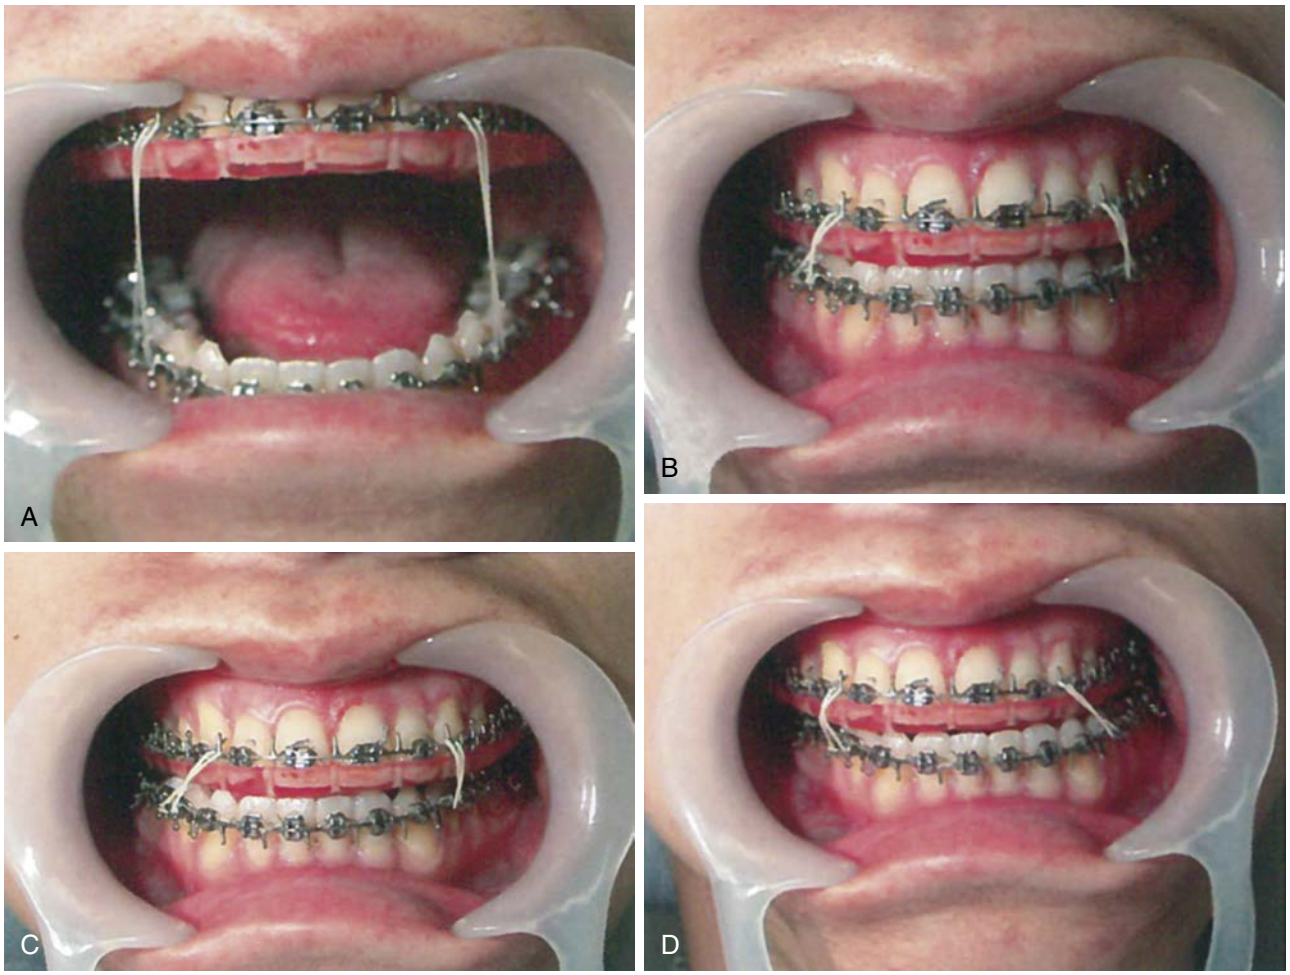
Given the lesser degree of complexity of the IVRO as compared to the SSRO, the incidence of permanent IAN paresthesia is much less. Recent studies have shown faster recovery of IAN sensation after IVRO compared to SSRO.[95,96] The IAN is not subject to stretching injury with the IVRO and the saw blade usually remains in less proximity to the nerve canal. Studies comparing long-term sensory disturbance after SSRO versus IVRO support this finding.[97,98] Many surgeons believe the incidence of permanent IAN paresthesia after IVRO is close to zero. The nature of subjectivity complicating neurosensory testing is likely the reason studies reporting the incidence of long-term sensory deficit after IVRO range from 0% to 30%.

Other Complications

In regards to infection and edema, there exists little difference in incidence or management of these complications when comparing the IVRO and SSRO. There are, however, certain more infrequently occurring complications specific to the IVRO. Inadvertent bone cuts may decrease the amount of bony contact between poorly overlapping segments and predispose to segment malpositioning. Medial displacement of the proximal segment or dorsal positioning may lead to unplanned changes in the appearance of the angle region and possibly lead to chronic pain. This arrangement may lead to impingement of the IAN with associated neurosensory deficit, but does not seem to impede eventual bony union.[99] Although one should strive for healthy intersegmental overlap, malunions and fibrous unions are exceedingly rare after the IVRO. Complete stripping of all soft tissue at the angle of the mandible has generated concern for the possibility of avascular necrosis of the proximal segment and should be avoided. In some cases where the tip of the proximal segment curves laterally or in cases where there is a large distance between the vascularity from the condyle area, the lower 5-7 mm of the proximal segment is removed to allow passive overlap of the segments.

There exists a significant potential for bleeding while performing the cephalad extension of the osteotomy.



• **Figure 5-26** Basic movements of the mandible required for postoperative active physiotherapy. **A,** Hinge opening movement. **B,** Protrusive excursion movement. **C** and **D,** Lateral excursion movement of the mandible.

Overpenetration through the medial cortex with the oscillating saw could potentially lacerate the internal maxillary artery as it courses medial to the ascending ramus. Another pitfall for hemorrhage during the IVRO exists where the masseteric artery passes through the sigmoid notch, making soft tissue retraction with a well-placed Bauer retractor critical for adjusting the depth of the saw cut as one moves superiorly.

Acknowledgments

The authors wish to acknowledge the previous edition's authors, Dr. Ingeborg M. Watzke and Dr. Hyung-Sik Park, for their previous contributions to this chapter.

Genioplasty

RISHI JAY GUPTA, DAVID S. PRECIOUS, STEPHEN A. SCHENDEL

Introduction

Surgical alteration of the chin is an important aspect of achieving or restoring global facial balance in the management of dentofacial deformities. Genioplasty is performed to restore muscle function and osseous anatomy of the anterior mandible. Cephalometric and three-dimensional (3D) analysis enables the clinician to assess the various components of the dentofacial complex, including the chin. In current practice, the two common genioplasty techniques include augmentation with an alloplastic implant or osteotomy and/or ostectomy.

Each technique has its benefits and limitations. Chin alloplastic implants have limitations when addressing vertical bony excess and improving muscle function and strain. However, chin alloplastic implants can facilitate lateral contour augmentation, which can be a problem when chin osteotomy is performed alone. Various genioplasty techniques by osteotomy-ostectomy have been described in the literature, which include sliding genioplasty, functional genioplasty with creation of a tenon and mortise, and sagittal split genioplasty. Osseous genioplasty is an osteotomy-ostectomy of the anterior mandible that helps maintain the lower anterior facial height to 55% of total anterior facial height. This procedure is indicated particularly when the long-face syndrome is caused by bony excess of the anterior mandible. Superior repositioning and advancement of the chin and myocutaneous structures produce both functional and esthetic benefits for the patient. Osseous genioplasty not only corrects cosmetic deformities and vertical height of the chin, but it also ameliorates hyperactivity of the mentalis muscle complex and improves obstructive sleep apnea syndrome through the advancement of the genioglossus muscle and genial tubercle complex. Anatomic placement of fixation devices used in genioplasty is an important long-term consideration.

Functional Genioplasty

The term *functional genioplasty* seems to represent something of a paradox because, in the past, surgery on the chin has been thought of primarily in the context of cosmetics. In humans, changes in form produce attendant changes in function; the functional genioplasty is an example of an operation that can bring about a beneficial change in function by altering the position and form of the chin and its associated myocutaneous structures.

The maxillary component of vertical excess of the anterior face has been described in detail with respect to both diagnosis[1,2] and treatment.[3,4] However, less attention has been directed to the anterior mandible as a component of the excessive vertical dimension. Muller[5] has stressed the importance of the state of balance that exists in the normal face between the hard structures of the lower face (namely, the maxilla, the mandible, and the teeth) and the soft tissue elements (namely, the tongue, the labiomental musculature, and the overlying skin). During growth, if the hard tissues and the soft tissues of the lower face are in balance, the lower face will register itself harmoniously in the rest of the face. Artists, among others, have interpreted this harmony as equality in height of the upper face and the lower face.

Subjective clinical impression of facial harmony and symmetry is imprecise. Fields and associates[6] have shown that experienced clinicians poorly categorize underlying skeletal deformities solely on the basis of evaluation of the soft tissue profiles. Wylie[7] demonstrated radiographically that the upper anterior face, measured from nasion (Na) to anterior nasal spine (ANS), constitutes 45% of the total anterior facial height and that the lower anterior facial height, measured from ANS to menton (Me), constitutes 55%. Delaire[8] has confirmed via architectural and structural craniofacial analysis that these percentages represent constants of ideal vertical facial height.

When an anomaly of form and function of the hard or soft tissue elements of the lower face is present during growth, it affects the neighboring structures, which together can produce a progressive regional disequilibrium until maturity is reached. This is demonstrated in cases with excessive ANS-Me distance in the presence or absence of vertical maxillary excess. The lips become incompetent in repose and no longer oppose the thrust of the tongue, which now can interpose itself between the teeth. To occlude the lips, active contraction of the labiomental musculature is

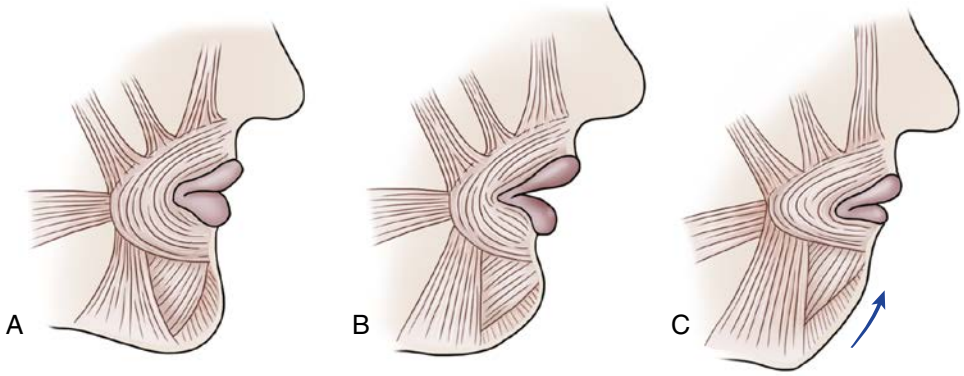
necessary; this, in turn, ultimately causes flattening of the soft tissue contour of the chin and can be associated with dental changes with associated gingival recession (Figure 6-1). On the other hand, deficient ANS-Me distance due to retrogenia or deep bite cause the patient to appear aged due to deep labiomental sulcus and redundant submental tissue. These anatomical discrepancies lead to functional habits that produce clinical problems, which represent the indications for surgical intervention.

Indications

Indications for genioplasty are as follows.

Vertical Excess

Vertical excess of the lower anterior facial height resulting from the anterior mandible requires a reduction genioplasty by removal of a precise amount of bone. A wedge resection and rotation of the inferior chin segment superiorly is the most predictable approach. Anterior advancement is sometimes required because most chins that are vertically long are also retrusive. If the soft tissue remains attached to the inferior border, then the soft tissue change is approximately 90% of the vertical osseous change. The following clinical signs and radiographic findings are present in patients with vertical excess of the lower anterior facial height (Figure 6-2).



• **Figure 6-1** **A,** Normal harmonious labiomental balance with lip competency. **B,** Open mouth posture associated with lip incompetency when labiomental muscles are at rest. **C,** Typical flattening of the anterior surface of the chin due to contraction of the labiomental muscles in an attempt to achieve bilabial contact.

• **Figure 6-2** **A,** Labiomental muscles at rest showing lip incompetency. **B,** Bilabial contact results in flattening of the contour of the chin. **C,** Muscle dysfunction evidenced by "mentalis strain."

Clinical Signs

1. Lip incompetence when the lips are in repose and a normal relationship exists between the maxillary incisor to the upper lip
2. Open mouth posture with interposition of the tongue between the teeth
3. Elevation of the mental soft tissues to obtain lip closure resulting in a strained appearance of the overlying skin on the chin with flattening of the profile and loss of labiomental sulcus
4. Thinning of the alveolar bone overlying the facial surfaces of the roots of the anterior mandibular teeth

Radiographic Findings

1. ANS-Me distance, which constitutes more than 55% of the total anterior facial height, in the absence of vertical maxillary excess
2. ANS-Me distance, which persists in constituting more than 55% of the total anterior facial height after predicted or actual appropriate correction of vertical maxillary excess, open bite, or anteroposterior dentofacial deformities

Vertical Deficiency

The vertical deficiency of the lower anterior facial height constitutes less than 55% of the total anterior facial height. A deep labiomental sulcus and redundant submental tissue may be present. Horizontal osteotomy and inferior repositioning of the chin segment or placement of alloplastic implant are used to vertically augment the symphysis region. The osseous change results in 100% of soft tissue change.

Anteroposterior Excess

Anteroposterior excess can be appreciated with deep labiomental sulcus and lip incompetence. Treatment includes a sliding genioplasty with posterior placement or shaving of the anterior mandible. This discrepancy is the most technically challenging to address. A posterior sliding genioplasty causes the inferior bony component to appear in the facial view, which can be unesthetic. The amount of bony shaving is limited due to concerns of stripping too much soft tissue and muscle from the chin leading to ptosis. Reducing the chin by more than 7 mm indicates significant skeletal disharmony, which may require bimaxillary surgery and shortening of the posterior facial height. This will lead to rotation of the pogonion posteriorly. Generally, soft tissue changes approximately 90% of the amount of bony change with a sliding genioplasty. If the soft tissue is stripped off the anterior mandible, care must be taken to resuspend the mentalis muscle to prevent ptosis of the chin.

Anteroposterior Deficiency

The anteroposterior deficiency of the symphysis region requires augmentation with an advancement osseous genioplasty or alloplastic implant. If the chin is narrow in the transverse dimension, then the face will appear more tapered after an advancement osseous genioplasty. An alloplastic genioplasty can be used for 4- to 5-mm advancements. A sliding genioplasty is used when the goal is to augment both the anterior and vertical dimensions. The soft tissue changes approximately 80% to 85% of the amount of bony augmentation. Furthermore, the anterior bony resorption can occur over time, resulting in 80% of the original bony advancement.

Associated Deformities of the Upper Lip or Cleft Lip/Cleft Palate

Residual and associated deformities of the upper lip or cleft lip/cleft palate, particularly in the case of insufficient cheiloplasty in which the upper lip is too short, can be further improved with a genioplasty. Superior repositioning of the mental osseous and the myocutaneous tissues can aid in achievement of lip competence and development of the upper lip.

Transverse Facial Asymmetries

Genioplasty can be utilized as a complementary procedure to adjust lower anterior facial height and horizontal asymmetry when maxillary and mandibular osteotomies are performed for correction of anteroposterior and transverse maxillofacial deformities. The sliding genioplasty will place the chin midpoint on with the midline of the face and correct asymmetries in the inferior border of the mandible.

Post-Orthodontic Treatment

Genioplasty can aid in stabilization of orthodontic treatment results by normalization of the osseous and myocutaneous elements of the lower face.

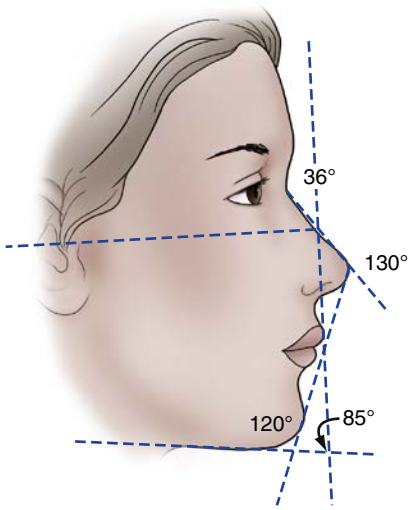
Genioglossus Advancement

The anterior mandible and attached genioglossus muscle are advanced to protract the tongue base, which increases the oropharyngeal space and alleviates obstructive sleep apnea symptoms.

Treatment Planning

A complete architectural and structural craniofacial analysis is carried out to determine the degree to which the individual patient varies from his or her "ideal." This analysis demonstrates all of the maxillofacial deformities and imbalances that require correction. The ideal analysis should also coincide with the clinician's clinical judgment.

Soft tissue esthetics are analyzed using a lateral facial photograph or a lateral skull film. The technique utilizes angles and their relative proportions to compare the major



• **Figure 6-3** Esthetic Soft Tissue Analysis. The following angles are used to analyze the facial profile: nasofacial angle, 30 to 40 degrees; nasomental angle, 120 to 132 degrees; mentocervical angle, 80 to 95 degrees to vertical and 110 to 120 degrees to nasomental line.

soft tissue units of the face[8] (Figure 6-3). The following are the major angles of the normal adult face:

1. Nasofacial angle, 30 to 40 degrees
2. Nasomental angle, 120 to 132 degrees
3. Mentocervical angle, 80 to 95 degrees to the vertical and 110 to 120 degrees to the nasomental line

The angles are formed from five lines. The horizontal line is drawn along the Frankfort horizontal or the true horizontal line from a plumb line on a cephalometric radiograph taken in the natural head position. The vertical line is perpendicular to the horizontal line and is drawn through the glabella or the subnasale. The subnasale point is the preferred location for the vertical line. The third line is drawn tangent to the nasal dorsum and will intersect the vertical line, forming the nasofacial angle. The fourth line is drawn from the nasal tip to the pogonion, called the nasomental line. The nasal dorsal line and the nasomental line form the nasomental angle. The upper lip is 1 to 2 mm behind the nasomental line, and the lower lip is 2 to 4 mm behind the nasomental line. The fifth line is drawn tangent to the menton passing through the innermost curve at the junction of the neck and submental areas. This line will form an angle with the nasomental line and the vertical line.

Some key soft tissue measurements must be evaluated when assessing the lower face. The labiomental angle is formed between the lower lip and chin, and the average value is 110 to 130 degrees. Excessively proclined lower incisor teeth, a prominent chin, and a reduced lower anterior facial height may lead to an acute labiomental angle (deep labiomental sulcus). The normal upper lip length is 21 mm plus or minus 2 mm for men and 19 mm plus or minus 2 mm for women. There should be a ratio of 1:2 when comparing the distance between the subnasale-stomion and stomion-menton. The pogonion is typically 1 to 4 mm behind the vertical line through the subnasale. Hyperfunction of the facial muscles should also be examined to assess for abnormal tissue contours and changes in lip position.

Although the principles and details of the skeletal analysis have been presented in previous articles,[9,10] a brief review is presented here of those points and lines that are relevant to determination of the amount of osseous resection and chin advancement that will be required for a vertically excessive lower facial height at surgery (Figure 6-4).

Line C3

The superior line of the cranial base is traced from point M, the junction of the nasomaxillary and nasofrontal sutures, to point Clp, the apex of the posterior clinoid process; it is extended until it intersects the external surface of the occipital bone at point Op, the most posterior extremity of the occipital bulbosity.

Line CF1

The anterior line of craniofacial balance is traced through point FM, the frontomaxillary articulation, perpendicular to line C3 in adult males but at an angle of 85 degrees in women and children.

Line CF4

The craniopalatal line is traced parallel to line C3 through point ANS, to a point just below the lowest point of convexity of the squamous occipital bone.

Line CF5

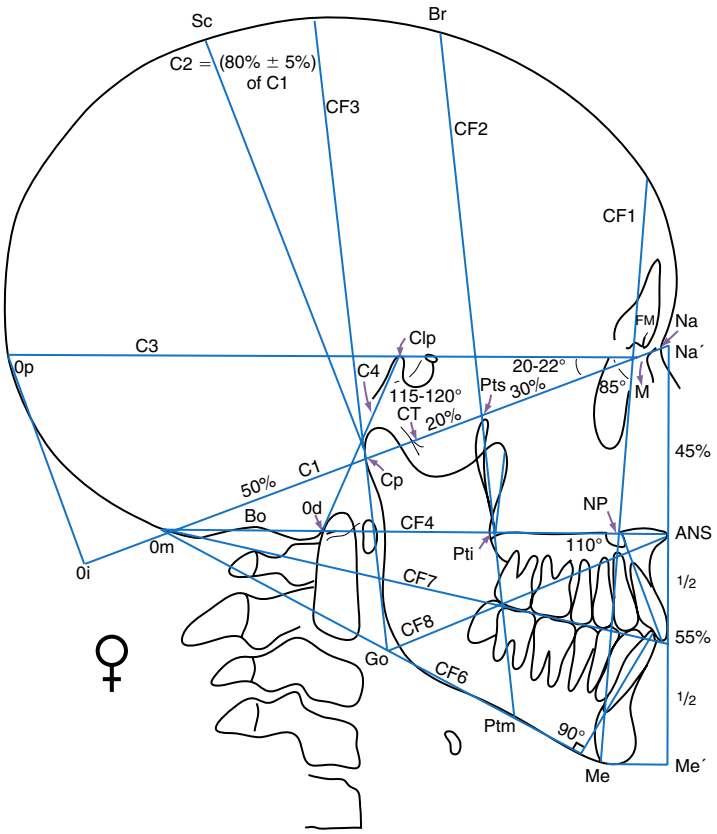
The line of theoretical facial height is traced, by convention, perpendicular to line CF4 through point ANS. It is extended superiorly to point Ná, the projection of point Na, then inferiorly to point mé, the location of which is determined by the following formula:

$$\text{Ideal total anterior facial height} = \text{Ná} - \text{mé}$$
$$\text{Ná} - \text{mé} = (\text{Ná} - \text{ANS}) + (\text{ANS} - \text{mé})$$
$$= 2(\text{Ná} - \text{ANS}) + (2(\text{Ná} - \text{ANS}))/10 \text{ mm}$$

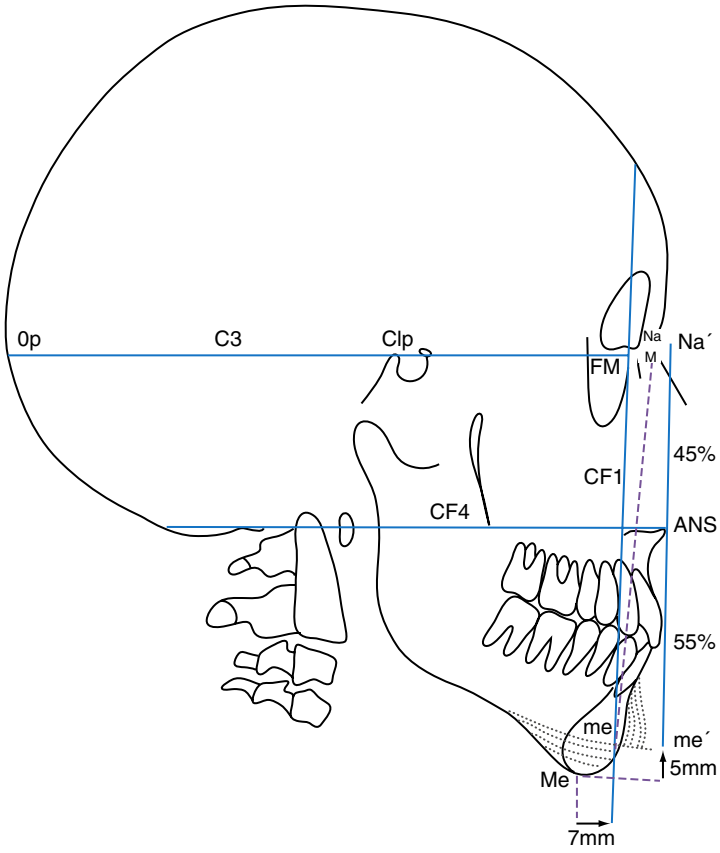
This formula is derived from the fact that the upper anterior facial height, Ná – ANS, constitutes 45% of the total anterior facial height.

Once the Ná – mé distance has been calculated, the arc of a circle (center Na with radius equal to the distance from Ná – mé) is traced via architectural and structural analysis. When this arc intersects line CF1, this is the "ideal" position of menton (point me). Both the amount of bone to be resected for the vertical correction and the distance by which the chin should be advanced can now be determined by comparing the ideal position of menton (me) with that of the patient's real menton (Me) (Figure 6-5).

This tracing maneuver is not valid when vertical maxillary excess, a significant open bite, or important anteroposterior deformities are present. In these cases, it is best to carry out the prediction tracing for correction of the major deformity, after which it is possible to apply the method described above to determine the amount of discrete osseous reduction and advancement of the chin.



• **Figure 6-4** Architectural and structural craniofacial analysis of Delaire.



• **Figure 6-5** Determination of "ideal" position of menton point (*me′*). Broken line represents the radius *(Na/me)* of the circle centered at *Na*. Coarse stippling represents vertical excess of the anterior mandible. Fine stippling indicates predicted contour of the chin, based on 5 mm of superior movement and 7 mm of anterior movement, of existing menton point *(Me)* to position of ideal menton point *(me′)*.

In the particular case of open bite, it is possible to gain an appreciation of the amount of bone that ultimately will have to be resected by tracing the arcs of two circles—one with the center point I (the incisal tip of the mandibular incisor tooth), the other with the center Me (real menton), both with radius (ANS – mé)/2 F002B 3 mm. Three millimeters must be added to the distance (ANS – mé)/2 to account for the depth of overbite that will be present after the open bite itself has been corrected.[11]

The treatment planning discussed thus far entails analysis of two-dimensional images and soft tissue. Advances in spiral 3D computed tomography (CT) scans and computer hardware and software have made virtual 3D craniofacial surgery possible. Various companies have developed protocols to obtain current patient data, which includes CT scan of the face, bite registration, and recent upper and lower dental casts, to provide computer-based virtual planning of the orthognathic cases. This can be used for surgical simulation, planning with morphologic studies, and growth analysis. Based on the final simulated movements, the surgical splints for orthognathic surgery can then be printed. Similarly, genioplasty cutting and plating guides can also be fabricated based on the simulated movements. 3D planning and data analysis will standardize the qualitative and quantitative longitudinal follow-up of patients in different centers and improve treatment outcome.

Surgery

Michelet Genioplasty

The genioplasty surgical procedure described by Michelet and colleagues[12] consists of a horizontal osteotomy of the anterior mandible, with construction by segmental ostectomy of a superior tenon and an inferior, lingual mortise. The resected fragments are wedge shaped by design and thus are perfectly suited for placement as bone grafts in other surgical sites (for example, in the bony defects created by multi-segment Le Fort osteotomy of the maxilla[13]).

This is often called a functional genioplasty and can be carried out as soon as the mandibular permanent cuspid and premolars teeth have erupted, after the age of 12. This procedure is performed, with the patient under general anesthesia, through a mandibular labial vestibular incision, which is extended from one premolar area to the other, after infiltration of local anesthesia with 1:100,000 solution of epinephrine. The anterior aspect of the mandible is exposed via subperiosteal dissection, which stops before the inferior border, thereby preserving the insertions of the labiomental muscles (see Figure 6-5, *A*). Specifically, these muscles include the mentalis, depressor anguli oris, and depressor labii inferioris, and part of the orbicularis oris.

The osteotomy cuts are outlined with a small burr (see Figure 6-5, *B*). The height of the vertical arms of the tenon corresponds to the magnitude of the predetermined bony resection. The inferior horizontal osteotomy then is completed with a reciprocating saw, after which the bicortical tenon is constructed through resection of lateral wedge-shaped pieces of bone (see Figure 6-5, *C*). A mortise now is cut in the mid-superior portion of the lingual aspect of the inferior bony fragment. The depth of the mortise is the difference between the amount of predetermined chin advancement and the thickness of the inferior bony fragment (see Figure 6-5, *D*). The inferior fragment then is advanced and is repositioned superiorly by fitting the mortise on the tenon.

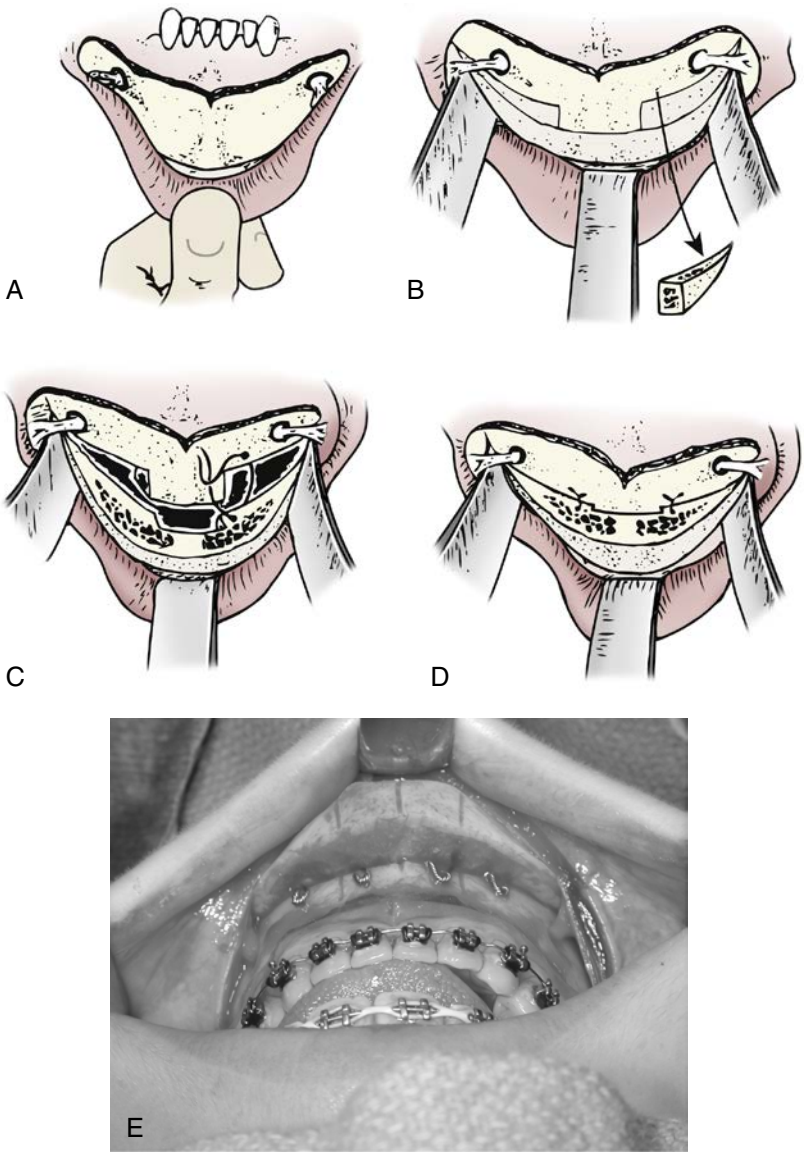
Fixation is accomplished by transosseous wires or single midline screws which are placed to create a directional pull where the anterior inferior mortise is brought into good apposition with the superior and now posterior tenon (see Figure 6-5, *E*). Watertight closure of the vestibular incision is accomplished with 4-0 polyglycolic acid sutures, after which a pressure dressing is placed for 5 days on the skin overlying the mental tissues (Figure 6-6). It is important to stress the simplicity of this technique. Morbidity is minimal, and a very low incidence of alteration in mental nerve function is associated with this procedure.[14]

Sliding Genioplasty

The sliding genioplasty is used for reduction and advancement of the chin (Figure 6-7). Periosteal elevation and muscle detachment are minimized to allow precise and predictable soft tissue repositioning. Long-term radiographic evaluation shows a stable advancement, with minimal bone resorption occurring at the superior edge of the distal segment. Bone deposition occurs near the B point of the alveolus.

This procedure can be done as an outpatient procedure under general anesthesia or with intravenous sedation. The anterior mandibular vestibule is infiltrated with local anesthetic and epinephrine from first bicuspid to first bicuspid. An incision is made from canine to canine on the inner surface of the lip 2 to 3 mm past the sulcus in order to leave an adequate sewing cuff. The initial cut is perpendicular to mucosa. Then, as muscle is transected, the angle of the cut is altered perpendicular to the bone and continued through the periosteum. A subperiosteal dissection is performed just inferior of the planned horizontal osteotomy. At least 5 mm of attached periosteum and muscle are left between the inferior border of the symphysis and the subperiosteal dissection. Detachment of all soft tissue from the distal segment results in chin sagging, retraction of the lower lip, and unpredictable soft tissue changes. Suture closure is assisted by slightly elevating mucosa superior to the incision.

The mental nerves are identified by placing the periosteal elevator at the corner of the incision and the inferior border of the mandible. The periosteum is elevated posteriorly and tented laterally, which exposes the neurovascular bundle without causing damage.



• **Figure 6-6** **A,** Subperiosteal exposure of the anterior surface of the chin and exposure of mental nerves. **B,** Outline of osteotomy-ostectomy design. **C,** Lateral bony wedges removed and creation of mortise and tenon. **D,** Superiorly repositioned and advanced inferior bony segment with attendant labiomental muscles. **E,** Clinical view showing excellent apposition of bony segments with fixation wires in an area of future bony apposition.

The mental nerve is superior to this position at the level of the canine apices. Once the mental nerves and foramina are visualized, the subperiosteal dissection is carried posterior and superior to them. If it is necessary to complete the osteotomy without tension on the mental nerves, the incision can be extended posteriorly above the nerves with scissors. A subperiosteal dissection is performed beneath the inferior border of the mandible adjacent to the nerves, which permits protective retraction for the bone cutting.

The osteotomy must be at least 4 mm below the incisor root apices to ensure tooth viability. The incisor length can be measured on the preoperative radiographs and is usually 24 mm from incisal edge to root apex. Calipers are used to mark the incisal midline 27 to 28 mm from the incisal edge. Burr holes (1-1.5 mm) are made 1 mm above and below the osteotomy line to keep the distal segment appropriately aligned at the time of fixation.

The osteotomy is made with a reciprocating saw from lateral to medial, with care taken to protect the nerve. Both the buccal and lingual cortices are cut simultaneously. In addition, the osteotomy should be 4 mm below the mental foramen because, as it extends posterior to the foramen, it enters the area where the nerve may dip inferiorly before its exit from the foramen. If a wedge ostectomy is being done, then the inferior osteotomy should be made before the superior osteotomy. This will prevent premature mobilization of the chin, which makes the second (inferior) cut more difficult.

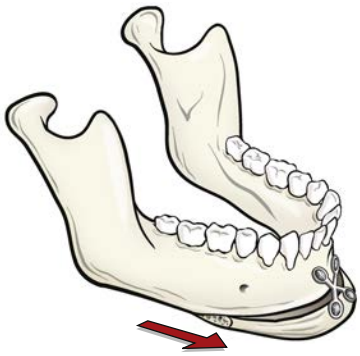
• **Figure 6-7** Pressure dressing with elastic bandage is placed on the skin overlying the mental tissues for 5 days.

A similar procedure is carried out on the opposite side, and mobilization is completed with an osteotome. The removal of the osteotomized bone or the advancement of the chin is performed next. The inferior segment is fixed with 26-gauge stainless steel wire, a cancellous screw, or plates and screws. If the advancement is minimal, fixation can be accomplished by two wires passed through the buccal cortex 1.5 to 2 mm from the midline on each side. If the advancement is more substantial, the wires must be passed through the lingual cortex of the distal segment as well; in these cases a midline wire or the screw is used. For large advancements that approach the total width of the inferior segment or where a strong pull by the omohyoid muscle rotates the distal segment inferiorly, a plate system is best used.

The surgical site is irrigated, and the incision is closed with a single layer of 4-0 absorbable suture that bites mucosa and muscle simultaneously. Chin dressing is placed for up to 5 days as described above. Patients are kept on a soft diet for 1 week and given perioperative antibiotics.

Sagittal Split Genioplasty

A common concern with the sliding osteotomy is the hourglass esthetic deformity seen in the frontal view due to the notching at the inferior border of the mandible. This



• **Figure 6-8** Sliding genioplasty. Osteotomy is made parallel to the occlusal surface. To increase vertical height, a bone graft is placed between the osteotomy site. To decrease the height, a wedge of bone can be removed.

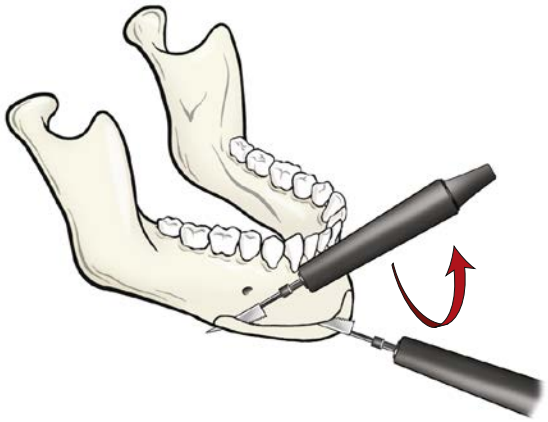
deformity is accentuated with increasing the inferior segment advancement, which may require additional bone grafting. The sagittal split genioplasty technique described by Schendel avoids the notching complications and is indicated for the retrusive chin that is slightly vertically short or long.[15]

This procedure can also be performed as an outpatient.

The mucosal incision and subperiosteal is performed as described above. Once the periosteum is elevated inferiorly and posteriorly to the mental foramen, the midline of the chin is marked with three burr holes. The middle hole is around 24 mm from the lower incisors' incisal edges, and the other two holes are on either side of the first hole. The osteotomy is begun below and slightly posterior to the right or left mental foramen. The reciprocating saw blade is then oriented vertically and in the sagittal plane (Figure 6-8). The cut starts approximately 6 mm below the mental foramen and exits at the inferior border. The saw is carried forward in this plane until the area mesial to the cuspid tooth is reached. At this point the saw blade is rotated into a horizontal position as the remainder of the cut is completed in the usual manner as shown, this results in a sagittal split of the lateral one third to two thirds of the inferior chin segment. Advancement of the inferior chin segment then does not result in a gap at the inferior border of the mandible behind the advanced segment. The area behind the advanced chin segment still has the normal vertical mandibular height because of the sagittal splitting and no through-and-through gap is created. This is similar to what happens with the sagittal split ramus osteotomy when the mandibular body is advanced (Figure 6-9). The inferior chin segment is then secured in the anterior region by rigid fixation using a chin plate and screws. The oral incision is then closed in a similar fashion and a chin dressing is placed as described above.

Alloplastic Genioplasty

Many different synthetic materials to augment the chin have been reported and described in the literature. Alloplastic genioplasty may be performed after the mandibular anterior



• **Figure 6-9** Sagittal split genioplasty. Orientation of the reciprocating saw for the sagittal sliding genioplasty. The saw is first oriented as vertical as possible with the blade in the sagittal sense lateral to the bicuspid teeth. The osteotomy is started at least 6 mm below the mental foramen and the blade exits at the inferior border in this region. The saw is then carried forward in the sagittal plane until the area mesial to the cuspid is reached. At this point the saw blade is curved into a horizontal position as its cuts and the remainder of the osteotomy is completed in the usual horizontal manner as shown. This results in a sagittal split of the lateral one third to two thirds of the inferior chin segment.

teeth have erupted. Rigid stabilization of the implant is important to ensure immobility and to prevent esthetic changes. Improver fixation and soft tissue coverage of the implant can lead to infections.

Alloplastic genioplasty is indicated for patients with retrogenia, minimal dentofacial deformity, and class 1 occlusion. Alloplastic genioplasty can be routinely combined with other esthetic procedures such as face-lift, rhinoplasty, and blepharoplasty. When compared to osseous genioplasty, this technique is simpler, has less postoperative pain, edema, and ecchymosis, and has a faster recovery. The surgical technique entails an intraoral approach as described above or an extraoral approach via an incision in the submental region. The dissection is carried down to the inferior border of the mandible. The alloplastic implant is placed subperiosteally and secured with screws.

Silastic chin implants do not allow bony in-growth into the implant and cause significant bone resorption with approximately 80% of soft tissue changes. This material is not commonly used today and not recommended. Porous block hydroxyapatite (Interpore 200) comes in a left and right segment that allows bony in-growth into the implant. The implant is stabilized with screws, and no bony resorption is clinically evident under the implant. This material is brittle and difficult to handle. Porous polyethylene implants contains interconnecting, omni-directional pore structure to allow for fibrovascular in-growth. This material comes in one or two segments and is also stabilized with a screw. No bony resorption is clinically evident under the polyethylene implant.

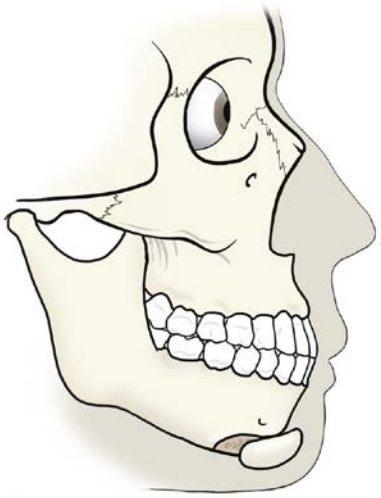
Complications

Osseous and alloplastic genioplasty can lead to various complications including infection, bone resorption, loss of osteotomized bone segment, displacement and esthetic concerns, paresthesia of lower lip and chin, mentalis dysfunction, and lip ptosis. Thorough irrigation and sterility of the implants is critical to prevention of infections. Bony resorption and displacement of the osseous or implant segments may require repeat surgeries to correct the issues. Lower lip and chin paresthesia can be avoided with careful dissection and avoidance of excessive traction on the nerve. If the nerve is transected, it should be repaired immediately. Lower lip ptosis may be caused by excessive detachment of the soft tissue from the inferior chin region or inadequate positioning and resuspension of the mentalis muscle.

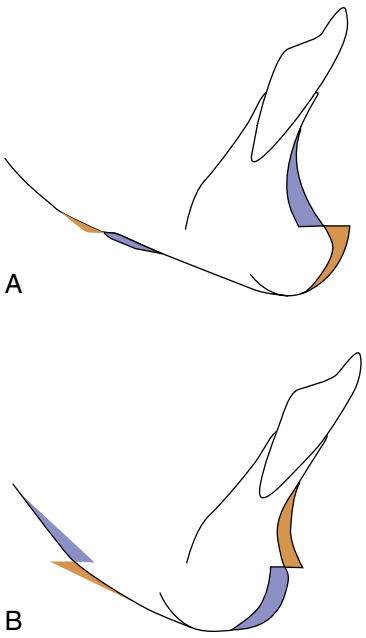
Fixation Devices and Long-term Bony Changes

In the evaluation of postoperative radiographs after genioplasty, it has been reported that the inferior segment can be posteroinferiorly rotated in an appreciable number of cases.[16] This undesirable movement is compounded when significant advancement and wire osteosynthesis are placed on the lingual cortex of the inferior fragment with no other support. Use of rigid internal fixation (RIF) with metal plates and screws or screws alone appears to provide the solution for minimizing this displacement. Some authors[17-20] have also advocated the use of RIF in genioplasty to achieve both segmental stability and optimum bony union, especially in extensive anterior repositioning of the inferior bony segment.

The studies of McDonnell et al.[21] with human subjects and of Ellis[22] in experiments with primates have described osseous changes in the anterior mandibular profile after advancement genioplasty that resulted from resorption of bone at the anterosuperior aspect of the inferior fragment and from apposition of bone on the labial surface of the mandible, superior to the osteotomy (Figure 6-10). In posterior repositioning, the inverse pattern was observed as bone was lost from the labial surface of the mandible superior to the osteotomy and was deposited on the anterosuperior surface of the inferior segment[23] (Figure 6-10). Regardless of the direction of the bony reposition, the sharp angularity of the immediate post-osteotomy profile is refined over time to a curved, relatively smooth form. In all cases in which the metal was situated in a region of bone loss, the metal was externalized from the bone, and where the metal was placed in a region of bony apposition, it was buried by new bone. The specific pattern of bone apposition and resorption observed after genioplasty forms the basis for placement of fixation devices in areas of future bone apposition.



• **Figure 6-10** Lateral facial view demonstrating the change that occurs with advancement of the inferior chin segment in the sagittal split genioplasty. Similar to the sagittal split ramus osteotomy after advancement of the tooth bearing, no through and through gap is created.



• **Figure 6-11** **A,** Stippled area indicates pattern of bone resorption, and solid area shows pattern of bone apposition following advancement genioplasty. **B,** Stippled area indicates pattern of bone resorption, and solid area shows pattern of bone apposition following "setback" genioplasty.

Overall, the sharp angles are softened, and a smooth, curvilinear profile is reestablished. The fact that the entire anterior mandible is placed into a new functional environment indicates that new demands or loads are applied throughout the region. Frost[24] states, "The architectural change produced by a change in bone loading usually improves the bone's ability to carry the new loads, so the architectural adaptations evoked by loads that threaten the structural competence reduce rather than accentuate that threat." Surgical intervention to restore facial balance creates new "physiologic" skeletal and soft tissue equilibrium. The pattern of osseous change observed reduces sharp edges and restores a smooth surface to the anterior mandible. This could represent a protective elimination of regions of stress concentration, as well as adaptation of the region to altered functional demands induced by concomitant orthognathic procedures and altered labiomental muscular function.

The magnitude of osseous change had been related to many factors. Tulasne[25] showed that at 6 months after genioplasty, adolescents underwent greater resorption than adults. Ellis et al.[22] demonstrated that greater tissue stripping favored increased resorption of bone after sliding genioplasty advancement in primates. Polido et al.[26] confirmed this finding with human subjects. Storum et al.[18] argue that minimal periosteal stripping and conservation of blood supply promote early revascularization of the inferior segment, and that this reduces net bone loss in the inferior segment. These latter authors also state that close bone approximation promotes early vascular bridging of the segments, osteogenesis, and enhanced stability of the segments. They conclude that maximum stability of the segments is required to achieve early osteogenesis. However, a distinction must be made between short-term bone healing and long-term adaptive modeling. In the short term, the use of rigid fixation as advocated by Wolford and Bates[20] may enhance bone healing. This is a basic tenet of the Association for the Study of Internal Fixation philosophy regarding the management of bone healing.[18] In the long term, metal placed in a region of bone modeling may become a liability, particularly if it is set in a region of resorption. On the basis of the observed pattern of bony change, it is recommended that fixation devices for genioplasty should be placed in areas of bony deposition. When this is not possible for clinical reasons, long-term monitoring of the relationships of the hardware, bone, and soft tissue may be prudent.

Conclusion

The genioplasty is a safe, predictable, and stable operation that can correct both functional and cosmetic aspects of dentofacial deformities. Osseous and alloplastic genioplasty permit improvement in form and normalization of functional habits through establishment or restoration of harmony among the osseous, dental, muscular, and cutaneous elements of the lower anterior face (Figures 6-11 through 6-16). Accordingly, it is a mandatory part of the orthognathic surgeon's skill set.

Inverted L Osteotomy for Management of Severe Mandibular Deficiency with Short Posterior Face Height

R. BRYAN BELL, ANDREW WEEKS

Introduction

Hugo Obwegeser popularized the term *vogelgesicht*, or bird-face deformity, to describe a facial skeletal abnormality that is characterized by severe mandibular retrognathism, short posterior facial height, steep mandibular plane angle, retrogenia, and skeletal class II malocclusion with or without anterior open bite[1] (Figure 7-1). The etiology of this facial dysmorphism is variable but is invariably caused by insufficient height of the mandibular condyle-ramus unit, as well as the resulting compensatory dentofacial changes.

Various orthognathic surgical techniques have been described to correct these disproportionate maxillomandibular relationships, generally involving bimaxillary advancement with counterclockwise rotation of the maxillomandibular complex. Obwegeser advocated elongation of the mandible by means of either a vertical osteotomy within the tooth-bearing area or sagittal split osteotomies of the mandibular ramus, combined with maxillary repositioning and osteoplastic genioplasty.[1] Although the mandibular body osteotomy that he advocated has not been widely used, primarily because of neurosensory disturbances and the need for interpositional bone grafting, use of the sagittal split osteotomy has been widely accepted. The problem with this technique, however, is that there are limits to the amount of mandibular advancement that can be achieved using sagittal split osteotomies, and significant lengthening of the ramus condyle unit is not possible (Figure 7-2). An alternative approach employs an older operation described in various manifestations in the early 20th century. The commonality between all of the so-called inverted L osteotomy (IVO) designs is that the ramus is horizontally sectioned above the mandibular foramen, joining a vertical cut anterior to the mandibular foramen and leaving the coronoid process attached to the proximal/condylar segment. This precludes any interference of the coronoid process with mandibular setback procedures and, more importantly, alleviates the temporalis muscular attachments to the coronoid process, theoretically minimizing muscular forces that contribute to relapse. This chapter reviews the use of a mandibular IVO as the preferred method for correction of bimaxillary deficiency with short posterior face height (Figure 7-3).

History of Mandibular Ramus Osteotomies

In 1846, Simon Hullihen described the first mandibular osteotomy for correction of a skeletal anterior open bite that resulted from scar contractures associated with a facial burn.[2] He performed a mandibular subapical osteotomy and repositioned the mandible backwards to correct the occlusion. Subsequent to that, V. P. Blair from St. Louis described a mandibular body osteotomy for correction of mandibular prognathism. The following year, Blair described a horizontal osteotomy of the mandibular ramus performed with a Gigli saw via a transcervical approach to facilitate mandibular advancement. In 1925, Limberg described a posterior oblique vertical ramus osteotomy, again via an external approach for correction of open bite malocclusions.

What we know today as the "inverted L osteotomy" (ILO) appears to have been independently described by Martin Wassmund and Hans Pichler in 1927.[3,4] This approach to advancing the mandible was performed via a transcervical incision and involved for the first time interpositional bone grafting (see Figure 7-3, *A*). Caldwell and Letterman modified the ILO technique in 1954, by taking the vertical cut through the sigmoid notch, subsequently termed the extraoral vertical ramus osteotomy (EVRO).[5]

The bilateral sagittal split osteotomy (BSSO) was described by Obwegeser in 1957 and quickly became the preferred

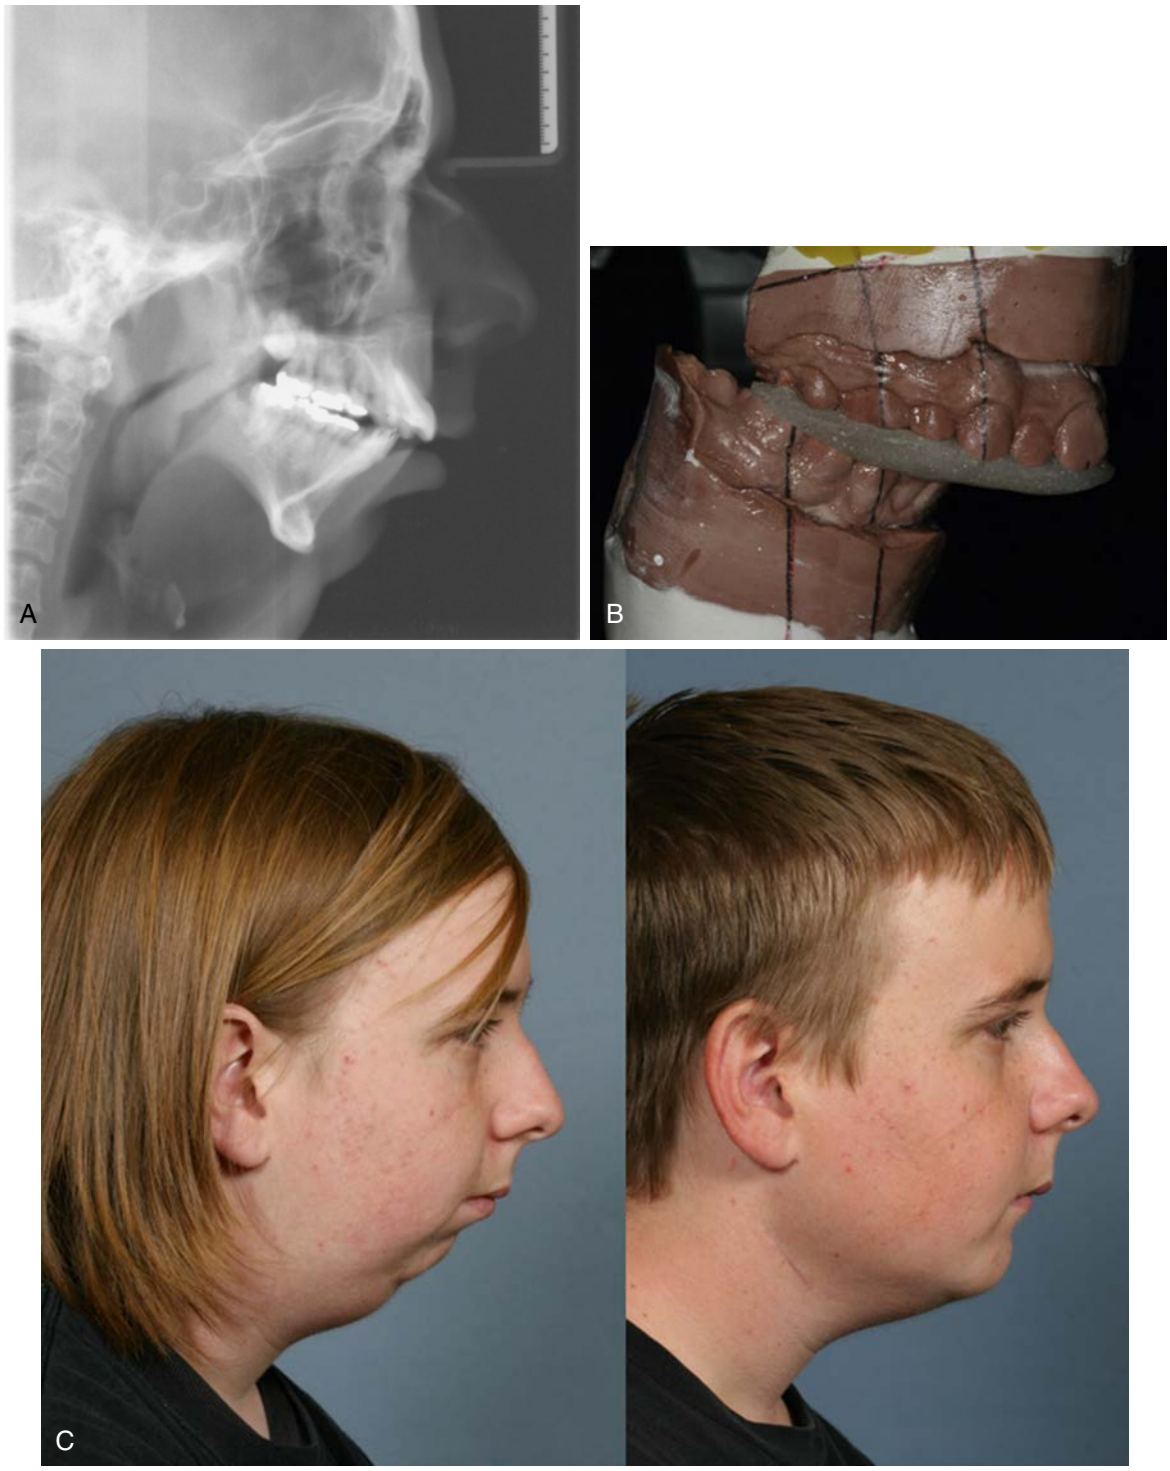
• **Figure 7-1** A 58-year-old woman with severe mandibular retrognathia and short posterior face height. **A**, Preoperative frontal repose. **B**, Preoperative profile. **C**, Preoperative lateral cephalometric radiograph demonstrating loss of posterior face height, downwards and backwards rotation of the maxillomandibular complex, and class II malocclusion.

technique for correction of mandibular deformities, primarily because of its versatility, predictability, and functional and esthetic results.[6] Because of this, the inverted L osteotomy never really gained popularity, likely due to the requirement for an extraoral incision and the related risk of marginal mandibular nerve injury, the additional time and morbidity associated with bone graft harvest, and fixation requirements.

In 1968, Caldwell modified the ILO by performing a "C" ramal osteotomy, again via an extraoral approach, allowing for greater bone contact and rotational advancements.[7] Then in 1970, Kent and Hinds described the intraoral vertical ramus osteotomy, although this was used primarily for treatment of prognathism.[8] In 1976, Levine and Topazian described an intraoral inverted L osteotomy,[9] to which additional modifications were made and rigid internal fixation was applied by Van Sickels and colleagues in 1990[10] (see Figure 7-3, *B*).

As virtual surgical planning (VSP) was introduced in the literature, Gateno,[11] Hirsch,[12] Bell,[13] and Farrell[14] and their co-workers have described innovative techniques that incorporate the use of interocclusal splints, guide stents, and cutting guides made using computer-aided design/computer-aided manufacturing (CAD/CAM) to optimize functional and esthetic outcomes.[11-15]

There is a paucity of literature regarding the inverted L osteotomy, and little is known about the long-term stability of results. However, because of improved instrumentation that has facilitated intraoral approaches, technologic advances in virtual surgical planning and cutting guides, as well as suboptimal results associated with sagittal split osteotomies in some cases of large advancement, there has recently been renewed interest in the inverted L technique.



• **Figure 7-2** A 17-year-old boy with severe mandibular retrognathia. **A**, Preoperative lateral cephalometric radiograph demonstrating severely shortened ramus, steep mandibular plane angle as well as decreased posterior airway space. **B**, Preoperative models demonstrating a severe class II malocclusion. **C**, Pre- and postoperative profile views showing increased posterior facial height and improved mandibular projection.

Indications

The inverted L osteotomy has been advocated for the surgical management of short ramus height, skeletal anterior open bite, and mandibular retrognathism.[16] Although it has been used extensively by a number of authors in the treatment of mandibular prognathism,[9,17-19] this chapter focuses on its use in mandibular deficiency. Short ramus deformities often require large mandibular advancements (greater than 15-20 mm) combined with counterclockwise rotation of the maxillomandibular complex to lengthen the ramus-condyle unit and advance the dentate portion

of the mandible (see Figure 7-3). Conditions that may lead to short posterior facial height include condylar degeneration resulting from juvenile idiopathic arthritis or other arthritic conditions, craniofacial microsomia, craniofacial dysostosis, condylar trauma, and mandibular hypoplasia[1] (Box 7-1).

In addition, some altered ramus morphology is also better suited for inverted L osteotomies than for intraoral sagittal split osteotomies. For example, older patients may be at greater risk of unfavorable split with BSSO because of reduced medullary bone and brittle cortical plates.[19] Similarly, patients with masseteric hypertrophy may have less medullary bone, again increasing the possibility of a "bad split."[16] Furthermore, skeletal morphology may be altered due to previous surgery, necessitating alternative ramus osteotomy designs (Figure 7-4).

Although there are no absolute contraindications for the inverted L osteotomy, patients who are prone to hypertrophic scarring or keloids would not be ideal candidates because of the necessity of an extraoral neck incision. However, recent advancements in virtual surgical planning make intraoral inverted L osteotomies an acceptable alternative.

Stability

Postsurgical stability of counterclockwise maxillomandibular advancement surgery has long been controversial. Much of the controversy, however, is predicated on data generated in the pre–rigid fixation era, which suggested that counterclockwise mandibular advancement using sagittal split osteotomies invited relapse.[20] Other factors influencing relapse after mandibular advancement include the amount of advancement, type and material of fixation, mandibular plane angle, proximal segment control, soft tissue adaptation, remaining skeletal growth, preoperative age, and skill of the surgeon[21] (Box 7-2). More recently, however, Wolford and colleagues have shown that counterclockwise maxillomandibular advancement surgery is actually quite stable when rigid internal fixation is used.[22,23] Of note, however, in the Wolford papers is that although the occlusal plane and mandibular plane was flattened and pogonion advanced significantly, the pterygomaxillary sling and condyle ramus unit was not lengthened to a considerable degree. Therefore, an alternative approach is needed for patients with shortening of the posterior face caused by loss of ramus-condyle height.

Several studies have demonstrated improved skeletal stability using the inverted L osteotomy for counterclockwise rotation of the maxillomandibular complex (Table 7-1). Farrell and Kent were among the first to demonstrate the skeletal stability of the inverted L osteotomy as well as the C osteotomy. Their retrospective analysis of 20 cases showed a 5% relapse of posterior face height at 21 months of follow-up.[24] Dattilo and colleagues subsequently demonstrated an average relapse of 11.4% for inverted L osteotomies used to correct anterior open bites, whereas relapse rates for BSSOs used in similar clinical scenarios was 20% to 24%.[25] Significantly, both of these studies were performed in the pre–rigid fixation era.

More recently, Aymach and co-workers carried out a retrospective review of inverted L osteotomies used for counterclockwise rotation of the mandible and showed no statistically significant change in B-point, pogonion, or mandibular plane angle at 1 year postoperatively.[26] Furthermore, Hay and associates demonstrated stable

results up to 2 years postoperatively when inverted L osteotomy was used to treat growing children with craniofacial microsomia.[27] Some relapse, however, was evident at 3 years after surgery. In a more recent case series, Zhu and colleagues showed minimal relapse in 11 patients who were treated with both intraoral and extraoral approaches in conjunction with semirigid fixation.[28] The reason behind the suggested increased skeletal stability of the inverted L osteotomy versus BSSO in counterclockwise rotations of the mandible is not entirely clear; however, studies have attributed the success of the

TABLE 7-1 Stability of the Inverted L Osteotomy: Pre-rigid versus Rigid Fixation

		Patients	Deformity	Points Measured	Relapse	Fixation	Mean Follow-up

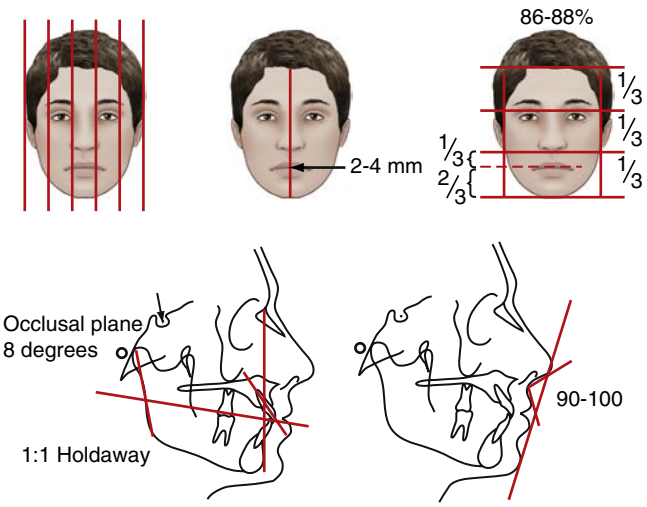
inverted L osteotomy to the use of interpositional bone grafts and passive positioning of the temporomandibular joint (TMJ) during surgery.

Another benefit to the use of the inverted L osteotomy over the BSSO is the decreased incidence of neurosensory changes involving the inferior alveolar nerve. Kobayashi and colleagues showed that the long-term prognosis for resolution of postsurgical neurologic disturbances was better in the inverted L osteotomy patients than in bilateral sagittal split osteotomy patients.[29] Naples and coworkers demonstrated a significantly higher subjective incidence of lower lip and chin hypoesthesia, but sensory testing did not show any significant difference.[30] In Zhu's case series of 11 patients, only 1 had temporary hypoesthesia.[28] Numerous studies demonstrate decreased neurosensory disturbances in vertical ramus osteotomies versus the BSSO,[31] which may be applicable to the inverted L osteotomy.

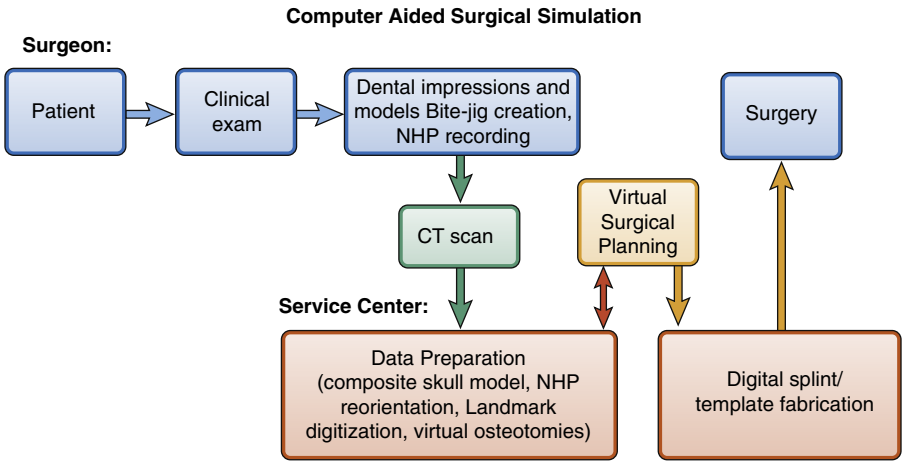


• **Figure 7-5** Ideal goals for facial proportions including equal facial fifths, 2 to 4 mm of incisor show at rest, bi-zygomatic width to lower facial height ratio of 86% to 88%, an occlusal plane angle of 8 degrees, a Holdaway ratio of approximately 1:1, and a nasolabial angle of 90 to 100 degrees.

Treatment Planning for Severe Mandibular Deficiency with Short Posterior Face Height

The senior author's (RBB) treatment approach to severe mandibular deficiency with short posterior face height involves a combination of clinical and radiographic evaluation. The goal in planning maxillomandibular repositioning is to achieve ideal facial proportions and a stable class I occlusal relationship (Figure 7-5). The horizontal fifths are analyzed for symmetry with respect to natural head position and taking into consideration asymmetry of the upper, middle, and lower facial thirds. Deformities of pitch, roll, and yaw must be identified and corrected. The anticipated vertical change in the maxilla is determined by what is needed to achieve a 2- to 4-mm lip-to-tooth ratio at repose. Additional vertical changes are planned based on the patient's anterior two-thirds face height relative to bizygomatic width, as well as linear vertical measurements of the lower facial third as described by Riolo and colleagues.[32] Osteoplastic genioplasty can be considered to increase or decrease the lower facial height as needed, so as to achieve a Holdaway ratio of 1:1 in men and slightly less in women. Occasionally, in tall patients with a relatively long face, malar augmentation can be performed to achieve increases in facial width rather than shortening the face. Next, the maxilla and mandible should be repositioned to achieve an ideal esthetic plane, with respect to nasolabial esthetics, which should result in a nasolabial angle of between 90 and 120 degrees (more for women, less for men).[33]

Particular importance is paid to alteration of the occlusal plane and ideal positioning of the anterior nasal spine to positively affect nasolabial esthetics. Furthermore, the position of the central incisors should be considered when rotating the maxilla in a counterclockwise fashion. Most of the time during treatment of short posterior face height, both the maxilla and mandible will be in a retruded position. This necessitates not only correction of the occlusal plane



• **Figure 7-6** Virtual surgical planning protocol.

and mandibular plane, but substantial maxillary advancement to reposition the anterior nasal spine and the central incisor in a forward position to favorably affect nasolabial esthetics. It is this anterior maxillary repositioning that often necessitates mandibular advancements on the order of 25 to 35 mm. This type of mandibular advancement cannot be predictably achieved with BSSO.

Virtual Surgical Planning

Preoperative computer imaging software has recently been designed to facilitate three-dimensional analysis and transfer of a virtual surgical plan to the patient by use of CAD/CAM software that has substantially affected orthognathic surgical treatment planning. Maxillomandibular deformities of pitch, roll, and yaw can be more accurately identified and corrected than with traditional methods of two-dimensional cephalometry and analytical model surgery.

Xia and Gateno and their colleagues described a computer-aided surgical simulation (CASS) for use in treatment planning of complex craniomaxillofacial deformities[34] (Figure 7-6). The patient is examined in the usual fashion for an orthognathic surgical procedure, and anthropometric measurements are obtained and analyzed. A bite jig is created that registers centric relation, and natural head position is virtually defined utilizing a gyroscope to obtain numerical values for pitch, roll, and yaw. Plaster casts are then obtained, and a computed tomography (CT) scan of the patient is performed with a bite jig in place and the patient in centric relation. The upper and lower stone casts are surface scanned and integrated into the CT images to create a composite image. A three-dimensional cephalometric analysis is performed, and maxillary and mandibular osteotomies are segmented out of the CT image (Figure 7-7). Deformities of pitch, roll, and yaw are virtually corrected and accurately assessed using precise angular and linear digital measurements. Inaccuracies in the virtual plan can then be corrected using a virtual image analysis. Finally the virtual reconstruction is transferred to the patient by printing an intermediate and final splint. The technique can be further augmented by combining it with the use of a stereolithography to pre-bend reconstruction plates or construct custom guide stents to accurately design osteotomies and shape bone grafts. This technique is particularly useful for the inverted L mandibular ramus osteotomy in cases of severe mandibular deficiency or asymmetry.

Surgical Technique: Extraoral Inverted L Osteotomy

A 3-cm retromandibular or Risdon incision is made below the angle of the mandible. The platysma is sharply incised and a subplatysmal flap is raised to expose the superficial layer of the deep cervical fascia. The fascia is incised with care to ensure that the marginal mandibular branch of the facial nerve is not in the vicinity, and the pterygomasseteric sling is exposed beneath a right-angle retractor. The posterior facial vein may be ligated and retracted superiorly to protect the marginal mandibular branch of the facial nerve. Once exposed, the pterygomasseteric sling is sharply incised, and the lateral aspect of the mandibular ramus is exposed in a subperiosteal fashion. With retraction along the posterior border of the mandible as well as the ascending ramus, the antelingula can sometimes be identified and used as a guide to approximate the position of the mandibular foramen. Alternatively, custom cutting guides can be used to ensure proper design of the inverted L osteotomy, which is then completed with a reciprocating saw. Care is taken to minimize the medial extent of the tip of the saw blade and to protect the retromandibular vein posteriorly. The osteotomy can be completed with the aid of an osteotome if desired. It is important to completely dissect free the sphenomandibular ligament and pterygomasseteric sling to allow for passive lengthening of the ramus and advancement of the distal mandibular segment.

Mobilization of the mandible can be facilitated by the placement of 24-gauge wires at the inferior posterior aspect of the distal segment, which are used to help pull the

mandible forward and relax the muscle attachments. The mandible is then repositioned into the prefabricated intermediate occlusal splint, and the patient is placed into intermaxillary fixation. Rigid internal fixation is then applied. The senior author prefers to use 2.0 locking reconstruction plates, which are pre-bent to a stereolithographic model. More recently, the senior author has employed custom plates and screws that provide an even more idealized fit and save operative time. It should be noted that before placement of rigid internal fixation, the proximal condylar segment must be positioned in the posterior superior portion of the glenoid fossa if possible. Autogenous iliac crest bone grafts can then be harvested and shaped according to templates provided by the virtual surgical plan, inset into the ramus defect as an interpositional graft, and secured with bicortical screws. Alternatively, a combination of coronoid bone grafts with or without allogeneic bone grafts and bone morphogenetic protein-II has been used by the senior author with excellent success. Once the procedure is repeated on both sides, the patient is released from intermaxillary fixation, and the occlusion is compared to that of the virtual surgical plan. Care is taken to ensure that the mandibular midline is in the desired position and that there is no unwanted asymmetry or cant to the occlusal plane. Following this, the Le Fort I osteotomy and genioplasty are performed in the usual fashion. The author prefers to use computer-generated guide stents to reposition the chin in these complex cases. The patient is placed into intermaxillary fixation for 2 weeks after the procedure, after which guiding elastics are used. A normal diet is resumed at approximately 6 weeks following surgery at which time the patient is returned to the orthodontist for finishing orthodontic treatment (Figure 7-8 and Table 7-2).

Surgical Technique: Intraoral Inverted L Osteotomy

The intraoral inverted L osteotomy, like its extraoral cousin, is performed before maxillary surgery. A 3- to 4-cm incision is made through the mucosa along the external oblique ridge similar to a standard BSSO incision. A subperiosteal dissection is carried out to expose the ascending ramus and coronoid process. A Kocher clamp may be used to aid in retraction. Dissection on the lateral aspect of the mandible is carried to the posterior border of the mandible. A J-stripper can be used to strip the periosteal attachments off of the posterior border (although this is not usually necessary), allowing placement of the Levasseur-Merrill retractor for visualization of the lateral aspect of the ramus. The medial aspect of the ramus is exposed in a limited fashion, and the lingula is identified if possible. Some authors advocate limiting this portion of the dissection, as the medial dissection has been shown to cause neurosensory disturbance.[18,35] A virtual guide stent is inserted and its accurate position is ensured by checking its adaptation to the inferior and posterior borders of the mandible (Figure 7-9 and Table 7-3). The osteotomy is then made on the lateral aspect of the mandible using an oscillating saw. Once separated, the guide stent is removed and the proximal and distal segments are mobilized. The patient is placed into intermaxillary fixation into the prefabricated intermediate splint. Guide stents are then applied for proper proximal and distal segment positioning, and prefabricated custom plates and screws are used to provide rigid internal fixation of the proximal and distal segments. An interpositional bone graft is placed as described previously, and the wound is closed with 3-0 chromic sutures. Following completion of the mandibular procedure, the maxillary osteotomy and genioplasty are performed as described earlier.

Complications

As with most orthognathic surgical procedures, complications from the inverted L osteotomy most commonly involve inferior alveolar nerve injury, bleeding, or unfavorable osteotomies. Inferior alveolar nerve injury is usually caused by inaccurate position of the vertical or horizontal segments of the osteotomy relative to the mandibular foramen. The prefabricated cutting guides are especially helpful to avoid this complication, given that there are no reliable landmarks of the mandibular foramen relative to the lateral aspect of the mandible.[36,37]

Bleeding encountered during the inverted L osteotomy is usually from injury to the inferior alveolar artery, masseteric artery, or retromandibular vein. Packing can readily control most bleeding.

Unfavorable osteotomies may occur if the horizontal cut is carried too far posteriorly, effectively performing a condylotomy. Should this occur, either the procedure can be aborted and the patient placed into intermaxillary fixation and treated as for a condyle fracture, or the vertical limb can be completed and rigid internal fixation applied to the condyle and remaining proximal segment of the ramus as one would do in a comminuted mandibular fracture repair.

Other possible complications include nerve injury to a branch of the facial nerve, most commonly the marginal mandibular branch, or rarely to the facial nerve trunk itself. Complete facial paralysis following this procedure warrants immediate exploration of the facial nerve and repair as appropriate. Ligation of the facial vein with retraction superiorly (known as the Hayes-Martin maneuver) may be employed to limit the possibility of facial nerve damage, although this is usually not necessary in the author's experience.

Finally, displacement of the condyle out of the glenoid fossa or fixation of the proximal and distal segments with the condyle inaccurately positioned can occur with both the intraoral and extraoral approaches. This unfortunate complication can result in midline discrepancies and facial asymmetry. It is best avoided by taking care to position the condyles in the posterior superior position within the condyle or using a proximal segment positioning plate as described by Van Sickels.[10]

Special Consideration: Juvenile Idiopathic Arthritis

Juvenile idiopathic arthritis (JIA) is a chronic childhood disease that can have profound effect on growth and development of the facial skeleton. Because the management of these patients is multidisciplinary and extends beyond the surgeon and orthodontist to rheumatologists and other physicians, the author's approach to this problem is included here as a special consideration.

The pathogenesis of JIA is derived from either inherited or environmental factors that produce an autoimmune reaction and result in the release of inflammatory mediators that cause joint effusion, resorption, limited range of motion, and ankylosis. Approximately 30% of patients with JIA have TMJ involvement.[38] Furthermore, there is a paucity of clinical symptoms, and approximately 50% to 70% of patients will be pain free. The most common sign is mandibular deviation upon mouth opening or limited mouth opening.

With regard to treatment of the TMJs, until the 1990s, the prevailing wisdom was that most children with JIA would "outgrow" the inflammatory component of their disease by adulthood. Data from multiple longitudinal studies published during the 1990s challenged this previous wisdom noting that remissions were, in fact, uncommon (between 31% and 63%) and joint erosion was significant, even in cases of "mild" disease.[39-41] The last decade has ushered in a new paradigm of combined aggressive medical and surgical therapy that involves the use of nonsteroidal anti-inflammatories, corticosteroids, methotrexate, and biologics such as tumor necrosis factor inhibitors and interleukin inhibitors.[42-44] Furthermore, rheumatologists and surgeons have advocated a more aggressive approach to local disease control using corticosteroid injections. The potential advantages of this approach are increased function, decreased symptoms, decreased joint damage, and decreased need for reconstructive or rehabilitative procedures.

Even when employing a proactive approach such as this, a minority of patients will have disease that is recalcitrant to local and systemic medications. Some patients will still require orthognathic surgery because of functional (limited mouth opening, malocclusion) or esthetic concerns, or both[45-47] (Figure 7-10).

When considering orthognathic surgery in a patient with a history of JIA, almost always the facial dysmorphology will be that described earlier: severe maxillomandibular deficiency, short posterior face height, steep mandibular plane angle, and class II malocclusion, with or without anterior open bite, limited mouth opening or TMJ ankylosis.

Orthognathic surgery can be considered in these patients taking into account the active disease process. As noted previously, most of these patients will have continued flare-ups and theoretically manifest persistent degenerative disease into adulthood. Given these constraints, strong consideration should be given to replacing the inflamed or destroyed TMJ in combination with maxillary and mandibular repositioning.[48] If a patient has a normal range of mouth opening and either nonexistent or diminutive condyles with no evidence of synovitis on magnetic resonance imaging, then that patient can be considered for bilateral inverted L osteotomies combined with Le Fort I osteotomy and osteoplastic genioplasty alone. However, if the patient has significant decrease in range of mouth opening or persistent synovitis within the TMJ, the senior author prefers to replace the joint with a custom alloplastic condyle and fossa prostheses (TMJ Concepts). Most of the time this will be a bilateral procedure; however, occasionally a unilateral joint replacement can be performed.

Special Consideration: ILOTMJ Replacement Combined with Orthognathic Surgery

Combined orthognathic surgery and TMJ replacement using VSP has been performed by the senior author since 2012[49] (Figure 7-11 and Table 7-4). The virtual surgical planning steps are as previously described in this chapter. Once completed, an osteotomy is designed to allow condylectomy in a fashion that facilitates joint replacement, with care taken to leave at least 3 cm of space for condyle and fossa replacement. Once this is accomplished, a stereolithographic model of the VSP is printed, and once it is approved, a custom condyle and fossa prosthesis is either designed, waxed, and casted, or designed virtually and printed. The mandibular osteotomies are performed first using custom guide stents. With the patient in intermaxillary fixation into the predesigned intermediate splint, the fossa and condyle prostheses are placed and stabilized with screws. Following this, the patient is released from intermaxillary fixation, and the mandibular midline and occlusal plane are evaluated for accuracy based on the preoperative virtual plan. The remainder of the operation is as detailed previously. The patient is placed into guiding elastics and returned to function rapidly.

Endoscopically Assisted Mandibular Osteotomies

BATYA R. GOLDWASER, MARIA J. TROULIS

Introduction

The first description of a mandibular osteotomy for the correction of prognathism and anterior open bite was by Simon Hullihen in 1849.[1] Since then, the major advance has been the sagittal split osteotomy, described in 1955 by Trauner and Obwegeser, which enabled surgeons to correct a variety of deformities with a single technique.[2] Other than minor technical modifications, the bilateral sagittal split osteotomy (BSSO) is still considered to be the workhorse for mandibular correction as it allows multidimensional movements. In the ensuing years, one of the main focuses in orthognathic surgery, and the field of surgery in general, has been reduction of patient morbidity. With the advent of rigid internal fixation, the need for routine postoperative maxillomandibular fixation has been eliminated.[3,4] In addition, controlled hypotensive anesthesia, patient positioning, and administration of perioperative steroids has decreased edema and postoperative pain and made the need for blood transfusion almost nonexistent.[5-7] Together this has resulted in an average hospital length of stay after mandibular osteotomy of only 1 to 2 days when standard techniques are used.[8,9]

The just-mentioned modifications in surgical technique and perioperative management have transformed mandibular corrective surgery into a safe and routine operation. However, available technology, widely used in general surgery, otorhinolaryngology, urology, and obstetrics and gynecology, has been underused in oral and maxillofacial surgery. With endoscopic assistance, the surgeon can visualize the entire ramus/condylar unit (RCU) using small, remotely placed incisions with minimal dissection, resulting in significantly decreased postoperative pain and swelling, minimal hospital stay, and rapid recovery with earlier return to normal activities.[10-13] A variety of mandibular osteotomies can be performed in this manner, including condylectomy, coronoidectomy, vertical ramus osteotomies with internal rigid fixation, and resection of pathologic lesions, as well as reduction and fixation of fractures and placement of mandibular distractors.[14-21]

Surgical Technique

A single approach to the RCU has been studied and implemented at the Massachusetts General Hospital. It includes marking out landmarks on the skin and then making a small, extraoral, submandibular incision (15 mm) to create a well-defined subperiosteal optical cavity. This approach results in less bleeding and swelling compared to intraoral approaches, and it allows the surgeon to view the mandible in a more natural "en face" orientation, making the learning curve less steep.[22] Another advantage of the extraoral approach is the ability to place the patient in maxillomandibular fixation without compromising access.

Anatomic landmarks are first marked on the skin and include the mandibular border and condyle and location of planned osteotomy (Figure 8-1). A 1.5-cm incision is made 1 finger-breadth below the angle of the mandible parallel to a neck skin crease. Dissection is then continued bluntly down to the pterygomasseteric sling which is incised in the avascular plane. Using an endoscopic elevator with a suction port, a subperiosteal dissection is continued up the lateral ramus establishing the optical cavity (Figure 8-2). Next, a 30-degree endoscope is placed in the wound and oriented parallel to the posterior border. This allows direct access to the entire RCU (Figure 8-3).[11-13] Anatomic landmarks are identified including the posterior border, the sigmoid notch, coronoid process, and anterior border of the mandible (Figure 8-4). A curved, long-handled retractor is placed in the sigmoid notch to maintain the visual field. Irrigation is performed through the endoscope irrigation port.[21]

Vertical Ramus Osteotomy

The most significant risk of mandibular ramus osteotomies for correction of prognathism is injury to the inferior alveolar nerve and subsequent postoperative neurosensory changes. This is true for both the BSSO which results in up to 100% chance of at least temporary paresthesia, as well as

the intraoral vertical ramus osteotomy (IVRO), which has a lower risk of injury, though more often permanent if it does occur.[23-26] In addition, the IVRO cannot be rigidly fixed and requires a course of maxillomandibular fixation. In contrast, the endoscopic vertical ramus osteotomy (EVRO) has minimal risk of nerve damage and the segments can be rigidly fixed under direct visualization.[23-26]

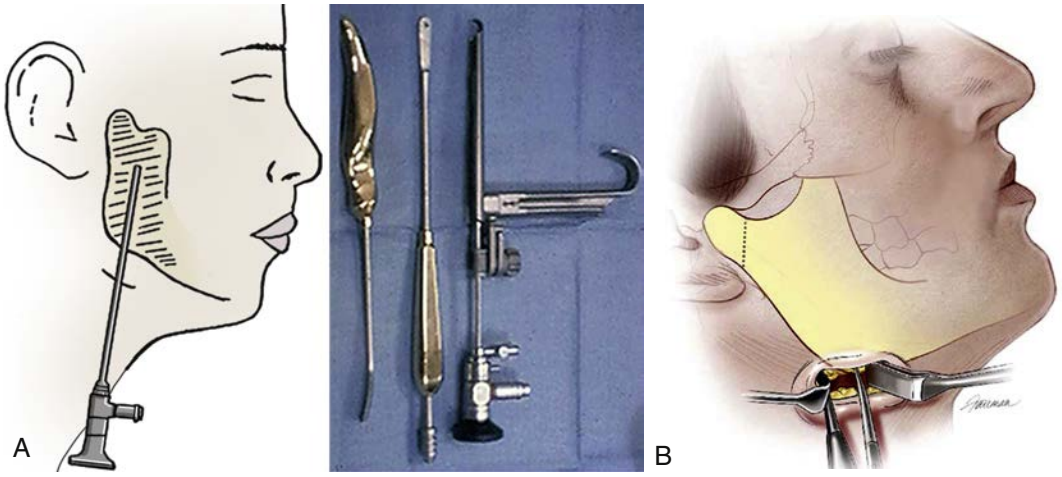
Once the endoscopic optical cavity has been developed, an osteotomy is made with a long-shaft reciprocating saw from the sigmoid notch to the mandibular angle. The medial pterygoid muscle is partially stripped to allow overlap of the proximal and distal segments. If more control of the proximal segment is needed, a clamp can be used. After placing the patient into maxillomandibular fixation (MMF) in the desired occlusion, the segments are fixated using three 12- to 14-mm length, 2.0-mm diameter screws or a rigid plate if there is minimal overlap of the segments (Figure 8-5). Screws can be placed either directly through the incision, or through a percutaneous trocar.[11-13] The same technique can be used for mandibular advancement, with placement of a bone graft in the gap if necessary.

• **Figure 8-1** Anatomic landmarks drawn on skin, including mandibular condyle, coronoid, angle, anterior and posterior border, zygomatic arch, planned incision, planned osteotomy, and path of endoscope.

In a 2004 retrospective analysis of 14 patients (23 sides) in whom this technique of EVRO was used, Troulis and Kaban reported a mean operative time of 37 minutes per side and successful rigid internal fixation in the preplanned occlusion through the 1.5-cm submandibular incision without the need for a trocar. Nine patients had mandibular prognathism with a mean setback of 4.7 mm (2 to 9 mm), and the remaining patients had mandibular asymmetry with asymmetric setback. Complications included temporary marginal mandibular nerve weakness, temporary inferior alveolar nerve paresthesia, and need for blood transfusion secondary to transection of the masseteric artery (n = 1). The majority of patients had less than 1 day hospital stay. Only one patient required prolonged MMF because of difficulty positioning the proximal fragment.[12] These findings were confirmed in a prospective study of 10 patients (17 sides) with mean operative time of 33 minutes per side. Follow up ranged from 3 to 5 years, with nine patients demonstrating skeletal stability and one patient with relapse secondary to late mandibular growth. There were no cases of facial nerve weakness. Four patients had temporary inferior alveolar nerve paresthesia. Average hospital length of stay was less than 2 days.[27]

Condylectomy

Indications for condylectomy include temporomandibular joint (TMJ) disorders that result in progressive change in shape or size of the condyle. These generally fall into

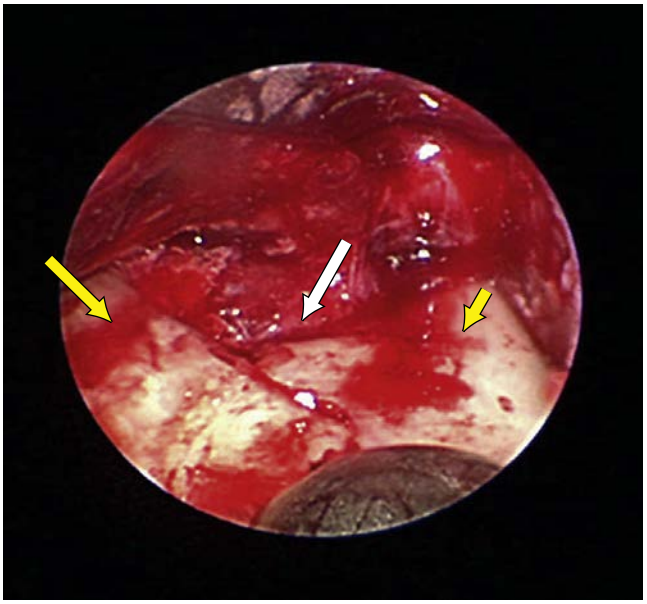


• **Figure 8-2** **A,** Diagram of vector of insertion (parallel to posterior border) and endoscopic instruments including suction/elevator, sigmoid notch retractor and camera. **B,** Incision and dissection. Schematic drawing of the dissection. Note the positioning of the Senn retractors, parallel to the marginal mandibular nerve.

two groups: condylar resorption or hyperplasia. Condylar resorption may be idiopathic, or due to trauma, arthritis, steroid use, neoplasm, or orthognathic surgery, and usually requires reconstruction with a bone graft or prosthesis at the time of condylectomy, and correction of secondary malocclusion.[28] Condylar hyperplasia, in contrast, results in overgrowth. If determined to be active, it either can be observed until the growth cycle is complete, or may be treated with a growth-arresting procedure, or high condylectomy, and subsequent ramus osteotomy to correct the malocclusion.[28,29] The diagnosis and management of these conditions is not the goal of this chapter, however. If low or high condylectomy, with or without reconstruction of the joint, is the treatment planned, the endoscopic approach can be used. This results in significantly decreased morbidity because the standard pre-auricular incision is avoided, thus eliminating risk to the frontal branch of the facial nerve in addition to decreasing the risk to the marginal mandibular branch.

The same 1.5-cm incision and dissection as described for the EVRO is used. To facilitate dissection of the condylar head and neck, the RCU is distracted inferiorly using a 26-gauge wire placed at the mandibular angle for traction.

In patients with condylar resorption being treated with condylectomy and costochondral graft reconstruction, the condylectomy is performed from the sigmoid notch to the posterior border and the condyle removed, exposing the undersurface of the disc. The patient is then placed into MMF, usually with a bite-opening splint on the involved side to account for the loss of vertical height that occurs with remodeling of the graft. The costochondral graft is then harvested using standard techniques and placed into



• **Figure 8-4** Case of subcondylar fracture. Optical cavity with view of fracture line from sigmoid notch *(white arrow),* coronoid *(long yellow arrow),* condyle *(long yellow arrow),* sigmoid notch, posterior border of mandible.

the glenoid fossa under endoscopic visualization of the graft and the meniscus. The graft is fixed with plates and screws, usually requiring a trocar for access[13,28,30-32] (Figure 8-6).

A retrospective review of 10 patients (17 sides), with a mean age of 32 (range 19-46) undergoing endoscopic condylectomy and costochondral graft, showed mean operating time of 52 minutes per side (not including rib harvest). Average hospital length of stay was 2.5 days, and in all cases the entire operation was performed via the 1.5-cm submandibular incision. The planned occlusion was achieved in all patients, and rigid fixation was applied. Bleeding was minimal given subperiosteal dissection under direct visualization. All patients remained in MMF for 10 to 14 days postoperatively. There was one case of transient unilateral marginal mandibular nerve weakness that resolved by 2 weeks postoperatively. The patient cohort has since more than doubled, with none suffering any persistent neurosensory changes of the facial, inferior alveolar, or lingual nerve.[13]

For condylar hyperplasia, the standard approach includes a preauricular incision to access the TMJ in order to resect the hyperplastic condyle. This is followed by standard orthognathic surgery for correction of any malocclusion. In contrast, with endoscopic assistance, a single submandibular incision is used. The condyle is dissected, a vertical ramus osteotomy is performed, and the entire proximal segment is removed. The hyperplastic condyle is resected ex vivo on the back table, and then the proximal segment replaced and rigidly fixed in a more superior position, correcting the occlusion simultaneously.[11,12,28,32] Long-term follow-up of more than 3 years showed mean relapse of 0.3 mm, despite total stripping of the proximal segment and use as a free bone graft.[27]

Mandibular Distraction Osteogenesis

For patients requiring mandibular advancement, distraction osteogenesis is a minimally invasive technique that can be used instead of the standard BSSO. In addition to the lower risk of IAN damage during the osteotomy, the gradual separation of the proximal and distal segments allows the soft tissues and neurovascular structures to expand as well, making larger movements better tolerated.[23-26]

Mandibular distractors can be placed using intraoral or extraoral incisions. The intraoral approach is essentially a variant of the BSSO incision, exposing only the area of the planned osteotomy and fixating the device in place, with significantly less dissection required. Endoscopy has been used for making the mandibular osteotomy, as well for extraoral placement of mandibular distractors in human cadaver and live minipig studies, using a modified approach to the one previously mentioned.[33] In this case, two 1-cm submandibular incisions are made. The first is a working port located directly in line with the osteotomy where the endoscope is inserted. The second incision is used to insert the device after dissection and partial corticotomy are complete. Bicortical screws are used to fixate the device in position, using either port. The corticotomy is then completed with an osteotome, avoiding the neurovascular bundle.[33] Work is underway to further miniaturize distractor devices, and once this is accomplished, endoscopic placement will become clinically feasible.[34,35]

Coronoidectomy

Coronoidectomy is usually performed in patients with limited mouth opening and a coronoid process that extends above the zygomatic arch. If the patient can open at least 20 mm, an intraoral incision can be used for access. However, this is often not possible, and a bicoronal flap is required for access. In contrast, with endoscopic assistance, the coronoid process can be approached using the same small submandibular incision described earlier, avoiding the morbidity associated with the coronal incision and dissection (Figure 8-7). Using the same approach described in this chapter, endoscopic coronoidectomy was performed on 11 patients (17 sides), with bilateral (n = 7) or unilateral (n = 3) coronoid hyperplasia. This was completed via the 1.5-cm submandibular incision without any long-term neurologic deficit, and resultant improved maximal incisal opening (>35 mm).[21]

Conclusion

Accessing the mandible with the aid of endoscopy via the minimally invasive surgical approach described here enables the surgeon to perform a variety of osteotomies using a single technique. Using a small, remotely placed incision, there is direct and magnified visualization of the operative field, requiring minimal dissection and tissue manipulation and resulting in reduced pain, swelling, and therefore overall recovery time. As the technology and skill become more widely available and refined, many of these operations, which traditionally necessitated prolonged hospitalization with high morbidity, may routinely be done in the outpatient setting.

Le Fort I

CORY M. RESNICK, BONNIE L. PADWA

Introduction

The Le Fort I osteotomy is the most common maxillary operation in orthognathic surgery. It is a versatile procedure that allows the maxilla to be repositioned in three planes of space. Alone or in conjunction with mandibular osteotomies, the Le Fort I osteotomy can be used to correct a wide range of dentofacial deformities.

History

The earliest description of a maxillary osteotomy for access to nasopharyngeal polyps was by von Langenbeck in Germany in 1859.[1] Cheever was the first surgeon in the United States to use maxillary mobilization with bone chisels to relieve nasal obstruction caused by recurrent epistaxis.[2] Le Fort's classic description of the natural planes of maxillary fracture was published in 1901.[3] Wassmund was the first to apply osteotomies at the Le Fort I level for correction of mid-facial deformities.[4] The technique was subsequently modified by several surgeons including Axhausen,[5] Schuchardt,[6] and Willmar.[7] In 1965, Obwegeser improved the precision of the Le Fort I osteotomy by suggesting complete mobilization of the maxilla so that repositioning was achieved without tension.[8,9] The operation was slow to gain popularity until Bell's 1973 description of the remarkably resilient maxillary blood supply.[10] Fueled by improvements in technique and the introduction of safe hypotensive anesthesia, the Le Fort I osteotomy has been increasingly utilized over the last four decades.

Indications

The Le Fort I osteotomy can be used to treat a wide range of dentofacial deformities. This operation can also be used for treatment for obstructive sleep apnea, preparation for prosthetic rehabilitation of atrophied maxillae, and access to nasopharyngeal and spinal cord tumors.[11]

The most common indication for a Le Fort I osteotomy is maxillary hypoplasia with a class III skeletal pattern (Figure 9-1). Maxillary hypoplasia can occur in multiple planes, and correction may require maxillary advancement, inferior positioning, and/or transverse widening. Often the maxillary hypoplasia extends to the infraorbital rims, and this can be addressed at the time of orthognathic surgery with a modified Le Fort I osteotomy or insertion of alloplastic malar implants.

Vertical maxillary excess (VME) is another common dentofacial deformity treated with a Le Fort I osteotomy (Figure 9-2). Patients with VME commonly complain about a "gummy smile" or impaired masticatory function due to an anterior open bite. Three main features characterize this deformity: increased mandibular plane angle, increased total anterior facial height, and decreased contribution of the upper facial height to the total facial height. The vertical position of the maxilla must be planned based primarily on assessment of the resting relationship of the upper lip to the anterior maxillary dentition; planning only to the smile will result in an undesirable esthetic outcome. Correction involves superior repositioning of the maxilla, often with correction of the occlusal plane; bimaxillary surgery may be required.

A Le Fort I osteotomy is often needed in conjunction with a mandibular osteotomy to correct dentofacial asymmetries, as in asymmetric mandibular growth, condylar hyperplasia, and hemifacial microsomia (Figure 9-3). In these cases, determination of the correct vertical position of the maxilla is necessary to identify the fulcrum for maxillary rotation.

Diagnosis and Planning

Meticulous diagnostic assessment and preoperative planning are necessary to obtain the desired functional and esthetic results; the principles of facial assessment and orthognathic surgical planning are covered elsewhere in this book. Clear communication between the surgeon and the orthodontist during the preoperative orthodontic treatment phase is also critical to a successful outcome.

