of, 630–631
monitoring in, 628
regional *vs.* general anesthesia on mortality in, 629
restlessness and incoherence in, 630
sodium ions and, 637
TURP syndrome in, 632–633, 633f
duration of surgery and, 634, 635f
factors in, 636
prophylaxis against, 639
signs and symptoms of, 630
treatment of, 639–640
laser, 648
monopolar, 647
postoperative management of
bacteremia in, 646
hypothermia and MI risk in, 647
perioperative MI diagnosis in, 647
post-TURP septicemia in, 646
shock in, bacteria-related, 646
preoperative evaluation and preparation for, 625–628
antihypertensive and antianginal medications in, 625
antiplatelet therapy in
perioperative risks with, 627
recommended, 626–627
cardiac condition in, 625
coronary angiography in, 625
coronary stents and, 626
with implantable cardioverter-defibrillator, 626
Q-wave *vs.* non–Q-wave infarction on reinfarction risk in, 625
stents in, approach with, 627–628
Trauma, 1221–1244
airway and breathing evaluation in, 831
circulation evaluation in, 831–832
diagnostic tests in, 832–833
disease and differential diagnosis of, 1223–1231
acute pericardial tamponade in
anesthetic implications of treatment of, 1224
complications of, 1223–1224
blunt abdominal trauma injuries in, 1227
classification in, 1223
diagnostic peritoneal lavage in
contraindications to, 1228
definition and use of, 1227–1228
focused abdominal sonography for trauma in, 1227
hemorrhage in, classification of, 1229
hemothorax in
massive, 1225
signs and symptoms of, 1225
thoracotomy for, 1225
initial assessment and management in, 1224
injuries with
in cardiac trauma, 1223
in thoracic trauma, 1223
mediastinum widening in, 1226–1227
pneumothorax in
categorization of, 1225–1226
occult, 1226
primary survey in, 1224–1225
secondary survey in, 1225
shock in
definition of, 1228
signs and symptoms of, 1229
types of, 1228
shock in, hemorrhagic (hypovolemic), 1228–1230
crystalloid *vs.* colloid therapy for, 1230
definition of, 1228
dextran or hetastarch for, 1231
hypertonic saline for, 1231
initial treatment of, 1230
pathophysiology of, 1229
thoracic aortic injury in, 1226–1227
initial assessment of, 831
intraoperative management of, 1232–1242
anesthesia induction in, 1232
anesthesia maintenance in, 1233
blood product transfusion guidelines in, 1239–1240
blood transfusion in, 1239
complications of, 1235–1236
on immune system, 1239
in Jehovah's witness, 1241–1242
in Jehovah's witness child, 1242
massive, complications, 1237–1238
massive, defined, 1237
massive, plasma to packed red blood cell ratio in, 1241
with type O RH-negative un–cross-matched whole blood, more than 2 units, 1235
without type and cross-match, 1234–1235
hypothermia in
adverse effects of, 1238–1239
definition of, 1238
treatment of, 1239
intraoperative awareness in, decreasing, 1233–1234
monitoring in, 1232

muscle relaxant in, 1233
oxygen–hemoglobin dissociation curve, quantifying shift in, 1238
peak airway pressure increase in, 1234
single-lung ventilation in, 1233
tension pneumothorax in
diagnosis of, 1234
treatment of, 1234
mental status and neurologic condition in, 832, 832t
postoperative management of, 1242–1244
acute lung injury in, 1242
acute respiratory distress syndrome in
definition of, 1242
treatment of, 1243
oliguria in, 1243–1244
rhabdomyolysis in, 1244
preoperative evaluation and preparation for
premedication in, 1231
tests in, 1232