The advent of three-dimensional (3D) virtual treatment planning has transformed the planning process and accuracy of the Le Fort I osteotomy (see Figure 9-3, *L-Q*).[12] The complex 3D anatomy of the maxilla and mid-face now can be evaluated in ways never before possible. Concepts

borrowed from the aeronautic industry such as pitch, roll, and yaw have been added to the lexicon of the orthognathic surgeon.[13] Furthermore, virtual surgical plans can be transferred to the patient via 3D printing of surgical stents with greater accuracy.

During the planning process, it is important to consider the long-term stability of the operation. The hierarchy of stability for movements of the maxilla and mandible in orthognathic surgery has been defined for both nonrigid (wire)[14] and rigid fixation.[15] Superior repositioning of the maxilla is the most stable maxillary movement, regardless of the method of fixation. Maxillary advancement and maxillary rotation are also stable movements. Inferior positioning of the maxilla is much less stable, and widening of the maxilla is inherently unstable.

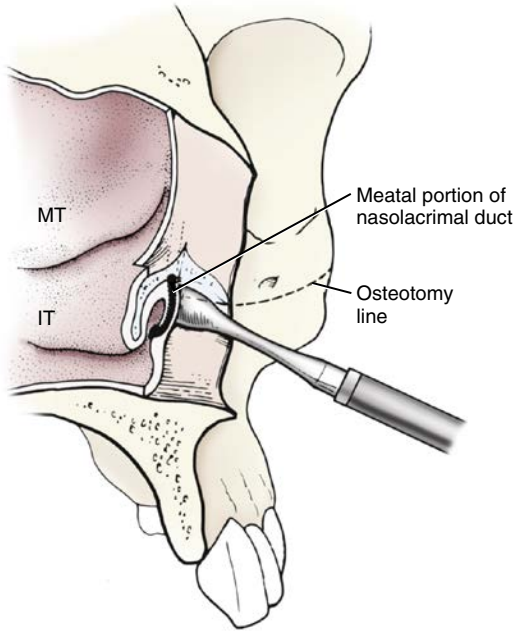
Surgical Anatomy

The paired maxillae are the central bones of the mid-face, and are each made up of a body and four projections: frontal, zygomatic, palatine, and the alveolar process. The maxilla forms the inferior and medial borders of the orbits. The infraorbital foramen is located a mean distance of 7.8 mm below the infraorbital rim in women and 8.5 mm in men.[16] The vascular and sensory supplies to the skin of the cheek, lateral aspect of the nose and upper lip exit the bone from this foramen. The anterior alveolar processes surround the piriform apertures and join to form the anterior nasal spine in the midline. The anterior nasal spine is the most anterior inferior attachment for the cartilaginous nasal septum, which extends posteriorly along the nasal crest and articulates with the vomer. The body of the maxilla contains the maxillary sinuses.

The hard palate is formed by the palatine processes of each maxilla anteriorly and the horizontal lamina of the palatine bones posteriorly. The greater palatine foramen is located on each side approximately 10 mm posteromedial to the second molar.

The nasolacrimal duct travels within the bony wall between the nasal cavity and the maxillary sinus before terminating below the inferior turbinate. The nasolacrimal duct can be injured during the Le Fort I osteotomy or during an inferior turbinectomy performed to allow superior repositioning of the maxilla (Figure 9-4).[17,18]

Posterolaterally, the maxilla articulates with the pyramidal processes of the palatine bones and the pterygoid plates of the sphenoid bone. This pterygomaxillary junction extends superiorly as a fissure, which ends at the pterygopalatine fossa. The terminal portion of the internal maxillary artery traverses the pterygopalatine fossa and gives off several branches that can be encountered during a Le Fort I osteotomy (Figure 9-5). The average distance from the inferior extent of the pterygomaxillary junction to the posterior superior alveolar artery is 15 mm, to the infraorbital artery is 32 mm, and to the descending palatine artery is 25 mm. The descending palatine arteries travel through the perpendicular plate of the palatine bones and are located approximately 34 mm posterior to the piriform rims and within 10 mm medial to the pterygomaxillary fissures.[19] Osteotomies of the lateral nasal walls and at the pterygomaxillary fissures must be completed carefully to avoid injuring these vessels. The internal maxillary artery is 23 to 25 mm superior to the base of the junction of the maxilla with the pterygoid plates, and its average diameter is 2.5 mm.



•**Figure 9-4** Relationship of the nasolacrimal duct to the Le Fort I osteotomy.

In addition to the direct vascular supply of the maxilla by the descending palatine arteries, there is a rich collateral vascular network from the soft palate supplied by the ascending pharyngeal arteries and the ascending palatine branches of the facial arteries (Figure 9-6). Bell's work revealed that ligation of the bilateral descending palatine arteries does not compromise the vascularity of the maxilla as long as the soft palate pedicle is preserved.[10,20,21]

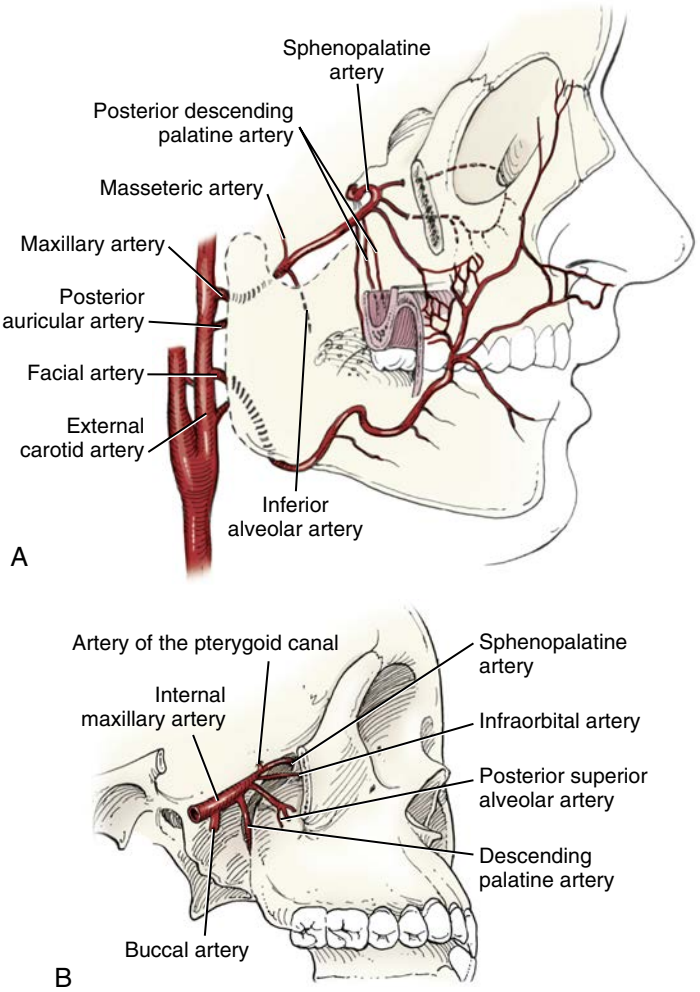
The pterygoid plexus of veins is located between the temporalis and lateral pterygoid muscles and between the medial and lateral pterygoid muscles. It receives tributaries corresponding to the branches of the maxillary artery and drains into the maxillary vein. Venous bleeding from this plexus may be encountered during the posterolateral maxillary dissection and pterygomaxillary disjunction.

Operative Technique

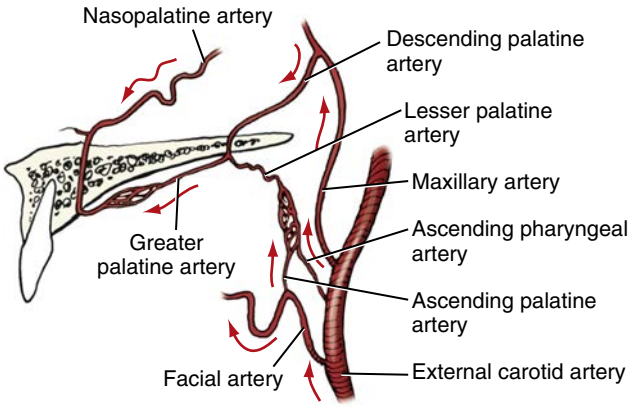
There are many acceptable modifications to the Le Fort I osteotomy and the sequence of steps may vary from surgeon to surgeon. The following is a description of the authors' preferred approach.

Anesthetic and Positioning Considerations

Controlled hypotensive anesthesia has been shown to reduce bleeding from mucosal and bone edges that contain a rich



•**Figure 9-5** **A,** Branches of the external carotid artery in relation to the maxilla. **B,** Terminal branches of the internal maxillary artery as it traverses the pterygopalatine fossa.



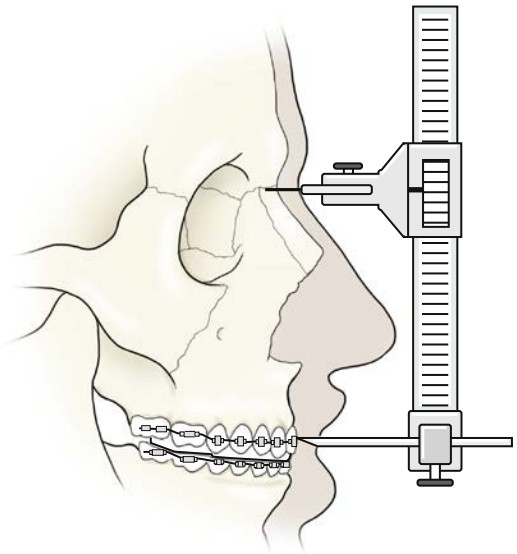
•**Figure 9-6** Arterial supply to the maxilla.

network of small vessels, which cannot easily be identified and controlled with surgical techniques. In healthy patients, a reduction in mean arterial pressure (MAP) of 30% below the patient's baseline with a minimum MAP of 50 mm Hg is safe.[22] In bimaxillary surgery, postoperative blood transfusions are necessary in 13% to 48% of patients who do not have controlled hypotension during the operation.[23,24] The need for transfusion has been nearly eliminated by using this technique. Placement of an indwelling bladder catheter for intraoperative monitoring of urine output as a marker of renal perfusion should be considered when using controlled hypotension.

After induction of general anesthesia, the patient is nasally intubated. A shoulder roll is inserted to extend the neck without creating hyperextension. A sterile preparation and draping is performed, leaving the orbits and nasion exposed. After the planned mucosal incision is marked, local anesthetic with vasoconstrictor (lidocaine with 1:100,000 epinephrine) is infiltrated in the labial sulcus. Palatal injection should be avoided so as not to induce vasoconstriction in the palatal pedicle.

External Reference Marker

An external reference marker is placed at the nasion to facilitate proper positioning of the maxilla in the vertical plane (Figure 9-7). Common techniques include insertion of a Kirschner wire or a bone fixation screw. Less invasive methods include marking with a skin scribe, a suture or tape, but



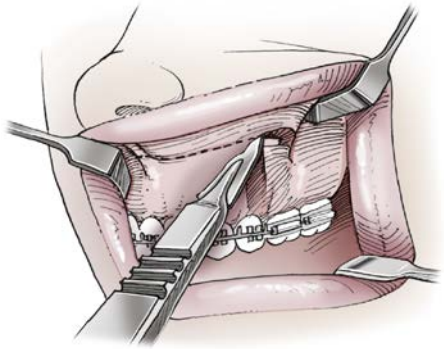
•**Figure 9-7** Measurement from an external reference marker at the nasion to an orthodontic bracket. (From Bell WH: *Modern practice in orthognathic and reconstructive surgery*, Philadelphia, 1992, WB Saunders.)

these may be less reproducible due to skin mobility at the site. External reference points have been shown to be superior to internal references (lines or burr holes placed on the maxilla above and below the osteotomy), which are prone to inaccuracy due to the complex three-dimensional movement of the maxilla.[25,26] Preoperative measurements are then obtained from the reference site to reproducible midline and lateral maxillary landmarks, typically the maxillary dental midline and the bilateral canine cusp tips or orthodontic brackets.

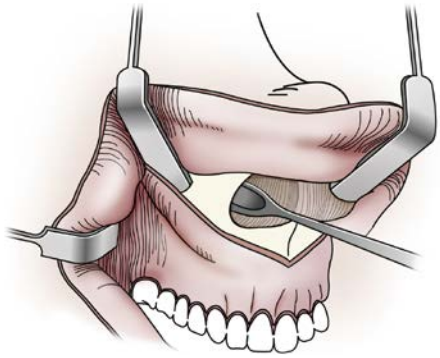
Incision and Subperiosteal Dissection

A vertical midline marking is made with a blade or electrocautery to aid in realignment of the incision during closure. A horizontal incision is created in the gingivobuccal sulcus about 5 to 10 mm superior to the mucogingival junction and from first molar to first molar (Figure 9-8). The Stensen duct papillae are identified and protected by retraction during the incision. The mucosal cut is made with the blade or electrocautery pen directed perpendicular to the mucosal surface. The blade is then redirected to be perpendicular to the underlying maxilla and continued through periosteum. The submucosal incision is brought inferiorly near the midline to avoid perforation of the nasal mucosa.

A periosteal elevator is then used with definitive sweeps to raise a subperiosteal flap. If the incision was made cleanly through periosteum, the subperiosteal flap will elevate easily. The dissection is continued along the anterior maxillary walls to the infraorbital foramina, medially to expose the piriform rims, and laterally to the zygomaticomaxillary suture. Dissection is then continued posterolaterally around the maxillary buttress to the pterygomaxillary fissure. Extra care must be taken during this portion of the dissection to remain subperiosteal at all times, because a small periosteal



•**Figure 9-8** A horizontal incision is made in the buccal vestibule 5-10 mm superior to the mucogingival junction. (Adapted from Miloro M, et al: *Peterson's principles of oral and maxillofacial surgery*, Hamilton, Ontario, Canada, 2004, BC Decker.)



•**Figure 9-9** A freer or Cottle elevator is used to dissect the nasal mucosa from the piriform rim and maxillary crest, beginning superolaterally and sweeping inferiorly and medially. (Adapted from Miloro M, et al: *Peterson's principles of oral and maxillofacial surgery*, Hamilton, Ontario, Canada, 2004, BC Decker.)

perforation may lead to herniation of the buccal fat pad which will complicate visualization for the remainder of the operation. If the buccal fat pad is encountered, it should be contained as much as possible with a patty and retracted away from the visual pocket. At this point the posterolateral pocket can be distended with a sponge or patties, which may be soaked in epinephrine or pseudoephedrine for additional hemostasis.

A periosteal elevator is then used to release the periosteum around the anterior nasal spine and define the edges of the piriform rims. A freer or Cottle elevator is used to dissect the nasal mucosa from the piriform rim and maxillary crest, beginning superolaterally and sweeping inferiorly and medially (Figure 9-9). The nasal mucosa is carefully separated from the caudal septum, and the elevator is directed posteriorly to lift the mucosa from the remainder of the maxillary crest. The nasal mucosal dissection is then completed superolaterally to the inferior turbinates.

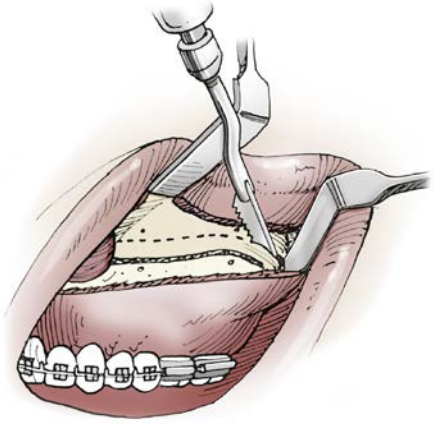
Maxillary Osteotomy

The canine and first molar root tips (the longest tooth roots) are identified on each side, and the osteotomy is planned

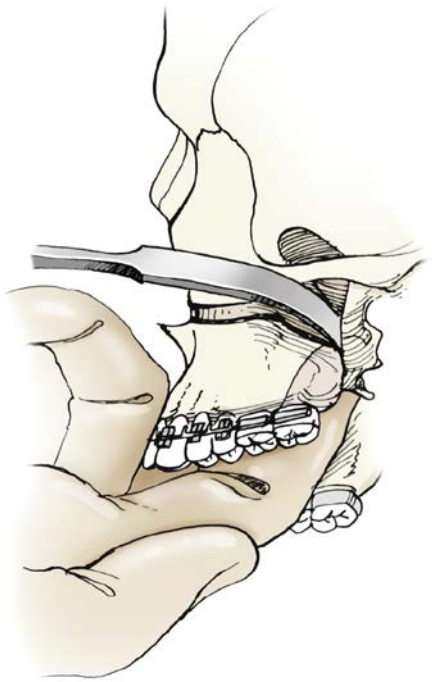
5 mm superior to these roots. A reciprocating saw or a piezoelectric saw is used to create a horizontal osteotomy beginning at the maxillary tuberosity and continuing through the maxillary buttress to the piriform rim on each side (Figure 9-10). A retractor is placed in the lateral piriform rim during this osteotomy to protect the nasal mucosa. The osteotomy is typically parallel to the occlusal plane, but can be angled as desired to facilitate the planned movements.

Pterygomaxillary Disjunction

A long curved osteotome is inserted into the pterygomaxillary fissure at a level at and inferior to the horizontal osteotomy (Figure 9-11). The osteotome is oriented in an anterior, medial, and inferior direction so that it will be driven into the fissure. A finger is placed intraorally on the pterygoid hamulus as an assistant taps the osteotome with a mallet. It is important that the operating surgeon holds the osteotome in one hand and palpates the hamulus with the other hand, as this bimanual tactile sensation is critical in determining when the disjunction has been achieved. The osteotome may be redirected as necessary to complete the disjunction to the level of the horizontal osteotomy. A small straight osteotome is then used to complete the osteotomy at the posterior maxillary wall to connect the horizontal osteotomy to the pterygoid fissure. The osteotome blade must remain in contact with the lateral maxillary wall at all times; if the osteotome strays medially, it may sever the descending palatine artery. These osteotomies are completed on the contralateral side.



•**Figure 9-10** A horizontal osteotomy is made from the maxillary tuberosity to the piriform rim on each side.

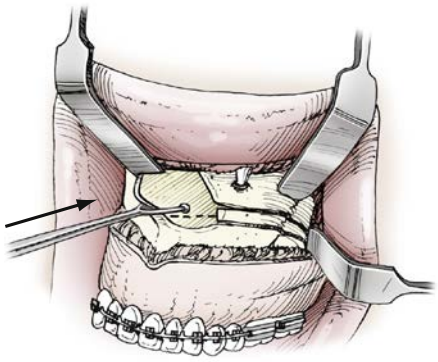


•**Figure 9-11** The maxilla is separated from the pterygoid plates with a long curved osteotome directed anteriorly and inferiorly while a finger is placed on the pterygoid hamulus.

Septal, Vomerine, and Lateral Nasal Osteotomies

A guarded nasal septal osteotome is inserted to engage the caudal nasal septum (Figure 9-12). A finger is inserted past the uvula to lie between the posterior nasal spine and the endotracheal tube. The osteotome is angled inferiorly toward the nasal floor and tapped with a mallet to osteotomize the septal cartilage and vomer. This is continued until the tip of the osteotome is palpated from the nasopharynx. This distance is typically 25 to 30 mm posterior to the anterior nasal spine.

A guarded lateral nasal osteotome is placed at the piriform rim with the guarded side abutting the nasal mucosa. The osteotome is directed slightly lateral to follow the anatomy of the nasal cavity, which is wider posteriorly than anteriorly. It is helpful to obtain direct visualization of this osteotomy as it progresses posteriorly, and this may be facilitated by applying slight inferior pressure on the maxilla just posterior to the anterior nasal spine with a bone hook. The operating room should be quieted during this osteotomy so that an audible change can be identified when the osteotome reaches the perpendicular plate of the palatine bone, which defines the posterior extent of the osteotomy. Continuing the osteotomy beyond this point will engage the



•**Figure 9-12** A guarded nasal septal osteotome is directed posteriorly and inferiorly, starting above the anterior nasal spine.

descending palatine vessels. This osteotomy is repeated on the contralateral side.

Down-fracture

When all of the maxillary osteotomies are completed, the maxilla must be down-fractured (Figure 19-13). Downward pressure using the thumbs on each side and a bone hook in the midline is typically all that is necessary to complete the down-fracture. Smith spreaders can also be used at the bilateral buttresses. The down-fracture should occur with minimal pressure. If significant resistance is encountered, the surgeon should stop and reevaluate all maxillary osteotomies, with special attention to the pterygoid disjunctions and the lateral nasal osteotomies, because they are the most difficult osteotomies to complete.

When the maxilla has partially down-fractured, the posterior osteotomies are evaluated. Specifically, the level of the osteotomies at the perpendicular plates of the palatine bones and the posterior walls of the maxilla are visualized, and should be redirected with osteotomes if necessary. The down-fracture is then completed.

Evaluation of the Descending Palatine Arteries

The descending palatine vessels are identified on each side. Bone should be carefully removed with a rongeur or small osteotome to clear the entrance of the vessels into the hard palate (Figure 9-14). The vessels should be evaluated for tears.

It is the authors' practice that ligation of these vessels is needed only if there are signs of damage and bleeding, or if posterior maxillary impaction requires their ligation to achieve the desired surgical movement. Sacrifice of one or both arteries, however, does not increase the risk for avascular necrosis.[21,27] There is a small risk of late postoperative nasal bleeding associated with pseudoaneurysm formation from unrecognized trauma to the vessel wall when the vessel is left intact.[28] For these reasons, some surgeons routinely ligate both vessels.

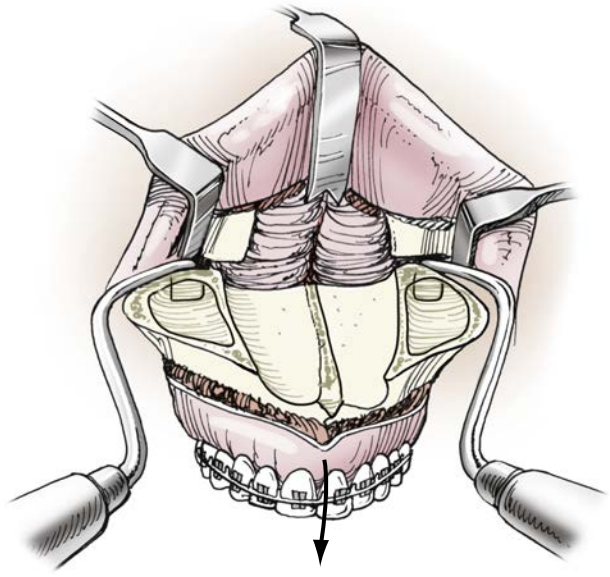
Mobilization of the Maxilla

Adequate mobilization of the maxilla such that it fits passively into the surgical splint in the planned position is imperative. If passive adaptation is not achieved, the mandibular condyles may be distracted from their centric relation positions when the maxilla is brought into the surgical splint and placed in intermaxillary fixation. This will result in a malocclusion after the release of intermaxillary fixation. Maxillary mobilization is achieved with Rowe disimpaction forceps and pterygoid lifts. Stretching of the soft tissue attachments may be achieved simply, or may be a prolonged process, especially in patients with large movements or a history of cleft palate.

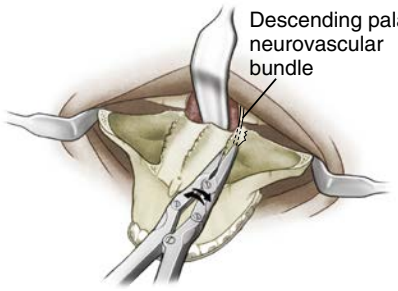
Maxillary Segmentation

When the preoperative plan calls for maxillary segmentation and the orthodontic setup has been completed with this in mind (including divergence of the dental roots in the planned segmental osteotomy positions), this is completed after the maxillary down-fracture. Separation in two to four pieces is generally well tolerated.[29] The incidence of aseptic necrosis, however, is higher in multi-piece compared to single-segment osteotomies, and increases with increased subdivision.[30]

Common patterns of segmentation include "2-piece" and "3-piece" osteotomies. In the "2-piece," a median osteotomy may be made from the interdental space between the central incisors to the posterior nasal spine. This allows for transverse widening of the maxilla posteriorly. However, the hard palate is thickest and the palatal mucosa is thinnest in the midline, making the risk for palatal mucosal tear high with this osteotomy design. Because the palatal soft tissue pedicle is critical to preservation of the maxillary blood supply, the osteotomy is often modified to take advantage of the thinner maxillary bone and thicker palatal soft tissue that is found between the midline and the medial maxillary



•**Figure 9-13** The maxilla is down-fractured. (From Fonseca RJ: *Oral and maxillofacial surgery*, Philadelphia, 2000, WB Saunders.)



•**Figure 9-14** The perpendicular plate at the entrance of the descending palatine vessel is removed with a rongeur.

sinus walls. With this modification, a midline osteotomy is made between the central incisors and through the premaxilla to the incisive foramen. Curved paramedian osteotomies are then made, extending to the posterior extent of the hard palate on each side. This "2-piece" design really creates three maxillary segments, which are attached only by palatal mucosa.

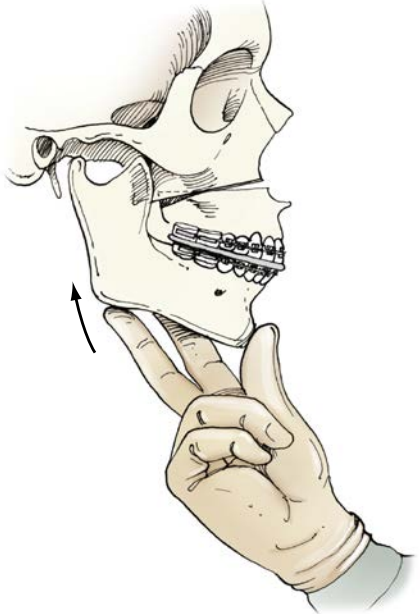
A "3-piece" design will facilitate posterior widening as well as independent vertical repositioning and rotation of the maxillary central and lateral incisors, with or without the canines. For the reasons previously stated, paramedian osteotomies are preferred to a midline osteotomy, allowing four sections to be created. Bilateral osteotomies are made extending from the interdental spaces either between the canines and first premolars or between the lateral incisors and canines, and extending to the incisive foramen. Paramedian osteotomies are then made from the incisive foramen to the posterior extents of the hard palate on each side.

Intermaxillary Fixation, Repositioning, and Adjustment

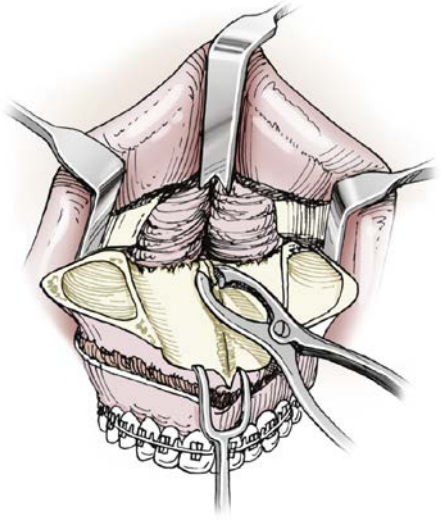
The maxilla is then positioned into the prefabricated surgical splint and intermaxillary fixation is applied with wires. The maxillomandibular complex is then rotated superiorly while posterior and superior pressure is applied to the mandibular angles to fully seat the condyles (Figure 9-15). Bony interferences are identified and marked.

All interferences should be identified and reduced prior to final maxillary positioning. The preoperative planning will help determine expected areas of interference. The maxillary buttresses and piriform rims commonly require reduction unless the maxilla is being inferiorly positioned. The posterior maxillary walls and maxillary tuberosities are also common areas of interference, sometimes abutting the pterygoid plates. The relationship between the caudal nasal septum and the maxillary crest should be evaluated to ensure that the septum does not buckle, particularly with superior positioning of the maxilla. If there is interference with the septum, a trough can be created along the maxillary crest with a rongeur or burr (Figure 9-16). Additionally, the perichondrium can be dissected from the caudal septum and a fine scissor can be used to resect the caudal septal cartilage (Figure 9-17). When a large superior movement of the maxilla is planned, the inferior turbinates may interfere with repositioning. Soft tissue and osseous turbinectomies may be necessary (Figure 19-18).

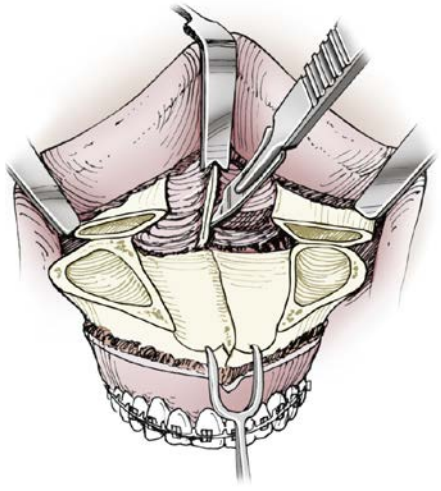
After all interferences have been relieved, the maxillomandibular complex is rotated superiorly and the final vertical position is checked by evaluating the maxillary incisors relative to the upper lip. The dental midline is observed to confirm proper maxillary positioning in the frontal plane.



•**Figure 9-15** Posterior and superior pressure is applied to the mandibular angles to fully seat the condyles.



•**Figure 9-16** Bone is removed from the maxillary crest to allow the nasal septum to sit passively without buckling.

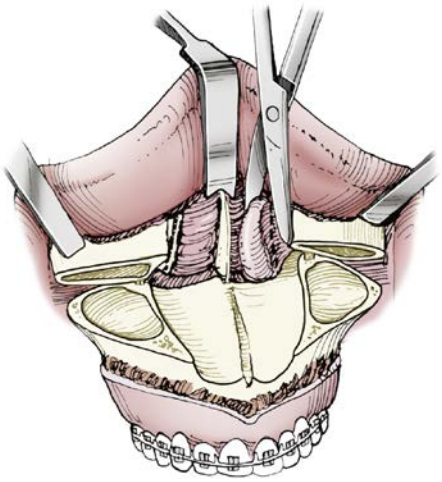


•**Figure 9-17** The cartilaginous nasal septum is exposed in order to perform a caudal septoplasty.

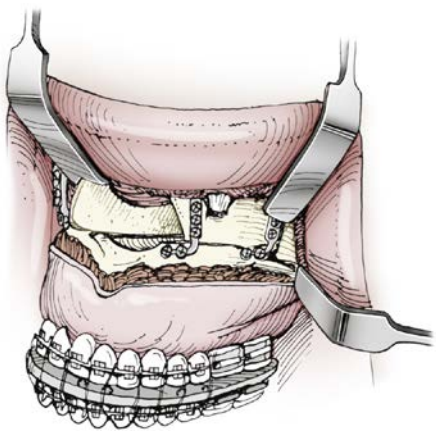
Measurements from the external reference point are repeated to confirm that the planned movements have been achieved and that no unintended cant has been created.

Maxillary Fixation

With the maxillomandibular complex rotated into its planned position and the condyles fully seated, fixation is applied. Rigid fixation has replaced wire fixation methods due to increased stability with rigid techniques.[31-33] Fixation is applied to the bilateral piriform rims and zygomaticomaxillary buttresses (Figure 9-19), according to the concept of the structural pillars of the facial skeleton.[34] The authors favor 0.7-mm thickness (rigid) titanium plates fixated with six 1.5-mm diameter and 6-mm long screws (three above and three below the osteotomy) at the piriform rims and 0.5 or 0.6 mm thickness (malleable) titanium plates fixated with six 1.5-mm diameter and 6-mm long screws at the zygomaticomaxillary buttresses. The plates must be adapted precisely to the maxillary walls prior to insertion to avoid inadvertent maxillary displacement during screw tightening. Each screw is inserted partially and then evenly tightened to distribute any remaining inaccuracies in plate adaptation. Resorbable bone plates may provide adequate fixation, particularly in smaller movements, and may be an alternative to titanium fixation systems.[35-40]



•**Figure 9-18** Inferior turbinectomy may be necessary when the turbinate interferes with superior maxillary repositioning.



•**Figure 9-19** The maxilla is stabilized with bone plates at the piriform rims and zygomaticomaxillary buttresses.

Bone Grafting

Repositioning the maxilla inferiorly such that no bone contact is maintained across the osteotomy is an unstable movement.[14,41,42] When this is planned, block or particulate bone grafting should be used to increase stability.[43,44] When bimaxillary surgery is performed, bone that is removed from the mandibular osteotomies may be available for grafting. Common extraoral autologous graft harvest sites include iliac crest and calvarium, and banked allogeneic bone also may be used.[45]

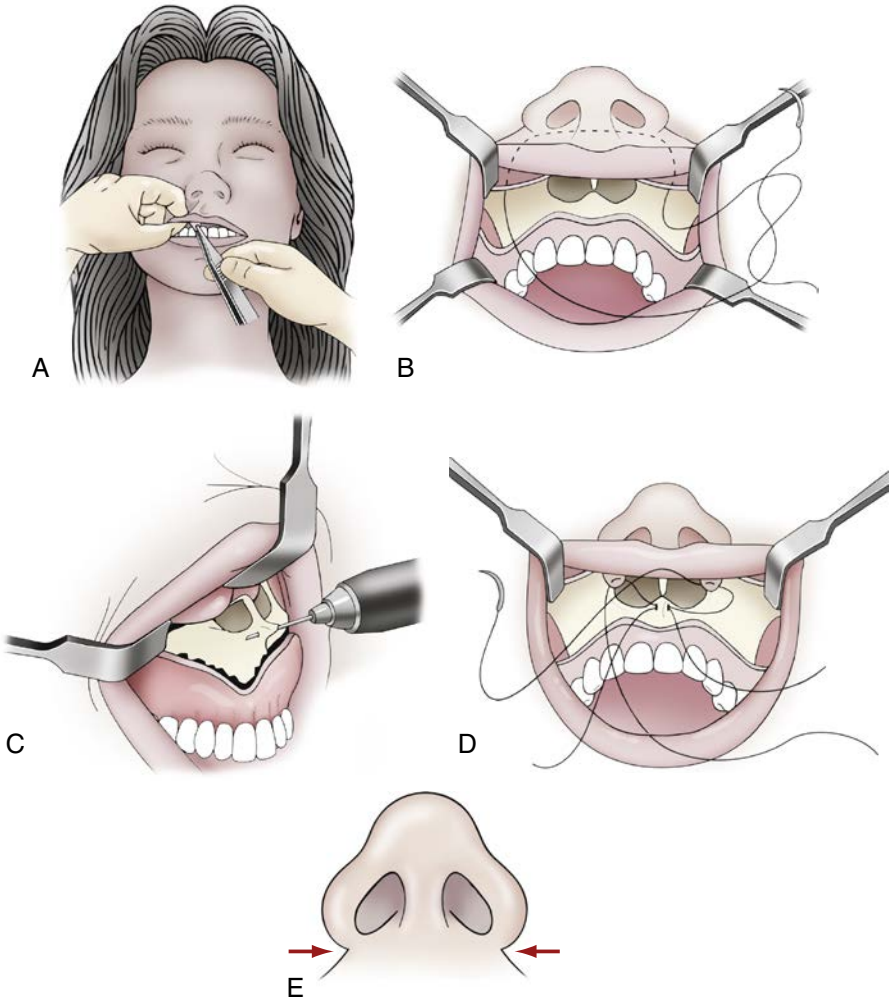
Occlusal Evaluation

Wire intermaxillary fixation is removed and the mandible is rotated up and down while applying posterior pressure on the chin to ensure condylar seating. The occlusion is evaluated, first with the splint in place and then with the splint removed. If the planned occlusion has not been achieved, intermaxillary fixation must be reapplied either with or without the surgical splint and maxillary fixation must be removed and repeated. The final occlusion must be evaluated honestly as this is the best opportunity to correct a discrepancy.

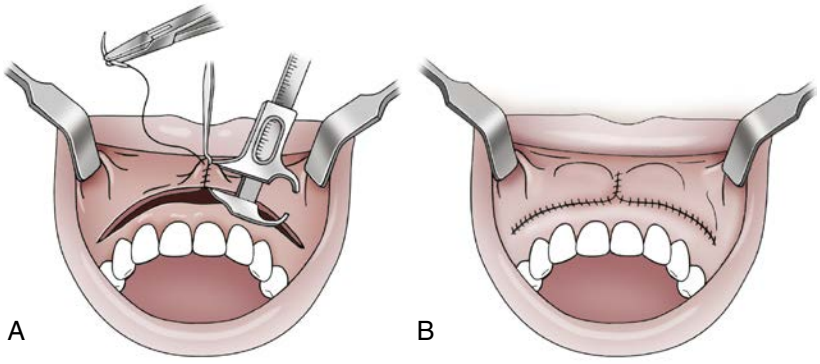
Alar Cinch and Wound Closure

The alar bases tend to widen due to detachment of the paranasal muscles during the dissection.[46,47] This widening may be lessened by insertion of an alar base cinch suture (Figure 9-20).[48,49] Various techniques have been proposed. The "classic alar cinch suture" involves identifying the fibroareolar tissue under each alae by applying extraoral pressure at the nasofacial skin folds, passing a non-resorbable suture through this tissue on each side from an intraoral approach, and tying the sutures in the midline.[50-52] The "reinsertion method" is performed by passing a non-resorbable suture from the intraoral wound through the skin at the nasofacial skin fold at the most lateral point of the alae, passing the suture back from the skin side to the intraoral wound through the same skin puncture site, and tying the sutures from each side in the midline.[51,52] The sutures may also be tied through a hole that is drilled in the anterior nasal spine. The "transseptal alar cinch suture" is similar to the reinsertion method, with the addition of a pass of the suture needle through the caudal nasal septum when traversing from one side to the other.[50] While no alar cinch technique can completely eliminate this widening effect, the reinsertion and transseptal cinch methods perform better than the classic alar cinch suture.[48]

The wound is then thoroughly irrigated with saline or Bacitracin-impregnated solution. Irrigation with high



•**Figure 9-20** Alar base cinch suture. **A,** Nasalis muscles are grasped with heavy forceps. **B,** A suture is passed through both nasalis muscles for alar base cinch. **C,** A drill hole is made through the anterior nasal spine to support the alar base cinch suture. **D,** A suture is passed through the hole and is tied. **E,** Cinching at the nasal base is confirmed. (From Betts NJ: Techniques to preserve or modify lip form during orthognathic surgery, *Atlas Oral Maxillofac Surg Clin North Am* 8:71-79, 2000.)



•**Figure 9-21** **A,** V-Y closure in the midline to lengthen the lip. **B,** Running suture for closure of the vestibular incisions. (From Betts NJ: Techniques to preserve or modify lip form during orthognathic surgery, *Atlas Oral Maxillofaci Surg Clin North Am* 8:71-79, 2000.)

pressure (70 psi) has been shown to decrease bacterial load more effectively than low-pressure lavage (1 to 2 psi).[53,54] The wound is then closed in either one or two layers (submucosa and mucosa or mucosa only). It is the authors' practice to perform a single-layer mucosal closure with 3-0 chromic gut suture in a running horizontal mattress fashion beginning posteriorly on each side. If lip lengthening is desired, a V-Y closure can be performed in the midline by elevating the mucosa with a single skin hook and suturing the two vertical limbs to one another (Figure 9-21).

Complications

Initial postoperative edema, bruising, and discomfort are expected. On average, 50% of swelling resolves by the third postoperative week, but some edema can remain for 6 to 12 months.[55] Transient neurosensory changes to the infraorbital and incisive nerve distributions (lower eyelids, upper lips, lateral nose, maxillary teeth, and gingiva) are typical. Most patients will experience temporary nasal and sinus congestion owing to edema and blood accumulation in the maxillary sinuses.

Complications can occur as early as the preoperative planning process. Inadequate assessment of the chief complaint and motivation to pursue surgery may lead to an unsatisfied patient even after a technically successful operation. Inaccurate facial assessment and diagnosis may contribute to an unesthetic result. Inappropriate planning, such as planning to the smile rather than the repose position in a patient with VME or failure to recognize a discrepancy between the centric relation and centric occlusion positions, may compromise the outcome. Incorrect orthodontic setup may limit the surgeon's ability to accomplish the desired correction. Insufficient patient preparation for the soft tissue changes that occur with a Le Fort I osteotomy, such as changes to the nasal alar base and tip, may also create an unhappy patient.

Intraoperative and postoperative complications occur relatively rarely. The risk for post-operative wound infection, abscess formation or maxillary sinusitis is only 1.1%,[56] and these typically respond to antibiotic treatment and sinus irrigation. The incidence of ischemic complications after Le Fort I osteotomy is estimated at 1%,[56] with loss of osseous and dental segments very rarely.[30] Deflection of the nasal septum off the maxillary crest can occur due to inadequate resection of the caudal septum and insufficient reduction of the maxillary crest, or due to trauma when the nasal endotracheal tube is removed.[56] The nasal septum should be evaluated immediately postoperatively because, if displacement has occurred, it is often correctible by gentle manipulation in the postoperative care unit. Sometimes a return trip to the operating room is necessary to reposition the septum.

Hemorrhage is the most concerning intraoperative and postoperative complication of the Le Fort I osteotomy.[57,58] The use of hypotensive anesthesia has significantly decreased intraoperative bleeding and the need for perioperative transfusion. In order of frequency, brisk intraoperative bleeding is most likely to occur from the posterior superior alveolar artery, the descending palatine artery, the pterygoid plexus of veins, the pterygoid muscles, or the terminal branches of the maxillary or internal carotid arteries.[59] The internal maxillary artery itself is less likely to be injured with proper osteotomy technique because the average location of this vessel is at least 10 mm superior to the superior aspect of the pterygoid osteotome during the pterygomaxillary disjunction.[59] If hemorrhage occurs intraoperatively and the source can be identified, the proximal and distal portions of the vessel should be ligated with hemoclips or sutures. Vessels such as the descending palatine artery tend to retract into the bony canal, which imparts a risk of delayed postoperative bleeding.[58] Additionally, a pseudoaneurysm that results from intraoperative trauma to the descending palatine artery may present with delayed postoperative nasal hemorrhage.[28,60] When the intraoperative source is venous or cannot be identified, controlled use of electrocautery, wound packing with vasoconstrictor-soaked sponges, microfibrillar collagen, and reverse-Trendelenburg positioning may improve hemorrhage control. Severe or uncontrollable hemorrhage can usually be managed with angiographic embolization in the interventional radiology suite.[60,61] Ligation of the external carotid artery has been shown to be minimally effective.[59]

If the osteotomies are inadequate, an unfavorable fracture may occur during maxillary down-fracture. Unfavorable fractures may extend into the orbit or skull base, or may fracture the horizontal process of the palatine bone or the pterygoid plates. These atypical fracture patterns can make mobilization and planned repositioning of the maxilla difficult or impossible. In rare cases, unfavorable fractures can lead to visual complications, damage to the cranial nerves within the pterygomaxillary fissure and the inferior or superior orbital fissures, or injury to the nasolacrimal ducts leading to postoperative epiphora. Unfavorable fractures can typically be avoided by meticulous osteotomy technique. The maxillary down-fracture should require minimal force. If significant force is necessary, this should alert the surgeon of the need to refine all osteotomies prior to proceeding with the down-fracture.

Moving the maxilla to its planned position can be difficult, particularly for large magnitude movements and in patients with a repaired cleft lip and palate. Inadequate mobilization and lack of passive repositioning into the surgical splint may lead to distraction of the mandibular condyles during maxillary fixation, resulting in a malocclusion when the intermaxillary fixation is released. This complication can typically be avoided by taking the time to adequately mobilize the maxilla intraoperatively, and with appropriate surgical planning. In very large movements and in some patients with cleft lip and palate, the use of distraction osteogenesis may be considered to allow the soft tissue envelope to slowly adapt to the change in maxillary position.

Pulpal tissues tend to tolerate the reduced vascularity that occurs after a Le Fort I osteotomy remarkably well. Vitality testing in the immediate postoperative period is not reliable, as 6% to 29% of teeth will test non-vital for up to 54 months after the operation.[62] However, pulpal necrosis does occasionally occur and may require endodontic treatment. Endodontic treatment should be delayed until at least 8 weeks postoperatively to confirm that spontaneous revascularization does not occur.[59]

Direct trauma to the teeth is possible with incorrect osteotomy design. Dental roots can be transected if the osteotomy is positioned too inferiorly.[63] The canine tooth is at greatest risk because it has the longest tooth root. If a segmental maxillary osteotomy is required, damage to the roots adjacent to the vertical osteotomies can occur. Additionally, lack of adequate remaining alveolar bone surrounding a tooth root after segmentation can lead to a periodontal defect.[64] Proper orthodontic preparation for segmental osteotomies with separation of the dental roots in the planned osteotomy sites is critical to avoid this complication.

Inadequate fixation, poor compliance with the prescribed period of a non-chewing diet, bruxism or traumatic dental occlusion may lead to fibrous non-union. This occurs in approximately 1% of Le Fort I osteotomies.[56] Unstable maxillary movements, particularly advancement with inferior repositioning with minimal or no bone contact may increase the risk for this complication.[65] Bone grafting of the defects created by inferior maxillary positioning may decrease this risk. Non-union requires re-operation with debridement of the fibrous tissue across the osteotomy gap, replacement or reinforcement of fixation, and bone grafting or use of bone morphogenetic protein.[66]

Summary

The Le Fort I osteotomy is one of the most common operations performed by orthognathic surgeons. Refinements in surgical and anesthetic techniques over the last century have made this a safe and predictable operation. Combined with methodical diagnostic and treatment planning approaches, the Le Fort I osteotomy can be used to correct a wide range of dentofacial deformities.

Le Fort I Segmental

JOHN F. CACCAMESE JR, ROBIN YANG

Segmental Maxillary Surgery

Transverse and sagittal maxillary plane discrepancies are commonly diagnosed problems with a prevalence of up to 15% in adolescents and up to 30% in adults.[1-3] Orthodontic compensation in some patients with minor discrepancies can be accomplished by buccal displacement of the maxillary teeth or lingual displacement of the mandibular dentition to establish a stable cusp-fossa relationship. Stable management of transverse maxillary deficiency with conventional orthodontics is limited by the capacity of the buccal bone and periodontium of the maxillary arch. The orthodontic management of sagittal occlusal plane problems such as anterior open bite with multiplanar maxillary occlusion is also fraught with relapse when excessive extrusion and uprighting is attempted. Orthodontic compensation, when applied inappropriately, can result in compromised dental health, function, and stability.

Surgical manipulation of the maxilla has historically been undertaken to treat certain isolated deformities of the maxilla using limited surgery of the anterior or posterior segments. As recently as the 1960s, the segmental Le Fort I osteotomy was popularized. While other options exist to treat transverse problems, including surgically assisted rapid palatal/maxillary expansion (SARPE or SARME), surgical mandibular narrowing, and rapid palatal expansion (prior to maxillary suture closure), most lack the ability to address sagittal and transverse plane issues at the same time. A complete diagnosis and problem list is important before undertaking treatment, as the segmental maxillary osteotomy is the most useful tool to control for transverse deficiency/excess, occlusal plane leveling, incisor angulation, and Bolton discrepancies—particularly at the incisor/canine interface. This chapter will review the use of the segmental Le Fort I osteotomy in the management of maxillary transverse and sagittal plane problems.

History

Initially, segmentation of the maxilla was difficult to achieve due to instability and access. Additionally, early operators were hesitant to completely mobilize the maxilla out of concern for vascular compromise.[4] Cohn-Stock was the first to introduce the anterior segmental osteotomy of the maxilla in 1921.[5,6] Wassmund subsequently modified the technique to one similar to what is utilized today.[7] Schuchardt developed a two-stage approach to the posterior maxillary segmental osteotomy whereby an initial palatal access was performed, followed by a delayed labial approach 4 weeks later to complete the lateral osteotomies.[8] West and Epker eventually described a procedure that involved the application of Schuchardt's two-stage technique and Kufner's single-stage posterior maxillary osteotomy for correction of posterior crossbites. This technique essentially separated the alveolus from the palate and was done in a single-stage fashion.[9,10] Heinz Köle then combined maxillary and mandibular subapical osteotomies to correct bimaxillary malocclusion.[11] Bell's landmark vascular studies of maxillary osteotomies eventually provided a scientific foundation for modern maxillary surgery.[12] Today, segmental maxillary surgery is most commonly performed via the standard Le Fort I osteotomy. Turvey further defined the importance and utility of segmental maxillary surgery in 1985. His series of 104 patients undergoing a combination of segmental maxillary osteotomies and grafting showed that a multi-segment maxilla was most appropriate to correct a hypoplastic maxilla in all three planes of space.[13]

Indications

Anterior Open Bite (Apertognathia)

The sagittal multi-planar maxilla, with vertical steps in the dental arch, is of particular concern when it is accompanied by an anterior open bite. Frequently, this pattern of growth also is accompanied by transverse maxillary hypoplasia and can contribute to the open bite. Nonsurgical orthodontic treatment is of questionable stability, especially if the treatment involves extrusion and uprighting of anterior teeth or buccal tipping of the posterior dentition. Initial reports for closure of anterior open bites with posterior dental intrusion using a variety of orthodontic anchorage appliances

have shown promise in select cases where the transverse relationship and Angle classification is appropriate.[14] Generally these techniques involve placement of bone-borne plates or screws in the posterior maxilla to generate skeletal rather than dental based force to intrude the posterior dentition and close the open bite. For some open bites—class I in particular—temporary orthopedic anchorage devices to intrude molar teeth have been used with some success. A study by Scheffler and Proffit found that moderate to severe anterior open bites were satisfactorily corrected with minimal tooth relapse.[15] If case selection is not appropriate, however, results can be well short of an optimal esthetic outcome for the patient.

While addressing sagittal occlusal plane problems in the orthodontic phase of preparation for segmental surgery, it is important not to attempt bite closure; in fact, many would advocate decompensation of the two planes of occlusion with separate or segmented archwires. Preoperative orthodontic open bite closure can lead to postoperative relapse, because the full magnitude of the deformity could be left unrecognized and subsequently undercorrected surgically. This is particularly problematic when the patient presents for consultation while in orthodontic appliances, with decompensation already underway or complete. Review of pre-treatment records can help to avoid these problems. If an open bite is recognized that has been orthodontically treated it is best to allow it to relapse prior to undertaking surgery.

If an anterior open bite is not due to a vertical step in the maxillary occlusion, segmental surgery can be avoided by altering the position of the occlusal plane until closure of the open bite is achieved, keeping in mind the esthetic needs of the patient. Some occlusions may be amenable to posterior maxillary impaction, whereas others with concomitant mandibular hypoplasia may benefit most from counterclockwise rotation of the occlusal plane. In this instance, care should be taken not to lengthen the ramus in the pterygomasseteric sling region because this can make the result more prone to mandibular relapse and recurrence of the open bite. When attempts to close an anterior open bite with clockwise rotation of the anterior maxilla and result in a posterior open bite, the gold standard of treatment is a segmental surgery.

Transverse Discrepancies

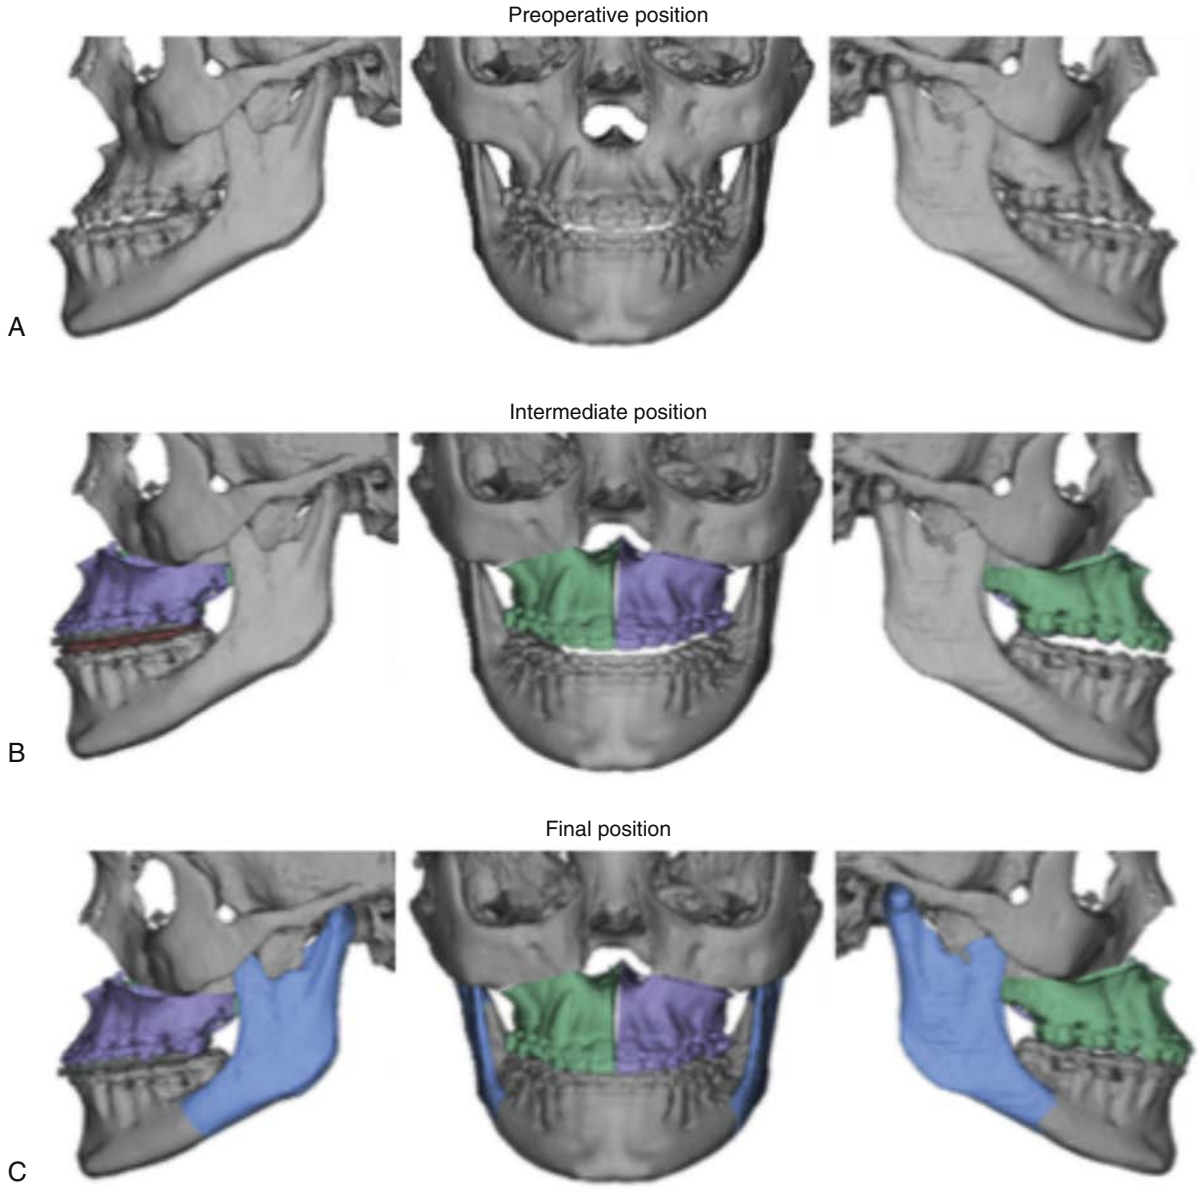
Minor transverse discrepancies are common dentofacial problems. These can be managed routinely with orthodontics alone. Many are realized in childhood and managed with orthopedic expansion and overcorrected slightly to allow for some relapse. In other instances, surgically improving the width of the maxilla is indicated to improve stability and arch form. Appropriate transverse arch relationships are important to optimize masticatory function as well as maintaining long-term mucosal health.[16] It is also important to understand that appropriate transverse relationships can enhance facial esthetics—especially the smile when buccal corrections are visible.

Transverse maxillary deficiencies often accompany vertical maxillary steps in the occlusion. When this occurs, maxillary segmental surgery and an appropriate retention plan are essential for the comprehensive treatment of the problem.

Presurgical Preparation

Presurgical planning for segmental maxillary surgery should be performed as per the surgeon's usual protocol. Usually, this begins by making the appropriate diagnosis at the pretreatment consultation so that an early discussion can be initiated with the orthodontist, and decompensation is carried out with a segmental osteotomy in mind. This includes preparation of the arch form in segments and the creation of space (if necessary) for the osteotomies. It is also important at this time to inform the patient that a segmental maxillary surgery is likely necessary. This will help the patient prepare for the longer course of splint therapy (6 weeks) that serves to provide transverse stability and immobilization of the maxillary segments at the occlusal level during the initial phases of healing and to prevent early recurrence of the crossbite or open bite.

Planning can be accomplished via a variety of methods including plain film analysis, model analysis, computed tomography (CT) scan evaluation, and of course, physical examination. The authors currently utilize virtual surgical planning (VSP) to facilitate preoperative planning and splint fabrication. This combines data from the physical exam, dental models, and three-dimensional (3D) CT derived anatomic information to best customize surgical outcomes for a given patient. While the preoperative and postoperative occlusion is still hand measured and articulated, this information is scanned and fused with the data from CT scan rather than performing model surgery on an articulator (Figure 10-1). Thorough evaluation of the magnitude of transverse discrepancy, anterior open bite, or both is undertaken with dental models that are properly articulated with a preoperative occlusal registration in centric relation. Interdental cuts are performed on the dental models and a best-fit occlusion is established and verified with the orthodontist to assure that the bite can be finished appropriately. In instances where an anterior Bolton discrepancy exists, plans for postoperative space to allow for restorations can be accommodated (especially in the lateral/canine area). The step or plane break in the maxillary occlusal plane is where the interdental osteotomy should be planned in open bite cases. This is usually observed between the lateral-canine region or the canine–first bicuspid region. When a transverse discrepancy exists, it is important to characterize the narrowing. If the intercanine and intermolar widths are both narrow, it may be beneficial to perform the osteotomies between the central incisors. For patients in whom there is a significant transverse discrepancy of this type (>7 mm), a V-shaped arch form, or teeth blocked out of the arch with the need for equal anterior and posterior expansion, a surgically assisted rapid palatal expansion (SARPE) can

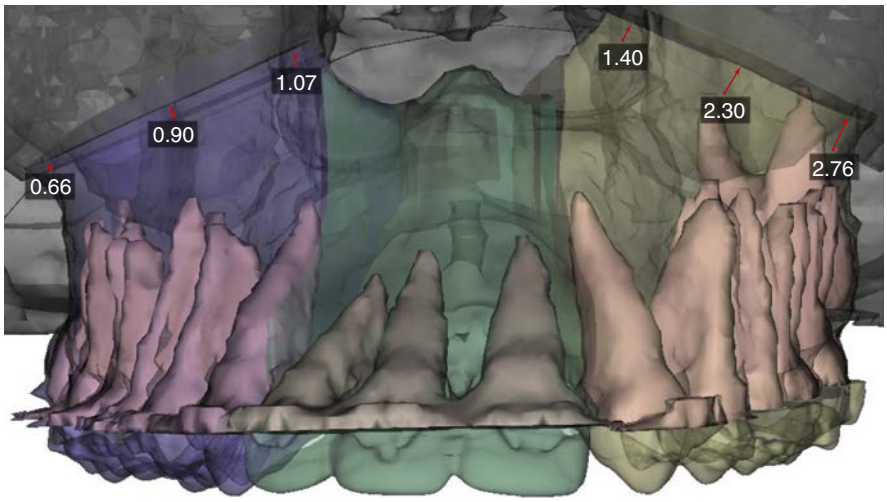


• **Figure 10-1** Virtual surgical planning. **A,** 3D CT of patient in natural head position and centric relation. **B,** Intermediate position of 2-piece segmental maxilla with mandible in centric relation. **C,** Final position of maxilla and mandible after BSSO (bilateral sagittal split osteotomy).

be considered as a first-stage operation. The indications and procedural details for this procedure are beyond the scope of this chapter and are discussed elsewhere. If the posterior region is narrow in isolation with adequate or near adequate intercanine width, an interdental osteotomy can be performed anterior or posterior to the canine.

Orthodontic preparation of the dentition prior to planned interdental osteotomies is helpful, though not always necessary. Ideally, 3 mm of space between the roots is established. This allows for the kerf of the saw blade (width of the osteotome), as well as the maintenance of healthy bone around the roots during healing. Parallel or divergent roots allow for ease of cutting and flexibility with the vector of the osteotomy. With the advent of 3D CT technology, the operative surgeon can now identify and visualize the osteotomy in three planes of view, which should help decrease the likelihood of damaging the dentition (Figure 10-2).

Once a final occlusion has been established with dental model planning, the models are scanned and sent for image fusion with the 3D CT images for virtual surgical planning and splint fabrication. The authors' preference is for the VSP engineers to fabricate the surgical splints. If the patient is scheduled for maxilla-first double-jaw surgery, a "sandwich" or "piggyback" splint (intermediate and final splint interdigitated as one unit) is typically utilized. This interdigitating splint decreases operative time by limiting the number of times the patient needs to have the maxilla wired into a surgical splint (Figure 10-3).



• **Figure 10-2** CT 3D view delineating canine anatomy to optimize cutting path during segmental osteotomy.

Surgical Technique

A standard vestibular incision is made in the maxilla with a broad mucosal pedicle left along the buccal surface and an adequate cuff of tissue for closure (5 to 7 mm). The incision should extend from the midline to the first molar on each side. Subperiosteal dissection should be performed to isolate the pyriform rim, lateral nasal walls, anterior nasal spine, and zygomaticomaxillary buttress.[4] Minimal mucosal/gingival dissection should be performed inferiorly towards the dentition with the exception of the location of the planned interdental osteotomy. The intention is to leave as much mucogingival tissue attached as possible to provide adequate blood supply for the alveolar structures. If the orthodontic surgical wire is a continuous one, it is sectioned in the vicinity of the segmental osteotomy to allow free manipulation of the segments and minimize intraoperative debonding or resistance to the planned surgical movements. This can be performed with wire cutters or with a diamond surgical burr. The authors prefer the use of a round diamond surgical burr because wire cutters can cause torqueing of the orthodontic wire and lead to inadvertent debonding. Once all of the soft tissue components of the nasal floor, wall, and septum are adequately released and the pterygomaxillary junction has been isolated, the traditional Le Fort I osteotomy should be performed in the usual fashion. Prior to down-fracture of the maxilla, the interdental segmental osteotomies can be performed as planned (Figures 10-4 and 10-5). In the authors'

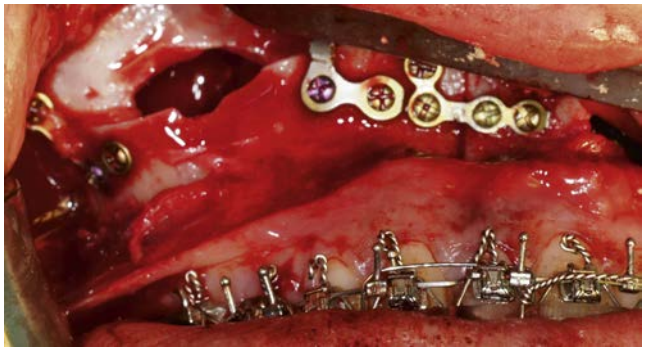
experience, executing these osteotomies with precision is difficult to perform with a fully mobilized maxilla, so they are done before the down-fracture. Careful planning, visualization of root prominences, and tactile feedback from the saw can prevent most iatrogenic damage to the dental roots. A finger should also be placed on the palate to palpate for the vibrations of the saw and ensure that it is not damaging the palatal tissue. The authors' preferred instrument to complete the interdental osteotomies is a rounded sagittal saw or sagittal safe blade (Figure 10-6). When properly used with judicious force, damage to the soft tissues of the palate is unlikely. The remainder of the standard maneuvers is then undertaken for the down-fracture of the maxilla.

Once the maxilla is down-fractured, the nasal mucosa is inspected and any residual attachments are elevated. Full mobilization of the maxilla is indicated to give the operator access to the posterior maxilla. This is easier to accomplish prior to completing the segmentation. The palatal segmental osteotomies can then be performed and are made from posterior to anterior on the hard palate to connect with the anterior interdental osteotomies. These osteotomies are usually made para-midline where the bone is thinner and the palatal mucosa is thick (see Figures 10-4 and 10-5). The thicker palatal tissue in this location is a buffer to help prevent iatrogenic mucosal damage. The authors use a reciprocating saw for this purpose, but lateral osteotomies can also be performed with a small fissure burr, a round burr, or even a piezoelectric osteotome. When the lateral palatal osteotomies are connected to the interdental (alveolar) osteotomies it is important to note that the bone in the incisive foramen region of the hard palate is thicker and will require a deeper bony cut. An osteotome or periosteal elevator can be used to finalize the mobilization once the cuts are complete. Occasionally a Smith spreader is helpful to completely mobilize the palatal or alveolar bone. Care must be taken with the forces applied at this point because the hard palate and gingival mucosa are relatively thin and inelastic tissues, susceptible to tearing.

Once the maxillary segments have been mobilized, the occlusal splint is wired into place. If a large degree of maxillary widening is anticipated the palatal tissues can be undermined from the palatal bone of the lateral segments with the use of a Woodson or similar elevator. Maintaining as much soft tissue to the dento-osseous segment is key. This will cause the height of the palatal vault to drop



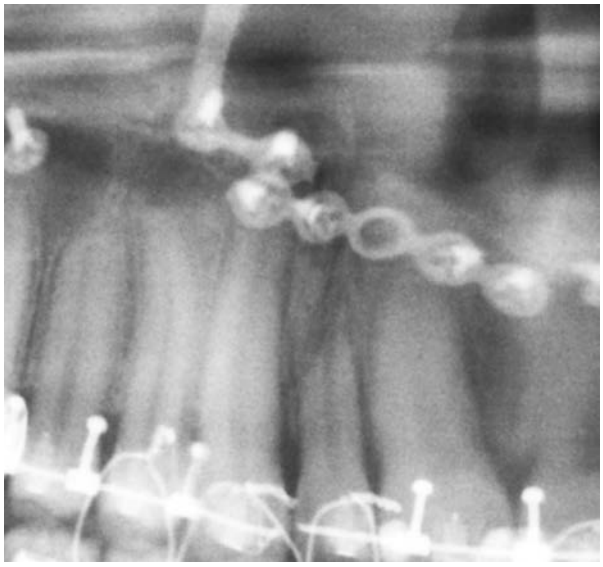
• **Figure 10-7** Placement of miniplates across segmental for additional stability.

a small amount but facilitate the maxillary expansion. It is important to not underestimate the strength and inherent noncompliance of the palatal mucosa. It may require multiple attempts at stretching, undermining, and manipulation in order for the maxilla to be passively seated into the final splint. One must assure the maxilla is freed completely so that the splint is not loaded with force and bending to the occlusion, only to rebound when the patient is released from maxillomandibular fixation. Wires can be placed through the anterior nasal spine or the buccal tubes of first molar bands to place gentle traction on the segments as needed to guide the segments into place. Once the maxilla is passively seated and the final splint is wired, the patient should be placed into maxillomandibular fixation. Necessary bone reductions are performed, and this bone can be used for interpositional bone grafts placed along the palatal gaps at the surgeon's preference. Likewise, grafts are placed in the interdental osteotomy gaps. This can help provide initial stability of the segments and help with healing. The maxilla is then positioned as it would be for any conventional Le Fort I osteotomy and the appropriate bone plates are placed for maxillary fixation. It is the authors' preference to place bone plates across the maxillary segments to help with additional early stability (Figure 10-7). When maxillomandibular fixation is released, the palatal tissue and the gingiva adjacent to the maxilla should be inspected for any signs of damage or ischemic compromise. Inadvertent tears in the palate or alveolar gingiva should be closed and then the Le Fort incision should be closed as to the operator's preference.

Postoperative Care

Management of patients after segmental maxillary surgery is similar to patient management after conventional single-piece Le Fort surgery with the exception of the need for postoperative splint use. Peri-operative antibiotics are given for 24 hours. Appropriate hygiene is also important to avoid early infection and optimize soft tissue healing. Patients are encouraged to start regular dental hygiene in the form of tooth brushing the day after surgery. Chlorhexidine mouth rinse is encouraged to assist with splint cleanliness. Each individual practitioner will determine his or her regime

• **Figure 10-8** Postoperative gingival recession and root exposure at the site of an interdental osteotomy for segmental surgery.



• **Figure 10-9** Fractured root at the site of an interdental osteotomy.

for occlusal splint therapy. The authors prefer to keep the patient in elastic maxillomandibular fixation for 1 week after surgery. The occlusal splint is left wired into place for a total of 6 weeks postoperative. Upon splint removal, the patient is encouraged to see the orthodontist the same or next day for insertion of a new stainless steel continuous archwire and a transpalatal appliance (TPA) that is used for transverse relapse prevention. The TPA is prefabricated based on the final surgical model width that was provided to the orthodontist. Typically the TPA is left in place for 3 months.

Complications

Loss of a dentoalveolar segment is a dreaded outcome after a segmental maxillary surgery, though exceedingly rare. Aseptic necrosis of the maxilla has been reported to occur in less than 1% of segmented cases.[17] The reported causes of aseptic necrosis range from patient factors such as smoking to iatrogenic surgical factors, which could result in compromised vascular flow to the maxilla.[18] There is no defined protocol for the treatment of aseptic necrosis of the maxilla, however, reported treatment options include surgical debridement of necrotic areas, expectant management with meticulous hygiene, hyperbaric oxygen therapy, antibiotics, and heparin.[18] Other local complications include damage to the dentition and gingiva, as well as localized periodontal defects associated with the interdental osteotomies (Figures 10-8 and 10-9). A small number of patients have been reported to develop pulpal necrosis requiring root canal treatment.[19] Lastly, relapse is always a concern given the inherent instability of maxillary expansion and open bite correction, however, this can largely be avoided with proper planning, intraoperative attention to detail, and a well devised postoperative retention strategy (Figure 10-10).

Combined Maxillary and Mandibular Osteotomies

BRENT GOLDEN, CAITLIN B.L. MAGRAW, MICHAEL JASKOLKA

History

Modern orthognathic surgery with combined maxillary and mandibular osteotomies has its origin in the second half of the 20th century. The initial burst of innovation came in the 1950s and 1960s as the various contemporary mandibular and maxillary osteotomy techniques were described and modified independently. These foundational procedures for correcting facial disproportion and malocclusion by maxillary and mandibular surgery were subsequently combined into a single stage of surgery where changes could be executed in the maxilla, mandible, and chin simultaneously. Amazingly, many of these advances can be attributed largely to the insights and vision of a single oral and maxillofacial surgeon, Hugo Obwegeser (Figure 11-1).

The bilateral sagittal split osteotomy (BSSO) was originally preformed by Obwegeser at the Medical University of Graz, Austria, in 1953,[1] although it was not published until 1955 in German[2] and English in 1957.[3] His technique was novel in its degree of control over mandibular length and healing, along with the advantage that it was completed intraorally. During this same period, he developed the intraoral sliding osseous genioplasty and included it in his English publication of 1957.[3] It should be noted that Hofer had published a similar sliding mandibular horizontal osteotomy in 1942; however, his approach was completed using an extraoral approach and was completed on a cadaver, not a patient.[1,4]

Although improvements in mandibular osteotomies allowed for greater interest and less morbidity in corrective jaw surgery, many patients still suffered from deformities involving the midface that were not adequately treated with mandibular surgery alone. Although there were historical precedents for maxillary osteotomies.[5-8] Obwegeser's description was the landmark that allowed the procedure to gain widespread use and utility. It was in 1964 that Obwegeser described a Le Fort I level osteotomy with a downfracture and mobilization technique through a horizontal circumvestibular incision that was both predictable and effective for treating jaw disproportion without substantial morbidity.[1] These advances culminated in the first bimaxillary surgery using a combination of BSSO and Le Fort osteotomy performed by Obwegeser in 1969, which he published the following year.[9]

Dr. Obwegeser famously presented in the United States on his innovations at Walter Reed Army Medical Center in 1966 and profoundly influenced the next generation of specialists treating these deformities. Major contributions from other surgeons and orthodontists have followed ever since.

Concomitant technological advancement in the field of fixation catalyzed further improvements as wire was replaced by bone plates and screws. Hans Luhr published his work on internal fixation in 1968,[10] allowing surgeons to incorporate this innovation in corrective orthognathic surgery with subsequent improvements in the predictability of osteotomy reconstruction, stability, and quality of life during recovery.

The 1970s and 1980s were a period of elucidating the biologic basis of these orthognathic procedures. Despite increased facility with the techniques as they gained popularity, orthognathic surgery needed scientific support for biologic plausibility[10-12] and the understanding of physiologic responses to treatment,[13-18] and attention was focused on defining the expectations with regard to skeletal and soft tissue responses following orthognathic surgery.

The details of surgical technique for each osteotomy in isolation are covered elsewhere in this text. This chapter's aim is to address the considerations involved in the combination of these techniques in a single stage including indications, stability, sequencing, and contemporary innovations.

• **Figure 11-1** Hugo Obwegeser. (From Posnick JC: *Orthognathic surgery: principles and practice*, St. Louis, 2014, Saunders, Copyright JC Posnick.)

Indications

Dentofacial deformity of a severity that would necessitate corrective jaw surgery occurs in between 2.5% and 5% of the U.S. population.[20,21] A thorough patient history, clinical evaluation, and relevant diagnostic records should generate accurate orthodontic and surgical diagnoses and a prioritized problem list from which all treatment objectives are set. Before undertaking corrective jaw surgery of any type, it is imperative to eliminate or control all acute systemic and oral disease as a precursor. Subsequently, the decision to operate with maxillary osteotomies, mandibular osteotomies, or a combination of the two is made based on the following:

1. Projection, proportion/balance, and symmetry of the facial hard and soft tissues
2. Functional status of the oral structures (including dental occlusion) and airway
3. Reported data on long-term stability of proposed interventions

Projection, Proportion, Balance, and Symmetry

Evaluation of projection, proportion, and symmetry is a fusion of clinical data collection compared against normative averages with personal esthetic clinical judgment. Here, the clinician uses accepted ideas about sagittal projection (e.g., balance of forehead, nose, lips and chin in profile), vertical proportion (e.g., facial index, facial thirds, incisor display), and transverse balance (e.g., orbitofacial symmetry, occlusal plane orientation, dental midlines) together with esthetic judgment to determine where the structural pathology exists. Although there are no clear boundaries between normal and abnormal, experienced clinicians generally agree on the presence or absence of disharmony in the three planes of space while allowing for some variance on degree. The majority of dentofacial deformity can be subcategorized into class III problems, long face problems, mandibular deficiency (short or normal face height), or asymmetry.

The pattern of patients seeking combined orthodontic-surgical treatment seems to have shifted in recent years, with patients who have a class III malocclusion (concave profile) becoming the majority.[22] The emphasis on projection of the jaws in the "class III" description should not distract the clinician from the concomitant vertical pathology that often exists with either backward rotation of the mandible when the face is long or overclosure when the face height is short. As surgical techniques have evolved to allow for treatment of midface deficiency in class III malocclusion, the overwhelming majority of patients are now treated with maxillary advancement, which is performed approximately half the time in isolation and half the time combined with mandibular setback.[23]

Patients with a convex profile can also comprise a significant portion of patients seeking treatment for dentofacial deformity. When face height is short or normal, then isolated mandibular advancement with or without genioplasty is often adequate. Conversely, patients with a convex profile and increased face height (long face deformity) frequently exhibit differences in both the maxilla (increased posterior vertical maxillary height) and the mandible (decreased projection, steep mandibular and occlusal plane).[24,25] Therefore, structural indications for bimaxillary surgery often exist for comprehensive treatment of the long face patient.

Asymmetry of a small degree is certainly a variant of normal and not detrimental. To begin to delineate pathologic asymmetry, it is useful to consider the transverse and the vertical dimensions separately, although most cases of asymmetry involve both. With appropriate orthodontic preparation and decompensation, the dental midlines as they relate to the facial and chin midline are quite reasonable surrogates for transverse skeletal asymmetry. Numerous studies have sought to identify how much the maxillary dental midline can deviate from the midsagittal plane before becoming socially detrimental, and most suggest that discrepancies of 2 mm or less are acceptable.[26,27] When the maxillary midline exceeds this amount, the diagnosis of transverse asymmetry is appropriate and consideration of surgery to correct the discrepancy is recommended.

Using the teeth at the occlusal plane also can provide information on vertical asymmetry, although it is important to note that many asymmetric conditions have bony disproportion distant from the dentoalveolus. Padwa and colleagues showed that a maxillary cant greater than 4 degrees was detected with 90% frequency by both professionals and laypersons, and Susarla later showed that the degrees of maxillary cant reasonably approximate the millimetric difference (i.e., 4 degrees ≅ 4 mm).[28,29] From this we can infer that occlusal canting greater than 4 degrees/4 mm is clearly pathologic, although lesser degrees of vertical asymmetry often benefit from correction as well. Of course, correction

of asymmetry overwhelmingly requires bimaxillary surgery because of compensatory changes between the jaws and the benefits of overcorrection in the asymmetric patient.

Functional and Esthetic Considerations

Functional considerations in determining the appropriateness of bimaxillary surgery include the need to create a balanced and stable occlusion, foster a patent airway with minimal obstruction, and support a healthy temporomandibular joint (TMJ). Achieving a balanced occlusion is a primary tenet of achieving an acceptable result and is dictated by orthodontic preparation, gross skeletal movement, and final orthodontic detailing. Additional coordination of the dental arches can require surgical segmentation when there is transverse incompatibility or a dual plane of occlusion. Notably, this surgical component of balancing the occlusion at the arch level may necessitate bimaxillary surgery even when projection, proportion, and symmetry are not markedly disturbed in both jaws.

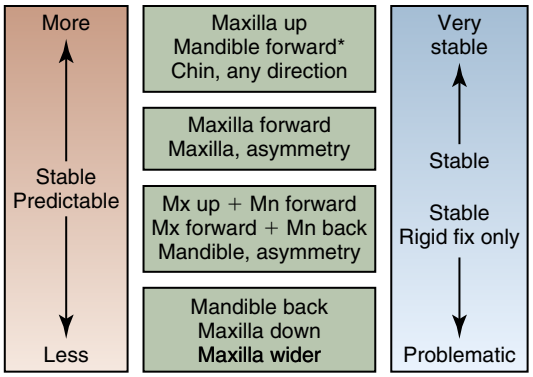
Of great significance in surgical planning is consideration of airway patency and adaptability. It has been well documented that bimaxillary advancement has a role and a clear indication for treatment of documented severe obstructive sleep apnea (OSA) that has not responded to continuous positive airway pressure (CPAP).[30,31] It has also been shown that mandibular setback surgery has implications for the pharyngeal airway by decreasing cross-sectional area[32,33]; however, a causative association with increased OSA has not been shown to date with modest movements.[34,35] In light of this, bimaxillary advancement is the most comprehensive approach for opening the airway at multiple levels in patients with known obstructive symptoms, and mandibular setback in at-risk populations should be minimized or avoided.

The effects of malocclusion and bimaxillary surgery on TMJ health or disease remains obscured by questions regarding the classification of disease, overwhelmingly retrospective and small-size studies, and varying clinical experience. Much remains to be studied, and the role of bimaxillary surgery in treating known degenerative TMJ disease or exacerbating symptoms of TMJ disorder is unclear.[36,37] To date, there has been no conclusive evidence to linking the two. In the patient with significant degenerative pathology, simultaneous alloplastic reconstruction of the TMJ with Le Fort I osteotomy has become a reality in select centers with TMJ reconstruction expertise.[38,39]

In addition to functional considerations, all treatment decisions must take into account the significant psychosocial impact of inherent esthetic changes. Smile design and facial balance must be factored into the final treatment decisions.

Stability

Individuals undergoing treatment of their skeletal facial deformities with orthognathic surgery expect their functional and esthetic results to be maintained for many years.



• **Figure 11-2** Hierarchy of stability. (From Proffit WR, Turvey TA, Phillips C: The hierarchy of stability and predictability in orthognathic surgery with rigid fixation: an update and extension, *Head Face Med* 30(3):21, 2007.)

Stability after orthognathic surgery is multifactorial, and it is important for surgeons to have an understanding of the principles that influence short- and long-term effects when planning treatment and counseling patients.

Relapse after orthognathic surgery is the result of either ongoing abnormal growth patterns or functional adaptations overpowering the anatomic form created by the surgeon. It is ideal to wait until the adolescent growth spurt is largely completed before treatment to minimize the negative effects of aberrant growth. Assuming minimal remaining growth, postsurgical changes seem to be related to the direction and magnitude of movement of each jaw, osteotomy techniques, fixation type used, and physiologic adaptation. In light of current knowledge about postsurgical stability, there do exist meaningful indications for bimaxillary surgery to improve the long-term outcomes in certain circumstances even when single-jaw surgery may be feasible.

When considering stability for orthognathic surgery, the most comprehensive information comes from the UNC data set as interpreted by Proffit and colleagues[40] (Figure 11-2). With class III correction, isolated mandibular setback registers as notably unstable, with up to 50% of patients experiencing clinically significant relapse of over 2 mm in the first year after surgery and 15% or more showing more than 4 mm of relapse (in the era prior to rigid fixation). Conversely, class III deformity can be treated with a stable outcome (defined as clinically significant relapse of less than 2 mm in at least 80% of patients and greater than 4 mm in almost none) if isolated maxillary advancement is used for movements of less than 6 to 8 mm and rigidly fixated bimaxillary surgery with maxillary advancement and mandibular setback is performed for larger movements.[21,40]

Posterior maxillary downgrafting is considered problematic with respect to stability, as 40% experience a postsurgical relapse of between 2 and 4 mm and another 20% have greater than 4 mm of change.[40] Because of this inherent instability, downgrafting of the posterior maxilla that lengthens the posterior face height is most often performed using an empirically derived combination of concurrent

mandibular surgery to decrease bite force in the early postoperative period, rigid fixation, and bone grafting of the maxillary defects.

Stability after bimaxillary surgery with mandibular advancement when the maxillomandibular complex (occlusal plane) is altered is dependent on the indication for treatment and direction of movement. When the mandible is advanced and only the anterior face height is increased to relieve vertical shortening, stability is well documented.[21] This is unlike mandibular advancement and superior repositioning by counterclockwise rotation in long-face patients, where stability is much more dubious. Introducing bimaxillary surgery to minimize counterclockwise movement with posterior maxillary impaction has historically been indicated. In contemporary practice, increasing the rigidity of fixation may allow for better stability of counterclockwise rotation, but further data will be helpful to support this change in practice.[21]

Technical Considerations for Performing Bimaxillary Surgery

Historical Norms and Orthodontic Collaboration

Soon after these techniques to treat dentofacial deformity became more widespread, orthodontists and surgeons began to appreciate that optimal outcomes were achieved only with coordinated care. Relatively early on, a three-phase protocol consisting of presurgical orthodontic preparation, surgical care with appliances in place, and a short phase of postsurgical orthodontic detailing became the standard of care.

Coordination of care between the orthodontist and surgeon ideally begins prior to starting definitive orthodontic care. This follows from the reality that orthodontic treatment markedly differs when decompensating dental changes for corrective jaw surgery versus camouflage treatment to fully compensate a malocclusion without surgery. Planning begins with the creation of a comprehensive patient database (chief complaint, clinical history and exam, anthropomorphic measurements, plain-film x-rays or three-dimensional [3D] radiographs, dental study casts, and bite in centric relation). Modern software tools allow for two-dimensional profile simulations that may aid in presenting a visual representation of possible treatment changes.[41] A prioritized problem list should be generated from all data to guide the development of definitive orthodontic and surgical treatment objectives.

Orthodontic treatment typically begins in advance of surgical care to allow for increased precision of surgical movements and to limit the amount of treatment following surgery. Although beyond the scope of this chapter, orthodontic objectives are generally to decompensate the incisor teeth vertically and anteroposteriorly, level and coordinate the dental arches, and provide stable appliances once surgery is imminent.

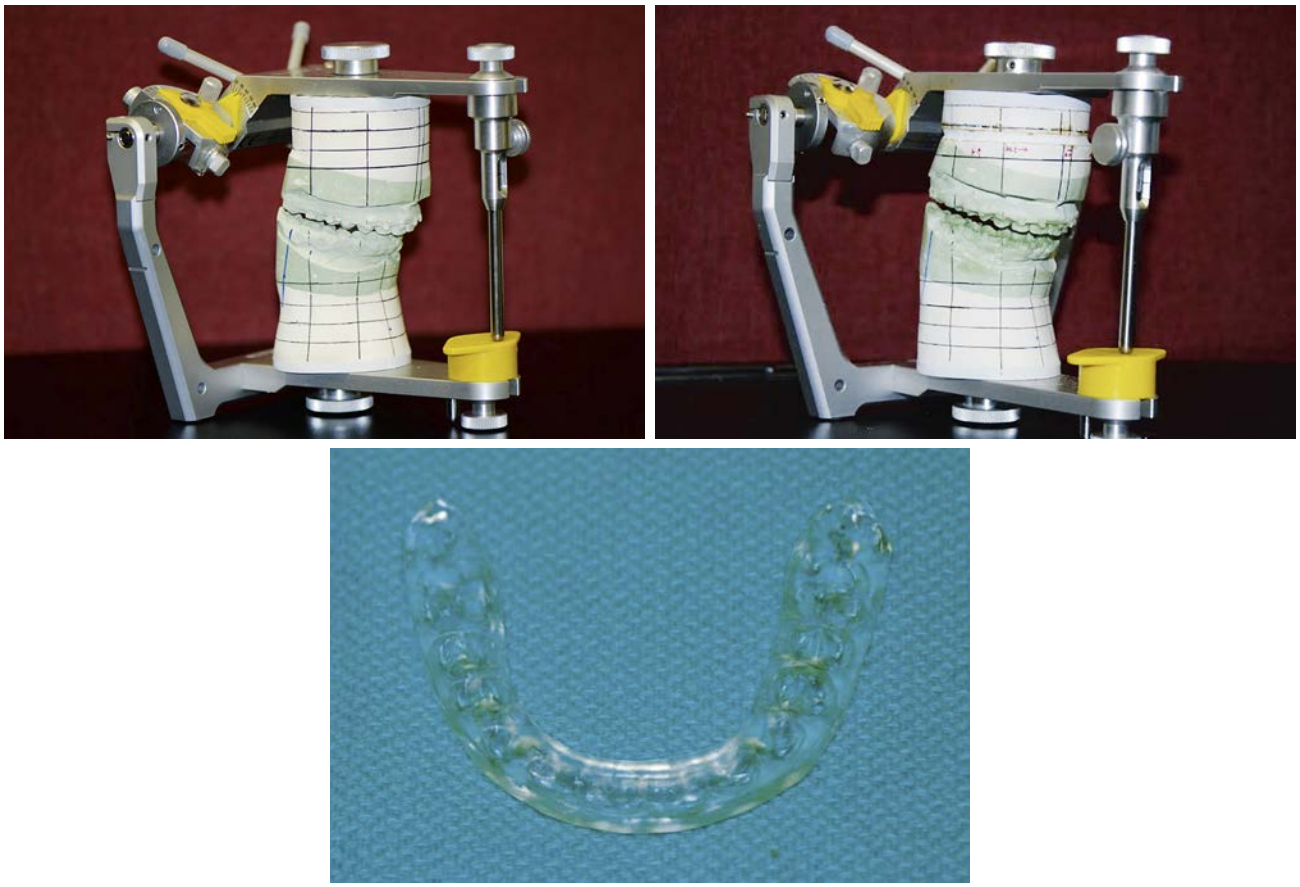
Once the patient is orthodontically prepared for surgery and a heavy arch wire is in place to stabilize the teeth for final surgical planning, comprehensive records (clinical history and exam, anthropomorphic measurements, plain-film x-rays or 3D radiographs, dental study casts, facebow transfer, and bite in centric relation) are updated. The final surgical plan is dictated by the prioritized problem list with the clinical exam preeminent. With increasing availability of advanced 3D imaging and virtual planning techniques, it is worth emphasizing that radiographs and 2D or 3D cephalometric references are adjunctive to the clinical exam but still do not fully capture hard and soft tissue relationships or the effects of animation and are not prescriptive of surgical movements in isolation.

The surgical plan is reliably translated to the operating room by using a custom fabricated interocclusal splint for each movement of the jaws (Figure 11-3). The process of creating a custom occlusal splint is fundamentally important to bimaxillary surgery and is known as model surgery. Model surgery in the late 20th century was entirely dependent on historical dental techniques using stone casts mounted on a semi-adjustable articulator. Because this process is so critical to achieving positive outcomes, the reader is directed to a full chapter dedicated to the specifics elsewhere in this text.

The greatest precision and best visualization of change with traditional stone model surgery occurs at the occlusal plane. In cases with significant asymmetry, virtual models and model surgery can greatly improve knowledge of changes at the bony landmarks more distant from the teeth and provide a substantive advantage. The expected relationships of the bone interfaces and landmarks are explicitly shown in the virtual environment with great advantage to the surgeon.

Maxilla-First Surgery

The traditional sequence of operative care begins with mandibular corticotomies without completing the sagittal osteotomy. The vertical position of the maxillary incisor teeth is referenced prior to the maxillary osteotomy by intraoperative measurements compared to soft tissue landmarks (i.e., medial canthus) or a K-wire pin placed in the nasal radix. The historical use of internal reference marks has largely been abandoned as external reference points have been shown to be more accurate.[42] The maxilla is then osteotomized and completely mobilized. If the maxilla needs to be segmentalized, this is accomplished after the downfracture, and the maxilla is placed into a final splint to stabilize the arch change. Placing the teeth into intermaxillary fixation using a custom intermediate occlusal splint creates the desired spatial relationship of the maxilla in every position except the vertical. The maxilla is then rotated into the correct vertical position, relying on the stable condylar centric relation position and the previously obtained external reference distances. Care must be taken to ensure that the teeth remain firmly in the occlusal splint and that the condyles do not rotate out of the fossa when assessing the maxillary final



• **Figure 11-3** Occlusal splints.

position. The maxilla is then fixated in place using titanium miniplates and screws or, alternatively, resorbable plates and screws. After maxillary rigid fixation, the intermaxillary fixation is released and the relationship of the mandible to the maxilla is confirmed by occlusal relationships both into the intermediate splint and without the intermediate splint in place.

Next, completion of the mandibular osteotomies takes place, and the distal segment of the mandible is mobilized. Intermaxillary fixation is again used in conjunction with the final occlusal splint to create the desired occlusal relationship and distal mandibular position. The proximal segments of the mandible are positioned with the condyle in the posterior-superior aspect of the glenoid fossa while the distal end of the proximal segment is related to the distal segment based on the judgment of the surgeon and the anticipated relationship of the bone at the osteotomy site. Care must be taken not to lengthen the posterior face height. Once the segments have been passively related, the mandible is fixated with rigid fixation using position screws, bone plates, or some combination of the two. Genioplasty or other mandibular contouring is typically carried out last while the patient is in stable intermaxillary fixation. Finally, the patient is released from intermaxillary fixation, and the relationship of the jaws is verified by occlusal match into the splint and without the splint in place. The final occlusal splint can be secured to either arch for any length of time up to 6 weeks or discarded. The patient is maintained in elastic bands and not kept in maxillomandibular fixation. Postoperative care is consistent with single-jaw surgery and detailed elsewhere in this text.

This sequence of "maxilla-first" surgery is influenced heavily by the historic use of semirigid wire fixation that led to a fear of intraoperative instability from loss of fixation in the mandible. Many surgeons elect to continue the application of this sequence out of comfort and tradition. The development and application of rigid internal fixation, however, has allowed this topic to become one of surgical preference and practicality. Even so, it should be noted that clear indications for surgical repositioning of the mandible first do exist.[43,44]

Mandible-First Surgery

Inconsistent Centric Relation of the Mandible

Occasionally, patients present with an inability to consistently reproduce a stable position of the mandible. This may be caused by structural or functional abnormalities of the TMJ complex (e.g., hemifacial microsomia) and poses several challenges to orthognathic surgical treatment planning and execution. The first example of difficulty can occur during record taking and bite registration. If the captured mandibular position is incorrect in relation to the maxilla, error can propagate during mounting of stone casts as well as virtual model fabrication (i.e., registration of the

high-resolution dental models to the skeletal model). The second example of difficulty can occur if the mandible is used as the intraoperative reference for repositioning the maxilla (as is the case in traditional sequencing with an intermediate splint). In either of these circumstances, if the maxilla is moved first, its final position is likely to be inaccurate.

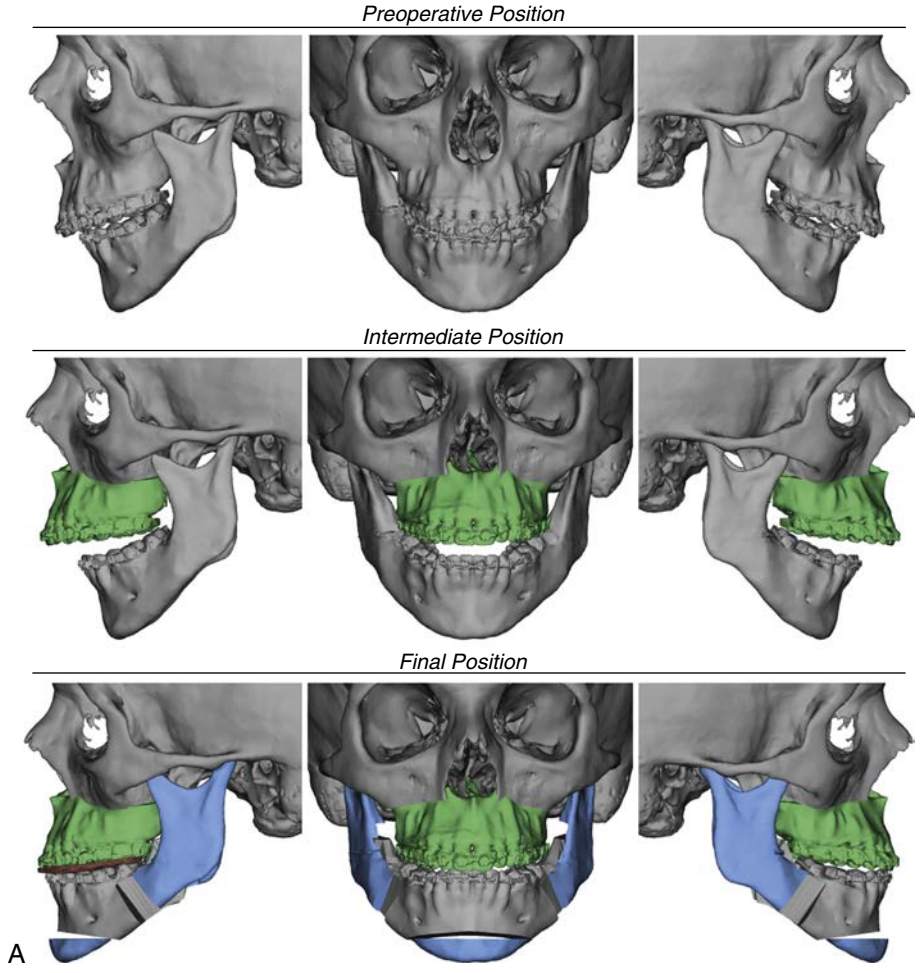
In the first example, "mandible-first" surgery will negate the inaccurate bite registration and mounting because of the use of the fixed maxilla as the reference with an intermediate splint. This can also be accomplished using the traditional sequence if a maxillary repositioning splint is used that is related to the fixed portion of the midface.[45]

Intraoperative Difficulty with Intermaxillary Fixation

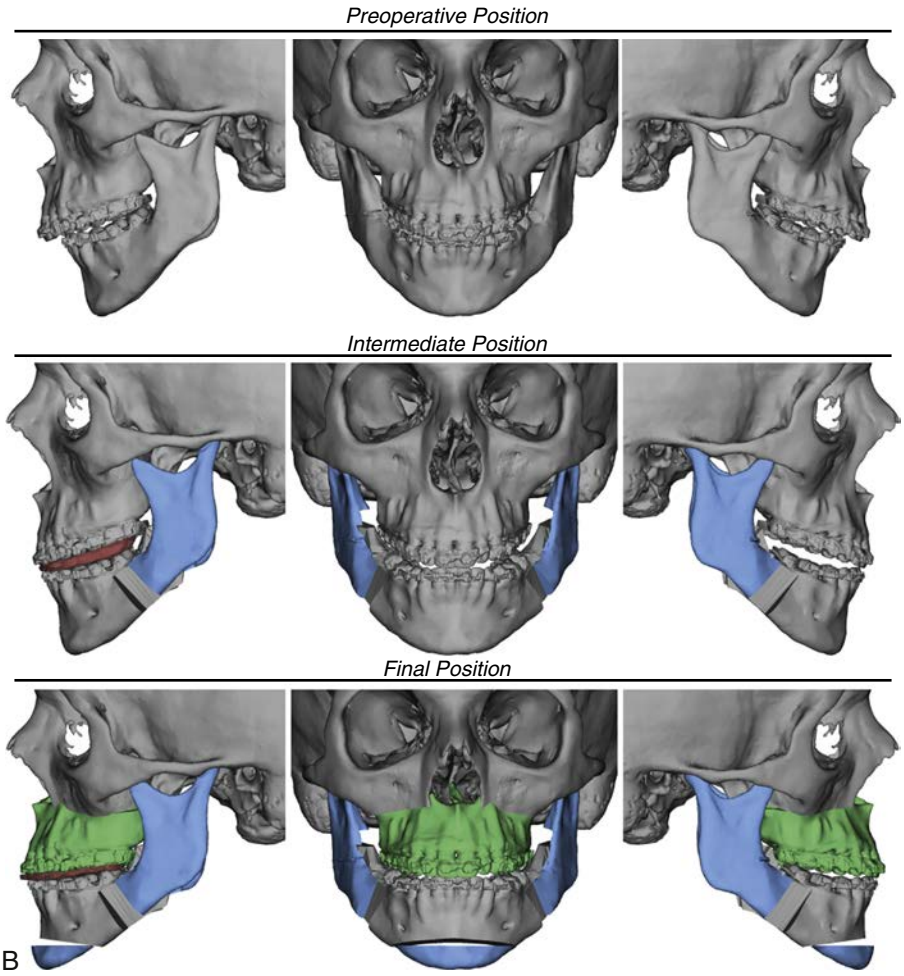
A variety of intraoperative technical challenges can be related to surgical sequencing. When counter clockwise rotation of the maxillomandibular complex is planned and executed with "maxilla-first" surgery, inferior and posterior opening of the mandible occurs. This can present two problems with the accurate positioning of the maxilla. If the movement is large enough, the mandible may actually be forced to translate out of the glenoid fossa, making the intermediate splint erroneous. Secondly, challenges can present because of the size of the intermediate splint and difficulty with placement of secure intermaxillary fixation. These issues can again be accounted for by initial mandibular surgical repositioning with the use of an occlusal splint or the use of the skeletally based maxillary repositioning splint (Figure 11-4).

A similar situation can occur when a patient with a preoperative class II occlusion is planned for both maxillary and mandibular advancement. Maxillary advancement first can make fabrication of an intermediate occlusal splint and placement of intermaxillary fixation challenging.

Last, the opposite situation can present when planning for mandibular repositioning first if the patient is planned to undergo significant clockwise rotation of the occlusal plane. In this circumstance, there is a clear indication to perform maxillary surgery first to minimize the intraoperative difficulties noted earlier.



• **Figure 11-4** Alternative sequencing: **A,** Maxilla-first surgery and the challenges in splint fabrication as well as the challenges of maintaining condylar position.



• **Figure 11-4, cont'd** **B,** The same case with improvements using mandible-first surgery.

Extraoral Surgery of the Mandible

Another consideration of surgical sequencing arises when either concomitant TMJ surgery or extraoral mandibular advancement (i.e., inverted L procedure) is planned. As discussed earlier, the predictable repositioning of the maxilla first using an intermediate occlusal splint is predicated on the reproducible positioning of the bilateral TMJ complex. In this circumstance, the maxilla may be repositioned first, followed by TMJ surgery and mandibular repositioning, but in this sequence, maintaining meticulous surgical sterility can be challenging. It is often more straightforward from an instrumentation perspective to perform the TMJ procedure first, followed by mandibular repositioning and finally maxillary repositioning.

Extraoral mandibular advancement is often planned in cases necessitating large mandibular advancements and bone grafting (i.e., Treacher Collins syndrome) or in those patients who require mandibular advancement with low tolerance for the potential of permanent inferior alveolar nerve paresthesia. Similar to those patients requiring TMJ surgery, it is often more practical from a sterility and instrumentation perspective to perform extraoral mandibular advancement first, followed by maxillary repositioning.

Contemporary Innovations

Early Surgery with Minimal Orthodontic Preparation

To accelerate the impact of positive changes from surgical intervention, "surgery first" sequencing was first reported by Brachvogel in 1991 with the goal of improvement of facial form first, followed by orthodontic correction.[46] A reduction in treatment time is attributed to more rapid postsurgical tooth movement associated with the regional acceleratory phenomenon.[47-53] To date, the literature consists largely of case reports[54,55] with a few larger case series.[56-58] Currently, application is most common in class III skeletal facial deformities with limited crowding and arch discrepancies; there continues to be wide variation in the details of the orthodontic and surgical treatment protocols in use.[59-62] The surgery-first paradigm presents exciting promise and patient benefit. Reports in the literature are beginning to delineate feasibility, indications, treatment protocols, outcomes, and stability,[58,63-65] but further study and high-quality evidence demonstrating equivalence or improvement over traditional sequencing is necessary before widespread adoption.

Computer-Aided Surgical Simulation (CASS) and Virtual Surgical Planning (VSP) in Orthognathic Surgery

Evolution

The application of computers to orthognathic surgical planning and simulation has been an incremental process, punctuated by several notable transformative events. The use of computed tomography (CT) and the ability to render axial data into 3D images[66] is the foundation of the transition from traditional 2D-based techniques. The ubiquity of cone-beam computed tomography (CBCT) now allows for the rapid acquisition of specific maxillofacial data with several advances over medical CT, including lower radiation exposure, upright patient positioning, improved convenience, and lower cost. The development of stereolithography, initially applied to the fabrication of physical 3D models,[67] has transformed into true rapid prototyping with an almost endless number of craniomaxillofacial surgery applications. Advances in hardware, as well as the development of specialized software applications such as 3D Surgery (Dolphin), ProPlan CMF (Materialise), and Maxilim (Medicim), have combined with the technologies discussed earlier to provide all of the tools necessary to create a virtual patient (including bone, dentition, and soft tissue), analyze the deformity, plan and simulate a surgical treatment, transfer the simulation to the operating room, and evaluate outcomes. In truth, neither the terms CASS nor VSP encompass the total paradigm shift that has occurred in state-of-the-art virtual orthognathic surgery—VOS.

Benefits

The application of new technology should be carefully considered before its adoption into clinical practice. Over the past 10 years, VOS has been refined and can be supported through the literature to show benefits in terms of improved patient outcomes[68,69] and reduced operative and overall surgeon time,[70] as well as a reduction in cost.[71] A beneficial impact on resident education and teaching is hypothesized and likely to be demonstrated in the literature in the future.

The Future

VOS is continuing to advance quickly both in terms of technology and implementation. It is predictable that in the near future, an exclusively digital-based workflow will evolve using current technology. This will be highlighted by the elimination of traditional impressions and the ability to rapidly and reproducibly establish final occlusion in single-piece and segmental cases. 3D printing technology is becoming less expensive, more accurate, and less time consuming and will also likely be found "in office" in the near future. The potential exists for haptic technology to upset the current workflow, but most likely this will first present as an educational tool in the application of true surgical simulation. Outcomes research using VOS technology will further define postoperative changes and stability and continue to refine algorithms for hard and soft tissue prediction as well as direct "ideal" treatment.

Conclusion

Dentofacial deformity causes a substantial quality-of-life burden for many people. Since the age of discovery in the middle of the last century, maxillofacial surgical techniques have been further developed and refined to produce predictable outcomes, especially when performed in a collaborative effort with an orthodontist. Combined surgery of the maxilla and mandible is a powerful tool that can address the overwhelming majority of facial skeletal malocclusion with data supporting the stability of results over time. The future holds the promise of further ongoing refinement with virtual orthognathic surgery.

CASE REPORT 11-1

Maxillary Hypoplasia, Transverse Deficiency, Mandibular Hyperplasia

A 16-year-old female patient presents with combined deformity of both jaws, including dental crowding, maxillary sagittal hypoplasia, maxillary transverse hypoplasia, and mandibular hyperplasia (Figure 11-5). Treatment is directed at the presenting problem list, so combined maxillary and mandibular surgery is planned. During the initial orthodontic phase of management, the dental crowding is relieved. In this case, the decision was made to coordinate the arches surgically in segments, so a transverse deficiency remains between the maxilla and mandible at the time of surgical planning. In preparation for surgery, dental models are obtained, as well as imaging that can be coordinated with the stone models. The maxillary cast is segmented into two pieces, and the arches are surgically coordinated. The final occlusion is set, and these records are then digitized for surgical planning. The final occlusal relationship is captured in a "final" splint for surgical execution. The maxillary move is completed first, and because the maxilla is stabilized, the final splint is secured to the maxillary arch only. A second "intermediate" acrylic splint generated from the surgical planning session relates the unstable maxilla to the stable mandible precisely in the sagittal and transverse dimension. The vertical position is set using an external vertical reference point. Following fixation, the mandible is osteotomized and secured into the final splint for completion of the surgical correction. In the final photos, the patient has been debanded and exhibits an accurate and stable correction.

Introduction

Many surgical centers have adopted intraoral distraction osteogenesis (DO) as another tool in the surgical-orthodontic armamentarium to help patients with dentofacial deformities who present with major growth deficiencies in three dimensions. Distraction osteogenesis also enables specific discontinuity defects (secondary to tumor resection, bone loss after trauma or infection) to be treated by utilizing bone transport. We will cover the new technologies, analyze morbidity, discuss costs, and critically review the indications with special attention to long-term outcomes and stability.

Virtual analysis, 3D models, and virtual prediction have made the surgical-orthodontic diagnosis, planning, and thinking process sequential, which makes the communication between the orthodontist, surgeon, patient, and family much easier.

Mandibular Widening

Distraction osteogenesis progressively stretches the bone and soft tissue envelope as the distraction appliances anchored to the bone.[1,2] After a complete osteotomy the surgical space are activated with collagen fibers that are then tightened and lengthened by controlled progressive pressure. These fibers and undifferentiated mesenchymal cells eventually mature into different tissue including: bone, muscles, mucosa, periosteum, and so on. This surgical philosophy treats the deformity creating new tissues through calibrated stimulation of the bone and soft tissues. The combination of orthodontics and surgery is the ideal modality to correct severe and untreatable deficiencies in the craniofacial region.[1,7]

Transverse Mandibular Deficiency

Severe dental crowding in a patient is usually part of a micrognathia, which will include a deficiency in growth in all of the three planes with skeletal and dental problems: anteroposterior (AP), transverse, and vertical. Today most patients are treated by orthodontics alone with limited results, such as teeth outside the alveolar bone, gingival recessions, premolar extractions, and poor facial esthetics and smile.[1-7]

Radiographs, photographs, dental models mounted in an articulator, clinical evaluation, and occlusogram should be analyzed to plan the ideal orthodontic and surgical treatment.

Clinical Indications for Mandibular Widening

- Narrow V-shaped mandibles
- Severe mandibular crowding to avoid dental extractions
- Scissors bite (Brodie's syndrome)
- Maxillomandibular transverse deficiency (tunnel smile, crocodile bite)
- Impacted anterior teeth to allow natural or forced eruption
- Retreatment after bicuspid extractions
- Congenital missing teeth

Dental Model Analysis

The amount of widening needed is calculated according to the following variables: Available space versus required space, inclination of the incisors (1 MPA = 90 degrees), deep bite or a marked curve of Spee, intermolar width, and size of the incisors

Soft and Hard Tissue Clinical Analysis

From the biologic standpoint, there should be a healthy periodontium around the teeth where the osteotomy is to be performed, with at least 1 mm of bone protecting the roots on either side of the osteotomy and to preserve vital bone capable of producing new bone under distraction. Lack of bone at the osteotomy can lead to delayed healing or periodontal defects. The osteotomy design and site are selected based on bone quantity between roots and inclination of the teeth. A Bolton discrepancy analysis is also performed to adequately calculate the amount of widening necessary

and to predict the final maxillomandibular anterior teeth overjet and overbite.

Surgical Planning

A variety of devices for mandibular widening have been developed since our first use in 1987. In our experience the tooth-borne lingual appliance or the UniArm device have been extensively utilized despite the hygiene concern, impingement of the tongue, inadequate access for activation, and the possibility of dislodging during surgery. It eases the surgical procedure and lessens expenses; the new uniarm device can be applied on either the buccal or the lingual side.

The bone-borne device to widen the mandible has very limited use today, because of costs and need for a secondary stage for removal. Equal surgical outcomes can be obtained with dental-borne, bone-borne or hybrid appliances.[2,7,8]

To avoid complications with the dental-borne appliance during or after surgery, several steps are fundamental to prevent distractor dislodgment. First, dental bands are selected one size larger than indicated, because in the welding process between the dental bands and the connector, the band metal contracts. Second, the orthodontist must position the distractor under the equator of the teeth, close to the gingival margin. Third, the appliance must be cemented to the teeth utilizing glass ionomer cement. Fourth, special attention must be given to the passiveness of the dental-borne appliance and parallelism to the occlusal plane. This is done to avoid inclination of mandibular segments that will result in asymmetric bone movements and consequent unilateral open bites and canted mandibular planes.[9-11]

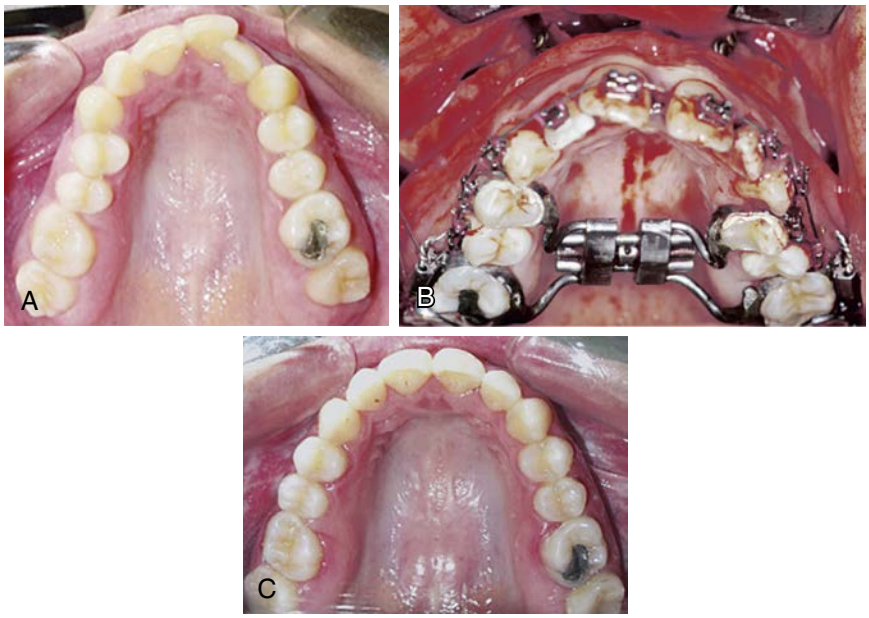
Presurgical orthodontics includes complete maxillary arch alignment and leveling, the teeth are aligned, diastemas are closed, the molars are verticalized, and an ideal maxillary curve of Spee is obtained. Once the maxillary teeth are ideally positioned, a final diagnosis and reevaluation is made to change the mandibular arch to the new maxillary alignment. No appliances are placed in the mandible until the maxillary arch form is complete. The lower arch dental movements are restricted to obtain adequate interdental space to perform the osteotomy without damaging the dental roots, and to select the mandibular widening device. The orthodontist evaluates and selects the best appliance according to the circumstances already mentioned (checking the variables involved, and more important, calculating the amount of widening required, based on the occlusogram[2,5,7,11]).

When performing maxillary widening (surgical assisted rapid palatal expansion [SARPE]) the maxilla is expanded equally anteriorly and posteriorly, (Figure 12-1), since the hyrax appliance will expand the maxilla symmetrically if all osteotomies are completed.[12]

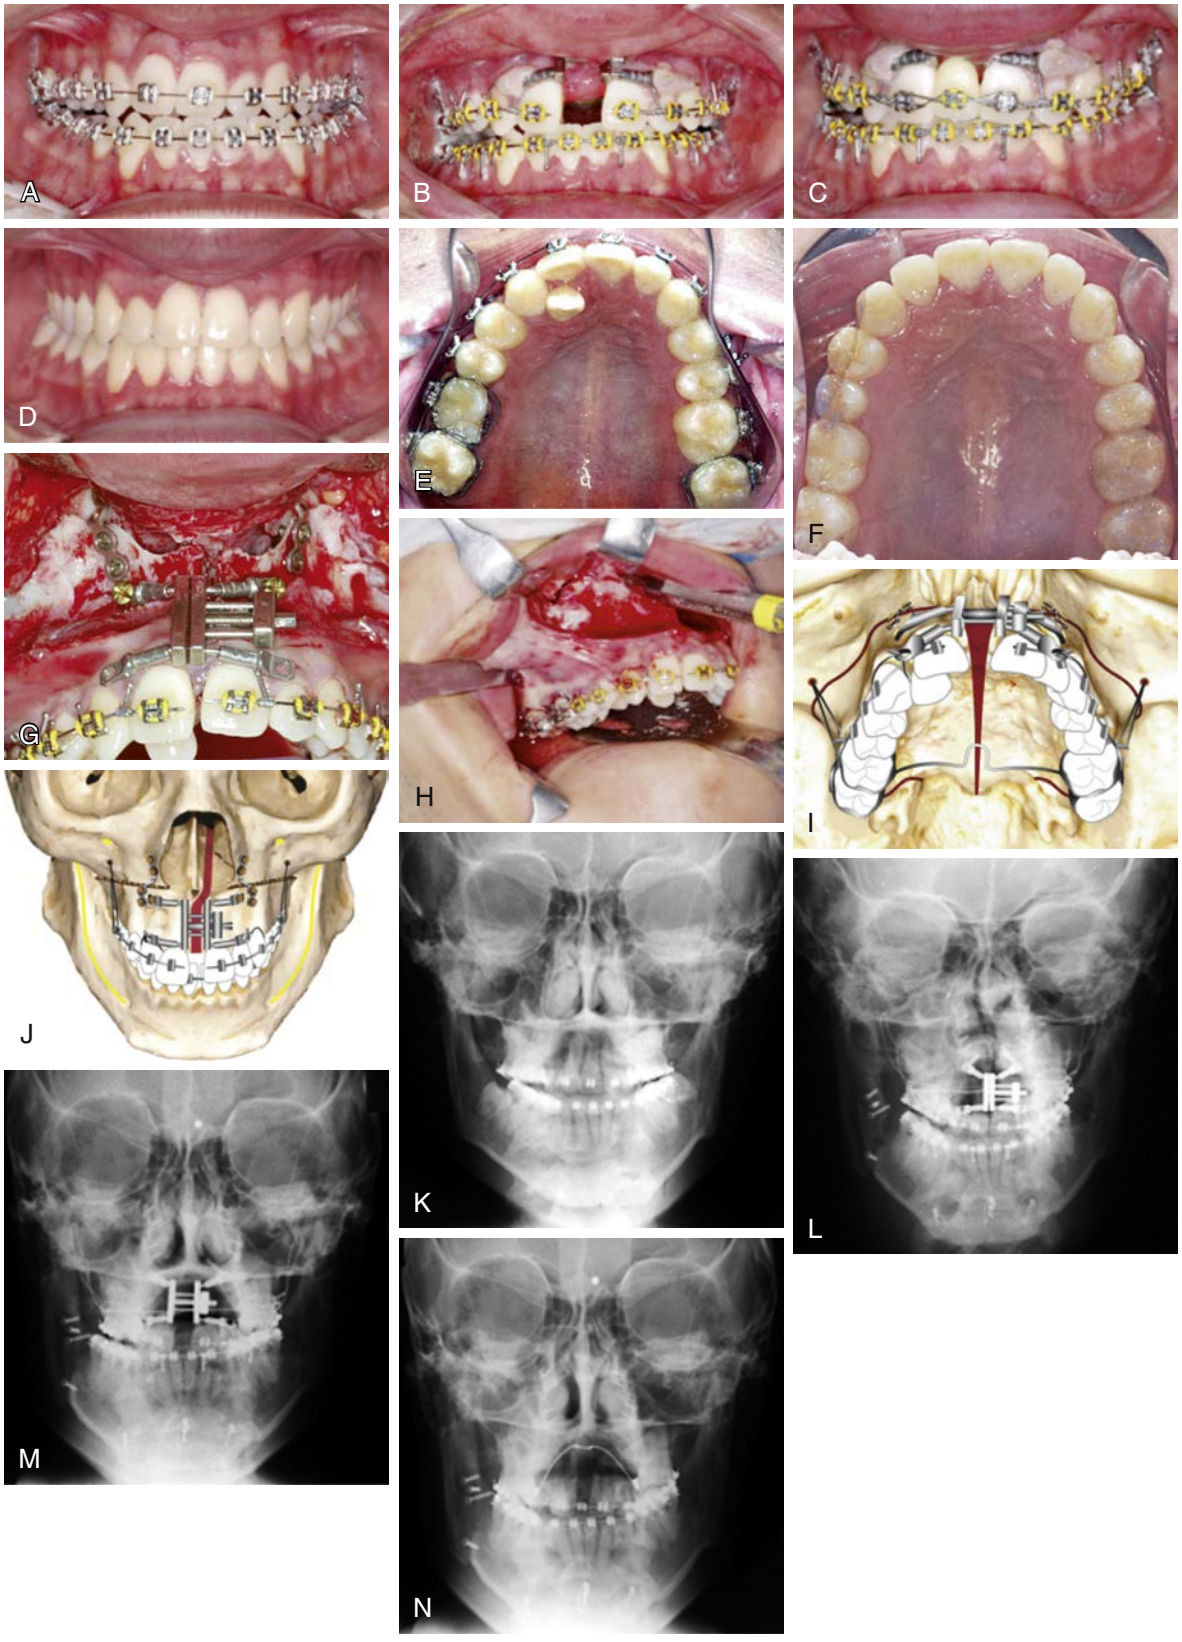
It is possible to widen the maxilla anteriorly or just posteriorly depending on the surgical technique and appliance positioning (Figure 12-2 and Figure 12-3); the maxilla can also be moved unilaterally, leaving one side uncut, which acts as an anchor for the distraction appliance. This permits unilateral expansion to occur.

A different scenario occurs when widening the mandible where the mandible is widened anteriorly and the distance decreases toward the back. As an example, from 7 mm widening in the incisors the intercondylar level only expands 0.9 mm; postoperatively there is always a transverse crossbite at the level of the canines and premolars that progresses to edge to edge at the first molars region and normal transverse bite at the second molar level. As the orthodontist closes the anterior gap the lateral crossbite is corrected. Planning must include all of these measurements that can be predicted in the models and occlusograms.[10]

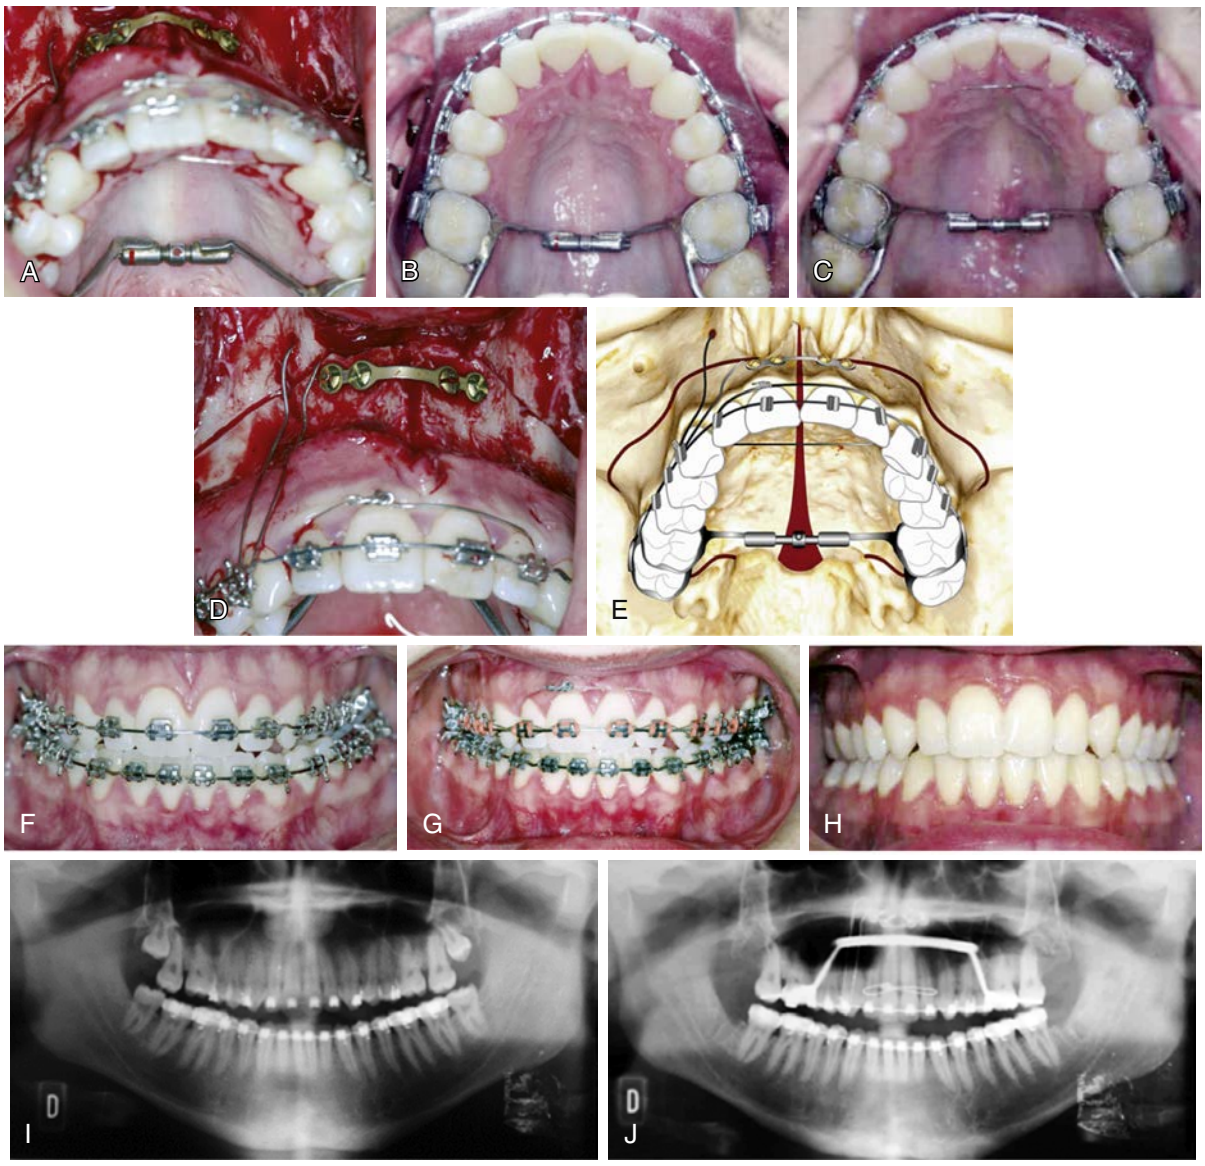
Significant major mandibular crowding accompanying a Brodie bite requires mandibular widening accompanied with



• **Figure 12-1** **A,** Moderate maxillary crowding in V-shaped maxilla. **B,** Intraoperative view. Simultaneous maxillary repositioning with midline distraction. **C,** Maxillary occlusal view in a 4-year follow-up.



• **Figure 12-2** Seventeen-year-old patient with 3D maxillary deficiency and right lateral incisor without space in the arch. A selective anterior expansion was performed. **A-D,** Frontal view before; after distraction; once the desired interincisor space was created, a pontic was placed in the edentulous space and secured with an orthodontic bracket; and end of treatment. **E** and **F,** Preoperative occlusal view of anterior maxillary moderate crowding and occlusal view after treatment. **G** and **H,** Le Fort I osteotomy is performed with complete down-fracture. When simultaneous maxillary advancement is accomplished, prebent 2.0-mm bone plates are used with distraction amount calculated and fixed in piriform area. **I** and **J,** A bone-borne distractor was utilized in the anterior maxilla; the posterior maxillary intermolar distance was fixed utilizing transpalatal bar. After 7 days of latency period the distraction device was activated, at a rate of 1 mm per day, until adequate widening was obtained. This space will be progressively eliminated by mobilizing the adjacent teeth, 3 months after surgery. **K-N,** Preoperative radiograph, latency period, after distraction, and final radiograph at the end of treatment.



• **Figure 12-3** Eighteen-year-old patient with posterior transverse deficiency and posterior crossbite. **A-C,** The surgical technique includes a Le Fort I osteotomy, preoperative occlusal view of anterior maxillary moderate crowding, and occlusal view after treatment. **D** and **E,** Le Fort I osteotomy is made with complete down-fracturing, an off the midline osteotomy anteroposteriorly ending between the central incisors. When expanding posteriorly, a 4-hole rigid fixation plate was used inferior to the anterior nasal spine, the orthodontic arch was not sectioned, and a bridle wire was passed and tightened around the 4 incisors. The distraction device was an inter first molar screw that was activated 7 days after surgery, at a rate of 1 mm a day, until the posterior expansion was obtained. The distraction screw was secured with acrylic and removed at 3 months; a transpalatal bar was maintained for the remaining orthodontic treatment, to ensure stability. **F-H,** Frontal view before, **(G)** after distraction and end of treatment, and **(H)** five years long-term follow-up. The occlusion was stable, with adequate interdigitation, midline coincidence, molar and canine class I were observed. **I** and **J,** Preoperative and postoperative panoramic radiographs.

maxillary widening to obtain an adequate final transverse maxillomandibular relation that avoids premolar extractions and improves the smile width. This treatment eliminates the sinking lips look from the profile view, which occurs with orthodontics with premolar extractions. The nickel titanium (NiTi) arches that are widely used in orthodontics are thermically activated and progressively move the teeth outside the alveolar bone limits. These orthodontic mechanics may produce gingival recessions and root resorptions; all of these problems can be avoided with proper diagnosis and increasing bone volume by mandibular widening.[10]

Widening the Symphysis or Parasymphysis Region

Surgical Procedure

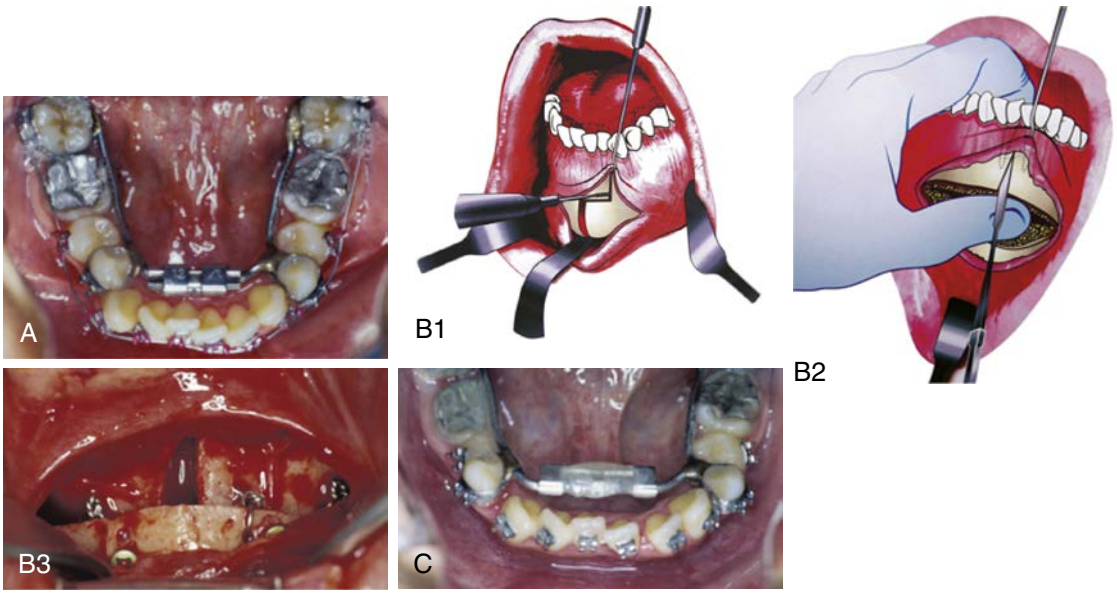
The incision is made 4 to 6 mm labial to the depth of the mandibular vestibule; the periosteum is reflected

• **Figure 12-4** **A,** Preoperative intraoral view demonstrating transverse mandibular deficiency. **B,** Vertical cut on the midline at the inferior border way up to 5 mm below the canine's apex, horizontal cut to the right side of the mandible and the final vertical osteotomy to reach the interdental space. **C,** A single-arm tooth-borne appliance in position. **D,** Preoperative occlusal view, (**E**) after distraction osteogenesis, (**F**) and finalizing orthodontics. **G,** Left inferior canine without space in the arch, (**H**) finalizing distraction protocol, **(I)** and postoperative lateral view during orthodontic final details. **J** and **K,** Preoperative and postoperative panoramic radiographs.

inferiorly to the inferior border of the mandible, where a small channel retractor is placed. The periosteum is carefully elevated and meticulously separated throughout the whole procedure, keeping in mind that much of the DO healing capacity originates from the periosteum. Next, the soft tissue between the mandibular central incisors is carefully reflected superiorly with a skin hook to the alveolar crest with minimal detachment of the neighboring tissues (Figure 12-4).[9-11]

Osteotomy

A vertical osteotomy is made through the symphyseal area with a reciprocating saw blade, starting at the inferior border of the mandible, sectioning both cortexes and continuing to the interdental space between the apices of the mandibular incisors. At this point the outer cortex only is cut with a straight handpiece and a 701 burr. No attempt is made to complete the cut to the lingual cortex between the roots of the teeth. It is important to select the site of distraction and to prepare the site by diverging the roots. The final sectioning is done with a mallet and a spatula osteotome. The forefinger should be used as a guide at all times to avoid tearing of the lingual soft tissues (see Figure 12-2). An alternative osteotomy site in severe crowding is between the lateral incisor and canine. The osteotomy should be completed interdentally and then continued toward the midline, since the lateral osteotomy would create an asymmetrical chin as the mandible widens (see Figure 12-4).[9-11]



• **Figure 12-5** **A,** Single-arm tooth-borne appliance that can be placed on the buccal or lingual. **B,** Conventional osteotomy for the genioplasty is performed 5 mm below the canine's apices, then a vertical osteotomy in the midline is performed. The genioplasty is fixed while a periosteal elevator remains in place at the inferior border of the vertical osteotomy. Note the bicortical screws to fixate the genioplasty. **C,** End of distraction. Acrylic is placed over the distractor screw for patient's comfort and to advance to soft diet.

Combined Mandibular Widening and Genioplasty

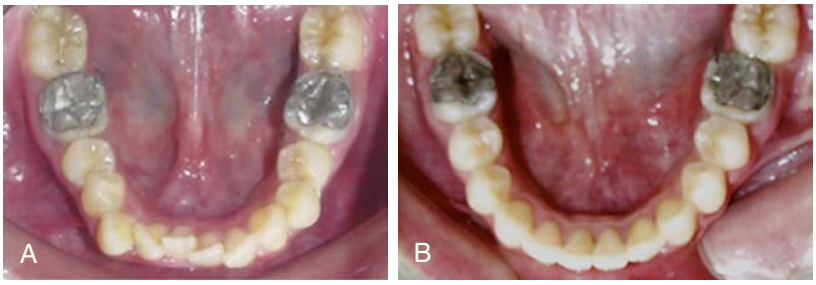
Osteotomy

Once the soft tissues have been properly separated, a channel retractor is placed through a tunnel underneath the mental nerve to the level of the first molar. A dental caliper is used to measure the canine from the lateral cephalometric radiograph, and the distance plus 5 mm is transposed to the mandible, measuring from the incisal edge to an area underneath the apex of the canine on either side. Vertical lines are marked to serve as reference lines. A reciprocating saw is used to perform a bicortical osteotomy at the inferior border of the mandible starting at the first or second molar region, coming anteriorly toward the symphyseal midline, passing by the reference lines; care must be taken not to injure the alveolar nerve in those patients with downward curve of the neurovascular canal, which may be close to the inferior border of the mandible. The surgeon's forefinger is used externally to avoid damaging the soft tissue as the saw goes through the bone on the lingual side. The osteotomy must be completed with the reciprocating saw (Figure 12-5).[9-11]

At this point, the inferior segment remains attached to the soft tissues. It is important to maintain this pedicle at all times, limiting the periosteal elevation to the minimum. The rest of the mandibular symphysis is intact at this moment; then, the reciprocating saw is used to perform a vertical osteotomy at the preselected distraction site. The rest of the surgical procedure is done as previously described. The genioplasty fixation is done with wires, screws or plates; a periosteal elevator is used to open a gap at the distraction site base (inferior immediate distraction, creating a gap), between the two bone segments to be distracted, forcing them open while the wires are tightened or plates are fixated. The distraction chamber will have a triangular shape at the end of the surgery with an open base at the bottom. Once the distraction appliance is activated, the interdental space opens, and the triangular chamber transforms into a vertical rectangle at the end of the distraction period. The surgical wounds are closed in the routine fashion. A pressure bandage is used for 3 to 4 days to limit the edema and allow primary soft tissue wound healing. A liquid diet and pureed diet is recommended for 2 weeks, then acrylic is placed on the distractor to add stability, and a soft diet is indicated. Finally, at 6 weeks the patient may return to regular food intake, avoiding heavy chewing until the twelfth week (Figures 12-6 through Figure 12-9).[9-11]

Distraction Protocol[2-12]

1. Osteotomy: The bone is completely separated either with a reciprocating saw or small fissure burr, under abundant irrigation to avoid overheating. Sometimes the final separation is done with a small chisel, after fixating the distraction device, preventing fragment displacement.
2. Latency period: Seven days after the osteotomy is performed the distraction device is activated. There is no activation for 7 days.
3. Rate and rhythm: the distractor is activated one millimeter once a day, or half a millimeter twice a day, until the desired activation is completed. Usually, the family is instructed to activate the appliance for the patient.
4. Consolidation: The distractor remains in place 60 days for each centimeter of distraction. This time allows



• **Figure 12-6** **A,** Same patient. Preoperative occlusal view of mandibular moderate crowding. **B,** Mandibular occlusal view 4 years after surgery.

• **Figure 12-7** Frontal view before, after distraction, and at the end of treatment.

mineralization deposits within the collagen fibers matrix. Removing the distractor before that time frame would produce distraction chamber contraction, deviation, or fracture.

5. Remodeling: This is the last distraction protocol phase. Function and orthodontics inter-maxillary elastics may mold the regenerate while muscles and other soft tissues settle into the last bone healing stage.
6. Variables: There are four important variables in distraction osteogenesis: age of the patient, amount of movement, quality of bone, and quantity of bone. These variables influence the distraction protocol; children may require a shorter latency period while an older patient would require an activation pattern of half a millimeter per day. Larger movements require much longer consolidation periods of up to a year.

Postoperative Care

At the end of the distraction, acrylic is placed over the distraction's rod and the wires around the teeth to provide more rigidity and advance the patient to a soft diet. At this time also the orthodontist adds a cosmetic acrylic tooth on the orthodontic arch to prevent the teeth from "walking" into the immature distraction area. After consolidation occurs, the appliance is removed and the clinician evaluates the radiographs for proper mineralization. The patient is referred to the orthodontist to continue the treatment. The interdental incisors distraction gap is filled with a plastic tooth, which is reduced 0.5 mm from each interproximal surface (1 mm) a month to progressively close the distraction gap and finish the orthodontic treatment. The orthodontic treatment is resumed 60 days after surgery for at least 6 months while the distraction chamber is still consolidating. The occlusion is carefully finished, and standard retention is indicated. The orthodontist must avoid moving the teeth into the newly formed distraction chamber. The trans-septal fibers will pull the adjacent teeth into the distraction chamber (in a matter of days) producing periodontal problems and loss of tooth vitality. It is advised to utilize wire ligatures to maintain the teeth in position during the consolidation period. Once good mineralization and distraction chamber radiopaque images are seen in the radiographs, the teeth are moved 1 mm per month, to slowly and progressively close the interdental space.

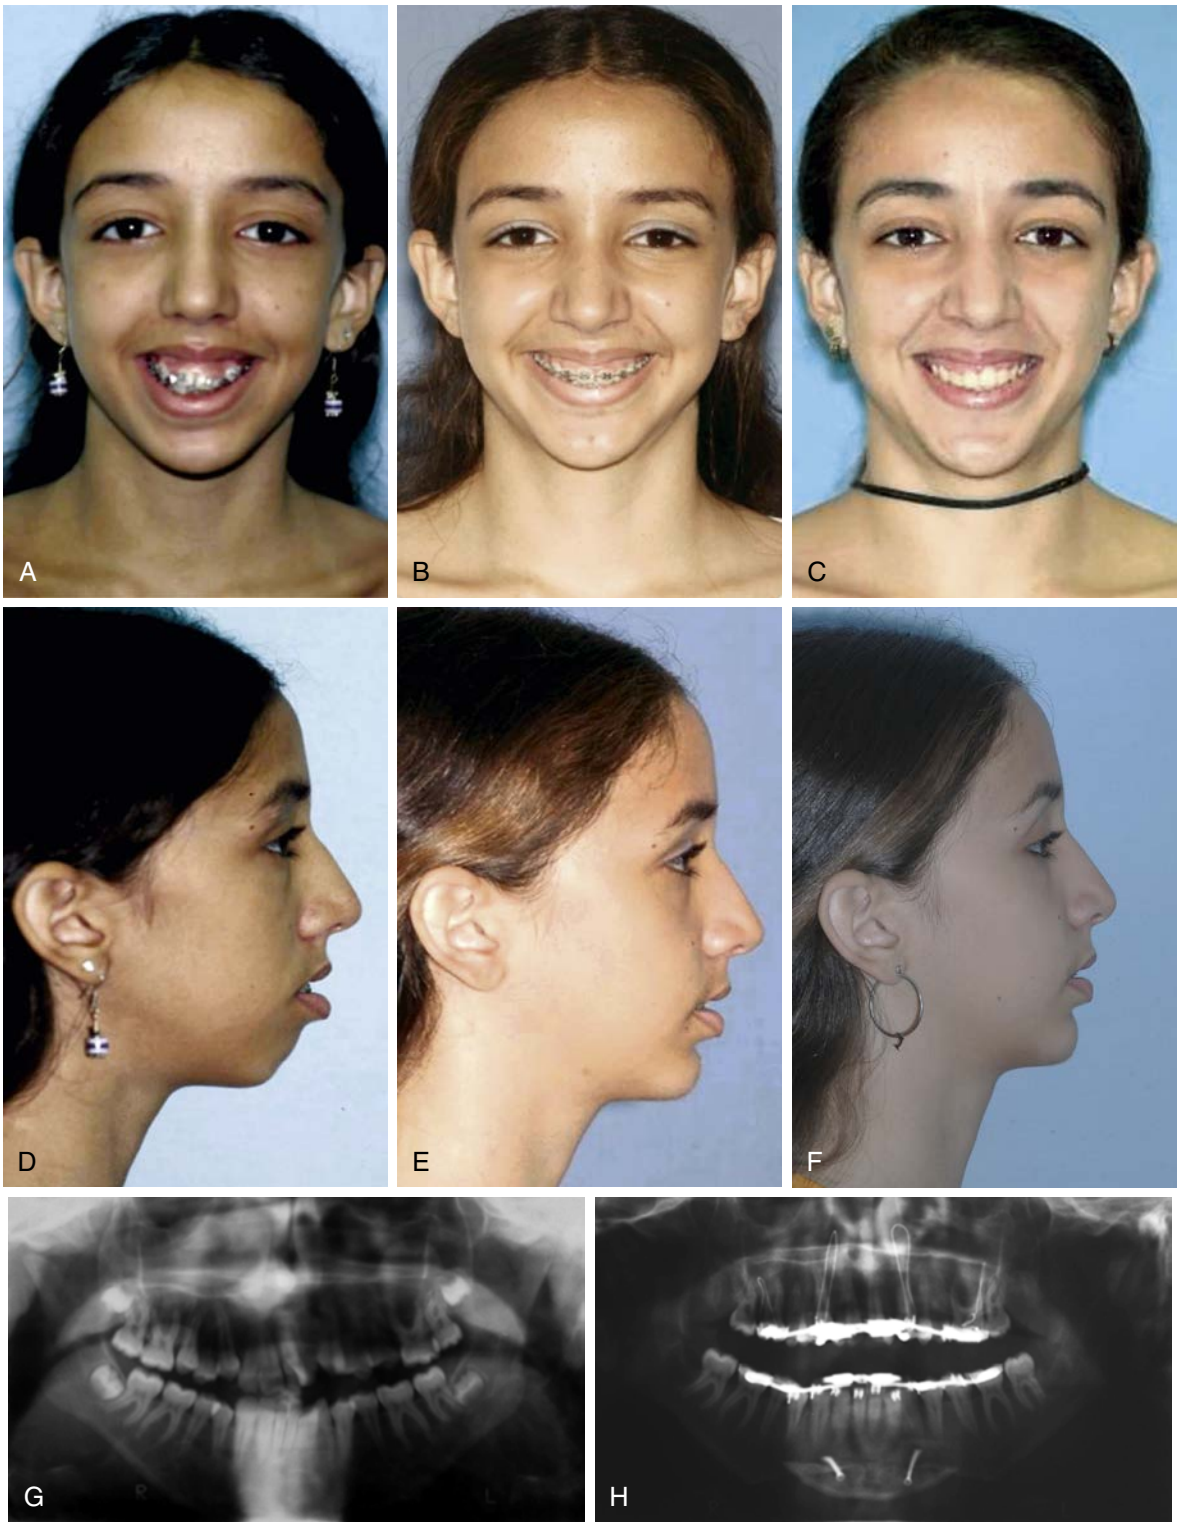
Mandibular Lengthening

Virtual analysis, 3D models, and virtual prediction have stepped strongly into the surgical-orthodontic scene to make the diagnosis, planning, and thinking process sequential and easier to communicate between the orthodontist, surgeon, patient, and family.

Intraoral distraction osteogenesis has been used since the late 1980s to achieve a mandible of normal size and anatomy. Complex 3D movements are possible and predictable. Since distraction osteogenesis follows a straight-line pattern, more than a single distractor device may be needed to successfully correct the myriad clinical presentations of mandibular deficiency. Precise preplanning considering the biomechanical effect of appliance orientation is fundamental for predictable widening and lengthening of the mandible[13-17] (Figure 12-10 and Figure 12-11).

Clinical Indications

- Major mandibular advancements
- TMJ degenerative joint disease as a precondition
- Sleep apnea (need to calibrate the advancement)
- Inadequate mandibular anatomy for conventional bilateral sagittal split osteotomy (BSSO)



• **Figure 12-8** Fourteen-year-old female patient with bimaxillary crowding and chin deficiency. **A-C,** Preoperative full-face view; notice the maxillomandibular transverse deficiency and black tunnels in the smile photographs. **B** and **C,** 3-D maxillary distraction and mandibular widening with genioplasty, after distraction osteogenesis and orthodontic treatment and finals results after 10 years of follow-up. **D-F,** Preoperative profile view, after surgery (notice the chin and mentolabial sulcus projection), and profile view after 10 years of follow-up. **G** and **H,** Preoperative radiograph and postoperative panoramic radiograph during the consolidation period.

- Secondary mandibular advancements (relapse of mandibular advancements after conventional BSSO)
- Children with severe mandibular deformities

Surgical Procedures[18-23]

- Horizontal ramus osteotomy
- Sagittal split ramus osteotomy
- Body osteotomy (anterior to the mental nerve)

Horizontal Ramus Osteotomy

A 3-cm full thickness incision is made over the mandibular external oblique line; meticulous subperiosteal tunneling dissection is performed to expose the buccal cortex. The periosteum, muscles, and soft tissues are minimally detached to maintain the best blood supply possible. A Kelley clamp is placed in the anterior border of the ramus as high as possible, and an inferior border retractor is placed just above the inferior alveolar nerve at its entrance just superior to the lingula. The reciprocating saw is used to perform the horizontal osteotomy, protecting the soft tissues using abundant irrigation to avoid overheating. The osteotomy is extended from the posterior border of the mandible anteriorly, keeping the forefinger over the skin, feeling as the mandible is sectioned. It is an incomplete osteotomy, since the jaw must be in one piece to ease placing the transcutaneous screws that fixate the distraction device. The vertical distraction appliance is preselected and carefully positioned in the planned location, and then the transcutaneous trocar is utilized to insert the bicortical screws (a minimum of three in either side). Other distractors should be fixated before the fracture is finalized. Most sutures are also finalized before the final osteotomy completion. Leaving a small opening to introduce the small straight chisel and torqueing movement allows the osteotomy to be completed while the distraction appliance is already well fixated in place.

Ramus Sagittal Split Osteotomy

A standard sagittal split osteotomy is performed, maintaining the inferior alveolar nerve intact in the distal segment. An intermediate splint is used and intermaxillary fixation is applied to either the orthodontic hooks or bone screws. Proximal segment fixation with one or two bicortical screws is accomplished. If the vestibule is wide, secondary to the buccinator muscle being low, the wound is closed and the distraction appliance is transmucosally fixated. Once adequate device stability is obtained, the mandibular provisional bicortical screws fixation are removed. The advantage of having the appliance extramucosally is that the distraction chamber will be watertight with no saliva and food contamination. No collagen fibers contraction occurs, poor callus formation is prevented, and no postoperative infections occur. This also facilitates removal of the distraction device at the end of the consolidation period.

For those patients requiring bilateral advancement, the distractor must be placed parallel to the axis of distraction, as the mandible is wider posteriorly and narrower anteriorly. This requires some adjustment to the appliance by creating a step of 5 to 8 mm to compensate for this important variation in mandibular width. If this is not considered, different problems will appear such as lateral torque of the condyle, loosening of the screws, and bending of the appliance.

An important issue is the temporomandibular joint. Once the device has been activated there will be reciprocal forces against the mandibular fossa, causing flattening of the condylar cartilage layer, thinning and perforation of the disc, subchondral bone formation, and loss of suprameniscal and inframeniscal spaces. It is fundamental to unload the joints as the mandible is advanced. Rectangular surgical orthodontic archwires with welded vertical pins are used to apply class II elastics, 6 to 8 ounces per side. These unloading forces will be maintained for the activation period as well as for the consolidation phase. The elastics are kept in place at least 3 months.

An anterior open bite might develop during the activation of the appliance because of lack of parallelism between the occlusal plane and the distractor rod. Once the appliance is fully activated, the distractor arm is released, and the mandible is rotated until the open bite is closed and placed in the final acceptable new occlusal position. This is performed under intravenous sedation in the clinic. Lateral cephalic radiographs are essential to plan and evaluate the bony movements.

Body Osteotomy (Anterior to the Mental Nerve)

A 2.5-cm incision is made in the vestibule. The periosteal layer is elevated to the inferior border of the mandible while carefully looking for the mental nerve. A channel retractor is placed and a vertical osteotomy anterior to the mental nerve, between the canine and premolar or between the two premolars, is executed. The reciprocating saw is utilized to perform the osteotomy from the inferior of the mandible superiorly bicortically, with the forefinger on the lingual side to avoid mucosal perforation, up to the level of the dental roots. Then a 701 fissure burr is used to make a line of holes between the dental roots with the soft tissue elevated superiorly. Then the holes are united, just sectioning the buccal plate with abundant use of irrigation; finally, a spatula osteotome and a mallet are used to complete the osteotomy. Interdental bridle wires around the neck of the teeth, two on either side, are placed for temporary fixation. The wound is closed and the distraction device is fixed transmucosally with bicortical screws and interdental wires reinforced with acrylic on top for stabilization at the teeth level. This avoids dental root damage. The indication for this technique is major anteroposterior movements and the possibility to obtain a larger movement at the inferior border of the mandible and smaller movement between the teeth. The mandibular nerve is left intact with no possibility of post-surgery

• **Figure 12-9** **A** and **B,** Same patient as in Figure 12-8. Lateral preoperative radiograph and after treatment. **C-F,** Intraoperative view with the palatal and lingual hyrax appliances placed by the orthodontist 48 hours before surgery. Le Fort I osteotomy was performed to widen the segments and combined mandibular widening with genioplasty. **G-I,** Lateral preoperative view after distraction during orthodontics finalization, and after 10 years of follow-up. **J-M,** Severe maxillary and mandibular crowding and V-shaped, occlusal view before and after.

paresthesia. This technique also improves the mandibular shape, by changing the gonial angle. The new space created between teeth is closed with orthodontics, either by reciprocal movements or advancing the posterior teeth anteriorly using orthodontics mini-implants for elastics anchorage at the canine level.

Postoperative Considerations

The distractors should be removed after ossification has occurred. Different variables are involved, including age of the patient, amount of movement, and quality and quantity of bone. Other variables include infection, inadequate stability during consolidation, poor patient selection, and some systemic diseases. The only reliable method for determining healing is the radiographic evaluation.

Post-surgical Orthodontics

Use of class II elastics is indicated both during the distraction and consolidation periods to prevent forces on the temporomandibular joints.

• **Figure 12-10** A 10-year-old child seen long after a subcondylar fracture, with severe mandibular deficiency and mandibular hypomobility (5 mm). Once the appliances are removed, the patient is referred to the orthodontist to complete the occlusion. It is recommended that the orthodontics appliances not be removed until 12 months after surgery to ensure adequate bone consolidation and stability; good communication within the team is encouraged.

Maxillary Distraction

Conventional craniomaxillofacial surgical techniques for advancements at different levels are less common today, secondary to major movement limitations. Other considerations include instability, bone grafting and extensive rigid fixation requirements that prolong the patient's recovery, and increased treatment costs. More important is the high infection rates, leading to meningitis and mortality. Distraction osteogenesis techniques allow for the development of frontal periosteal flaps to seal the anterior cranial fossa, the bony contact between the osteotomized bone flaps, and separation by distraction, without an open window for contamination. The distraction chamber wall separates the nasal and cranial cavities, allowing the craniofacial surgeons a safer, predictable, and low-morbidity surgical technique, with low mortality.[24-28]

Preoperative Planning and Surgical Technique

Patients with 2D or 3D maxillary deficiencies are treated by intraoral distraction osteogenesis to lengthen, widen, and/or augment vertically the maxillomalar complex at different osteotomy levels according to the individual clinical situation. Standard records including complete radiographs, CT scan, and photographs are obtained, and articulated dental and stereolithographic models are used to assist in planning. All patients undergo a combined surgical-orthodontic treatment to ideally correct the 3D problems[27-30] (Figure 12-12).

For a high Le Fort I, a conventional incision and osteotomy is accomplished, the maxilla is freely mobile, and two maxillary distractors are placed bilaterally, anchored to the base of the zygoma and fixed to the maxilla with the vectors determined by the 3D planning. Those patients requiring either a modified Le Fort III or classic Le Fort III osteotomy require an additional transconjunctival approach (Figure 12-13); the osteotomy divides the malar process, runs medially across the orbital, and continues underneath and obliquely anterior to avoid the nasolacrimal duct, reaching the piriform rim. The posterior maxilla is separated at the pterygomaxillary suture. Finally, two wide-curved osteotomes are placed behind

(**R2,3** from Kademani D, Tiwana PS: *Atlas of oral and maxillofacial surgery,* Saunders, St. Louis, 2016.)

the maxillary tuberosities to free the malar-maxillary complex. Once it is completely free, the distractors are fixed with screws to the zygoma, the anterior-superior arm is fixed transmucosally to the maxilla above the teeth, and the anterior-inferior arm is either wired to the teeth or fixed transmucosally depending on the osteotomy level. A flexible connector is attached to the distractor activation head in those cases where the appliance was buried under the soft tissues.[24-30]

When maxillary widening is needed, a tooth-borne appliance is placed presurgically and a midline osteotomy is accomplished.[12] After all appliances are in place, a 2-mm activation is performed. The distraction protocol consists of a 7-day latency period with an adjustment rate of 1 mm per day until the desired movement is obtained. A 5- to 7-month consolidation period, corroborated by radiographs (depending on the quantity of activation), is required. The distractors are removed under intravenous sedation, with a small incision bilaterally at the distractor sites. The postero-superior plate is sectioned and left behind. There is no need to reopen the complete incision to remove the postero-superior parts of the distraction device.[25]

The age of treatment is based on three major considerations: the canine eruption level, the anatomic situation of the infraorbital nerve, and the nasolacrimal duct; underestimating any of these landmarks will permanently damage these structures, with untoward consequences. After an early consolidation period the patient is referred to the orthodontist to continue the occlusion finishing phase. The distractors are left in place until adequate consolidation is obtained; this period may vary between 3 and 12 months,

• **Figure 12-13** A 35-year-old with Crouzon syndrome underwent subcranial Le Fort III. according to age of the patient, amount of movement, and quality and quantity of bone. The devices are not particularly uncomfortable, and patients accept them well. Patients can return to school or work and conduct a normal life while the maxilla is properly healing.[25-30] This is an advantage over extraoral devices.

Distraction osteogenesis with intraoral devices allows maxillary 2D or 3D corrections without bone grafts, heavy rigid fixation, and facial scars. It requires meticulous surgical-orthodontics planning, adequate surgical timing and individual osteotomy design, vector control, and careful placement of the distractor according to the patient's needs. It is unacceptable to damage teeth, infraorbital nerves, and/or lachrymal ducts.[25-30]

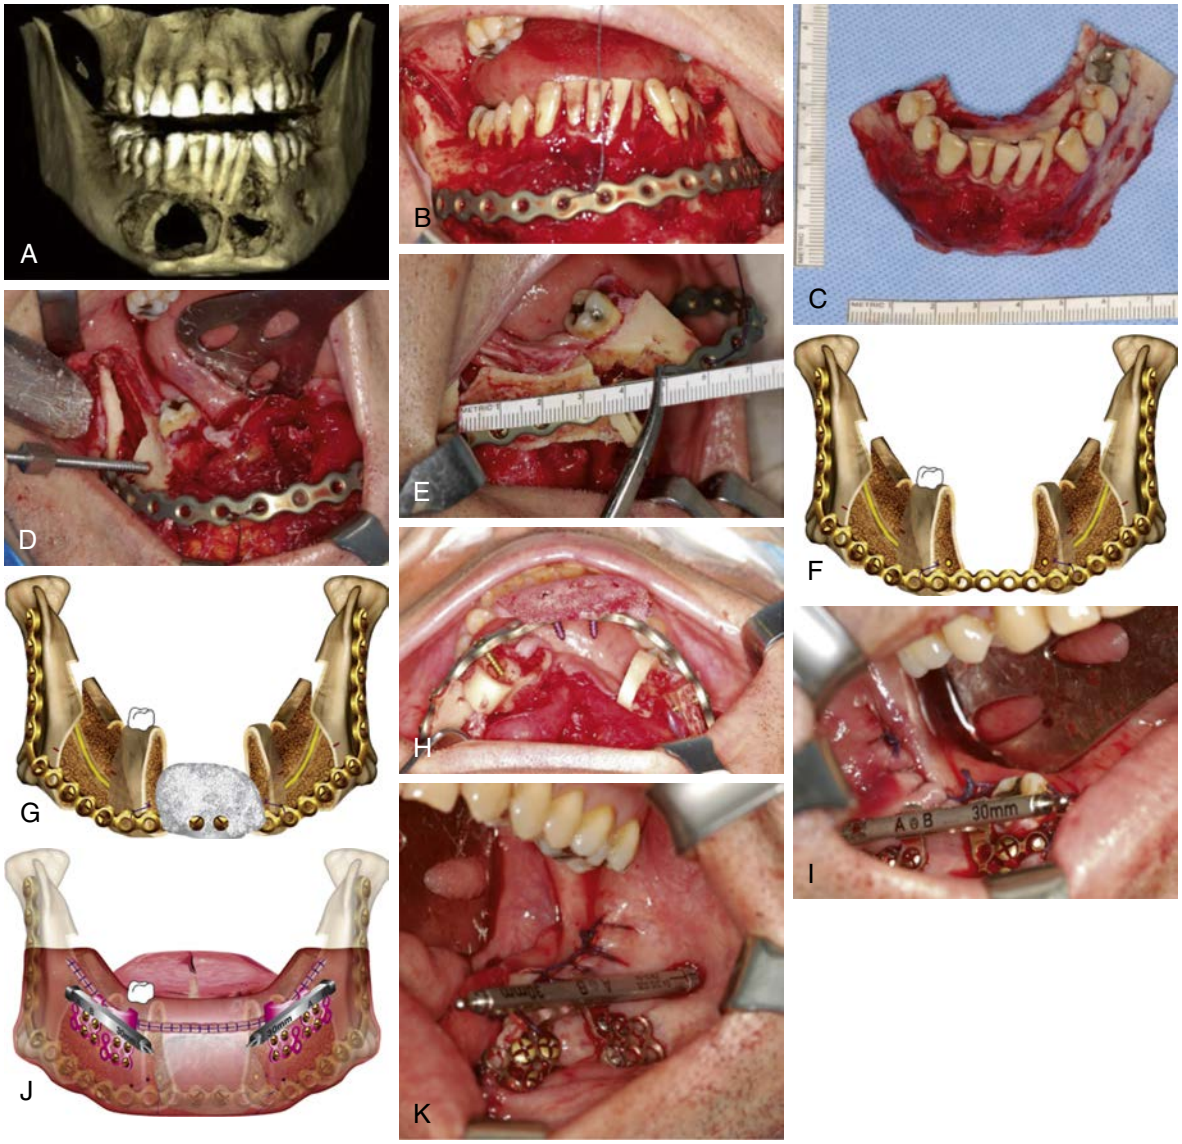
Bone Transport

Bone transport is based on the concept of creating bone and soft tissues following the biologic principles of distraction osteogenesis. An osteotomy is performed, keeping adequate blood supply to the bone fragments. After collagen fiber matrix formation between the two segments (latency period), the bony fragments are separated progressively at a fixed rate and rhythm until the moving fragments collide. This is called the *docking site*. In order to unite the fragments, the tissue in between requires removal and either the segments are compressed or bone grafted, which is called *docking site surgery*. Depending on the number of segments traveling for the reconstruction, the surgery can be classified as bifocal, trifocal, tetrafocal, or pentafocal. Obviously, more segments traveling around the mandibular arch allows better positioning, less travel distance, and the possibility to create a true mandibular shape. This is particularly important when creating the parasymphyseal curvature and the mandibular angle. Distraction osteogenesis goes from point "A" to point "B" in a straight fashion; secondary fractures or several fragments are required to obtain curves and angles.[31-38]

The bone transport concept is based on blood supply and careful vector management (Figure 12-14 and Figure 12-15).[31,38-40]

Indications for Bone Transport

- Patients medically compromised where major bone grafts are not indicated
- As an alternative for reintervention after an unsuccessful bone graft reconstruction
- Following removal of benign tumors



• **Figure 12-14** Ameloblastic carcinoma in 45-year-old male patient. **A-C,** Three-dimensional reconstruction tomography before resection is important to check reconstruction plate position and make posterior holes for screw. This allows easy plate insertion after resection. **D-F,** Plate is fixed on position. Pediculated osteotomized segments reconstruction was performed by bilateral sagittal splint, gaining 35 mm each part. Diagram shows the technique. Notice second molar position after sagittal splint advancement and fixation with reconstruction screws to the plate. The medial soft tissue attachment is maintained to allow vascularity. **G** and **H,** Porous polyethylene prosthesis fixed to the anterior plate segment to maintain chin soft tissue during distraction osteogenesis. **I-K,** Bilateral 30-mm appliances in trifocal bone transport to complete anterior mandibular defect.

- Reconstructing gunshot wound defects
- Managing osteomyelitis
- Treating malunions or nonunions.

Presurgical Preparation

Stereolithographic models, CT scans, and panoramic and cephalometric x-rays are used for surgical planning and prediction. The 3D model is very useful for planning large reconstructions with the exact measurements for prebending the reconstruction plate or devices, determining the distraction vector, and the location of the screws.

Principles

Ilizarov[1] studied the biology of distraction histogenesis and found periosteal and endosteal preservation to be the most important biologic variable. Abundant irrigation and small incisions are mandatory, cooling the bone while cutting; other critical variables are the quantity and quality of bone, degree of movement, soft tissue coverage, and protocol of distraction.[40-42]

- Because the distraction will occur in a linear plane, from point A to point B, the distraction chamber will form bone in a straight line. The stretched collagen elastic fibers will progressively mineralize in the

• **Figure 12-15** Same patient shown in Figure 12-14. **A** and **B,** Preoperative panoramic view, and during bone transport. **C-E,** After distraction period the appliance is maintained on position during mineralization to maintain segments stabilization, and is moved after this period. During consolidation, zygoma implants and conventional dental implants were inserted. **F-I,** Preoperative dental view, during bone transport, after distraction osteogenesis during consolidation (notice the second molar place in midline), and final prosthesis on dental implants. **J** and **K,** Preoperative facial frontal view and final results after 2 years follow-up. Notice excellent esthetics and functional results, avoiding facial scars and creating mandibular contour continuity.

months after surgery to finally convert into calcified bone.

- The size of the transport disc plays an important role in large reconstructions, especially when the symphysis is involved. The disc needs to be large enough for future sectioning in one or two segments as the bone travels along the defect to comply with the distance needed for the reconstruction and to create the mandibular curvature.
- The hourglass deformity effect will be formed if a single bone disc needs to travel a long distance, or if the original thickness is not enough to recreate good bone. The disc must be from 1.5 to 2.0 cm in thickness, height, and length.
- The soft tissues will also advance along and recreate soft tissues with the bone being transported. The significance of this becomes very important in major reconstructions because it includes all the musculature and other soft tissues.
- When bone transport is performed based on the symphyseal bone, special consideration for a genioplasty takes place in order to maintain the symmetry of the chin.

Bifocal Distraction[40-42]

Surgical Technique

A distraction disc is used to create new tissues for reconstructing the mucosa and bony defects. In bifocal bone transport, there are two healing areas: the osteotomy site where the distraction chamber is created and the junction where the traveling disc and the other end meet. This is based on two surgical stages:

- *First surgical stage:* Placement of the reconstruction plate, removal of the affected area, fixation of the distractor, and acute intraoperative activation of 2 mm. The disc travels as the osteotomy parts are distracted, until the disc meets with the host site. The rate is 1 mm a day after the latency period, and progresses until there is bony contact.
- *Second surgical stage:* Once the two bone segments are in contact, the cartilage-like tissue is removed and the distractor is activated. Local bone grafts are placed in between and two rigid fixation plates are placed utilizing bicortical screws. Radiographs are very useful to visualize bone formation and mineralization.

Multifocal Distraction

The concept is based on the use of as many bone discs as needed for the distraction to repair the defect and rigid fixation to maintain the segments in place.

The reconstruction plate is placed holding the bone segments in the correct position with at least three bicortical screws on each segment. For defects including the body and half or all of the symphyseal area, a complete side-to-side reconstruction plate is indicated. The appliance travels on top of the plate for vector control and it is placed supraperiosteally in order to prevent distraction chamber contamination with food and saliva, preventing infections and chamber contraction. Maintaining the biologic principle of DO of periosteal nutrition to the area is critical for success. Major angle-to-angle reconstructions are performed by stages.

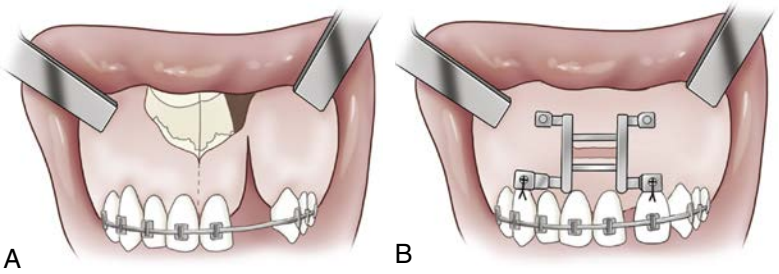
- *First stage:* The tumor is resected after fixating the reconstruction plate, to avoid segment displacement, and distraction devices are fixated with transport disc design. Ideally, a 15-mm disc must be obtained and a 2-mm intraoperative activation is performed. This first disc is usually from the angle of the mandible or from the most posterior part of the body. This segment will travel up to the canine area. To avoid plate exposure in the symphyseal area (secondary to muscle traction), a chin silicon prosthesis is placed temporarily to the most anterior part of the plate. As the two lateral discs (distraction discs) come forward, they bring all the soft tissues. The chin prosthesis is removed once the segments are advanced to the parasymphysis area.
- *Second stage:* Reconstruction of the symphysis. Once the first disc reaches the canine area, the traveling disc is sectioned in half, forming a new disc. This is done using intravenous sedation. Rigid fixation of the posterior portion of the original disc to the reconstruction plate is accomplished and the distractor is removed. The anterior portion of this disc will continue traveling across the symphysis with a new distractor. It is very important to consider the rigid fixation of the already transported disc to the plate. This avoids the spring effect which occurs because of the contraction of the collagen fibers before the mineralization period. The consolidation period for major movements is prolonged for many months.
- *Third stage:* At the end of the distraction, docking site surgery is indicated to promote healing between the two docking segments. This is a short and simple procedure to be done under intravenous sedation.

Distraction Protocol

A 7-day latency period (no activation) is followed by a 1-mm or 0.5-mm activation once a day, until distraction is completed (the activation will be performed by the patient, family member, or office staff). The distractors remain in place for 2 months per each centimeter during the consolidation period as a fixation system, until they are exchanged for bicortical screws from the reconstruction plate to the bone.

Docking Site Surgery[36,41,42]

The docking site is the area where the two bone segments meet. At the end of treatment, the edges of these two bones are usually hypotrophic and sclerotic and covered by fibrous tissue. To close this gap at the end of the distraction, a docking site surgery is required. The two edges should be as closed



• **Figure 12-16** **A** and **B,** Diagrams show the alveolar defect and the treatment planning by intraoral bone transport.

as possible and the non-vital bone needs to be removed. A mucoperiosteal incision with minimal periosteal elevation is used to expose both ends; it is necessary to obtain a network of neoangiogenesis from the bone marrow and periosteum to enhance healing and promote better bone consolidation. The bone edges are prepared by making multiple perforations with a 701 burr into the cortical and medullary bone. The distractor is activated until the two segments closely meet, and then the bone graft obtained from the chin and tuberosity is placed over the joining bones. Additional osteoinductive material (e.g., rh-BMP2) can also be added. Rigid fixation is used to keep the two bone segments united either by the reconstruction plate or by two miniplates, depending on the bone stability and amount of reconstruction; the suture is protected with N-2-butylcyanocrylate to isolate the surgical site from the oral bacteria (see Figure 12-15).

Physiotherapy

The patient must be on a soft and liquid diet for a long period of time, and the masticatory function is diminished. This leads to mandibular hypomobility with the consequences of interincisal opening reduction at the end of the treatment. Functional and physiologic exercises are advised three times a day for 20 minutes to stimulate masticatory movement.

Dental Implants in Bone Transport

Today implant technology allows the use of inclined dental implants converted to parallel utilizing multi-unit abutments. Also the use of zygoma implants can be considered in areas where good quality and quantity of bone is available, but the implant base is placed where the prosthodontist can fabricate a fixed or hybrid dental rehabilitation. Most patients would have excellent bone in the symphysis area where zygoma implants could be inserted and the abutment base located at the level of canines or premolars (see Figure 12-15).

Maxillary Bone Transport

Indications:

- Tumor resection
- Trauma
- Palatal distraction
- Velopharyngeal incompetence
- Alveolar clefting in the adult

Horizontal Maxillary Bone Transport[43-49]

Surgical Technique

Alveolar clefts are treated with the orthodontic arch to guide the bony segment (Figure 12-16 and Figure 12-17). A small incision is made at the depth of the vestibule through the mucosa, muscles, and periosteum. The flap is elevated and small retractors are used to expose the bone adequately in a tunnel fashion. The transport disc is designed for each specific case, either bifocal or trifocal. The interdental osteotomy is performed with irrigation to avoid bone overheating. The osteotomy is completed with a spatula osteotome and the flap is carefully closed to enhance endosteal healing. The distractor is fixed over the reconstruction plate to the distraction disc and to the fixed maxilla with 2-mm positional screws and interdental wires. A latency period of 7 days is followed by activation of 0.5 mm every 12 hours (0.5 mm twice a day) until the two bony segments meet, or until the segment has arrived at the final distraction point.

Docking Site Surgery

Once the two segments dock with each other, a second procedure is required for uniting the two segments. The epithelial tissue between the two segments is removed, as well as the hypotrophic bone edges from each disc, adding some local bone graft and closing the wounds with the surrounding soft tissue excess as described for the bone transport for the mandible.

Future of Distraction Osteogenesis

Research studies have improved the biological knowledge, and there have been new developments in technology, especially in the area of miniaturizing and trans-oral distraction devices and the use of BMP-2 to improve and accelerate the healing process. There are enough data for long-term evaluation, making these procedures available to patients predictably and safely. Different research studies are trying to diminish the consolidation period using bone morphogenetic proteins, platelet enriched plasma, calcium, and other catalysts for the healing process. There are fewer indications for external devices. Education plays

• **Figure 12-17** **A-D,** Preoperative lateral intraoral view. A small incision is made deep in the sulcus to osteotomize the transport disc. The cut begins with a 701 burr in the cortical bone above and high between the dental roots under abundant irrigation. A spatula osteotome is used through the small incision to complete the osteotomy. Intraoral distractor placement is completed and wounds are closed. **E-I,** Occlusal and frontal intraoral views. **J-N,** Bone discontinuity on the left side and its alveolar reconstruction after bone transport. A plastic pontic is placed over the chamber awaiting the mineralization for implant position.

a major role in selecting patients, applying the biologic principles and using the best technology available. As long-term studies are published more frequently and the variables are better identified, this new tool in oral and maxillofacial surgery will be the technique of choice in many major craniofacial deficiencies.

Concomitant TMJ Total Joint Prosthetic Reconstruction and Orthognathic Surgery

LARRY M. WOLFORD

Introduction

Temporomandibular joint (TMJ) disorders/pathology and dentofacial deformities commonly co-exist. The TMJ pathology may be the causative factor of the jaw deformity, develop as a result of the jaw deformity, or the two entities may develop independent of each other. This chapter will focus on the most common TMJ pathologies that are indicated for TMJ total joint prostheses as well as orthognathic surgery. The health and stability of the TMJ is dependent on the structural integrity, position, and presence or absence of disease or injury affecting the articular disc, condyle, fossa, and associated soft tissues. The TMJ hard and soft tissue components may become degenerated, arthritic, and nonsalvageable with any of the following TMJ pathologies: articular disc dislocation (long duration), adolescent internal condylar resorption (AICR), reactive arthritis, ankylosis, congenital deformation or absence of the TMJ, trauma, connective tissue and autoimmune diseases, previously failed TMJ surgery, and other end-stage TMJ pathologies.[1-4] These TMJ conditions are often associated with dentofacial deformities, malocclusion, TMJ pain, headaches, myofascial pain, TMJ and jaw functional impairment, ear symptoms, and sleep apnea. Patients with these conditions may benefit from corrective surgical intervention including TMJ reconstruction with total joint prostheses, orthognathic surgery, and other adjunctive procedures. Many clinicians may have difficulty identifying the presence of a TMJ condition, diagnosing the specific TMJ pathology, and selecting the proper treatment for that condition. This chapter should improve the clinician's diagnostic and treatment planning skills, particularly in the end-stage TMJ pathologies requiring TMJ total joint prostheses.

Although most TMJ patients have associated symptoms, approximately 25% of patients with significant TMJ pathology/disorders may be asymptomatic. These patients are diagnostically challenging when undergoing orthognathic surgery because the TMJ pathology may not be recognized or treated appropriately, resulting in a poor treatment outcome with potential redevelopment of the skeletal and occlusal deformity by condylar resorption or overdevelopment as well as initiation of worsening pain, headaches, jaw and TMJ dysfunction, and other TMJ symptoms.[5] However, there are clinical and imaging factors that can indicate the presence of TMJ pathology in the asymptomatic patient.

Many clinicians choose to ignore the TMJ pathology and perform only orthognathic surgery for these types of cases, but this treatment philosophy can result in continuation or exacerbation of the presurgery TMJ pathology and reproduce the original deformity with worsening occlusion, jaw dysfunction, facial imbalance, and pain. Clinicians who address the dentofacial deformities and TMJ pathologies that require total joint prostheses can perform the surgery in one stage or two separate stages. The two-stage approach requires the patient to undergo two separate operations and anesthesia, significantly prolonging the overall treatment. However, performing concomitant TMJ and orthognathic surgery in these cases significantly decreases treatment time and provides better outcomes, but requires careful treatment planning and surgical proficiency in both surgical areas.

In the author's 26-year experience of using patient-fitted TMJ total joint prostheses, approximately two thirds of patients requiring total joint prostheses can benefit from concomitant orthognathic surgery for improvement in function and airway and breathing capabilities, better esthetic outcomes, and reduction or elimination of pain.

Patient Evaluation

It is important to know the patient's concerns, history, symptoms, and treatment expectations. We have previously published detailed information on patient evaluation for

• **Figure 13-1** Patients should be evaluated: **A,** In the frontal view with the pupillary and ear planes parallel to the floor, and **B,** in the clinical Frankfort horizontal plane (a line from the tragus of the ear through the bony inferior orbital rim) parallel to the floor.

orthognathic, TMJ, and sleep apnea surgery including clinical, radiographic, MRI, and dental model analyses,[1-4,6] so this information will not be included here.

However, it is important to realize that these patients are sometimes misleading in their clinical presentation because their "natural head position" may posture their head hyper-extended, lower jaw and chin tipped upward and forward to make the chin appear more prominent, but more specifically to open their oropharyngeal airway to improve their ability to breathe. If the patients are not evaluated with a proper corrected head position, the amount and degree of maxillary and mandibular retrusion and asymmetry may be missed: thus the importance of evaluating the patient with the pupillary plane and ear plane parallel to the floor in the frontal view (Figure 13-1, *A*), and clinical Frankfort horizontal plane (a line from the tragus of the ear through the bony infraorbital rim) parallel to the floor in the profile view (see Figure 13-1, *B*). Obviously there will be some variance in some individuals, but this is a basic guide.

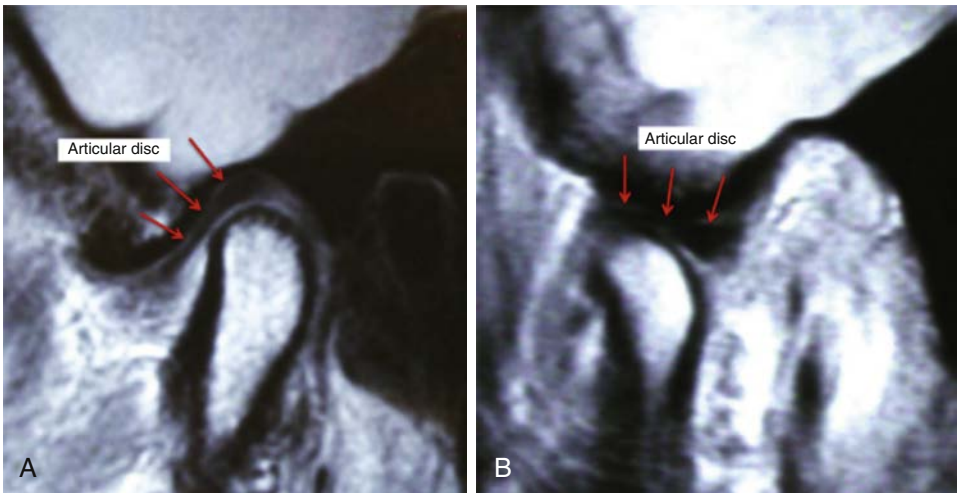
Common factors in patients requiring TMJ total joint prostheses that are frequently overlooked by clinicians are: A-P and posterior vertical maxillary and mandibular hypoplasia, decreased oropharyngeal airway, nasal airway obstruction, and sleep apnea issues. Patients with TMJ pathologies, particularly those with condylar resorption, may experience progressively worsening breathing and sleep apnea issues. Patients with sleep apnea symptoms may be indicated for a sleep workup including polysomnography.

Many sleep apnea patients also have TMJ issues that need to be addressed at the same time or before orthognathic surgery is performed to provide a stable, predictable outcome and decrease preexisting pain. Advancing the maxillary and mandibular complex in a counterclockwise direction improves facial balance, and the oropharyngeal space opens significantly to improve the airway. Our studies[7-11] have shown that with double-jaw surgery with counterclockwise rotation of the maxillomandibular complex, with the first 10 mm of advancement measured at menton, the oropharyngeal airway opens up 65% to 70% of the amount of mandibular advancement. With 10 to 15 mm of advancement, the oropharyngeal airway continues to open, but at about 55% to 60% of the mandibular advancement. When the mandible is advanced 15 to 20 mm, the oropharyngeal airway continues to open, but only at about 40% to 45% of the amount of mandibular advancement.[1]

Imaging

Radiographic evaluation is helpful in the diagnostic process, and cone-beam computed tomography (CBCT) technology makes low-cost, low-radiation scans accessible. With CBCT imaging, the oropharyngeal and nasal airways can also be evaluated as well as the lateral and anteroposterior cephalometric images, TMJ tomograms, and panograph. The lateral cephalometric analysis can determine the severity of the jaw deformity, dental alignment, airway dimensions, and so forth.

One of the best diagnostic tools for TMJ disorders is magnetic resonance imaging (MRI) because it allows evaluation of TMJ disc position, morphology, mobility, extent of joint degenerative changes, inflammation, and the presence of connective tissue/autoimmune diseases. It can help in the diagnosis of TMJ disorders in the silent joint in which disc displacement and degenerative changes can be present, may not make noise or be particularly uncomfortable or painful, but may contribute to poor outcomes if only orthognathic surgery is performed. CT scans, bone scans, three-dimensional (3D) imaging may be helpful in



• **Figure 13-2** **A,** MRI of a normal TMJ in closed position with disc in position. **B,** Open view showing good translation forward of condyle and disc.

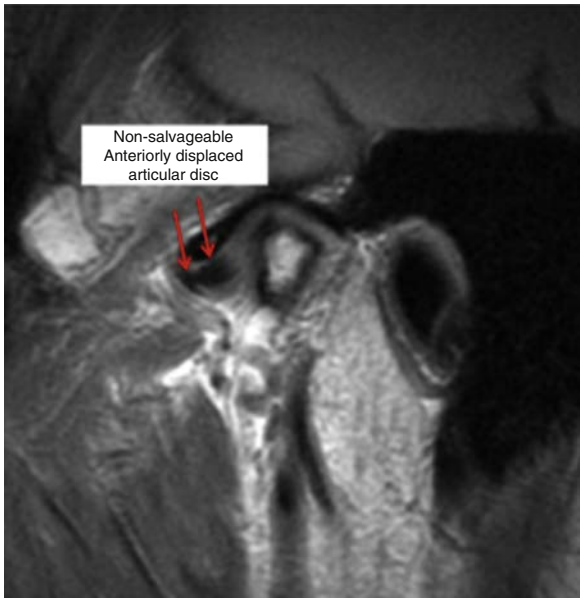
diagnosis and treatment planning. 3D stereolithic modeling is necessary for manufacture of patient-fitted TMJ total joint prostheses.

MRI Evaluation

Magnetic resonance imaging is one of the most important diagnostic tools that we have in evaluation, diagnoses, and treatment planning for TMJ pathology. In general, T-1 MRIs are helpful in identifying disc position, alteration in bone and soft tissue structures, and interrelationships of the bony and soft tissue anatomy. T-2 MRIs are more helpful in identifying inflammatory responses in the TMJ. The importance of disc position cannot be overemphasized. For MRI evaluation of the TMJs, a 1.5 Tesla or more powerful machine is recommended. "TMJ coils" are necessary to achieve diagnostic quality images of the TMJs. The basic views that are most helpful for TMJ diagnoses include: (1) sagittal views in centric relation and in maximum opening, (2) coronal views in centric relation, and (3) dynamic views, if available. The MRI imaging can be correlated to CBCT imaging of the TMJs for joint space and greater interpretation of bony pathology. Figure 13-2 shows a normal TMJ MRI with healthy structures and the disc in position.

Disc Displacement

When discs are anteriorly displaced for an extended time period they may become non-reducing, deformed with loss of the intermediate zone and thickening of the posterior and anterior bands (Figure 13-3). Also, there may be a degenerative process developing in the discs in which there is a breakdown of the cartilaginous substance with vascular invasion and degeneration. When discs are displaced and become non-reducing, the degenerative process progresses more rapidly as compared with displaced discs that reduce. When discs advance to a certain level of deformation and degeneration, they become nonsalvageable. In this situation

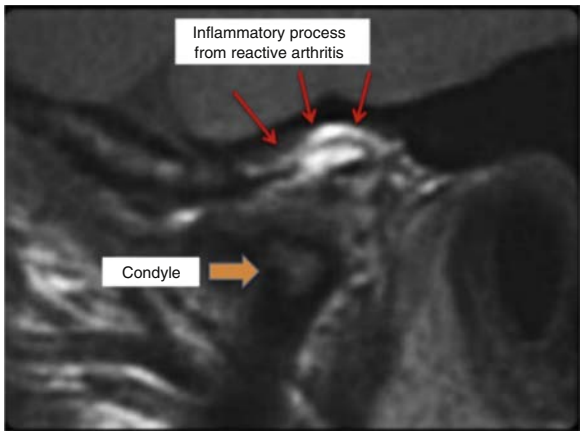


• **Figure 13-3** The articular disc is anteriorly displaced and significantly deformed, degenerated, and nonreducing, rendering it nonsalvageable. The condyle is arthritic.

when concomitant TMJ and orthognathic surgery are necessary, patient-fitted total joint prostheses are indicated to produce the most predictable and high quality outcome.

Adolescent Internal Condylar Resorption (AICR)

Adolescent internal condylar resorption (AICR) is a TMJ condition that develops during pubertal growth between the ages of 11 to 15 years, predominantly in females (ratio 8:1 females to males).[1-4,12,13] Clinically, the mandible will be noted to slowly retrude into a class II occlusal and skeletal relationship with a tendency towards anterior open bite. These patients all have high occlusal plane angle facial morphologic profiles. On the MRI, these cases present with a



• **Figure 13-4** T2 MRI of right TMJ with reactive arthritis and significant condylar resorption. The inflammatory process is noted to occupy a significant volume between the fossa and arthritic condyle.

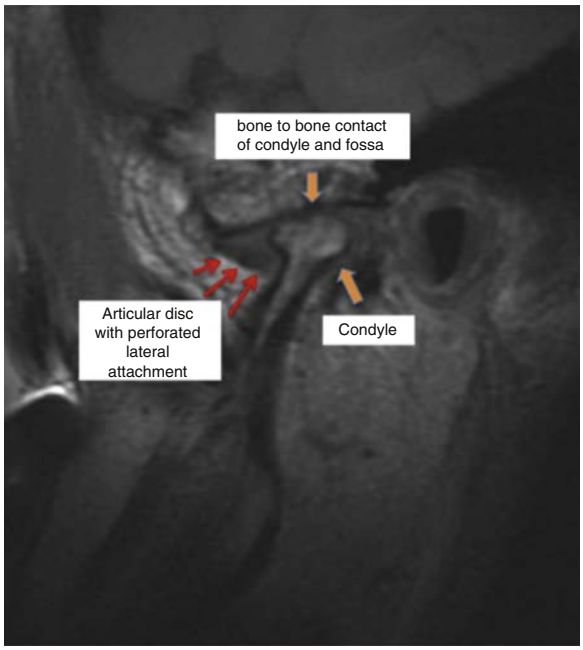
condyle that is slowly becoming smaller in size in all three planes of space and the disc is anteriorly displaced similar to Figure 13-3. In some cases, there is significant thinning of the cortical bone on top of the condyle contributing to the inward collapse of the condylar head in this pathologic process. The articular discs are anteriorly displaced and may or may not reduce on opening. Non-reducing discs will degenerate and deform at a more rapid rate as compared with discs that reduce. Our studies demonstrate that AICR is arrested if the articular discs are put back into position on top of the condyle and stabilized with the Mitek anchor technique. Results are best for AICR if the TMJ surgery for disc repositioning is performed within 4 years of the onset of the pathology. After 4 years the discs may become nonsalvageable and condyles significantly resorbed, at which point the indicated treatment becomes patient-fitted total joint prostheses to repair the TMJs and advance the mandible.

Reactive Arthritis

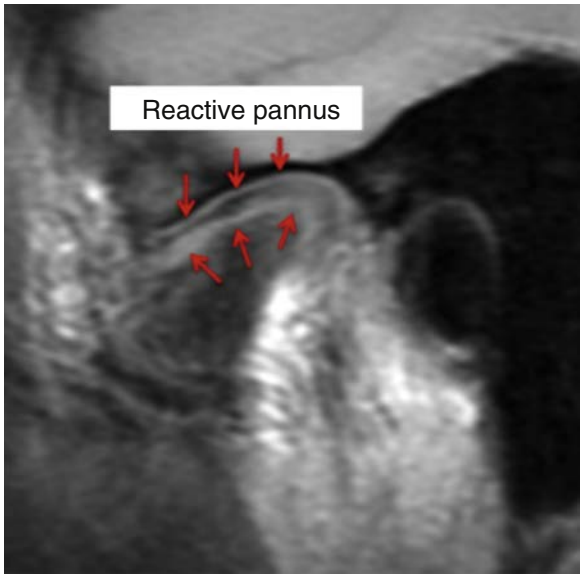
Reactive arthritis is commonly caused by bacterial or viral entities[1-4,14-19] and may show a localized area of inflammation with erosion of the condyle and/or fossa. It also can present as a more profuse inflammatory process through the bilaminar tissues and capsule (Figure 13-4). Surgical indication may include removal of the nidus of inflammation and repositioning the articular disc if salvageable. With extensive destruction of the TMJ, a total joint prosthesis is indicated.

Perforations

Perforations can occur in the TMJ area resulting in bone-on-bone contact. When perforations exist the discs are usually anteriorly and/or medially displaced. Almost always these perforations are posterior to the posterior band of the articular disc or lateral to the disc, and rarely do perforations occur through the disc itself (Figure 13-5). Clinically, crepitation will usually be present and, on the MRI, there will be evidence of bone-on-bone contact, arthritis of the condylar head and/or fossa, as well as an anteriorly displaced disc.



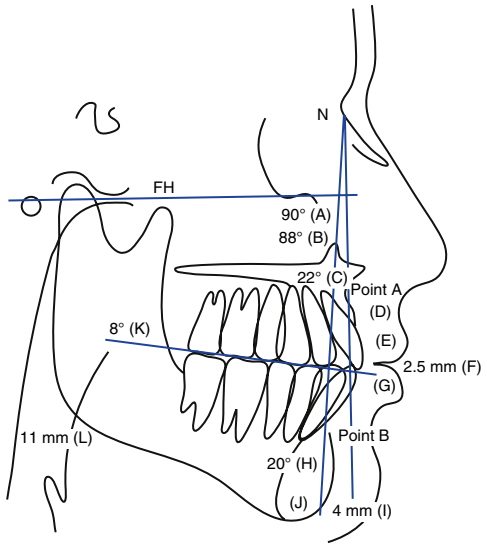
• **Figure 13-5** MRI of left arthritic condyle with perforation of the bilaminar tissue posterior to the anteriorly displaced disc. Bone-to-bone contact of condyle and fossa is observed with crepitation on jaw function.



• **Figure 13-6** There are common TMJ changes in connective tissue/autoimmune disease. The disc may be in position but with a reactive pannus (gray tissue) surrounding the disc that destroys the disc, condyle, and articular eminence. The remaining condyle may have a "mushroom" appearance.

Connective Tissue/Autoimmune Diseases

The MRI presentation of connective tissue/autoimmune diseases is fairly pathognomonic. In these conditions, the articular disc often is in a relatively normal position, but there is progressive condylar resorption, "mushrooming" of the remaining condyle, and often resorption of the articular eminence, with slow but progressive destruction of the articular disc that is surrounded by a reactive pannus (Figure 13-6).[1-4,20-24] This presentation almost always



• **Figure 13-7** Cephalometric tracing landmarks and measurements to aid in diagnosis and treatment planning.

indicates the requirement of a total joint prostheses for jaw reconstruction to eliminate the pathologic process in the joint. Use of autogenous tissues in this scenario could result in the disease process attacking autogenous tissues placed into the joint, with subsequent failure.

Cephalometric Analysis

Cephalometric analysis is an important assessment for diagnosis and treatment planning for TMJ patients because the most dominant facial type with TMJ pathology is the high occlusal plane angle facial morphology with a retruded maxilla and mandible. Normal cephalometric relationships used by the author are demonstrated in Figure 13-7, and are described in detail in previously published papers.[3,6]

One of the primary factors contributing to sleep apnea is a decreased oropharyngeal airway which is commonly seen in TMJ patients, particularly with a history of TMJ condylar resorption. The normal cephalometric A-P dimension from the posterior pharyngeal wall to the soft palate and posterior pharyngeal wall to the base of the tongue is 11 mm, plus or minus 2 mm. In patients who have a retruded maxilla and mandible, this airway may be significantly decreased. Accompanying these deficiencies is usually a high occlusal plane angle. The normal cephalometric angle of the occlusal plane to the Frankfort horizontal plane is 8 degrees, plus or minus 4 degrees. With a retruded maxilla and mandible (particularly with condylar resorption), the occlusal plane commonly is significantly increased and is a factor to be addressed in the treatment planning.

There is a triad of factors that commonly go together in TMJ patients: (1) a high occlusal plane angle facial morphology associated with retruded maxilla and mandible, (2) nasal airway obstruction related to hypertrophied turbinates and/or nasal septal deviation or spurring, and (3) TMJ pathology. Our recent study[25] evaluated 1234 consecutive patients referred to the author for orthognathic surgery requiring at least maxillary osteotomies. There were 603 patients (49%) with hypertrophied turbinates requiring partial turbinectomies and 278 patients (23%) requiring nasal septoplasty. For patients requiring partial turbinectomies (n = 603), 84% had maxillary hypoplasia, 72% had mandibular hypoplasia, 69% had a high occlusal plane angle, and 49% of the patients required concomitant TMJ surgery. A female predominance was seen in the data reviewed. Approximately 67% of the turbinectomy cases and 73% of concomitant turbinectomy, orthognathic, and TMJ surgery cases involved female subjects. A strong correlation has been established between hypertrophied nasal inferior turbinates, hypoplastic maxilla and mandible, and a steep occlusal plane. Our findings correlate with other studies evaluating the morphology of mouth breathing and nasally obstructed patients.[26-29] Therefore, patients with the high occlusal plane angle facial morphology with a retruded maxilla and mandible should be assessed for nasal airway obstruction, decreased oropharyngeal airway, and sleep apnea, as well as TMJ pathology (even if asymptomatic).

Comprehensive Diagnostic List and Treatment Plan

Following completion of all necessary and required evaluations, a comprehensive diagnostic list can be compiled. A definitive treatment plan can then be established to address these issues and other treatment options that may be available to allow the patient to make an informed decision as to the preferred treatment.

Occlusal Plane Alteration

The correction of dentofacial deformities often requires double-jaw surgery to achieve a quality functional and esthetic result and address the airway issues. An often ignored but important cephalometric and clinical interrelationship in the diagnosis and treatment planning for the correction of dentofacial deformities is the *occlusal plane angulation.*[6,30-32] The occlusal plane angle is formed by the Frankfort horizontal plane and a line tangent to the cusp tips of the lower premolars and the buccal groove of the second molar. The normal value for adults is 8 degrees ± 4 degrees. An increased (high) occlusal plane angle usually is reflected in an increased mandibular plane angle (dolichocephaly), and a decreased (low) occlusal plane angle usually correlates with a decreased mandibular plane angle (brachycephaly).

High Occlusal Plane Facial Type

The common functional and esthetic characteristics of the high occlusal plane facial morphology generally include the following:

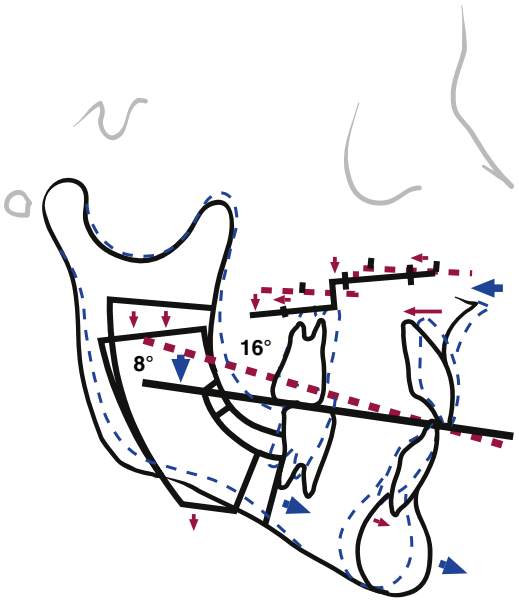
- Increased occlusal plane angulation (occlusal plane greater than 12 degrees)

- Increased mandibular plane angulation
- Anterior vertical maxillary hyperplasia and/or posterior vertical maxillary hypoplasia
- Increased vertical height of the anterior mandible and/or decreased vertical height of the posterior mandible
- Decreased projection of the chin (anteroposterior micrognenia)
- Anteroposterior and vertical posterior mandibular and maxillary hypoplasia
- Decreased angulation of maxillary incisors, although overangulation can occur
- Increased angulation of mandibular incisors
- Class II malocclusion is common, although class I and class III malocclusions also can occur
- An anterior open bite may be accompanied by an accentuated curve of Spee in the upper arch
- In more pronounced cases in which the occlusal plane approaches the slope of the articular eminence, the following may occur: loss of incisal guidance, loss of canine rise occlusion, and the presence of working and nonworking dental interferences in the molar areas
- The more severe cases may demonstrate moderate to severe sleep apnea symptoms as a result of posterior displacement of the tongue base and soft palate constricting the oropharyngeal airway (normal oropharyngeal airway space is 11 mm ± 2 mm)
- Nasal airway obstruction related to hypertrophied turbinates and/or septal deviation or spur
- TMJ pathology

Surgical Decrease of the Occlusal Plane

In the high occlusal plane facial type, the indicated surgical correction may include a counterclockwise rotation of the maxillomandibular complex to decrease the occlusal plane angle. In open bite cases the maxillary occlusal plane and the mandibular occlusal plane may be different and each should be evaluated independently. For illustrative purposes, a class I case is used with the maxillary incisor edge as the center of rotation (Figure 13-8). The anatomic changes that occur with the counterclockwise rotation include the following:

- Occlusal plane angle decreases
- Mandibular plane angle decreases
- Maxillary incisor angulation increases (the same amount that the maxillary occlusal plane decreases)
- Mandibular incisor angulation decreases (the same amount that the mandibular occlusal plane decreases)
- Projection of the chin increases relative to the lower incisor edges
- Posterior facial height may increase
- Prominence of the mandibular angles may increase
- Maxillary incisor edges move forward relative to the perinasal area
- Incisal guidance and canine rise occlusion improves, and posterior working and nonworking interferences are eliminated
- Oropharyngeal airway increases

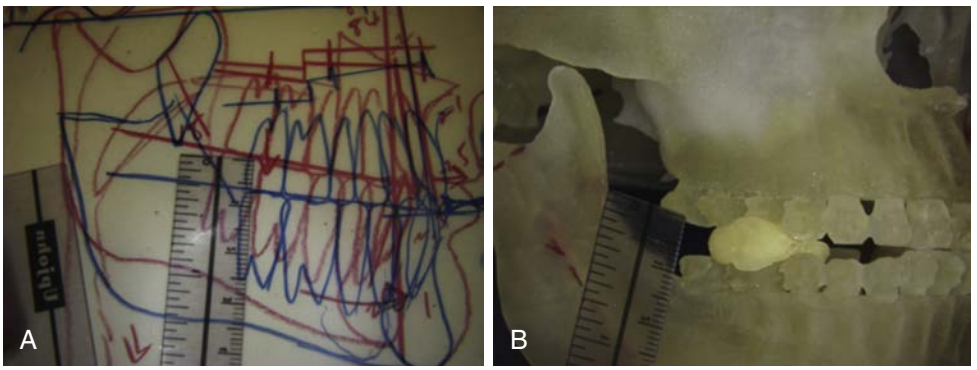


• **Figure 13-8** Surgical decrease of the occlusal plane from the dotted line to solid line (counterclockwise rotation) rotates the chin forward, decreased prominence of the perinasal areas, maxillary incisor angulation increases, mandibular incisor angulation decreases, and the oropharyngeal airway increases.

The center of rotation affects the aesthetic relationship of the jaws with the other facial structures. In the illustrative case shown in Figure 13-8, the center of rotation is at the maxillary incisor edge. Counterclockwise rotation of the maxillomandibular complex results in the perinasal area, subnasale area, and the nasal tip moving posteriorly but the mandible and chin moving forward. If rotation is around point A or higher, then the perinasal area and the nose are less affected, but the maxillary incisor edges come forward, increasing the anteroposterior support to the upper lip. The mandible and chin come further forward, demonstrating the significant esthetic difference that the alteration of the occlusal plane can make.[6,30-32] When decreasing the occlusal plane angle and advancing the mandible counterclockwise, the oropharyngeal airway increases approximately 50% to 70% of the advancement measured at the genial tubercles.[7-11]

Concomitant TMJ Total Joint Replacement and Orthognathic Surgery (C-TJR-OS)

Treatment planning for C-TJR-OS cases is based on cephalometric analysis, prediction tracing, clinical evaluation, MRI, and dental models, which provide the template for movements of the upper and lower jaws to establish optimal treatment outcome in relation to function, facial harmony, occlusion, and oropharyngeal airway dimensions. For patients who require total joint prostheses, a medical grade computed tomographic (CT) scan (of the maxillofacial region) with 1-mm overlapping cuts is recommended and includes the TMJs, maxilla, infraorbital rims, and mandible.



• **Figure 13-9** **A,** Measurement of the cephalometric tracing and prediction tracing for the amount of open bite produced at the second molar after counterclockwise rotation of the mandible into its final position. The original cephalometric tracing is in *red,* and the prediction tracing is in *blue.* **B,** Duplication of the measurement obtained from the prediction tracing to the final mandibular position on the stereolithic model (usually requiring creation of posterior open bites) and fixating the mandible to the maxilla with quick-cure acrylic.

The surgeon has two options for model preparation to aid in the construction of patient-fitted total joint prostheses using the TMJ Concepts System (Ventura, CA): traditional protocol versus virtual surgical planning (VSP).[33,34]

Traditional C-TJR-OS

Treatment planning for C-TJR-OS cases is based on prediction tracing, clinical evaluation, and dental models, which provide the template for movements of the upper and lower jaws to establish optimal treatment outcome in relation to function, facial harmony, occlusion, and oropharyngeal airway dimensions. For patients who require total joint prostheses, a CT scan is acquired of the maxillofacial region that includes the TMJs, maxilla, and mandible with 1-mm overlapping cuts. Using these CT scan data, a stereolithic model is fabricated, with the mandible as a separate piece. Using the original cephalometric tracing and prediction tracing (Figure 13-9, *A*), the mandible on the stereolithic model is placed into its future predetermined position using the planned measurements for correction of mandibular anteroposterior and vertical positions, occlusal plane alteration, pitch, yaw, and roll. The mandible is stabilized to the maxilla with quick-cure acrylic. Repositioning the mandible into its final position usually requires the development of posterior open bites on the model (see Figure 13-9, *B*). Because the mandibular position on the stereolithic models is established using hands-on measurements, the operator's manual dexterity and 3D perspective play a critical role in setting the mandible in its proper and final position. This step can predispose the planning process to a certain margin of error.

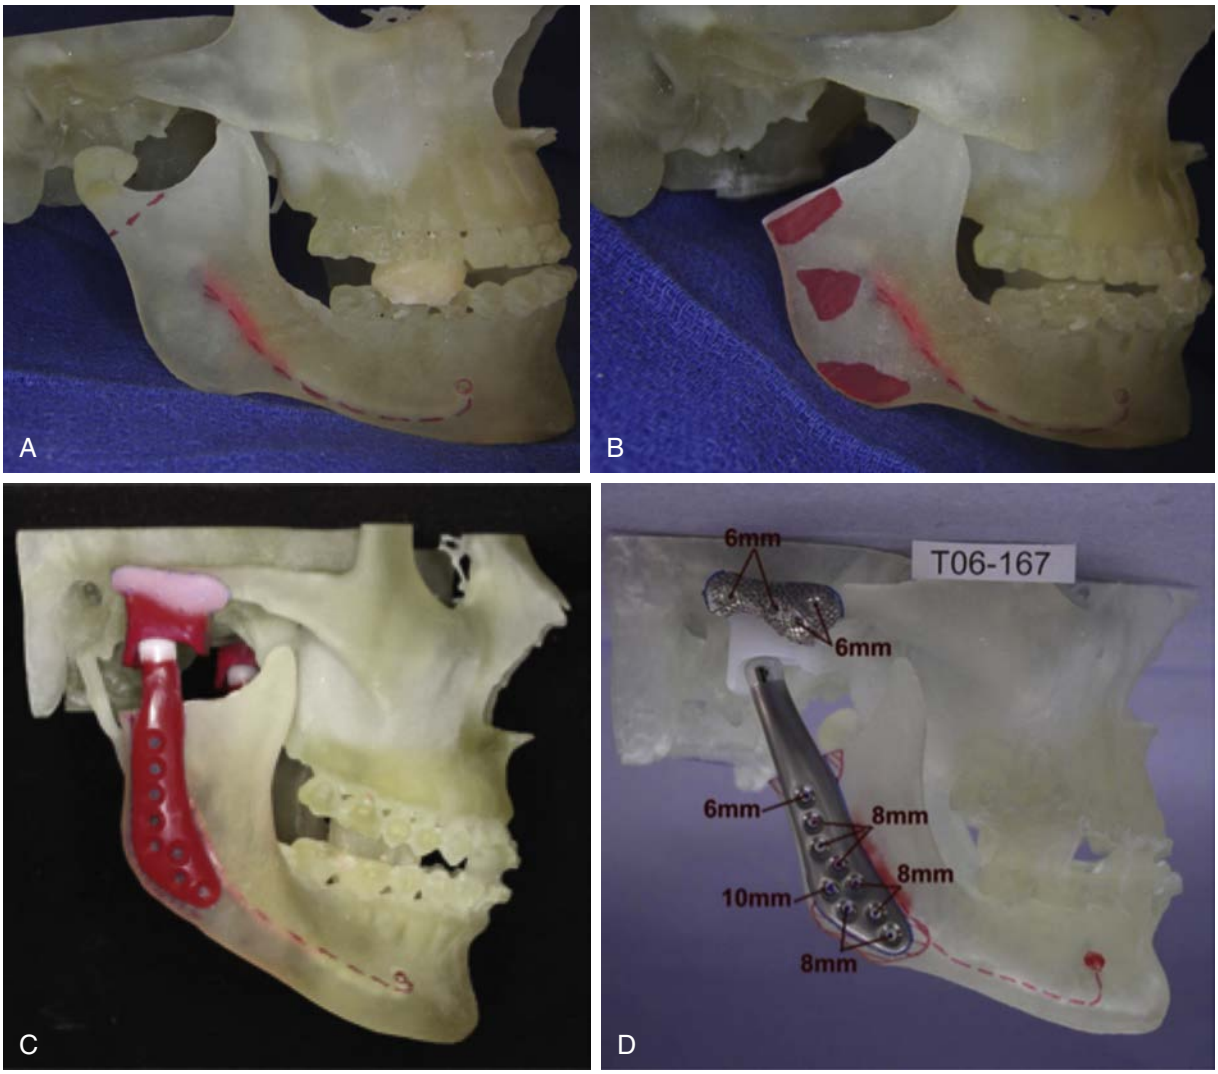
The next step requires condylectomies as well as preparation of the lateral aspect of the rami and fossae (Figure 13-10, *A* and *B*) for fabrication of the patient-fitted total joint prosthesis. The goal of this step is to recontour the lateral ramus to a relatively flat surface in the area where the mandibular component will be placed. The fossa requires recontouring only if heterotopic bone or unusual anatomy is present. The recontouring areas are marked in red for duplication of bone removal at surgery. Because most patients with TMJ problems requiring C-TJR-OS can benefit from counterclockwise rotation of the maxillomandibular complex, the stereolithic model will likely be set with posterior open bites, because the maxilla is maintained in its original position. To accommodate the prosthesis, 20 mm of space is required between the fossa and ramus.

Once the stereolithic model is finalized, the model is sent to TMJ Concepts (Ventura, CA) to perform the design, blueprint, and wax-up (see Figure 13-10, *C*) of the custom-fitted total joint prostheses for approval by the surgeon before manufacture of the prostheses. The period from CT acquisition to the manufacturer's completion of the patient-fitted prostheses is approximately 8 weeks. The final prostheses (see Figure 13-10, *D*) are sent to the hospital for subsequent implantation. The numbers on the printout indicate the length of screw necessary for bicortical engagement.

Prior to surgery, the surgical procedures are performed by the surgeon on articulator-mounted dental models. The mandible is repositioned on the articulator, duplicating the movements performed on the stereolithic model, and the intermediate splint is constructed. The maxillary model is repositioned, segmented if indicated, and placed into the maximal occlusal fit. Then, the palatal splint is constructed, or an occlusal splint if the surgeon prefers.

Protocol for Traditional C-TJR-OS

1. CT scan including the entire mandible, maxilla, and TMJs
2. Fabrication of stereolithic model with the mandible separated
3. Surgeon positions the mandible on the stereolithic model into its final position and fixates it
4. Remove condyles and recontour the lateral aspect of the rami and fossae if indicated



• **Figure 13-10** **A,** Model set for ramus and fossa preparation. The level for condylectomy is marked. **B,** The stereolithic model after condylectomy and recontouring of the fossae and rami (marked in *red*). Accommodation of the prosthesis requires 20 mm space between fossa and ramus. **C,** Stereolithic model with prosthesis wax-up for surgeon approval before manufacture. **D,** Prosthesis constructed. Numbers indicate recommended length of screws for bicortical stabilization of the joint components.

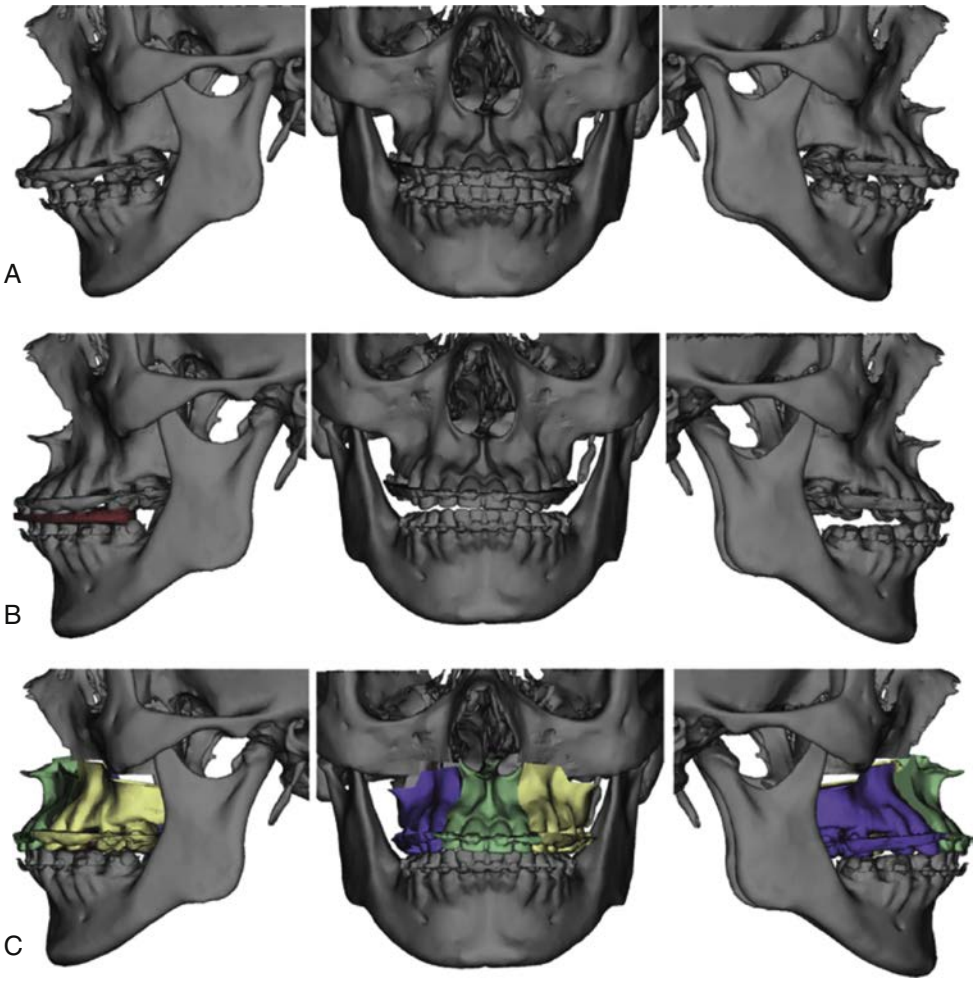
5. Model sent to TMJ Concepts for prostheses design, blueprint, and wax-up
6. Surgeon approves total joint prostheses blueprint and wax-up
7. Manufacture of custom-fitted total joint prostheses
8. Prostheses sent to hospital for surgical implantation
9. Dental model surgery for fabrication of splints
10. Surgery performed as planned

Steps in Traditional Orthognathic Surgery, Intermediate, and Palatal Splint Fabrication for C-TJR-OS

1. Acquisition of dental models
2. Mounting maxillary and mandibular dental models on an articulator
3. Reposition the mandibular dental model, duplicating the positional changes acquired on the stereolithic model
4. Fabrication of intermediate splint
5. Reposition maxillary dental model with segmentation if indicated
6. Construction of palatal splint (or occlusal splint if the surgeon prefers)
7. Ready for surgery

Virtual Surgical Planning

Virtual surgical planning (VSP) utilizes computer technology to simulate the planned surgical procedures. Over the past decade, computer-assisted surgical simulation (CASS) technology has been integrated to many maxillofacial surgical applications,[35,36] including dentofacial deformities, congenital deformities, defects after tumor ablation, post-traumatic defects, reconstruction of cranial defects,[37] and reconstruction of the TMJ.[33,34] CASS technology applied to orthognathic surgery can improve surgical accuracy,



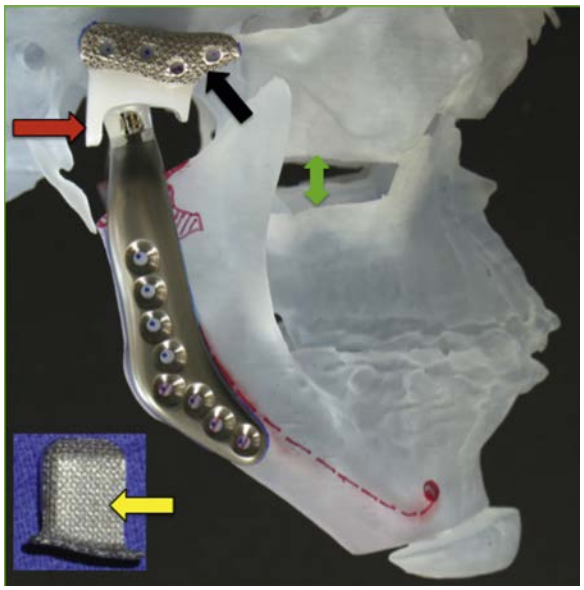
• **Figure 13-11** Staged computer-aided surgical simulation (CASS). **A,** Simulated preoperative position of the maxilla and mandible. **B,** The maxilla and mandible in the simulated intermediate position, with the maxilla in its original position, but mandible in its final position with the mandibular surgery performed first for fabrication of the intermediate splint. **C,** The final position of maxilla and mandible, after counterclockwise rotation-advancement of the mandible and segmented maxilla, for the production of a palatal splint or occlusal splint if the surgeon prefers.

provide intermediate and final surgical splints, and decrease the surgeon's time input for presurgical preparation compared with traditional methods of case preparation. Data for VSP in orthognathic surgery cases can be obtained from CBCT scans, but better quality simulation and accuracy can be acquired from medical grade CT scans of the jaws with 1-mm overlapping cuts.

Protocol for C-TJR-OS Using CASS

For C-TJR-OS cases, the orthognathic surgery can be planned using CASS technology and moving the maxilla and mandible into their final position in a computer-simulated environment (Figure 13-11, *A, C*). Using the computer simulation, the anteroposterior and vertical positions, occlusal plane alteration, pitch, yaw, and roll are accurately finalized for the maxilla and mandible based on clinical evaluation, dental models, prediction tracing, and computer-simulation analysis. Segmentation of the maxilla can be simulated. Figure 13-11, *B* simulates the mandible in its final position and the maxilla in its original position for fabrication of the intermediate splint since the mandible is usually repositioned first before the maxilla.

Using Digital Imaging and Communications in Medicine (DICOM) data, the stereolithic model is produced with the maxilla and mandible in the final position and provided to the surgeon for removal of the condyle and recontouring of the lateral rami and fossae if indicated. The stereolithic model is sent to TMJ Concepts for the design, blueprint, and wax-up of the prostheses. Via the Internet, the design, blueprint, and wax-up are approved by the surgeon. Then, the custom-fitted total joint prostheses are manufactured. It takes approximately 8 weeks to manufacture the total joint patient-fitted prostheses. Figure 13-12 demonstrates the basic design of the TMJ Concepts patient-fitted prosthesis. The black arrow points to the mesh framework on the underside of the custom-fitted titanium shell that secures the polyethylene articulating portion of the fossa component. The yellow arrow points to the mesh on the superior surface of the fossa component



• **Figure 13-12** Stereolithic model fabricated after simulated maxillary and mandibular advancement to the final position. Condylectomy and recontouring of the lateral rami and fossae were performed and prostheses manufactured. The basic design of the TMJ Concepts patient-fitted prosthesis is observed. The *black arrow* points to the mesh framework on the underside of the custom-fitted titanium shell that secures the polyethylene articulating portion of the fossa component. The *yellow arrow* points to the mesh on the superior surface of the fossa component that allows osseo-integration with the fossa bone. The *red arrow* points to the posterior stop of the fossa, a necessary component for mandibular advancement and stability. The *green arrow* shows the bony defect created from the counterclockwise rotation of the posterior maxilla. These defects require bone or synthetic bone grafting and rigid fixation for stability of the maxilla.

that allows osseointegration with the fossa bone. The red arrow points to the posterior stop of the fossa, a necessary component for mandibular advancement and stability. The green arrow shows the bony defect created from the counterclockwise rotation of the posterior maxilla. These defects require bone or synthetic bone grafting and rigid fixation for stability of the maxilla.

Approximately 2 weeks before surgery, final dental models are acquired including two maxillary models if the maxilla is to be segmented or dental equilibration is required. One of the maxillary models is segmented if indicated, dental equilibration is performed, and the segments are placed in the best occlusion fit with the mandibular dentition and the maxillary segments are fixed to each other. The dental models do not require mounting on an articulator. The three or four models (two maxillary and one mandibular, or two mandibular models if equilibrations or dentoalveolar surgery are done on the mandible) are physically sent to the VSP company for scanning and simulation into the computer model. Alternatively, with an i-CAT machine, the models can be scanned and digitally sent to the VSP company, although the accuracy may not be quite as good as sending the actual models.

Because the author's surgical protocol routinely performs the TMJ reconstruction and mandibular advancement with the TMJ Concepts total joint prosthesis first, the unsegmented maxillary model is simulated into the original maxillary position and the mandibular model is simulated into the mandible in its final position. The intermediate splint is constructed (see Figures 13-11, *B*, 13-13, *A* and *B*). Then, the segmented maxillary model is simulated into the computer model in its final position, with the best occlusal fit with the mandibular occlusion, and the palatal splint is fabricated (see Figure 13-13, *C* and *D*) or an occlusal splint is made if the surgeon prefers. The dental models, splints, and images of the computer-simulated surgery are sent to the surgeon for implementation during surgery.

Steps in C-TJR-OS Using CASS

1. CT scan of entire mandible, maxilla, infraorbital rims, and TMJs (1-mm overlapping cuts recommended)
2. Processing of DICOM data to create a computer model in CASS environment
3. Correction of dentofacial deformity, including final positioning of the maxilla and mandible, with computer-simulated surgery
4. Stereolithic model constructed with jaws in final position and sent to surgeon for condylectomy as well as rami and fossae recontouring if indicated
5. Model sent to TMJ Concepts for prostheses design, blueprint, and wax-up
6. Surgeon approval of design, blueprint, and wax-up via the Internet
7. TMJ prostheses manufactured and sent to hospital for surgical implantation
8. Two weeks before surgery, acquisition of final dental models (two maxillary, one or two mandibular models if dental equilibrations are required); one maxillary model is segmented and models equilibrated if indicated to maximize the occlusal fit; models sent to the VSP company, or digitally sent
9. Models incorporated into computer-simulated surgery for construction of intermediate and final palatal splints
10. Models, splints, and printouts of computer-simulated surgery sent to surgeon

Using CASS technology for C-TJR-OS cases eliminates the "traditional" steps requiring the surgeon to manually set the mandible into its new final position on the stereolithic model, thus saving time and improving surgical accuracy. Although dental model surgery is necessary only if the maxilla requires segmentation or equilibration, the models do not require mounting on an articulator. This saves considerable time by eliminating the time required to mount the models, prepare the model bases for model surgery, reposition the mandible, construct the intermediate occlusal splint, and make the final palatal splint. With CASS technology, the splints are manufactured by the VSP company.

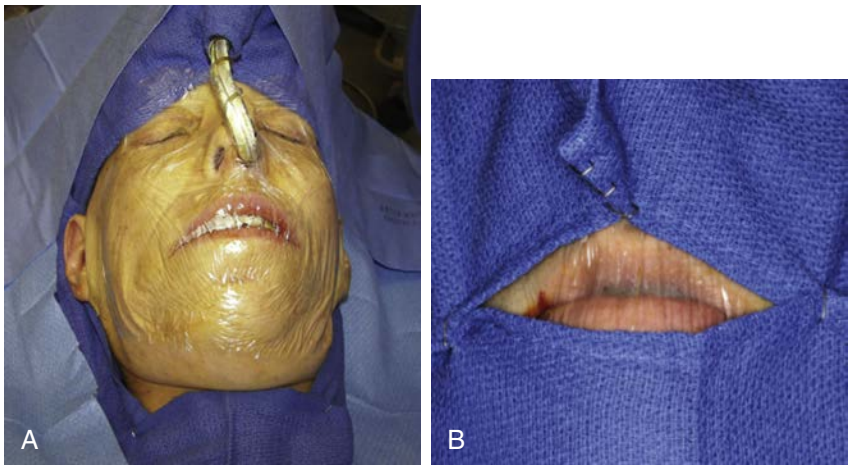
• **Figure 13-13** **A-B,** Intermediate splint is printed from the CASS model with the mandible in the final position and maxilla in the original position. **C,** Palatal splint printed and **(D)** inserted.

Surgical Sequencing for C-TJR-OS

1. Condylectomy
2. Coronoidotomy or coronoidectomy
3. Detach the masseter and media pterygoid muscles from ramus
4. Mobilize mandible
5. Maxillomandibular fixation with intermediate surgical splint
6. Placement of total joint prostheses
7. Bilateral TMJ fat grafts harvested from the abdomen or buttock
8. Maxillary osteotomies and mobilization
9. Turbinectomies, septoplasty, etc.
10. Maxillary segmentation and application of the palatal splint if indicated
11. Maxillary rigid fixation and bone grafting
12. Adjunctive procedures such as genioplasty, rhinoplasty, UPPP, facial augmentation, etc.

A potential risk to patients receiving TMJ total joint prosthesis is infection. The occurrence rate is less than 2% with greater risk for patients on immunosuppressant medications such as rheumatoid patients or others with connective tissue/autoimmune diseases. Bacterial or viral contamination of the prosthesis can occur during surgery or develop at a later time from bacterial seeding through a hematogenic route or localized bacterial sources. As a result, strict adherence to sterile technique for the procedures performed can prevent or reduce the chance of infection associated with the implantation of total joint prosthesis, and concomitant orthognathic surgery.

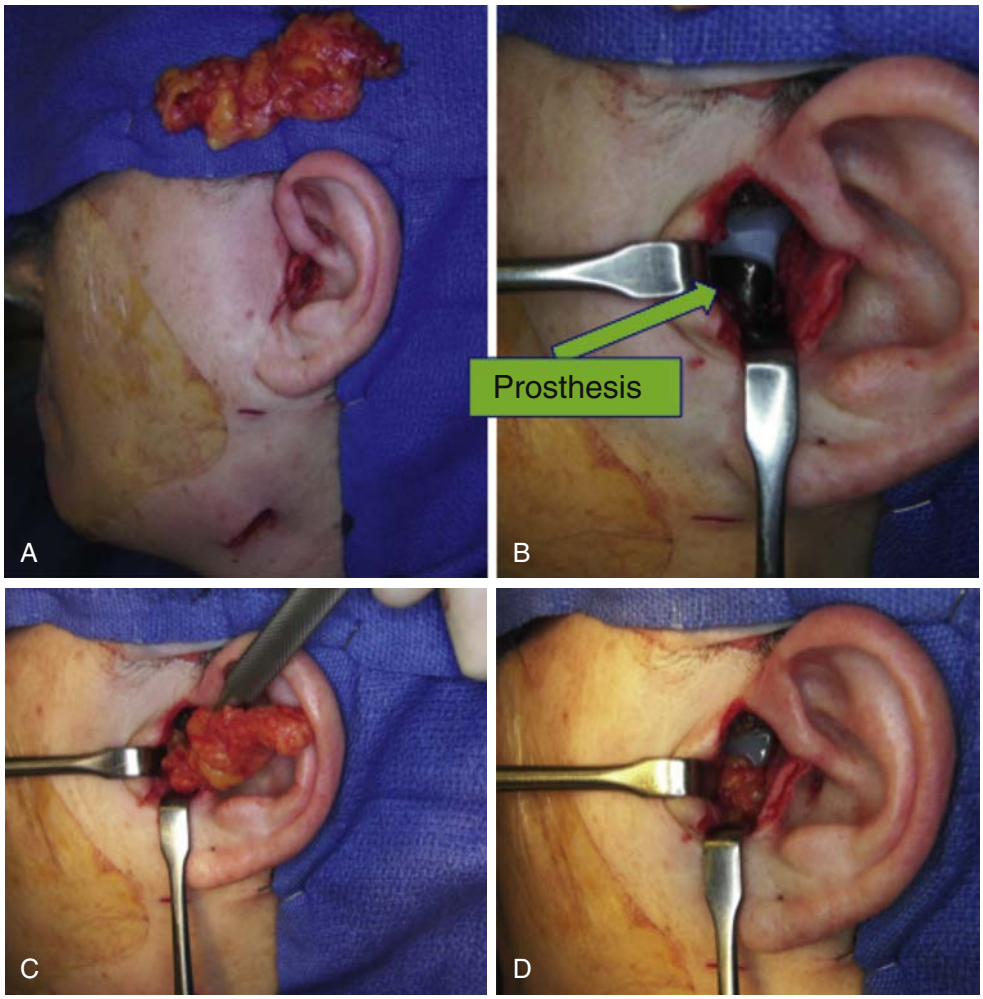
The TMJ Concepts prosthesis uses design principles and materials that are proven highly successful and are the gold standard in orthopedic joint reconstruction for hip and knee replacements. The prosthesis consists of a fossa component with a commercially pure titanium framework covered with a mesh and an ultra-high molecular weight polyethylene functional component fused to the mesh on the bottom side of the framework. The fossa component is attached to the lateral rim of the fossa with four 2-mm diameter screws. The mandibular component is composed of a titanium alloy shaft with a cobalt-chromium alloy head with the prosthesis secured to the mandibular ramus with seven to nine 2-mm diameter bicortical screws. The fossa and mandibular components osseointegrate with the fossa and ramus respectively.



• **Figure 13-14** **A,** After preparation of the face, neck, ears, and oral cavity, a Tegaderm Film dressing, 6 × 8 in, is applied to seal off the oral cavity and nasal airway from the surgical field. **B,** Following mobilization of the mandible, sterile towels are draped around the face and mouth to prevent contamination of the extra-oral surgical sites. The Tegaderm dressing is cut to provide access to the oral cavity for placement of the intermediate splint and maxillomandibular fixation.

Surgical Procedure

1. After surgical prepping including the face, neck, mouth, ears, ear canals, nose, endotracheal tube, and abdomen, the abdomen, face, and neck are draped, the mouth and nose are isolated by application of a Tegaderm film dressing (6 × 8 inches), and the ear canal is gently packed with cotton (Figure 13-14, *A*).
2. The TMJs are approached through an endaural or pre-auricular incision to perform the condylectomy, joint debridement, and coronoidectomy (when the mandible is significantly advanced or vertically lengthened). The bone from the condylectomies and coronoidectomies is saved for use in grafting the bone defects that may be associated with the maxillary osteotomies.
3. Submandibular incisions are used to access the ramus to reflect the masseter and medial pterygoid muscles and to mobilize the mandible in a downward and forward direction. The lateral aspect of the ramus is prepared duplicating the alterations on the stereolithic model.
4. Following mandibular mobilization, the oral cavity is isolated by draping with sterile towels, exposing from commissure to commissure (see Figure 13-14, *B*). The Tegaderm is cut through and the oral cavity is entered. If the case includes bilateral total joint prostheses, then the intermediate splint is inserted and maxillomandibular fixation applied. If it is a unilateral total joint prosthesis case, then go to Step 5.
5. For unilateral total joint prosthesis, using separate instrumentation, a contralateral mandibular sagittal split osteotomy is performed and mandible mobilized on that side. The intermediate splint and maxillomandibular fixation are applied. Rigid fixation is placed to secure the mandibular segments and the incision is closed.
6. The temporary towels are removed, the surgeon changes gloves and gown, and the mouth is sealed off once again with a Tegaderm film dressing.
7. The total joint prostheses are inserted and fixed in position. A stab incision can be made about 1 centimeter below the earlobe and a trocar inserted to place screws in the holes at the top of the prosthesis that are difficult to access from the submandibular incision.
8. The surgical areas are thoroughly irrigated with saline with a final rinse using betadine solution. The masseter muscles are reattached to the mandible and submandibular incisions are closed.
9. Fat grafts are harvested from the abdomen or buttock with establishment of good hemostasis and closure of the incisions. A small drain can be inserted in the donor area if good hemostasis cannot be achieved.
10. The articulating area of the prostheses is thoroughly irrigated with saline through the endaural or pre-auricular incisions with a final rinse using betadine solution. The fat grafts are packed around the articulating area of the prostheses (Figure 13-15, *A-D*) and the incisions closed.
11. The oral cavity is then entered, maxillomandibular fixation released, and the intermediate splint removed.
12. Maxillary osteotomies are performed and maxilla mobilized. Intranasal procedures are done such as turbinectomies and septoplasty if indicated.
13. The maxilla is segmented, palatal splint inserted, and maxillomandibular fixation applied. The maxilla is rigidly fixated with four bone plates and bone grafting at the osteotomy sites as indicated.
14. The alar base cinch suture is placed and maxillary incision closed in a V-Y design.



• **Figure 13-15** **A,** Fat harvested from abdomen for placement around the articulating area of the prosthesis. **B,** Patient-fitted prosthesis exposed via the endaural incision. **C,** Packing the fat into the joint area. **D,** Completion of fat packing and ready for incision closure.

15. Bone screws or temporary anchoring devices (TADs) can be placed in the alveolar bone area if the surgeon prefers, so that the required post-surgery interarch elastics to support the mandible and occlusion can be applied to these devices and not tooth borne, which could extrude or displace the teeth.
16. Any other adjunctive procedures can be performed such as genioplasty or rhinoplasty. Special care must be taken when performing a concomitant genioplasty procedure to use a conservative dissection along the symphysis/body region to prevent communication with the total joint prosthesis implantation site.

Appropriate IV antibiotics are used while in the hospital and then PO antibiotics for an additional 7 to 10 days. This patient management scheme should minimize the risk of infection.

Post-surgically, light force vertical elastics are necessary to support the mandible because the muscles of mastication are detached during surgery and may take a few weeks to reattach and provide adequate support to the mandible. Otherwise, post-surgical patient management is the same as routine double-jaw orthognathic surgery.[38,39]

CASE STUDY 13-1

This 19-year-old female had the onset of TMJ problems at the age of 15 secondary to bilateral TMJ reactive arthritis. She had previous orthodontics with four first bicuspid extractions from the age of 13 to 16 followed by splint therapy for 2 years, but the TMJ pathology and mandibular retrusion continued to worsen. She presented with a significant A-P hypoplasia of both maxilla and mandible and developed a class II anterior open bite occluding only on the second molars (Figures 13-16, *A-C;* 13-17, *A-C;* 13-18, *A*). She also had hypertrophied turbinates with nasal airway obstruction. Presurgery her TMJ pain was 8 (0 = no pain or no limitations; 10 = worst pain imaginable or total loss of function), headaches 7, jaw function 6, diet 7, and disability 6. Maximum incisal opening was 35 mm, but 27 mm without significant pain. CBCT (Figure 13-19, *A-D*) shows advanced arthritis with significant condylar resorption compatible with reactive arthritis. Presurgical MRI (Figure 13-20) shows the arthritic changes in the joints, low grade inflammatory response particularly on the left side, and the severely degenerated articular discs rendering them nonsalvageable, thus, the necessity for patient-fitted TMJ Concepts total joint prostheses to reconstruct the TMJs and advance the maxillomandibular complex in a counterclockwise direction. This case was prepared with the protocol of C-TJR-OS using CASS for virtual surgical planning as previously described.

The patient underwent the following surgical procedures: (1) bilateral TMJ reconstruction and counterclockwise rotation-advancement of the mandible (16 mm at pogonion) with TMJ Concepts total joint prostheses, (2) multiple maxillary osteotomies to counterclockwise rotate and advance the incisors 8 mm and upward positioning 5 mm (see Figure 13-18, *B*), (3) bilateral mandibular coronoidotomies, (4) bilateral TMJ fat grafts (harvested from the abdomen), and (5) bilateral partial nasal inferior turbinectomies.

At 2 years post-surgery she has a stable skeletal and occlusal relationship, improved facial balance, and good nasal and oropharyngeal airways (see Figures 13-16, *D-F*; 13-17, *D-F*). TMJ pain 0, headaches 0, jaw function 1, diet 2, disability 0, and incisal opening of 42 mm.

• **Figure 13-16** A 19-year-old female with bilateral TMJ reactive arthritis, with retruded mandible and maxilla. **A-C,** Presurgery clinical pictures. **D-F,** Clinical images at 2 years post-surgery for (1) bilateral TMJ total joint prostheses with counterclockwise rotation of the mandible, (2) maxillary osteotomies, (3) bilateral coronoidectomies, (4) bilateral TMJ fat grafts, and (5) bilateral partial turbinectomies.

Fat Grafts

Early on in the use of total joint prostheses, a common problem encountered in approximately 35% of the patients was post-surgical fibrosis and heterotopic bone formation around the prostheses causing jaw dysfunction, decreased incisal opening, and pain.[40] In 1992, Wolford developed a technique to place fat grafts (harvested from the abdomen or buttock) around the articulating area of the total joint prosthesis to eliminate the dead space. This prevents blood clot formation in the space around the prosthesis that could provide a matrix for fibrous ingrowth and pluripotential cells migrating into the area that could develop heterotopic bone and dense fibrotic tissues. Also, in patients with previous failed alloplastic implants, the fat graft blocks out a large area in which the foreign body giant cell reaction (FBGCR) and reactive bone may otherwise redevelop. Wolford et al.[40-42] have demonstrated the improved outcomes for patients using fat grafts packed around the prostheses compared to patients that did not receive the fat grafts relative to function, pain, and elimination of additional surgical procedures for joint debridement. Mercuri et al.[43] reported the efficacy of the fat grafts packed around the prostheses in TMJ ankylosis cases.

Treatment Outcomes Using These Treatment Protocols

Dela Coleta et al.[44] evaluated 47 female patients for surgical stability following bilateral TMJ reconstruction using TMJ Concepts patient-fitted TMJ total joint prostheses, TMJ fat grafts, and counterclockwise rotation of the maxillomandibular complex with menton advancing an average of 18.4 mm and the occlusal plane decreasing an average of 14.9 degrees. Average follow-up was 40.6 months. Results demonstrated minor maxillary horizontal changes while the mandibular measurements remained very stable.

Pinto et al.[45] evaluated the same 47 female patients relative to pain and dysfunctional outcomes. Patients were divided into two groups based on the number of previous surgeries: group 1 had zero to one previous surgery while group 2 had two or more previous surgeries. Significant improvements (37% to 52%) were observed for TMJ pain, headaches, jaw function, diet, and disability. MIO increased 14%. Group 1 patients had better pain and jaw function results than group 2 patients. For patients who did not receive fat grafts around the prostheses and had previous failure of Proplast-Teflon (Vitek Inc., Houston, TX) or Silastic (Dow-Corning Inc., Midland, MI) TMJ implants, more than half required secondary surgery including TMJ debridement for removal of FBGCR, fibrosis, and/or heterotopic bone formation. These two studies demonstrated that end-stage TMJ patients could be treated in one operation with TMJ Concepts patient-fitted TMJ total joint prostheses, fat grafts, and maxillomandibular counterclockwise rotation for correction of an associated dentofacial deformity with good stability and improvement in pain and TMJ function.

Although the life expectancy of this device is unknown, Wolford et al.[46] recently published a 20-year follow-up

CASE STUDY 13-2

This 18-year-old patient (Figures 13-21, *A-C*; 13-22, *A-C*; 13-23, *A*) developed severe juvenile idiopathic arthritis (JIA), onset at age 7 years with milder effects in multiple other joints, had sleep apnea, nasal airway obstruction related to hypertrophied turbinates, and pain. TMJ pain was at 7, headaches at 7, myofascial pain at 7, jaw function at 7, diet at 6, and disability at 6. Incisal opening was 33 mm. MRI sagittal imaging of the left TMJ (Figure 13-24, *A*) and right TMJ (see Figure 13-24, *B*) demonstrates the classic appearance of JIA with: (1) loss of condylar height, (2) A-P mushrooming of the condylar stump, (3) articular disc in position between the remaining condyle and fossa, (4) resorption of the articular eminence, (5) Reactive pannus surrounding the disc, and (6) condyles positioned forward in the fossa. In the coronal view (see Figure 13-24, *C*) the condylar stumps are very narrow in a medial-lateral dimension with significant loss of vertical height. This patient was a candidate for patient-fitted TMJ Concepts total joint prostheses to reconstruct the TMJs and advance the maxillomandibular complex in a counterclockwise direction.

The treatment plan (see Figure 13-23, *B*) in a single-stage surgery included: (1) bilateral TMJ reconstruction and mandibular advancement (21 mm) in a counterclockwise direction with TMJ Concepts/Techmedica total joint prostheses, (2) bilateral coronoidectomies, (3) bilateral TMJ fat grafts, (4) multiple maxillary osteotomies with counterclockwise rotation to move the anterior aspect upward and posterior aspect downward, and advancing the incisors 4 mm,

• **Figure 13-21 A-C,** 18-year-old female with JIA and grossly resorbed mandibular condyles, severely retruded mandible and maxilla, and high occlusal plane angle facial morphology. **D-F,** The patient is seen at 3 years post-surgery demonstrating significantly improved facial balance and function.

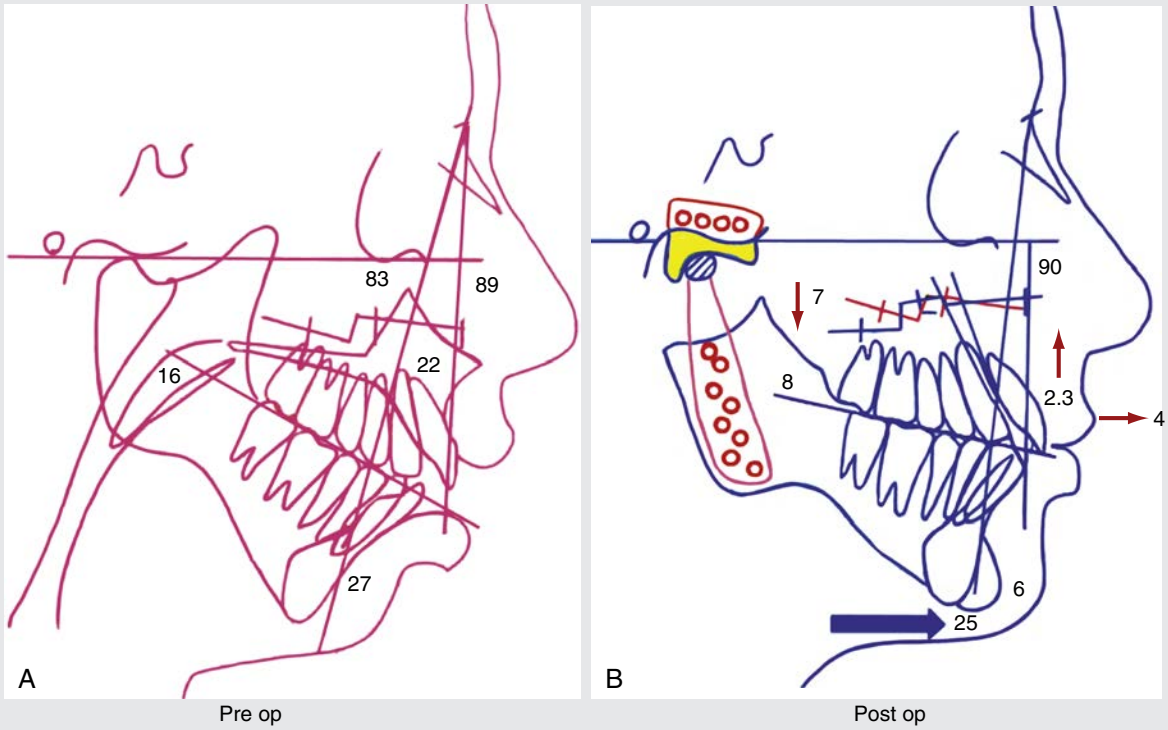
CASE STUDY 13-2—cont'd

(5) 4-mm bony genioplasty with pogonion advancing a total of 25 mm, and (6) bilateral partial inferior turbinectomies.

The traditional C-TJR-OS protocol was used to prepare this case for surgery with the surgery performed on the stereolithic model by the surgeon for manufacture of the TMJ total joint prostheses, then duplicated on the articulator-mounted dental models for construction of the intermediate and final palatal splints.

With the counterclockwise rotation of the maxillomandibular complex and the genioplasty, the pogonion advanced 25 mm. The patient is seen at 3 years post-surgery (see Figures 13-21, *D-F*; 13-22, *D-F*) with good facial balance, skeletal and occlusal stability, significant reduction in pain, and an incisal opening of 39 mm.

• **Figure 13-22** **A-C,** A significant anterior open bite is present and class II occlusion. **D-F,** At 3 years post-surgery she demonstrates a stable class I occlusion.



Pre op Post op

• **Figure 13-23** **A,** The cephalometric analysis shows the severe jaw deformity and high occlusal plane angulation. **B,** The prediction tracing demonstrates the counterclockwise rotation of the maxillomandibular complex. The chin is augmented 4 mm with pogonion advanced a total of 25 mm.

• **Figure 13-24** MRI of the TMJ T-1 sagittal views. **A,** Left TMJ. **B,** Right TMJ; show classic JIA imaging with (1) loss of condylar height, (2) A-P mushrooming of the condylar stump, (3) articular disc in position between the remaining condyle and fossa, (4) resorption of the articular eminence, (5) reactive pannus surrounding the disc, and (6) condyles positioned forward in the fossa. **C,** Coronal view shows the loss of condylar height and transverse narrowness of remaining condylar stump.

study of 56 patients who had received the Techmedica total joint prosthesis between 1989 and 1993. There were statistically significant improvements in all parameters including incisal opening, jaw function, TMJ pain, and diet, with 85.7% of the patients reporting significant improvement in their quality of life. The greater the number of previous TMJ surgeries, the lower degree of subjective improvement patients reported, but they did report increased objective mandibular function and improved quality of life. There were no reports of device removal due to material wear or failure.

Wolford et al.,[20-24,44-53] Mercuri et al.,[22,24,46,54-60] and others[61-64] have published numerous studies in reference to outcome data using TMJ total joint prostheses. A summary of these publications has produced the following facts in reference to the TMJ Concepts total joint prosthesis:

1. TMJ Concepts prostheses are superior to autogenous tissues for end-stage TMJ reconstruction relative to subjective and objective outcomes[23,47,57,58,60]
2. After two previous TMJ surgeries, autogenous tissues have a very high failure rate, whereas patient-fitted total joint prostheses have a high success rate[23,46,59,60]
3. No donor site morbidity
4. Increased number of previous TMJ surgeries produces a lower level of improvement related to pain and function outcomes compared to patients with no to one previous TMJ surgeries[21-24,45-47,52-60]
5. Failed TMJ alloplastic reconstruction (i.e., P/T, Silastic, metal-on-metal articulation, etc.) can create a foreign-body giant cell reaction and/or metallosis, best treated by joint debridement and reconstruction with patient-fitted total joint prostheses[21-24,45-47,50,53,56]
6. Fat grafts packed around the articulating area of the prostheses improves outcomes relative to decreased pain, improved jaw function, and decreased requirement for repeat surgery [40-43]
7. Osseointegration of the TMJ Concepts fossa and mandibular components occurs and is important for long-term stability[20,22-24,44,45-47,51-55]
8. Posterior stop on the fossa component is important to stabilize the joint, jaw position, and occlusion[20,23,21,44,45,51,52]
9. Concomitant orthognathic surgery can be performed at the same time as the TMJs are reconstructed[20,23,21,44,45,51,52]
10. A 20-year follow-up study[46] demonstrated improvements in pain, jaw function, diet, incisal opening, and quality of life

Age for Surgical Intervention

Although there are individual variations, females usually have the majority of their facial growth (98%) complete by the age of 15 years and males by the age of 17 to 18 years.[65] Predictability of results and limiting correction of the jaw and TMJ pathology related deformities to one major operation can best be achieved by waiting until growth is relatively complete if only the TMJ total joint prostheses are placed without maxillary surgery, particularly if only a unilateral prosthesis is required. However, there are definite indications for performing surgery during the growing years such as progressive TMJ deterioration, ankylosis, masticatory dysfunction, tumor removal, pain, and sleep apnea. Performing surgery during growth may result in the need for additional surgery at a later time to correct a resultant deformity and malocclusion that may develop during the completion of growth. Additional surgery is a greater probability with unilateral prosthesis and a normal contralateral TMJ if surgery is performed during the growing years. In addition, some orthognathic surgical procedures have a profound affect on subsequent facial growth and development, including maxillary Le Fort I osteotomies, where maxillary A-P growth is arrested, but the vertical alveolar growth of the maxilla and mandible continues contributing to a downward and backward rotation vector of facial development, but the occlusion should stay together. Therefore, bilateral TMJ patient-fitted total joint prostheses and maxillary osteotomies can be done at an earlier age with predictable results.

If repeat orthognathic surgery is required at a later time, the advancement of the mandible with the TMJ total joint prosthesis can be accomplished by one of four surgical options: (1) intraoral ramus sagittal split osteotomy; (2) extraoral sagittal split ramus osteotomy (ESSRO); (3) advance the mandible forward relative to the prosthesis by removing the screws from the mandibular component, separate it from the ramus, advance the mandible along the patient-fitted prosthesis and refixate the prosthesis with bone screws to the mandible in its new position; or (4) replace the mandibular component of the total joint prosthesis with a new longer mandibular component that would be reattached to the mandibular ramus after the mandible is moved into its new position.

We have previously published on maxillary and mandibular orthognathic surgery and the effects on growth, with guidelines for age considerations for surgical intervention[66-68] as well as TMJ surgery effects on facial growth.[69] We have successfully treated juvenile idiopathic arthritis (JIA) patients (ages 12–14 years and older) with the protocol described above in one stage with good functional and esthetic results without requiring secondary procedures.[20] These cases are predictable when performed at age 13 years or older in females and 15 years or older in males. However, the vector of facial growth will change in younger patients to a downward and backward direction.

Summary

Healthy and stable TMJs are necessary for quality treatment outcomes in orthognathic surgery. If the TMJs are not stable and healthy, orthognathic surgery results may be unsatisfactory relative to function, esthetics, skeletal and occlusal stability, and pain. The oral and maxillofacial surgeon should be suspicious of possible TMJ problems in the following types of patients:

1. High occlusal plane angle facial morphologies with retruded maxilla and mandible;
2. Class II high occlusal plane angle and retruded mandibular morphological type, particularly those with anterior open bites;
3. Progressively worsening class II occlusal and jaw relationship;
4. Facial asymmetry, particularly with progressive worsening; and
5. Patients reporting headaches, TMJ pain, myofascial pain, history of clicking and popping of the TMJs, and/or ear symptoms.

The surgeon should not ignore these symptoms. With one or more of these symptoms, patients should be evaluated for possible TMJ pathology. An MRI of the TMJs can aid in identification of the specific TMJ pathology and treatment options. Failure to recognize and treat these conditions for patients requiring orthognathic surgery can result in significant relapse, increased pain, and greater complexity of subsequent treatment.

During the past 25 years, major advancements have been made in TMJ diagnostics and the development of surgical procedures to treat and rehabilitate the pathologic, dysfunctional, and painful TMJ. Research has clearly demonstrated that TMJ and orthognathic surgery can be safely and predictably performed at the same operation, but it does require the correct diagnosis and treatment plan and a surgeon with expertise in both TMJ and orthognathic surgery. The surgical procedures can be separated into two or more surgical stages, but the TMJ surgery should be done first. With the correct diagnosis and treatment plan, combined TMJ and orthognathic surgical approaches provide complete and comprehensive management of patients with co-existing TMJ pathology and dentofacial deformities.

Surgery for Accelerated Orthodontic Movement

CHARLES D. HASSE

Introduction

Since Professor Hugo Obwegeser's initial presentation to American oral and maxillofacial surgeons in 1966,[1] the science of orthognathic surgery has developed exponentially from life-threatening surgery to accurately planned computer-based surgery, performed meticulously and safely.[2] A myriad of clinical techniques have been introduced, and esthetic and radiographic parameters have developed over the past five decades to enable oral and maxillofacial surgeons and orthodontists to effectively manage dentofacial deformities.

Today, contemporary surgical orthodontics is a rapidly changing paradigm with the advent of new technology, new surgical techniques, and new products. In this regard, perhaps the most significant changes in conventional orthodontics have resulted from improvements in wire metallurgy, bracket design, and adhesive chemistry. Many of the preceding chapters have addressed surgical advances, particularly relative to hospital-based procedures. The purpose of this chapter is twofold: first, to present an effective surgical technique to facilitate accelerated orthodontic tooth movement in an office or outpatient surgery setting; and second, to illustrate how combining this technique with conventional orthognathic surgery can result in the correction of most facial deformities with their accompanying dental malocclusion in a time frame previously considered to be unattainable.[3] The introduction of adjunctive surgery to facilitate orthodontic tooth movement offers a significant benefit to our orthodontic colleagues in their ability to care for their patients, providing results that are stable, predictable, and reproducible with little morbidity.[4]

History of Corticotomy Surgery

Corticotomy-facilitated orthodontics is a technique that has gained little popularity in the modern era of orthognathic surgery. Nevertheless, a brief review of the history of corticotomy surgery is essential to understand and appreciate how the current technique of accelerated osteogenic orthodontics as developed by Thomas and William Wilcko[5] has evolved. Heinrich Köle[6] is generally credited with the introduction of corticotomy procedures, but his work was preceded by the efforts of others. Specifically, Talbot,[7] Skogsborg,[8] Bichlmayr,[9,10] Schönwald,[11] and Neumann[12] all introduced techniques to weaken bone through surgery. Spanier[13] developed a modification of Bichlmayr's technique and used it to augment orthodontics. Köle's technique, which he called "corticotomy surgery," necessitates cutting through both the buccal and lingual alveolar cortical bone surfaces but stopping short of the cancellous bone, thus preventing damage to the roots and preserving an adequate blood supply to the operated segments. According to Köle, the main resistance to tooth movement was encountered in the continuous cortical layer of bone. He theorized that this was likely attributable to the slower remodeling process in the cortical bone in comparison to medullary bone. He reasoned that by disrupting the continuity of the cortical layer, the speed of the tooth movement would be greatly increased. Accordingly, Köle performed cortical bone block surgery in which he moved blocks of bone that contained teeth. It was Köle's belief that leaving the medullary bone relatively intact would avoid periodontal injury and tooth devitalization. He theorized that because a block of bone was being moved rather than individual teeth, the root resorption previously attributed to rapid tooth movement of unaltered bone would not occur. Dr. Köle's combined corticotomy/osteotomy procedure was adopted almost without alteration by Horvath and Rehçk,[14] by Dal Pont,[15] and by Edland and Subrtova,[16] but it never gained wide acceptance or use by most oral and maxillofacial surgeons from 1970 to 2000.

Following Köle's work, in 1978, Epker and Paulus[17] reported their experience using corticotomy surgery to accompany orthodontic movement. Anholm and colleagues[18] reported correcting Class II cases using corticotomy facilitated surgery. Gantes[19] and coworkers reported their observations on the effects of the periodontium following corticotomy surgery. Finally, Suya[20] reported having successfully treated 395 Japanese patients combining corticotomy surgery with orthodontic tooth movement. All of these works had a common denominator of correcting malocclusions through what the Wilckos termed "bone block" surgery. That is, orthodontic correction was not a product of individual teeth orthodontically moving through bone, but rather, the movement of a surgerized block of bone that contained teeth.

The Wilckos proposed a different theory as to why corticotomy surgery was successful with their introduction of Wilckodontics at the 1998 Annual Scientific Session of the American Association of Orthodontists.[21] In Wilckodontics, or accelerated osteogenic orthodontics (AOO), or periodontally accelerated osteogenic orthodontics (PAOO), the Wilckos incorporated the principles of orthopedic surgeons Gavriel Ilizarov[22] and Harold Frost[23] into a successful technique for rapid movement of teeth through use of a bone healing process termed "regional acceleratory phenomenon."

Regional Acceleratory Phenomenon

Russian orthopedic surgeon Gavriel Ilizarov introduced the concept that stressing bone increases metabolic and cellular generation, resulting in new bone formation. Ilizarov was later called "the Magician from Kurgan" by his contemporaries, but most of his early theories regarding bone formation were disregarded as heresy and outside of conventional thinking.[22] It was not until Ilizarov successfully treated the Russian Olympic high jumper Valery Brumel, who had been seriously injured in a motorcycle accident, that his work was accepted. Today, many consider Ilizarov to be "the father of osseous distraction."

Harold Frost,[23] an orthopedic surgeon at Henry Ford Hospital in Detroit, Michigan, embraced Ilizarov's theorems and took them one step further. Not only did Frost recognize that stressing bone through injury induced a reciprocal metabolic response at the cellular level, but he saw that there was a direct correlation between the degree of bone injury and the intensity of the healing response. Frost coined the term "regional acceleratory phenomenon" or RAP to describe the stages of recovery and intensity of bone healing following injury. Bone healing normally proceeds in successive stages, termed the fracture, granulation, and modeling/remodeling stages. A separate regional acceleratory phenomenon speeds up each of the other stages. Frost theorized that osteoclast and osteoblast cells that make intercellular substances at each stage do not exist in sufficient numbers to heal the bone at the moment of injury. They are made by local multicellular mediator mechanisms that contain precursor and supporting cells, capillaries, lymph, and innervation, plus local autocrine and paracrine regulation. Under the influences of local and systemic agents, these mediator mechanisms determine whether new local osteoclasts and osteoblasts will appear, as well as when, where, how many, what kind, and for how long.

Beginning within a few days of the initial injury, RAP recruits osteoblasts and osteoclasts to accommodate healing of bone following surgery. RAP peaks at 1 to 3 months and is believed to take approximately 6 months to resolve itself. Frost described the process of RAP as a type of "SOS mechanism" that induces a dynamic remodeling process to potentiate local healing and tissue defense. After bone injury there is a temporary acceleration of localized soft and hard tissue remodeling. This proceeds to decalcification/recalcification of bone, which is completed within 6 months.

Using animal studies, Yaffe and associates[24] confirmed that RAP was observed and was indicated by a striking resorption of the cortical bone both on the surface and the bone proper following mucoperiosteal flap surgery in the jawbone of Wistar rats. This led to widening of the periodontal ligament space. Analyzing calcium retention data, Yaffe and colleagues concluded that an acceleration in mineral release occurred within the first weeks following injury, after which time the organic matrix was resorbed. The maximum alveolar resorption was seen approximately 3 weeks after surgery. The alveolar bone did recover, almost but not completely, to control levels 120 days following surgery. It was suggested that RAP may be responsible for increased mobility immediately following periodontal surgery and that bone dehiscence following full-thickness flap surgery may occur where bone is especially thin.

Accelerated Osteogenic Orthodontics

Using the principles of Frost and the results of the animal studies by Yaffe, Drs. Thomas and William Wilcko developed a coordinated approach to surgically facilitated orthodontic treatment. In 1995, the Wilckos patented their technique, initially known as "accelerated osteogenic orthodontics" (AOO) or "Wilckodontics"[25] but later termed "periodontally accelerated osteogenic orthodontics"[26] (PAOO). The Wilckos noted that following corticotomy surgery, there was a marked reduction in mineralization of the alveolar bone. They decided to incorporate the RAP phenomenon to facilitate tooth movement. They observed that it was possible to move teeth farther and faster with less resistance. They postulated that the collagenous matrix reorganizes during the process and that the periodontal ligament reorganizes while it is in a highly excitatory metabolic state resulting from the RAP phenomenon.

This reorganization results from the induced injury to bone caused by corticotomy surgery and decortication of the overlying alveolar surface. The periodontal ligament loses its memory because of high cellular turnover during the reorganization, and subsequently the teeth are more susceptible to movement through the application of directed orthodontic forces. To this mix, the Wilckos added a slowly resorbing cortical particulate allograft to maintain an open network for the proliferation of

bone-forming cells. During healing, the bone naturally goes through a phase known as osteopenia, where its mineral content is temporarily decreased. The tissues of the alveolar bone release rich deposits of calcium, and the new bone begins to mineralize in an estimated 3 to 8 weeks. While the bone is in this transient state, properly executed orthodontic technique can move teeth very quickly, because the bone is softer and there is less resistance to the orthodontic forces.

The Wilckos believed that somewhere between the time frame reported by Yaffe, of 120 days for bone to recover, and the 180 days reported by Frost, as to the completion of the decalcification/recalcification process, lay the window of opportunity for the orthodontist to move teeth at this highly accelerated rate. After this time frame, tooth movement was believed to return to its pretreatment state.

Two studies, one in humans[27] and the other in dogs,[24] provide additional insight as to the duration of the regional acceleratory phenomenon and its influence on the rate of tooth movement. Based on the results of these two studies, it seems that the length of the RAP influence is about 120 days. Although the authors acknowledge that it could be a bit longer, the regional acceleratory phenomenon does end, and with it, the impact on accelerating tooth movement. In our own experience in working with numerous orthodontists during the past 10 years, we conclude that the duration of the regional acceleratory phenomenon after corticotomy facilitated tooth movement is effective for a period of about 180 days in adults.[28]

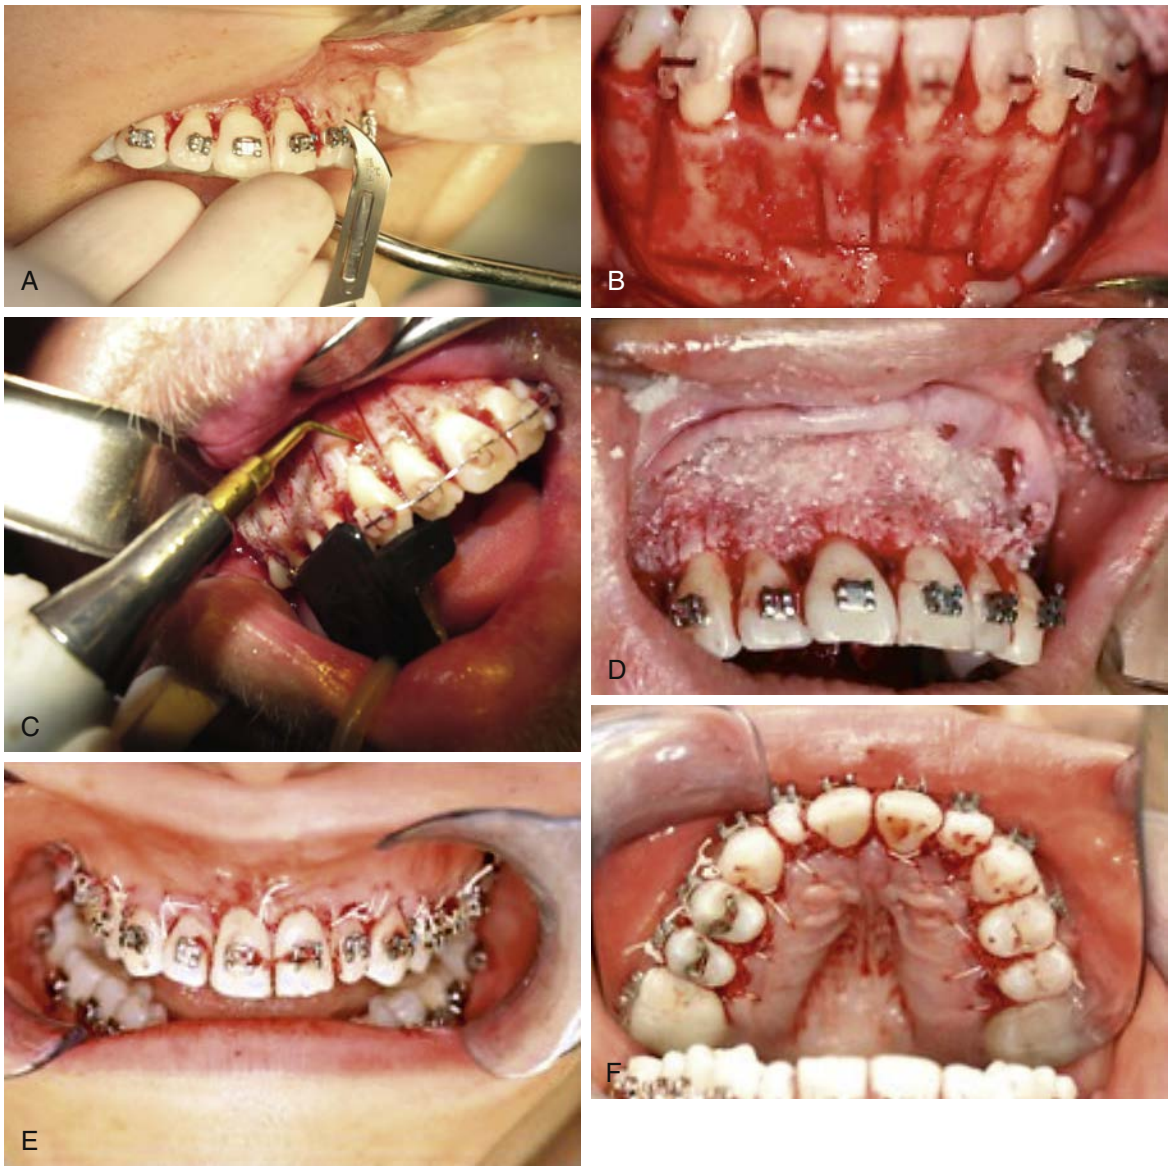
Surgical Technique

The AOO technique as described by the Wilckos[5] is a combination of contemporary orthodontic therapy and surgical intervention. Fixed edgewise orthodontic appliances are placed during the week prior to surgery and non-extraction orthodontic treatment initiated. Full-thickness mucoperiosteal flaps are reflected both labially and lingually around all teeth to be moved orthodontically. In developing the flaps, we favor making a sulcular incision with a 12B scalpel blade, but a 15 scalpel blade, an Orban knife, or a "beaver blade" are viable alternatives depending on surgeon preference. Regardless of the approach, the most important aspect in developing the full-thickness mucoperiosteal flaps is maintaining the mucosal integrity of the papillae. Failure to do so can result in soft tissue dehiscence and periodontal problems. Some surgeons favor an alternative approach,[29] the use of a circumvestibular incision with tunneling. In our own experience, we reserve this approach principally for cases in which there is extreme crowding. This is because, when employing the conventional approach, we experienced some difficulties in repositioning and maintaining papillary height after reflection of the soft tissues.

Once adequate exposure to the bony alveolus is gained, corticotomy surgery is performed on both the labial and lingual aspects of the teeth to be moved. Ideally, the corticotomy cuts should be placed interproximally between the outline of the root surfaces, with the vertical cut terminating about 2 mm short of the crestal bone. Wilcko[30] initially performed the corticotomies using a high-speed dental drill with a no. 2 round burr and copious irrigation. We recommend using an ultrasonic micro-vibratory saw blade (Mectron, Piezosurgery Inc., Columbus, OH) instead, because we believe that it cuts more efficiently and with less potential chance for damaging teeth. When using the piezo-surgery unit, the OT7 surgical tip is ideal for making the interproximal corticotomy cuts. The horizontal connecting cuts below the apices can be effectively placed using the Piezo OT 8R or OT 8L angled saw blades. Once the interproximal saw cuts are completed, the surgeon then further decorticates the bone overlying the root surfaces using a small round burr. Care should be taken not to extend the "bleed holes" too deep, because it is indeed possible to injure the enamel surface of the underlying teeth. The Piezo OP 6 conical diamond burr can be used to create the bleed holes in situations in which the overlying bone is thin. The combination of the corticotomy cuts and stippling with bleed holes should be sufficient to induce the regional acceleratory phenomenon.

A composite bone graft combining freeze-dried demineralized bone and anorganic bone mixed in a 10% clindamycin (Cleocin) solution is wetted and spread in fairly equal proportions over the operated bone. In areas where there are root dehiscences or periodontal defects, it is advisable to use additional bone augmentation. Although some surgeons report that they do not feel that it is necessary to graft the palatal or lingual sides,[31] the Wilckos believed that the alveolar augmentation was critical to support and strengthen the periodontium, reasoning that the addition of bone to the alveolar housing of the teeth ensures root coverage as the dental arch form is modified and expanded. We agree with this argument and have found that the grafting of both labial and lingual sides, particularly when correcting transverse arch discrepancies, is essential to provide a long-term, stable result (Figure 14-1).

With rapid development and improvement in bone grafting materials and techniques, questions frequently center around the use of modern bioengineering technology to enhance the accelerated osteogenic orthodontic process. For instance, can the surgeon use Hemaseel (fibrin glue), PRP (platelet-rich plasma), membranes/barriers, rhBMP-2 (bone morphogenic protein), stem cells, or autogenous bone grafts to somehow improve the process? As of this writing, we do not have the answers, because there has not been sufficient research on modifying the technique as presented here. However, it should be noted that we have experienced outstanding results without significant variance from the technique as described by the Wilckos. Furthermore, it could be argued that by using PRP or rhBMP-2, for example, the time frame associated with RAP could be accelerated, resulting in less time for the orthodontist to effectively move teeth. Certainly research is needed to improve our understanding of the process and, ultimately, to determine how to obtain the best results for our patients. Once the bone grafting is complete, closure ensues with placement of an interproximal mattress stitch. We leave the sutures in place for 3 weeks, and favor using Gore-Tex suture both for its ease of placement between interproximal contacts and for its ability to remain intact for an extended period.



• **Figure 14-1** **A**, Sulcular incision with 12B scalpel blade. **B**, Corticotomy cuts 2 mm short of crest. **C**, Decortication with "bleed holes." **D**, Composite bone graft placed. **E**, Interproximal mattress sutures (labial view). **F**, Gore-Tex closure (palatal view).

The surgery can be performed under local, moderate sedation or general anesthesia. If the surgeon is treating an entire arch or both arches, we recommend the use of general anesthesia with the patient intubated nasoendotracheally and the airway protected. The reasons for this are twofold. First, the length of time necessary to complete a full arch case varies from patient to patient and most certainly depends on the skill of the surgeon, but 1 to 1½ hours per arch is not an uncommon timeframe. In our opinion, this is a lengthy period of time to maintain patient comfort if surgery is performed under local anesthesia only. Additionally, if a moderate sedation technique is employed, the cumulative effect of inducing a large volume of intravenous medication over long periods of time can be detrimental to the patient. Second, the piezo-surgery unit, by its very nature as an ultrasonic appliance, generates a lot of water, and the positioning of the patient's head during surgery, to allow access to the lingual and palatal areas to make the bone cuts, leaves an unguarded airway vulnerable to excessive fluids and difficulties with evacuation. Accordingly, in our approach, if we are performing AOO on more than eight teeth, we will usually intubate the patient.

Depending on the amount of surgery performed, it is not uncommon for the patient to abstain from normal activities for 2 or 3 days. We recommend a progressive diet starting with liquids and blenderized foods for the first few days, with advancement from soft chew to regular diet 2 weeks post-surgery. We avoid the use of steroids or nonsteroidal anti-inflammatory medications (NSAIDs) because they are prostaglandin inhibitors and can inhibit osteoclastic activity, which is crucial to the demineralization process essential to the regional acceleratory phenomenon. The

Gore-Tex sutures are usually removed in the third postoperative week.

Orthodontic Technique

The orthodontist may begin to move teeth within 2 to 3 weeks. The orthodontic techniques employed are standard to routine orthodontic treatment, but are significantly accelerated by the RAP induction. Because the teeth can move so rapidly, *it is highly recommended that orthodontic visits be maintained every 2 weeks*, to prevent untoward movements that could set the treatment back.

Orthodontic Technique

The following keys have been found helpful from an orthodontic treatment standpoint:

- Completely engage the brackets from the initiation of orthodontic treatment
- Use the largest Ni-Ti wires from the start
- Advance the wires as fast as orthodontic movement will allow
- If width expansion is desired, place a Hyrax expander 4 weeks after AOO surgery (Figure 14-2)
- Large tooth movements (particularly transverse width expansion) should be completed within the RAP time frame of 4 to 6 months
- TADS or other anchorage devices may be incorporated at any time to facilitate movement
- On occasion, if a tooth does not move as desired, give consideration to a repeat surgery

Indications, Contraindications, and Benefits of AOO

Indications, Contraindications, and Benefits of AOO

In our experience, accelerated osteogenic orthodontics has resulted in the successful correction of certain specific malocclusions with long-term stability:

- Dental crowding
- Impacted and transposed teeth
- Traverse maxillary width constriction
- Open bite malocclusions
- Maxillary hypoplasia with class III malocclusions of less than 4 mm underbite
- Class II dental malocclusions in children with less than 4 mm overbite
- Rapid setup of cases requiring orthognathic surgery to correct the skeletal malformation

Additionally, the AOO approach has been found to be extremely effective in orthodontic re-treatment cases due to relapse or in situations in which phase II orthodontics was completed early on and the patient experienced latent growth as an adolescent. Another clinical situation in which AOO has proven to be most beneficial is in the management of TMD patients who have a resultant disocclusion or malocclusion after the use of a repositioning orthotic appliance (splint), which often can result from a discrepancy between the centric occlusion and centric relation of the patient.

• **Figure 14-2** **A**, Transverse arch discrepancy with Hyrax in place (before accelerated osteogenic orthodontic [AOO] surgery); **B**, AOO + expansion with Hyrax can add 6 to 7 mm in cross-arch width.

There are relatively few contraindications to the accelerated osteogenic orthodontic approach. Preexisting oral infection and oral pathology should obviously be treated before beginning AOO treatment. Routine maintenance dentistry and dental prophylaxis should be accomplished prior to treatment from both an orthodontic and surgical standpoint. Advanced generalized periodontal bone loss of greater than 5 to 6 mm is a relative contraindication dependent on the clinical examination and stability of the teeth in bone. Patients with medical conditions that are being managed with long-term use of medications such as NSAIDs, corticosteroids, or immunosuppressives (e.g., patients with arthritis) are not good candidates for accelerated osteogenic orthodontics because of the osteoclastic inhibition inherent in the use of those drugs. Patients with osteoporosis may not be suitable candidates for treatment depending on their bone density values. Patients who are using bisphosphonates to treat this condition are *not* candidates for surgery unless the bisphosphonate treatment is aborted and a reasonable "drug holiday" has ensued. The use of CTX markers as advocated by Marx[32] and the judgment of the treating oral and maxillofacial surgeon are paramount in treating these patients to prevent osteonecrosis of the jaw.

The benefits of the accelerated osteogenic surgery approach are many. The most attractive advantage particularly from the patient standpoint is the accelerated timeframe. Most cases that are corrected by AOO solely can be completed within six to eight months. In general, this time

period represents 1/3 of the time compared with a conventional orthodontic approach. But there are other advantages to consider. As the Wilckos noted,[21] teeth can be moved farther using this approach. Additionally, the greater alveolar volume from grafting and the resultant better support to the periodontium provide greater stability and, accordingly, the potential for less relapse and fewer periodontal problems. The Wilckos[5] advocate this approach to achieve improved esthetics. A balanced occlusion supports lip function better and results in less perioral muscle strain, particularly in class II patients. AOO treatment has proven to be effective in rapid recovery of transposed and impacted teeth for delivery into the dental arch. The indirect benefits of AOO should not be overlooked. The need for fewer permanent extractions results in better support to the soft tissue matrix and an improved facial profile. The need for, and the cost of, conventional orthognathic surgery is eliminated in many instances. This is particularly helpful in borderline orthodontic/surgery cases in which surgical intervention is needed but does not take place because of expense, lack of insurance coverage, or the desire not to have a major "hospital-type" surgery. Similarly, in this author's experience, the need to perform a surgically assisted rapid palatal expansion (SARPE) has been replaced for the most part by the combined employment of AOO surgery and a Hyrax appliance activated as a rapid alveolar distractor. The indirect benefit of the psychological effect on patients cannot be ignored. Hasse[33] suggested that with long-term orthodontic treatment in teenage patients and young adults, depression and lack of a healthy self-image frequently becomes a byproduct that should not be ignored. Last, one cannot downplay the importance of returning the patient to the general dentist with a completed case in a timely fashion. The ability to reach the end point in a treatment continuum is important so that our patients are not lost in an abyss of endless years of orthodontic care (Figures 14-3 through 14-6).

AOO Combined with Orthognathic Surgery

We have shown a variety of clinical situations in which accelerated osteogenic orthodontics is invaluable as an adjunctive means to treat malocclusions. The potential for greater stability, improved periodontium, and a significantly shorter treatment time has made this approach a most valuable addition to our surgical armamentarium. However, in our opinion, one of the greatest advantages of using AOO is the ability to set up orthognathic surgery cases in rapid fashion. Patients who have true skeletal discrepancies pose significant challenges to the orthodontist in coordinating the arches in preparation for orthognathic surgery. The desired leveling and aligning of the arches that precedes surgery can be difficult to achieve, particularly in patients with prognathism, asymmetry, or excessive yaw, roll, or pitch. The orthodontist can reach the desired end point much more quickly by incorporating the AOO-facilitated technique. It

is also much easier to correct the dental compensation by taking advantage of the regional acceleratory phenomenon inherent to the AOO procedure.

In 2013, Hasse reported results of a retrospective study of 30 patients who were treated with combined skeletal/dental malocclusions using AOO and orthognathic surgery.[3] In the study, 13 patients underwent single-jaw surgery and 17 patients had both Le Fort osteotomies and lower jaw surgery (either sagittal split osteotomies or intraoral vertical oblique osteotomies). The average orthodontic setup time was about 17 weeks, and the mean total treatment time was 43 weeks. On completion of their treatment, the patients were placed into retention following conventional orthodontic protocol.

Following this recommended protocol, we feel confident that regardless of the complexity of the dentofacial deformity, treatment can be completed from beginning to end within 1 year while leaving the patient with a stable, reproducible occlusion and very little morbidity (Figure 14-7).

Orthodontic Technique

Based on the results of the study, Hasse proposed the following treatment timetable when combining AOO and orthognathic surgery treatment:

- AOO surgery performed at week 1
- Orthodontics initiated at week 2 to 3
- Rapid alveolar distractor (Hyrax) placed at week 4 (if needed)
- Orthognathic surgery performed at weeks 17 to 20
- Orthodontics resumes 6 to 8 weeks after orthognathic surgery
- Debanding and completion of active treatment by weeks 36 to 50
- Orthodontic retention

Alternative Options for Clinical Acceleration

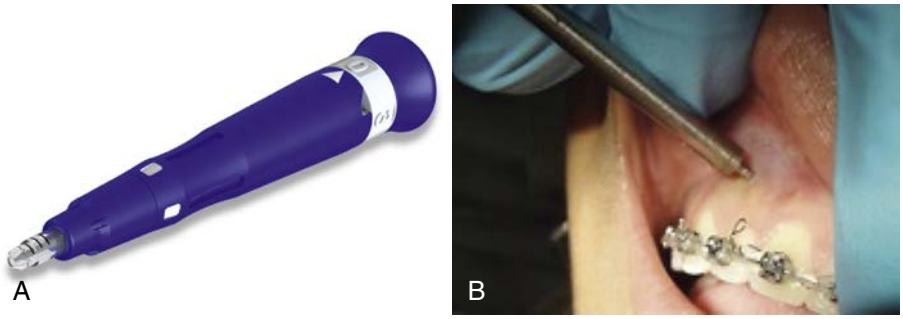
Alternative treatment options to the accelerated osteogenic orthodontics technique have recently been introduced as effective means to facilitate orthodontic movement. These methods bear mentioning for the sake of completeness, but in our opinion, they lack both the efficacy and versatility of the AOO approach. These modalities purport to use the regional acceleratory phenomenon to accomplish an accelerated rate of tooth movement.

In the piezo-incision technique, vertical interproximal incisions are made, below the interdental papilla, on the buccal aspect of the maxilla or mandible, 1 week after bonding brackets. These incisions are kept minimal, just to allow sufficient access for the piezo surgical saw. The piezo saw is used to create a cortical alveolar incision through the gingival opening to a depth of approximately 3 mm. Because of the rapid and temporary demineralization that occurs in response to the RAP effect, tooth movement is accelerated and treatment time is reported to be decreased as much as 60%. Because the interdental corticotomies are placed without the benefit of a full-thickness flap, grafting, if deemed necessary, must be performed through tunneling. In our opinion, there are several drawbacks to this technique when compared with AOO surgery. Specifically, access is limited because of the tunneling approach. It is difficult to graft much bone if needed because of the small incisions. Introduction of bleed holes in the AOO technique not only increases the RAP response but induces osteopenia, making it easier to move the teeth through less dense bone because it is softer and there is less resistance to orthodontic forces. Finally, it is not optimal to place an incision line directly over an osteotomy cut (Figure 14-8).

A second alternative treatment modality that has gained favor with some orthodontists is the use of a technique termed "alveolar micro-osteoperforation." In this instance, a device similar to a ratchet screwdriver is used to perforate the alveolus directly through both keratinized and mobile gingiva. The depth of the perforations or bleed holes is limited to 3, 5, or 7 mm and is controlled by setting the device through an adjustable depth dial. Proponents of this technique contend that the surgical injury to the periodontal tissue results in receptor activator of nuclear factor-kappa ligand (RANKL) gene expression on the surface of osteoblasts. This in turn increases osteoclast formation on the pressure side of the periodontal ligament during force application to an individual tooth. These factors are thought to activate the RAP, resulting in bone remodeling and ultimately accelerated tooth movement. This technique can probably best be used to complete simple space closure or in clinical situations where few teeth require repositioning. In our opinion the amount of the RAP that is induced through this approach is minimal. Also, it does not provide for bone augmentation, which is critical to expanding the alveolar housing as well as covering bony fenestrations and dehiscences.

Discussion

The preceding pages have presented an effective technique for using accelerated osteogenic orthodontics to facilitate orthodontic tooth movement. We have shown a multiplicity of clinical situations in which AOO can be successfully used to treat various dentofacial deformities and malocclusions. Specifically, we demonstrated that that the AOO procedure alone has been effective in treating mild class III malocclusions; moderate open-bite deformities; transverse width discrepancies up to about 6 to 7 mm in arch compromise; borderline orthodontic extraction cases; clinical situations requiring bite correction following mandibular orthotic appliance (splint) treatment; repositioning of impacted and transposed teeth; and orthodontic retreatment cases.



• **Figure 14-8** **A**, Alveolar microperforation device. **B**, Placement of perforations to facilitate orthodontic movement.

Additionally, we believe that one of the greatest benefits of the AOO technique is realized when using accelerated osteogenic orthodontics to set up an orthognathic surgery case. We concur with the Wilckos that the added bone during the RAP phase of metabolic reorganization leads to greater stability because of the increase in alveolar housing, coverage of exposed root surface and bony dehiscences, and healthier periodontium. A significantly shortened treatment time, combined with the potential for greater stability, improved periodontium, and the elimination of the need for major orthognathic surgery in many instances, makes the AOO technique a most valuable adjunct to our surgical armamentarium.

In a recent article, Kokich and Mathews[34] questioned the need for accelerated osteogenic orthodontics, stating a rationale for the case against corticotomy-induced orthodontics. Their major contention was that the efficacy of this technique as measured by how well treatment works in clinical trials or laboratory studies under ideal conditions has not been proven because there have not been sufficient studies to justify its use in clinical situations. We agree with their contention that, as of this writing, there has not been sufficient research with regard to the accelerated osteogenic orthodontic technique. We are hopeful that, with a greater acceptance of the technique in the future, this will be rectified as new ideas and clinical studies are developed. However, from our clinical experience, the effectiveness of AOO (that is, how well the technique works in daily practice) and the efficiency (evaluation of the value received relative to costs in terms of time, expense, and morbidity) is exceptional. In our opinion, a technique that can be performed rapidly with little morbidity, and can potentially save the cost of hospitalization generally associated with orthognathic surgery, warrants serious consideration for routine use. We feel that using this approach is a valuable addition in the service that surgeons can offer to our orthodontic colleagues, and, more importantly, to patient care.

Acknowledgment

The author wishes to acknowledge and thank the following individuals for their excellence in orthodontia and their contributions to the care of patients presented in the text: Gerald R. Eidenmuller, DDS and Shawn L. Miller, DMD, MMSc. Also, thank you to Lisa Holtgraver for her valuable assistance in the preparation of the manuscript.

Orthognathic Surgery for Obstructive Sleep Apnea

CAROLYN DICUS BROOKES, SCOTT B. BOYD

Introduction and Prevalence of Obstructive Sleep Apnea

Obstructive sleep apnea (OSA) is a prevalent chronic disease characterized by pharyngeal collapse during sleep. One large landmark study estimated that 24% of middle-aged men and 9% of middle aged women have OSA,[1] where OSA is defined as an apnea-hypopnea index (AHI) of more than 5 events per hour. More recent studies suggest a prevalence of OSA in middle-aged adults of just over 25%.[2,3] A recent review suggests that 1 in 5 adults has at least mild OSA (AHI 5 to 15) and 1 in 15 has moderate (AHI >15 to 30) to severe (AHI >30) OSA.[4]

The main objectives of this chapter are to:

1. summarize the pathophysiology and clinical features of OSA;
2. describe the essential components of patient evaluation including diagnostic criteria and outcome measures;
3. summarize treatment options for OSA;
4. describe maxillomandibular advancement (MMA) for management of adult OSA; and
5. discuss the clinical effectiveness and safety of MMA.

Pathophysiology of Obstructive Sleep Apnea

A detailed discussion of the pathophysiology of OSA is outside the scope of this chapter; however, a brief review of some of the major physiologic factors involved in OSA will help the surgeon understand various treatment modalities. Upper airway anatomy can predispose to collapse, through either decreased diameter or other factors, including traits of the surrounding soft tissue and decreased lung volumes. If anatomy predisposes to collapse, the decreased upper airway dilator activity (including that of the genioglossus muscle) observed during sleep may contribute to obstructive episodes.[5,6] Stability of ventilatory control and arousal threshold may also play a role in OSA.[5-8]

In OSA, sleep becomes fragmented, which diminishes time spent in deeper sleep stages and results in excessive daytime somnolence. Patients or bed partners may report snoring, observed apneas, or gasping on awakening. Oxygen desaturation, hypercarbia, and sympathetic activation occur.[5,8,9] Untreated OSA is associated with hypertension[2,4,10-13] and cardiovascular disease, including cardiac arrhythmias,[10,13] coronary artery disease,[13] congestive heart failure,[8,13] and increased risk of cardiovascular events. In men, untreated severe OSA significantly increases the risk of fatal and nonfatal cardiovascular events (odds ratio 2.87 and 3.17, respectively) as compared with non-snoring, age- and body mass index (BMI)-matched men without OSA.[15] OSA has been shown to increase the risk of stroke[16] and all-cause mortality; this risk seems to be higher with more severe OSA.[16] OSA is linked to insulin resistance and Type 2 diabetes.[14,17,18]

OSA has neurocognitive sequelae, as well. Vigilance, motor coordination, and executive functioning may be compromised by untreated OSA.[19] These factors may underlie the increased rate of motor vehicle collisions seen in patients with untreated OSA.[20,21] OSA is also associated with decreased quality of life[22-24] and depression.[25,26]

Major risk factors for OSA include obesity, male gender, and increasing age.[2,3,27,28] Craniofacial anomalies are also linked to OSA; this is discussed later in the chapter.

Patient Evaluation

Symptoms and History

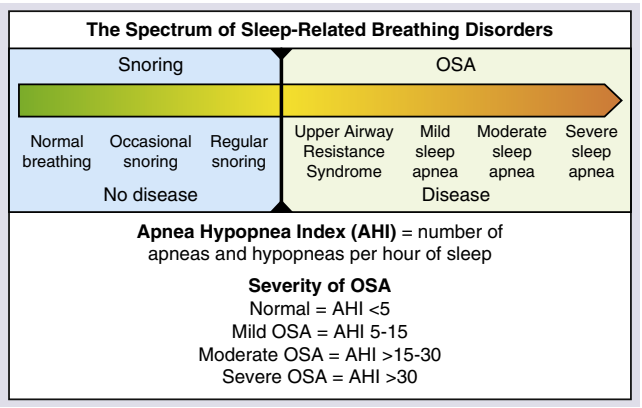
Sleep quality is assessed by inquiring about snoring, excessive daytime sleepiness, witnessed apneic episodes, gasping/choking during sleep, non-refreshing sleep, morning headaches, decreased libido, and irritability.[9] Symptoms related to cognitive dysfunction such as decreased concentration and memory loss as well as impaired occupational performance should be noted.

Multiple validated instruments exist to assess sleepiness and quality of life. The Epworth Sleepiness Scale (ESS) is an easily administered questionnaire that is used to assess subjective sleepiness. The patient is asked to rate the likelihood of falling asleep during various activities from 0 to 3; the total score ranges from 0 to 24, with 10 or greater representing excessive or pathologic sleepiness.[29,30] The Functional Outcomes of Sleep Questionnaire (FOSQ) is a 30-question self-administered, disease-specific quality of life instrument that assesses multiple domains including activity level, vigilance, intimacy and sexual relations, general productivity, and social outcome. The total score ranges from 5 to 20, with normal defined as greater than or equal to 18.[31] The Sleep Apnea Quality of Life Index (SAQLI) is another sleep-specific quality of life instrument that assesses function in four domains: daily functioning, social interactions, emotional functioning, and symptoms. An optional fifth domain evaluates treatment-related symptoms.[32]

Sleep Studies

The gold standard for diagnosis of OSA is overnight, laboratory-based polysomnography (PSG), which defines the presence and severity of OSA. During PSG, electroencephalography, electrooculography, and chin electromyography are used to detect stages of sleep. Respiratory effort is measured by inductive plethysmography to assess rib and abdominal motion. Airflow at the nose and mouth is detected through thermal sensors or nasal pressure gauges. Oxygen saturation is also monitored by pulse oximetry. Leg electromyography and body position are measured. While multiple metrics are reported, the most commonly used index is the apnea-hypopnea index (AHI). The AHI is the number of apneas and hypopneas per hour of sleep. Apneas are defined as a drop in airflow of at least 90% lasting at least 10 seconds. An apnea is considered obstructive if respiratory effort is maintained or increased. There is some controversy regarding the definition of hypopnea, but the 2014 scoring manual of the *American Academy of Sleep Medicine* (AASM) defines a hypopnea as an event lasting more than 10 seconds with a greater than 30% reduction in airflow accompanied by either an arousal or greater than 3% oxygen desaturation from the pre-event baseline.[33] AHI determines disease severity (Figure 15-1). The respiratory disturbance index (RDI) is another commonly reported index and represents the number of apneas, hypopneas, and respiratory event related arousals (RERAs) per hour.

A streamlined home monitoring study that measures at least airflow, respiratory effort, and oxygenation is more convenient for patients and more cost-effective; this makes evaluation more accessible. Non-inferiority of portable home monitoring studies versus laboratory PSG has been demonstrated in select populations.[34] An AASM consensus statement recommends using portable monitoring in select patients with high pretest probability of moderate to severe OSA without certain comorbid conditions.[35] This is primarily because, when scoring portable monitoring studies, the number of respiratory-related events is scored over total recording time rather than total sleep time—this can result in underestimation of AHI/RDI and thus false-negative results. Portable monitoring studies may also play a role in monitoring response to therapies and in arriving at a diagnosis for those who cannot tolerate a laboratory-based PSG. Portable monitoring should be conducted and interpreted by accredited sleep centers or boarded sleep medicine specialists.[9,35]



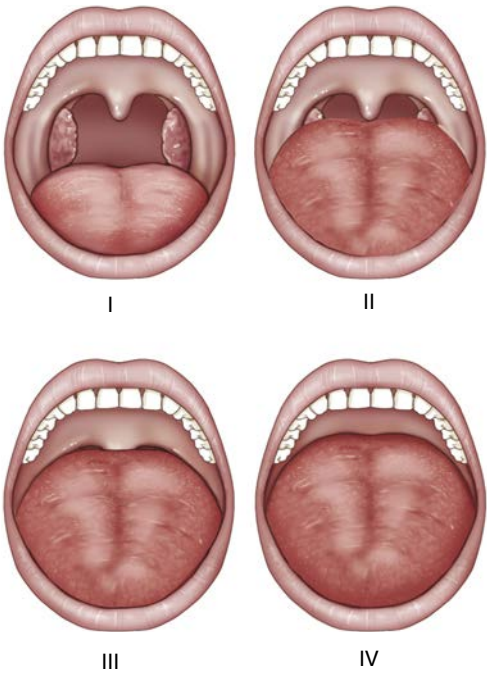
• **Figure 15-1** The spectrum of sleep-related breathing disorders.

Physical Examination

Physical examination involves recording of vital signs, body mass index (BMI), and neck circumference, as well as a description of the airway, from the nose to the visualized pharynx. Attention is paid to potential sites of nasal obstruction, tongue size and position, palatal length and thickness, and pharyngeal crowding. A simple clinical evaluation and staging system was introduced by Friedman to document palate position, tonsil size, and BMI (Figures 15-2 and 15-3 and Table 15-1).[36] It was initially proposed as a tool to predict responsiveness to uvulopalatopharyngoplasty (UPPP).

Additional upper airway assessment to determine the sites of obstruction is important as it allows for targeted intervention. Awake nasopharyngeal endoscopy with Muller's maneuver (forced inspiration with closed nasal and oral airways) is the classic method to assess level of obstruction. The site (retropalatal and/or retrolingual) and magnitude of the obstruction (0%, 25%, 50%, 75%, or 100%) are noted. Greater than 75% obstruction is typically considered severe, and surgical correction of the obstruction at the involved anatomic site(s) is indicated.

Drug-induced sleep endoscopy (DISE) was more recently introduced with the putative advantage of more closely mimicking the sleeping state. One comparative study suggests that, though the two are equally good at detecting retropalatal collapse, DISE identifies retrolingual collapse more often, particularly for those with low Friedman score.[37] A systematic review suggests that DISE in addition to awake endoscopy changed the surgical plan in just over 50% of cases, usually due to newly noted hypopharyngeal or laryngeal obstruction; however, there is conflicting evidence about whether DISE results in improved surgical



• **Figure 15-2** The Friedman Palate Position is based on visualization of structures in the mouth with the mouth open widely without protrusion of the tongue. Palate grade I allows the observer to visualize the entire uvula and tonsils. Grade II allows visualization of the uvula but not the tonsils. Grade III allows visualization of the soft palate but not the uvula. Grade IV allows visualization of the hard palate only. (From Friedman M, Ibrahim H, Joseph NJ: Staging of obstructive sleep apnea/hypopnea syndrome: a guide to appropriate treatment, *Laryngoscope* 114(3):454-459, 2004, with permission.)

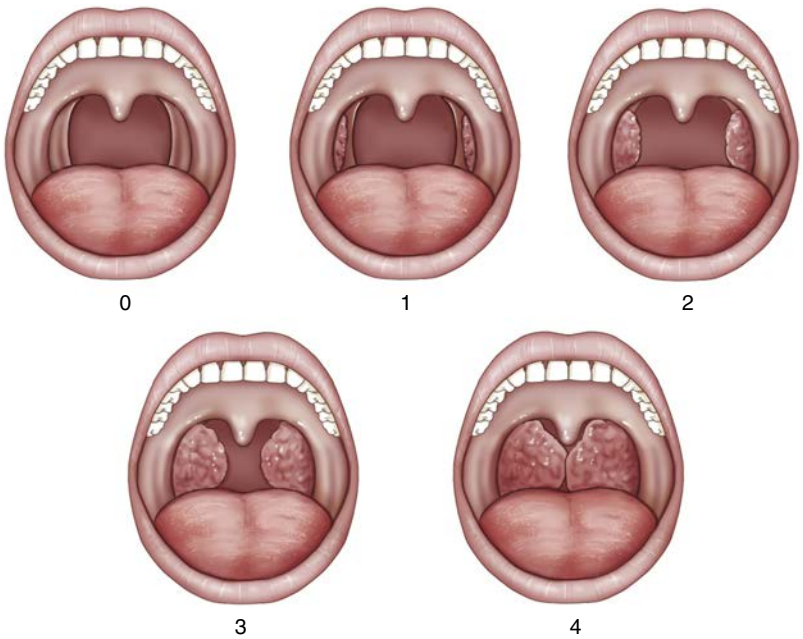
outcomes, and concern has been raised that DISE may lead to unnecessary surgical interventions. Further, there is no consensus about the ideal anesthetic agent to be used for DISE.[38] Its role will likely continue to evolve.

Treatment of Obstructive Sleep Apnea

The goals of treatment are to eliminate OSA (AHI <5 events/hour) or to significantly reduce the severity of OSA (AHI ≤15 events/hour); to improve nadir oxygen saturation; to alleviate symptoms such as sleepiness; to address sequelae of OSA such as cardiovascular and neurocognitive issues; and to improve quality of life.

The AHI is the metric most commonly used to assess success of OSA treatment. Surgical cure is defined as a reduction in AHI to less than 5 events per hour. Surgical success has historically been defined as a 50% or greater reduction in AHI to less than 20 events per hour.[39] Although a greater than 50% reduction in the AHI is likely associated with better outcomes, the use of the just-described, generally accepted definition of surgical success facilitates comparison of outcomes.

Although the AHI is the primary reported measure of successful treatment, it does not take into account other important health-related and functional outcomes such as sleepiness, quality of life, or cardiovascular health. A recent publication by the AASM recommended the use of metrics that assess quality of life (e.g., FOSQ, SAQLI, and SF-36), sleepiness, and reduction in cardiovascular risk based on assessment of weight and blood pressure.[40] Resolution of



• **Figure 15-3** Tonsil size is graded from 0 to 4. Tonsil size 0 denotes surgically removed tonsils. Size 1 implies tonsils hidden within the pillars. Tonsil size 2 implies the tonsils extending to the pillars. Size 3 tonsils are beyond the pillars but not to the midline. Tonsil size 4 implies tonsils extend to the midline. (From Friedman M, Ibrahim H, Joseph NJ: Staging of obstructive sleep apnea/hypopnea syndrome: a guide to appropriate treatment, *Laryngoscope* 114(3):454-459, 2004, with permission.)

TABLE 15-1 Friedman Staging System

	Friedman Palate Position	Tonsil Size	Body Mass Index
Stage I	1	3, 4	<40
	2	3, 4	<40
Stage II	1, 2	1, 2	<40
	3, 4	3, 4	<40
Stage III	3	0, 1, 2	<40
	4	0, 1, 2	<40
Stage IV	1, 2, 3, 4	1, 2, 3, 4	<40

All patients with significant craniofacial or anatomic deformities.
Modified from Friedman M, Ibrahim H, Bass L: Clinical staging for sleep-disordered breathing, *Otolaryngol Head Neck Surg* 127(1):13-21, 2002; with permission.
From Lee NR: Evaluation of the obstructive sleep apnea patient and management of snoring, *Oral Maxillofac Surg Clin North Am* 21(4):377-387, 2009.

sleepiness should be documented using subjective scales (e.g., Epworth Sleepiness Scale) or objective measures (e.g., multiple sleep latency test).[9]

Importantly, any therapeutic intervention should have a long-term, durable treatment response, because OSA is a chronic, lifelong disease. Although there is no consensus about frequency of follow-up, all patients who undergo treatment for OSA require long-term monitoring to allow detection of recurrent disease.[41] It is worth noting that the benefits of surgical intervention do not require patient adherence and are thus enjoyed during every hour of sleep. This must be considered when comparing surgical and nonsurgical treatment outcomes. Finally, the ideal treatment should carry minimal risk of morbidity and mortality.

Nonsurgical Treatment

Continuous Positive Airway Pressure

Continuous positive airway pressure (CPAP) is the first-line treatment of choice for OSA and should be offered to all patients diagnosed with OSA. CPAP is highly efficacious and virtually eliminates OSA.[42] For most patients, lifelong use is required for disease control.

CPAP splints the upper airway, helping to maintain patency during sleep. Increased lung volumes due to PAP may further stabilize the upper airway.[43] CPAP improves sleepiness as well as functional outcomes including quality of life and both cognitive and driving performance.[9,43,44] However, these metrics do not improve for all patients even when CPAP is used consistently (>7 hr/night).[44] CPAP also decreases sympathetic activation and may improve functional residual capacity and control of hypertension.[43]

Acceptance, or patient willingness to attempt to use PAP, ranges from 72% to 91%.[43] Unfortunately, adherence to CPAP therapy is far from universal; one review cited a nonadherence rate of 46% to 83%, when adherence was defined as PAP use for at least 4 hours a night.[45] The duration of nightly use required for maximal benefit has not been established, though longer nightly use seems to yield more benefits,[46] including decreased 5-year mortality.[47] Barriers to adherence may include mask discomfort or skin breakdown; ocular, nasal, and pharyngeal dryness; nasal congestion or rhinorrhea; claustrophobia; and noise and bulk of the device.[9,43,46,48-50] CPAP is the most common positive airway delivery method, but other modalities such as bilevel and auto-titrating PAP may increase adherence for certain patients. Although highly effective, alternative treatments are required for those who refuse or cannot tolerate CPAP.

Oral Appliances

Oral appliances (OAs) used for treatment of OSA enlarge the upper airway by modifying the position of the tongue and associated structures of the upper airway. The recommended OA is a custom, titratable tooth-borne appliance designed to advance the mandible, thereby pulling the tongue forward.[51] OAs are less cumbersome than PAP devices and are generally well tolerated.[51] OAs reduce snoring, sleepiness, and blood pressure and improve quality of life[51] and have been shown to yield comparable results to CPAP in terms of the latter three parameters as well as improvement in cognitive function.[52] They have been shown to reduce AHI over a range of OSA severity, though CPAP tends to outperform OAs in terms of AHI reduction and improvement in nadir SpO_2.[51]

Adherence to OAs seems to be similar or slightly better than use of CPAP.[52] OAs are more effective in less obese patients and those with skeletofacial deformities.[53] Treatment effect seems to be proportional to the degree of mandibular advancement. Some patients (particularly those with mild to moderate OSA) may benefit from advancement to 50% of maximal protrusion, while others (e.g., those with severe OSA) may require advancement to 75% of maximal protrusion. Side effects increase beyond 50% of maximal protrusion, so it is recommended that the devices be titrated to effect.[53] Temporomandibular joint dysfunction, inadequate protrusion, and insufficient teeth to support the device are relative contraindications.[9] Discomfort and hyper-salivation or xerostomia may limit adherence. Long-term monitoring for adherence, worsening OSA, and dental and skeletal changes is required.[51,54]

Behavioral Treatment

Weight loss can improve AHI[55,56]; 10% weight loss predicts a 26% reduction in AHI. Minimizing weight gain is also important, as a 10% weight gain predicts a 32% increase in AHI.[56] Unfortunately, many individuals find it exceptionally difficult to maintain a 10% weight loss on a long-term basis.

Avoiding the supine positions during sleep may be helpful for some patients.[7,9] All those with OSA should be educated about good sleep hygiene practices, such as avoiding alcohol (which can also predispose to airway collapse), caffeine, and screen time before bed; regular exercise may also be beneficial.[9,54]

Medications

Intranasal steroids may be a helpful adjunct for patients with OSA and nasal obstruction.[9] Modafinil may be used to address daytime sleepiness that is not alleviated by PAP or other treatment modalities, provided other causes of daytime somnolence (e.g., depression, other sleep disorders, insufficient sleep, poor adherence to therapy) have been ruled out.[9]

Surgical Treatment

Preoperative Assessment

Candidates for surgical intervention are those with obstructive anatomy who are either intolerant of CPAP/OAs or have inadequate disease control with CPAP/OAs. Candidates must understand the risks, alternatives, and benefits of the proposed operation and must choose to proceed; they must be expected to tolerate the procedure medically. Several general principles apply to preoperative assessment before all surgical modalities to address OSA. The surgeon must confirm the diagnosis and establish the severity of OSA objectively through PSG. Attention should be paid to AHI, nadir oxygen saturation, and percentage of sleep time spent with an oxygen saturation of less than 90%. As with any surgical patient, medical history must be thoroughly reviewed, with a focus on potentially undiagnosed comorbid conditions. Engagement of the relevant physicians to optimize the patient's health preoperatively is critical.

Surgical Treatment Other Than Maxillomandibular Advancement

Bariatric Surgery

Bariatric surgery effectively achieves weight loss; it is indicated for patients with a BMI of 35 or greater with comorbidities or 40 or greater when diet and activity have proved ineffective. Bariatric surgery can be a helpful adjunctive treatment for OSA and generally results in more weight loss and more pronounced reduction in AHI than do nonsurgical weight loss interventions.[55] Unfortunately, OSA can return even in the absence of weight gain, so long-term follow-up is crucial.[57]

Tracheostomy

Tracheostomy bypasses the upper airway and has a nearly universal success rate with dramatic reduction in number of apneic episodes as well as sleepiness. Tracheostomy may also confer a mortality benefit over no treatment. However, significant morbidity limits its application in the OSA population, and it is generally considered only for patients who have failed, refused, or are not candidates for other interventions or those who require urgent correction of severe hypoxemia, particularly in the setting of severe cardiovascular disease.[58]

Tonsillectomy

Tonsillectomy is the treatment of choice for children with OSA in the absence of craniofacial anomalies.[59]

Palatal Procedures

Uvulopalatopharyngoplasty (UPPP) was originally described by Fujita and involves removal of the tonsils, uvula, and posterior velum with closure of the pillars.[60] Lateral pharyngoplasty may be added. AHI does not reliably normalize after UPPP for patients with moderate to severe OSA and is thus recommended only as an adjunctive treatment.[41] A meta-analysis reported a mean 33% reduction in AHI with a mean postoperative AHI of 29.8.[61] Complications may include bleeding, hypernasal speech, nasal regurgitation, and taste disturbances.[61]

Extended uvulopalatal flap or EUPF may be more effective than UPPP in select patients; one group reported success in 84% and cure in 40% of patients with a mean reduction in RDI from 44.5 to 13.4.[62]

Laser-assisted uvulopalatoplasty (LAUP) involves a series of laser ablations of the soft palate to shorten and stiffen the uvula and velum. Although some studies have reported large reductions in AHI, it is not generally recommended for OSA, as outcomes are not reliable enough to justify surgical risks.[41,61]

Radiofrequency treatment of the palate (or tongue) and palatal implants, both designed to stiffen the palate, may be effective in patients with mild to moderate OSA who do not tolerate PAP or OAs.[41] A meta-analysis of RFA treatments showed a reduction in AHI from 23.4 to 14.2.[61] The same analysis reported a mean 26% reduction in AHI after placement of palatal implants.[61]

Genioglossal Advancement with or without Hyoid Suspension

Genioglossal advancement (GA) refers to genial tubercle advancement; this may be accompanied by hyoid myotomy and suspension (GAHM). This procedure is rarely carried out in isolation but can be effective in conjunction with other therapies addressing retropalatal obstruction. A review of hypopharyngeal surgical options for OSA in subjects treated with palatal surgery reported surgical success of GA in over 50% of patients in some series; GAHM yielded variable results with a surgical success rate of 22% to 77% and was more likely to be successful in patients with a lower BMI and lower baseline AHI.[63] A series that coupled GAHM with palatal surgery reported 78.3% short-term surgical success and 65.2% long-term surgical success.[64]

Hypoglossal Nerve Stimulator (HNS)

Stimulation of the hypoglossal nerve activates airway dilators, including the genioglossus muscle. Implantable stimulators are a relatively recent addition to the surgical options for patients with OSA and received U.S. Food and Drug Administration (FDA) approval in 2014 for treatment of moderate or severe OSA in adults. In addition to a generator, the stimulator has leads that sense respiration and that stimulate the nerve during inspiration; the device is titrated postoperatively.

A multicenter, prospective cohort study known as the STAR (Stimulation Therapy for Apnea Reduction) Trial reported that, at 1 year after implantation of the device, the median AHI decreased 68% from 29.3 to 9.0 events per hour; quality of life also improved.[65] At 3 years after implantation, the same group reported that median AHI decreased from 28.2 to 6.2 events per hour; surgical success was achieved in 74% of the subjects followed for 3 years, though not all subjects used the device nightly.[66] Another study reported surgical success in 55% of subjects at 1 year post-implantation.[67] Symptoms and quality of life also seem to improve.[65-67] Hypoglossal nerve stimulation seems to be more successful in patients with a lower BMI, AHI less than 50, and an anteroposterior (vs. concentric) pattern of palatal collapse during DISE.[68,69] Complications include neurosensory deficit, tongue abrasion, and discomfort from the stimulator.[66,67]

Nasal Surgery

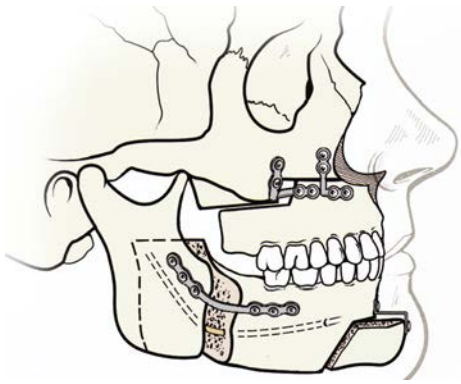
Nasal procedures, such as septoplasty or turbinectomy, are designed to improve nasal airflow. Though this may lead to resolution of OSA in certain patients with mild OSA, it is generally used as an adjunctive procedure only. A recent systematic review indicates that isolated nasal surgery in OSA patients may reduce therapeutic CPAP device pressures and may increase CPAP use in some patients.[70]

Tongue Reduction

Glossectomy and radiofrequency ablation of the tongue base are additional strategies to address hypopharyngeal obstruction. Both strategies have variable success rates, with reported surgical success from 20% to 83% based on AHI.[63] Transoral robotic surgery for OSA is less morbid than glossectomy and appears to be more effective for treating OSA. As part of a multilevel surgical approach, it may reduce the AHI and improve sleepiness.[71] However, cost and morbidity limit its role.

Maxillomandibular Advancement

Maxillomandibular advancement (MMA) addresses multiple levels of obstruction, decreasing airway collapsibility by advancing its skeletal framework.[72] MMA involves surgical facial advancement through concomitant maxillary and mandibular osteotomies (Figure 15-4). Candidates for MMA are those who meet criteria for surgical management of OSA and either have skeletofacial deficiency or can esthetically tolerate MMA. Those with severe OSA are likely to derive the most benefit from MMA. If the patient is a candidate for other forms of therapy that have not been tried or discussed, these should be reviewed with the patient, either by the surgeon or by a sleep specialist.



• **Figure 15-4** Schematic diagram of maxillomandibular advancement procedure consisting of Le Fort I maxillary osteotomy with step modification, bilateral sagittal split ramus osteotomies, and genial advancement. Shaded areas depicts sites of piriform rim recontouring and anterior nasal spine reduction. (From Boyd SB: Management of obstructive sleep apnea by maxillomandibular advancement, *Oral Maxillofac Surg Clin North Am* 21(4):447-457, 2009, with permission.)

MMA was initially advocated as phase II surgery for those who failed to improve after phase I surgery, which included UPPP and genioglossal advancement with hyoid myotomy.[73] However, a recent comparative study evaluated the effectiveness of MMA and UPPP. The study found that MMA alone is more effective than UPPP alone and that UPPP followed by MMA (phase I surgery followed by phase II surgery) is no more effective than MMA alone.[74] Offering MMA as a primary procedure confers additional benefits over staged surgery, including decreased total treatment time, fewer surgical and anesthetic risks to the patient, and an improved cost:benefit ratio.

Preoperative Assessment

In addition to the general presurgical history considerations outlined earlier, the initial consultation should focus on determining the patient's candidacy for MMA in particular. Prior therapy for OSA and its outcomes must be reviewed. The patient should be queried about prior facial trauma and orthodontics as well as any concerns with speech and masticatory or temporomandibular joint (TMJ) function. Esthetic goals should also be noted.

The physical examination must include vital signs and body mass index. The remainder of the examination is quite similar to that undertaken in a routine orthognathic consultation. Special attention is paid to sites of obstruction and need for presurgical orthodontics. Assessment should include a complete, multi-view facial analysis; mandibular range of motion and TMJ function; occlusal analysis; dental and periodontal status; anterior rhinoscopy; and cranial nerve function. The tongue, tonsils, velum, and posterior and lateral pharynx should be inspected at rest and with phonation to visualize potential sites of obstruction. If the

• **Figure 15-6** Airway analysis for obstructive sleep apnea. Linear measurements are depicted, but volumetric and cross-sectional measurements of each region can be made with preferred cone-beam computed tomography imaging. Each airway space is associated with a skeletal or dental landmark to facilitate measurement of the association between the magnitude of maxillary and mandibular movements and corresponding changes in the associated airway space. *A*, Subspinale; *B*, supramentale; *DPA*, deep pharyngeal airway; *Go*, gonion; *H*, hyoid; *HPA*, hypopharyngeal airway; *I*, incisal edge of maxillary central incisor; *N*, nasion; *NPA*, nasopharyngeal airway; *OPA*, oropharyngeal airway; *PAS*, posterior airway space; *Pg*, pogonion; *TV*, true vertical reference line with patient in natural head position; *UAL*, upper airway length.

surgeon is trained in endoscopy, an in-office endoscopic assessment of the pharynx can be very helpful. Alternatively, a colleague's endoscopic report can be reviewed or requested.

Records should include full facial and intraoral photographs and either plain panoramic radiograph and lateral cephalogram (with posteroanterior cephalogram if asymmetry is present) or a cone-beam CT scan (CBCT). Cephalometric analysis, although limited by the static representation of the airway, can be performed before and after treatment to assess baseline airway and skeletal characteristics and the corresponding changes resulting from surgery (Figures 15-5 and 15-6).

As with all orthognathic records, care must be taken to ensure that records are taken in centric relation. Natural head position and a relaxed lip posture are critical, as well. Patients with baseline obstruction may assume a head-up position to improve the airway; records taken in this position may be misleading. If consideration is being given to altering the current occlusion, impressions for study models should be taken.

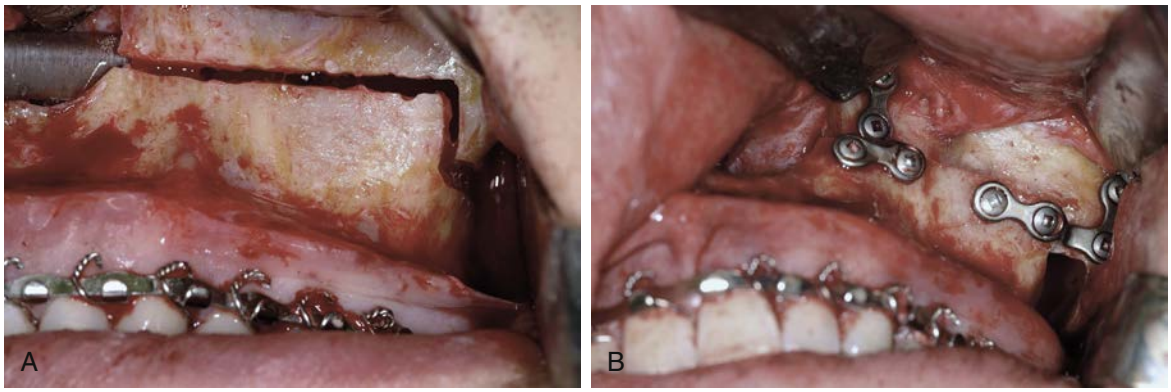
Surgical and Anesthetic Planning

Mounted study models or virtual surgical planning are used to plan the patient's proposed maxillomandibular movements and to fabricate an intermediate and, if the surgeon prefers or if poor occlusion requires it, a final splint to translate the plan into the operating room. Though some advocate on-table advancement of the maxilla to the greatest extent possible, the authors believe that the maxillofacial surgeon's application of traditional orthognathic surgery planning principles yield maximal functional and esthetic benefit for the patient.

Few data are available about the degree of advancement required to achieve maximal benefit for the patient with OSA. An often-cited study suggests that mandibular advancement should be at least 10 mm.[75] However, a recent systematic review found no association between degree of mandibular advancement and surgical success on either study-level or patient-level analysis.[76] The review did report a higher surgical success rate with larger maxillary advancement (mean 9.9 vs. 8.4 mm) based on study-level analysis; the same held true with both uni- and multivariate patient-level analysis. In a multivariate analysis, the odds ratio for surgical success was 1.97 per 1 mm maxillary advancement.[76] A recent small-cohort study of 43 subjects who underwent smaller advancements (mean 5.2 mm in maxilla and 8.3 mm in mandible) reported 100% surgical success and 50% surgical cure in the subset of patients with AHI data (n = 12), suggesting that our understanding of the amount of advancement required to achieve surgical success is still evolving.[77]

Counterclockwise rotation of the maxillomandibular complex has been proposed to maximize mandibular advancement while minimizing the cosmetic impact of the surgery in the nasomaxillary region. This approach may benefit select patients. A recent meta-analysis found that there are insufficient data to determine whether MMA patients treated with counterclockwise rotation benefit more, but the study demonstrated that both strategies result in a significant reduction in AHI.[78]

Photographic predictions can be used to help the patient visualize the type of facial change that can be anticipated. A series examining hard to soft tissue change ratios in patients treated with MMA along with piriform



• **Figure 15-7** Total Le Fort I maxillary osteotomy with modified step design of lateral wall **(A),** reduction of anterior nasal spine and recontouring of piriform rims, followed by placement of maxillary bone plates at piriform rim and maxillary buttress **(B).** (From Boyd SB: Management of obstructive sleep apnea by maxillomandibular advancement, *Oral Maxillofac Surg Clin North Am* 21(4):447-457, 2009, with permission.)

and anterior nasal spine osteoplasty and alar cinch suturing reported a 0.9:1 ratio of soft to hard tissue throughout the upper and lower lip and chin; nasolabial angle became slightly more acute as forward rotation of the lip exceeded rotation of the nasal tip.[79] Each surgeon's technique will vary slightly, so critical analysis of one's own outcomes is imperative.

Anesthetic Management

A difficult airway should be anticipated, so appropriate review by the anesthesia care team is imperative. Most patients can be managed with fiberoptic nasal intubation, and the need for tracheostomy is rare. Careful attention should be paid to patient padding and positioning to minimize pressure sores and nerve injuries.

The degree of deliberate hypotension may be limited by baseline control of hypertension and comorbidities; if able, at least some degree of controlled hypotension should be used to minimize blood loss. Steroids may be administered to minimize postoperative edema.

Surgical Techniques

If expansion of the maxilla, mandible, or both is required, this is undertaken as a first-stage operation for surgical rapid maxillary expansion and/or mandibular midline osteotomy with distraction. Surgical rapid maxillary expansion has been shown to improve AHI (mean 56.2% reduction) and ESS (mean 12.5 to 7.2) as an isolated procedure.[80] In some cases maxillary expansion can be achieved through multi-piece maxillary osteotomies at the time of MMA.

Unless orthodontic appliances are in place, arch bars are applied at the beginning of the maxillomandibular advancement procedure. A Le Fort I osteotomy and bilateral sagittal split ramus osteotomies are completed; the merits of mandible first versus maxilla first surgery have been discussed elsewhere, and sequencing should be performed according to the surgeon's preference.

The authors generally complete the maxillary osteotomy first; a stepped osteotomy design may be used to maximize bone contact (Figure 15-7, *A*).[81,82] The maxilla is mobilized until it can be passively advanced to the desired final position. A judicious and progressive amount of pressure is used to mobilize the maxilla in order to minimize the risk of eliciting a trigeminocardiac reflex, which has been observed following maxillary osteotomies.[83] If encountered, consideration could be given to blocking the reflex with the use of a vagolytic drug. Following mobilization of the maxilla at the Le Fort I level, the intermediate occlusal splint is introduced and maxillomandibular fixation (MMF) is applied. The maxillomandibular complex is rotated closed, ensuring proper condylar seating. Interferences are carefully removed to achieve the desired vertical incisor position, which may be assessed based on either the lip position or an external reference point, such as a nasal Kirschner wire. The piriform aperture and the anterior nasal spine are recontoured as necessary to minimize unesthetic nasal changes. The maxilla is fixated into its desired position by placing plates at the nasomaxillary and zygomaticomaxillary buttresses (see Figure 15-7, *B*). Because of the large advancement, the surgeon may elect to use heavier plates and/or locking screws. With good bone contact, grafting is not generally required, though the surgeon may elect to place self-retentive grafts over the advancement gap to prevent soft tissue ingrowth during healing.

Bilateral sagittal split ramus osteotomies are then completed; the mandible is mobilized until it is readily advanced to its final position. MMF is again applied, using a final splint if indicated. With the condyles seated, the mandible is secured by the surgeon's preferred technique using either bicortical positional screws or plates and screws. MMF is again released, and occlusion is assessed.

If planned, a genial tubercle advancement or genioplasty is then performed through an anterior mandibular vestibular incision.

Once a satisfactory result has been obtained, the wounds are irrigated and closed. An alar cinch suture is placed prior to closing the maxillary vestibular wound in a V to Y fashion to minimize vermilion thinning.

Postoperative Care

Postoperative care is generally the same as that for patients undergoing routine orthognathic surgery and includes postoperative prophylactic antibiotics, additional steroids per surgeon preference, analgesics, and a non-chew diet.

Additional considerations for the MMA patient are directed toward airway management and comorbidities. Generally patients can be extubated in the operating room once they are sufficiently alert. Deep extubation is not recommended. Communication with the anesthesiologist is important as it is desirable to minimize agitation and the resultant increase in blood pressure, which can cause bleeding. Postoperative CPAP is rarely required; however, continuous oximetry and close observation for apneas are important for at least the first night. This may require admission to the intensive care unit. The patient is then transferred to the floor, provided there are no residual airway concerns. Opioid-sparing analgesia is employed to minimize narcotic use. Once patients are able to maintain good oxygen saturation on room air overnight, ambulate with minimal assistance, tolerate a non-chew diet, perform good oral hygiene, and achieve adequate pain control with oral analgesics, they may be discharged home. Patients are typically seen in the office every 1 to 2 weeks for the first 6 to 8 weeks after surgery. If in orthodontic appliances they return to the orthodontist at an agreed-upon interval, typically 4 to 6 weeks postoperatively.

A repeat PSG and review of sleep symptoms, both subjectively and using ESS and FOSQ, is important. Though an ideal interval for this has not been established, performing these assessments 3 to 6 months postoperatively allows recovery from the procedure and normalization of new patterns (Figure 15-8).

MMA Risks and Complications

Risks for MMA are similar to those associated with conventional orthognathic surgery and include pain, swelling, bleeding, infection, nonunion, relapse, malocclusion, altered facial sensation, unfavorable cosmetic outcomes, septal deviation, decreased mandibular range of motion, and need for hardware removal. Careful attention must be paid to postoperative airway management. Additional risks relate primarily to medical comorbidities.

In a systematic review, major complications (myocardial infarction, arrhythmia, and mandible fracture) were seen in 1% of subjects; minor complications excluding malocclusion and altered sensation were reported in 3.1%.[76]

A recent case series[84] evaluated 30 subjects; none required tracheostomy or reintubation, and none had serious cardiovascular, respiratory, or neurologic complications. Mandibular range of motion was maintained; TMJ function remained stable or improved. Of the 30 subjects, 2 experienced local wound infections controlled in the outpatient setting and 5 had subsequent hardware removal. Two subjects developed a malocclusion postoperatively. Only one subject required transfusion. Four patients (13.8%) reported worsening of facial appearance. Another series of 50 subjects reported no cardiovascular or respiratory events; 4% experienced bleeding and 2% phlebitis. Late hardware infection occurred in 16% and required hardware removal in 10%.[85]

The increased age of the average patient undergoing MMA presumably decreases the potential for neural recovery. Nonetheless, one series[85] reported that nearly 50% of subjects had full return of sensation an average of 18 months postoperatively. Another case series found that 40% of patients had a subjective decrease in lower lip/chin sensation, but the reported long-term change in sensation ranged from no problem to a moderate problem in terms of quality of life.[84]

Skeletal relapse may occur after any orthognathic surgery; however, reported relapse is generally minimal and deemed clinically insignificant after MMA.[77,86]

Regurgitation and hypernasality are theoretical complications, particularly if UPPP has been performed previously; however, these seem to be rare.[87] In a systematic review, velopharyngeal insufficiency was reported only in patients who had had prior phase I surgery.[76]

MMA Outcomes

A systematic review and meta-analysis of MMA outcomes showed significant improvement after MMA in terms of AHI (from mean 63.9 to 9.5), nadir oxygen saturation (from 71.9% to 87.7%), and sleepiness (ESS 13.2 to 5.1). Overall patient-level success rate was 84%. In a patient-level multivariate analysis, subjects with a lower preoperative BMI and those who underwent a larger maxillary advancement were more likely to experience surgical success.[76] Another systematic review and meta-analysis of outcomes after various surgical interventions to address OSA reported an 87% reduction in AHI after MMA with a mean postoperative AHI of 7.7 when MMA was performed as primary surgery.[61] The same review reported a 33% reduction in AHI after UPPP.

A more recent meta-analysis looked at 45 studies including 518 subjects; the authors reported a reduction in AHI from a mean of 57.2 to 9.5 with a mean 80% reduction in AHI.[88] Nadir oxygen saturation improved from mean 70.1% to 87%, and ESS score improved from mean 13.5 to 3.2. Surgical success rate was 85.5% with 38.5% cure in those subjects with AHI reported. Factors associated with surgical cure based on multivariate analysis were younger age, lower preoperative AHI, and higher preoperative nadir Spo_2. Subjects with a higher preoperative AHI tended to have lower baseline nadir Spo_2. Although less likely to achieve surgical success/cure, these subjects experienced a greater improvement in nadir Spo_2 and a greater reduction in events/hour than did those with lower baseline AHI. Genial tubercle advancement did not affect PSG outcomes.

In studies that compared preoperative AHI in patients treated with CPAP with post-MMA AHI, no difference was noted; MMA was as effective for these patients as CPAP.[76] A prospective randomized trial comparing outcomes using autotitrating positive airway pressure (APAP) versus MMA

• **Figure 15-8** Frontal facial **(A),** lateral facial **(B),** and lateral cephalometric **(C)** images of a 59-year-old man with severe obstructive sleep apnea (apnea-hypopnea index [AHI] = 45), decreased posterior airway space, and concomitant maxillofacial skeletal deformities (mandibular retrognathia, transverse maxillary hypoplasia, and transverse mandibular hypoplasia). Frontal facial **(D),** lateral facial **(E),** and lateral cephalometric radiograph **(F)** of the patient at long-term follow-up 5.5 years after maxillomandibular advancement (MMA). The patient had total resolution of obstructive sleep apnea (long-term post-MMA AHI = 0.8), increased posterior airway space, and correction of maxillofacial skeletal deformities and malocclusion. (Modified with permission from Conley RS, Legan HL: Correction of severe obstructive sleep apnea with bimaxillary transverse distraction osteogenesis and maxillomandibular advancement, *Am J Orthod Dentofacial Orthop* 129(2): 287, 2006.)

in subjects with severe OSA demonstrated similar reductions in AHI and sleepiness with these interventions.[89] Importantly, reduction in AHI after MMA has occurred despite stable or increased BMI.[61,84]

Systematic reviews suggest that blood pressure control improves after MMA.[61] A recent study reported long-term reduction in diastolic blood pressure following MMA.[84] A retrospective analysis demonstrated reduction of systolic (SBP) and diastolic (DBP) blood pressure after MMA by 3.8 mm Hg for SBP and 2.5 mm Hg for DBP, with larger reductions in the subset of patients with a diagnosis of hypertension.[90] This modest reduction in blood pressure is comparable to the reported impact of CPAP on blood pressure in a large systematic review and meta-analysis, which showed SBP reduction of 3.2 mm Hg and DBP reduction of 2.87 mm Hg.[91]

Subjective sleepiness (as assessed by ESS) and quality of life (as assessed by FOSQ) have been shown to improve after MMA.[76,84,88,92-95] A meta-analysis of CPAP therapy showed a mean reduction in ESS of 2.94 points, with a larger reduction of 4.75 in those with severe OSA and severe sleepiness.[96] Meta-analyses of MMA have shown larger reductions in ESS score from 13.2 to 5.1[76] and 13.5 to 3.2.[88]

An important question is whether MMA is a viable option for those with extremely high AHI values. Subjects intolerant of CPAP with an AHI greater than 100 who underwent MMA were evaluated retrospectively in a recent case series[94] where mean AHI values dropped from 117.9 to 16.1. Six of 13 subjects experienced surgical cure, and an additional 4 had a postoperative AHI less than 15. Mean ESS score dropped from 12.9 to 5. Interestingly, one subject's postoperative AHI was 95.5, though daytime somnolence improved and the subject would recommend the surgery to others. The authors were unable to identify any factors that explained this outlier response. Only one subject reported unfavorable facial changes, but family and friends saw the changes as positive.

Adjustment to a new facial appearance may be challenging for the MMA population; however, the majority of patients are satisfied with their facial appearance postoperatively. In a subject group treated to cephalometric norms, over 50% of patients were satisfied with their facial appearance, 13% were disappointed, and 5% were unsatisfied. Interestingly, these outcomes did not correlate with preoperative maxillomandibular retrusion, degree of advancement, or reduction in AHI. Of these patients, 94% said they would recommend the procedure to friends or family.[85] Other studies confirm high patient satisfaction after MMA.[76,89]

Linear and volumetric changes in the upper airway have been observed after MMA, as measured by CBCT. Specific changes include increases in airway volume, minimal cross-sectional area, and anterior-posterior dimension, along with decreases in airway length and airway resistance.[77,97-102] These changes likely result in decreased collapsibility of the upper airway and are associated with decreases in AHI.

Conclusion

MMA is an effective treatment for patients with moderate to severe OSA and has a favorable risk-to-benefit ratio. When performed alone, it is more effective than UPPP and offers similar benefit to CPAP, OAs, and upper airway stimulation. There is compelling evidence that MMA should be the treatment of choice for patients with moderate to severe OSA who are intolerant of CPAP or OAs.

Perioperative Management of the Orthognathic Patient

LEWIS C. JONES, MICHAEL JASKOLKA

The perioperative management of patients seeking orthognathic surgery begins before the initiation of orthodontic therapy and continues indefinitely after their operation. The aim of this chapter is to review many of the preoperative factors that help determine the appropriateness of orthognathic surgery as a treatment modality for each individual patient. It also addresses the postoperative course, including management of early complications.

In general, there are two distinct patient populations that seek orthognathic surgery: the first are those with significant dentofacial deformity (DFD), and the second are those with obstructive sleep apnea (OSA). This chapter addresses the management of both populations.

In the DFD patient, the first surgical consultation ideally occurs before the initiation of orthodontic treatment. A preliminary treatment plan is developed after a discussion of the patient's chief complaint(s), physical exam, and review of other records (orthodontic models and radiographs). Treatment plan options may include orthodontic camouflage versus correction of the underlying skeletal deformity and should take additional patient-specific factors into account. It is at this point that the process of "informed consent" begins, as patients and their families should understand the nature of the surgical procedures that may be performed, as well as the inherent risks and benefits. In addition, any significant medical comorbidities that may lead to further testing, consultations, or alternative treatment recommendations should be identified.

For the OSA patient, the first surgical consultation is generally focused on the evaluation of the severity of their disease. This is likely to include a history (focused on symptoms and prior interventions), physical exam, review of polysomnographic testing, radiographic evaluation, and nasoendoscopy. Once the decision has been made to offer the patient jaw advancement, the majority of the preoperative planning relates to evaluation and optimization of existing medical comorbidities. Preoperative orthodontic preparation may or may not be part of the treatment plan depending on the patient's interest, medical condition, and occlusion—but the patient must understand that orthodontics may be indicated following surgical treatment.

Dentofacial Considerations

Growth and Timing

The patient's maturity at the time of surgery directly affects their propensity for relapse. When concern for continued growth exists, serial cephalometric images 6 to 12 months apart should demonstrate that the patient is not actively growing before proceeding with surgery.[1] Alternatively, analysis of hand-wrist films has been used as a predictor for facial growth for decades, and cervical spine imaging has also been described in estimating growth cessation[2-4] (Figures 16-1 and 16-2).

The timing of surgery also depends on the severity of the skeletal discrepancy, functional restrictions, and psychosocial considerations. Literature describing early correction of dentofacial deformities with orthognathic surgery is sparse, with relatively small studies showing a variety of results with regard to relapse in the growing, adolescent patient. One study of 22 patients undergoing bilateral sagittal split osteotomy (BSSO) for mandibular retrognathia demonstrated that relapse rates correlated with the amount of advancement—with those greater than or equal to 10 mm more likely to experience significant relapse due to condylar remodeling/resorption.[5] Several other studies have demonstrated stability, including Epker, Schendel, and Wolford's series of 12 patients in 1978, which demonstrated good stability following advancement of growing class II patients.[6] Studies such as these demonstrate the need for patient counseling regarding surgical timing. It is important to explain that early intervention, although more predictable in instances such as the advancement of a hypoplastic mandible/maxilla than that of a setback of a hyperplastic jaw, may require additional orthodontics and/or surgery if the corrections are outgrown.

• **Figure 16-1** Hand wrist film of skeletally immature patient. Note the open epiphyseal plates in the phalanges and lack of sesamoid bone at the thumb.

• **Figure 16-2** Hand wrist film of skeletally mature patient with closed epiphyseal plates and presence of sesamoid bone at thumb.

Asymmetry

Growth resulting in asymmetry requires the surgeon to investigate the cause of the growth pattern. Significant asymmetries can result from processes that are congenital (e.g., hemifacial microsomia), acquired (e.g., trauma, pathology), or idiopathic (e.g., hemimandibular hypertrophy, Parry-Romberg syndrome). Slowly developing asymmetries will allow for compensation in the opposing arch, thus initially masking the etiology of the asymmetry. Conversely, rapidly developing asymmetries are more apparent, as they do not allow for dental compensation. Depending on the differential diagnosis, additional studies may be required, such as a technetium-99m (^{99m}Tc) nuclear scan or single-photon emission computed tomography (SPECT) to evaluate for active uptake that indicates continued growth at the condyle.[7,8] In some cases, growth-arresting high condylectomy may be attempted to limit progressive deformity. In congenital conditions, arguments can be found in the literature both for and against early versus delayed intervention at the completion of skeletal maturity. The final category of conditions are those such as Parry-Romberg syndrome and idiopathic condylar resorption, which may necessitate a waiting period to ensure that the atrophy has ceased or "burned out" before corrective surgery is pursued. The condylar resorption patient should be made aware that even a quiescent condyle can undergo reactivation of the resorptive process following surgery, as several reports have demonstrated.[9-11]

Presence of Third Molars

The management of third molars in the context of orthognathic surgery has been debated, with many practitioners preferring to extract before surgery. At the very least, they are an inconvenience during the osteotomies of the mandible (and occasionally the maxilla). Cases have been made both for and against removal of third molars before surgery.[12,13] However, a prospective study has shown that their presence does not cause an increase in complications.[14] If they are to be removed prior to surgery, the recommended time frame is 6 to 9 months before the desired surgery date to allow for bony healing.[15]

Orthodontic Considerations/Preparation

Traditionally, orthodontic treatment comprising dental decompensation and independent arch coordination is completed before orthognathic surgery. Occasionally, in sleep apnea cases with a stable occlusion, orthodontic therapy may not be required at all. In some cases, surgery can be performed before orthodontics. In most of the "surgery-first" cases, no severe asymmetry exists, there is minimal orthodontic complexity and only mild jaw discrepancy, and the surgery is being performed for either airway or esthetic reasons.[16,17]

A patient who is orthodontically prepared for surgery should have final orthodontic models, photographs, and radiographs taken in preparation for final surgical planning. A passive stainless steel archwire placed 2 weeks before impressions ensures that no orthodontic movement of the teeth occurs between the time when final records are taken and the day of surgery. Surgical lugs should be placed between as many of the teeth as possible, usually only a few days before surgery to minimize discomfort. A case with inadequate surgical lugs can lead to intraoperative interarch instability and compromise the final result. Segmental surgery should have verification of root divergence

on radiographs in the regions of the planned osteotomies. The final plan and occlusion should be reviewed with both the patient and the orthodontist. Limitations of the surgical procedure should be noted (e.g., maxillary expansion with segmental maxillary surgery) so that the orthodontist can make appropriate plans for postoperative occlusal detailing. If an occlusal splint is to be used, it may be trialed for fit before the day of surgery. If orthodontic elastic traction is to be used postoperatively, patients may be provided supplies to practice with in advance of surgery. Intraoral manipulation of elastics can be frustrating in the setting of paresthesia, swelling, and pain (Figure 16-3).

Traditional sequencing of orthognathic surgery allows for orthodontic decompensation before surgery followed by orthodontic finishing. However, depending on the case and the orthodontist, surgery can be performed first. The concept of a regional acceleratory phenomenon in the 3 to 4 months following surgery is the theory behind the shortened treatment phase observed in these patients. This has been described by various surgeons, with the caveat that only mild to moderate crowding exists and that the arches are reasonably well coordinated.[18-20] This is a paradigm shift in the traditional method that will continue to be explored as its merits and limitations are further borne out in the literature.

Preoperative Informed Consent

The process of informed consent begins during the initial consultation and continues during the treatment planning appointments. The final appointment before surgery should include a detailed conversation with the patient regarding their expectations of the surgery, early postoperative period, and final goals/outcomes. This meeting allows the patient to ask additional questions and allows the surgeon to review the expected time frame for postoperative pain and swelling that will progress/increase for 48 to 72 hours following surgery. Risks discussed should include blood loss (and the remote possibility of need for transfusion), hardware placement, possible maxillomandibular fixation (planned or due to unfavorable fractures), and possible need for future procedures such as hardware removal. Temporary sensory nerve deficits in the trigeminal (V2/V3) distribution are expected in many cases, and in some cases the marginal mandibular motor nerves are also at risk of injury. Discussion of nerve injury should include the risk of permanent hypoesthesia, anesthesia, dysesthesia, or motor weakness within the context of the treatment plan. The patient must comprehend the importance of postoperative oral hygiene despite the difficulties imposed by edema, sutures, elastics, and an oral splint. Postoperative dietary restrictions and the need for supplementation should also be reinforced. Last, appropriate recovery time should be reviewed, as unrealistic expectations can discourage the patient if they feel they are not healing or progressing quickly enough.

• **Figure 16-3** Final occlusal splint on models. Ideally this should have enough buccal dimension to allow for holes for passing a wire to secure the splint to the maxillary archwire, but maintain a low profile to avoid undue patient discomfort.

Systems-Based Medical Evaluation

A systems-based patient evaluation should include review of cardiovascular, pulmonary, renal, neurologic, hematologic, musculoskeletal, mental health, and endocrine systems as they relate to both surgical and anesthetic risk. Absolute medical contraindications, where the risks associated with treatment are likely to outweigh the benefits, should be identified at the outset and may affect the overall treatment plan. Otherwise, the recognition of medical conditions that require optimization or specialized perioperative management is necessary. As the prevalence of orthognathic surgery as a treatment modality is expanded to include patients with congenital conditions, older age cohorts, and those with OSA, the population of patients seeking orthognathic surgery grows more medically complex.

Cardiovascular

Orthognathic surgery can stress the cardiovascular system. In addition to the possibility of significant blood loss, general anesthetics for maxillary surgery often incorporate a component of hypotensive anesthesia that requires cardiac compensation to maintain end-organ perfusion. Both the anesthesiologist and surgeon should be aware of the patient's cardiovascular risk factors in light of the planned surgery and anesthetic, including the timing and duration of the permissive hypotension. The preoperative history and physical will initiate the cardiovascular evaluation.

Pediatric cardiovascular conditions are highlighted by congenital malformation. The most common include valvular abnormalities (stenosis/regurgitation/bifid malformations) and aortic coarctation, as well as more complex conditions such as tetralogy of Fallot, transposition of the

great vessels, and truncus arteriosus. As pediatric cardiology and cardiothoracic reconstruction continues to advance, many patients with a history of congenital malformation are candidates for orthognathic surgery. Cardiac electrophysiologic abnormalities such as Wolff-Parkinson-White or long Q-T syndrome, paroxysmal supraventricular tachycardia, and sick sinus syndrome can also be present, more commonly in the adolescent patient.

Adult populations can present with a history of any of the above as well as acquired cardiovascular disease such as coronary artery disease, arterio/atherosclerosis, aneurysms, and/or hypertension. Arrhythmias such as atrial fibrillation are more common at advanced ages. Previous history of procedures and cardiovascular medications taken to mitigate these conditions should be elicited in the initial exam. As medical (and surgical) management of these conditions continues to expand, a thoughtful plan for perioperative management of these patients is required.

OSA patients seeking maxillomandibular advancement (MMA) surgery should be closely monitored for undiagnosed cardiovascular disease. OSA is a risk factor for hypertension, and evidence is mounting to suggest OSA as an independent risk factor for coronary artery disease. Untreated, severe OSA is also associated with increased cardiac mortality.[21-25]

The cardiovascular portion of the physical exam includes auscultation of the heart for normal S1/S2 sounds and a regular rate and rhythm. Any deviation from normal prompts further workup and referral to the patient's primary physician or cardiologist. The cardiovascular exam also includes assessment of the patient's extremities. This can illuminate peripheral vascular disease and congestive heart failure, as distal pulses are palpated and lower extremities inspected for edema. This swelling may be an indication of heart failure, which would also correlate with signs such as jugular venous distention and presence of a third heart sound. Finally, although most patients will receive antibiotics prior to incision, it is imperative that all patients requiring prophylaxis due to concerns for infective endocarditis receive preoperative antibiotics.[26] The most recent recommendations by the American Heart Association are listed in Box 16-1.

• BOX 16-1 2007 American Heart Association Guidelines for Infective Endocarditis Prophylaxis

1. Prosthetic heart valve or valve repair with prosthetic material
2. History of endocarditis
3. Heart transplant with abnormal heart valve function
4. Congenital heart defects that have not been fully repaired, those repaired with residual defects, and those repaired with prosthetic material (covered for 6 months postoperatively)

From Ball JW, Dains JE, Flynn JA, editors: *Seidel's guide to physical examination*, ed 8, St. Louis, 2015, Mosby.

Patients with cardiac conditions will most often require consultation with the patient's managing physician and review of existing laboratory work and studies. Most cardiac patients will have undergone multiple studies that may include 12-lead electrocardiography (ECG), echocardiogram, magnetic resonance imaging (MRI), and computed tomographic or conventional angiography. Patients should also be questioned regarding a history of angina, activity limitations, prosthetic implants, irregular heartbeat, and medication regimens that may affect their perioperative care. Discussions regarding exercise/activity tolerance will allow insight into the patient's overall cardiovascular status. The New York Heart Association's classification (first established in 1928 and subsequently amended) stratifies patients with heart failure according to tolerance of physical activities[27] (Table 16-1). Various activities have differing metabolic equivalents of task (METs); one MET is defined as the resting metabolic rate (or the amount of oxygen consumption at rest, sitting in a chair), which is equivalent to approximately 3.5 mL O_2/kg/min.[28] Therefore, an activity requiring 7.5 mL O_2/kg/min is a 2-MET activity (Table 16-2). A decreased ability to tolerate activities with minimal

TABLE 16-1 NYHA Classes of Heart Failure

Class	Functional Capacity
I	Cardiac disease present but does not limit physical activity. Physical activity does not cause inordinate fatigue, palpitation, dyspnea, or angina.
II	Cardiac disease that causes slight limitations in physical activity. Patient is comfortable at rest. Physical activity (ordinary) does result in fatigue, palpitation and/or angina.
III	Cardiac disease with marked limitation of physical activity. Patient is comfortable at rest. Less than ordinary activity induces fatigue, palpitation, and/or angina.
IV	Cardiac disease results in inability to have any physical activity without discomfort. Symptoms may even be present at rest.

TABLE 16-2 Metabolic Equivalents of Various Activities

Activity	METS
Driving a car	2
Yoga	3.2
Golf (riding cart/carrying clubs)	2-3/5.1
Bicycling	4.8
Swimming (2.5 km/hr)	6.8
Racquetball	8-12
Running a marathon	13.3

or moderate METs should raise concerns regarding the patient's ability to tolerate a general anesthetic for an elective procedure. Finally, many cardiovascular medications such as antiplatelet/anticoagulation therapies (aspirin, clopidogrel/prasugrel, Xa inhibitors, warfarin) and beta-blockers require the attention and coordination of the surgeon and cardiologist in their perioperative management.

Pulmonary/Airway

The patient's surgical tolerance is also closely tied to their pulmonary status. Some of the changes in the respiratory system that occur during a general anesthetic include decreased lung volume and vital capacity (due to supine positioning that changes the diaphragmatic action), decreased lung compliance, and decreased mucociliary clearance.[29] These changes affect all patients, but those with preexisting pulmonary dysfunction are more likely to have postoperative complications.

Pulmonary diseases encountered in the adolescent orthognathic population may include asthma, history of bronchopulmonary dysplasia, and inherited disease such as cystic fibrosis (CF). Adults with pulmonary disease can also have a history of the above as well as chronic obstructive pulmonary disease (COPD)/emphysema, pulmonary fibrosis, pneumoconiosis, and manifestations of systemic diseases such as sarcoidosis and lupus. Both adult and pediatric pulmonary diseases are most easily discussed when categorized into restrictive and obstructive disease processes, although there may be significant overlap in many conditions, such as CF.

The main types of restrictive lung disease include extraparenchymal processes (or chest wall disorders) such as obesity and kyphosis, and intraparenchymal processes such as pulmonary fibrosis, sarcoidosis, and pneumoconiosis. Restrictive lung diseases are characterized by a normal or increased ratio of forced expiratory volume 1 (FEV1) to forced vital capacity (FVC) (since both are decreased) and an overall decreased total lung capacity of less than 80% of expected.[30]

Obstructive lung diseases include diseases such as asthma and COPD. Obstructive pulmonary disease is demonstrated by a decrease in FEV1 with maintenance of a normal FVC, such that the FEV1/FVC ratio is decreased to less than 0.7. A review by the American College of Physicians of the existing literature with regard to preoperative pulmonary risk stratification for non-cardiothoracic surgery demonstrated that chronic obstructive pulmonary disease was the most frequently identified risk factor determining postoperative pulmonary complications.[31]

Asthmatics are at increased risk for perioperative complications such as bronchospasm.[32] Asthma encompasses a wide range of reactive airway disease and is classified according to severity and degree of control. The severity is divided into intermittent and persistent disease, with persistent disease being further categorized as mild, moderate, or severe (Table 16-3). All asthmatic patients should be questioned regarding their frequency of rescue inhaler use (beta agonist), their maintenance therapy, and their last emergency visit or hospital admission due to their disease. These questions will help to categorize the severity and degree of control of each asthmatic patient. The surgeon should ensure that each patient is optimized before surgery. Optimization of pulmonary diseases is demonstrated on pulmonary function tests and spirometry. If FEV1 results are less than 80% of baseline, then further optimization, often with inhaled corticosteroids, should be administered and pulmonary function restored before surgery.[33,34]

Systemic disease with pulmonary implications such as cystic fibrosis, sarcoidosis, and lupus can greatly affect the treatment plan in the patient seeking orthognathic surgery. These patients will require direct communication with the patient's pulmonologist for risk stratification. Some of these patients may not be candidates for an elective general anesthetic, and thus for elective surgical intervention. This determination must be made early in the treatment phase so that orthodontic camouflaging can be initiated instead of decompensation for surgical preparation. The decision to proceed with surgery should be based on the results of pulmonary testing to stratify risk for the risk/benefit analysis with both the pulmonologist and the patient.

Cigarette use is an independent risk factor affecting the likelihood of a postoperative pulmonary complication. A well-designed prospective cohort study demonstrated an odds ratio (OR) of 5.5 for postoperative pulmonary complications between smokers and nonsmokers, with 22% of smokers developing postoperative complications compared

TABLE 16-3 Asthma Severity Classification

Classification	Symptom Frequency and Need for Short Acting B-Agonist	FEV1	Required Oral Corticosteroids for Exacerbations	Interference with Normal Activity
Intermittent	≤2 days/week	>80% and normal between exacerbations	≤1× per year	None
Persistent-mild	>2 days/week, not daily	>80%	>2× per year	Minor limitations
Persistent-moderate	Daily	60%-80%	>2× per year	Some limitations
Persistent-severe	Multiple times per day	<60%	>2× per year	Extreme limitations

to only 4.9% of nonsmokers. This same study demonstrated that reduction in smoking just before surgery increased the OR to 6.7.[35] This increased risk in the smoking reduction group is likely linked to increased sputum production and continues for up to 2 months.[29] For this reason, smoking cessation should continue to be encouraged in all patient populations, and elective surgical procedures should be scheduled for a minimum of 2 months following cessation.

The pulmonary portion of the physical exam includes auscultation of all lung fields as well as an evaluation of the airway. Airway evaluation entails noting potential difficulties with management of both ventilation and intubation, both of which have been well described in the anesthesia literature. Mask ventilation problems correlate with increased body mass index (BMI), advanced age, macroglossia, facial hair, edentulism, low thyromental distance, increased modified Mallampati grade, and history of snoring (many of which correlate with the diagnosis of OSA).[36] Intubation difficulty is often noted in patients with decreased mouth opening, an increasing Mallampati classification (Table 16-4), short thyromental distance (<7 cm), inability to achieve a correct "sniffing" position due to cervical spine arthritides, and excessive cervical soft tissue.[37,38] As the airway is assessed, the surgeon should be mindful of the potential for postoperative swelling of the surrounding soft tissues that can lead to airway embarrassment, specifically in the OSA patient. Prolonged intubation or even a planned tracheostomy can help ensure a secure airway in the postoperative period in what may otherwise be a tenuous airway. A tracheostomy may seem aggressive as an adjunct procedure, but may be indicated by the pulmonary status of the patient if the need for a prolonged ventilator taper is expected.

Pulmonary testing to determine disease type/severity may include pulmonary function testing, which measures lung volumes and capacity as well as flows (peak expiratory flow/forced expiratory flow 25% and 75%). Exercise testing in a stress test format will demonstrate the effect of activity on pulmonary function. Gas diffusion tests can help determine how well gases are transferred from lungs to the circulating blood. These tests can help stratify pulmonary risk for the anesthetic/procedure.

Renal

Renal disease can affect surgery in regard to metabolism and clearance of drugs as well as electrolyte balance and fluid volume homeostasis. Renal disorders seen in the pediatric population can be structural (renal agenesis, hypoplasia, dysplasia, vesicouretural reflux), inherited (autosomal recessive polycystic kidney disease), or acquired (minimal change disease, polyarteritis nodosa, and nephritic processes).[39]

Adult renal processes of concern include any chronic kidney disease (Table 16-5)—which most frequently result from diabetes and/or hypertension.[40] Other diseases less commonly encountered that affect the kidneys are sarcoidosis, lupus, autosomal dominant polycystic kidney disease, and vasculitides. Finally, although the end-stage renal disease patient on dialysis is not likely to present for orthognathic or maxillomandibular advancement surgery, they may present for consultation after renal transplant and will require special perioperative considerations.

The physical examination of the patient should include an evaluation of fluid volume status through checking skin turgor, auscultation of heart and lungs, and an extremity exam for edema. The remainder of testing for renal function and/or structural abnormalities includes both laboratory work and imaging studies. Laboratory testing can include urinalysis to evaluate for hematuria, proteinuria, cast formation, presence of leukocyte esterase or nitrites, or abnormalities of specific gravity. A basic metabolic panel (or Chem 7) will evaluate electrolytes (K^+, Na^+, Cl^-, HCO_3^-) and renal function/hydration (through creatinine and blood urea nitrogen). Imaging studies ordered by the physician managing the renal disease may include renal ultrasound, cystourethrogram (CUG—usually a voiding CUG to check for reflux), or computed tomography. In some scenarios, a renal biopsy is required for definitive diagnosis.

Perioperative management of these patients includes pre-, intra-, and postoperative considerations. Depending on the underlying renal disease, metabolic panels assessing for electrolyte abnormalities should be checked at regular intervals beginning before induction. Electrolyte disturbances should be corrected before induction of anesthesia as they can lead to cardiac dysfunction/arrhythmias. Drugs administered to patients with impaired renal function may require dose adjustments depending on the medicine administered and the patient's glomerular filtration rate (GFR). Transplant patients will often remain on potent steroids and immune modulators as a component of their antirejection regimen and may require stress-dose steroids or other considerations

during the perioperative period. The patient should be euvolemic before surgery and can remain euvolemic with proper management of medications and intraoperative fluid volumes. Placement of a Foley catheter (advised on all procedures longer than 3 hours) allows for monitoring of urine output and thus perfusion of the kidneys throughout surgery. Adequate urine output for a well-perfused kidney is 0.5 to 1 mL/kg/hr, and a mean arterial pressure of 60 mm Hg is required to maintain adequate end-organ perfusion including the kidneys. Anatomic genitourinary abnormalities such as hypospadias or urethral strictures may require the Foley catheter to be placed by a urologist.

Neurologic

Neurologic abnormalities cover a wide variety of diseases and conditions. In the adolescent population, these include attention deficit disorder (with or without hyperactivity), autism spectrum disorders, seizure disorders, movement disorders (Tourette syndrome, dystonias), neuromuscular disorders (muscular dystrophies and myopathies), cerebral palsy, congenital defects (spina bifida), and hereditary disorders such as neurofibromatosis. In addition to these, adult populations can have a history of neuromuscular junction disease (myasthenia gravis) or one of several types of headaches (tension, migraine, cluster, etc.). Occasionally patients are seeking orthognathic surgery and "fixing their bite" as a means to treat the headaches.[41]

A thorough preoperative neurologic assessment includes examination of extremities for function, strength, and sensation in addition to the routine cranial nerve examination. The cranial nerve exam should elaborate on any preoperative deficits. This also provides an opportunity to explain the expected distribution of postoperative hypoesthesia in the maxillary and mandibular distributions of cranial nerve V.

Perioperative medication management is paramount in this patient population. Patients with attention deficit disorders should continue their medications for the hyperactivity/attention deficit disorders, as missed doses of these medications can result in a less cooperative and adherent patient in the postoperative period. Seizure disorders require further insight regarding type of seizures (partial or generalized tonic-clonic), possible triggers, and frequency/degree of control of the disorder on their current medication regimen. Seizure disorders are a contraindication for maxillomandibular fixation; thus, procedures requiring postoperative MMF (such as vertical ramus osteotomies) should be avoided and caution should be exercised even with elastic MMF in the postoperative period. Antiseizure medications should be scheduled without interruption, but conversion to a different medication, route of administration, or dosage may be required in the postoperative period. Finally, patients with gingival overgrowth due to phenytoin may require gingival recontouring in conjunction with their orthognathic surgery for the most esthetic result.

Neuromuscular junction diseases such as myasthenia gravis require consultation with the patient's neurologist. Surgery should be planned during a stable phase of the patient's disease, which usually equates to a patient without current requirements for steroids, or only low-dose maintenance steroid treatment (depending on the patient's disease severity).[42] Intraoperatively, the inhalational anesthetics have a more profound effect in this patient population; for this reason, total intravenous anesthesia (TIVA) with propofol is used as an effective alternative to avoid profound, prolonged muscular relaxation.[43] These patients have an increased risk of postoperative respiratory insufficiency with any of the following criteria: disease duration greater than 6 years, pyridostigmine daily dosage greater than 750 mg, and vital capacity less than 2.9 L.[44] The surgeon should also be aware of any immunosuppressive therapy that will have deleterious effects on postoperative healing.

Muscular and myotonic dystrophies exhibit a high rate of malocclusions that may require orthognathic surgery for optimal treatment.[45-47] The surgeon should be aware that this patient population is known to have significant comorbidities, such as a high rate of cardiac involvement in Duchenne muscular dystrophy. Most surgeries in this population will require coordination with the patient's pulmonologist, because they will often require supplemental postoperative pulmonary therapy including measures such as noninvasive positive-pressure ventilation (NPPV).[44]

Patients with spina bifida and cerebral palsy have an especially high rate (40% to 48%) of latex sensitivity.[48-50] A latex-free environment is advisable for these patients, even if they have not previously been diagnosed with an allergy. Finally, all patients, regardless of preexisting conditions, require careful padding of pressure points before the initiation of surgery to help avoid any postoperative sequelae of compressed nerves that can result in hypoesthesia/numbness. Proper positioning may be especially challenging in certain instances (such as the cerebral palsy patient) because of contractures.

Hematologic

Surgery requires an appropriate response on a hematologic level for proper hemostasis and healing. Hematologic disorders that disrupt this process are concerning to the surgeon, including diseases that cause a bleeding diathesis, hypercoagulable states, or anemias.

In the pediatric population, the heritable diseases with bleeding tendencies include hemophilia A and B, von Willebrand factor disease, and platelet disorders such as Bernard-Soulier syndrome. Inherited hypercoagulable states include factor V Leiden, as well as protein C and S deficiencies. Sickle cell anemia also leads to clot formation as well as decreased hematocrit/hemoglobin (Hct/Hgb). Other types of anemia will present with decreased hemoglobin levels due to varying etiology (iron deficiency, B_{12} deficiency, hereditary spherocytosis, thalassemias). Some patients with severe hematologic disease will not be candidates for elective surgery.

Acquired bleeding tendencies that are more likely to surface in adult populations include medication induced anticoagulation/platelet dysfunction and thrombocytopenia due to various other medical conditions (liver disease, splenomegaly, etc.). Hypercoagulable states can be due to cancer, obesity, oral contraceptives or coexisting diseases such as lupus. Adult populations can also present with anemia due to dietary deficiencies, GI disorders (decreased absorption of B_{12}, folate, iron), or other coexisting disease such as chronic kidney disease.

The initial patient history should reveal bleeding tendencies, including anticoagulation and/or antiplatelet drugs that will require perioperative coordination with the patient's prescribing physician. Additionally, herbal supplements such as chamomile, motherwort, ginkgo, garlic, ginger, bilberry, ginseng, turmeric, and willow all affect platelet function and/or the coagulation cascade. In most cases, they should be discontinued several weeks before surgery.[51] All patients should be questioned regarding bleeding and bruising tendencies. A discussion with female patients can elicit history of menorrhagia, which is often the first manifestation of a bleeding diathesis. Bruising that is noticed during physical exam should prompt further questions to illuminate any tendency toward bleeding/bruising that may be related to a bleeding diathesis.

A history of previous thrombosis should prompt consultation regarding the patient's future risk of thrombosis and current management including anticoagulation. Depending on the severity of thrombosis and the patient's history, they may be on long-term anticoagulation. Coordination with the patient's managing physician should take place before surgery to determine timing for holding preoperative anticoagulation and resuming it postoperatively. In some circumstances, medications may need to be altered or transitioned to a different dose or form of administration.

Patients with sickle cell anemia should be optimized before surgery and managed with the goal of avoiding a sickle cell crisis. Optimization is accomplished by maintaining a hemoglobin of 10 g/dL (some patients require transfusion and/or hydroxyurea to accomplish this goal). Sickle cell crises can stem from dehydration, anxiety, pain, infection, hypoxia, hypotension, or acidosis. In order to avoid these, adequate hydration, pain control (with good local anesthesia during surgery and appropriate control postoperatively), supplemental oxygen, and avoidance of hypotension (even during downfracture) should be implemented. Antibiotics (both preoperative single dose and postoperative course) are recommended, as infection can precipitate a crisis, and autosplenectomy (which can occur due to sickle cell anemia) can increase the risk of various infections.

Patients with known or suspected hematologic disorders should be further characterized and investigated. This is accomplished through laboratory studies such as an international normalized ratio, prothrombin time, and activated partial thromboplastin time (INR, PT, and aPTT), bleeding time, and platelet function testing.

Before surgery, all patients (unless contraindicated) can be encouraged to take a multivitamin with iron, B_{12}, and folate. This can ensure that in the weeks leading up to surgery there are adequate stores for hemoglobin production. Daily requirements for menstruating women are approximately double those for men.[52]

Intraoperative blood loss (IOBL) can be prevented through a variety of measures. A recent meta-analysis of measures used in attempts to decrease IOBL during orthognathic surgery demonstrated varying degrees of success with use of the antifibrinolytics, including IV tranexamic acid (TEA), topical TEA, yunnin baiyao (an herbal supplement), and aprotinin.[53] Permissive hypotension during the maxillary portion of the procedure will also aid in decreasing IOBL.[54] Another factor within the control of the surgeon is the length of surgery, which will decrease blood loss with a corresponding decreased operative time.

All postoperative patients will have decreased ambulation and increased venous stasis (one of the requirements for the Virchow triad for thrombosis). Appropriate prophylaxis for deep venous thrombosis should include use of mechanical methods such as sequential compression devices (SCDs) and/or thromboembolism deterrent (TED) hose, because these carry minimal risk to the patient. Pharmacologic agents (heparin, enoxaparin, argatroban) help inhibit thrombosis formation and may be required in high-risk patients. Risk of thrombosis in the pediatric patient is less than that in adults. Published pediatric registries demonstrated an incidence of 0.07 to 5.3 per 10,000 admissions, most of which were associated with serious underlying disease or central venous lines.[55,56] Adult populations have an incidence of venous thromboembolic events of 1 to 2 per 1000 patients per year.[57] With this in mind, the MMA patient with multiple comorbidities may warrant pharmacologic therapy to help avoid thromboembolic complications during hospitalization in the postoperative period.

Musculoskeletal

Musculoskeletal (MSK) conditions should be identified and assessed during the physical exam because they affect the operation, the postoperative course, and relapse rates. Pediatric conditions affecting the MSK system with relevance to orthognathic surgery include juvenile idiopathic arthritis (JIA) and idiopathic condylar resorption, as well as Down syndrome, scoliosis, cerebral palsy, and muscular dystrophy. Adult conditions affecting the MSK system include autoimmune diseases such as scleroderma and rheumatoid arthritis as well as the degenerative process of osteoarthritis.

Patients with idiopathic arthritis and condylar resorption will require a detailed discussion regarding the potential for relapse or development of an anterior open bite in the years following surgery. Several studies have demonstrated stability of orthognathic surgery in patients with JIA.[1,58] However, patients with idiopathic condylar resorption do

have a higher potential for relapse.[59] Because of this, various treatment algorithms exist. Kaban has advocated waiting for orthognathic surgery until 2 years of documented inactivity of the resorption by ^{99m}Tc scan.[60] Posnick has advocated a minimum of 1 year of inactivity (also best evaluated by ^{99m}Tc bone scan) and demonstrated that an intact cartilaginous cap leads to improved long-term stability.[61] Wolford advocates for temporomandibular joint (TMJ) surgery in conjunction with orthognathic surgery for the removal of hyperplastic synovial tissue and disc repositioning/anchoring over the condyle.[62] Regardless of the method or algorithm chosen, the informed consent process must include the propensity for relapse in this population, where even the surgery to correct the occlusion may reactivate the resorption.

The MSK implications of Down syndrome require attention to positioning. Down syndrome is associated with atlanto-occipital instability, and one recent study in an adult population found radiographic incidence of 17.5% of atlanto-occipital instability and 11.2% with atlanto-axial instability.[63] Positioning is also important to optimize intubation and ventilation in patients with scoliosis, connective tissue conditions such as scleroderma, or rheumatologic conditions.

All patients, regardless of preexisting joint disease, should have a baseline TMJ evaluation for the presence or absence of popping, clicking, or crepitance; range of motion including maximal incisal opening and excursive movements; and identification of any abnormalities. TMJ symptoms should be addressed before orthognathic surgery. Various circumstances may arise in which an orthognathic procedure may be combined with a TMJ procedure. In each of these cases, careful planning and realistic expectations are paramount.[64] Expectations and results with regard to resolution of TMJ abnormalities following orthognathic surgery vary widely—the patient must acknowledge and understand this prior to operative intervention.[41,65,66]

Mental Health

The psychosocial implications of orthognathic surgery must not be overlooked. Some patients will present with psychological disorders, some of which may even affect their motivation for orthognathic surgery.[67] A study of 89 patients at Stanford demonstrated that 12% screened positive for body dysmorphic disorder and 38% had depressive symptoms.[68] Although many patients are excited to have their surgery performed and their underlying dentofacial deformity corrected, other patients will struggle with their new appearance after their procedure.[69] Therefore, any underlying mental illness should prompt the surgeon to initiate a discussion regarding the patient's motivation for surgery and the postoperative physical and emotional obstacles, including depression.[70] Known or suspected mental illness should also prompt a referral or consultation with a mental health professional for assessment and counseling.

Obesity

The rise in obesity in the pediatric populations is evident—obesity in adolescents aged 12 to 19 has increased from 5% in 1980 to 21% in 2012.[71-73] The epidemiology of obesity in adults shows that 35% of U.S. adults are obese.[74] These trends indicate that maxillofacial surgeons can expect to encounter obesity more often in patients presenting for orthognathic surgery. The obese patient has compromised lung function, an increased rate of complications, and an increased rate of comorbid diseases such as sleep apnea, reflux, cardiovascular disease, diabetes, arrhythmias, and poor wound healing.[75]

Obesity results in restrictive lung disease as evidenced by reduced functional residual capacity, vital capacity, and total lung capacity. It is important (from an anesthesia standpoint) to ensure preoxygenation with 100% oxygen before induction to maximize the patient's limited reserve to maintain saturations during induction.[76] Incentive spirometry and mobilization should also be part of the postoperative protocol in an effort to re-expand the alveoli.

Obese patients also have an increased risk of gastroesophageal reflux disease (GERD).[77] Patients with GERD (obese or nonobese) are at increased risk of aspiration; preoperative medications such as metoclopramide and proton pump inhibitors can be administered to decrease this risk.[75] Orogastric or nasogastric tubes can be placed to empty stomach contents before extubation and minimize risk of immediate post-extubation aspiration—especially in those who are in intermaxillary fixation (IMF).

Obesity (BMI >30 kg/m^2) is also one of the risk factors for developing OSA and as such is often observed in the patient presenting for MMA. Some of these patients will have undergone bariatric surgery and must be nutritionally optimized before and after surgery. This includes adequate protein (minimum of 1.5 g/kg ideal body weight per day) as well as supplemental vitamins and minerals that vary depending on the bariatric procedure that was performed.[78] Some of these patients may require special considerations with regard to postoperative medications, such as the lap band patient who cannot swallow pills.

Endocrine

The most likely endocrine disorders encountered in the orthognathic population are diabetes, thyroid disorders, and adrenal suppression secondary to chronic corticosteroid use. As the prevalence of obesity increases, the comorbid diseases such as diabetes will also become more prevalent. In 1980, 5.6 million people in the United States had a diagnosis of diabetes; 31 years later in 2011, that number had almost quadrupled to 20.9 million.[79] Patients with diabetes mellitus have an increased risk of adverse postoperative outcomes and are at risk for nephropathy, cardiovascular disease, cerebrovascular disease, dental disease (periodontitis), peripheral vascular disease, and neuropathies.[80] The American Heart Association places diabetics in the same

high-risk category as patients with known coronary artery disease.[81] Diabetics are more likely to have ischemic disease without the accompanying chest pain (silent ischemia).[82] As such, a patient with diabetes may require ECG or other cardiac workup before their anesthetic. Other preoperative evaluations could include a basic metabolic panel to evaluate abnormalities associated with glucose shifts, as well as baseline renal function, which can be compromised because of diabetic nephropathy. Optimization of preoperative glycemic control is also important and is evaluated by the Hgb A1c laboratory value. An A1c value less than or equal to 7 indicates average blood glucose of less than 154 over the 120-day life cycle of the average red blood cell. Patients with A1c values greater than 8.0 should be referred back to their endocrinologist and have elective surgery deferred until better glycemic control is attained.[83]

Perioperative and intraoperative glucose management should include cessation of pharmacotherapies that can increase the likelihood of undesirable side effects. Metformin, in the setting of dehydration, can lead to lactic acidosis, and although this is a rare complication, it carries a high mortality rate (50%).[84] Postoperative insulin can be required in patients who have previously taken only oral hypoglycemics. This allows for appropriate control of blood glucose in the setting of altered oral nutrition and/or difficulty with pill swallowing early in the postoperative period. Initially, a sliding scale with regular insulin may be implemented, but this insulin regimen should be transitioned to include longer-acting insulin. Specific recommendations can be found in articles specific to hyperglycemia management of the non-ICU patient.[85] Often, the patient's endocrinologist is consulted to help with glycemic control in the early postoperative period and to help with planning for future home glycemic control.

As insulin pumps are increasingly used for glycemic control, the surgeon and anesthesiologist will need to develop a plan for their management. It has been demonstrated that the intraoperative and postoperative continuation of insulin pumps is safe and effective for glucose control provided there is proper glucose monitoring to avoid hypoglycemic episodes.[86,87]

Thyroid disease often manifests when patients are in a hyperthyroid or hypothyroid state. Signs and symptoms of hypothyroidism include cold intolerance, dry skin, fatigue, and bradycardia. Conversely, hyperthyroidism may manifest as heat intolerance, unexplained weight loss, anxiety, muscle tremor, tachycardia, and the characteristic exophthalmos of Graves disease. Both hyper- and hypothyroid patients can have changes in the overall shape of the thyroid gland, which can have implications for intubation if the thyroid is enlarged and impinging on the trachea.[88] Changes in the patient's voice should raise concerns for this rare presentation. Hypothyroid and hyperthyroid states should be resolved under the direction of an endocrinologist, and the patient should be euthyroid as evidenced by laboratory testing of thyroid-stimulating hormone (TSH), thyroxine and triiodothyronine (T_4, T_3), and free T_4 before surgery.

Patients with a history of chronic steroid use can raise concerns for adrenal insufficiency. Traditionally, stress-dose steroids have been recommended for patients who have been taking daily doses for over 2 months that exceed 5 mg prednisone, 25 mg hydrocortisone, 4 mg triamcinolone, or 0.75 mg dexamethasone. The stress dose recommended is 50 mg hydrocortisone IV (single dose) for minor surgery, and 50 mg hydrocortisone IV every 8 hours for 40 to 72 hours for major surgery.[88-90] However, as recently as 2013 the necessity of stress dose steroids has been questioned because of the paucity of evidence that supports this practice.[91] The surgeon should, at a minimum, be familiar with the various steroids and their equivalent doses (Table 16-6).[92] Many surgeons incorporate perioperative steroids for the orthognathic patient, because they have been shown to aid with postoperative pain, swelling, trismus, and nausea/vomiting.[93,94] Dosing regimens range from a single intraoperative dose to multiple doses following the procedure.

Finally, the adult orthognathic patient who presents with progressive development of class III open bite should be questioned further regarding changes in finger/ring size, foot/shoe size, and/or vision suggestive of acromegaly. These patients will require further workup including serum levels of insulin-like growth factor 1 (IGF-1), growth hormone, and possible MRI depending on lab results to evaluate for a pituitary tumor.

"Routine" Preoperative Laboratory Testing

The population of patients seeking jaw surgery spans differing ages and medical conditions. The majority of young, healthy patients undergoing straight forward single jaw surgery are not likely to require from any preoperative testing. However, the appropriate preoperative testing depends on each individual patient's condition and risk for both the specific procedure(s) and anesthetic technique. Laboratory values including a complete blood count (CBC) to check hematocrit/hemoglobin as well as platelet count, coagulation studies (PT/PTT/INR). A bone morphogenetic protein (BMP) level with its accompanying electrolyte levels,

TABLE 16-6 Equivalent Steroid Dosages

Steroid	Equivalent Dose
Betamethasone	1.2 mg
Dexamethasone	1.5 mg
Methylprednisolone	8 mg
Triamcinolone	8 mg
Prednisone	10 mg
Prednisolone	10 mg
Hydrocortisone	40 mg
Cortisone	50 mg

glucose level, and renal function studies may also be appropriate. In addition to patient/procedure specific labs, ECG and chest radiographs can be considered in preoperative evaluation.

Postoperative Management

Postoperative management should include regimens to control pain, nausea, hemostasis, edema, infection, psychological adjustment, occlusion, nutrition, paresthesia, local wound care, and activity. This includes the identification and management of early postoperative complications.

Pain Control

Some surgeons advocate preoperative administration of analgesics. Tuzuner performed a prospective study of orthognathic patients who were randomized to receive preoperative tramadol, diclofenac, or saline. Less analgesic was required for postoperative pain control in the treatment group, without difference between the different medications, as compared to the placebo group.[95] Administration of corticosteroids has also been shown to aid in decreasing postoperative pain.[96] Prior to anesthetic emergence, additional long-acting local anesthesia can be injected at the surgical sites. Although the neuropraxia resulting from the surgery should theoretically leave the patient without pain, some patients will still complain of pain beginning immediately after surgery—and as all maxillofacial surgeons are aware, there is no substitute for adequate local anesthesia.

Early postoperative pain control is best accomplished with intravenous medications including a combination of nonsteroidal anti-inflammatory drugs (NSAIDs), acetaminophen, and opiates for breakthrough pain. As the patient increases oral intake, pain regimens should be transitioned to the oral route, with IV options remaining in place as needed. Changing to orally administered medications allows the team to develop a regimen for pain control that is easily transitioned to home care. Opiate medications for postoperative analgesia should be readily tapered to non-opioid regimens to avoid negative side effects such as nausea, constipation, and addiction.

Nausea

Postoperative nausea and vomiting (PONV) is quite common and occurs in approximately 41% of orthognathic patients in the first 24 hours after surgery.[97] A recent study of 252 consecutive orthognathic cases at University of North Carolina documented postoperative nausea in 67% of patients and 27% with episodes of emesis.[98] This is usually be attributed to one of the following triggers of PONV: intraoperative use of inhalational anesthetics (centrally mediated at the chemotactic trigger zone [CTZ]), oral bleeding that is swallowed during surgery or postoperatively (gastric irritation), or use of postoperative opioids (also at the CTZ).

It is important to note that some of the demonstrated factors that increase incidence of postoperative nausea include female gender, the use of nitrous oxide as an anesthetic component, the length of surgery, dehydration, and postoperative use of morphine for pain control.[79] There exist both pharmacologic and mechanical methods of treating PONV. On the preventative front, meticulous hemostasis with repair of any nasal mucosal lacerations and well-approximated mucosal wound closure will reduce the amount of blood that is swallowed postoperatively. In addition, an orogastric (or a carefully passed nasogastric) tube may be placed in order to empty the stomach and removed before emergence/extubation. Some surgeons elect to maintain a nasogastric (NG) tube overnight following surgery. This can be placed on intermittent-low wall suction and may prevent accumulation of blood in the stomach and avoid the gastric irritation that can result. It is the authors' opinion, however that the presence of the NG tube is irritating and may lead to agitation and nausea.

Pharmacologic treatment of nausea typically consists of ondansetron, droperidol, and/or promethazine. Adult doses of ondansetron (a 5HT-3 receptor antagonist) as an antiemetic will range from 4 to 8 mg and may cause constipation, especially in combination with the narcotics often used for pain control.[99] Therefore, when both are administered, a laxative or stool softener should also be considered. Another possible complication associated with the administration of ondansetron is the potential for QT interval prolongation that can lead to arrhythmia, particularly in patients at high risk for torsades de pointes.[100] Droperidol (a potent dopamine D_2 antagonist with some additional antagonist activity at histamine and serotonin receptors) is given in doses as low as 0.625 mg for its antinausea effects. Like ondansetron, it has a black box warning due to the potential for QT prolongation. Promethazine (a first-generation antihistamine) is given in doses ranging from 6.25 to 25 mg per dose. Because of the antihistamine effects, sedation is a side effect that may not be desired. Studies have shown that a dose of 6.25 mg is effective in quelling PONV and results in decreased sedation compared with higher doses.[101] Intravenous and rectal routes are available (in addition to oral) for the nauseated patient. IV promethazine should be diluted and delivered slowly due to the tissue injury that can otherwise result.[102]

While orthognathic surgery is associated with high rates of PONV, proper communication with the anesthesia care team can help mitigate this undesirable side effect. Other multimodal therapies have been used to decrease PONV, such as that by reported Anderson and colleagues. This study demonstrated that the use of TIVA with administration of ondansetron, droperidol, steroids, scopolamine, gastric decompression, postoperative avoidance of opioids, administration of prokinetic erythromycin, and maintenance of IV fluids at a minimum of 25 mg/kg decreased postoperative nausea from 70% in the control group to 24% and postoperative vomiting from 28% to 11%.[103]

Various combinations of this therapy can be tailored to the specific patient and procedure.

Hemostasis

When addressing postoperative bleeding, it is important to consider the site, severity, and thus possible source. Slow oozing from the incision sites is common and can usually be halted with gentle pressure. Hematomas are rare but can develop in the hours following surgery. The most concerning is a floor-of-mouth hematoma (following a genioplasty), which can cause airway distress/embarrassment.[85] Once identified, it may require evacuation; this should be accomplished in a controlled setting and includes an attempt to identify the source of bleeding before closing. If concern for airway compromise exists, the patient may require prolonged intubation.[104]

Postoperative nasal bleeding can be common, such as dark blood draining from the nose associated with tears in the nasal mucosa or residual blood from within the maxillary sinuses. However, bright red blood, brisk bleeding, or large volumes may indicate an active bleeding venous or arterial source (Table 16-7).[105] Delayed bleeding (presenting 1 to 2 weeks postoperatively) is often due to a descending palatine vessel wall injury that occurred at the time of surgery.[106] Fortunately, hemorrhagic complications are rare, occurring in less than 1% of patients for both Le Fort I and bilateral sagittal split osteotomies and 1.2% for intraoral vertical ramus osteotomies.[107-110] Depending on the clinical presentation, the patient may require hemostatic interventions including head of bed elevation, topical pharmacologic treatment (oxymetazoline, phenylephrine, topical thrombin), local mechanical measures (nasal packing anterior and/or posterior), return to the operating room for exploration and direct control, or interventional radiology (IR) for select embolization. The setting of treatment (bedside, OR, IR) should be determined by the stability of the patient, severity of bleeding, and access to appropriate equipment.

TABLE 16-7 Skeletal Structures and Associated Vasculature

Skeletal Structure	Arterial	Venous
Maxilla (Le Fort I)	Internal carotid Internal maxillary Descending palatine Sphenopalatine	Pterygoid plexus
Mandible (BSSO/IVRO)	Masseteric Facial Inferior alveolar	Retromandibular Facial Inferior alveolar
Mandible (genioplasty)	Sublingual	Deep lingual

BSSO, Bilateral sagittal split osteotomy; *IVRO,* intraoral vertical ramus osteotomy.

Edema

Postoperative edema following orthognathic surgery can be significant and alarming to patients and their families. Swelling often persists for many weeks, with approximately 50% resolving by 3 weeks.[111] Phillips and colleagues demonstrated in a prospective study of 170 patients that 75% of orthognathic patients experience minimal (if any) problem with swelling by day 22 after surgery. Of the remaining 25%, only 10% stated that the swelling was substantial, and by postoperative day 30 this number decreased to only 3%.[112] In order to minimize postoperative edema, care should be taken with intraoperative intravenous fluids to avoid volume overload.[113] Dissection should be limited to only the regions required, avoiding wide undermining of the soft tissues. Control of bleeding throughout surgery helps limit extravasation of blood into soft tissues that can contribute to postoperative ecchymosis and inflammation.

Administration of corticosteroids, when not contraindicated because of comorbidities such as diabetes, can help subdue some of the postoperative edema. The administration of steroids, in combination with hypotensive anesthesia and rigid fixation, has also been shown to correlate with decreased length of hospitalization following orthognathic surgery.[114] Steroids most often used include dexamethasone, methylprednisolone, and betamethasone; they are administered in various dosing regimens ranging from a single dose to three doses over 24 hours.[115,116] When selecting a glucocorticoid, the surgeon should be aware of the mineralocorticoid effect of the specific steroid used, as each has a different profile of activity in this regard (Table 16-8).[117] This mineralocorticoid effect will cause aldosterone-like effects on sodium (and therefore extracellular fluid) retention as well as a slight hypokalemia and alkalosis. The administration of steroids is not without controversy due to their potential (albeit rare) side effects, including avascular osteonecrosis, adrenal suppression, psychosis, decreased healing potential, and gastric ulceration (especially in light of concomitant stress and NSAID administration).

TABLE 16-8 Relative Glucocorticoid and Mineralocorticoid Activities

Steroid	Relative Glucocorticoid Activity	Relative Mineralocorticoid Activity
Cortisol	1.0	1.0
Cortisone	0.8	1.0
Prednisolone	4	0.8
Methylprednisolone	5	Almost 0
Dexamethasone	30	Almost 0

Cortisol is arbitrarily assigned a value of 1.0.

Cold temperature can help to soothe and cool the mid/lower face and decrease edema. Various types of cooling therapy can be applied, ranging from ice packs to coolant-infused polar packs that ensure cold therapy for a longer duration. Care should be used, however, to avoid any prolonged, extreme cooling of the skin that can lead to epithelial damage over areas with hypoesthesia due to surgery. Additional noninvasive measures such as facial support stockings and elevation of the head of bed can also aid in minimizing edema.

Infection

As with any surgery, early (first 24 hours) low-grade fevers are assumed to be due to atelectasis.[118] In the weeks that follow, signs of fever, swelling, or drainage from the incision sites are concerning for surgical site infection, including infected hardware or bone grafts. Fortunately, early infections are quite rare and are most often minor and managed with oral antibiotics, nasal decongestants, and local irrigation/wound care. Occasionally, more severe infections may require debridement and bone grafting.[105] Immunocompromised hosts (e.g., diabetics, chronic steroid users) and tobacco users are at higher risk for infection. One study by Thorén and colleagues indicated that smoking significantly increases the risk of infection following orthognathic surgery.[119] A 2015 Cochrane database review of antibiotics and orthognathic surgery showed some benefit in long-term (defined as greater than 24 hours after surgery) antibiotics for the prevention of infection in orthognathic surgery.[120] This same analysis failed to show a significant difference in prevention of postoperative infection between short-term (24-hour) regimens and a single presurgical dose of antibiotics. For these clean-contaminated procedures, a Peridex oral rinse before injections/incisions and a preoperative antibiotic administered within 1 hour before incision are recommended.

Psychological State

Most patients are excited regarding their postoperative appearance/changes; however, occasionally these changes in appearance—even if they help conform to cephalometric norms and appear esthetically pleasing to others—can be quite distressing to a patient. The patient should be forewarned that they are likely to experience an emotional low as the effects of the steroids wane in the days following surgery. Reassurance and positive reinforcement by the entire surgical team can help, but this may not be enough to combat postoperative despondency, or in some cases even depression. Prompt referral to appropriate resources such as a psychiatrist or psychologist is necessary in instances where there is any concern about the patient's psychological state following surgery. It is also the surgeon's responsibility to help the patient understand that their feelings are a part of the postoperative healing process and that the patient can be helped by mental health care professionals.

Dentition/Occlusion

Many surgeons use a splint for determining the final occlusion. Some surgeons elect to wire the splint into the maxilla or mandible for a number of weeks (2 to 6) following surgery, especially if the final position does not result in a balanced occlusion. Splints are generally left in place for 6 weeks following segmental surgery to help aid in what is a relatively unstable movement in the hierarchy of stability (maxillary expansion). Methods of stabilization may include a rigid splint that is thick or incorporates a transpalatal wire or strap, or the use of additional heavy wire ligated to molar headgear tubes (Figure 16-4).

Archwires that are cut during surgery for segmental surgery should be replaced postoperatively by the patient's orthodontist with a continuous archwire. Orthodontic tooth movement is often delayed for 6 weeks postoperatively, by which time osteotomy consolidation has occurred and the occlusal splint, if used, has been removed. However, as previously discussed with the "surgery-first" treatment, some orthodontists prefer early orthodontic movements after surgery based on the regional acceleratory phenomenon.

Elastics can be used to guide the operated mandible into the correct condylar position, can help with patient comfort by supporting closure of the mandible, and can begin to "settle" the occlusion if no splint is present. The configuration of elastics may vary over time depending on the desired changes to the occlusion. Nomenclature for placement of elastics is based on the malocclusion that would be addressed by the vector of pull. For instance, class II elastics will have a vector pulling the mandible forward with the elastic engaging a maxillary orthodontic lug anterior to the mandibular lug. However, elastics should be used with caution if the patient has an operated maxilla against an unoperated mandible. They are of limited use because the unoperated mandible has no need to undergo manipulation with elastics as the condyles have not been repositioned. Second, the

• **Figure 16-4** Patient with final splint in place. The patient had adequate surgical orthodontic lugs for elastics as needed and maintained good hygiene around a low-profile splint secured with six 24-gauge wires (central incisors, canines, and first molars).

force generated from an intact mandible in elastics against an operated maxilla may exceed that which is tolerated by the maxillary fixation.

Loss of fixation may be demonstrated by postoperative films, rotation of the proximal segment of the mandible, mandibular deviation to the fractured/failed side, or mobility of the maxilla. Treatment is by washout and replacement of fixation, heavier fixation, and/or IMF.

Diet

The patient should be prepared for their postoperative, non-chew diet before surgery. Generally, the diet for the first 6 weeks should consist of liquid or soft, non-chew foods (e.g., mashed potatoes, scrambled eggs) with a high caloric and protein content. The Internet is an excellent resource for "jaw surgery cookbooks."[121] After 6 weeks, the patient can progress over the next month to a regular diet. Any mobility or concern regarding fixation may require continuation of the soft diet (and possibly liquid diet with MMF) to prevent non-union or a fibrous union.

It is important to remind the patient that calories are easy to come by on a liquid or non-chew diet, but that the source of calories is very important. The amount of protein in a diet varies depending on many factors, but in general the post-surgical diet should include 1 to 1.8 g/kg/day for ideal body weight of protein. Proper nutrition consists of 10% to 35% proteins, 45% to 65% carbohydrates (avoiding simple sugars in place of complex carbohydrates), and limiting fat content to below 30% (with trans fatty acids <10%).[122,123] Recommendations to attain proper caloric intake include protein supplementation through a powder additive to shakes, or Ensure/Boost supplements. Vitamins and trace elements are also a crucial part of the healing process. For example, vitamin C is imperative for collagen production. Some weight loss is to be expected, but should be closely monitored as healing is an anabolic process and will require a surplus of calories. If the patient is losing weight, additional supplementation should be recommended, which can often be accomplished through smaller, more frequent meals.

The use of straws should be avoided for the first 2 weeks following surgery to prevent generation of intraoral negative pressure. Negative pressure can add to incision breakdown or dehiscence, and straws can be quite difficult for a patient to use because of the V2/V3 hypoesthesia. Instead, encourage the patient to use a regular spoon and drink from a regular glass or cup. Occasionally, a patient may require feeding syringes to help accommodate postoperative ingestion of fluids and soft foods. Some patients experience difficulty swallowing with a hypoesthetic velum following a Le Fort osteotomy and/or and insensate tongue after retraction of the lingual nerve during mandibular surgery. The best treatment for these patients is reassurance and continued encouragement.

Paresthesia

The paresthesia expected in the inferior alveolar, infraorbital, and occasionally lingual distributions should be discussed in detail with the patient—including the possibility of permanent paresthesias. Sensation generally begins to return from the superior aspect to the inferior aspect, with the chin/lip being the last region to return. Return of sensation will likely take weeks to months. If the patient expects this, they are not alarmed when they have residual paresthesias several weeks after surgery. A 2011 meta-analysis of studies showed that following a BSSO, 63% had neurosensory disturbance (mental distribution) at 7 days, 49% at 14 days, 42% after 1 month, 33% after 6 months, and 12.8% at 1 year.[124] More importantly, in most cases the area of permanent paresthesia is quite small and does not appear to affect quality of life. One study demonstrated that 98% of BSSO patients with long-lasting neurosensory disturbance still stated that they would undergo surgery again and recommend it to other patients.[125] Additionally, sensory retraining exercises have proven to have a beneficial effect on patients' perceived hypoesthesia and can be implemented in the early weeks following orthognathic surgery.[126]

Intraoral Wound Care

It is paramount that the patient understand the importance of postoperative hygiene—and that they maintain it. A mouth full of debris on orthodontic appliances, occlusal splints, and/or the dentition is a setup for wound dehiscence, exposed hardware, postoperative infections, and other complications. Patients often require frequent encouragement, and sometimes demonstration or assistance postoperatively, in order to better understand expected postoperative hygiene. Twice daily Peridex rinses can also aid with maintenance of oral hygiene, especially in patients with a splint in place or in IMF. Follow-up visits should also be used to re-demonstrate proper hygiene as necessary. The mucosa should be healed before use of a Water Pik, which is a rather common patient inquiry.

Each postoperative visit also includes examination of the dentition, supporting gingiva, and incision sites (for dehiscence). Dusky tissue concerning for venous congestion and pale tissue suggestive of arterial insufficiency both indicate vascular compromise. Tissue perfusion/drainage concerns should be addressed immediately, as this can be a precursor to delineation of a necrotic segment. Management includes removal of anything (such as a splint) that may be impinging on the tissue, placement of tissue dressing such as Vaseline-impregnated gauze, elimination of any mobility, and close monitoring.[127]

Nasal Care

Patients should be instructed to avoid nose blowing for a minimum of 2 weeks (provided maxillary surgery was

performed). Nose blowing can cause subcutaneous emphysema via expressed air through the osteotomies and into the submucosal tissues. It can also cause bleeding due to disruption of the healing membranes/mucosa. Oxymetazoline can be used to help with congestion in the first 48 to 72 hours following surgery, after which it should be stopped to avoid rhinitis medicamentosa. The patient can continue to use nasal saline to keep nasal passages clear and moist. After 2 weeks, the patient can usually begin to gently blow their nose.

Postoperative deviation of the septum can occur following Le Fort surgery. This is generally associated with inadequate stabilization of the septum at the time of surgery (septal anchoring stitch), insufficient resection/contouring of the nasomaxillary crest, or displacement at the time of extubation. The deviated septum can be repositioned under sedation and supported with the placement of sutures, nasal packing, or stents (Figure 16-5). If packing is used, prophylactic antibiotic coverage is recommended to avoid the unlikely but severe complication of toxic shock syndrome.

Extraoral Wound Care

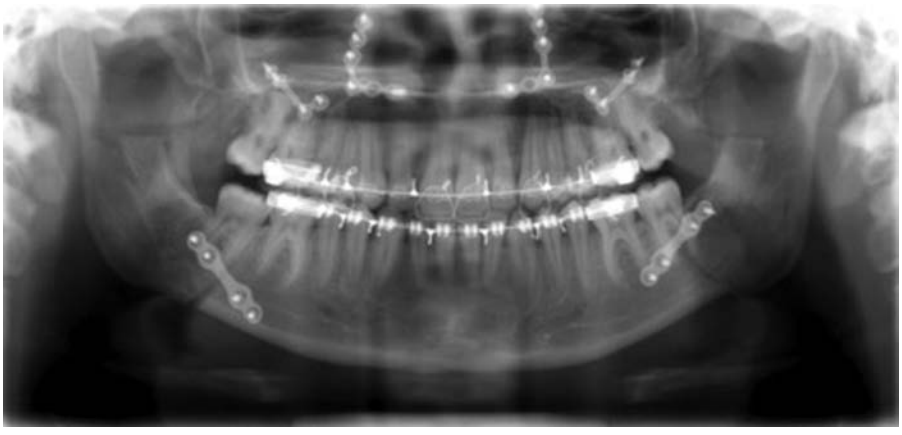
If cutaneous incisions were used (trocar or approach to the mandible for inverted-L or C osteotomies), they should be placed symmetrically in resting skin tension lines. Postoperative wound care with regular cleansing and the maintenance of a moist wound-healing environment will attain the best cosmetic result. If nonresorbable sutures are present, they should be removed 5 to 7 days postoperatively. Once primary epithelialization is complete, application of SPF moisturizer (30+ or greater) and massage will help to limit pigmentation and speed scar maturation. Scar creams and ointments (e.g., Mederma, vitamin E, copper, silicone gel, or sheeting) are used in accordance with patient/surgeon preference. The incisions should be evaluated for 6 to 9 months for undesirable healing, which may require intervention (steroid injection, dermabrasion, or laser therapy).

Activity

Patients undergoing single-jaw surgery should plan on at least 1 week off from normal activities including work, school, and exercise. With increasing complexity of condition and surgical treatment comes an expectation of longer convalescence. Patients should be encouraged to avoid strict bed rest, as this can lead to problems with their pulmonary condition and venous stasis or deep vein thrombosis. Patients should walk throughout the day (although initially they will likely require someone at their side because of effects of anesthesia and narcotics). Normal activities should be resumed slowly, beginning with school and work (non-strenuous). Exercise should be avoided for the first 2 to 4 weeks and then can be resumed beginning with light exercises. Patients often need to be reminded to resume activities slowly, and that it may require up to 4 to 6 months to return to presurgical levels of fitness. Activities with the potential for contact to the head and neck region (such as basketball) should be avoided for the first 6 to 8 weeks to allow for bony union and healing.

Facial Exercises

After the first 2 weeks, patients can be instructed to perform reanimation exercises. These mimetic exercises should be performed in front of a mirror. Activities such as a big smile and lip pursing can help to restore the full function of the facial muscles that are divided during surgery.



• **Figure 16-5** Panoramic image demonstrating a deviated nasal septum following a Le Fort I advancement with posterior impaction and a bilateral sagittal split osteotomy advancement. The posterior nasal septum was inadequately reduced, resulting in posterior nasal septal deviation.

Summary

Patients undergoing orthognathic surgery require detailed preparation in the orthodontic, medical, and surgical domains. The surgeon must develop a perioperative plan with the patient's input and guide the patient through any unforeseen complications. It is vital to maintain the patient's confidence through honesty and candor. This will prevent miscommunication and misrepresentation of the surgical process and give the conscientious patient realistic expectations as to the necessary preparation, recovery, and outcomes associated with orthognathic surgery.

Mandibular Surgery: Prevention and Management of Complications

INGEBORG M. WATZKE

Introduction

An old surgical adage indicates that if you have not encountered any complications you have not performed enough surgery yet. Any type of surgery involves a certain risk of complications. The latter may occur at any time during the surgical procedure, or may be a consequence of improper presurgical treatment. Complications are unforeseen events not expected under normal circumstances, resulting in greater morbidity of the surgical procedure. The frequency and severity of complications in mandibular surgery are generally low. Most complications, such as hemorrhage or unanticipated bone split can be sufficiently controlled and corrected during surgery. Others, such as injury to the inferior alveolar nerve, require additional postoperative treatment. Informing the patient about such complications is crucial—not only for medical legal reasons but also to enhance the patient's cooperation in postoperative therapeutic measures.[1]

Orthognathic surgery is considered safe and has been used for a long time, especially in the mandible.[2] Many of its complications can be predicted and prevented easily. The crucial element in prevention is careful treatment planning and excellent technical training for the achievement of a favorable functional and surgical outcome. Reviews have reported various outcomes, depending on their date of publication. This might be the consequence of better trained and more skillful surgeons and better understanding of surgical management. In a retrospective study published in 1996, Van de Perre[3] registered a 10% complication rate in 2047 patients; these included one death and 39 largely life-threatening complications. In another retrospective study, Panula[1] registered a 0.16% rate of serious complications in 655 patients. Ayoub[4] reported a complication rate of 6.8% in 821 patients; no serious or rare events were observed. In 2007 Chow[5] registered a complication rate of 6.7% in 1294 patients; 7.4% of these were related to postoperative infections. In 2012 Steel[6] et al. searched the published literature for unusual and rare complications and found that "complications are rare in orthognathic surgery although it does involve a number of rare risks, depending on the exact techniques used." In 2013 Iannetti[7] reviewed 3236 patients and found the following immediately after surgery: neurosensory deficits in 19%, bone fractures in 1.5%, infection in 2%, TMJ dysfunction in 11%, and miscellaneous nonsevere complications in 0.16%. He stated that orthognathic surgery is quite safe, and that some complications were related to the surgeon's experience and not strictly to the operation itself. Today complications in orthognathic mandibular surgery are rare and severe complications quite infrequent.

Common Risk Factors Influencing the Frequency of Complications

General risk factors may cause intraoperative complications or postoperative problems during any surgical procedure. The WHO defines risk factors as follows: *A risk factor is any attribute, characteristic or exposure of an individual that increases the likelihood of developing a disease or injury.* Risk factors include obesity, hypertension, and alcohol or nicotine abuse. Any of these risk factors could cause impairment during or after an operation.

Nicotine Abuse

Tobacco use has been associated with poor gingival healing, periodontal disease, stomatitis, leukoplakia, and oral cancer.[8] Smoking or secondary smoking is a risk factor that affects wound healing processes in the gums. Smoking is associated with postoperative wound healing complications,[9] a higher incidence of postoperative nausea and vomiting, and a higher risk of postoperative infection.[10] Mechanisms responsible for these effects have not been fully elucidated. Tobacco smoke contains a complex variety of compounds, all of

which—and not nicotine alone—are responsible for vasoactive and other effects. Toxic constituents include nicotine, carbon monoxide, and hydrogen cyanide. Tissue perfusion is reduced by vasoconstriction due to nicotine. Tissue oxygenation is decreased because carbon monoxide binds to hemoglobin 200 times more strongly than oxygen. The enzyme system responsible for oxygen transportation is blocked by hydrogen cyanide, which further reduces the oxygenation of tissue. Wound healing is the physiologic response to any disruption of surface integrity, and occurs in four overlapping phases: hemostasis, inflammatory phase, proliferative phase, and maturation. A chronic wound may develop when any of these stages is altered. Wound healing may also be compromised by infection. Infection is a serious complication in orthognathic surgery, associated with adverse postoperative outcomes. (See Infection section in this chapter.)

Venous Thromboembolism

Venous thromboembolism (VTE) is a dreaded complication of many surgical procedures. Its incidence depends on predisposing factors in the patient as well as process-related risk factors. Knowledge of these factors enables the surgeon to estimate the overall risk and assess the need for prophylactic measures. When prophylactic measures are undertaken, the risk of their side effects, such as a higher risk of hemorrhage, must be included in the overall assessment.

Intervention-related Risks of Orthognathic Surgery

The intervention-related risks of orthognathic surgery are poorly investigated; we have data from three retrospective studies and one small prospective study (Table 17-1). A total of 6716 patients were investigated.[11-14] The incidence of thromboembolic events was 9/6716, which amounts to approximately 1/1000. One significant limitation of these studies is that the majority of thromboembolisms occurred immediately post-surgery; those that possibly occurred later and were also caused by the intervention were not registered. Three of the 10 patients with thromboembolisms had risk factors for perioperative thromboembolic complications.

Registration of Patient-related Risk Factors for Perioperative Thromboembolism

Several scores have been developed for the registration of patient-related risk factors for perioperative thromboembolism. The scores are based on studies in which the occurrence of VTE in relation to personal risk factors was investigated for various surgical interventions. The score developed by Caprini[15] for the assessment of patient-related risks is recommended by the Guidelines of the American Colleges of Chest Physicians.[16] A total of 35 risk factors were included in this score. Each risk factor is assigned a specific number of points. The total score determined for the existing risk factors in a patient indicated the individual's personal risk of developing a perioperative thromboembolism (Table 17-2).

In the adaption of this model by the ACCP, the risk of VTE is rated very low (0-1 point), low (2 points), moderate (3-4 points), or high (≥5 points). Although the model was not developed using rigorous statistical methods, it is relatively easy to use and appears to permit a fairly clear distinction between patients with a low, moderate, or high risk of VTE.

TABLE 17-1 Incidence of Venous Thromboembolism (VTE) in Orthognathic Surgery

Author	Patients (n)	TE (n)	Incidence%
Van de Perre[11]	2049	3	0.15
Blackburn[12]	129	2	1.55
Forouzanfar[13]	411	2	0.48
Verlinden[14]	4127	2	0.05
Total	6716	9	0.13

Procedure in Orthognathic Surgical Interventions

Assuming an incidence of approximately 1:1000 for the intervention-related risk of orthognathic surgery,[11,14] patients with a low personal risk (Caprini score of 0-2) were below this level and would therefore not benefit from pharmacologic prophylaxis.

A risk of 60/1000 (corresponding to a Caprini score of 7-8) is reported for patients with a high personal risk when undergoing plastic surgery,[16] which has an intervention-related risk similar to that for orthognathic surgery. Thus, these patients would benefit from pharmacologic prophylaxis.

Sagittal Split Osteotomy (SSO)

Complications in orthognathic surgery may be divided into three categories: preoperative, perioperative, and postoperative.

Preoperative Complications

Laboratory errors such as false bite registration, incorrect mounting of casts, or improper model surgery may serve as the starting point of subsequent complications and a poor surgical outcome. Accurate diagnosis, treatment planning and appropriate preoperative orthodontic treatment are crucial factors for a stable and favorable esthetic outcome.

Accurate Diagnosis

Correct diagnosis and interdisciplinary treatment planning is a prime goal and a crucial element of successful long-term results. An accurate diagnosis prior to treatment determines the surgical procedure and the esthetic outcome.

Surgery in one jaw limits surgical bone movement of the lower jaw when dental compensation is insufficient. Correct orthodontic and surgical treatment, planned by the

TABLE 17-2 Risk Factors for Perioperative Thromboembolism

1 Point	2 Points	3 Points	5 Points
Age 41-60 y	Age 61-74 y	Age ≥ 75 y	Stroke (< 1 mo)
Minor surgery	Arthroscopic surgery	History of VTE	Elective arthroplasty
BMI >25 kg/m^2	Major open surgery (> 45 min)	Family history of VTE	Hip, pelvis, or leg fracture
Swollen legs	Laparoscopic surgery (>45 min)	Factor V Leiden	Acute spinal cord injury (< 1 mo)
Varicose veins	Malignancy	Prothrombin 20210A	
Pregnancy or postpartum	Confined to bed (>72 h)	Lupus anticoagulant	
History of unexplained or recurrent spontaneous abortion	Immobilizing plaster cast	Anticardiolipin antibodies	
Oral contraceptives or hormone replacement	Central venous access	Elevated serum homocysteine	
Sepsis (< 1 mo)		Heparin-induced thrombocytopenia	
Serious lung disease, including pneumonia (< 1 mo)		Other congenital or acquired thrombophilia	
Abnormal pulmonary function			
Acute myocardial infarction			
Congestive heart failure (< 1 mo)			
History of inflammatory bowel disease			
Medical patient at bed rest			

VTE, venous thromboembolism. (Data Originally Published by Caprini 1991[15] and Modified by Gould 2012[16].)

orthodontist and the surgeon, are mandatory for a stable and esthetic outcome.

Inadequate preoperative orthodontic treatment and its failure may hinder a favorable surgical outcome and result in unstable occlusion.

Treatment Planning

Computer-aided and virtual planning[17] with intraoperative occlusion-based positioning systems appear to provide more accurate surgical results.[18] The authors state that virtual planning and the use of computer-aided manufacturing technology have improved preoperative assessment and surgical outcomes. Treatment time and operating time also were reduced. A recent study by Zinser[19] compared three planning systems. They found that CAD/CAM designed splints showed the highest precision for maxillary planning transfer and kept the condyles in their central position in the temporomandibular joint. They stated that CAD/CAM splints and surgical navigation were an alternative approach to the use of classic intermaxillary occlusal splints. However, long-term accuracy and stability as well as cost implications will have to be investigated in the future.

Preoperative Orthodontic Treatment

Orthodontic dental compensation and adequate transverse coordination are essential. Tooth size discrepancies may hinder proper adjustment of the mandible and the maxilla at the time of surgery. Insufficient orthodontic appliances or active orthodontic wires may be a significant problem for the surgeon.

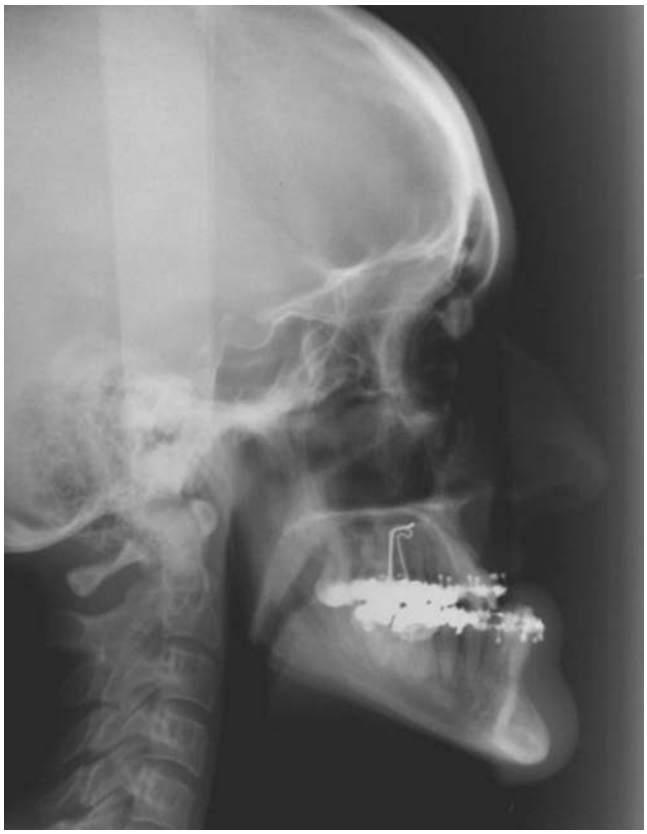
Transverse Discrepancies

Severe discrepancies of the maxilla and the mandible that cannot be corrected by orthodontic treatment alone require bimaxillary surgery (Figures 17-1 and 17-2). This decision must be made prior to orthodontic treatment. In patients with the maxilla in correct vertical or sagittal position, surgical palatal expansion is an option in adults whereas conventional orthodontic therapy might be successful in children.

In adults, orthodontic expansion beyond a few millimeters will produce either buccal tipping of the maxillary molars or lingual tipping of the mandibular molars (Figure 17-3). The molars are likely to collapse when orthodontic devices are removed, leading to crossbite or an open bite. Handelman[20] found several patients with post-surgical elongation of the molars as they tipped back to their original position. This led to clockwise rotation of the mandible and an open bite condition after surgery. Therefore, expansion of the maxilla after closure of the maxillary suture should be performed under surgical assistance, using a palatal appliance (surgically assisted rapid palatal expansion, SARPE) (Figure 17-4).

Transverse discrepancies in the *canine* region do not permit advancement of the mandible into a correct dental class I position, resulting in an increased overjet and dental class II.

In patients with transverse discrepancies and severe dental crowding, especially in the front region, SARPE will be the choice of treatment even in those who need Le Fort I osteotomy as a second procedure because of sagittal or vertical problems (Table 17-3).



• **Figure 17-1** Severe class III malocclusion requiring combined surgical orthodontic treatment.

• **Figure 17-2** Severe open bite malocclusion requiring combined surgical orthodontic treatment.

Incisor Inclination and Leveling Curve of Spee

Correct incisor inclination in relation to chin position is crucial for a stable functional as well as a good esthetic result. Protruded incisors have to be retroclined before surgery in patients with neutral chin position. This can be achieved either by extraction of premolars or by extraction of one incisor (Figure 17-5). In a patient with a protruded chin incisor inclination can be more than 90 degrees to the mandibular plane to give a good esthetic result (Figure 17-6).

The timing of leveling the curve of Spee prior to surgery or post-surgery depends on the patient's anterior face height. In patients with a short face, leveling should be performed after surgery by premolar extrusion. In patients with a normal anterior face height it should be performed prior to surgery by intrusion of the incisors and extrusion of the premolars. In patients with a long face, intrusion of the incisors should be performed prior to surgery even when it involves reducing the anterior face height with additional genioplasty (Table 17-4).

Cases

In the presence of a moderate to severe mandibular deficiency, and proclined lower incisors, the ideal position of the mandibular anterior teeth is best achieved by extraction of premolars. This creates space for correct inclination of the incisors. However, this is not true of all patients with a mandibular deficiency and greatly depends on the position of the chin.

Patients with a "strong" chin need more incisor protrusion (Figure 17-7) than those with a "weak" chin. If the incisors are tipped back to a 90 degree position to the mandibular plane, the chin will be too protruded after mandibular advancement (Figure 17-8). Reduction of chin projection with genioplasty yields poor esthetic results (Figure 17-9).

Patients with chin hypoplasia and incisor protrusion will benefit from genioplasty advancement. In cases where the chin has to be moved forward more than 6 mm the esthetic outcome may be unsatisfactory. This results in a deep sublabial fold and an unharmonious appearance. In this case two-step genioplasty is indicated (Figure 17-10).

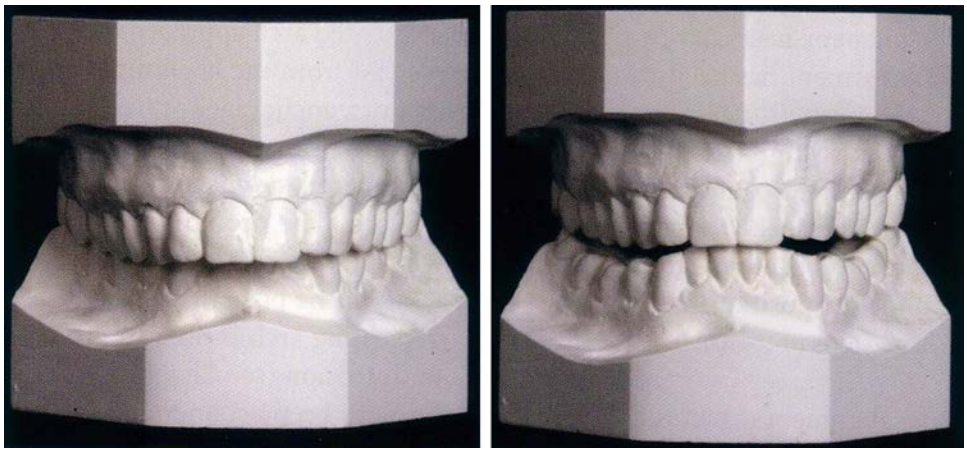
In patients with mandibular deficiency, a strong chin, and a short anterior face height, chin protrusion can be reduced by rotating the chin downward and backward; this provides a favorable esthetic result (Figure 17-11).

Patients with an excessive anterior face height will need vertical reduction. Genioplasty can then be performed in all directions and there is more freedom for incisor inclination (Figure 17-12, *A*).

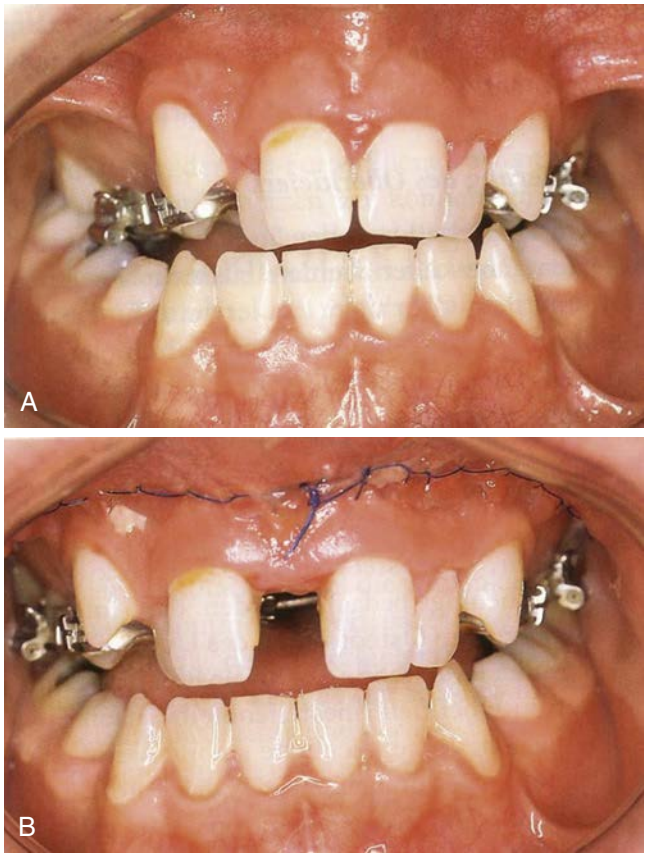
Intraoperative Complications

Nerve Injury

Neurosensory disturbance is one of the most common complications in mandibular surgery.[21,22] Nerve injury during SSO may involve the inferior alveolar nerve (IAN),



• **Figure 17-3** A patient with mandibular deficiency and severe posterior transverse discrepancy when the mandible is advanced.



• **Figure 17-4** **A,** Severe transverse discrepancies and dental crowding in upper front indicate SARPE. Palatal appliance (Hyrax) is in place for SARPE. **B,** The maxilla is widened during surgery as much as possible to allow correct alignment of the teeth orthodontically.

TABLE 17-3 Treatment of Transverse Discrepancies in Adult Patients with Mandibular Deficiency

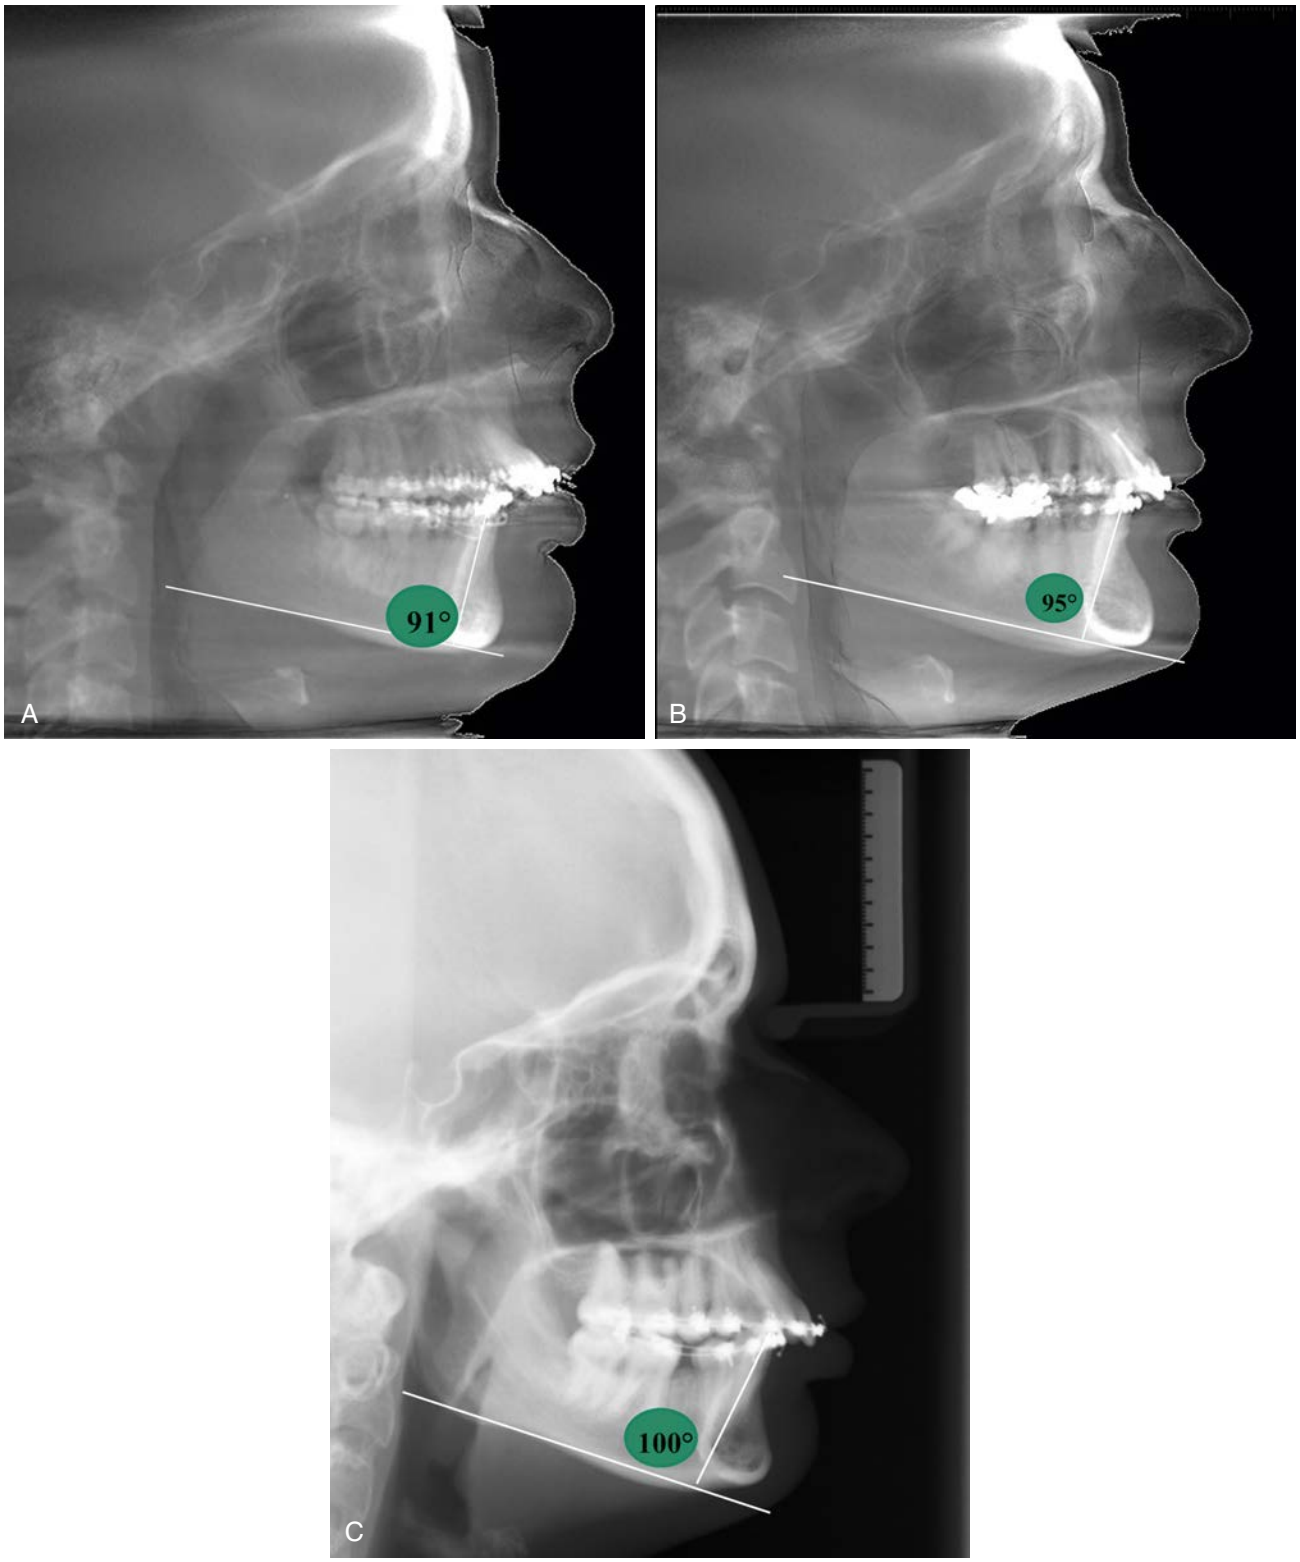
Diagnosis	Therapy
Front crowding + good nasolabial angle	No extraction + SARPE
Front crowding + nasolabial angle <90 degrees	Premolar extraction and orthodontic treatment
Front crowding + nasolabial angle >110 degrees	No premolar extraction + SARPE +/– Le Fort I osteotomy

• **Figure 17-5** Protruded inferior incisors were up-righted with orthodontic treatment to allow mandibular advancement for class I occlusion. The required space for tip-back was created by extraction of one lower incisor.

the lingual nerve, or in very rare cases the facial nerve. The injury may be caused by blunt trauma, stretching, a tear or a cut. Transection rates of 2% to 3.5% have been reported in the published literature.[23]

Inferior Alveolar Nerve

The IAN is at great risk for injury during various stages of sagittal split osteotomy because the osteotomy is performed in close proximity to the inferior alveolar nerve. The location of the IAN in the mandible may vary. Some mandibular deformities seem to be associated with abnormal locations of the IAN. In mandibular prognathism, for instance, it usually runs very close to the cranial edge of the mandible. This is particularly important in patients with a long vertical but short horizontal ramus of the mandible, occasionally accompanied by loss of posterior



• **Figure 17-6** Incisor inclination depending on chin projection. **A,** Patient with normal anterior face height; Incisors inclination is 90 degrees to mandibular plane. Holdaway ratio 1:1 after mandibular advancement. **B,** Patient with mandibular deficiency and deep bite. The chin position is slightly prominent. Incisor inclination is 95 degrees. Mandibular advancement and rotation down to correct the deep bite leads to 1:1 holdaway ratio. **C,** Mandibular deficiency and chin deficiency. The lower incisors are protruded. Treatment plan should have been premolar extraction to allow the lower front teeth to tip back. In this case advancement genioplasty will be necessary to give a good esthetic result.

TABLE 17-4 Orthodontic Treatment, SSO +/– Genioplasty in Relation to the Patient's Chin Position

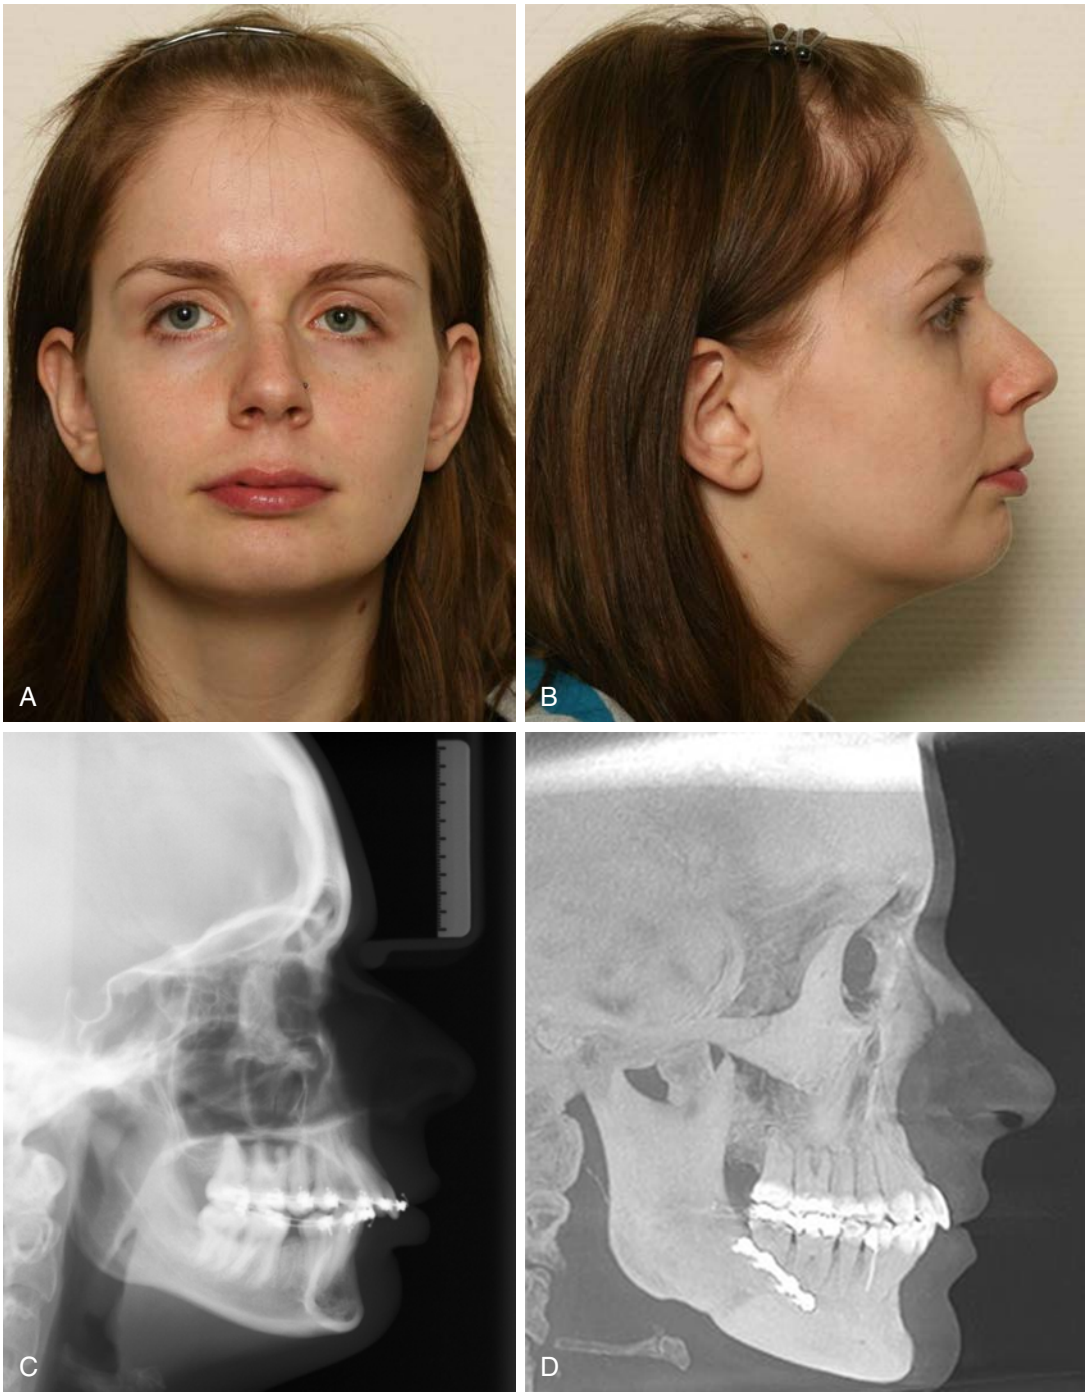
Face height	Chin	Incisor inclination	Leveling	Genioplasty
Normal face height	HR 1:1	90 degrees	Incisor intrusion and premolar extrusion	No
	HR >1:1	>90 degrees	Incisor intrusion, premolar extrusion	No
	HR <1:1	90 degrees	Leveling pre- or postoperative	Yes
Short face	HR 1:1	90 degrees	Premolar extrusion postoperative	Yes
	HR >1:1	>90 degrees	Premolar extrusion postoperative	Yes
	HR <1:1	90 degrees	Premolar extrusion postoperative	Yes
Long face	HR 1:1	90 degrees	Incisor intrusion preoperative	Yes/No
	HR >1:1	>90 degrees	Incisor intrusion preoperative	Yes/No
	HR <1:1	90 degrees	Incisor intrusion preoperative	Yes/No

teeth (Figure 17-13). Penetration of the saw through the mandibular cortex will easily tear the nerve and may lead to its rupture during splitting. Occasionally, the IAN runs along the inferior border of the mandible, which makes it susceptible to laceration during drilling or sawing at the inferior border. Cone-beam CT scan demonstrates the anatomic position of the IAN clearly before surgery and has thus made it easier to avoid injury.

The presence of an unerupted third molar during surgery has been suggested as a factor that increases the risk of neural deficit. Paresthesia results from manipulation of the nerve when the neurovascular bundle has to be dissected from the proximal segment or released from the bone canal in the proximal segment. In addition, the roots of third molars are frequently located close to the mandibular canal and may tear the nerve upon their mobilization.

Stages of possible damage of IAN during sagittal split osteotomy are as follows:

1. Application of local anesthesia on the inside of the ascending ramus may cause nerve injury (closed injury). It is best avoided by targeting the middle of the lingual surface of the ascending mandibular ramus and keeping contact with the mandible when pushing the needle forward.[24]
2. During osteotomy the IAN is occasionally lacerated at the site of its entrance into the mandible. This can be prevented by protecting the site with a periosteal elevator and the tip of the suction apparatus (Figure 17-14).
3. When connecting the cranial cut with the horizontal osteotomy line, the IAN may be injured when the saw is set too deep into bone and the nerve runs close to the cranial edge. In mandibular prognathism, the nerve is sometimes very close to the superior surface. To avoid this complication it is important to cut only cortical bone.
4. Lesions of the IAN in the anterior vertical part of the osteotomy are usually caused by the proximity of the mandibular canal to the lateral mandibular cortex in the second molar region. The risk of a neurosensory disorder is significantly greater when the distance between the mandibular canal and the buccal cortex of the mandible is 2 mm or less. With regard to the distance between the mandibular canal and the buccal cortex, Yoshida[25] reported a distance of less than 1.2 mm in 91% of osteotomy sites where a severe neurosensory disorder after BSSO was experienced. The subjective evaluation of the neurosensory disorder was still abnormal at the three-month follow-up. Hallikainen[26] found the distance of the canal and the buccal cortex less in patients with prognathism than in the mandible deficiency. Placement of the saw in a 45 degree angle when making the buccal cortical osteotomy helps to avoid this complication.
5. The IAN may be torn by forced manipulation during the splitting process, especially in patients with a small bone marrow space and a long mandibular angle.[27] This can be avoided by using rotating instruments only to open the mandibular cortex. Therefore the osteotome should penetrate the mandible very superficially during splitting (Figure 17-15). Once the two cortices are separated, the tip of the suction device should be inserted into the gap (Figure 17-16). This is helpful in detecting any false position of the nerve in the outer cortex, where it can be easily freed with an elevator. Once the bone split has been completed, the IAN should be in the distal segment. Occasionally it is completely caught on the proximal side (Figure 17-17). It is less damaging for the nerve to leave it in the proximal segment, but this is only true in class II patients when the mandible is brought forward. It cannot be done when the mandible has to be set back. In these cases the nerve has to



• **Figure 17-7** Pre- and postoperative photographs and x-rays of a patient with mandibular deficiency and slightly reduced chin position. **A,** Full face she shows a deep sublabial fold. **B,** On profile view the lower lip is sucked in behind the upper incisors. • **Figure 17-7, cont'd**

be freed from the proximal segment so that the distal segment can be set back.

6. The nerve is exposed to blunt trauma during osteosynthesis, due to cancellous bone fragments that were not removed before fixation. Therefore, after splitting it is very important to remove all cancellous bone fragments from the proximal segment opposite the nerve canal, using a bone rasp. Small debris must be removed by meticulous rinsing before positioning the fragments for stabilization.
7. During osteosynthesis, the IAN can be injured by the burr, the heat of rotating instruments, or by screws set too close to the nerve.

Several precautions help to avoid traumatic injury to the IAN:

1. Knowledge of the anatomy of IAN with the aid of cone-beam CT scan
2. Correct placement of the osteotomy line on the inner cortex of the ascending ramus and 45 degree placement at the horizontal ramus
3. Careful splitting and release of the IAN from the proximal segment with an elevator
4. Meticulous rinsing and removal of cancellous bone fragments before osteosynthesis
5. Placement of screws perpendicular to the bone surface and along the cranial border or the use of bone plates.

Lingual Nerve

Injury to the lingual nerve during SSO is a rare event. Despite the fact that high injury rates of 9%[28] up to 19% [29] have been reported, the majority of studies mention no injury or much lower rates. A few situations during surgery might expose the nerve to potential danger.

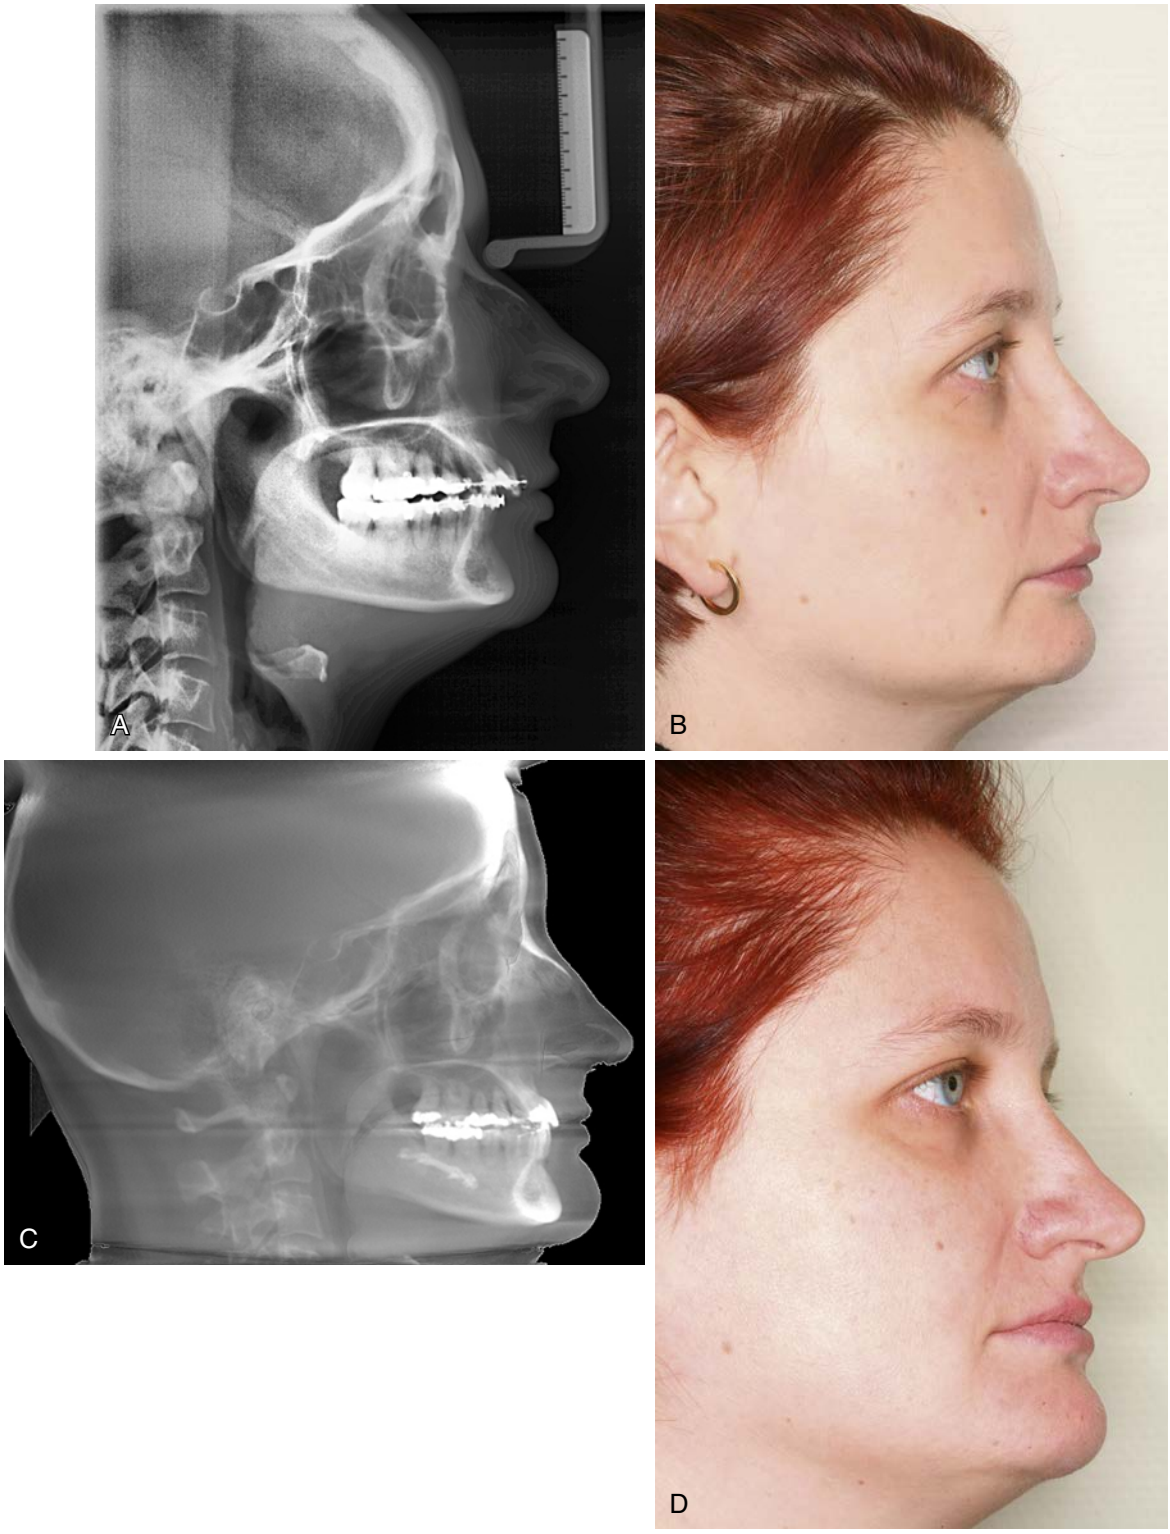
Application of local anesthesia may damage the lingual nerve.[30] Placement of excessively long bicortical screws on the superior border of the mandible for osteosynthesis might damage the nerve when the screw passes through the lingual cortex. It seems safe to use screws measuring 15 mm in length. In patients who need longer screws, the depth of the drilled hole should be measured.

This complication may result in painful dysesthesia when eating and speaking. Reoperation and removal of the screws may be necessary. The use of plates and monocortical screws prevents this complication.

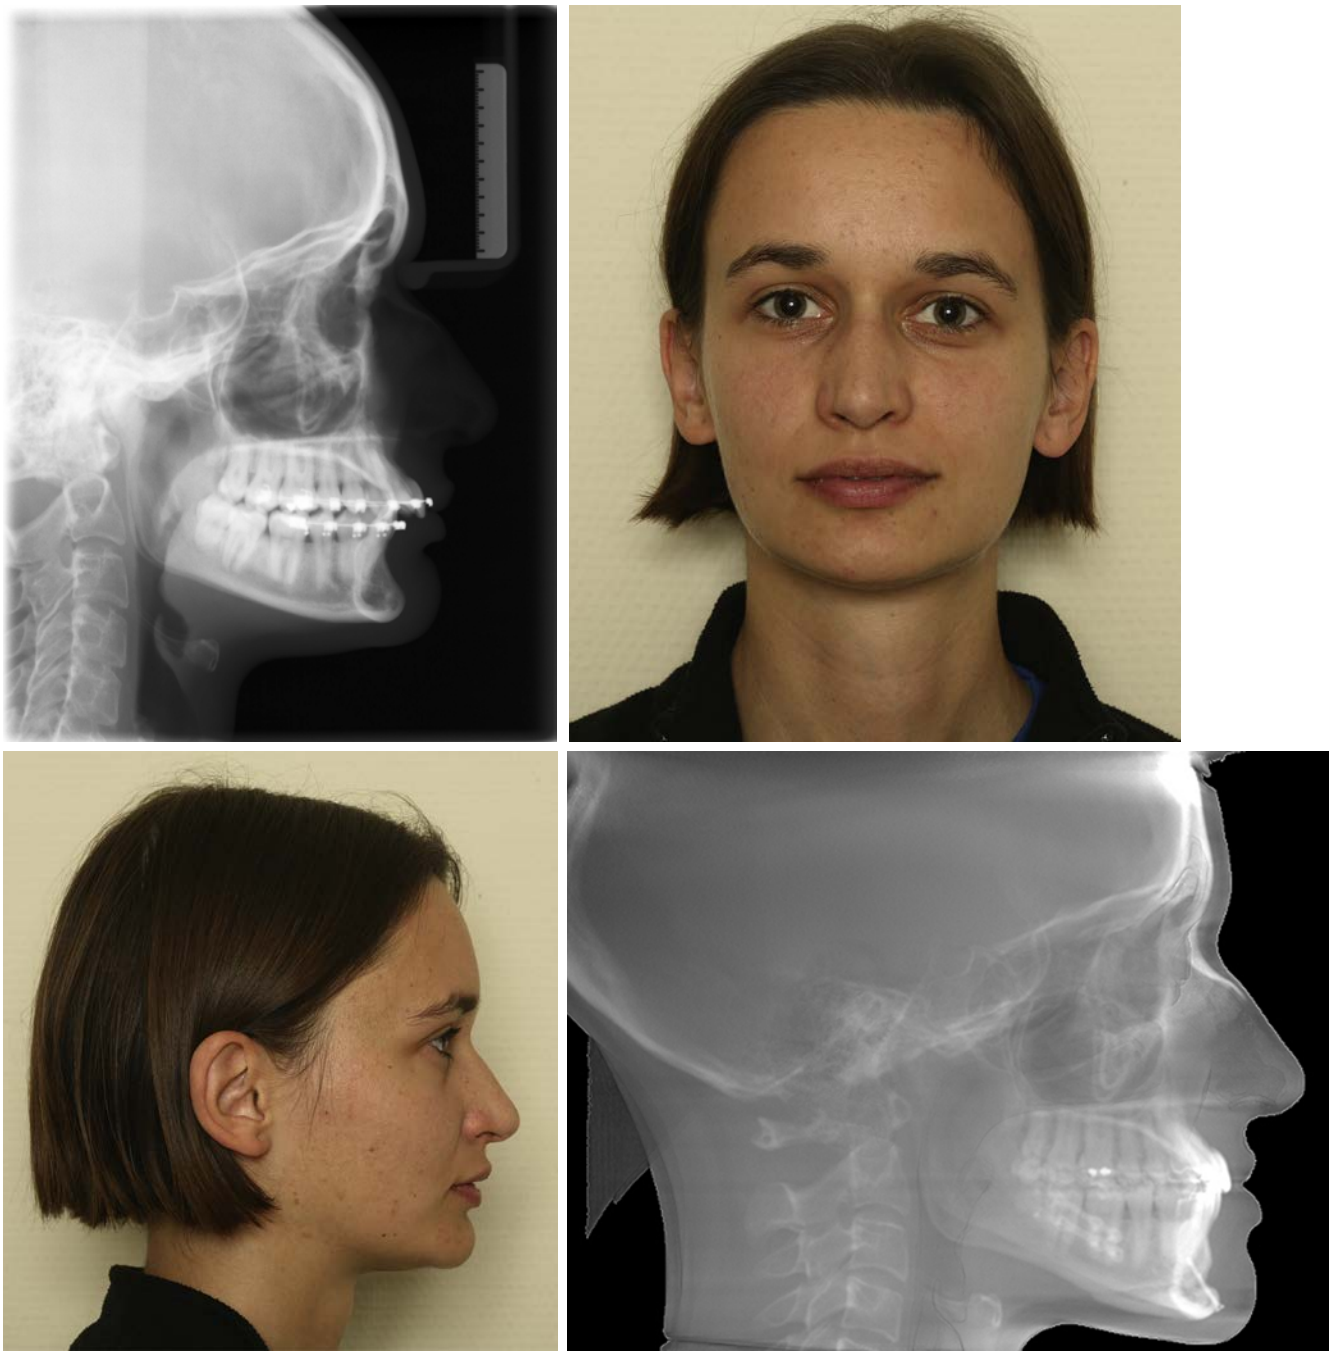
Hematoma after severe bleeding on the inner side of the mandible will exert pressure on the lingual nerve. This may cause temporary paresthesia of the tongue. It is marked by sensory defects on the affected side of the tongue and the loss of taste. Acute interventions are usually not necessary because the dysesthesia will resolve spontaneously over time. Extensive hematoma should be drained to achieve rapid recovery. The nerve will recover within a few weeks and return to normal.

Facial Nerve

Although the incidence of facial nerve injury during SSO is low (0.38 %),[31] it is a serious and frightening condition for the patient. In large mandibular setbacks the nerve might be compressed directly or by a styloid process fracture, and cause palsy or weakness of the nerve.[32] This is especially true when the medial cut at the inner cortex of the ascending ramus is extended to the posterior border, leading to a long cut.



• **Figure 17-8** Pre- and postoperative photographs and x-rays of a patient with mandibular deficiency and chin hyperplasia. **A,** X-ray shows inclination of lower incisors is 95 degrees. **B,** Short lower face height, mandibular deficiency, chin in good position before mandibular advancement. **C-D,** After mandibular advancement the chin appears protruded mainly because of excessive soft tissue.



• **Figure 17-9** Pre- and postoperative photographs and x-rays of a patient with mandibular deficiency and chin hyperplasia, short anterior face height, and excessive soft tissue at the chin. Mandibular advancement and reduction genioplasty results in an unpleasant outcome.

Continued

• **Figure 17-9, cont'd.**

Severe bleeding, causing excessive hematoma after surgery, may exert pressure on the facial nerve and impair its function.[33] In cases of extensive bleeding, meticulous hemostasis should be performed to avoid extensive hematoma.

In patients with large mandibular setbacks, short cuts at the inner cortex of the ascending ramus or bone reduction of the posterior border of the proximal segment avoid pressure to the nerve.

Unfavorable Bony Splits

A specific but not very common problem of sagittal split osteotomy is the unfavorable bony split. Its frequency varies between 2% and 20%[1] and it may occur either on the distal tooth-bearing segment or the proximal segment. Identifying the causative problem before it occurs can minimize the risk of an unfavorable bony split. Usually a minimal amount of pressure is needed for splitting the proximal and distal segments with a chisel. When resistance is encountered or a buccal plate fracture develops, the cuts need to be re-evaluated and redirected before proceeding.

Poor split of the distal segment most commonly affects the lingual cortical bone posterior to the third molar. This can be managed by performing an inferior vertical ramus osteotomy (IVRO) to separate the fragments, especially in mandibular setback cases. It may result in sequestration of the fragment, delayed union, malunion of the osteotomy site, or even infection. Stabilizing the bone fragment with a bicortical screw during surgery may prevent these postoperative complications.

Unexpected splits of the proximal segment may occur before or after splitting of the mandible. A developing inadvertent split may be prevented when it is recognized before the fracture is completed. Osteosynthesis with a bone plate placed perpendicularly over the fracture will solve the problem.

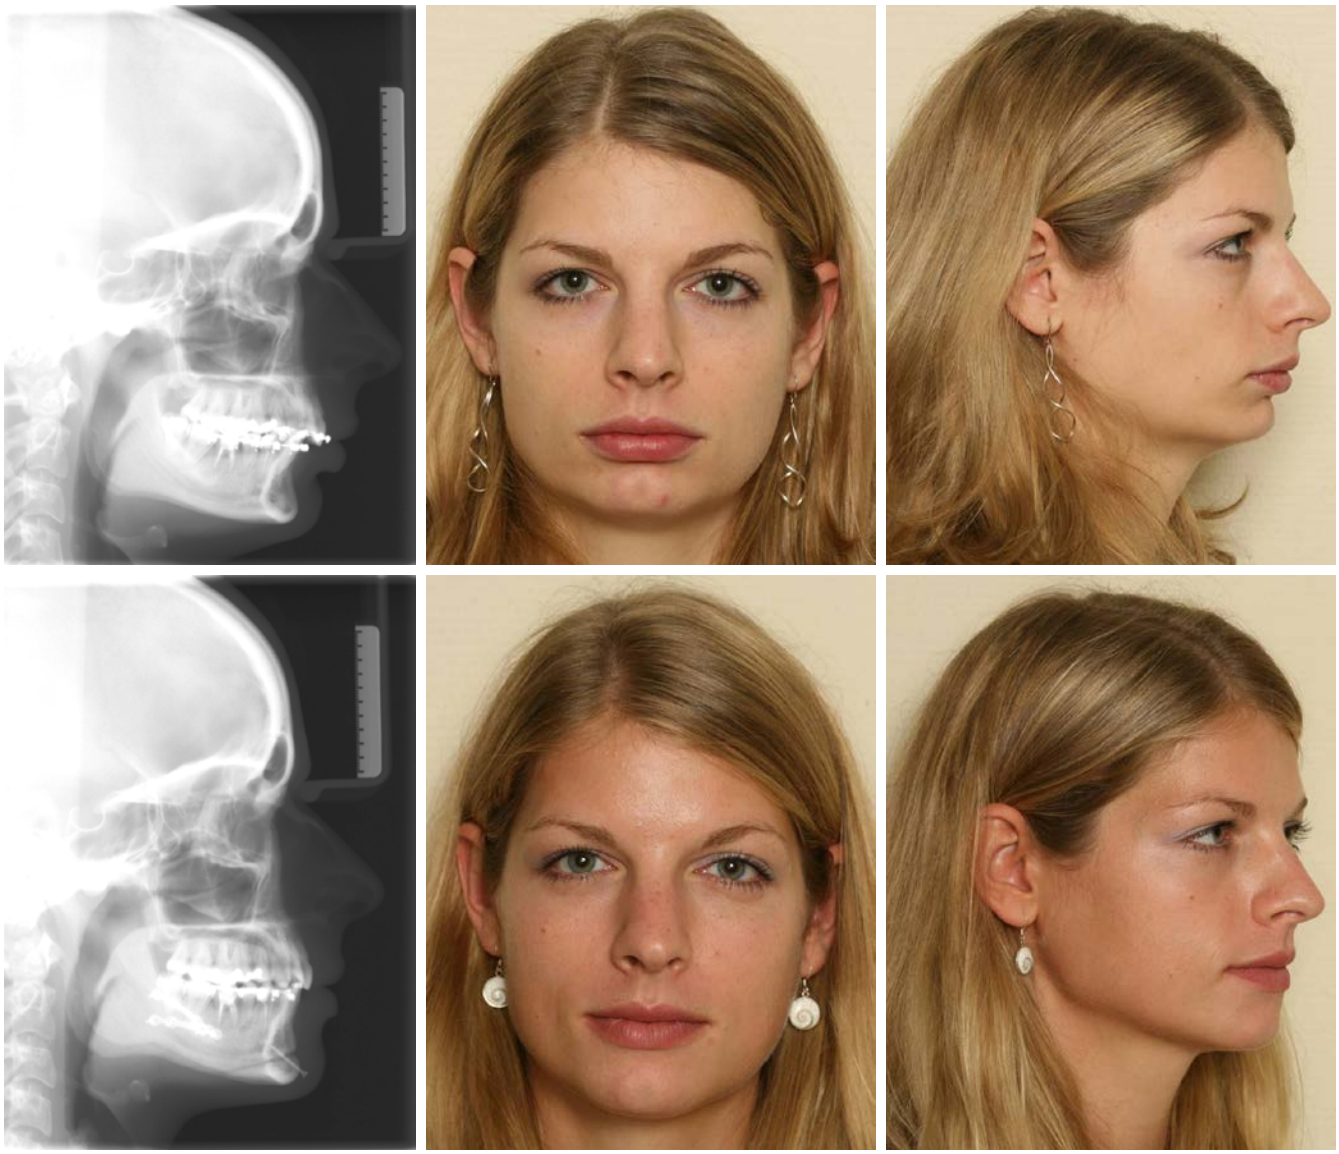
A frequent cause of a poor split is improper osteotomy of the cortical bone at the inferior border and wedging with the osteotome, especially when bone is used as a fulcrum during splitting. Therefore, careful inspection of the inferior border and the outer cortex is mandatory.

Certain predisposing factors are likely to cause an unanticipated split: difficult anatomic conditions, poor osteotomy design, or the presence of impacted third molars.

1. The anatomy of the ascending ramus may vary. Anatomic features, including the width and thickness of the ascending ramus as well as the positions of the canal, have been studied.[34] The thickness of the ramus may also differ. Lack of cancellous bone between the two cortical bone layers makes the split more difficult and hinders exact separation of cortical and cancellous bone.
2. Correct cuts through cortical bone, either with a reciprocating saw or a burr, is a primary prerequisite to avoid a bad split. This is especially true when the cut is made on the inner side of the ascending ramus and the inferior border before using the chisel on the osteotomized bone.[35]
3. A high risk of unanticipated fractures during BSSO has been associated with the presence of impacted third molars. Impacted third molars have been reported to compromise the anatomic structure of the mandible and cause adverse proximal and distal segment splits. However, the subject is controversial. Some authors suggest removal of third molars at least 6 months, but preferably 9 to 12 months prior to surgery,[36] whereas others found no reduction in the incidence of fractures when impacted third molars were removed at the time of surgery.[37,38] Modification of SSO has been suggested to avoid this complication.[39]

In a series of 1176 sagittal splits, we found a significant correlation between female gender, age older than 40 years,

• **Figure 17-10** **A,** Patient with mandibular deficiency and chin hypoplasia. **B,** The lower incisors are protruded more than 105 degrees. **C-D,** After advancement of the mandibula the chin would still be too far back. She needed chin advancement in 2 steps to give a harmonious appearance.



• **Figure 17-11** Patient with mandibular deficiency and short face. Lower face height is too short even after mandibular advancement. Correction with additional genioplasty produces well balanced facial appearance.

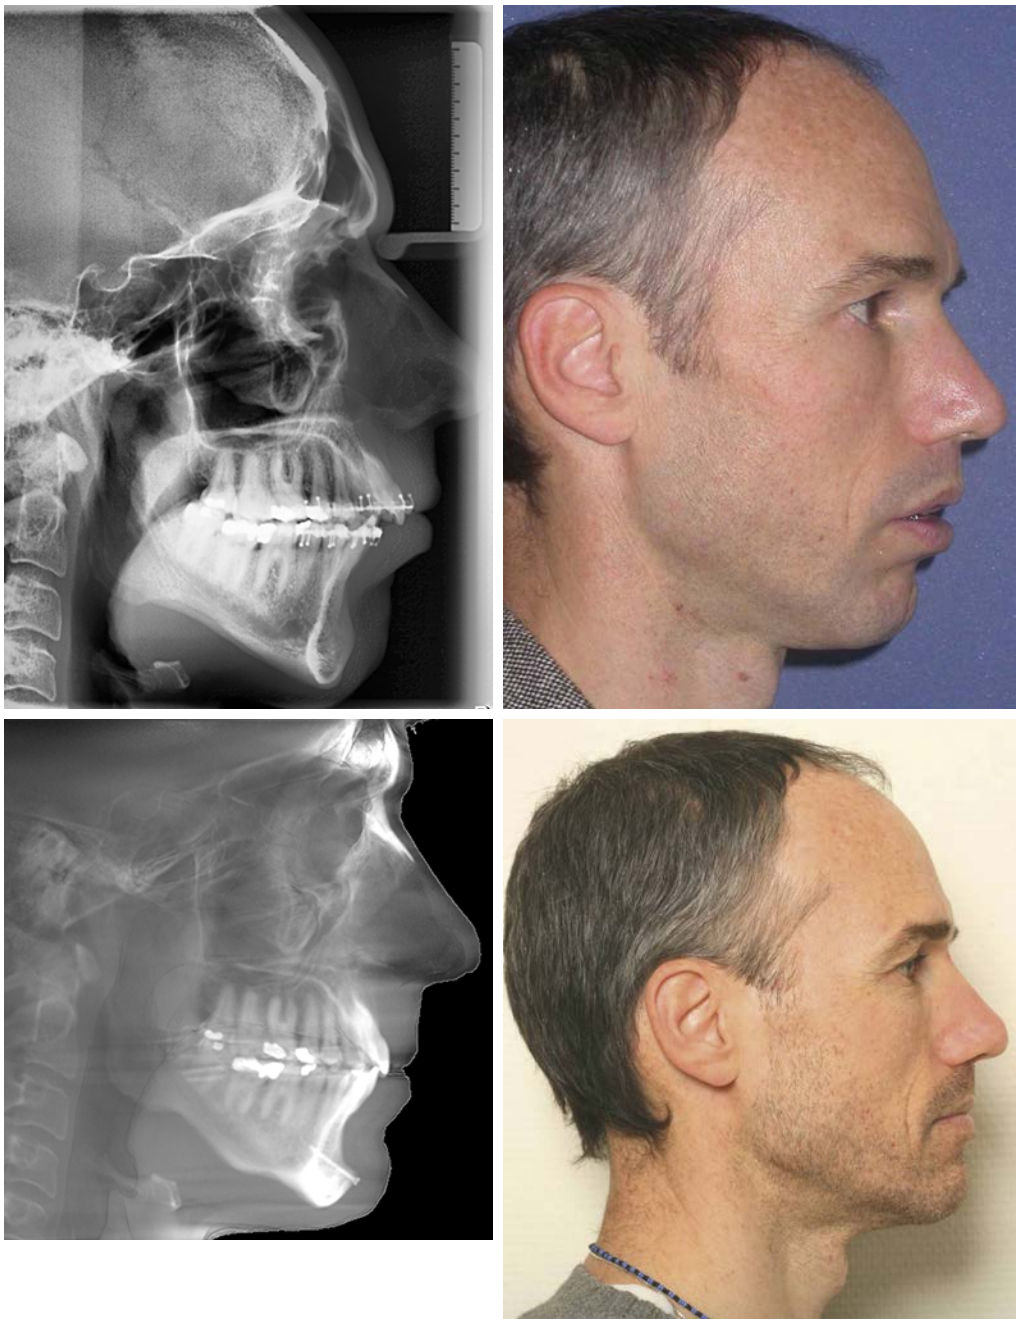
and an obtuse gonion angle (<115 degrees) but no correlation with the presence of third molars (P=0.867).[40]

Fracture of the lingual plate or the buccal plate is not uncommon when nonerupted third molars are present. The buccal cortex of the mandible is normally very thin in the posterior aspect of the second molar (Figure 17-18). The presence of a third molar makes splitting even more difficult because there is a paucity of medullary bone between the cortices. Fractures may affect the lingual cortex during removal of the tooth, or the outer cortex during splitting. A horizontal fracture of the ramus and even a fracture of the condylar process make reduction and fixation of the remaining segments difficult.[41] Plates, bicortical screws, or a combination of both may be used to stabilize the fractured bony segments (Figure 17-19). Usually the intraoral approach for osteosynthesis is not sufficient; an extraoral access will be needed to insert plates and/or screws.

Unanticipated bone splits do not influence stability or the long-term success of SSO. In a report published in 2008, Veras et al.[42] observed no difference in temporomandibular dysfunction, including pain and/or clicking. The authors concluded that poor splits, when treated appropriately, have good chances of achieving normal function although some mandibular movements may be compromised.

Hemorrhage

Uncontrolled bleeding is a rare condition in mandibular surgery. In most cases it is caused by the clumsy use of rotating instruments or chisels, a sign of unfamiliarity with the surgical procedure. The retromandibular vein and the inferior alveolar vessels may be injured inadvertently. In rare cases the facial artery may be injured at the gonial notch. Bleeding rates of 38% have been mentioned in earlier reports.[43,44] Most bleeding can be treated by packing. Severe bleeding



• **Figure 17-12** Patient with mandibular deficiency, chin deficiency, and long face. After mandibular advancement, lip incompetence is still present. After an additional advancement genioplasty and reduction of anterior face height by removing bone from the symphysis the face is well balanced.

requiring blood transfusion is a rare occurrence in BSSO.[1] Recent reports mention a low incidence (1%) of severe bleeding.[45] In a report published by Foran,[46] the chronic intake of energy drinks was held responsible for excessive intraoperative bleeding in two patients. Foran's suspicion is based on several reports attributing intraoperative and postoperative bleeding to the herbal constituents of these beverages. All cases were marked by diffuse bleeding that could not be clearly assigned to a single source.

Even when bleeding is minor it tends to make the surgical procedure more difficult by precluding optimal sight of the anatomic structures, which may result in further surgical complications, such as nerve injuries or an unfavorable bony split. Minor bleeding also increases the duration of surgery, which by itself is an established cause of complications. Most bleeding is minor and can be controlled by the use of local anesthetics, a gauze pack, or direct ligation of the affected vessel.

Minor oozing may occur at the very beginning of surgery, when insufficient time (<10 minutes) has elapsed for vasoconstriction after the administration of local anesthesia. Another frequent reason for bleeding in this phase is inadvertent

• **Figure 17-13** Position of mandibular nerve canal.

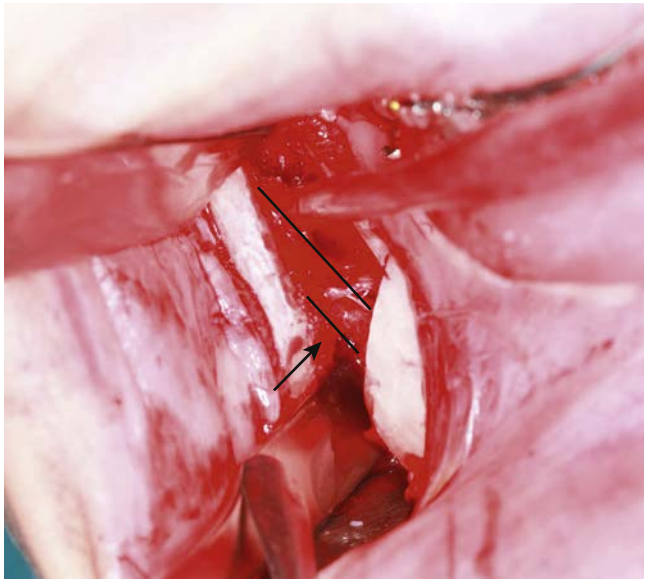
• **Figure 17-16** Suction device in gap.

laceration of the masseter muscle during the incision of the vestibular mucosa. This can be avoided by meticulously cutting the mucosa all the way through to the periosteum. The cut goes medial to the muscle down to the periosteum, which is then opened by blunt dissection. Although not dangerous, both types of bleeding are associated with poor visibility of anatomic structures and prolonged operating times.

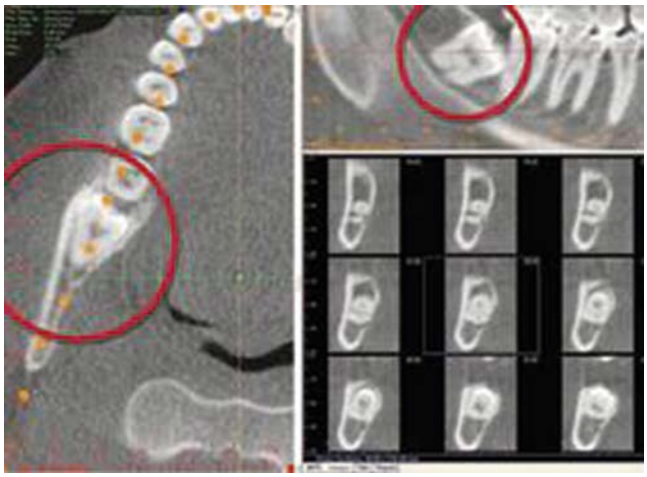
During osteotomy, bleeding from the medial pterygoid muscle occurs at the lingual surface of the ascending mandibular ramus when the periosteum is not completely released from bone. Surgical exposure of the periosteum must be started from the anterior aspect of the ascending ramus. Bleeding may also occur at this stage due to laceration of the retromandibular vein or branches of the superficial temporal veins by the use of surgical instruments such as drills or osteotomes.[45] This can be prevented by using a periosteal elevator to protect soft tissue from the caudal aspect and the suction device from the cranial aspect, as mentioned earlier (see Figure 17-14).

Bleeding from the facial artery may occur during removal of soft tissue from the inferior mandibular border. Such bleeding must be treated with a suture. This can be problematic because visual access is very limited in this region. A neck incision may be required to control bleeding from this area.

Bleeding from the inferior alveolar artery may occur when bone fragments after osteotomy are separated by using



• **Figure 17-17** Nerve remains in proximal segment.



• **Figure 17-18** Impacted third molar, no cancellous bone between tooth and buccal cortex.

a bi-beveled osteotome. Bleeding can be easily treated by ligation because visual access is optimal in this location. This complication can be avoided by cautiously splitting under good vision. The latter can be achieved by placement of the suction tip at the bottom of the split. Careful exposure and release of vessels (and nerves) from the proximal fragment are also important.

Malpositioning of the Proximal Segment

Control of the proximal segment is the most important aspect of long-term stability. Early postoperative relapse occurs when the proximal segment is not positioned properly in the fossa or the condyle is torqued, and this may cause postoperative pain. Pushing the proximal segment posteriorly may also provide good gonial angle projection but puts stretch on the muscles of mastication.

Different methods have been proposed to control the condyle in the fossa before splitting.[47] However, none of these methods has gained acceptance. In fact, long-term results were not better than those in patients treated without these aids.

Vertical Subcondylar Ramus Osteotomy (IOVRO)

The vertical subcondylar ramus osteotomy is described as "one of the simplest osteotomies to perform."[48] Currently its use is confined to significant mandibular setbacks. Initially it was performed by the extraoral approach,[49] but today it is performed intraorally. Complications during surgery include unfavorable bony splits, injury to the neurovascular bundle, and bleeding.

Unfavorable Osteotomy

This may be caused by incorrect positioning of the saw. A saw positioned too far posteriorly may lead to a subcondylar osteotomy instead of a vertical cut parallel to the posterior side of the ascending ramus.[50]

• **Figure 17-19** Bad split, osteosynthesis with bone plate perpendicular to fracture.

Nerve Injury

The incidence of nerve injury in vertical subcondylar ramus osteotomy ranges between 0% and 35%. The incidence is less than it is in SSO.

Two possible causes have been described in the literature.

1. When the saw is placed too far forward in the vicinity of the foramen of the neurovascular bundle, the nerve may be cut. Specific instruments, placed correctly during the surgical procedure, help to avoid this complication. The complication can also be minimized by radiographic identification of the lingual nerve on cone-beam CT scans.
2. In severe mandibular prognathism, the distal segment is pushed back against the proximal segment, causing the nerve to tear. To avoid pressure on the nerve, a bone segment can be cut out of the proximal segment.

Overall, IOVRO appears to be superior to SSO in terms of neurosensory disorders.

Hemorrhage

The inferior alveolar, masseter or maxillary arteries are at risk during surgery. Retromandibular veins may also be injured. Severe hemorrhage, as reported in earlier times, is rare today[51] because of better instruments (Bauer retractor) that help to protect soft tissue.

Bleeding is treated by ligation of the injured artery; venous bleeding is treated by the use of local anesthesia and/or packing.

Injury to Soft Tissue

Soft tissue injuries may occasionally occur during the osteotomy. Prime among these is injury to the lips due to rotating instruments or the saw. The lips are especially vulnerable when splitting is performed at the inferior edge of the mandible with the shank of the burr or saw blade.

Injury to muscles on the inner side of the ascending mandibular ramus due to rotating instruments may occur during osteotomy when the saw or the rotating instruments are not moved correctly along the bone. Most of all, it should be ensured that the ascending mandibular ramus in the posterior aspect is inclined outward. Therefore, the saw or the rotating instrument should be moved from the inner frontal aspect to the outer posterior aspect.

Early Postoperative Complications

Early Postoperative Sequelae

Pain, nausea and vomiting, limited range of motion, and social and functional impairment are common sequelae of orthognathic surgery. Most patients experience a certain degree of postoperative swelling and edema. Bruising and temporary neurosensory alterations are also common, occurring to a greater or lesser degree in nearly all patients after SSO. The severity of swelling and hematoma depend on the duration of the surgical procedure, the degree of surgical trauma, the quantity of intravenous fluids, postoperative medication, the patient's personal condition, and predisposing risk factors.

Postoperative Nausea and Vomiting

This is the most common postoperative complication after general anesthesia and usually occurs within 24 hours after surgery. Silva et al.[52] investigated 553 patients postoperatively and noted the following major predictive factors: female gender, young age, non-smokers, and the presence of predisposing factors (e.g., prior history of motion sickness, vertigo, or migraine headaches). This was confirmed by Grabowska-Gawel et al.,[53] who reviewed 253 patients who had undergone different types of surgery under general anesthesia. The authors also registered a correlation between postoperative nausea and vomiting and obesity, and patients anesthetized by younger or less experienced anesthetists.

Despite the Consensus Guidelines for the management of postoperative nausea and vomiting that were introduced in 2003, 2007, and 2014,[54] the authors of a recent publication registered "no substantial decrease in postoperative nausea and vomiting while reviewing the literature."[55] Investigating 204 patients undergoing orthognathic surgery, the authors found the female gender, a larger quantity of intravenous fluid, and the use of nitrous oxide to be risk factors for postoperative nausea. Postoperative vomiting was more common in patients who had undergone additional procedures and received morphine. The administration of antiemetic drugs that act at different receptor sites has been considered more effective than single drugs.[56] Additionally, in high-risk patients the best results were achieved by avoiding volatile anesthetics.[57]

In a report published by Brookes[58] in 2015, a multimodal protocol was used in patients undergoing Le Fort I osteotomy. The authors observed no significant reduction of postdischarge nausea and vomiting compared to patients who were not treated in accordance with this protocol. Immediate post operative nausea and vomiting were significantly reduced.

Airway Obstruction

Airway obstruction is rare in mandibular surgery and might be a consequence of severe bleeding.[59] The sublingual artery, which runs close to the periosteum at the symphysis, could be damaged on the inner side of the ascending ramus of the mandible.

Edema

Edema is the result of an inflammatory process after surgery. In most cases it is not hazardous, but is nevertheless distressing for the patient (Figure 17-20). Edema is usually not correlated with the duration of the surgical procedure or the complexity of surgery. In a prospective investigation in 2014, Madelon van der Vlis et al.[60] found that 50% of the swelling resolved within 3 weeks after surgery. Only 20% of the initial swelling remained after 3 months. The volume of initial swelling was correlated with BMI, but the statistical power was limited by sample size. A high BMI was associated with the greatest severity of swelling and the fastest resolution rate in the initial weeks after surgery while a low BMI was associated with less swelling that resolved at a slower rate.

Edema is a temporary condition and best treated with a head bandage, ice packs, corticosteroids, nonsteroidal anti-inflammatory agents, and physical therapy (Figure 17-21).

Bruising

Bruising as a consequence of surgery is caused by the metabolic breakdown of blood into fascia spaces. It can be fairly extensive and may migrate along the interconnecting fascia planes along the neck down to the chest. It is only a cosmetic nuisance and resolves usually within 2 weeks (Figure 17-22).

Limited Range of Motion

A limited range of motion immediately after surgery results from the alteration of the condyle and soft tissue. The limitation is temporary. Most patients regain their normal mouth opening within 6 months. In some patients, physical therapy may be indicated to accelerate the process.

Temporary *neurosensory deficit* is a common concomitant symptom of all bilateral sagittal split osteotomies. The gums, the lips, and the skin below the lips down to the chin may be affected by this condition.

Infection

The incidence of infection with orthognathic surgery is reported to range from 3.4% to 60% in the published literature. Wound dehiscence and/or infection are now rare complications and usually are related to poor oral hygiene. Tobacco smoking appears to be an additional risk factor. Contributing factors are long operating times, the patient's age, the presence of foreign bodies, sequester formation after bone fracture, or hematoma. The use of prophylactic antibiotics during and after surgery has substantially reduced the risk of infection. No consensus has been achieved yet in regard to dosage or the type of antibiotics. Long-term dosing appears to reduce the risk of infection after surgery compared to short-term dosage.[5] In a study by Bouchard[61] in which 336 patients were investigated, infections were registered in 11.3%. The majority of these were minor wound infections that could be treated with antibiotics. Fixation materials were removed in 3% of the patients. One patient experienced non-union and required a bone graft for reconstruction and six patients had bone sequestrations that were removed. All patients were treated with antibiotics and corticosteroids. The authors did not mention whether splints were used during and after surgery.

A few cases of actinomycosis infection have been reported.[62] Surgery is known to be a predisposing factor for cervicofacial actinomycosis. The use of antibiotics leads to resolution of the infection within a few months.

Flawless oral hygiene is a prerequisite to avoid infection, and is initiated preoperatively by patients undergoing

• **Figure 17-20** Postoperative swelling.

• **Figure 17-21** Head bandage.

• **Figure 17-22** Severe postoperative hematoma.

orthognathic surgery. However, swelling and anxiety may impair the patient's post-surgical oral hygiene. Postoperative controls at close intervals are therefore mandatory. Because the patient's occlusion at this stage is not the desired final result, the patient must wear a surgical splint to maintain the correct maxilla-mandible relationship. Without the splint this may cause loosening of the osteosynthesis material and subsequent "traumatic" infection. Another error-prone step is wound closure. When the wound margins do not close adequately, food debris or bacteria may enter the wound, which will then not close at the respective site. Smoking also influences wound healing and should be entirely stopped at least perioperatively. Additionally, antibiotics for 4 days (2 × 1 g penicillin) postoperatively are administered.

Late Postoperative Complications

Neurosensory Disturbance (NSD)

Postoperative neurosensory disturbance of the lower lip and the chin is a common consequence of orthognathic surgery and a major concern in mandibular osteotomy. It is the most commonly reported complication in mandibular surgery, with incidence rates of 9% to 85%.[28] D'Agostino et al.[63] registered long-term NSD rates of 10% to 30%.

Many factors may cause NSD, including the patient's age, the magnitude of movement, the surgeon's skill and experience, the degree of nerve manipulation, and direct injury to the nerve.

Types of Sensory Nerve Impairment

Paresthesia is marked by abnormal sensation. The symptoms include tingling, burning, prickling, itching, and even partial numbness. *Dysesthesia* includes exaggerated amplified responses to a noxious stimulus (hyperalgesia) and/or pain which can be triggered by stimuli such as a light touch (allodynia). *Anesthesia* is marked by the total absence of sensation to all forms of stimuli.

A NSD is generally considered to be caused by mechanical damage to the IAN (open injuries), such as compression, a tear, or a cut due to surgical instruments. Even when the IAN is not visibly traumatized during surgery, a postoperative neurosensory deficit may occur (closed injury.) This may be caused by edema, hematoma, or direct damage to cancellous bone fragments after stabilization or incorrect placement of screws.

Types of Nerve Injuries

Neuropraxia, the mildest form of injury, is caused by a temporary interruption of nerve conduction without axonal discontinuity. It is mainly produced by simple concussion without anatomic disruption and axonal degeneration. Neuropraxia is usually marked by temporary numbness or paralysis, followed by complete recovery within a time. No surgical repair is necessary.

Axonotmesis is caused by the interruption of some axons due to a traumatic injury and prolonged conduction failure. The injury is usually induced by a severe crush, contusion, or stretching of the nerve. Initial symptoms of the recovery of sensation, such as tingling, burning, itching or hypersensitivity, do not start until 6 to 8 weeks after the injury. The final recovery of sensation is frequently less than normal and takes several weeks or even years. Surgical repair is required within 6 to 9 months after the injury to restore good nerve function.

Neurotmesis is complete severance or internal physiologic disruption of the entire nerve. The consequence is permanent loss of conduction of sensory impulses. All nerve tissue distal to the nerve injury undergoes degeneration and is replaced by scar tissue. Recovery of sensation is not achieved when surgical repair of the nerve is not performed promptly. The result is permanent anesthesia and occasionally a painful sensation. When total anesthesia persists for longer than 3 months after the nerve injury, surgical repair should be performed within 3 to 6 months—before the distal axonal tubes start to degenerate and the process of axonal tubular atrophy becomes irreversible.[64]

Inferior Alveolar Nerve

Patients might experience varying degrees of trigeminal sensory deficits for 6 months or longer. Immediately after surgery the prevalence ranges from 12% to 100%. Long-term follow-up investigations have shown sensory alteration in 0% to 85% of patients 1 or 2 years after BSSO. However, this depended to a great extent on the methods used to test the neurosensory disturbance and the presence of additional genioplasty.[65] It also reflects variations in the number of persons investigated in the study groups.

Significant sensory deficits such as numbness, pain, burning, tingling, or hyposensitivity may affect the lips or the chin after injury to the IAN. Lip biting during mastication or difficulty in eating, brushing teeth, speaking, shaving, or kissing are distressing for the patient.

This complication depends on several predisposing factors, such as the patient's age, the surgeon's skill, the magnitude of mandibular movement, and additional genioplasty.[66] Patients seem to adapt to mild sensory deficits and report sensory function as normal despite slightly altered sensation objectively. Long-term sensory loss is rare because recovery of sensation usually occurs during follow-up. After 1 year most patients report to their pre-surgical level of sensation.

The duration and quality of neuropathy is mainly related to the severity of trauma. Seddon's classification is helpful in diagnosing and establishing the prognosis of nerve injuries.[64]

Injury to the peripheral branches of the mandibular nerve during osteotomy may cause prolonged or permanent sensory impairment.

A prolonged neurosensory disturbance is strongly related to age[67] and the degree of manipulation of the IAN during surgery. Any laceration or damage to the sensory fibers of the IAN may cause a postoperative neurosensory disturbance of the lower lip and chin.

Nerve injuries are clinically described as "open" or "closed." Open injuries are those observed by the surgeon when they occur. Unintentional severance of the inferior alveolar nerve may occur during sagittal split osteotomy.

Immediate primary repair by suturing the nerve ensures the best result.

Closed injuries are not seen at the time of their occurrence (laceration of nerves by cancellous bone fragments, osteosynthesis screws or blunt trauma during sagittal splitting of the contralateral side), and may or may not be suspected. Closed injuries should be followed by repeated examinations every 4 weeks. If the patient experiences an unacceptable loss of sensation or a painful or unpleasant sensation, microsurgical repair is the only means of restoring the sensation of the nerve. Vitamin B and stimulation of the affected skin in accordance with a protocol may also be helpful.

The estimated prognosis of recovery is 96% within 2 months; the rate is higher in younger patients.[68] A greater incidence of paresthesia was observed in older patients and when additional genioplasty was performed.[69]

The long-term incidence of paresthesia ranges between 0% and 20%. The risk of sensory deficit is higher when genioplasty is combined with sagittal split osteotomy.[21]

Lingual Nerve

A transient disturbance of the lingual nerve may occur in some cases. Its incidence varies, but is reported to be as high as 19%.[29] However, the high percentages were noted in studies based on patient questionnaires.

A disturbance of the lingual nerve usually resolves spontaneously, but persistent anesthesia was noted in older reports.[70]

Facial Nerve

Impairment of the facial nerve is rare, but constitutes a devastating complication for the patient. Its incidence is less than 1% in BSSO and was reported only in setback procedures. The prognosis of facial nerve impairment is good in cases of partial loss of function, but poor in complete loss of function.[32]

TMJ Arthropathy

TMJ dysfunction such as joint noise (clicking) or pain is a relatively common condition in the general population; its incidence is 20% to 25%.[71] The prevalence of TMJ dysfunction in patients with a dentofacial deformity is approximately the same as it is in the rest of the population.[72] The reported frequency is 20% to 50%.[73] The most frequent symptoms are pain and clicking. Malocclusion is regarded as one cause of TMJ dysfunction in the general population.[71] Earlier reports mention preoperative TMJ dysfunction in as many as 41% of patients.[74] In most studies, TMJ dysfunction was found to be improved after orthognathic surgery; worsening of symptoms was noted in a small percentage.

The position of the mandibular condyle is almost always changed during mandibular surgery. This is most likely due to a certain degree of rotation around and across the condylar axis. However, there are no data to show that this influences the development of post-surgical TMJ dysfunction. All patients develop some limitation of mouth opening after surgery. This is partly due to muscle stripping during surgery and soft tissue edema after surgery. However, there might also be some limitation due to condyle displacement during surgery and condylar adaptation post-surgery. This short-term effect does not imply long-term dysfunction. Remodeling of the condyle is very likely to occur in the post-surgical period and patients usually regain their presurgical function some months after surgery.

Displacement of the Condyle

Postoperative displacement of the condyle may occur in the anteroposterior or the vertical plane, or due to rotation. The resulting condylar torque induces a clinically apparent midline shift post-surgery, which is occasionally painful. Anteroposterior or vertical malposition of the condyle leads to occlusal changes postoperatively. Clinically this is manifested as immediate skeletal relapse after surgery. Hypomobility is another sign, indicative of lateral or medial condylar displacement.

Failure to seat the proximal segments properly into the fossa during surgery will result in condylar displacement. This is the main reason for TMJ symptoms after BSSO in patients without symptoms prior to surgery. Condylar resorption has been described as a consequence of such malposition.[75]

In a prospective investigation of 27 patients, Franco et al.[76] noted displacement in 21%. Displacement occurred twice as often on the right side as on the left side after mandibular advancement 1 to 3 years post-surgery.

The preoperative management of existing TMJ dysfunction is controversial. Some authors suggest that TMJ derangement should be corrected prior to surgery, failing which the symptoms could worsen or even lead to condylar resorption.[77] Others found that orthognathic surgery alone establishes skeletal and occlusal harmony, and leads to the resolution of TMJ symptoms, which then improve without intervention.[78,79] We suggest orthodontic splint therapy in patients with preexisting pain before undergoing BSSO. Conservative manual reduction of a displaced disc during surgery is routinely performed.

Resorption of the Condyle

Condylar resorption rates of 1% to 31% have been reported in the published literature.[80] Skeletal predisposing factors for condylar resorption include a high mandibular plane angle, a condyle with posterior inclination, or a low posterior-to-anterior face height ratio.[81] Contributing surgical factors include counterclockwise rotation of the proximal segment, preoperative TMJ dysfunction, or vascular necrosis of the condyle as a consequence of traumatic stress during surgery.[82] Proper positioning of the proximal segment into the fossa after splitting the mandible is of utmost importance to avoid postoperative TMJ problems, including condylar resorption.

Relapse

The stability and predictability of orthognathic surgery have improved due to the evolution of surgical techniques and

instrumentation. Relapse rates differ in the published literature and seem to be highly dependent on the presurgical diagnosis. Relapse is a multifactorial problem and must be addressed individually. Proper diagnosis, adequate treatment planning, and the correct surgical technique and its skillful application are incumbent upon the surgeon. Soft tissue and muscle tension and orofacial habits influence postoperative stability. Additional factors that influence relapse are the type of fixation,[83] the magnitude and type of mandibular movement, the position of the proximal segment, and disc displacement.

In a study addressing the influence of the type of fixation, no difference in stability was noted when rigid or wire fixation was used in a sample of 120 patients.[84] Other authors have registered greater stability when using rigid internal fixation[66,85] and when the patient's anterior face height was maintained or increased (clockwise rotation).[72] Recent publications showed no difference in stability when absorbable screws were used.[86]

Contradictory results have been published on the risk of relapse in relation to the type and magnitude of mandibular movement. Reports on isolated mandibular setback are rare, with relapse rates ranging from 7.1% to 51.4%. In mandibular prognathism, the majority of authors mention the magnitude of surgical setback, especially in growing individuals, as the most important factor affecting long-term stability. In a review, Costa et al. noted a relapse rate of 33%.[87] Many authors consider the magnitude of setback and clockwise rotation to be the main reason for relapse.[88] The inclination of the ramus also appears to influence stability.[72]

Immediate relapse occurs in patients undergoing mandibular advancement, with functional TMJ problems based on disc displacement, when the disc was not repositioned prior to surgery. During the surgical procedure it is then impossible to place the condyle correctly into the fossa. After surgery the anteriorly displaced disc slips back into the fossa because of complete relaxation of the muscles and the absence of chewing. Condylar displacement appears to be another reason for immediate relapse. As the condyle is forced too far posterior into the fossa, immediate relapse occurs. The condyle may also be distracted or malpositioned relative to the glenoid fossa. Postoperatively the condyle settles back into the glenoid fossa, which results in unsatisfactory occlusion.[1]

Several authors have reported on the use of positioning devices to secure the condyle in proper position during BSSO. However, positioning devices do not seem to improve the functional or morphologic outcome of the TMJ after BSSO. Full mobilization of the distal segment and removal of all obstructive bone fragments are crucial to enable free and passive positioning of the bone segments.

Long-term relapses in mandibular deficiency are most frequent in cases of large mandibular advancement (greater than 6 mm) and in nongrowing patients.[83] Some authors established a correlation between relapse and counterclockwise rotation.[72]

Rare Complications

A few rare complications after BSSO have been reported in the published literature, mainly in case reports. These are either local complications due to the surgical procedure and the technique itself, or systemic medical problems after surgery[6] (Box17-1).

Screw loosening immediately after surgery necessitates reoperation; the estimated incidence is 2%.[89] Yoshioka et al.[90] compared the incidence of material-related complications when using different fixation devices. The authors registered breakage in 8.2% when using biodegradable miniplates compared to 3.3% when using titanium miniplates.

Reintubation after soft tissue swelling and hemorrhage compromising the airway are rare in mandibular surgery.

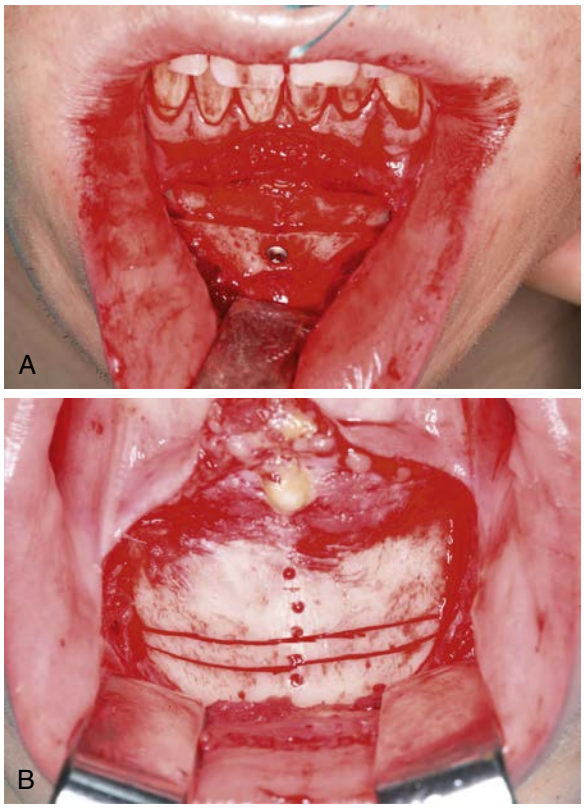
Steroid acne reaction[91] has been reported occasionally. In all cases it resolved after a few months without treatment.

• Box 17-1 Rare Complications in Orthognathic Surgery

Injury to cranial nerves II, III, IV, V, VI, VII, VIII, X, XI, and XII
- Ophthalmoplegia
- Neurosensory deafness
- Secretomotor rhinopathy
- Frey syndrome
- Altered tear secretion
- Haemolacria
- Blindness
- Adie pupil

Surgical ciliated cyst
Traumatic neuroma
Dysphagia
Compartment syndrome
Severe eustachian tube malfunction
Cerebrospinal fluid leak
Cerebrovascular accident (stroke, subarachnoid hemorrhage)
Retrobulbar hemorrhage
Severe hemorrhage
Arteriovenous fistula/false aneurysm/carotid-cavernous sinus fistula
Cavernous sinus thrombosis
Ischemic finger injury
Acute pulmonary edema/apnea
Pneumomediastinum/pneumothorax
Bone graft donor-site infection
Osteonecrosis of maxilla/mandible
Avulsion of maxilla
Condylar dislocation
Condylar resorption (progressive, idiopathic, condylar, atrophy)
Vomero-sphenoidal disarticulation
Perforated lateral nasal wall/septum
Oroantral/oronasal fistula
Brain abscess
Actinomycosis
Malignant hyperpyrexia/herniation of tube cuff/tube sectioning
Conversion disorder
Severe clinical depression
Loss of orthodontic bracket into airway
Death

Steel BJ, Cope MR: Unusual and rare complications of orthognathic surgery: a literature review, *J Oral Maxillofac Surg* 70:1678-1691, 2012.



• **Figure 17-23** Genioplasty in two steps for advancement more than 6 mm.

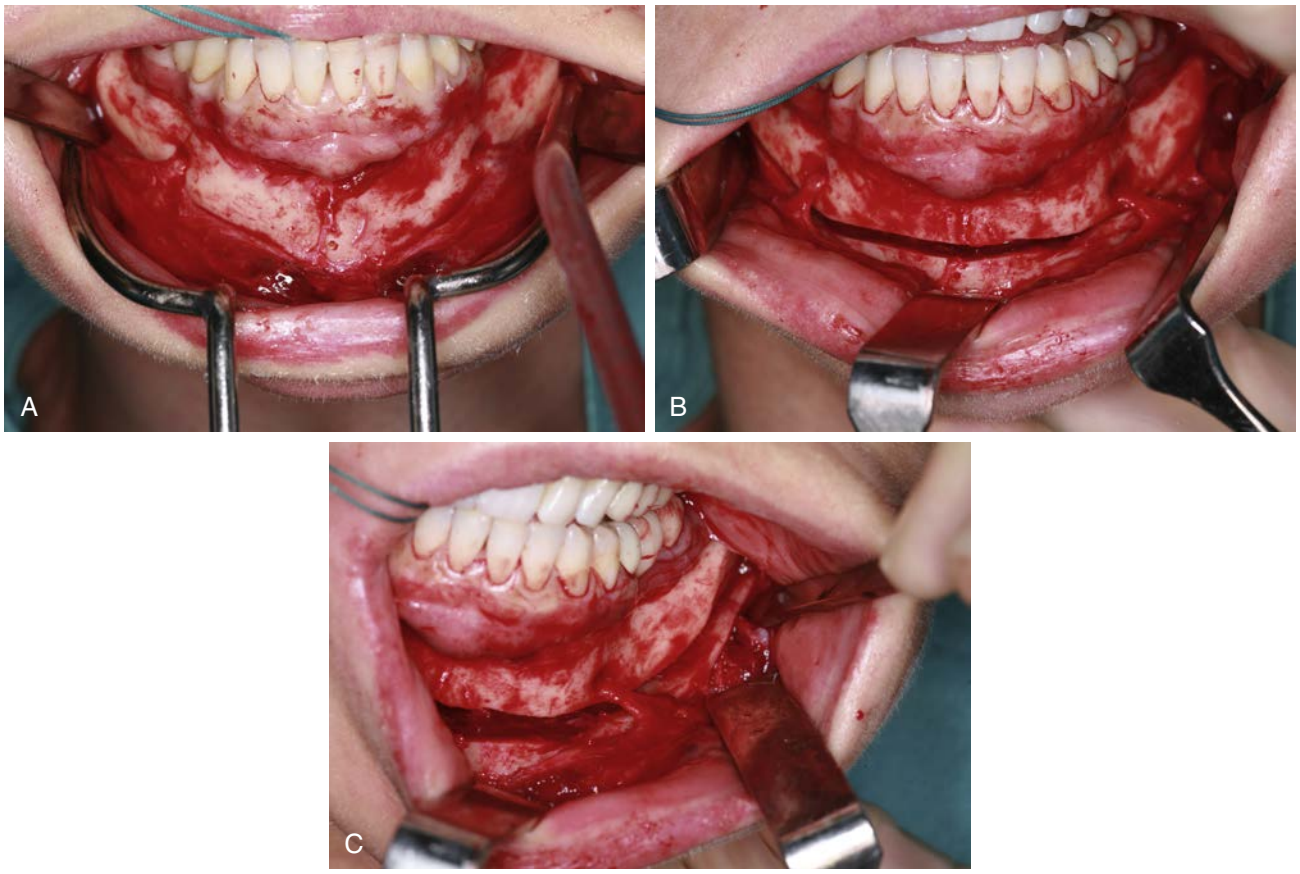
A few rare serious complications such as VTE are causally related to SSO (see earlier).[11]

Genioplasty

Genioplasty can be performed either alone or in combination with other orthognathic procedures. It may alter form in the vertical, anteroposterior, or transverse dimension, and is a perfect tool to harmonize facial proportions. Complications are rare when the operation is performed correctly. Mandibular hypoplasia and chin hypoplasia may require genioplasty advancement more than 6 mm, which creates an unsatisfactory deep labiomental fold that gives an unharmonious appearance. In this case, two-step genioplasty is indicated (Figure 17-23).

Chin wing osteotomies (Figure 17-24) allow not only changes of chin position but also harmonize mandibular angle projection.[92,93] They are also successfully used in patients with obstructive sleep apnea[93] when conventional maxillomandibular advancement is not indicated. The procedure is very effective, simple and safe if it is performed correctly. Complications are rare; however, neurosensory deficit might occur because the inferior alveolar nerve is exposed during the procedure (Figure 17-25). To avoid osteonecrosis it is particularly important that the cut bone segment remains attached to soft tissues and is thick enough to keep its vascularity.

• **Figure 17-24** This patient with a perfect occlusion suffers from lip incompetence due to lower border deficiency and long face. Chin wing osteotomy is indicated to reduce anterior lower face height.



• **Figure 17-25** Chin wing osteotomy. **A,** Surgical procedure. **B,** When freeing the bone from periosteum, care is taken not to injure the nerve. **C,** The cut is set below the nerve canal and soft tissue stays attached for vascularization.

• **Figure 17-26** Soft tissue incision for genioplasty is placed well out in the facial mucosa. This prevents per secundam healing.

Failure of Wound Healing

Wound dehiscence may occur when the mucosal incision is placed close to the attached gingiva in the vestibule. The incision is an important step when performing genioplasty. It should be placed well out into the facial mucosa, in the lower lip (Figure 17-26). It starts anterior to the mental foramen and crosses high in the loose mucosa to the other side. The submucosal tissue is then dissected along and through the muscle, to the periosteum. This permits wound closure in layers, at a distance from the osteotomy and the vestibule, which are the regions prone to the stress from movement.

Neurosensory Disturbance

Damage to the neurovascular bundle is rare when care is taken during initial soft tissue dissection and bone cuts. When vertical height is reduced, it might be necessary to free the nerve out of the canal; this may cause a postoperative neurosensory deficit. When vertical height needs to be reduced significantly, a wide piece of bone must be removed. It may then be necessary to free the nerve out of the canal, which may impair nerve function.

A variety of treatment modalities have been suggested. "Wait and see" for up to 3 weeks is one strategy. The administration of vitamin B and stimulation of the affected skin in accordance with a protocol is a second strategy. Treatment with steroids after surgery has been found to improve this condition significantly compared to 27 patients who received no steroids.[95]

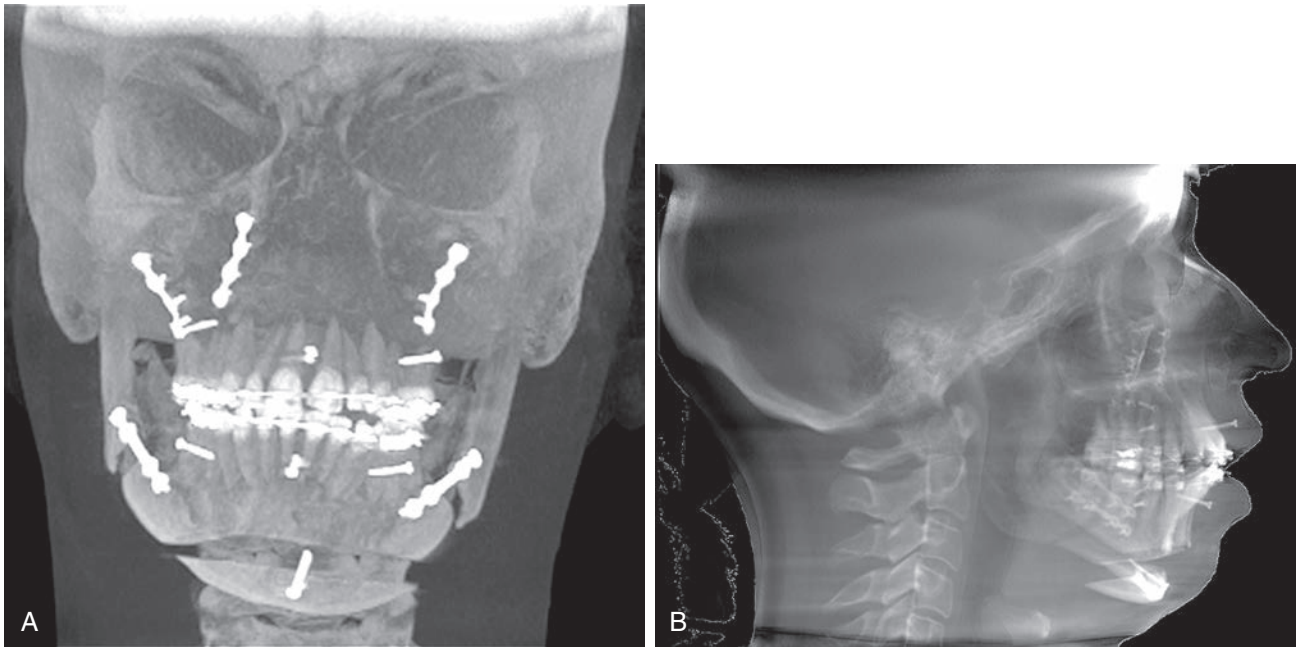
Loosening of Screw or Bone Plate

Bone displacement is a rare complication that can occur immediately after surgery. It is marked by loss of chin

projection and a "long face." Once identified, it must be corrected by the replacement of screws with a bone plate and screw stabilization (Figure 17-27).

Displacement of Synthetic Implants

Synthetic implants are rarely used by maxillofacial surgeons although their use has become an increasingly popular cosmetic procedure for chin retrusion and microgenia. Implants are usually placed in a pocket under the periosteum. They are usually not fixed with screws. Traumatic displacement or migration of chin implants may occur. Chin implant malposition is also a common complication and can occur in all spatial planes. Incongruous midline discrepancies are distressing for the patient. It is imperative to find the true midline and to correct the situation preferably by osteotomy (Figure 17-28).



• **Figure 17-27** Genioplasty bone displacement after screw loosened.

• **Figure 17-28** **A-C,** Patient with asymmetry after chin implant. The implant was removed and followed by a conventional genioplasty.

Continued

• **Figure 17-28, cont'd** **D-E,** Symmetry and better chin projection was achieved.

18 Rhytidectomy

ELDA L. FISHER

Introduction

For many years the face-lift or rhytidectomy has been the lynchpin of cosmetic surgery. In the early years of face-lift surgery, an elliptical portion of skin around the ears was excised and the skin margins were reapproximated to create a skin-only lift. Variations of this lift exist today. They vary from simple skin excision techniques coupled with thread lifts to deep plane sub-SMAS face-lift with complex vectors of pull. With so many options, the face-lift is still the most commonly performed cosmetic surgery on the face, second only to blepharoplasty.

The first reported face-lift was performed in 1901 by Eugene Hollander in Berlin. This was completed by excision of an elliptical incision of skin in the temporal region. Skin excision techniques were the mainstay of face-lift surgery until the 1970s, when Skoog introduced surgeons to the superficial musculoaponeurotic system (SMAS). This introduced surgeons to a deeper plane for face-lift dissection which was deep to the SMAS. Initially, dissections in this plane were limited anteriorly to the extent of the anterior aspect of the parotid capsule. Dissections that are limited to the anterior parotid, while still widely performed as technique today, do not fully address anterior cheek laxity. In the 1990s, advances in anatomic understanding of the distribution of the facial nerve allowed for further anterior dissection of deep to SMAS and platysma. These techniques included the composite flap face-lift (SMAS and skin en bloc dissection) and the two-plane face-lift (a skin flap and separate SMAS flap) allowed for increased mobility of the mid-face tissues and increased vectors of pull in the mid-face. The "high-SMAS" technique developed by Barton and the two-plane technique developed by Stuzin are deep-plane techniques that have allowed effacement of the nasolabial fold and jowls by various suspension techniques to address mid-face and lower face laxity.

Deep-plane variations of these face-lifts are still widely used and popular today; however, the newer variations that include less dissection with SMAS plication, lateral SMAS-ectomy, have become highly popular because they yield good outcomes for those with minimal to moderate anterior mid-face laxity, are technically easier to perform, and minimize risk to the facial nerve. In general, four generations of rhytidectomy have been described[25] (Table 18-1).

In 2014 there were 128,266 face-lifts performed in the United States, making it fifth overall in performed cosmetic surgical procedures. The majority of these face-lift procedures are superficial face-lifts or included a SMAS-ectomy or SMAS-plication. Interestingly, the overall rate of face-lift surgery in the United States has declined over the past 5 years. With the advent of more noninvasive facial rejuvenation procedures such as high viscosity facial fillers, many patients are opting for nonsurgical treatment.[1] The patient population seeking face-lifts has also changed over the years. Once a procedure that was essentially only performed on older women, it is now not infrequently performed on men and women from their early 40s and into their 90s. This demographic change in patients seeking a more youthful face has created an enormous boon in the facial cosmetic surgery industry, and has led to the advent of minimally invasive surgical techniques and nonsurgical adjuncts such as fillers, neurotoxins, and lasers, which are described in other chapters of this text.

Patient Evaluation

Evaluation of prospective patients for face-lift surgery considers three main areas: (1) medical history, (2) facial esthetic evaluation, and (3) psychosocial considerations. It is important that appropriateness for surgical intervention is considered in all three areas prior to the establishment of a surgical treatment plan. This will not only ensure the best possible outcomes for satisfaction of both the patient and surgeon, but will also optimize patient safety.

A thorough medical history is required prior to the planning of any surgery. This often begins with a history questionnaire that should detail any current or previous medical conditions and all prior surgical procedures. Any complications associated with previous surgical procedures are also noted, and include any peri-operative excess

TABLE 18-1 Generations of Rhytidectomy

	Generations of Rhytidectomy
I	Subcutaneous dissection only with variable skin undermining
II	Subcutaneous dissection with SMAS plication or imbrication
III	Subcutaneous dissection with SMAS plications or imbrication + deep mid-face dissection
IV	Composite dissection (Deep plane face-lift)

bleeding, postoperative infection, wound healing problems, and any complications that resulted in patient dissatisfaction with the procedure. The patient should have regular care from a primary care physician established, and the most recent history and physical exam should have been within the previous year. The patient's overall physical fitness for surgery is a combined medical assessment of the patient's overall physical condition, anesthetic risk, and ability to heal postoperatively. Appropriate consults should be obtained for patients with cardiovascular, pulmonary, renal, hematologic, or other systemic diseases that may affect surgical outcomes.

All medications, including over-the-counter medications and herbal supplements, should be listed and whether or not the patient is actually taking the medication should be noted. Anticoagulants are of particular concern, and include NSAIDs, herbal supplements such as ginseng and gingko biloba, and high dose vitamin E or fish oil. If possible, all anticoagulation should be suspended prior to surgery. Patients that require ongoing anticoagulation may need a short-term anticoagulant bridge such as low-molecular weight heparin so that anticoagulation can be stopped in the immediate perioperative phase only and resumed postoperatively.

Social history is also an important aspect of patient selection. Any history of smoking should be thoroughly investigated to rule out current smokers from elective cosmetic surgery. The rate of skin sloughing in smokers is almost three times the rate of nonsmokers (7.5% compared to 2.7%).[2] Use of illicit drugs such as cocaine, MDMA (3,4 Methylenedioxymethamphetamine), and other stimulants should also disqualify prospective candidates from elective cosmetic surgery because these drugs can compromise cardiovascular health and perhaps have secondary effects on flap microvasculature. Heroin or opioid abuse should also disqualify patients from elective surgical procedures, for obvious reasons. Heavy alcohol use should also be investigated, as this can compromise coagulation and nutritional status, leading to hematoma formation or poor healing potential respectively.

All past surgical history should be reviewed with the patient, including anesthetic history. The surgeon should have caution before proceeding with surgery if the previous surgeries include a laundry list of cosmetic surgical procedures, raising red flags for body dysmorphic disorder or a patient with unrealistic expectations for surgery. Anesthetic history may elicit a history of postoperative nausea and vomiting, which is undesirable for any surgical patient but particularly those patients who are immediately post-surgical from a face-lift. The anesthesiologist can usually tailor the anesthetic regimen to minimize postoperative nausea and vomiting in these patients.

A psychological history will give the surgeon an idea about the patient's motivations for surgery. Uncontrolled psychiatric conditions are a contraindication to elective cosmetic surgery. Body dysmorphic disorder should be considered in patients who have had repeated or a seemingly excessive number of cosmetic procedures performed.[3] Similarly any patient who has unrealistic expectations for surgery should not undergo cosmetic surgical procedures.

A physical examination of the patient should be performed that includes cardiovascular, pulmonary, gastrointestinal, and neurologic systems including a cranial nerve exam. Any previous surgical incisions should be examined for scarring tendencies. In addition to the surgeon's own physical exam findings, the surgeon may consider reviewing a recent history and physical exam from the patient's primary care physician to determine if the patient is optimized from a medical standpoint for surgery.

The examination of the face begins with excellent preoperative photographs. These should be taken with a black or blue background in unshaded light. Photos should include frontal face in repose and smiling, bilateral three-quarter views, bilateral lateral views, and posterior ear on each side. Isolated photos of the hairline, brows, eyes, and perioral regions should also be included. The hairline should be visible in all photos, therefore bangs need to be retracted with a headband, and lateral and posterior ear photos should also have all hair obscuring the hairline retracted.

Evaluation of the face should be addressed in a systematic manner. The face is typically divided into horizontal thirds and vertical fifths. The upper third includes the forehead, brows, and upper eyelids. These areas are not addressed with a face-lift. The middle third includes the nose and nasolabial folds, lower eyelids, and cheeks. Only the cheeks are addressed in this third. The nasolabial fold can be addressed with deeper-plane or extended face-lifts, and the patient should be aware that there may be minimal improvement in deep nasolabial folds with superficial plane face-lifts.[5-7] It should also be noted when assessing this area whether the patient is thick or thin skinned as this may affect the longer term surgical outcomes.[4] The lower face includes the lips and perioral region, the lower cheek and jowls, and neck. The face-lift procedure is the only procedure that addresses jowling. The neck is addressed with cervicoplasty with or without platysmaplasty, and this should be clear to the patient because there may be an expectation for neck laxity correction. Perioral rhytids are not addressed by either face-lift or cervicoplasty procedures, and this should be made clear to the patient because

this is a common area of complaint in the aging patient. Other important findings during facial evaluation include the hairline, skin color (Fitzpatrick scale), rhytids (Glogau scale), sun damage, scarring, and facial asymmetries. Special attention should be addressed to the earlobe as face-lift closure technique may affect its appearance; any deviation from normal lobe appearance preoperatively should be identified to the patient.

Because many patients desiring face-lift procedure also complain of neck laxity, the profile of the neck should be addressed and is easily characterized by the Dedo classifications system[26] (Table 18-2). Application of this classification system may help the surgeon plan the appropriate procedures for lower face improvement (Figure 18-1). Other factors to consider in the neck are the degree of skin redundancy, the degree of platysmal banding, cervicomental angle, hyoid position, and submental fat accumulation. A desirable cervicomental angle is 90 degrees. Patients with an inferiorly positioned hyoid bone that (below the 4th cervical vertebrae) necessarily have an obtuse cervicomental angle that is not corrected by cervicoplasty or plastysmaplasty.[2] Ptosis of the submandibular glands can also contribute to unfavorable neck appearance, which requires a separate submandibular gland suspension procedure in addition to conventional neck lifting procedures.[8,9]

The preoperative evaluation appointment should conclude with a presentation to the patient of all surgical procedures necessary for optimal facial esthetics, and the timing and anticipated costs of those procedures. Preoperative counseling should include a description of postoperative time for recuperation, pain management expectations, and anticipated postoperative swelling, bruising, and "downtime." Patients should be advised to avoid any products with nicotine, including e-cigarettes and nicotine gum and patches. Avoidance of blood thinning agents is also stressed, including avoidance of aspirin, NSAIDs, and fish oil for at least 2 weeks prior to surgery. Postoperative instructions should be reviewed in written and verbal form, and the patient should be able to verbalize understanding of all instructions.

It is important to remind the patient that postoperative bruising typically lasts for at least 2 weeks, and thereafter can usually be covered by make-up. Postoperative swelling can last for months, so the final outcome of the face-lift procedure may not be achieved until several months postoperatively. Additionally, the patient should be reminded that consistent postoperative follow-up is imperative.

TABLE 18-2 Dedo Classification of Facial Profiles

	Patient Profile	Surgeon
I	Normal	Well-defined cervicomental angle Good muscle tone No submental fat
II	Cervical skin laxity	Obtuse cervicomental angle due to relaxed skin
III	Submental fat accumulation	Requires submental lipectomy
IV	Platysma muscle banding	Requires muscle clipping, plication, or imbrication
V	Retrognathia or micrognathia	Requires genioplasty or orthognathic surgery
VI	Low hyoid	Difficult to alter Inform patient of limitations

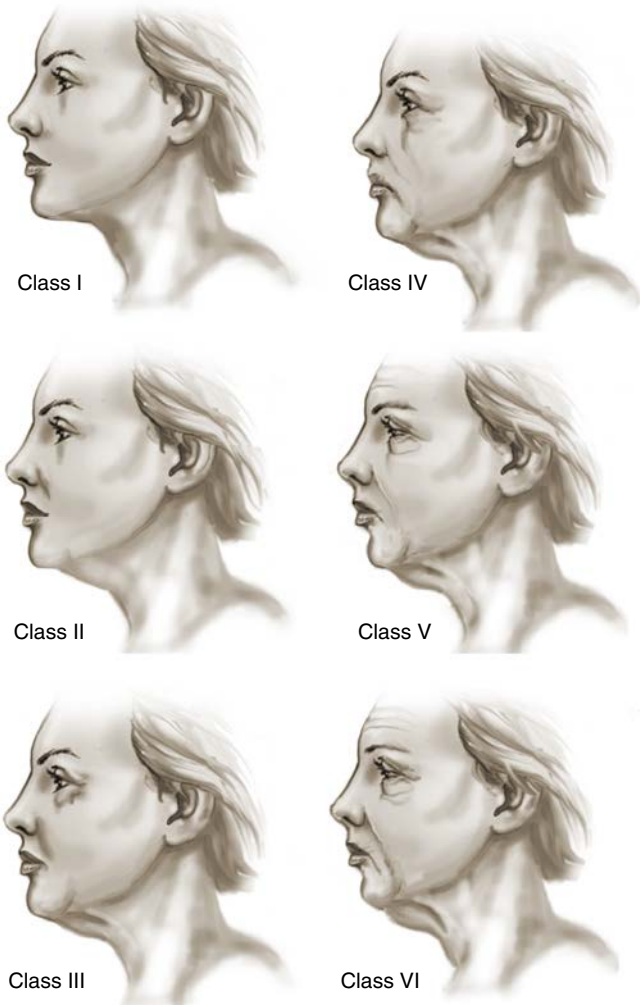
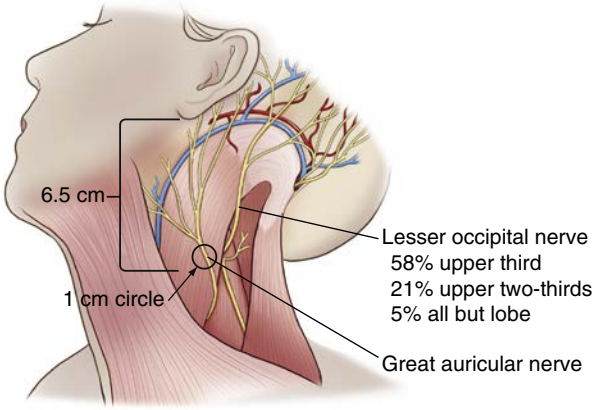
Anatomic Considerations

Vascular Anatomy

The anatomy of the arterial supply to the face and venous drainage in the area of face-lift dissection is significant, not only to avoid injury to the vessels, but also for consideration of flap viability postoperatively. From a surgical standpoint,



• **Figure 18-1** Six classes of facial neck profiles by Dedo.



• **Figure 18-2** Marking of McKinney's point.

the most frequently encountered vessels in face-lift surgery are the external jugular vein and the transverse facial artery.

The internal jugular vein is encountered during the neck dissection that begins posterior to the ear and descends superficially above the sternocleidomastoid muscle. Prior to surgery, McKinnney's point is marked on the skin surface at 6.5 cm inferior to the bony external auditory meatus at the midpoint of the sternocleidomastoid muscle. McKinney's point marks the site of the greater auricular nerve as it crosses over the belly of the sternocleidomastoid muscle.[27] A 1-cm radius from this point is demarcated in all directions. The anterior portion of the resultant circle will identify the site of the jugular vein as it passes the anterior border of the sternocleidomastoid muscle (Figure 18-2). Upon dissection of the neck flap, care should be taken in the area to maintain a superficial plane to avoid injury to this vessel. If the vessel is injured, the surgeon will encounter significant bleeding. Proximal and distal ligation with silk suture is the appropriate treatment. Prior to closure, hemostasis in this area must be verified to avoid the accumulation of hematoma in the posterior auricular region and neck area.

The transverse facial artery is the most significant arterial contributor to the lateral face. The site of perforation of the transverse facial artery is marked preoperatively on the skin surface 2.5 cm lateral and 3 cm inferior to the lateral canthus of the eye. A circle with a 0.5 cm radius is marked around this point, creating a site of caution for the surgeon at this area of dissection. Disruption of the transverse facial artery may contribute to skin flap necrosis and hematoma formation.

Facial Nerve Anatomy

The facial nerve is the master of facial expression, and postoperative dysfunction is devastating to face-lift surgery. The facial nerve exits the stylomastoid foramen and travels between the digastric and stylohyoid muscles inferiorly and anteriorly into the substance of the parotid gland. The nerves travel in the fibrous tissue within the parotid gland that separates the deep and superficial lobes of the gland. The nerve splits into two major divisions, superior and inferior. The superior branch gives rise to the temporal and zygomatic branches, while the inferior division gives rise to the buccal branch, marginal mandibular branch, and cervical branch. Both divisions are important in face-lift surgery and caution to protect these branches is paramount to successful outcomes. The buccal and zygomatic branches are highly arborized medial to a vertical line drawn from the lateral canthus, and injury to these branches that results in paralysis of noticeable long-term injury is unlikely. The frontal and marginal mandibular branches are terminal and significantly less arborized, so careful dissection is crucial to avoid long-term injury resulting in permanent facial weakness or paralysis. Branches of the facial nerve innervate all of the muscles of facial expression, and typically from their deep surfaces, only three of the muscles of facial expression are innervated from the superficial surfaces: the buccinator, the mentalis, and the elevator anguli oris.

The facial muscles are enclosed by the SMAS below the zygomatic or the temporoparietal fascia above the level of the zygoma. In the lower face the facial nerve courses deep to the platysma except where it innervates the buccinator, levator anguli oris, and mentalis. The marginal mandibular branch courses inferiorly from the parotid and along the inferior border of the mandible, deep to the platysma, and within the superficial layer of the deep cervical fascia. An anatomic study published by Dingman and Grabb demonstrated that in 19% of cadaveric specimens, the nerve travels up to 1 cm below the inferior border of the mandible posterior to the facial artery, and anterior to the facial artery the nerve was found at or above the inferior border of the mandible in 100% of dissections.[10] It should be noted that in some anatomic studies, the nerve has been found as low as 4 cm below the inferior border.[11]

The superior division of the facial nerve courses superiorly within the substance of the parotid gland and proceeds along the Pitanguy line toward the temporal region.[12] This line is marked by an inferior point at 0.5 cm below the tragus and superior point 1.5 cm above the lateral brow. The branches emerge from the parotid and cross the zygomatic arch approximately 2.5 cm anterior to the external auditory meatus.[13] At this crossing the nerve is most vulnerable to injury, however, in a sub-SMAS dissection plane, it is protected within the fat just deep to the temporoparietal fascia.

Surgical Technique

Patient Marking

Identification of key patient landmarks is helpful to guide the extent of dissection both in the subcutaneous and, if necessary, sub-SMAS plane. All markings should be completed in the preoperative area while the patient is in an upright position. The incision line should be marked bilaterally with an indelible marking pen. The preauricular crease is the appropriate site for the incision. At the tragus, the incision can remain pre-tragal (which is this author's preference), or extend on the tragal margin or intratragal. Incisions that extend intratragally are well hidden; however,

contracture often pulls the tragus anteriorly, leaving an unnatural appearance to the contours of the ear and direct line of site into the ear canal, an unmistakable sign of previous face-lift. Superiorly the incision extends around the superior aspect of the ear, leaving a pedicle before turning anteriorly and superiorly with a curve in the hairline.

Inferiorly the incision wraps under the earlobe, and extends two-thirds of the way superiorly along the posterior aspect of the ear, staying just inside the posterior ear crease. Incisions made directly in the crease will contract posteriorly and leave the scar in a noticeable area posterior to the crease. At the superior extent of the posterior incision, the incision extends posteriorly in an arched fashion into the hairline to create a semicircle, and extends postero-inferiorly in the hairline, terminating at level of the inferior aspect of the mastoid process.

Additional markings are made at point on the face 2 cm lateral and 3 cm inferior to the lateral canthus, marking the site of the perforating branch of the transverse facial artery.

The anterior border of the sternocleidomastoid is marked bilaterally by having the patient attempt to rotate the head against firm opposing pressure. McKinney's point is marked 6 cm inferior to the external auditory meatus (EAM) to the center of the sternocleidomastoid. A 1-cm diameter circle is marked at this point to maintain awareness of the greater auricular nerve, XII cranial nerve, and internal jugular vein, all which emerge from the sternocleidomastoid within 1 cm of this site.

Intraoperative Technique

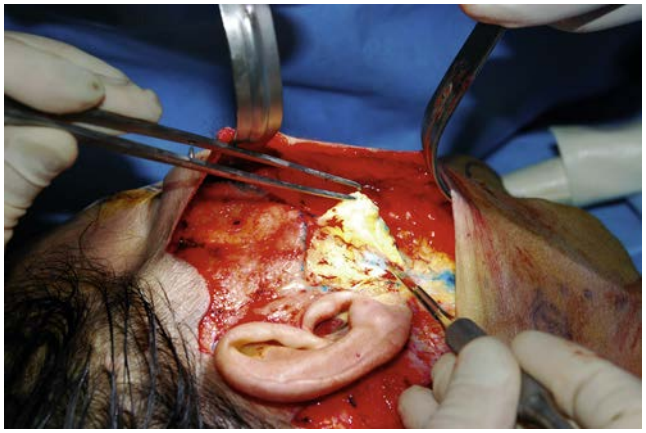
Once the patient is intubated, he/she should be appropriately positioned. The face should be turned to expose the first side of the face-lift. If the eyes are to be taped, be sure they are taped gently and do not obscure the natural lines on the face. An alternative to taping is placement of corneal protectors. The hairline should be clipped bilaterally superior to the ear and in the posterior extent of the incisions. This author preps the face twice, first with chlorhexidine including the hair, and a Betadine cotton pellet is placed in the EAM bilaterally. At this time, 3 mL of methylene blue are injected intraorally into the Stenson's duct bilaterally. This stains the parotid gland blue, making identification of the parotidomasseteric fascia very easy upon dissection. A second prep of the skin is then completed with Betadine.

There are a variety of techniques for local anesthetic infiltration. Local anesthesia is infiltrated along the incision line with 2% lidocaine 1:100,000 epinephrine. The surgeon can then opt to use additional local anesthetic in a tumescent formula for hydrodissection and hemostasis in the subcutaneous place. There are many tumescent formulations, and one example is a mixture of 20 mL of 2% lidocaine 1:100,000 epinephrine with 180 mL of normal saline, totaling a 0.2% lidocaine solution with 1:1,000,000 epinephrine solution. The tumescent solution is delivered by cannula at four distinct sites: temporal, infralobular, mastoid, and if performing a cervicoplasty, submentoplasty or platysmaplasty with rhytidectomy, then also in the submental area.

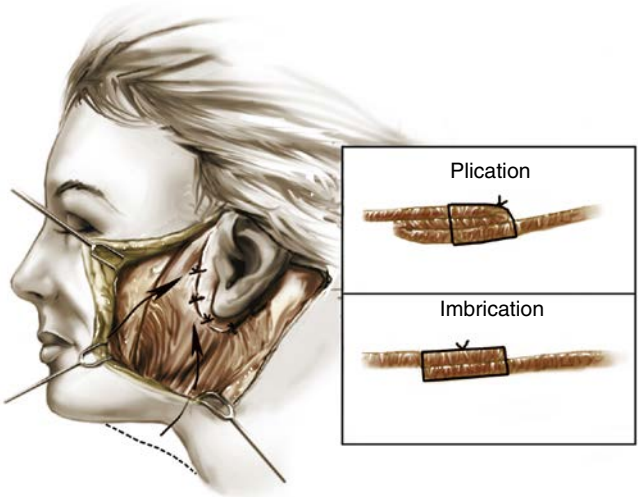
• **Figure 18-3** Skin flap dissection.

The tumescent solution is delivered in the subcutaneous plane superior to the SMAS and platysma, and approximately 1 cm beyond the planned limits of subcutaneous dissection. This requires a total of approximately 200 mL to complete the bilateral face. Tumescent solution requires between 5 and 10 minutes for optimum effectiveness, and therefore should be completed 5 minutes prior to incision.

The incision is initiated in the temporal region with a No. 10 or No. 15 blade. The blade is held at a sharp angle oblique to the skin and directed toward the skin flap. This scything of the incision line preserves the hair follicles and diminishes alopecia along the incision line. The incision is carried along the preauricular regions, inferior to the lobe and posterior-auricular region, and then onto the mastoid and into the posterior hairline. The dissection of the subcutaneous flap is performed in the same progression, beginning temporally and extending into the cheek from the preauricular region, and into the neck in the inferior lobe and mastoid areas. The subcutaneous dissection should be completed approximately 5 to 7 cm from the incision line in the preauricular area and leave at least 4 mm of skin to preserve the blood flow to the skin flap (Figure 18-3). Exercise caution while performing the subcutaneous dissection in the posterior auricular neck while directed toward the SCM; continuous verification of the marking of McKinney's point should keep the surgeon cautious of injury to the greater auricular nerve, which is damaged in 5% of rhytidectomy procedures. The skin flap should remain superficial here, and deep dissection may also traumatize the accessary nerve or the jugular vein, which is a difficult complication to manage for hemostatic control because visualization during dissection and with hemorrhage is often suboptimal. Bipolar cautery should be used throughout the dissection with judicious use of Bovie cautery on the skin flap to avoid skin



• **Figure 18-4** Marking and dissection under SMAS.



• **Figure 18-5** Plication versus imbrication.

necrosis. Dissection should always proceed in a dry, well visualized field. The skin flap dissection can be completed with a No. 10 blade or with scissors dissection.

After the skin flap has been adequately undermined, attention is directed toward the SMAS. A skin-only facelift without manipulation of the SMAS will not adequately address the laxity of the anterior malar region or deep nasolabial folds. Manipulation of the SMAS layer can be accomplished with plication, imbrication, or sub-SMAS dissection (Figure 18-4). Plication is the process of folding the SMAS over onto itself to achieve repositioning. Imbrication involves incision of the SMAS with either excision or overlapping edges to achieve the desired position. Plication sutures can be placed in the SMAS adjacent to the angle of the mandible, and sutured superiorly to the fascia at the inferior aspect of the tragus. A second plication suture can be placed in the SMAS lateral to the oral commissure and secured to the fascia overlying the inferior aspect of the zygoma superior to the tragus. Additional plication suture can be placed the SMAS and sutured to the posterior-auricular and cheeks regions to achieve the desired amount of tightening in multiple superior-posterior and lateral vectors (Figure 18-5).

Sub-SMAS or imbrication techniques require an incision in the SMAS that is initiated 1 cm anterior to ear. Bonnies blue can be used to mark the incision line into the SMAS. This typically has a vertical component extending from the anterior ear region into the platysma, and a horizontal component that parallels the zygomatic arch and extends just to the point where the zygomatic arch turns inferiorly at the lateral malar region. This is at the area that was previously marked on the skin as the region where the perforating branch of the transverse facial artery emerges. Additional dissection deep to the SMAS can be completed and there are various techniques for further dissection both superiorly and toward the nasolabial fold that are beyond the extent of this chapter. Dissection under the SMAS is facilitated by identifying the blue color of the parotid gland stained with methylene blue. This allows for easy identification of the sub-SMAS plane without extension deep to the parotidomasseteric fascia where the seventh cranial nerve may be injured. Once the incision through the SMAS is completed, the SMAS layer is grasped with forceps and dissection is completed sharply with a No. 15 blade under the SMAS to the desired extent. Once undermined, the SMAS flap can be pulled in various vectors to achieve the desired lift. The corner of the superior posterior SMAS at the ear–zygoma intersection is then cut with scissors at an approximately 45 degree angle at the level of the desired keystone suture; a suture placed here is then firmly secured to the fascia at the superior posterior lateral aspect of the zygomatic arch. Excess SMAS can then be excised with scissors and the remaining edges of the same are then sutured to the posterior and superior aspects of the SMAS respectively to achieve the appropriate amount of lift in these vectors. Aside from the keystone sutures, SMAS suturing can be completed with slow resorbing 2-0 sutures and can be interrupted or in a running fashion (Figure 18-6).

Once the SMAS suturing has been completed, the patient's head is returned to a neutral position without extension or flexion of the neck. The skin is redraped. Excess skin is carefully excised to match the incision line. It is important to close the skin flap under minimal or no tension to minimize scar formation and reduce chances of skin necrosis. The skin vector should mimic the SMAS vector in a posterior-superior direction. Before the skin flap is trimmed, skin staples are placed in key areas to position the flap, and then excess skin is excised with a No. 15 blade in short segments.

Skin closure in all regions is completed first with closure of the subdermal layer with 3-0 interrupted restorable sutures with buried knots. The skin in the temporal region is closed with 4-0 or 5-0 fast absorbing gut in a running interlocking fashion, which best everts the skin margins. A 6-0 Prolene or nylon suture is used in the vertical portion of the incision at the preauricular area and posterior bowl area, again in a running interlocking fashion to best evert the skin margins (Figure 18-7). The incision from the posterior bowl and into the posterior mastoid region extending inferiorly along the hairline can be closed with plain gut in a running

• **Figure 18-7** Closure. **A,** Standard closure with nylon suture in running interlocking fashion at preauricular region. **B,** Alternative closure with subcutaneous sutures and application of Dermabond in preauricular region and staple closure in posterior auricular region. (Courtesy Tirbod Fattahi, MD, DDS, FACS.)

interlocking fashion. Prior to completion of the skin closure on the first side, local anesthetic should be injected into the second side approximately 5 to 8 minutes prior to incision. Additionally, prior to skin closure the surgeon should establish excellent hemostasis with electrocautery and with the additional use of aerosolized fibrin glue if desired. This minimizes the risk of hematoma formation. If using fibrin glue, the skin flap should be held in place with firm pressure for 5 minutes prior to suturing.

A dressing of antibacterial ointment is placed along the incision line, followed by a gauze and bandage pressure dressing, such as a Barton-style dressing, to minimize hematoma formation. Care should be taken to avoid placing this dressing too tightly as this can cause significant discomfort for the patient. Additionally the ears should not be folded, but allowed to extend in their natural direction out from the dressing. Dressings should remain in place until postoperative day 1 (at least 12 hours to a maximum of 36 hours). The surgeon should remove the dressing and examine for hematoma formation or early flap necrosis. Some surgeons choose not to place any dressing, citing that pressure dressings may decrease hematoma formation but increase the pressure necrosis of the flap. In these instances, this author recommends placement of a TLS drain at least in the posterior auricular flap where most hematoma formation occurs, to be removed on postoperative day 1.

Immediate Postoperative Care

Once the dressing or drain is removed, the patient should be instructed in wound care. Incision lines should be cleaned twice daily with warm water and a gentle baby washcloth or 50/50 solution of H_2O_2 and water. This is followed by application of a thin line of antibiotic ointment. The hair

can be shampooed starting on postoperative day 3 with care to avoid the incision lines and only using unfragranced, mild shampoo, such as Neutrogena or Johnson and Johnson baby shampoo. Nonrestorable sutures are removed from the preauricular region on postoperative days 5 to 7. No hair dye should be applied within 6 weeks postoperatively.

The author recommends that the hair is colored approximately 5 days preoperatively to a new and noticeable different color and to a new hairstyle that will cover the incision lines if blow-dried appropriately, even in the temporal region where the hair will be clipped. This is important to minimize the observation of friends and relatives to the face-lift procedure and redirect their attention to these more superficial changes.

The patient should make every effort in the 6 months postoperatively to avoid sunlight exposure to the incision lines (Figure 18-8).

Complications

Prevention of complications begins in patient assessment. Some relative contraindications to face-lift surgery include smoking, poorly controlled hypertension, use of anticoagulants, poor nutritional status, use of immunosuppressants, and any other poorly controlled medical condition such as diabetes or COPD. Overall incidence of complications after face-lift surgery is approximately 1.5%,[14] which includes local and systemic complications. The incidence of major systemic complications such as cardiopulmonary dysfunction or venous thromboembolism is less than 0.1%.[14]

Hematoma

Hematoma formation is the most common postoperative complication of face-lift surgery and major hematoma requiring surgical intervention occurs in 1.1% of patients.[14] Hematoma formation is more common in males than females with one study suggesting the rates as 4.4% in males versus 1.3% in females.[14] The presence of postoperative hematoma can have significant consequences on the outcome of face-lift surgery, including flap necrosis and, in severe situations, airway compromise. Major factors influencing hematoma formation are smoking, aspirin or NSAID use, male gender, perioperative hypertension, and concomitant platysmaplasty.[15] The surgeon should take pre-, intra-, and postoperative precautions in preventing hematoma formation. Preoperatively, patient selection is paramount to success. Smokers and patients with poorly controlled blood pressure should not undergo elective cosmetic surgery procedures. Platelet inhibiting medications and any other medical or herbal anticoagulation should be suspended at least 2 weeks prior to surgery. Intraoperatively, hemostasis should be obtained throughout the surgery with meticulous attention to small bleeding vessels. Hemostasis should be rechecked prior to closure at the patient's normal preoperative blood pressure. This author finds that the best way to check for hemostasis is with the overhead OR lights off and with the use of surgical headlight illumination under the flap. Use of a fibrin glue prior to closure may aid in hemostasis and prevention of hematoma formation.[16] Small drains to bulb suction can also be placed during closure. If used, the active portion of the drain should traverse the preauricular area, descend inferior to the mandible and into the lateral neck, and exit at or around the mastoid closure site. Postoperative use of a Barton-like pressure dressing may be maintained for 12 to 24 hours postoperatively until the first postoperative check (Figure 18-9).

Skin Necrosis

Skin necrosis is reported to occur in 1% to 3.6% of face-lift surgery. Higher incidences are found in subcutaneous versus sub-SMAS face-lift techniques because the incidence of ischemia is higher in thin skin flaps. Additional causes of skin necrosis are excessive tension on skin flaps at closure, hematoma formation, excessive pressure dressings, and in patients who are smokers. Skin necrosis most commonly occurs at the skin flap just superior to the auricle of the ear and the skin flap over the mastoid process, representing the sites of the thinnest skin involved in face-lift surgery. Areas of necrosis are addressed with local wound care measures, and most cases will heal without the need for surgical debridement or skin grafting procedures (Figure 18-10).

Infection

Infection is a rare complication of face-lift surgery, representing less than 0.3% of patients.[14] Prevention of infection includes perioperative IV antibiotics directed at *Staphylococcus* species prior to incision. Postoperative auricular infections may not be covered by the typical pre-incision antibiotic because they are commonly *Pseudomonas* species. These types of postoperative infections are often managed with oral quinolones, but may require incision and drainage. Postoperative use of Bacitracin ointment at the incision site for 5 days may aid in prevention of infection. Patient compliance with postoperative wound care instructions will also reduce incidence of infection and should include gently cleansing the incision site with mild soap (such as Johnson and Johnson Purpose) and warm water twice daily.

Patients with impaired immune function have a higher risk of postoperative infection. In the setting of the use of immunosuppressants such as adalimumab and etanercept (Humira and Enbrel), these drugs should be discontinued with approval from the prescribing physician prior to face-lift surgery and may be restarted postoperatively. If discontinuation of medications is unavoidable, the surgeon should consider a prolonged course of postoperative antibiotics. Diabetic patients should maintain tight glycemic control in the perioperative period.

• **Figure 18-10** Skin necrosis in the preauricular and supra-auricular portions of the flap. This is also commonly seen in the posterior auricular region just over the mastoid process. In these areas, the skin flap may become excessively thin and contribute to skin necrosis.

Nerve Injury

Injury to the facial nerve is one of the more devastating complications of face-lift surgery because it can produce permanent and obvious disfigurement. The incidence of permanent injury to the facial nerve is largely reported at 0.1%.[17,18] Transient nerve dysfunction in the immediate postoperative period is normal, and is a result of edema, prolonged effect of local anesthetics, or traction on the nerve. Spontaneous recovery is noted either early in the postoperative period in the case of edema or prolonged effect of local anesthesia, or later by 3 to 4 months in cases of substantial nerve traction or dissection. The buccal branch is the most commonly injured branch, but because of the great arborization of this branch, injuries are often less clinically significant compared with injury to other facial nerve branches.[19] Permanent injuries to the frontal or marginal mandibular branch are less forgiving cosmetically and produce an asymmetric smile and inability to purse the lips. Damage to the frontal nerve branch is less common in superficial plane face-lifts because the nerve is protected by the fat overlying the zygoma. Damage to the frontal branch results in a drooping brow and dysfunction of the ipsilateral forehead musculature. Marginal mandibular nerve damage is characterized by asymmetric smile caused by dysfunction of the lip depressor muscles, and is prevented with meticulous dissection at the level of the mandible and just inferior to it (Figure 18-11). Damage to the cervical branches may mimic damage to the marginal mandibular branch. This can be distinguished by having the patient evert the lower lip; if mentalis function is intact, then the injury spares the marginal mandibular branch.[20] If nerve transection is identified intraoperatively then the nerve should be repaired with 7-0 nylon or other nonresorbable suture. In cases of permanent nerve deficits, the patient should be referred to a specialist for nerve repair or facial reanimation procedure. It should be noted, however, that those procedures have limited success.

Neurosensory disturbances are common in the immediate postoperative period and are typically transient, lasting 4 to 6 weeks in the postoperative period. This type of temporary hypoesthesia is the result of necessary disruption of the cutaneous innervation with the elevation of the skin flap. Permanent paresthesias occur in 5% of face-lift

• **Figure 18-11** Damage to marginal mandibular nerve branch. Note injury to right marginal mandibular branch demonstrated by weakness of the depressor muscles of the right lip and lower face.

patients.[21] The most commonly injured sensory nerve is the greater auricular nerve. The site of this nerve, McKinney's point, should be marked preoperatively at the midpoint of the sternocleidomastoid muscle 6.5 cm caudal to the bony external auditory meatus.[22] A margin of 1 cm around this point will also identify the site of the internal jugular vein, typically 0.5 cm anterior to the nerve, and caution the surgeon to keep the dissection plane superficial in this area. Damage to this nerve results in paresthesia of the lower two-thirds of the ear and the associated pre- and posterior-auricular skin.

Scarring and Alopecia

Hypertrophic scarring can occur with any surgical procedure. A complete history from the patient including inspection of previous surgical scars may elicit a history of hypertrophic scarring or keloid formation. Keloid formation is most common in African-American patients. Patients at risk for hypertrophic scarring should be informed preoperatively, and a plan for postoperative management should be in place prior to surgery. Perioperative management may include silicone sheeting, steroid injections, and extended follow up. Hyperpigmentation of scars is common with direct sun exposure, and patients should be cautioned to avoid direct sun exposure in the first 6 months postoperatively and thereafter to use a broad spectrum (UVA and UVB) sunscreen with at least SPF 30 or greater and reapply liberally. Scarring is also minimized by tension-free skin closure and eversion of the skin margins at closure. The appearance of postoperative scars can be minimized by use of microneedling techniques or laser skin resurfacing.

Alopecia along the incision line occurs as a result of several factors. Excessive skin tension at closure will result in a smooth widened scar with central alopecia. Improper beveling technique in the hair-bearing areas will also result in alopecia, as the bevel should be angled such that viable hair follicles are deep to the reapproximated superficial flap. Limiting the use of electrocautery on the scalp margin and avoiding electrocautery on the skin flap margin after excision of excess skin will also decrease the likelihood of development of alopecia. For treatment of alopecia at the incision site, the bald area should be excised and the resultant margins should be close primarily without tension.

• **Figure 18-12** Pixie ear deformity. Note the loss of the free lobule of the earlobe and subsequent elongation secondary to elongated attachment to the cheek tissue.

Ear Deformities

Ear deformities often occur after inappropriate closure of face-lift surgery. Most common is the "pixie" ear deformity that results when the earlobe is pulled inferiorly onto the cheek skin. This causes an elongated area of attachment between the cheek and lobe and loss of the free lobe portion (Figure 18-12). The incidence of this complication is 5.7%.[11] The primary means of preventing pixie ear deformity is reattachment of the SMAS layer to the deep layer of the fascia surrounding the conchal bowl followed by judicious skin trimming in the lobe area of the flap leaving at least 1 to 2 mm of perilobar skin. Correction of pixie ear deformity should be delayed until at least 6 months postoperatively, and requires excision of a medially based triangle of skin at the lobe-cheek junction.[23]

Change in the projection of the ear may also occur after face-lift surgery resulting in increased auriculocephalic angle and the appearance of protruding ears. This is caused by damage to the musculature approximating the auricular

cartilage to the skull. Avoiding disturbance to these muscular and ligamentous structures is best completed by avoiding incision directly in the auriculocephalic crease and instead placing the incision 3 to 4 mm onto the skull posterior to the crease. Correction of overprojection is completed through standard otoplasty and should also be delayed until at least 6 months postoperatively.

Parotid Sialocele

Parotid sialocele is a rare complication of face-lift surgery. It is often noted by postoperative day 7 but may be evident as early as postoperative day 3. This complication is rare in superficial plane face-lift but is more common in deep-plane face-lifts where the capsule of the parotid gland is adjacent to the surgical plane. If the parotid capsule is violated, facial swelling may occur and is particularly noticeable with food intake. Diagnosis is confirmed with aspiration of saliva from the swelling. Conservative management with pressure dressing and aspiration generally results in resolution in 1 to 5 weeks. Additionally, the use of botulinum toxin for persistent parotid sialocele may ameliorate the condition.[24] Rarely, persistent sialoceles may require radiation or sialadenectomy.

The Use of Lasers in Maxillofacial Surgery

NATASHA FÜRCHTGOTT, BRIAN C. PATERSON, BERNARD J. COSTELLO

Introduction

Laser light is an important tool used in a wide variety of disciplines. Since its conception, it has been implemented in research laboratories, communication systems, surveying, manufacturing, diagnostic medicine, and surgery. Medical applications have been described for multiple specialties such as ophthalmology, otolaryngology, plastic surgery, gynecology, general surgery, and oral and maxillofacial surgery.

Surgical lasers become a useful tool in the surgeon's armamentarium because of their precision and ability to provide target-selective treatments. In addition to being an adjunct to conventional surgical methods, lasers are now the treatment of choice or the sole treatment modality for a variety of pathologies. Thanks to better delivery systems and reduced cost, lasers have moved into private offices rather than being exclusive to operating rooms in health systems and academic centers.

History

Laser light is the brightest monochromatic (single color) light that exists today.[1] The term *laser* is an acronym for *l*ight *a*mplification by the *s*timulated *e*mission of *r*adiation. In 1917, Einstein postulated the theoretic basis for laser production by introducing the concepts of absorption, spontaneous emission of energy, and stimulated emission of energy when he discussed the interaction of atoms and electromagnetic radiation. That article, "Zur Quantem Theorie der Strahlung" ("The Quantum Theory of Radiation"),[2] was the basis for many attempts to produce stimulated emission of radiation, which was finally achieved in 1954 by Gordon, Zeiger, and Townes[3] with the fabrication of the MASER (microwave amplification by the stimulated emission of radiation).

It was not until 1960, however, that the first working device (a synthetic ruby diode laser) was developed by Maiman, coining the term *laser*.[4] This device produced electromagnetic radiation at a wavelength of 0.69 μm in the visible range of the spectrum. Zaret was the first one to describe how lasers interact with living tissue by creating ocular lesions in rabbits.[5] Since then, and the development of the neodymium:yttrium-aluminum-garnet (Nd:YAG) and carbon dioxide (CO_2) lasers, a plethora of surgical techniques and applications has been described and refined for the use in the head and neck region.

Principles of Laser Physics

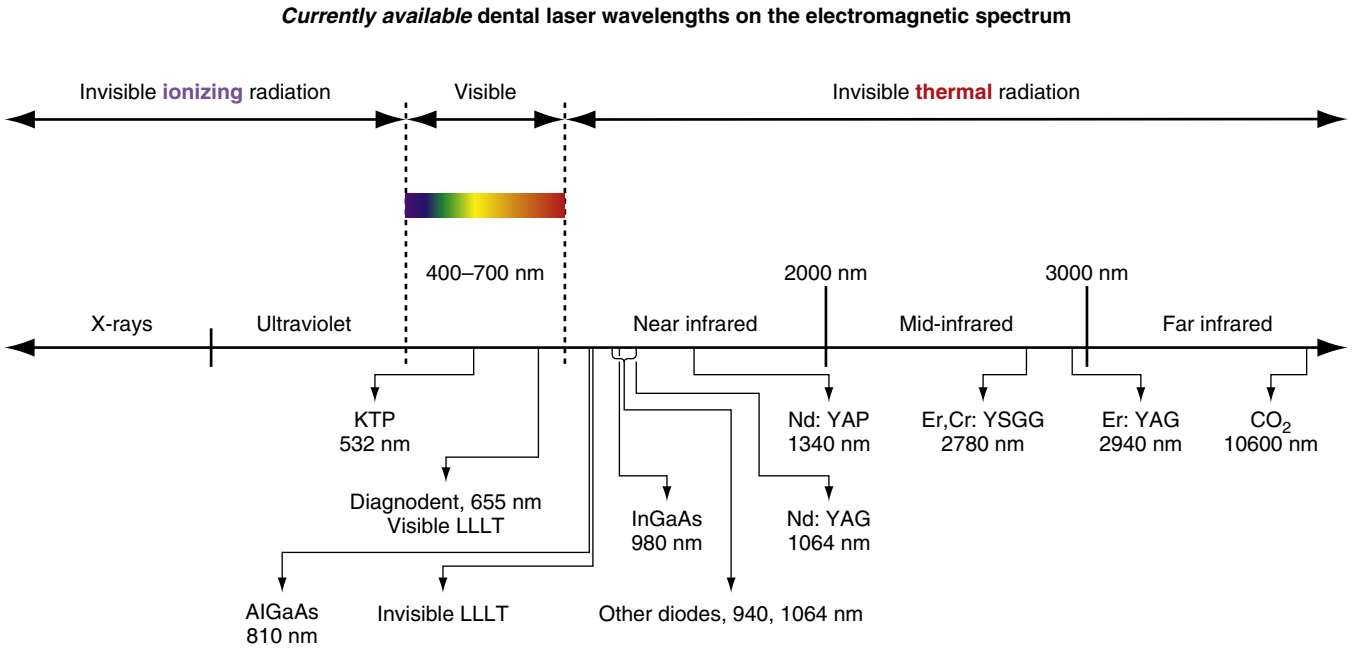
The term "light" is generally accepted to be electromagnetic radiation ranging from 1 nm to 1000 μm in wavelength. The visible spectrum ranges from 400 to 700 nm. If the energy beam from a laser is in the visible spectrum, it will be of only one distinct color (Figures 19-1 and 19-2).[6]

The laser instruments that are typically used for oral and maxillofacial surgical procedures that emit visible light are: argon laser (blue wavelength of 488 nm, or blue-green wavelength of 514 nm) and the KTP laser (green wavelength of 532 nm). The other lasers used emit invisible laser light in the near, middle, and far infrared portion of the electromagnetic spectrum: diode lasers (various wavelengths between 800 and 1064 nm), Nd:YAG laser (1064 nm), Er,Cr:YSGG laser (2780 nm), Er:YAG laser (2940 nm), and CO_2 laser (9300 and 10,600 nm)

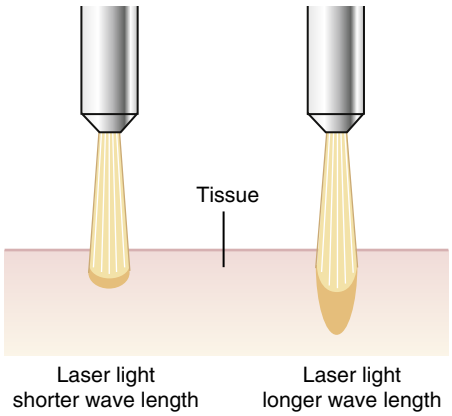
In order to understand stimulated emission, an understanding of the Neils Bohr 1915 model of the atom and quantum physics is helpful. Although the simple diagram of the atom is not fully accurate by today's understanding, it is still useful for demonstrating laser principles.

In the model of the atom, electrons orbit the nucleus in a limited number of fixed orbits, and each electron is balanced by a proton within that nucleus. Under the right circumstances an electron can go from its ground state, which is a low energy state, to an excited or higher energy state. Energy, which can be in the form of electromagnetic radiation (e.g., light), must be applied to the atom for an electron to change its orbit. Similarly, when an electron drops from a higher to a lower state, the atom must give off energy, in the form of kinetic energy or electromagnetic radiation (Figure 19-3).[1]

Excitation that comes from the electron interacting with light (a photon) is termed *absorption*. Because the atom always seeks to be stable, the electron will spontaneously drop back to its lowest energy state by giving off energy



• **Figure 19-1** Part of the electromagnetic spectrum showing division into ionizing, visible portion, and nonionizing portion. (From Convissar RA: *Principles and practice of laser dentistry*, ed 2, St Louis, 2016, Elsevier, Inc.)



• **Figure 19-2** Laser wavelength.

emitted as a photon of light, and this process is called *spontaneous emission of radiation*. An atom in a high energy state can transition faster than the spontaneous process into a lower energy state when a photon of the correct amount of energy interacts with it. This process results in the emission of two identical photons after colliding, which have the same energy and direction, and this is called *stimulated emission of radiation*.

Lasers are electro-optical devices that produce intense beams of light which are monochromatic, coherent, and highly collimated. It is extremely pure *(monochromatic)* when compared to other sources of light. It is temporally and spatially coherent because the waves of light oscillate in phase over a given time and they are equal and parallel across the wave front. Collimation refers to the beam's property of being unidirectional and parallel. Light from a laser typically has very low divergence and can travel very long distances or can be focused to a very small spot (Figure 19-4).[1]

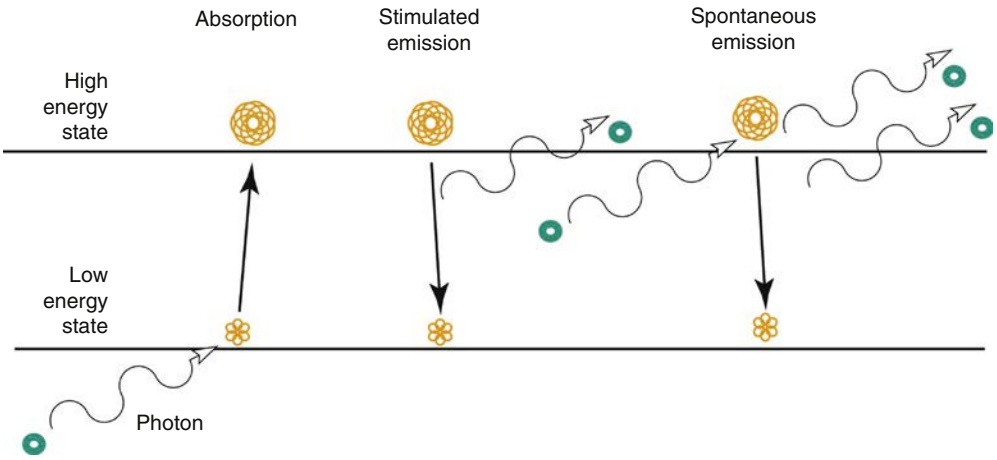
All lasers have similar components: an optical cavity (or optical resonating chamber) and two mirrors, one that is fully reflective and one that is partially transmissive. The optical cavity is filled with an active medium such as argon, neodymium:yttrium-aluminum-garnet, or carbon dioxide. Each laser has a source of energy to excite the atoms within this medium in the form of an electric current, chemical, or another light source. As the energized atoms interact with each other and return to the ground state, photons of identical wavelength are emitted. When the photons interact with other atoms in excited states, they stimulate the emission of more photons. The mirrors serve as a positive feedback mechanism by reflecting the photons back and forth and therefore amplifying the stimulated emission of radiation (Figure 19-5).[6]

Use of the Surgical Laser

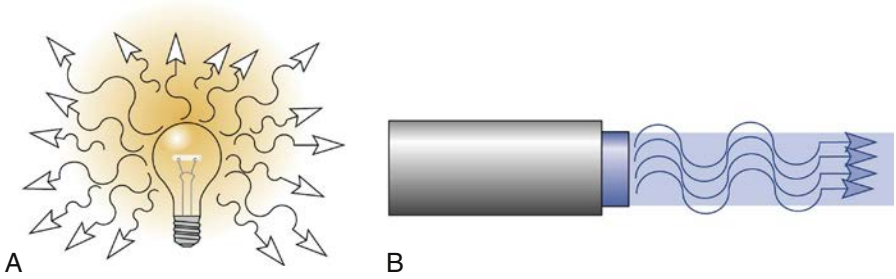
The laser, as an instrument for surgical procedures, can be used for multiple different purposes, and the variables a surgeon can control for are its power, spot size, pattern, and the exposure time.[1]

Power

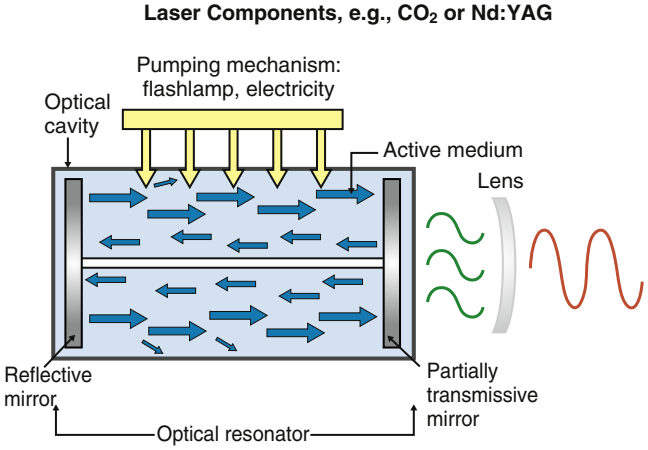
Power is measured in watts and can be kept constant throughout the surgery. Its effects on tissue are directly dependent on the beam's exposure time and spot size. Therefore, power as a variable is better described when speaking in terms of irradiance to the target tissues. Irradiance, measured in W/cm^2, describes the intensity of the beam at the focal spot, and is useful to determine the depth of tissue injury that a certain amount of power can cause.



• **Figure 19-3** The interaction of light (a photon) with an atom. Three processes are shown: the absorption of a photon by an atom in a low energy state, the spontaneous emission of a photon from an atom in an excited state, and the stimulated emission of a photon by a second photon of the same wavelength from an atom in the excited state. (From Flint PW, Haughey BH, Lund VJ, et al: Laser surgery: basic principles and safety considerations. In Flint PW, editor: *Cummings otolaryngology head and neck surgery*, ed 6, Philadelphia, 2015, Saunders, pp 884-898.)



• **Figure 19-4** **A,** Light emitted from a conventional lamp. The light travels in all directions, is composed of many wavelengths, and is not coherent. **B,** Light emitted from a laser travels in the same direction and is a single wavelength, and all the waves are in phase; the light is coherent. (From Flint PW, Haughey BH, Lund VJ, et al: Laser surgery: basic principles and safety considerations. In Flint PW, editor: *Cummings otolaryngology head and neck surgery*, ed 6, Philadelphia, 2015, Saunders, pp 884-898.)



• **Figure 19-5** A gas or solid active-medium laser, such as CO_2 or Nd:YAG laser. (From Convissar RA: *Principles and practice of laser dentistry*, ed 2, St Louis, 2016, Elsevier.)

Spot Size

To produce the appropriate irradiance, the surgeon selects the spot size and the power of the laser. The following mathematical equations demonstrate the relationship between power and the beam's radius.

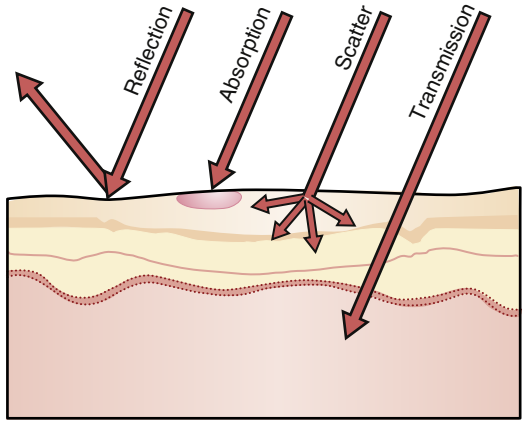
$$\text{Irradiance} = \text{Power} \div \text{Surface Area}$$

and

$$\textit{Surface area} = \pi r^2$$

This explains how, at a given power, increasing the size (radius) of the beam will cover more surface area but have a smaller irradiance effect over the tissues.

Lenses focus the active beam and the focal point is used for incision and excision of tissue during surgery. The focal point varies with delivery systems. Fiberoptic devices have a focal point located at the tip of the fiber, and noncontact devices such as the CO_2 laser have focal points that can be 1 to 12 mm away from the tissue surface. As the beam moves away from the tissue, the diameter of the spot will increase, compromising the irradiance and dissipating the energy, as discussed previously.



• **Figure 19-6** Four potential laser-tissue interactions. (From Convissar RA: *Principles and practice of laser dentistry*, ed 2, St Louis, 2016, Elsevier.)

Exposure Time

By varying the exposure time, the surgeon can vary the amount of energy delivered to the tissue. Fluence is the amount of time that a laser beam irradiates a unit area of tissue at a constant irradiance. It is expressed in J/cm^2, and can be varied by working in a continuous versus pulsed mode.

Types of Lasers

1. Continuous-wave mode: the beam has constant power over time, resulting in a long, continuous exposure.
2. Quasi-continuous-wave lasers or gated-pulse mode: the beam is made discontinuous by the opening and closing of a mechanical shutter. Advanced units have computer-controlled shutters and allow for very short pulses, commercially known as "super pulse" or "ultra speed."
3. True pulsed lasers or free-running pulsed mode: the beam is emitted for microseconds, followed by a very long time in which the laser turns off.
4. Q-switched (quality switched) lasers: generate extremely high-energy pulses over short (nano- or picoseconds) pulse durations and are used primarily for treating pigmented lesions.

Interactions of Laser Light and Tissue

The electromagnetic radiation from a laser can have four effects on target tissue: reflection, absorption, transmission, and scattering (Figure 19-6).

With reflection, there is no effect on the target tissue and the beam that is reflected can damage an unintended target such as the unprotected eyes of staff within the operating room.

Absorption of the laser is the most desirable effect, and it depends on tissue characteristics such as pigmentation (chromophores and their importance will be discussed later) and water content. The amount of absorption determines the amount of selective tissue destruction, whereas the amount of scatter determines the amount of peripheral tissue damage. The greater the absorption of a wavelength by a particular tissue, the more effective that laser is at selectively removing that tissue. The principal effect on tissue that absorbs laser light is photothermal reactions. This is the principle by which lasers are used for incisions, excisions, ablation, vaporization, and coagulation.

Transmission of the beam has no effect on the superficial tissue and can be useful in some cases where the target tissue is distant and a layer of tissue must be bypassed by the inciting beam to reach it, such as procedures where the retina is the target tissue and the laser must transmit through the fluid globe contents.

Scattering of the laser light weakens the intended energy and dissipates the effect, potentially causing unwanted effects in adjacent tissue.

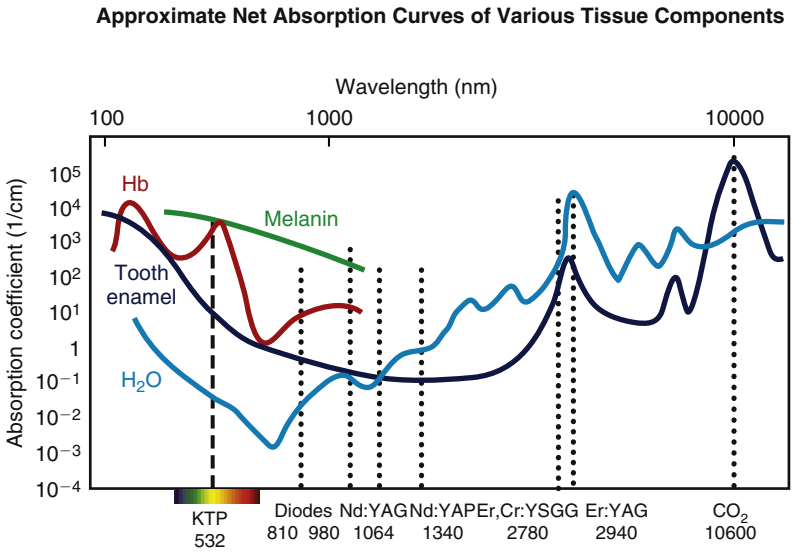
The basis of all laser–tissue interactions was described elegantly in 1983 by Anderson and Parish's introduction of the *selective photothermolysis* (SP) concept.[7] A wide variety of surgical procedures, including hair removal, treatment of pigmented lesions, removal of varicose veins, and tattoo removal, have been made possible thanks to the understanding of tissue optics and laser properties.

Precise removal of specific kinds of tissue is based on the tissue's inherent absorption of particular wavelengths. When laser light is directed at tissue, compounds within the tissue called chromophores absorb the wavelength of light. The absorption characteristics are based on the amount of chromophores within the tissue. Natural chromophores can include water, melanin, hemoglobin, protein, and lipid. Artificial chromophores can include dye, ink, and carbon particles. For example, hemoglobin has greater absorption of the violet and green-blue portions of the spectrum; consequently, hemoglobin absorbs the green-blue photon energy of the argon laser well. Laser energy at this wavelength is converted to heat to destroy microvessels laden with hemoglobin by being selectively heated. Surrounding tissues without hemoglobin are affected minimally by the heat produced (Figure 19-7).

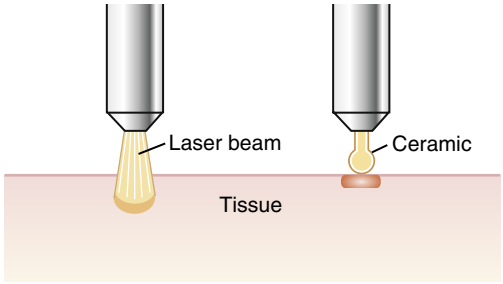
In 2004 Manstein and colleagues[8] described *fractional photothermolysis* (FP), launching another era of lasers in dermatology. With the concept of FP, patterns of very small, nonselective thermal damage zones are used to stimulate skin remodeling without scarring. Physiologically, there is minimal inflammation in response to the electromagnetic insult, accompanied by the desired effect of epidermal regeneration, induction of metalloproteinases, and formation of a new dermal matrix.

Mechanical Design of Laser Devices

The light is delivered from the laser chamber to the tissue in a variety of ways. Some laser systems use a fiberoptic cable. Other lasers allow the light to pass down an articulated arm system consisting of a series of tube containing partially reflective mirrors to direct the beam. This is initially somewhat cumbersome to use, but the surgeon quickly adapts. A hollow wave guide is another delivery mechanism, which utilizes a hollow tube with an inner reflective surface that delivers the light. These are generally cheaper than most articulated arm systems. There is a limit to the bending that the waveguide tolerates, and damage can be done to



• **Figure 19-7** Laser absorption chart. (From Convissar RA: *Principles and practice of laser dentistry*, ed 2, St. Louis, 2016, Elsevier.)



• **Figure 19-8** Laser delivery systems.

the reflective surface. If the wave guide is bent and kinked, laser light can escape from the damaged area and become a hazard. The wave guide must then be replaced.

After laser light is produced by excited atoms in the chamber and is delivered down a fiberoptic cable, articulated arm, or hollow waveguide, it must be delivered to the tissue by a contact or noncontact mechanism. Most lasers have a handpiece with a lens attachment. In noncontact laser systems, the lens allows the beam of light to be focused or defocused to a particular spot size (Figure 19-8).

Some noncontact or free-beam laser systems have angled mirrors to direct the beam either at 90 or 120 degrees. Surgery in the floor of the mouth and other difficult areas is easier when using these mirrors. A thorough safety check must be performed prior to use of the laser to prevent any unexpected or deviant direction of the laser beam. Prior to each use the operator should confirm that the laser beam is coincident with the aiming beam when using a noncontact handpiece laser system. Free-beam surgical lasers have also been included into the surgical microscope. Free-beam lasers have been used in various capacities through the operating microscope to aid in dissection and, recently, anastomosis techniques.

Contact laser systems offer the advantage of tactile sense during operating. Because touch is a major feedback mechanism of surgical technique, some surgeons feel more comfortable using contact systems. For example, some Nd:YAG lasers have a handpiece with specially designed, interchangeable sapphire or ceramic tips. The tip is heated when the laser is activated, enabling tissue to be cut and coagulated simultaneously with a precise "light-powered scalpel." These tips come in a variety of shapes and sizes. When precise cutting or ablation of an area is desired, the appropriate handpiece tip is selected. This offers some flexibility for different surgical goals.

Asymmetric crystals can be used to modify the emitted photons and can double, triple, or even quadruple the wavelengths of the laser source. There are now tunable liquid dye lasers that can be tailored to a desired wavelength based on the dye medium that is used.

The exposure time is the amount of time the operator keeps the laser light directed at the tissue. Exposure time varies with each delivery system and is commonly manipulated by choosing either continuous-wave, pulsed, superpulsed, ultrapulsed, flash-scanned, or Q-switched mechanisms. In the continuous-wave laser the beam does not fluctuate with time. It produces a uniform flow of radiation as the operator activates the laser and directs the beam. When tissue is exposed to laser energy, there is peripheral damage to surrounding tissues caused mostly by heat. The amount of peripheral damage is predominantly time dependent. When the exposure time is kept short, there is insufficient time for the thermal energy created to be conducted beyond the target tissue, limiting the amount of peripheral tissue damage. Table 19-1 shows the tissue changes seen with increasing temperatures created with laser energy.

Unlike continuous-wave lasers, pulsed lasers deliver photons in the form of single pulses or trains of pulses. The rate of pulsing is measured in pulses per second. The pulse width

TABLE 19-1 Temperature Effects of Laser Energy on Tissues

Temperature °F	Tissue Effect
37-60 °F	Tissue retraction and conformational protein changes
>60 °F	Protein denaturation and protein coagulation
90-100 °F	Tissue carbonization and tissue char
>100 °F	Tissue ablation

is defined as the time required for the pulse to rise from zero intensity to maximum intensity and return to zero again. The average power generated by a train of pulses is determined by the pulse power multiplied by the pulse repetition rate and the pulse width. The time allowed for the energy to be absorbed by the target tissue and dissipate is the tissue relaxation time. Understanding the concept of relaxation time is extremely important in order to achieve selective tissue destruction with the least amount of peripheral tissue damage. For tissues such as skin, blood vessels, and muscle, the tissue relaxation time can be calculated. Based on this value, if the pulses generated are given with enough time for the tissues to relax or cool, energy dissipates before significant damage can be done to the surrounding tissues.[9] In other words, when quick enough pulses are created, a lower amount of peripheral tissue damage occurs.[10]

Superpulsing was introduced soon after conventional pulsing. Lasers that have the ability to superpulse achieve higher peak powers per pulse with even shorter pulse widths than conventional pulsing. This decreases the amount of lateral tissue damage further and makes for even more precise incisions and ablations.

When the fluence, or the energy given to a particular area, is greater than the tissue vaporization threshold, and the pulse width is less than the thermal relaxation time of tissue, the tissue is vaporized with each pulse and no significant thermal damage occurs beyond the site of laser impact.[7] Superpulsing lacks high enough peak powers to reach the vaporization threshold and ablate tissue effectively while still staying under the thermal relaxation time of skin (approximately 700 μs).[9] Modifications of these systems to increase pulse speed created ultrapulsing, which has allowed for specific removal of tissue with even less significant lateral tissue damage than conventional or suprapulsing methods. This technology is commonly used in skin resurfacing procedures.

Similar to ultrapulsing, flash-scanning modifies the laser to control tissue damage by reducing heat diffusion into the surrounding tissues by a different mechanism. This laser uses a continuous-wave which can generate circular patterns of laser energy by using movable mirrors. High energy is delivered to the target tissue for brief periods of time. By minimizing the amount of time the laser is directed at any one tissue area, the lateral thermal damage is reduced. This is because the laser is in contact with the target tissue less than the calculated thermal relaxation time. Like the ultrapulse laser systems, this technology is used for skin resurfacing procedures.[11]

Q-switching or quality switching is a process in which the beam output is controlled by concentrating all of the energy into single, intense pulses of short duration, approximately 25 nanoseconds. These bursts are achieved with an extremely fast electromagnetic switch in the laser cavity that allows the excitation of the active medium to build up with the shutter closed. The shutter is opened when the energy reaches a maximum, and a brief, powerful pulse, or series of pulses, is released.[12] This form of pulsing has been particularly useful in the treatment of the nevus of Ota, which is described later in this chapter.

Laser Safety Considerations

The laser as a surgical instrument must be used with caution. It poses a safety risk to the patient and to the operating room personnel.

In the United States, laser safety guidelines are created by the American National Standards Institute (ANSI). The current laser safety guidelines are ANSI Z136.1–2007, and the health care specific guidelines are ANSI Z136.3–2011.[13,14]

Most hospitals require evidence of training in laser use and safety measures in order to grant laser use privileges to surgeons. Although each institution should have its own regulatory committee for the safe use of lasers, there are certain basic safety considerations that must be considered universally no matter which setting the laser is used in.

Medical lasers are regulated by the U.S. Food and Drug Administration (FDA). Lasers are classified into four risk categories (I-IV). Class I lasers are safe under all conditions, they have very low power and can be found in devices such as CD players. Class II lasers are also considered safe to eyes because the blink reflex is able to limit the exposure; they can be found in laser pointers. Class III lasers can cause retinal damage but indirect reflections should be safe. Class IV lasers can cause ocular injury or fire even if they're reflected off a matte surface.

The risks associated with laser use can be classified into three categories: atmospheric contamination (laser plume), gas embolism, and inappropriate energy transfer. The most serious adverse events arising from the intraoperative use of lasers when performing procedures in the head and neck area are airway fires or surgical drape fires.[15] The risk for personnel in the room is retinal damage that may lead to permanent blindness due to the globe's ability to concentrate the beam and pigment content that would absorb the visible wavelengths.

Laser plume can contain toxic gases, combustion byproducts, and cellular debris (dead and alive). The mutagenic potential of the plume from the CO_2 laser on 1 g of tissue is equivalent to the inhalation of three unfiltered cigarettes.[16] It can also contaminate the atmosphere with viable infectious microorganisms and viral DNA from human papilloma virus (HPV).[17-20]

Although evidence for transmission to humans is weak and there have been no documented cases of transmission of infectious disease in the OSHA databank, the potential threat still justifies taking precautions with smoke evacuator suction units located within 1 cm of target site and high-filtration masks.

The gas content for laser tip cooling in some laser systems has been reported to cause serious and sometimes lethal venous embolisms when performing hysteroscopic, laparoscopic, tracheal, and nasal surgical procedures.[21-24]

The direct laser beam or its reflection off a surface can cause serious injuries to unintentional targets within the operating room. Perforation of viscera or large bore blood vessels and the creation of pneumothoraces have been reported when the depth of tissue injury exceeds that of the intended treatment area. Severe ocular injuries can occur where the blink reflex is too slow to guard against laser injuries and the laser has sufficient power. Patients' eyes must be taped closed and covered with saline-based opaque materials or covered with metal shields.[25] Protective eyewear for personnel in the room needs to be color-specific for the type of laser being used and have side shields. Eyewear should also be hung next to the warning signs at each entrance to the surgical area. For each wavelength there are specific protective glasses to prevent laser injury to the eye. Each pair of glasses is marked with the wavelength and type of laser with which they are used. All eyewear should be examined for cracks or scratches and replaced if these defects are present (Figures 19-9 and 19-10).

It is estimated that about 550 to 650 surgical fires occur every year. This is a low number considering the nearly 65 million annual surgical cases. Most of these fires occur in the airway (34%) or the head and face (28%).[26] The potential for fire ignition increases with the presence of an oxygen- or nitrogen-rich environment, therefore the team must ensure the lowest possible FiO_2 (fraction of inspired oxygen) during the use of a laser beam; it is generally accepted that the FiO_2 has to be lower than 0.3 to appropriately reduce the risk of fire. Similarly, the use of nitrous oxide (N_2O) must be completely avoided; this gas easily exothermically dissociates, releasing energy and free oxygen.[27] Helium mixed with oxygen is used in some systems, and it is commercially available for use in laser cases.

The fuel sources to the OR fires are more commonly the endotracheal tubes, drapes and towels, alcohol-based prep

solutions, phenol-based chemical peel solutions, and some hair or skin products such as makeup.

When intravenous sedation is indicated, the patient should receive only non-oxygen-enriched air through face mask or nasal cannula. If the patient requires supplemental oxygen to maintain adequate oxygen blood saturation, the general recommendation is that the patient should be intubated with an ETT or an LMA should be placed. During a general anesthetic for nonairway surgery the goal is to incorporate several strategies: ventilating through a cuffed or tightly fitting ETT, using laser-resistant tubes, filling the cuff with saline instead of air, and using water-soaked sponges around the tube at the site of work and at the glottis.[28]

Standard polyvinylchloride (PVC), red rubber, and silicone ETTs have been studied for their flammable properties and all of them have been shown to allow ignition and behave as blowtorches when being used with a CO_2 laser. Laser-protective metallic adhesive materials have been used in the past and have now been replaced by FDA-approved laser-resistant endotracheal tubes. These tubes are either made of metal or are nonmetallic with a metal reinforcement (Figure 19-11). Each one of the commercially available tubes is approved for a specific type of laser and they are not indestructible, therefore precautions must be taken universally with laser use.[28]

The nominal hazard zone (NHZ) is defined as the surgical area in which the laser is used and could potentially cause injury or damage, usually related to eye exposure. This zone can vary in size from the entire operating room to a defined square-footage around the laser unit itself. Calculating the NHZ is beyond the scope of this chapter but it is often supplied to the consumer by the laser manufacturer. The NHZ is determined by looking at the wavelength of light, the maximum power, the type of delivery system, the diameter of the beam, and various other physical characteristics of the light produced. The greater the calculated NHZ zone, the greater the probability that injury can occur. A continuous-wave carbon dioxide laser that produces a focused beam of light is more likely to cause injury than a Nd:YAG laser with a sapphire tip that requires contact for the laser to cause tissue damage. Consequently, the carbon dioxide laser would have a larger NHZ compared with the Nd:YAG laser. The NHZ should be plotted out around the laser, and safeguards should be put in place based on this zone to prevent injury. For simplicity, many operating rooms define the NHZ as the space within the four walls of the room in which the laser is being used. Signs should be posted at all possible entry points warning passers-by and people potentially entering the room that laser safety precautions must be adhered to. These signs should state the wavelength and type of laser being used.

One person who works in the environment should be designated as the laser safety officer. This person should be familiar with all of the standards of laser safety and is charged with enforcing the standards of laser safety in the operating room. The laser safety officer also has the responsibility of updating the safety precautions should any new recommendations arise. The entire staff must have a firm understanding of the importance of laser safety.[28]

The laser system is required to have certain safeguards built into its design. One of the most important safety aspects of the laser system is the use of a key to turn on the laser. Keys to the laser should be kept in a standard, safe location at all times not left in the laser. The laser can be operated only by authorized personnel by using the key. This helps to prevent others who are not certified in laser operations and safety from gaining access to the laser.

Another safeguard present in all surgical laser systems is a self-testing protocol that automatically activates when the laser is turned on. This system self-checks the programming connections and integrity of the laser system prior to use each time the laser is turned on. However, some manual tests still need to be performed. If there is an aiming beam, such as the helium-neon aiming beam of the carbon dioxide laser, the precise direction of the aiming beam must be

correlated with the invisible carbon dioxide beam. This can easily be tested by wetting a tongue depressor and performing several test pulses on a side table to correlate the beams. This should be done before every procedure using the laser.

Visual inspection of the electrical cords, pedal, and all exterior mechanical parts should be done regularly to ensure integrity of the system. Any damage or defects should be repaired immediately. To prevent electrical injuries, no solutions should be used or spilled near the cables.

When preparing the patient for surgery, no alcohol-based preparation solutions should be used in order to prevent ignition and severe burns, and if they must be used one should allow for sufficient drying time. Wet towels and gauze are used to drape the patient, and they should be moistened throughout the procedure to prevent ignition of the drapes by the laser. An open basin of sterile water with an irrigating syringe should be available in case a fire should develop. Other fire precautions include never placing hot fiberoptic cable or handpieces on the drapes. A nonreflective basin can be used for storage while the components are still hot. Of course, a fire extinguisher should always be readily available.

There is probably no other anesthesia emergency that requires a more rapid and correct response than an airway fire. If a fire occurs, the procedure must be stopped immediately. There should be no hesitation to remove the endotracheal tube and sponges around it and stop the flow of all gases. Additionally, saline should be poured into the airway. If this does not stop the fire, a CO_2 fire extinguisher should be used and the fire alarm needs to be activated.

Finally, all surgeons using a laser should have current certification based on state, local, and hospital guidelines. Certification should be obtained for each type of laser being used, and continuing education courses should be attended at regular intervals. Nursing and assistant staff should have in-service and continuing education seminars to ensure compliance with all laser safety guidelines. These sessions should include hands-on experience with the surgical laser systems and updates on new safety implementations.

Clinical Laser Systems

Many laser systems are on the market, each with its own benefits and drawbacks. This section describes the basic components of surgical lasers and discusses the types of surgical lasers and their uses in treating various pathologies.

Carbon Dioxide Laser

The carbon dioxide laser emits light in the invisible mid-infrared portion of the spectrum at a wavelength of 10,600 nm. It was developed by Patel in 1964 and has been the dominant laser in surgical use thus far.[29] This laser uses a mixture of carbon dioxide, nitrogen, and helium as its medium. The medium is usually excited by a high-voltage electrical current.

Because the photons from this laser cannot be transmitted in a fiberoptic cable, it is necessary to use an articulated arm or hollow waveguide to deliver the beam to one of the available handpieces. Since the carbon dioxide beam is invisible, a red helium-neon laser is often used in parallel, or in near parallel, as an aiming beam. As will be addressed in the section on laser safety, it is always necessary to verify that the active laser is directed at the same area as the aiming laser.

The carbon dioxide laser can be delivered in several modes. When the continuous-wave mode is chosen, the laser delivers a constant beam of energy as the operator steps on a pedal. Regular pulsing modes are also available, in which the operator can set the number of pulses per second. Superpulsing, ultrapulsing, or flash-scanning is also available on some models, with the delivery of short, high-powered pulses. These pulse energies can be many times greater than the continuous-wave output, allowing the surgeon to make cleaner incisions with reduced peripheral tissue damage.[10] The carbon dioxide laser is commonly used for excision and ablation of various types of superficial lesions and for skin resurfacing.[11] Because the chromophore that absorbs the carbon dioxide wavelength is water, the carbon dioxide laser is the most commonly used laser in the oral cavity. The depth of penetration can be as shallow as 0.2 mm, with very little scatter, reflection, or transmission. Therefore, the carbon dioxide laser is extremely effective and the most commonly used laser by oral and maxillofacial surgeons.

Argon Laser

The argon laser was developed at Hughes Aircraft Research Laboratories by Bridges in 1964.[30] The conventional argon laser delivers a green-blue light beam in the 488- or 514-nm range. The argon gas medium is activated by electrical current. Unlike the carbon dioxide laser, this laser can be used with a fiberoptic cable and handpiece. It can be used in the continuous-wave or pulsed mode using contact or non-contact delivery systems. Because the argon beam is highly absorbed by hemoglobin, it is an excellent hemostatic laser and can also be used to excise gingival soft tissue lesions. It is also effective in the treatment of some superficial vascular hemangiomas (port-wine stains). In the past it was used for the removal of some tattoos, but it caused an unacceptable amount of hypertrophic scarring, especially in children.[31,32] Other lasers have supplanted the argon laser for most of its indications.

ND:YAG Laser

Developed by Geusic and coworkers in 1964, with a wavelength of 1064 nm, the neodymium:yttrium-aluminum-garnet (Nd:YAG) laser emits light in the near infrared area of the spectrum.[33] A flashlamp is used as the energy source to activate a Nd:YAG crystal. This system uses a fiberoptic cable to deliver the light to a conventional handpiece and uses a lens to produce a free beam of laser light.

As in the carbon dioxide laser, an aiming beam is needed, as this laser produces invisible light. This laser can also be used with specially designed sapphire or ceramic tips and used as a contact laser scalpel or ablation tool, with excellent hemostasis and cutting abilities.[34] The Nd:YAG laser is available in continuous-wave, pulsed, or Q-switched modes and is excellent for the treatment of vascular lesions and intraoral and extraoral pigmented lesions and for achieving hemostasis. Pulse widths as short as 10 nanoseconds can be achieved when using a Q-switched delivery system. The Nd:YAG laser has also been used in open TMJ arthroplasty, malignant lesion excision, black and blue tattoo pigment removal, and experimental treatments for periodontitis.[35-39]

This laser system has been associated with venous gas embolism complications because of the gas coolant used for the laser tip.[24]

HOL:YAG Laser

The holmium:yttrium-aluminum-garnet (Hol:YAG) laser emits laser light at 2140 nm in the infrared region of the spectrum. Because its laser light is invisible, an aiming beam is used. As in the Nd:YAG laser, a crystal is used as the laser medium, as well as an aiming beam. The Hol:YAG laser system uses a fiberoptic cable to deliver laser energy in the pulsed mode. This laser can be used in both noncontact and contact mode. Interestingly, it works well in a water medium and is absorbed well by synovium and joint surfaces. The Hol:YAG laser has been extensively used in endoscopic orthopedic surgery. It is also extensively used in the TMJ for lysis of adhesions and sculpting of fibrocartilaginous disc tissue.[40,41] The Hol:YAG laser has also been used experimentally in oral lesion ablation and gingival surgery.[42]

ER:YAG Laser

Recently, the use of the erbium:YAG (Er:YAG) laser for facial resurfacing and incision and ablation of soft tissue has been introduced. This laser operates at a wavelength of 2940 nm via an articulated arm. This technique has not undergone long-term studies or proved to be more effective than carbon dioxide techniques currently used. Prospective trials are under way that compare this new modality with current methods. The presumed advantage of the Er:YAG laser system is its ability to remove superficial skin layers even more precisely than the carbon dioxide laser, thereby causing less adjacent tissue damage. Combined Er:YAG–carbon dioxide laser systems are now available that claim to decrease the amount of tissue damage relative to carbon dioxide laser systems alone. This theoretically allows reorganization of collagen with less total energy, quicker healing times, and decreased incidence of prolonged erythema.

KTP Laser

This laser is a modified version of the Nd:YAG laser. With the addition of a frequency-doubling crystal, this laser emits light at the 532-nm wavelength, or half the wavelength of the Nd:YAG. This system usually utilizes a fiberoptic cable with a handpiece. Its absorption is similar to that of the argon laser and has been used in the treatment of vascular and pigmented lesions, tattoo removal, blepharoplasty, and some endoscopic procedures.[43]

Q-Switched Ruby Laser

The Q-switched ruby laser produces visible, pulsed red light at the 694-nm wavelength. This red light is absorbed well by melanin and green and blue-black pigments. Pulse widths as small as 20 nanoseconds can be achieved with currently available systems. Fiberoptics can be utilized with a handpiece to treat some pigmented lesions and tattoos effectively.[44-46] Multiple sessions are required for these procedures, but this laser is remarkably effective in removing pigmented lesions and blue and black tattoos with minimal scarring. The slightly longer wavelength allows for greater depth of penetration and is more effective in the removal of deeper lesions The nevus of Ota has been successfully treated with this laser with excellent results.[47-50]

Flashlamp-Pumped Pulsed Dye (FLPPD) Laser

This laser produces yellow visible light in the 400- to 1000-nm range and is most commonly tuned at 510, 577, or 585 nm. The specific wavelength desired is determined by the dye chosen. The desired wavelength can be tuned to the specific tissue to be removed, offering great flexibility. For example, at 510 nm the chromophore melanin can be targeted and various benign melanin-containing lesions can be ablated, whereas at 585 nm the laser selectively targets oxyhemoglobin within vascular abnormalities. This versatile laser is used in treating many pigmented and hemopigmented lesions, scar revision, achieving hemostasis, photodynamic cancer therapy, ablation of salivary gland and kidney stones, and tattoo removal.[51-53]

Copper Vapor Laser

At wavelengths of 511 and 578 nm, this laser is similar in specificity to both the KTP and argon lasers. Its medium is highly heated copper, which produces copper gas. The light produced by this reaction is delivered down a fiberoptic cable in the pulsed mode. It is effective in treating hemangiomas, such as port-wine stains, or large superficial telangiectasias, and it has also been used to ablate some pigmented lesions such as lentigines, ephelides, lentiginous nevi, and tattoos.[54,55]

Excimer Laser

These lasers emit ultraviolet light at 193 to 351 nm, using halide gases for a medium. The name is short for "excited dimer." In this system electrical current charges halide gases to excite photons. This laser uses fiberoptic cable to deliver

pulsed laser energy. It is currently used for keratotomy to reshape corneal tissues and correct poor vision. There has been debate about its safety and concern regarding the environmental byproducts of the laser and their possible toxic and carcinogenic effects.[56]

Alexandrite Laser

This Q-switched laser produces red light of 755 nm from a crystal of alexandrite and uses a flexible waveguide. It is well absorbed by green, black, and dark-blue pigments. The long wavelength allows for deep penetration, allowing it to be used for the treatment of pigmented lesions that extend deeper into the dermal layer. This laser is used in the lightening of congenital nevi, but this technique is not recommended by many surgeons because of the possibility of malignant degeneration. The Q-switching mechanism produces a high intensity pulse of 50 to 100 nanoseconds that is used effectively in the removal of tattoos with blue, green, and black pigments.[57-59]

Surgical Laser Technique

The laser may make certain procedures easier, but only in the hands of an experienced surgeon who understands the concepts of laser light and its interaction with tissue. Lasers are superior to many other modalities in surgery when basic principles are adhered to during their use. The goal of laser surgery is to excise or ablate the target tissue with as little damage to surrounding tissue as possible. In other words, the surgeon wants to maximize tissue removal while minimizing thermal injury. Understanding the principles of heat dispersion based on the wavelength, power, and duration of action is essential for determining the technique for a given situation. In some cases, using multiple lasers and techniques can be helpful when the need for excision, hemostasis, and ablation demands different wavelengths to achieve an optimal result. As in all surgical endeavors, careful planning always pays off, and the right choice of laser is of paramount concern.

Because the carbon dioxide laser system is most often used in oral and maxillofacial surgery, most of the examples here include surgical techniques using this laser. Although techniques vary between different laser types, delivery systems, and even manufacturers, the basic principles of laser surgery can be applied to all lasers. Individual laser manuals have guidelines for use with specific recommendations about power densities, spot sizes, and techniques. Manufacturer guidelines should be read thoroughly prior to the use of any laser system. New standards of care are rapidly introduced in the field of laser surgery, and the clinician must be aware of the most current treatments and techniques available.

Basic techniques using the free-beam laser for photocoagulation, incision, and ablation are discussed in the following sections, with descriptions of techniques for many types of pathology. Contact laser techniques are also discussed, with emphasis on their particular attributes.

Photocoagulation Techniques

The carbon dioxide laser can be used to coagulate or photoablate vessels smaller than 500 μm in diameter. Larger vessels are usually better managed with electrocautery or suture ligatures. The laser is used in a defocused mode to a spot size of approximately 2 mm with a power density less than 5 W. Direct pressure on the area is helpful in stopping some of the blood from filling the bed of the wound. Because the carbon dioxide laser is absorbed readily by water, the area must be relatively dry for effective coagulation of the vessels. Pools of blood will absorb nearly all of the energy before the vessel itself is coagulated. Simply wiping the wound prior to lasing should allow the surrounding connective tissue and the vessel itself to be lased using a crisscross or circumferential pattern. This is accomplished using a continuous or pulsed beam. Increasing the exposure time heats the tissue to critical temperatures needed for hemostasis. If bleeding persists, however, other methods of hemostasis should be employed.

Other lasers with beams that are more specifically absorbed by hemoglobin (such as those of the Nd:YAG or KTP laser) can be used. Because hemoglobin is a major chromophore for these types of lasers, blood components are directly lased, and the surrounding vessel is damaged by collateral heat after being initially coagulated. The crisscross or circumferential pattern can be used in a defocused mode with these lasers. Contact lasers can be used by keeping the ceramic or sapphire tip in contact with the bleeding area for a slightly longer period of time. Again, electrocautery or suture ligature techniques should be used for larger blood vessels.

Incisional and Excisional Techniques

The carbon dioxide laser is a superb light scalpel. This laser offers several advantages in incisional biopsy techniques when compared with scalpel surgery. The nearly bloodless field allows for excellent visualization of the specimen during surgical removal, aiding in obtaining discrete margins and minimizing damage to adjacent structures. The laser also tends to produce less postoperative bleeding, pain, and scarring than does scalpel surgery. Many lesions do not need suturing after being excised with laser techniques.

An important point to consider in biopsy technique with lasers is the lateral zone of thermal necrosis. Usually an extra 500 μm of margin is required around the lesion to account for the laser's effect on the adjacent tissue. This zone of necrosis is generally less than 500 μm when using the carbon dioxide or contact Nd:YAG laser. Pogrel and colleagues determined this layer to be anywhere from 5 to 100 μm in width, with an average thickness of 86 μm.[60] Some pathologists will have difficulty interpreting the specimen if the laser margin is too close to the lesion. Free-beam Nd:YAG lasers tend to have larger zones of thermal necrosis than carbon dioxide or contact Nd:YAG lasers. This occurs because the effective penetration of the longer wavelength present in the free-beam Nd:YAG

laser can be 3 to 5 mm deeper than the carbon dioxide or contact Nd:YAG laser. Therefore, the free-beam Nd:YAG laser is not ideal for intraoral biopsy techniques. This is less of a problem with the contact mode. Specially designed tips of the contact Nd:YAG laser do not normally transmit thermal heat further than 500 μm from the incision line because the energy is concentrated at the sapphire or ceramic tip.

The technique for incisional biopsy is relatively simple. First, topical, local, or general anesthesia is administered as the procedure indicates. Local anesthetic blocks are generally preferred over infiltrations because the water content of the anesthetic solution may change the absorption characteristics of the tissue when using the carbon dioxide laser. The area should be dried prior to using the laser to increase the accuracy of absorption of the energy. The area of the biopsy can be marked with a marking device or, more commonly, can be outlined with the laser. Some violet or blue marking pens may interfere with the tissue absorption of some lasers whose beams are absorbed well by these colors. To outline the specimen, choose a single or slow repeating pulse mode and mark the area of the incision, remembering to include the extra margin necessary when using the laser. Choose the smallest spot size available, to decrease the zone of thermal necrosis around the incision line, and an appropriate energy density based on the tissue being incised. The carbon dioxide laser can usually be set at 3 to 6 W with the smallest spot size. A row of dots can be used to outline the specimen with the desired margin. Standard biopsy techniques are adhered to when deciding what portions of a lesion are to be removed with the incisional technique.

After the specimen has been outlined, the adequacy of the margin should be re-evaluated. The power density is adjusted for the particular tissue, and the incision is made to the desired depth. The tissue is undermined as needed, using a forceps to hold the specimen away from the bed as the incision is advanced. Gentle tension on the specimen with a forceps is used to deliver the lesion as it is surgically removed. Care should be taken not to lase the previous incision areas, as char will accumulate, causing increased heat and more lateral tissue damage. If char does accumulate, it may be wiped away with a moist sponge. Another common mistake is not advancing the laser handpiece into the wound site as the incision gets deeper. If the handpiece stays in the same position, the distance increases and the beam becomes defocused as the incision site becomes deeper. Advancing the handpiece into the incision keeps the spot size (and distance) constant.

As the specimen is removed, remember to be aware of adjacent structures that may be injured by changing the direction of the laser beam. The laser beam must always be aimed into the lesion, and adjacent structures and anesthesia equipment must be properly protected. Hemostasis is achieved if necessary with the techniques described previously. Many lesions can be left open; however, if they are sutured, an extra 2 days should be allowed for healing because the laser impedes epithelial migration. The specimen should be handled in the usual manner, and the pathologist informed of the use of the laser.

Ablation or Vaporization Techniques

One of the great advantages of the laser is its ability to ablate or vaporize lesions layer by layer. This not only has many applications for removing discrete benign lesions, but is also particularly useful in eradicating multiple, diffuse lesions of the oral cavity. A defocused laser has the ability to remove lesions layer by layer to the desired depth quickly and without the scarring and contraction seen with other surgical maneuvers.[61] Conservative tissue sculpting with minimal excess tissue removal can be achieved quickly and cleanly. However, a disadvantage of this technique is the eradication of the specimen for histologic examination, requiring that all lesions being considered for ablation be sampled for biopsy prior to removal. Only the rare lesion that is known to be benign by history and physical examination, and/or biopsy (e.g., small capillary hemangioma or amalgam tattoo) can be removed by ablating without biopsy.

The technique for ablation of lesions is also relatively simple. An anesthetic plan is implemented as indicated by the type of procedure and the size of the lesion. The laser is defocused to a spot size from 0.5 to 3 mm, depending on the size of the lesion. This maneuver decreases the power density given to the tissue and allows for removal of superficial layers of tissue. Generally, 5 to 10 W of power on the carbon dioxide laser is adequate for efficient and controlled ablation of a lesion layer by layer. Higher powers are required for larger lesions if larger spot sizes are to be used. The continuous mode or regular pulsing is often used, but superpulsing or ultrapulsing may be used as well. Quicker pulsing, as described previously, allows for higher energies to be delivered to the target tissues with less collateral damage. Pulsing that is too slow causes skip areas that can result in nonuniform removal of the lesion. The lesion is outlined as in the excisional technique. A systematic and geometric pattern is then made over the lesion. Crisscrossing patterns of horizontal, vertical, and oblique lines can be used while clearing the wound of char between passes. Making a pattern ensures that the lesion is removed equally in all regions. This pattern is continued until the lesion is completely removed to the desired depth. Smaller lesions can be done with single pulses and a smaller spot size to increase accuracy. Intraoral lesions heal remarkably well with little postoperative care. Depending on the specific procedure, skin lesions can be dressed, if desired, with a small amount of antibiotic ointment and sterile gauze or other dressing. Lesions that tend to recur, such as lichen planus, can be treated multiple times without the great degree of scar contracture seen with scalpel excisions or other modalities.

Contact Laser Techniques

The contact laser has several advantages over the traditional free-beam or noncontact laser. The Nd:YAG and Ho:YAG lasers are commonly used as contact lasers. The biggest difference is the surgeon's ability to gain tactile feedback from the handpiece while operating. Some surgeons find the

free-beam laser technique difficult at first because of the lack of feedback. The specially designed tips of contact lasers allow for transmission of laser energy to the tissue directly from the tip surface. The beam diverges rapidly from the end of most tips, so the effect of the laser is concentrated to just around the tip surface. There is less tissue penetration and less collateral tissue damage when compared with some free-beam lasers. This is helpful when the surgeon desires to incise or ablate tissue without damaging any adjacent structures that would be harmed by free-beam penetration, such as in the lysis of adhesions within the TMJ. Contact lasers that have wavelengths that are well absorbed by oxyhemoglobin are well suited for the excision of some lesions with increased vascularity.

Another one of the benefits of contact laser surgery is the utilization of the wavelength conversion effect. When contact laser tips are manufactured with a slightly absorbent coating, an extremely large amount of heat energy can be created directly at the tip. The laser energy is converted to heat energy directly at the tip of the handpiece, which removes the dependence of absorption of the tissue. With a change of the tip, the laser is no longer dependent only on its wavelength to create an effect, as a very high temperature is created at the tip of the handpiece. This heat can be used to incise or ablate a wide variety of tissues. On the other hand, when a less absorbent tip is used, the normal absorption characteristics of the laser are restored and tissue selectivity is available in a contact form. This alleviates some of the need for multiple lasers in a single case. Further study is needed to evaluate the efficacy of these laser systems in specific procedures, but these systems may alleviate the need for multiple, expensive laser systems.[62-64]

Wound Healing After Laser Surgery

Wound healing after laser surgery has received much attention since the first applications of the surgical laser. Most studies dealing with oral and maxillofacial laser wounds have examined the carbon dioxide laser. Many attempts have been made to qualify and quantify the dynamics of healing after a laser is used on a variety of tissues. Many of the data are conflicting and not of significant statistical power to be compelling. There have been many reports comparing wound healing after the use of lasers versus that with other modalities. Laser wounds are thought by many to produce less postoperative pain, although this has yet to be convincingly documented in the literature.

As mentioned in the discussion of tissue interactions, the typical laser wound is created by multiple mechanisms. Mistakenly thought of as a burn, the laser-tissue interaction actually involves many cellular and subcellular events other than heat damage. There is vaporization of intracellular fluid that helps disintegrate cell structure almost instantaneously, and the subcellular structures are often vaporized as well. This likely occurs without the normal cascade of cytokines seen in acute inflammation. Slower healing due to delayed epithelial migration and decreased scar formation (possibly due to changes in collagen conformation at the wound surface) have been observed by many investigators. Nerve endings have been shown to be histologically sealed, lending some evidence to claims of decreased postoperative pain in these patients—although this finding has been disputed in the literature.[65,66] Decreased postoperative pain in these patients may also be due to an altered inflammatory response in laser wounds. The finding of fewer myofibroblasts at wound edges after laser surgery has been postulated as the reason for the lessened scarring and contraction seen, although this too has been questioned by some authors.[66-71] Evidence suggests a possible role for the helium-neon laser in accelerating wound healing of scalpel and laser incisions.[72-77]

Intraoral Laser Procedures

Incisional and Excisional Procedures

Gingivectomy, Operculectomy, Frenectomy, and Tuberosity Reductions

Lasers can help avoid the elevation of large flaps and limit the inflammatory response, all increasing patient comfort. Compared to scalpel excisions, excision with lasers is thought to have less scar contracture.[78] The CO_2, diode, and ND:YAG lasers are all commonly used in removal of gingival tissue.[79] The CO_2 laser is extensively used due to its multiple advantages in soft tissue procedures including hemostasis and minimal thermal damage to adjacent tissue. The reduction in postprocedure bacteremia is also seen with the carbon dioxide laser over more conventional methods of incision or excision.[80] It is extremely important to know the wavelength of the specific laser that is being used and the tissue that is being excised. For example, the carbon dioxide laser has a wavelength of 10.6 nm and is primarily absorbed by water. The diode and ND:YAG lasers function at a wavelength near infrared and are therefore, minimally absorbed and have a greater depth of penetration. These lasers will be especially useful in hyperemic or vascular gingival tissue.[81] For incisional or excisional procedures the lasers are used in the focused mode, maintaining a small spot size.

The carbon dioxide laser is particularly well suited for removal of gingival tissue. Most gingival surgery can be performed quickly in a bloodless field and with very little postoperative pain. Gingivectomy may be indicated to decrease periodontal pocket formation or to reduce hypertrophic gingival areas due to poor oral hygiene or medications such as calcium channel blockers, Dilantin, or cyclosporin. The beam is focused using the smallest spot size, and a power is selected. Most continuous-wave lasers can be set at 2 to 10 W to remove gingival tissue effectively. A similar incision design, external bevel, that is used during conventional gingivectomy should be used when completing a gingivectomy with a laser. The specimen is excised and hemostasis is obtained using the photocoagulation technique. Massive gingival hypertrophy should be grossly debrided first, using the excision method. Proper protection of the teeth

and bony structures can be achieved with tooth guards or any broad, flat surgical instrument that has been rendered nonreflective.

Palliation of pericornitis can be achieved by excising the operculum with the carbon dioxide laser. Removal of this redundant tissue is often helpful in patients who cannot schedule removal of third molars for several months, although patients should be informed of the temporary nature of this procedure. Antibiotics are prescribed as needed.

Removal of a prominent frenum is perhaps one of the simplest, quickest, and most effective procedures a surgeon can perform with the carbon dioxide laser. The area is anesthetized with local infiltration and dried with a gauze. The frenum is incised using a small spot size to lyse the fibrous band. When the tissue band is thicker, the entire frenum should be excised. This is accomplished by grasping the tissue with a hemostat at its inferior and superior attachment. The tissue is then excised by directing the laser along the hemostat beaks. No closure is necessary, and hemostasis is obtained by defocusing the beam using the photocoagulation technique. Patients have little if any postoperative discomfort.

Prominent maxillary tuberosities may interfere with the fabrication of a denture prosthesis and often need to be reduced. When the bulk of the tissue is mucosa, not bone, the laser can be used to excise a wedge of tissue and undermine the flaps in a bloodless field. Bony reduction can be accomplished in the usual manner with a rongeur or rotary instrument. Redundant soft tissue can be excised with the laser, and the incision lines are approximated with sutures. In some cases the excess soft tissue can be ablated to an adequate height. However, this eliminates the possibility of bony reduction, and the surgeon must be very careful not to perforate the mucosa and injure the bone. This will cause bony necrosis in this region and may precipitate an oroantral fistula.

Epulis Fissuratum and Pyogenic Granuloma and Granulation Tissue Excision

Excision of an epulis fissuratum may be performed rapidly without loss of vestibular depth by using the carbon dioxide laser. A small spot size is chosen with a power of 4 to 8 W using the continuous-wave or pulsed modes. Traction is applied to the lesion using forceps, and it is excised along its base. If necessary, the laser may be defocused to photocoagulate the bed, and the wound heals without suture placement. The patient should be warned not to wear the denture for several days, and a soft tissue liner may be used in the area of question after the denture flange has been adjusted. Patients experience little, if any, postoperative pain.

Granulomatous soft tissue masses are vascular lesions that are well suited for excision with the carbon dioxide laser. The Nd:YAG or argon lasers can be used alone or in conjunction with the carbon dioxide laser if desired. These lesions can appear similar clinically to Kaposi's sarcoma or other neoplasms. For this reason, ablation is generally not an option, and the excisional or incisional biopsy techniques are utilized.

The laser is focused with a small spot size. Power settings can range from 5 to 10 W using either continuous-wave or pulsed modes. When excising the entire lesion, the extent of the base can be easily visualized in the nearly bloodless field offered by the laser. The beam can be defocused to obtain hemostasis as needed and to remove remnants of the lesion layer by layer if necessary.

Pigmented Lesions

Pigmented lesions of the oral cavity can occur in many varieties, including traumatic amalgam tattoo, congenital nevi, melanoma, or other pigmented neoplasm. A careful history and physical examination must be undertaken to ascertain if the lesion is primary or metastatic. Lesions certain to be benign by history and examination may be ablated, but only after careful consideration because this technique removes any meaningful attempt at staging should carcinoma arise from the site. The basic excisional technique described previously can be used to remove these intraoral lesions. The carbon dioxide laser is focused maximally, and a power setting of 4 to 10 W is used. The specimen is excised and sent for histologic examination. When performing incisional or excision biopsy procedures it is important to remember that the laser can cause a zone of lateral necrosis, and the incision design should be placed 0.5 mm beyond the normal incision design with a scalpel. Diagrams indicating the exact location, size, and characteristics of the lesion should be present in the medical record and on the submitting form for pathologic examination. A specialist in oral dermatopathology is best suited to evaluate these lesions, which, at times, are difficult to classify and grade.

Mucocele and Mucous Retention Cysts

These lesions are easily treated with the laser. The bloodless field makes it easy to localize the extent of the lesion during excision. The carbon dioxide laser is set with the smallest spot size and a power setting of 4 to 10 W. The continuous-wave or pulsed modes may be used. It is useful to outline the lesion with individual pulses to mark the incision line prior to excision. Only when the lesion's depth has been reached should the surgeon undermine and completely remove the lesion. Adjacent minor salivary glands should be bluntly dissected with a scalpel, scissors, and/or a hemostat and then excised with the laser. This minimizes the chance for recurrence of the mucocele. Photocoagulation can be used to obtain hemostasis. The wound is sutured only if cosmetic closure is needed. Most do not need to be sutured, and most patients have a benign postoperative course.

Implant or Tooth Exposure

The role of lasers in perisurgical implant care has expanded in recent years and is continuing to evolve as lasers become more popular. Initially utilized in the uncovering of fixtures at the second stage of implant reconstruction, lasers are now used in other areas such as preparation prior to placement of osseointegrated fixtures. These techniques must be undertaken with care because of adverse reactions of certain laser

wavelengths with implant fixture materials. Again, a firm understanding of the physics behind tissue *and* fixture interaction with the laser light is essential. The consequences of underestimating the laser–fixture interaction were seen early on while using the Nd:YAG laser on peri-implant tissue. The Nd:YAG laser was shown to have an adverse thermal effect on the fixture, which then destroyed the surface layer of plasma-sprayed titanium.[82] Lasers are relatively contraindicated for use with hydroxyapatite-coated implants because both Nd:YAG and carbon dioxide lasers remove the outer coating and expose the metal core. Simple tissue recontouring can be accomplished with these lasers only when it is certain that the fixture coating will not be exposed.

The carbon dioxide laser is useful in primary or secondary soft tissue recontouring by using the defocused technique. A relatively low power setting of 2 to 6 W is used in the continuous or pulsed mode to sculpt tissue to its desired contour. The low power setting helps avoid unwanted heating of the implant fixture, which may increase failure rates of implant fixtures.[60] The same technique is used for exposing the implant during second-stage uncovering. This allows for premium tissue contouring and a bloodless field. The emergence profile of the implant can be easily optimized when careful tissue recontouring is performed. There is often no need for sutures when using this technique, and patients can often undergo impression procedures on the same day.

The treatment of peri-implantitis is an area of research that is continuing to evolve. Peri-implantitis is a difficult complication to treat. Current methods of treatment of peri-implantitis are topical antimicrobial agents such as citric acid, chlorhexidine, or tetracycline and surgical treatment with mechanical or chemical debridement of the implant surface. The CO_2 laser can also be used to decontaminate peri-implant defects. In a dog model it has been demonstrated that carbon dioxide lasers can effectively decrease contamination and increase bone formation.[83,84] In a study by Tosun et al. it was shown that a CO_2 laser used at 6 W, 20 Hz, and a 10-ms exposure time/pulse with a 10-second application period (0.8-mm spot size) eliminated 100% of the *Staphylococcus aureus* on sandblasted, large-grit, acid-etched surface titanium discs.[85] Diode laser has become more popular due to its lower cost compared to other lasers. The diode laser, like the CO_2 laser, can be used to treat peri-implantitis. The CO_2 and diode lasers have varying bacterial sensitivities based on the bacterial species present.[86] The Nd:YAG laser works well for decontaminating the implant surface, however, it can cause a significant increase in the temperature of the implant and cause changes of the implant surface. Diode lasers and CO_2 lasers have not been found to affect the implant surface.[87]

Exposure of soft tissue impacted teeth can be accomplished with the use of a surgical laser. This is especially helpful in the palate when exposure is needed for orthodontic bonding. In the traditional surgical technique, hemostasis after exposure of an impacted tooth is often difficult when attempting to place an orthodontic bracket. This problem is alleviated when using the carbon dioxide laser because exposure of the tooth using the laser in a defocused mode is essentially bloodless. Alternatively, the contact Nd:YAG laser may be used, but special care must be taken not to injure the embedded tooth with excessive heat from the laser tip.

Lasers can be used during any "surgical extraction" where an incision and a flap is elevated. Again, the benefits of using a laser as opposed to a scalpel will increase hemostasis and can help with decontamination of the surgical site. These properties can be extremely helpful in patients with coagulopathies or poor hygiene resulting in gingival inflammation and irritation. Once a tooth has been extracted the laser can aid in reducing the bacterial load within the socket or surrounding tissue, such as in a patient with pericoronitis.

Apicoectomy

An apicoectomy is used to eliminate periapical disease and can be thought of as a salvage procedure. The CO_2 laser can be used not only for the incision but also to remove the infected periapical tissue, allowing for bacterial decontamination. The CO_2 laser will aid in hemostasis, allowing better visualization of the root apex. Additionally, it has been shown to be effective in preparing the root apex for retrograde filling and can seal dentinal tubules.[88]

Ranula and Sialolith Removal

A ranula present in the floor of the mouth can easily be marsupialized with the carbon dioxide laser using power settings of 5 to 8 W in the continuous or pulsed mode. Tissue forceps are used to grasp the lesion, and the laser is used to outline the dome of the lesion. The base and walls of the lesion are lased in a defocused mode to help prevent recurrence. Sutures are not needed, and a benign postoperative course can be expected. Marsupialization of a ranula is associated with a high recurrence rate, but this procedure may be indicated in some patients who cannot undergo an excision of the sublingual gland, which is the preferred treatment.

The carbon dioxide laser can be used to locate and remove a distal sialolith within the floor of the mouth. First the location of the sialolith is ascertained using a diagnostic modality such as a sialogram or plain radiographs. The carbon dioxide laser is focused at 3 to 5 W in a continuous or pulsed mode to make an incision over the salivary gland duct. Once the stone is encountered directly by the laser beam, a bright spark occurs, thus localizing the sialolith. Sutures are usually not required, and the wound is left open to prevent stricture formation.

Vestibuloplasty

The carbon dioxide laser is useful in performing a submucosal or secondary epithelialization vestibuloplasty. Both of these techniques leave an open bed of surgically altered tissue that can cause postoperative pain and bleeding when performed with standard techniques. Use of the surgical laser ensures a bloodless field and may result in less postoperative pain. Studies showing the success of these procedures in both the maxilla and the mandible are needed to evaluate the degree of secondary contracture and scarring when compared with standard techniques.

Only the initial incision for vestibuloplasty with split-thickness skin grafting should be made with the carbon dioxide laser. This leaves a well-defined edge to suture the graft to once the site has been prepared. The deeper extent of the incision should *not* be made with the laser, however, because the laser inhibits epithelial migration and the total bloodless field does not allow for the much needed inhibition during the first 48 to 72 hours of graft survival.

Laser-Assisted Uvulopalatoplasty (LAUPP)

This technique for the surgical treatment of chronic snoring, upper airway resistance syndrome (DARS), and obstructive sleep apnea (OSA) has been shown to be successful in carefully selected patients. A basic understanding of these disorders is helpful when attempting to use the laser in treating these disorders. Clinicians are referred to any number of excellent resources on the comprehensive management of the continuum of snoring, DARS, and OSA both in this text and elsewhere.

Treatment of these disorders is sometimes complex and may involve several medical maneuvers as well as surgical procedures. Clinicians who wish to treat snoring, DARS, and OSA must have a clear understanding of the consequences of the various treatments for each of these disorders. The procedures for LAUPP in simple chronic snoring, DARS, and mild OSA are described in the following paragraphs, but it is wise for each clinician to have his or her patients consult with a sleep specialist prior to performing LAUPP. Clinicians need to be certain that they explain to patients that OSA is usually multifactorial and performing a LAUPP alone may not cure their disease.

Contraindications to LAUPP include moderate to severe OSA, as these patients may not have the pharyngeal lumen reserve to tolerate postoperative edema. It is for this reason that proper diagnostic tests and consultation are critical when treating any patient with any symptoms of DARS or OSA. Sleep specialists can be helpful in coordinating the staging of treatment and identifying other procedures, such as advancement geniotomies, tonsillectomy, and orthognathic surgery, that may be indicated in select patients.

Diagnosis of snoring, DARS, and OSA includes a careful history and physical examination, including nasopharyngoscopy. Often simple snoring can best be evaluated by asking the patient's sleeping partner to describe patterns and relative loudness of the snoring. The partner may describe apneic episodes, indicating the need for further workup. Additional diagnostic modalities such as cephalometric analysis, polysomnography, computed tomography, and static or functional magnetic resonance imaging may be useful in patients with DARS or OSA. Causes of and contributing factors to snoring, UARS, and OSA include obesity, muscular laxity, alcohol and central nervous system depressant use, smoking, hypothyroidism, macroglossia, and some craniofacial abnormalities. When surgical intervention is considered an option, the success rates have often been better than 75% for simple snoring.[89-92]

The uvulopalatopharyngoplasty for the treatment of snoring was introduced by Ikematsu in 1964. It required general anesthesia, was commonly associated with postoperative velopharyngeal insufficiency, and caused significant postoperative pain.[93] In the late 1980s in France, Kamami developed LAUPP. This was found to be a simpler procedure with fewer postoperative sequelae, and it has gained popularity since its introduction. LAUPP is best suited for the patient with simple chronic snoring.[91] The procedure is described in one-stage and multistage techniques. Some patients may not tolerate the one-stage technique because of the increased postoperative pain and recovery time, but many patients and clinicians prefer it to the three to five visits required in a multistage technique. It should also be noted that the tonsils can be ablated using the laser, which causes a reduction in size of the tonsils and may not require removal if the upper airway space has increased.[94]

It should be noted that patients who are vocalists, wind instrument musicians, or professional speakers should be made aware that characteristics of their voice or their ability to produce sound from a musical instrument may be permanently altered. Certain dialects rely on specific sounds made by using the uvula in a specialized manner, and any change in the turbulence of airflow can change the production of sound. This procedure is avoided in patients with clefts or others who are at risk for velopharyngeal insufficiency. Patients should be evaluated for occult or standard submucous cleft palate. These may be relative or absolute contraindications for some patients; therefore, a specific informed consent should be designed to address these concerns.

This procedure can be done in an office setting with local anesthetic, eliminating the need for an overnight admission to the hospital after an uvulopalatopharyngoplasty in the operating room.[94] This helps to decrease health care costs for the patient. To perform the procedure, the patient is placed in a comfortable, upright position. Topical anesthetic spray is applied to the nostrils and posterior oropharynx, including the palate. Once the topical anesthetic becomes effective, approximately 1.5 mL of 2% lidocaine with 1:100,000 epinephrine is injected into the uvula at its base and the junctions of the soft palate. The carbon dioxide laser is by far the most frequently used laser, but some clinicians prefer the Nd:YAG contact laser system or the argon laser system. A specially designed handpiece with a backstop is used on a carbon dioxide laser system in conjunction with a high-speed suction evacuation system. A standard handpiece may be used, but some form of protection, such as a tongue depressor, must be present beyond the palate to protect the posterior pharyngeal wall from injury. Because the tissue is thick in this region, the laser is set in the focused mode with a power of 8 to 20 W in the continuous or pulsed mode.

In the multistage technique, the inferior half of the uvula is ablated or excised, being careful to have the patient exhale while lasing to prevent inhalation of the plume. Vertical incisions of approximately 5 to 10 mm just lateral to the uvula are made through the thickness of the soft palate. If desired, the tonsillar pillars can be decreased in prominence

with the laser to further increase the size of the airway. However, it is recommended that clinicians do not ablate the tonsil because significant bleeding can occur.

In the one-stage procedure the lateral vertical cuts are initially made in a longer fashion. These vertical incisions terminate just prior to the insertion of the levator palatini muscle, which should be marked prior to surgery. Once these incisions are made, the uvula is reduced to a normal presurgical length measured from the new base.[95]

Postoperative care is identical for both techniques and involves prescribing analgesics, smoking cessation, and a soft diet with avoidance of hot or frozen foods. Antibiotics are not indicated. Some clinicians prescribe a tapered steroid dose starting postoperatively. Although the likelihood is remote, airway compromise can occur with any surgical intervention in the pharynx. Complications include pain, bleeding, airway compromise, and velopharyngeal incompetence.

Ablation Techniques

It is important that a clinical or histological diagnosis is confirmed prior to any ablative procedures with the laser. Ablation does not provide tissue for biopsies. Ablation techniques work exceptionally well for superficial lesions.

Gingivoplasty: Hypertrophic Gingiva

Gingival hyperplasia is a disorder seen in some patients who take Dilantin, calcium channel blockers, cyclosporin, or a combination of these.[96-99] It can be idiopathic or occur for a variety of other reasons. Renal transplant patients may be prescribed both calcium channel blockers and cyclosporin and are particularly likely to acquire this disorder. This condition is amenable to ablation with the carbon dioxide laser. Prior to the development of the laser, these patients were difficult to manage with sharp dissection and electrocautery owing to inadequate hemostasis and the possibility of injury to the teeth. The carbon dioxide laser, used primarily in the defocused mode, is used to ablate gingival tissue in a near-bloodless field. Even severe, recurrent cases can be treated more easily and with significantly less morbidity using this technique. The laser is ideal for this use due to its ability to obtain hemostasis while removing tissue and decreased postoperative discomfort. Another condition where patients may exhibit gingival hyperplasia and pigmentation is Sturge-Weber syndrome. The gingival hyperplasia may be a result of increased vasculature or Dilantin use, which can be used to control seizures.[100] Since these lesions have a propensity to bleed, using a laser is valuable in aiding in hemostasis.[81]

The technique involves topical, local, or general anesthesia, or a combination, depending on the degree of hyperplasia and cooperativeness of the patient. The carbon dioxide laser is set at a relatively high power setting of 10 to 30 W, depending on the relative keratotic or fibrotic nature of the tissue. Defocusing the laser to a spot size between 0.5 and 2.5 mm allows good control for sculpting the tissue without injuring adjacent teeth or bony structures. Ultrapulsing is recommended, although slower pulsing or even use of the continuous mode is acceptable. Special attention is directed at protecting the adjacent teeth with an ebonized instrument, such as a No. 9 periosteal elevator, or carefully placed matrix bands. Enamel burns from the carbon dioxide laser are not only unsightly but also demineralize and are highly susceptible to caries.

Epithelialization occurs over the course of 2 to 3 weeks, and careful postoperative instructions are given to the patient or caregiver, or both. A soft diet, analgesics, and intermittent rinses with chlorhexidine are helpful in the postoperative period. Antibiotics are recommended only in patients susceptible to bacterial infection. Close follow-up for the first few weeks and a regimen of good oral hygiene are important in preventing further exacerbations and recurrences. Should reoperation be necessary, little scarring is seen when using the laser as compared to earlier sharp or electrocautery techniques.

Lichen Planus and Nicotinic Stomatitis

Lichen planus is a common disorder with a presumed autoimmune etiology and a variety of clinical forms. Most commonly, the reticular form is seen on the buccal mucosa with the characteristic Wickham's striae. Ulceration may or may not be present in the reticular form. Erosive lichen planus can be seen on a variety of mucosal surfaces. Patients often present with a burning sensation and request treatment to alleviate the discomfort. Both of these varieties are usually treated with various local and systemic therapies. The surgical laser can be used as an adjunct to palliate the lesions rather than remove them, especially in patients with disease that is refractory to conventional treatment modalities. Trehan and Taylor used a low dose excimer 308 nm laser for a small group of patients with refractive oral lichen planus. They found that the majority of the patients had a positive response in their symptoms and improvement in their erosive lichen planus on clinical examination.[101] Case studies also have shown the palliative effects of diode lasers in the treatment of the burning sensation and pain cause by oral lichen planus.[102]

The carbon dioxide laser, however, is more commonly used to treat these lesions by setting a medium power of 10 to 15 W in the defocused mode. Ablative patterns of crosshatching are used to treat the region. Patients report decreased discomfort in the area treated with the laser. Some evidence exists that suggests possible malignant degeneration of these lesions; therefore, staining with toluidine blue and selective biopsy are recommended.

Premalignant and Dysplastic Lesions

Lesions in this group are classified according to the degree of cellular atypia seen on biopsy. Treatment of these lesions is of great importance because of the risk of development of

carcinoma. It is for this reason that clinicians should generally not ablate these lesions with a laser prior to incisional biopsy. Leukoplakias, erythroplakias, and some erosive lichen planus lesions fall into this category and should be carefully evaluated. Ablation of these lesions removes the possibility of staging, should carcinoma be present. Adequate discussion of the comprehensive treatment of premalignant and malignant lesions is found in many sources and is beyond the scope of this chapter.

Again, biopsy is required to determine the amount of cellular atypia and to rule out malignancy. Toluidine blue staining can be used to highlight areas of high cellular activity.[103,104] Cells with especially active nuclei preferentially retain the stain. Regions of high uptake of this vital stain are then selectively sampled for biopsy in attempts to rule out carcinoma in diffuse surface mucosal lesions. The area of question is prepared with a solution of 1% acetic acid and is irrigated and dried with suction and gauze before a 1% toluidine blue stain is applied. The acetic acid solution is then briefly reapplied to decolorize the area. This procedure is technique sensitive in that overzealous use of acetic acid removes the vital staining of the atypical areas as well as those without cellular atypia. Preferentially stained areas are then sampled for biopsy using the incisional techniques described previously. Specimens are submitted for pathologic examination, being sure to inform the pathologist of the technique used and the specific locations of the specimens.

If the results conclude that each of the specimens is benign, the choice remains of whether to ablate the lesion using vaporization techniques or to excise the lesion to an adequate depth using a focused technique. Opinions vary concerning treatment of these lesions. Lesions in areas such as the floor of the mouth, with malignant transformation rates as high as 25%, can be ablated, although some clinicians question the adequacy of removal of all of the tissue with malignant potential.[105] Adequate studies comparing the local malignant transformation rates after using these techniques are needed. Focused excision of these lesions with the carbon dioxide laser is identical to the techniques described for removal of other intraoral lesions. Careful outlining of the lesion is performed by using a low power setting and a slow, repetitive pulse mode. A 3- to 5-mm margin is suggested, with care taken to provide the pathologist with an extra 500 μm when using the laser.

If the surgeon is comfortable with the benign nature of the lesion, ablation can be performed by defocusing the laser beam and increasing the power setting as needed to remove the lesion to an adequate depth. Lesions that are especially thick and hyperkeratotic require higher power settings because they contain little water. In some cases it may be easier to excise these lesions and then ablate the deeper layer in a defocused mode. Diffuse lesions, however, are amenable to the ablation technique because it is relatively rapid and requires no suturing or grafting. Sharp excision usually causes a great degree of morbidity and postoperative scarring with contracture. This makes the prospect of reoperation in these regions difficult. Laser ablation results in significantly less scarring, being especially useful in verrucous-type lesions with high recurrence rates and the frequent need for surgical re-excision.

This technique can be especially effective in the floor of the mouth. Lesions in this region can be ablated without fear of injury to the salivary gland duct orifices, which remain patent despite distal ablation or resection (presumably due to the decreased swelling and scarring seen in laser surgical procedures). Suturing is usually not needed, and postoperative antibiotic treatment is of little value in most cases. Mild analgesics and chlorhexidine rinses are recommended.

Multiple studies have analyzed the cure rate and recurrences after treatment with laser ablation of leukoplakias or oral dysplastic lesions over the last decade with good results and fewer complications.[106] Roodenberg and colleagues followed 70 patients for just over 5 years and found a 90% cure rate in patients with leukoplakias.[107] Thompson and Wylie studied 57 consecutive patients with oral dysplastic lesions that were treated with a CO_2 laser over 4 years. They found that the laser successfully treated 55 of those patients. Seventy-six percent of patients did not have a recurrence over a mean 18-month follow-up.[108] These studies demonstrate that CO_2 lasers are effective means of treating oral dysplastic lesions with less morbidity than conventional methods.

Careful follow-up is especially important if ablation techniques are used. Some clinicians advocate regular use of toluidine blue staining as a screening method for carcinoma at these follow-up visits. Patients who may be unreliable should probably undergo standard sharp excision.

A newer therapy that has been trialed in the treatment of precancerous oral lesions is photodynamic therapy (PDT), which is a minimally invasive tool that has been used to target these dysplastic tissues in the head and neck, skin, and gastrointestinal tract.[109] Photodynamic therapy includes giving the patient a photosensitizing agent prior to the procedure, which is preferentially absorbed by the cells to be ablated. The first-generation photosensitizers are 5-aminolaevulanic acid (5-ALA), photofrin, and verteporfin. The second-generation photosensitizers, such as Foscan (temoporfin; metatetrahydroxyphenyl chlorine (mTHPC)), have been approved for use in head and neck cancer.[110] Most photosensitizers are systemically administered; however, they can also be topically applied for skin lesions. The laser beam is then delivered to the area directly or via a dispersive medium. Intra-abdominal cancers can be targeted using a sensitizer and a lipid medium that is poured into the abdominal cavity. The laser beam is delivered to the medium, which disperses the energy within the abdominal cavity to multiple areas where the lipid contacts tissue. Photodynamic therapy can be added to more conventional treatment modalities. PDT can be delivered under local or general anesthesia.

Jerjes et al. enrolled 147 consecutive patients with oral dysplastic lesions who were treated with 5-ALA topically and mTHPC-PDT intravenously. After appropriate time, a diode laser was used to treat the dysplastic tissue. The results

of this study showed an 11.6% recurrence rate and 11 of the 147 patients (7.5%) underwent malignant transformation.[110] This study validates the use of photodynamic therapy in the treatment of oral precancerous lesions.

Problems with this technique, and other PDT techniques, include severe tissue burns and less than impressive selectivity for tumor cells. It is extremely important to inform the patients to avoid sunlight to prevent unwanted photosensitivity until the photosensitizing agent is cleared from the body.

Solar Cheilitis or Actinic Keratitis

Actinic keratitis is a premalignant lesion that requires surgical removal to prevent progression to squamous cell carcinoma of the lip. Biopsy confirms the dysplastic nature of these lesions, characterized by silvery white hyperkeratosis and atypical wrinkling of the lip surface. These lesions can appear ulcerated or flaky. Initial biopsy is done in areas that appear the most dysplastic, and, once carcinoma has been excluded, laser removal of this lesion may be indicated.

Another method of treatment of these lesions includes the "lip shave," which involves sharp, superficial dissection of the epithelial lip surface involved. This technique is fraught with considerable discomfort and scarring. Laser ablation and resurfacing of the area offer less scarring and often less postoperative pain. Ultrapulsing has been used effectively to remove dysplastic tissue layer by layer and resurface the lip with new epithelium. Other techniques have used an operating microscope with laser attachments to further enhance the ability to remove the dysplastic tissue selectively. Resurfacing techniques are discussed in the section on maxillofacial cosmetic and dermatologic laser surgical procedures, but setting the laser with a focused mode at about 5 W and using a computer pattern generator to ablate and resurface areas of the lip has proven to be very effective.

Recent literature supports the use of Er:YAG for treatment of actinic cheilitis. This method of treatment offers the patient an option for elimination of actinic cheilitis with a good cosmetic outcome. The Er:YAG laser may even produce less hypopigmentation than treatment with the CO_2 laser, leading to a superior cosmetic result.[111] Some believe that the Er:YAG laser should be a first-line treatment for actinic cheilitis.[112] The addition of photodynamic therapy to treatment with the Er:YAG laser produces greater results than phototherapy alone.[113]

Antibiotic ointment, sunscreen, and instructions to keep the area very clean are important postoperative interventions. It is also important to schedule the patient for regular visits to re-evaluate the areas in question for dormant carcinoma, as this can manifest itself decades after removal of the initial lesion.

Malignant Lesions

The removal of carcinoma and carcinoma in situ with surgical lasers is performed regularly in conjunction with comprehensive staging and resection. Advantages of using the laser include a hemostatic field allowing the surgeon to better delineate the clinical margins of the tumor, decreased scar formation, and sealing of the lymphatics and blood vessels, which may decrease metastatic spread during manipulation of the tumor. Either the focused free beam carbon dioxide or contact Nd:YAG laser can be used to remove lesions once they have been initially sampled for biopsy and staged accordingly. Ablative techniques are not recommended because submission for pathologic diagnosis is critical to evaluate adequate margins and plan for possible adjunctive postoperative therapy. Principles of tumor removal remain the same, depending on the region of the tumor, histologic type, size, nodal involvement, presence of metastasis, and grade. Lasers can be especially helpful in palliative debulking of tumors, as many of these tumors are highly vascular.

Papillomatosis or Papillary Hyperplasia

These lesions are treated with the carbon dioxide laser in the ablative manner previously described, using power settings of 10 to 20 W in a defocused mode. High volume suction devices are used to evacuate contaminated smoke from the field. Care is taken not to injure any underlying bone, as necrosis and oroantral communication may occur when obliterating tissue of the palate or maxillary alveolar ridge. The contact Nd:YAG laser with a flat probe has also been used by some clinicians. Either technique offers excellent hemostasis, and patients tolerate the procedure well when their denture is adjusted and a soft tissue liner is used.

Aphthous and Herpetic Ulcer Palliation

The palliation of aphthous and herpetic ulcers in the oral and perioral regions can be accomplished with the use of the carbon dioxide laser. Patients often report decreased pain but experience somewhat slower healing than without laser treatment. Low power settings of only several watts in a slightly defocused mode are used to "tan" the lesion and are effective in palliating the discomfort, although the exact mechanism by which the pain relief occurs remains uncertain.

Intraoral Vascular Lesions

Mulliken helped differentiate the types of vascular lesions based on their endothelial components and characteristics. This classification system is helpful in determining the method of treatment of intraoral vascular lesions. Much confusion still exists regarding terminology used to describe vascular lesions, and this tends to confuse issues of treatment. Clinicians are referred to Mulliken's excellent texts and articles regarding this subject.[114] Small intraoral lesions tend to be straightforward in most cases and are easily ablated using the carbon dioxide, argon, tunable dye, or contact Nd:YAG lasers. The argon, tunable dye, and contact

Nd:YAG lasers are often better suited for these lesions owing to the high absorption of their wavelengths by hemoglobin. These lasers offer better hemostasis and more selective tissue destruction.

Various techniques of ablation using a crisscross or spiraling circular pattern can be used. Some clinicians prefer to use a glass slide to depress the lesion slightly and aim the beam through the slide to visualize and control the selective ablation better. Other techniques advocate insertion of a fiberoptic tip into the lesions in various planes. More than one treatment may be needed to decrease or ablate the lesion adequately.

Maxillofacial Cosmetic and Dermatologic Laser Surgical Procedures

The surgical laser has many uses in the realm of cosmetic surgery, but it is merely a tool to be used for very specific indications. In the hands of an experienced laser surgeon, the laser may make facial resurfacing more accurate and predictable than the techniques of dermabrasion and chemical peel. It can improve the ease of dissection and hemostasis during blepharoplasty and endoscopic cosmetic procedures. However, it does not replace the usefulness of face-lift, liposuction, augmentation, or submental plication procedures. Both clinicians and patients must be aware of both the usefulness and the limitations of this technology. Considerable dialogue with each patient is warranted when discussing the procedures outlined in the following sections, and the expectations of all parties involved must be within reason.

Facial Resurfacing

The surgical laser has revolutionized the resurfacing of facial skin. Although dermabrasion and chemical peels have worked to decrease wrinkles, the carbon dioxide and Er:YAG lasers offer excellent results with a more accurate and reproducible technique. As a greater percentage of the population becomes older, the demand for facial rejuvenation techniques continues to increase. Additionally, the advent of ultrapulsing, computer pattern generators, and flash scanners has increased the precision and efficiency with which laser energy is distributed. Selective photothermolysis is possible with the current laser delivery systems, thereby decreasing collateral tissue damage. The Er:YAG laser is absorbed by water to a greater extent than the CO_2 laser and therefore penetrates the tissue to a lesser degree, allowing for superior ablation of the epidermis and papillary dermis and less deep thermal damage.[115] These technologies decrease the scarring seen with older carbon dioxide laser resurfacing methods because the ablation is accurately and repeatably taken to the level of the midreticular dermis. Areas ablated below this level tend to scar. As the tissue heals, new elastic fibers reorganize and realignment of collagen fibers occurs in a more parallel fashion, creating a more youthful, shiny, smooth skin surface.

This technique works well for fine wrinkles but only softens deeper wrinkles. The areas most commonly treated include perioral and periorbital fine wrinkles, although improvement is seen in all areas with fine wrinkles.[116,117] Deeper wrinkles associated with more muscular action, as seen in large forehead lines, respond less favorably. Patients with fair skin of Fitzpatrick types I to III do best with this treatment, whereas darker skin types tend to have postsurgical pigmentary changes. Patients with a history of radiation therapy in the expected treatment area, scleroderma, immunologic skin disorder, or prior use of isotretinoin (Accutane) should usually be excluded from these treatments because their healing may be markedly different from those with normal skin. This may result in increased scarring. As with other laser treatments, procedure-specific consents and a detailed discussion of the postoperative course are required. Preoperative photographs should be taken for documentation purposes. It is helpful to have photographs of other patients available who have undergone resurfacing procedures showing different treatment phases.

Preoperative courses of topical retinoic acid to initiate the healing process, hydroquinone to deplete the melanocytes, or glycolic acid, or a combination, may be considered. Most clinicians advocate giving acyclovir perioperatively as well. It is imperative that patients are instructed to wear sunblock during the healing process. Patients should be instructed to arrive at the clinic with a cleanly washed face, and a mild cleanser is used just prior to resurfacing. Protective eyeshields are placed, and all nontreatment areas are protected with nonflammable drapes or wet gauze, or both. These patients do best with local anesthetic block techniques and intravenous sedation. Perioperative antibiotics and steroids are used by some clinicians, although their efficacy has not been proven.

Because several lasers are used for the purpose of facial resurfacing, only general statements can be made in this text. Each laser's manual and the current literature should be consulted for specific techniques. Areas with thin, delicate skin, such as the periorbital region, require less energy and fewer passes of the laser, whereas the thicker perioral region generally requires more energy and more passes of the laser.

The layers of the epidermis and the superficial to the midreticular dermis are ablated using cosmetic units of the face as a guideline. The midreticular dermis has a slightly yellow color (reminiscent of chamois), and this represents the endpoint. The borders of lased skin can be gently "fanned out" by using lower powers and a pattern of lower density, allowing for a gentle transition between treated and untreated skin. Visible contraction of the skin is evident as treatment continues.

Postoperative care consists of meticulous wound care. Various occlusive dressing schemes have been reported in attempts to keep the treated area moist. Many surgeons prefer an "open technique," whereby topical ointments are used during the healing phase. The patient should be seen frequently within the first week, weekly for a month, and then monthly until the erythema resolves completely. Makeup

can be worn after epithelialization is complete, usually in about 12 to 14 days. An annual visit is helpful to document progress and to take photographs.

Among complications, hyperpigmentation is not uncommon and is usually self-limited. Hydroquinone cream can be used to improve blending. Other possible complications include hypopigmentation, scarring, erythema, induration, ectropion, herpes simplex activation, and infection. Postoperative erythema may last for 3 to 6 months and can be hidden with gentle makeup products once initial healing has taken place. The learning curve is considerable with these techniques, and the need for attention to detail cannot be overemphasized. Proper certification and continuing education are extremely important, as both the techniques and the technology change rapidly.

Blepharoplasty

The technique for blepharoplasty can be aided by using a carbon dioxide, KTP, or Nd:YAG laser for the dissection to help create a bloodless field.[118,119] Currently, the carbon dioxide laser is most often used with this technique. Existing techniques utilizing cautery or radiofrequency devices for hemostasis are certainly comparable to the laser techniques in the hands of some surgeons. Each surgeon must make his or her choice regarding personal success rates and comfort with the laser technique. Whereas standard techniques of blepharoplasty require basic surgical instruments, the laser technique involves a significant set-up cost. Clinicians who are comfortable with the noncontact carbon dioxide laser may find that dissecting with this laser in the focused mode can aid greatly in keeping the field exceptionally dry and decreasing the amount of periorbital ecchymosis seen after some blepharoplasty procedures. Thorough preoperative evaluation, surgical strategies, and other aspects of this procedure are explained elsewhere in this text. The addition of the laser is briefly reviewed below.

Preoperative photographs are taken, and anesthetic and surgical plans are formulated. If blepharoplasty alone is planned, intravenous sedation with local anesthetic infiltration and topical ophthalmic anesthetic are usually sufficient; however, if additional procedures are being performed, general anesthesia may be warranted. Once the patient is comfortable, corneal shields are placed. A scalpel is used to make the initial incisions, although the focused laser is advocated by some for this step as well. In both upper and lower blepharoplasties, the dissection can then be advanced with the use of the laser in the pulsed and focused modes. The beam may be defocused to help with hemostasis as needed. The fat pads are removed with the carbon dioxide laser, using a wet cotton-tip applicator as both a dissecting tool and to prevent the beam from injuring adjacent tissue. Contact tips of the KTP or Nd:YAG lasers offer tactile sense during removal of the fat pads. The incisions are then closed in the standard fashion. If minor periorbital skin laxity exists, some thought should be given to the need for resurfacing if skin is not resected at the time of blepharoplasty. Instructions to keep the head elevated and to use cold compresses are important for minimizing swelling and ecchymosis. Topical ophthalmic antibiotic ointment or drops may be prescribed for several days postoperatively.

Complications directly related to the laser include misfires of the laser, causing damage to the skin, eyelashes, or components of the globe, depending on the laser used. Other complications of blepharoplasty include lacrimal gland injury, entropion, ectropion, infection, wound dehiscence, and persistent erythema. The laser can be another effective tool in this already successful procedure. A great degree of familiarity with both the standard surgical procedure and the laser choice is important to avoid complications.

Vascular Lesion Treatment

Probably the most dramatic use of the surgical laser is in treating vascular lesions. Mulliken was the first to describe and redefine the classification system currently used for vascular lesions, based on vascular endothelial cell characteristics.[120] Three groups exist in this classification system: (1) hemangiomas, (2) vascular malformations, and (3) ectasias. Further description is based on the vessel type (or combination of vessels) seen with histologic analysis (e.g., lymphangioma).

Hemangiomas are benign and present at birth or within the first few months of life. They do, however, experience a rapid proliferative phase for variable amounts of time. After this growth phase, an involution period begins in which the lesion shrinks over the course of several years, usually becoming barely noticeable. Unlike hemangiomas, vascular malformations are always present at birth and do not exhibit a rapid proliferative or involution phase. They grow slowly with the patient's growth. They can affect surrounding tissues, including bone, and may develop granulomatous elements later in their course. Port-wine stains and several other malformations associated with syndromes such as the Osler-Weber-Rendu, Sturge-Weber, or ataxia-telangiectasia syndromes belong to this group. Ectasias, such as telangiectasias, are acquired and can grow with age.

Much of the excitement generated about lasers early in their development was due to their potential for use in selectively ablating tissue of deforming vascular lesions that would otherwise require sophisticated and often deforming excisions and flap reconstructions.[121-123] Although many different lasers have been used for a variety of lesions, the pulsed dye laser at 577 or 585 nm continues to be considered the most effective.[124,125] Delivery systems have improved significantly, although no other laser has been shown to be more clinically effective or vascular specific. Many other lasers are effective at removing the lesion but exhibit undesirable postsurgical skin changes such as excessive scarring and hypo- or hyperpigmentation. Several laser systems and their advantages and disadvantages for commonly treated vascular lesions are discussed in the following sections. Combination laser therapy may be indicated for some lesions, depending on the patient's particular response to treatment. Controversy exists regarding

when to treat (if at all) various forms of hemangiomas and other vascular lesions. Any clinician who treats these types of lesions should be well versed in the past and current literature regarding treatment strategies. Results can be disfiguring if an incorrect diagnosis is made or the wrong laser is chosen for treatment.

Skin Pigmented Lesion Removal

Pigmented lesions can be among the most unpredictable of all lesions treated with the surgical laser. Nevertheless, some discrete indications exist for using the surgical laser for their removal. Excision with skin grafts, flap advancements, or free flaps generally leaves disfiguring scars in the maxillofacial region. Laser treatment, resurfacing, or ablation can lighten or completely remove some lesions, greatly improving the esthetics.

The target cell in these pigmented lesions is the melanocyte, specifically the melanosome (organelle responsible for the synthesis of melanin).[126,127] Melanosomes absorb a variety of wavelengths, and the lesions vary in depth.[128,129] Lesions that extend into the dermis require deeper penetration by the laser and are best treated by lasers with longer wavelengths. Greater energies are required for these deeper lesions. As with other laser ablations, the tissue is heated to critical temperatures and the targeted cells are evaporated.

The lasers commonly used for these lesions are selected because of their depth of penetration and tissue selectivity. The pulsed tunable dye laser at 510 nm is commonly used to treat superficial pigmented lesions such as café au lait macules and other lightly colored macules.[129,130] The short wavelength and quick pulse rate are well suited for lesions that are superficial in nature. Powers of 2 to 3 J/cm^2 along with spot sizes around 5 mm are generally adequate for treatment. The area should be evaluated 6 weeks after treatment for signs of lightening or hyperpigmentation. The latter can be treated with hydroquinone and glycolic or retinoic acid topically daily until the hyperpigmentation resolves. If the lesion has been lightened, treatment can generally be performed in 6- to 8-week intervals, depending on the individual healing. The frequency-doubled Nd:YAG at 532 nm has been successful in treating the superficial lesions as well. Powers of 2 to 3 J/cm^2 are used with 2-mm spot sizes for effective treatment in many cases. Krypton and copper vapor lasers have been used to treat superficial pigmented lesions, but they generally cause more tissue damage than necessary and are considered by most to be inferior to the pulsed dye laser.

The noncontact Nd:YAG laser at 1064 nm (8 J/cm^2), the Q-switched ruby laser at 694 nm (5 to 6 J/cm2), and the Q-switched alexandrite laser at 755 nm (6 to 7 J/cm^2) are used to treat deeper lesions such as nevi of Ota, nevi of Ito, blue nevi, and melanotic nevi.[50,131,132] These lasers are effective because their longer wavelengths penetrate deeper into the dermal tissues without causing undue scarring or other undesirable tissue effects. They have also been used to treat superficial lesions effectively.

Patients should be carefully evaluated prior to initiating laser treatment of these lesions. The choice of laser depends greatly on the correct clinical diagnosis. Previous history or family history of malignancy arising from epidermal and dermal lesions excludes the patient from laser ablation in any lesion with even minor malignant potential because total ablation with the laser cannot be guaranteed and staging would be altered should malignancy develop. Patients must also be cautioned that some lesions will not respond to even repeated laser treatments and, rarely, may worsen in appearance when treated with a laser. A procedure-specific consent is especially important in these cases to educate all concerned parties.

On physical examination of the lesion and the surrounding skin, the clinician should note the Fitzpatrick skin type, as lighter shades of skin tend to respond better to laser treatments. Darker skin types may have problems with hyperpigmentation after laser treatment. Once the diagnosis is made, the patient must be made aware of the number of treatments that are generally required for particular lesions. While lentigines are superficial and can be treated easily with one to three visits, a nevus of Ota or café au lait nevus can take six visits or more to be adequately treated. Some lesions, such as melasma and postinflammatory pigmentation, do not respond to laser treatment and should be treated with other means, such as a chemical peel, when warranted.

Preoperative photographs are necessary for documentation and assurance for the patient that the lesions are improving over time. Such subtle changes occur with some lesions that the initial presenting photograph may help the patient to continue with the multiple sessions needed.

When these procedures are performed, the area of skin is thoroughly cleaned with mild soap and water. Some authors advocate the use of topical anesthetic creams for patient comfort, however, intravenous sedatives help patient comfort significantly. Children with extensive lesions are often treated in the operating room with a general anesthetic. A fan is sometimes useful for patient comfort. The wound care is similar to that for laser resurfacing.

Tattoos are simply a form of pigmented lesion that often can be lightened or even totally removed with the surgical laser. They require special attention because different pigments respond differently to different surgical lasers.

Surgical, Burn, and Acne Scar Revision

Since the beginnings of laser treatment of epidermal tissues, studies on the effects of a variety of lasers on scars have been done and have yielded less than impressive results. In the past, steroid therapy, cryosurgery, dermabrasion, radiotherapy, silicone gel sheeting, and excisional therapy have all failed to show acceptable and repeatable clinical improvement. Even with earlier carbon dioxide, argon, and other laser treatments, the recurrence rates were high. Alster and other groups used the pulsed dye laser at 585 nm to treat various types of scarring, with significant clinical improvement.[133]

Studies have directly compared pulse dye lasers to a CO^2 ablative fractional laser (AFL) and the results show that both show improvement in treated scars. The pulse dye laser improved the color of the scar and the AFL showed a vast improvement on the contour of the scar. However, the difference in the improvement between the two lasers was not statistically significant.[134] Treating scars with a combination of pulse dye lasers and CO_2 AFL may further improve the esthetic result of scar revision.

As with other laser treatments, patients with Fitzpatrick skin types I to III usually benefit most from these treatments, and scars that are slightly erythematous usually lighten more than others. It is extremely important to analyze the scar prior to treatment. The scar may be hypertrophic, atrophic, erythematous/hypervascular, or a combination. Each class of scars is treated differently. For example, revision atrophic scars involve treating the surrounding tissue with the laser to allow the scar to blend with the adjacent tissue. A hypertrophic scar is revised by lasering the scar to reduce it to the level of the adjacent skin.[135] The use of lasers to treat hypertrophic scars can be added to existing management strategies such as topical steroids, intralesional steroid injections, compression dressings, and silicone dressings.

Topical or local anesthetic is usually adequate for patient comfort, but care must be taken not to inject local anesthetic directly into the lesion because this may change the absorption of the laser energy. A 5- to 8-mm spot size is used with fluences at 6 to 7.5 J/cm^2. The entire scar is treated, and the patient is instructed to keep the area clean and bandaged lightly during this time. A regimen of postoperative care similar to that with facial resurfacing may be used. Antibiotic ointment may be used, and perioperative acyclovir may be prescribed if the scar is in a region of previous herpes simplex activation. The scar should be re-evaluated at 6 weeks for response. Several treatments may be necessary and are given at 6- to 8-week intervals. Complications include worsening of the scar, hyperpigmentation, and persistent erythema. Combined therapies, including carbon dioxide laser resurfacing, chemical peels, and topical retinoic acid treatments, may improve overall results and are currently being evaluated.

Hair Transplant and Hair Removal

Unger has published extensively on hair transplantation using micrografts and the added benefits of using the ultrapulse carbon dioxide laser as an adjunct.[136,137] Hair transplantation with excised grafts leaves rows of hair that are easily visible and a hairline that is unnatural and easily noticed. The advent of micrografting helped decrease the unsightly appearance of rows of plugged hair. Smaller slits are made to place the microcut hair grafts in place. In some patients, however, these slits tend to produce dark lines coursing through the hairline where the micrografts have been placed into the slit made by a scalpel. The carbon dioxide laser is used to make the recipient sites slightly wider, creating an even more natural hairline. A great deal of experience is required to master the technique.

Larger areas can be treated in one sitting when compared to the laborious process of electrolysis. About one third of all patients can expect the treatment to be permanent. This is equal to or better than the results seen with electrolysis. Alexandrite, Nd:YAG, and ruby lasers have been selected for their specificity for the red- and near infrared–sensitive dermal tissues. The selectivity may decrease the chance for the scarring seen in some cases of electrolysis. One company has used a carbon-based solution applied to the hair-bearing area to engulf the hair papilla, making it susceptible to the heat effects of the laser. The heat then destroys the follicle and causes a reduction in hair-producing elements in that area. Several treatments are frequently needed to achieve an acceptable result. More research is necessary to evaluate these new treatments before standardized therapy is available.

Endoscopic and Microscopic Laser Surgery

The use of minimally invasive and microscopic surgical techniques has recently been augmented by the application of laser surgical techniques. Laser TMJ arthroscopy and arthroplasty, laser-assisted endoscopic facial cosmetic surgery, and endoscopic laser lithotripsy of salivary gland stones are currently being evaluated. Since the learning curve is rather large, clinicians should be comfortable with both the standard surgical technique and the laser surgery before attempting to perform these procedures. In the hands of a skilled operator, these techniques expand the capabilities of previous methods.

Laser Arthroscopy and Arthroplasty of the TMJ

The difficulty of treating some TMJ disorders has been evident since Annadale's first surgical attempts in 1887.[138] The addition of lasers in the treatment of TMJ disorders with arthroscopy has offered a less invasive means of management then traditional open TMJ surgery. As seen with many other uses of the laser previously mentioned in this chapter, the laser offers many advantages over conventional arthroscopic instrumentation, including improved coagulation, allowing better visualization and much greater precision. CO_2 and Er:YAG lasers were not very effective in TMJ arthroscopy due to the synovial fluid environment.[139] McCain's contributions to arthroscopy have advanced the field significantly, and techniques by Hendler and Koslin have been described as sculpting fibrocartilaginous and retrodiscal tissue safely and easily with the Hol:YAG laser.[41,140,141] These techniques developed out of the knee arthroscopy experience pioneered by Fanton and Dillingham.[142] Previous techniques using the Nd:YAG laser were attempted but caused significant damage to adjacent tissue owing to the depth of penetration of this laser. As previously mentioned, Trauner showed that the Hol:YAG laser was less damaging to the surrounding tissues when sculpting fibrocartilage.

The Hol:YAG laser is a pulsed, mid-infrared laser at 2100 nm that works well in a saline environment and can be used with a fiberoptic quartz fiber. This allows for easy manipulation within the joint using standard triangulation techniques described by McCain with a quartz fiber. Generally, a power setting of 0.8 J and a pulse rate of 10 Hz can be used to ablate and sculpt tissue effectively. The Hol:YAG laser can be used for discectomy, synovectomy, hemostasis, treatment of anterior disc displacement, dissection of fibrous adhesions, and scarring of retrodiscal tissue in the treatment of hypermobility.[135] Mazzonetto and Spagnoli describe meniscectomies through an arthroscope using a Hol:YAG laser to remove the disc and then using more traditional rotary instruments to recontour the condyle and glenoid fossa.[143] As with most TMJ procedures, the adjunctive physical therapy and use of an occlusal splint is still extremely important in the management of patients with TMJ disorders.

In another application, some clinicians have augmented open arthroplasty techniques by using either the contact Nd:YAG or the carbon dioxide lasers for the dissection.[144] Techniques with and without the use of an operating microscope have been described and may significantly aid in the avoidance of nerve injury. The operating microscope can incorporate a coaxial laser with joystick control to aim the laser within the microscopic field. Comparative studies are needed to evaluate these techniques.

Lasers in Endoscopic Facial Plastic Surgery

Endoscopic facial cosmetic surgery is in great demand owing to the appeal of the minimally invasive techniques utilized. Facial cosmetic procedures are described elsewhere in this text, but the aspects relating to carbon dioxide, KTP, or Nd:YAG laser techniques are mentioned in the following sections. Some clinicians have incorporated a laser to aid in the dissection and ablation of fibrous bands and muscular tissue of the procerus and corrugator musculature.[145-147] Small incisions are used to pass minimally invasive instrumentation to the desired surgical site. In endoscopic brow lift surgery, small incisions are made in the scalp area to dissect within a subgaleal or subperiosteal plane, or both, to alter the muscular action of the procerus and corrugator musculature as well as reposition the brow soft tissue.[148] Some clinicians advocate the use of either the carbon dioxide or the Nd:YAG laser for all or part of the dissection to decrease intraoperative bleeding and postoperative ecchymosis.

Endoscopic Laser Lithotripsy of Salivary Gland Stones

Several groups have described a technique for removing or ablating stones endoscopically with the use of a rigid TMJ arthroscope or similar-sized endoscope and the flash-lamp pumped dye laser.[149,150] These techniques have evolved out of the rather extensive urologic laser lithotripsy literature and continue to be improved. The endoscope is advanced within a salivary gland duct to view the stone, and the laser fiber is advanced to ablate the stone. This technique may restore salivary flow in a significant number of individuals with the advantages of minimally invasive surgery.

Low Level Laser Therapy in Oral and Maxillofacial Surgery

Recently, there have been extensive discussions about using low level laser therapy (LLLT) in oral and maxillofacial surgery. LLLT was first used by Mester in 1967. It was this work that initiated the use of low level laser therapy as a biostimulator.[151,152] LLLT uses a phototherapeutic process with visible and near infrared lasers (400 to 1000 nm). The LLLT varies from other lasers in that LLLT causes minimal temperature changes in the tissue.[151] A study by Rodrigo and colleagues analyzed the effects of LLLT on wound healing in rats. They came to the conclusion that the rats that were exposed to red and infrared lasers had the most advanced healing, especially of the wounds that were distal to the site of laser therapy.[153] LLLT is considered relatively safe due to the athermal effect on tissue, causing minimal destruction of tissue that can been seen with other laser systems.[154] The exact mechanism of LLLT has not been fully established. On a cellular level, LLLT has shown to increase proliferation of fibroblasts, endothelial cells, and keratinocytes.[151] The photostimulatory effect of LLLT is thought to cause the release of growth factors leading to cell proliferation.[155] The vast majority of research on LLLT is with wound healing. Most literature describing the use of LLLT in oral and maxillofacial surgery is case reports or small sample size studies. It has been experimentally used for treatment of myofascial pain, TMJ osteoarthritis, wound healing, bone healing, mucositis, and periodontal therapy. It is thought that LLLT increases the pain threshold by altering the neuronal stimulation, which may be similar to transcutaneous electrical nerve stimulation (TENS) or acupuncture. LLLT also affects the production of prostaglandin, which can have an effect on pain and swelling.[154] LLLT has recently been approved by the FDA for treatment of alopecia and has been shown to stimulate hair regrowth.[156]

The management of dental extractions in patients on bisphosphonate therapy or antiresorptive and antiangiogenic medications is constantly debated. A recent study conducted in Italy explored the intraoperative use of low-level Nd:YAG therapy during the extractions and then weekly for the first 6 weeks and additionally until mucosal healing was achieved. The addition of LLLT during and after tooth extraction appeared to improve healing in patients receiving bisphosphonates.[157]

LLLT is a safe noninvasive treatment modality in the management of temporomandibular disorders (TMD). The results of various studies are mixed. Some feel that it is more effective than placebo treatments. LLLT can be added to other conservative treatment approaches such as splint therapy, anti-inflammatory medications, physical therapy,

and diet modification. The research indicating that LLLT is helpful in reducing pain in TMD uses varying protocols of low-level laser treatments and needs to be standardized.[158]

Continued research on the mechanism of the effects and the applications of LLLT in oral and maxillofacial surgery needs to continue.

Summary

Although the theoretical principles of lasers and surgical applications remain quite constant, the better understanding of tissue interactions and development of safety measures to prevent catastrophic iatrogenic events are of utmost importance to the surgeon's practice.

20
Basic Rhinoplasty

JAMES KOEHLER

The popularity of cosmetic surgical procedures continues to increase. Between 2000 and 2015 the number of surgical and nonsurgical treatments increased by 39%. In 2015 it was estimated that the U.S. population spent $13.5 billion on surgical and nonsurgical cosmetic procedures. Approximately 13 million procedures were performed in 2015. The number of procedures has increased by 538% since 1997. In 2015 rhinoplasty was the sixth most common procedure overall and the second most common surgery performed in men.[1]

Cosmetic surgery of the nose is often considered one of the most difficult esthetic operations. This is partly because the nose holds a prominent position on the face and irregularities or asymmetries cannot be easily camouflaged. Also, subtle postsurgical changes will occur over the course of a year or more. If a surgeon does not perform long-term follow-up of patients, he or she will not gain an appreciation for how well his or her surgical techniques withstand the test of time. For many years, cartilage grafting and destructive techniques to the alar cartilages were performed. In the short term, many of these noses would look good. However, with time, some of these techniques have demonstrated unpredictable long-term results.[2] A return to more conservative and nondestructive tip techniques has come back into favor with the hope that long-term favorable esthetic results can be achieved without compromising the nasal airway.[2-5]

As in any surgery, a solid understanding of the anatomy and physiology is essential. Taking time to listen to the patient's concerns and desires is critical to help formulate the surgical goals and determine if the patient is suitable for surgery and has realistic expectations. Once the patient decides to proceed with surgery, the surgeon must perform a comprehensive examination, taking into consideration the dynamic influence of the skin type, bone and cartilage structure, and anatomic limitations. Creating a detailed three-dimensional plan with a structured sequence will help the surgeon achieve more predictable results.

Mastering the complexity of rhinoplasty is something that cannot be captured in a single chapter. It takes years of training, experience, and continuing medical education to become comfortable with the many techniques that must be tailored to each patient. This chapter will hopefully provide a foundation to build on.

Nasal Anatomy

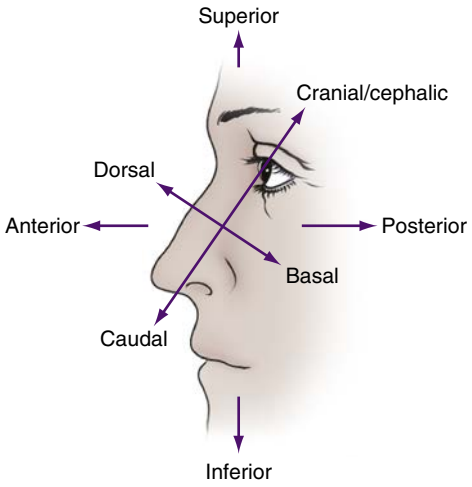
The descriptorss used to describe relative spatial relationships include the standard anatomic terms: *anterior, posterior, superior,* and *inferior,* as well as *dorsal, basal, caudal,* and *cephalic* (or *cranial*) (Figure 20-1). The terms used to describe the surface anatomy assist the surgeon in defining problem areas of the nose and facilitate treatment planning (Box 20-1).

The thickness of the skin varies along the dorsum of the nose. In the region of nasion, the skin is fairly thick and mobile. It quickly thins over the nasal dorsum and is generally thinnest and most mobile in the mid-dorsal region (rhinion). In the nasal tip the skin becomes thicker and more adherent and has an increased sebaceous content.

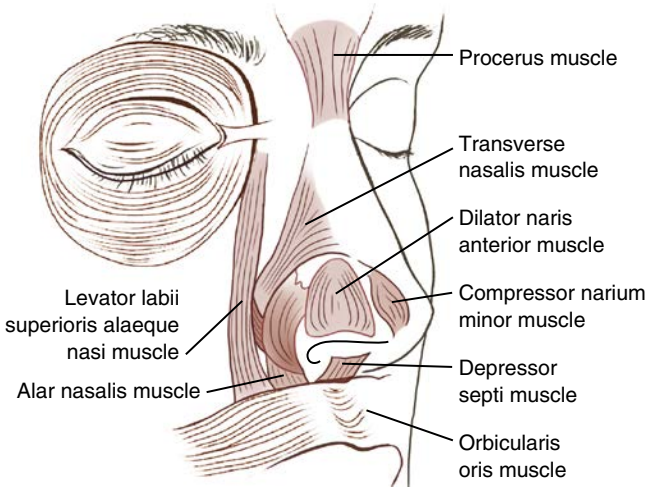
The muscles of the nose are encased in the nasal superficial musculoaponeurotic system (SMAS). This is a fibromuscular layer that separates the skin and subcutaneous tissue from the nasal cartilage and bone. The SMAS of the nose is continuous with the SMAS of the face. Violating the SMAS can result in increased bleeding, scarring, and postoperative edema; therefore the dissection should be between the cartilage and bone and the SMAS (Figure 20-2).

The muscles of the nose can be divided into four categories: the elevators, the depressors, the compressors, and the dilators. The paired depressor septi nasi muscles can cause inferior displacement of the nasal tip during smiling. This smiling deformity should be recognized preoperatively and addressed by resection of these muscles in order to achieve a cosmetic result.[6]

There is a rich blood supply to the subdermal vascular plexus of the external nose, which arises from branches of both the internal and external carotid arteries. The internal carotid artery supplies the external nose via the dorsal nasal artery (a branch of the ophthalmic artery) and the external nasal artery (a branch of the anterior ethmoid artery).



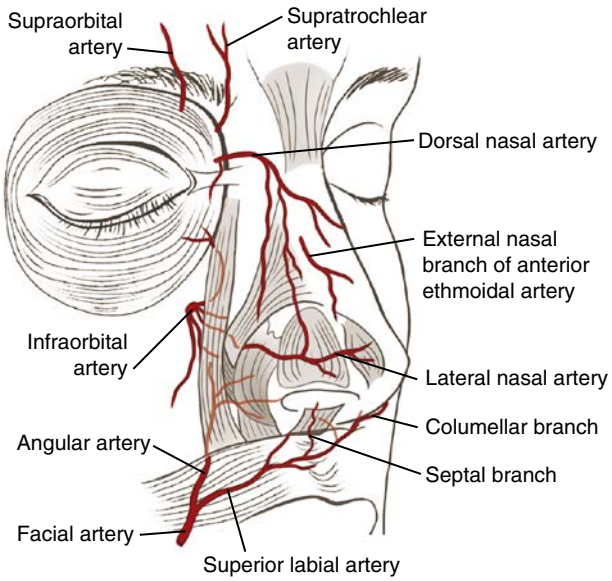
• **FIGURE 20-1** Relative spatial relationships. When one anatomic part is described relative to another, the standard anatomic descriptors are used, including anterior, posterior, superior, and inferior. Specifically when referring to nasal relationships additional terms are used including dorsal, basal, caudal, and cephalic. This figure shows the direction indicated when describing one part as it relates to another. (From Austermann K: Rhinoplasty: planning techniques and complication. In Booth PW, Hausamen JE, eds: *Maxillofacial surgery*, New York, 1999, Churchill Livingstone.)



• **FIGURE 20-2** Nasal musculature. The nasal muscles are generally not addressed in rhinoplasty procedures with exception of the depressor nasal septi muscles. The depressor septi muscle, if overactive, can cause inferior displacement of the nasal tip during smiling and may require resection as part of the rhinoplasty procedure. (From Jewett B: Anatomic considerations. In Baker SR, ed: *Principles of nasal reconstruction*, ed 2, 2011, Spinger.)

• BOX 24-1 Surface Landmarks

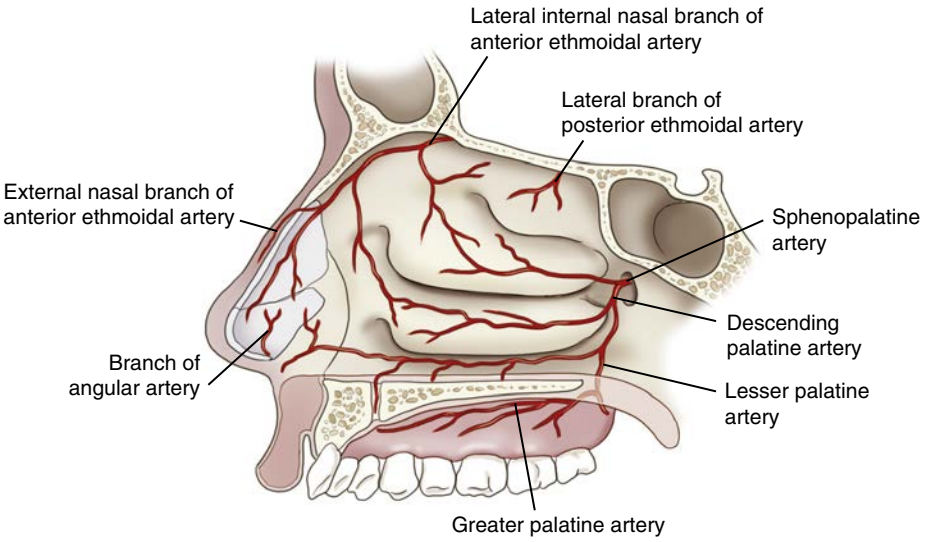
Radix: The deepest depression of the nasal dorsum, located at the junction between the frontal bone and the nasal bones.
Glabella: The most forward projecting portion of the forehead, located at the midline between the supraorbital ridges.
Rhinion: The osteocartilaginous junction formed by the nasal bones and upper lateral cartilages.
Dorsum: The anterior surface of the nose formed by the nasal bones and upper lateral cartilages.
Supratip break: The slight depression seen in profile at the point where the nasal dorsum joins the lobule of the nasal tip.
Infratip lobule: The portion of the tip lobule located between the columella and the most projected portion of the nasal tip.
Tip defining points: For proper nasal tip definition four points should be visualized. These four points are composed of the supratip break, the infratip lobule, and the most projected portion or domes of the lower lateral cartilages.
Alar sidewall: The rounded eminence forming the lateral nostril wall.
Alar-facial junction: The depressed groove formed at the junction where the ala joins the face.
Columella: The skin that separates the nostrils at the base of the nose.
Nasofrontal angle: The angle formed between the forehead and nasal dorsum as seen in profile view.
Nasolabial angle: The angle formed by the columella and the upper lip as seen in profile view.
Pronasale: The most projected portion of the nasal tip.



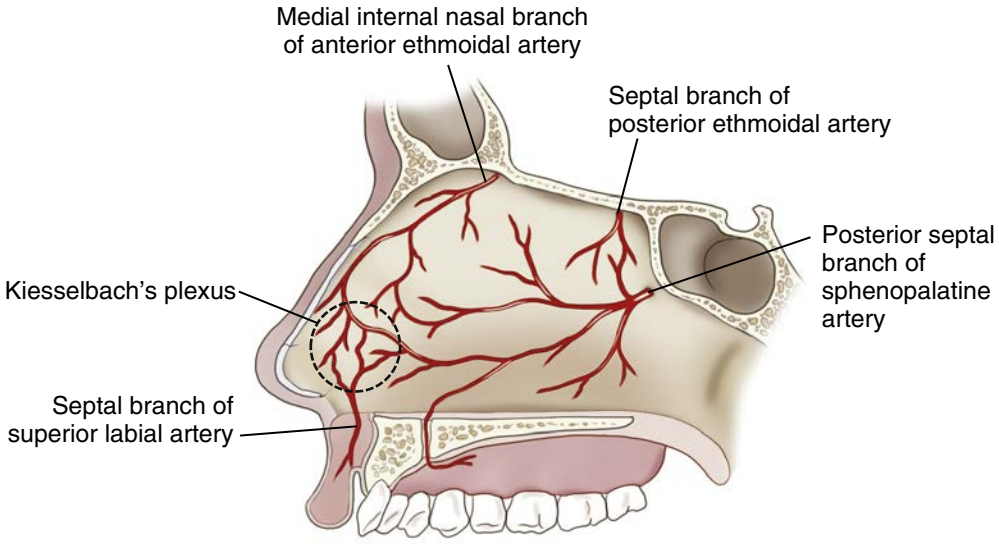
• **FIGURE 20-3** Arteries of the external nose. The arterial blood supply of the nose comes from both the external and internal branches of the carotid artery. The primary blood supply to the nasal tip comes from the lateral nasal arteries, which are branches of the facial artery. The lateral nasal artery course is superficial to the alar cartilages, approximately 2 to 3 mm above the alar groove. (From Jewett B: Anatomic considerations. In Baker SR, ed: *Principles of nasal reconstruction*, ed 2, 2011, Spinger.)

The external carotid artery provides blood supply via the facial artery branches (angular artery, lateral nasal artery, alar artery, septal artery, and superior labial artery) (Figure 20-3).

The internal nose is supplied by the internal and external carotid branches (Figure 20-4). From the internal



• **FIGURE 20-4** Arteries of the lateral nasal wall. The anterior and posterior ethmoidal arteries (branches of the internal carotid) supply the superior portion of the lateral nasal wall. Branches of the internal maxillary artery supply the inferior portion of the lateral nasal wall. (From Jewett B: Anatomic considerations. In Baker SR, ed: *Principles of nasal reconstruction*, ed 2, 2011, Spinger.)

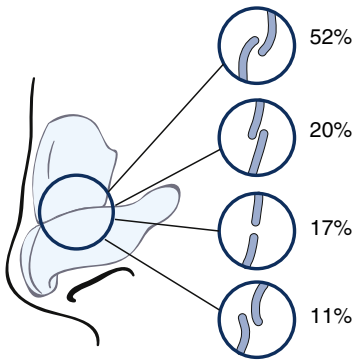


• **FIGURE 20-5** Arteries of the nasal septum. Kiesselbach's plexus, a common site of epistaxis, is located in the anteroinferior portion of the nasal septum. This region represents the anastomosis of the sphenopalatine, greater palatine, superior labial artery, and anterior ethmoidal arteries. (From Jewett B: Anatomic considerations. In Baker SR, ed: *Principles of nasal reconstruction*, ed 2, 2011, Spinger.)

carotid, the ophthalmic artery branches into the anterior and posterior ethmoidal arteries. The anterior ethmoidal artery supplies the anterosuperior part of the septum and the lateral nasal wall. The posterior ethmoid artery supplies the septum, lateral nasal wall, and superior turbinate. From the external carotid, the internal maxillary artery branches that supply the internal nose include the sphenopalatine artery and the greater palatine artery. The sphenopalatine artery supplies most of the posterior part of the nasal septum, lateral wall of the nose, roof, and part of the nasal floor. The greater palatine artery supplies a portion of the anterior and inferior portion of the nasal septum.

A common site of epistaxis is known as *Kiesselbach's plexus* (also termed *Little's area*) (Figure 20-5). This area is located in the anteroinferior part of the nasal septum and represents the anastomosis of the sphenopalatine, greater palatine, superior labial artery, and anterior ethmoid arteries.[7] The venous drainage of the nose is primarily from the facial and ophthalmic veins.

One concern during nasal surgery is the possibility of compromised blood flow to the nasal tip if the surgeon performs an external rhinoplasty. Cadaver dissection, lymphoscintigraphic studies, and histologic examinations confirm that the primary blood supply to the nasal tip comes from the bilateral lateral nasal arteries, which course in a plane



• **FIGURE 20-6** Confirmations of the scroll. The upper and lower lateral cartilages have an intimate connection with each other, known as the scroll. More common configurations include interlocked (52%), overlapping (20%), end-to-end (17%), and opposed (11%). (From Lam SM, Williams EF III: Anatomic considerations in aesthetic rhinoplasty, *Facial Plast Surg* 18:209, 2002.)

superficial to the alar cartilages in the subdermal plexus approximately 2 to 3 mm above the alar groove.[8,9] The blood supply allows a columellar incision to be made without fear of vascular compromise. Some surgeons believe external rhinoplasty remains more edematous for longer postoperative periods because of disruption of veins and lymphatics in the columellar region. Anatomic studies show few veins and minimal lymphatics in this region, and the tip edema noted by some is purely subjective.

The paired nasal bones as well as the frontal process of the maxilla provide support to the upper nose. The nasal bone is thickest where it joins with the frontal bone and tapers as it joins with the upper lateral cartilages. The nasal bones have an intimate connection with the upper lateral cartilages and overlap them by 6 to 8 mm. The connection between the nasal bones and upper lateral cartilages should not be violated because this could result in internal nasal valve obstruction and asymmetry.

The lower lateral cartilages form the nasal tip and connect with the upper lateral cartilages in a union described as the *scroll* (Figure 20-6). There are various configurations of the scroll.[10,11] The scroll is described as interlocked (52%), end-to-end (17%), overlapping (20%), or opposed (11%). The scroll provides significant support to the nasal tip. Removing cephalic strips of cartilage from the lower lateral cartilages or performing an endonasal rhinoplasty violates this junction. The lower lateral cartilage is divided into medial and lateral crura. The medial crura are in intimate contact with the nasal septum and provide tip support. The lateral crura extend superiorly and form dense fibroareolar tissue attachments with the pyriform aperture. The intermediate crus is defined as the area where the medial crura diverge before turning to become the lateral crura proper. The highest point of the intermediate crus is an important surgical landmark known as the *tip defining point.*

The nasal septum is formed by both bone and cartilage. The ethmoid and vomer provide bony support posteriorly. The quadrangular cartilage provides support anteriorly.

Support for the nasal tip is classified into major and minor divisions. The major tip support comes from the size, shape, and strength of the lower lateral cartilages, the attachment of the medial crura of the lower lateral cartilage to the caudal septum, and the fibrous attachment of the lower lateral cartilage to the upper lateral cartilage. The minor tip support comes from the nasal spine, the membranous septum, the cartilaginous dorsum, the sesamoid complexes, the interdomal ligaments, and the alar attachments to the skin.[10]

The sensory nerve supply to the skin of the external nose is supplied by the ophthalmic and maxillary divisions of the trigeminal nerve (Figure 20-7). Branches of the supratrochlear and infratrochlear nerves supply the skin in the region of the radix and rhinion. The lower half of the nose is supplied by the infraorbital nerve and the external nasal branch of the anterior ethmoidal nerve (a branch of the nasociliary nerve that arises from the ophthalmic branch of the trigeminal nerve).

The main sensory nerve supply to the nasal septum comes from the internal nasal nerve (a branch of the anterior ethmoidal nerve) and the nasopalatine nerve. The lateral nasal wall sensation is supplied by the anterior ethmoidal nerve, branches of the pterygopalatine ganglion, branches of the greater palatine nerve, the infraorbital nerve, and the anterior superior alveolar nerve.

The Consultation

In cosmetic surgery the initial consultation is probably the most important appointment. During this visit the patient will decide if he or she trusts you and your staff enough to proceed with surgery. From the surgeon's perspective, it is important to determine if the patient is a suitable candidate for cosmetic surgery and that he or she has realistic expectations.[12,13]

First, the surgeon should determine the area of the nose that concerns the patient the most. It is sometimes helpful to have the patient point the areas out with a cotton tip applicator in the mirror. Next, pertinent history should be obtained. Has the patient had previous cosmetic surgery? If so, what were his or her experience and satisfaction with the procedures? Be wary of patients who seek a different doctor for each procedure and denigrate the previous surgeon. Also, be concerned if the patient offers excessive praise about you or your reputation and states that he or she knows you will be able to correct the previous surgical errors made by the last doctor. Other important history should include previous trauma, nasal and septal surgeries, difficulties with nasal breathing, allergies, cocaine use, and the use of intranasal medications. If the patient has had previous septal surgeries, prepare the patient for the possible need for auricular cartilage harvesting in the event that you need cartilage at the time of surgery.[14]

Reviewing photographs will also help the surgeon understand the patient's expectations. Patients who are overly critical may not be good candidates for surgery. Imaging is not

entirely accurate and is best used to show something simple, such as what the reduction of a dorsal hump would do for the profile or the benefits of chin augmentation.

It is essential to determine those patients who are unsuitable from a psychiatric standpoint to undergo the operation. It is estimated that 5% to 7% of all cosmetic surgery patients have a diagnosis of body dysmorphic disorder. In rhinoplasty surgery the incidence may be as high as 20.7%.[15] According to the *Diagnostic and Statistical Manual of Mental Disorders, 5th Edition* (DSM-V), the following criteria must be met for a patient to be diagnosed: the patient is preoccupied with an imagined defect of appearance or is excessively concerned about a slight physical anomaly; repetitive behaviors such as mirror checking, excessive grooming, skin picking or comparing their appearance with others; this preoccupation causes clinically important distress or impairs work, social, or personal functioning; and another mental disorder (such as anorexia nervosa) does not better explain the preoccupation. Those patients with body dysmorphic disorder seeking rhinoplasty tend to be younger, more depressed, more anxious, and preoccupied with the nose, as demonstrated by frequent touching and looking in the mirror. Cosmetic surgeons should be aware of this disease because the suicide rate has been found to be 45 times higher than in the general population.[16]

It is also wise to avoid operating on someone whom you just do not like. If your personalities clash, it is often best to avoid doing the surgery. You should imagine managing such a patient if a complication were to arise, and if this scenario is seen as too difficult, then it is often wise for the patient to choose another surgeon.[12,13,17,18]

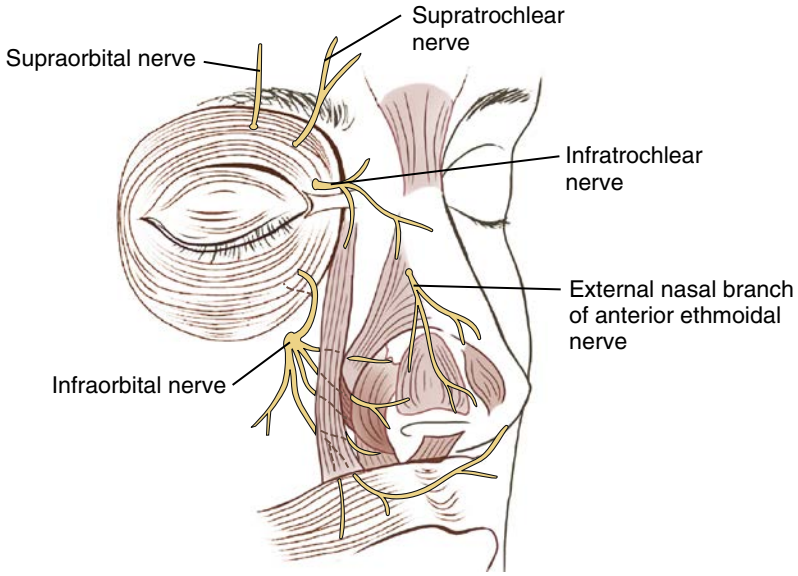
Patients are typically seen again the week before surgery for their preoperative appointment, at which time photographs are taken. An additional set of photographs is taken the morning of surgery. It is important when taking photographs of the nose to obtain six main views, including full-face frontal, full-face right and left oblique, full-face right and left lateral, and basilar views. Standardization of photographic technique is essential for proper operative planning and for obtaining high-quality before and after photographs to be used in future consultations.

Clinical Examination

When performing an examination of the nose, both the esthetics and function must be assessed. The examination should be done in a thoughtful and systematic way to ensure that nothing is overlooked. I typically begin with the external nasal examination and finish with the intranasal speculum examination.

Upper Nose and Dorsum

The upper nose and dorsum are assessed first. From the frontal view, note any gross asymmetries, lateral bony irregularities, or deviation of the dorsum. Next, determine if the width of the upper nose is adequate or excessive. The upper nasal width should be approximately 80% of the alar width, assuming that the alar width is not excessive. Normal alar width should approximate the patient's intercanthal distance. In a profile view, evaluate the position of the radix (the greatest depth of the nasofrontal depression). The radix should be located vertically between the superior palpebral margin and the upper eyelid margin. The nasal length (distance from radix to nasal tip) is also affected by the position of radix. If the radix is low, the patient will have the appearance of a short nose, and if it is high, the patient will have the appearance of a long nose.



• **FIGURE 20-7** Sensory nerves of the external nose. The ophthalmologic divisions of the trigeminal nerve that supply the nose include the supratrochlear and infratrochlear nerves. The remainder of the nose is supplied by branches of the maxillary division of the trigeminal nerve. (From Jewett B: Anatomic considerations. In Baker SR, ed: *Principles of nasal reconstruction*, ed 2, 2011, Spinger.)

In the profile view the depth of the nasofrontal depression should be approximately 4 to 9 mm anterior to the corneal plane (Figure 20-8). The depth of the radix can greatly affect the nasofrontal angle. The ideal nasofrontal angle is between 115 and 130 degrees. The nasofrontal angle tends to be more acute in men and more obtuse in women. A deep radix creates a more acute nasofrontal angle and a shallow radix creates a more obtuse angle. When examining the nose in profile, also note any dorsal hump deformities.

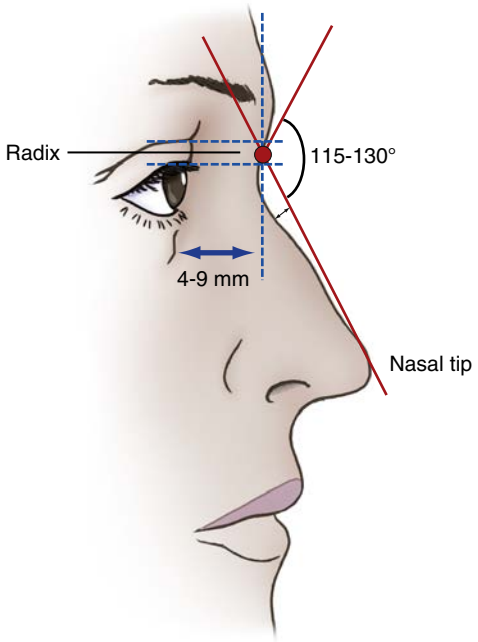
Nasal Tip

Control of the nasal tip is critical in rhinoplasty surgery. Proper assessment of the problems with the nasal tip is important in planning the surgical technique. The shape of the nasal tip itself should be evaluated first. Is the tip bulbous, boxy, pinched, twisted, or asymmetric? Next, look at the tip definition. There should be four tip defining points including the supratip, the infratip, and the most prominent portion of the intermediate crus (the junction between the medial crura and lateral crura of the lower lateral cartilage). From the profile view, identify the supratip break and the infratip break (also known as the *columellar-lobule angle*). The distance from the supratip break to the infratip break should be divided equally by a line drawn parallel to the floor through the pronasale (the most forward point of the tip of the nose).

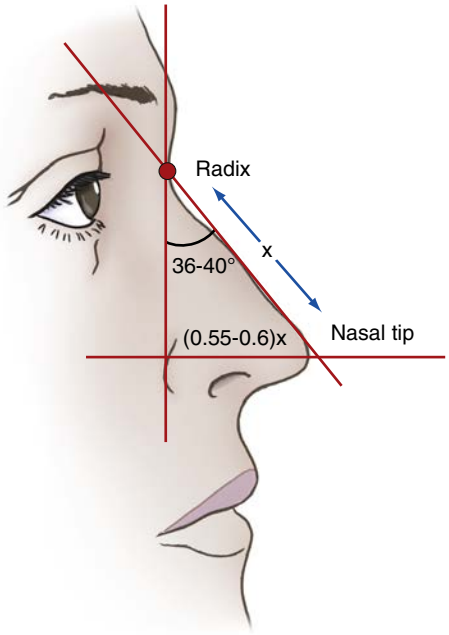
The tip projection and support should be assessed next. The nose should not be easily compressible when pushing on the nasal tip with an index finder. If the cartilages are weak and the nose is easily compressed, consideration should be given to crural strut grafts to increase support. There are several ways to evaluate the tip projection. No one method is superior, and each method has its limitations.[19] The most commonly quoted method is Goode's method. This definition states that the ideal tip projection is 0.55 to 0.6 RT, where RT is the distance between radix and pronasale[20] (Figure 20-9). Tip projection is usually measured as the distance from the alar groove to the most projected portion of the nasal tip (pronasale). Simon's method states that the length of the upper lip from subnasale to labrale superioris should be equal to the tip projection measured from subnasale to pronasale.[20] Another method is to draw a tangent through the most projected portion of the upper lip. This line should bisect the nose such that 50% is tip and 50% is nasal base. If more than 60% is nasal tip, the nose is considered overly projected.[21]

The relationship of the dorsum to the nasal tip should also be evaluated. The dorsum should be approximately 2 mm below a line drawn from radix to pronasale in women and just below or even with the line in men.

The columella is then assessed. First, look at the columellar-lobular angle. This is defined as the angle created where the tangents of the columella and infratip lobule intersect. A normal columella-lobular angle is 36 to 40 degrees. Next, the relationship of the ala and columella is assessed. From



• **FIGURE 20-8** Dorsal profile and position of radix. The radix is located vertically between the superior palpebral margin and the upper eyelid margin and is typically 4 to 9 mm anterior to the corneal plane. The ideal nasofrontal angle is between 115 and 130 degrees and tends to be more acute in men and obtuse in women. The nasal dorsum typically lies 2 mm behind a line drawn from radix to nasal tip in women and on this line in men. (From Austermann K: Rhinoplasty: planning techniques and complication. In Booth PW, Hausamen JE, eds: *Maxillofacial surgery*, New York, 1999, Churchill Livingstone.)



• **FIGURE 20-9** Goode's method of nasal projection. The ideal tip projection is 0.55 to 0.60 RT, where RT is the distance between radix and pronasale provided that the nasofrontal angle is between 36 and 40 degrees. (From Austermann K: Rhinoplasty: planning techniques and complication. In Booth PW, Hausamen JE, eds: *Maxillofacial surgery*, New York, 1999, Churchill Livingstone.)

the profile view, imagine a line drawn from the base of the nostril to the tip of the nostril that bisects the ala and the columella (Figure 20-10). In a properly proportioned nose, the columella and alar rim should be equidistant from the line, and approximately 2 to 4 mm of columella should show.[17] When there is a large amount of columella showing, the problem may be due to a hanging columella, alar retraction, or a combination of both (Figure 20-11). Conversely, if there is little columella showing in the profile view, the problem could be with a retracted columella, a hanging ala, or a combination of both. Determining the problem is essential because the management of each of these problems is different.

The nasal tip rotation is then evaluated. This is often measured by using the nasolabial angle. This angle is formed by the intersection of the tangents of the columella and the upper lip. A normal nasolabial angle is 95 to 110 degrees in women and 90 to 95 degrees in men. This angle can be affected by the inclination of the upper incisor teeth.

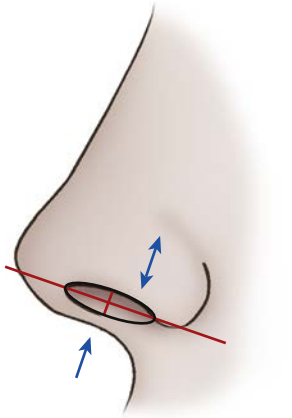
While the patient is evaluated in profile, the chin projection relative to the nose should not be overlooked. Often a nose looks much larger when the patient has a weak chin. A simple method to evaluate chin position is to look at the relative position of the chin to the subnasale perpendicular. In a profile view a woman's chin should be on or slightly behind an imaginary vertical line from the subnasale perpendicular, and in men it should be on or slightly in front of this line. Consideration for a chin implant or genioplasty should be done in cases of microgenia to keep the nose and chin in better balance.

Skin Thickness

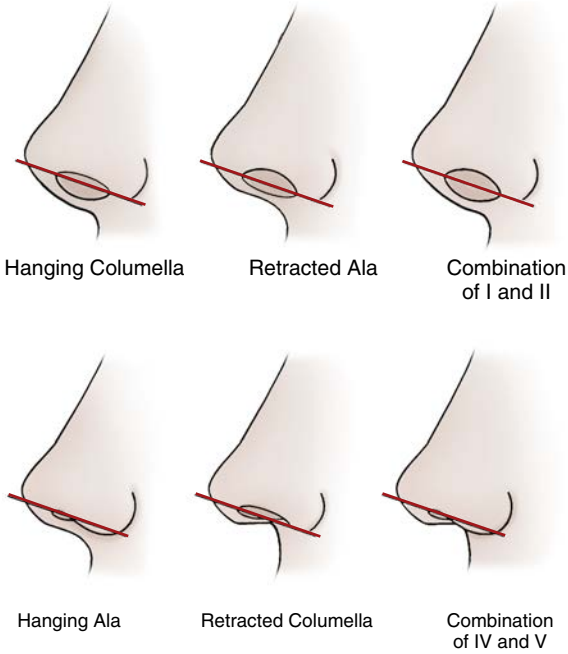
The nose should be palpated to assess the skin thickness. A patient with thin nasal skin will show dramatic changes with alteration of the underlying bone and cartilage, and this limits room for error because little is camouflaged by the thickness of the skin. On the other hand, thick-skinned individuals require more aggressive sculpting of the nasal skeleton in order to see significant change. Although thick skin may mask imperfections, it does not redrape as well and can result in underlying fibrosis and formation of a polybeak deformity (supratip scarring). Better results are possible with average to thin-skinned patients; however, the margin for error is smaller.

Nasal Function

Lastly the functional aspects of the nose must be evaluated. Have the patient breathe normally through the nose, then have him or her take a deep breath through the nostrils. Observe for collapse of the ala and occlusion of nasal breathing. The airflow through the nose is regulated by the internal and external nasal valves. The external nasal valve is formed by the lower lateral cartilage (Figure 20-12). In severe cases, collapse of the external nasal valve can be seen when the nares become occluded on even gentle inspiration. This problem is more common in patients with narrow nostrils, overly projected nasal tip, and thin alar sidewalls. External nasal valve collapse is also commonly seen in patients having previous rhinoplasty surgery with excessive trimming of the cephalic portion of the lower lateral cartilages. It may also be seen with increased age and



• **FIGURE 20-10** Alar-columellar relationship. The ala and columella should be an equal distance from a line that bisects the nostril through the tip and base. Two to 4 mm of columellar showing is considered normal. (From Gunter JP, Rohrich RJ, Friedman RM: Classification and correction of alar-columellar discrepancies in rhinoplasty, *Plast Reconstr Surg* 97:643, 1996.)



• **FIGURE 20-11** The alar-columellar relationship. When there is a large amount of columella showing, the problem may be due to a hanging columella, alar retraction, or a combination of both. Conversely, if there is little columella showing in the profile view, the problem could be with a retracted columella, a hanging ala, or a combination of both. (From Gunter JP, Rohrich RJ, Friedman RM: Classification and correction of alar-columellar discrepancies in rhinoplasty, *Plast Reconstr Surg* 97:643, 1996.)

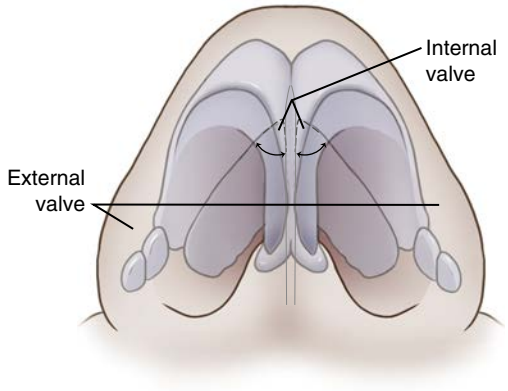
in facial nerve paralysis. The external nasal valve collapse can be corrected by deprojecting an overprojected nose, realigning the lateral crura into a more caudal orientation, and placing alar batten grafts to provide structural support and prevent collapse.[22-24]

The internal nasal valve is formed by the junction of the septum and the upper lateral cartilages (see Figure 20-12). The angle formed should be a minimum of 10 to 15 degrees to maintain patency. Deviation of the nasal septum or separation of the upper lateral cartilages from the nasal bones can lead to obstruction. This problem is also seen after rhinoplasty if the patient has had weakening of the upper and lower lateral cartilages. These patients often have a pinched appearance in the supraalar region. The Cottle test is used to evaluate obstruction at the internal valve by using a finger to laterally pull the cheek and lateral wall of the nose, thereby opening the nasal valve. Nasal airflow that is dramatically improved by the Cottle test indicates that the internal nasal valve requires correction. These patients often achieve symptomatic relief by the use of external taping devices. Surgical correction involves the placement of spreader grafts between the septum and upper lateral cartilages and/or cartilage flaring sutures to increase the angle of the lower lateral cartilages with the nasal septum[22,24] (Figure 20-13).

The nose is inspected last with a nasal speculum. Observe for any deflections or perforations of the nasal septum, bone spurs, enlargement of turbinates, or any nasal pathology.

Planning

In preparation for surgery, it is helpful to review the presurgical photographs and compile a problem list. The surgeon should have a clear plan as to what techniques will be employed to address the various problems and the sequence in which these problems will be corrected.



• **FIGURE 20-12** The external and internal nasal valve. The external nasal valve is formed by the lower lateral cartilages. The internal nasal valve is formed by the junction of the septum with the upper lateral cartilages. The angle formed between the septum and upper lateral cartilages should be a minimum of 10 to 15 degrees to maintain nasal patency.

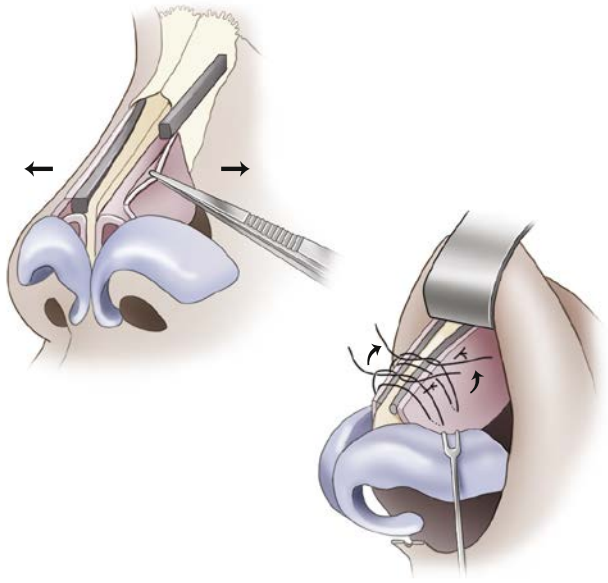
Incisions for Rhinoplasty

There are a number of incisions commonly used in rhinoplasty. The choice of incision is determined by whether an open or closed rhinoplasty is performed.

Marginal incisions connected by a transcolumellar incision are commonly used in open rhinoplasty (Figure 20-14). The marginal incision parallels the caudal edge of the lower lateral cartilages. The incision begins just caudal to the lateral crus and parallels the caudal edge of the lower lateral cartilage until the medial crura begin to flare. It differs from a rim incision in that the rim incision parallels the alar rim. The problem with a rim incision is that the soft tissue caudal to the lateral crus is disrupted, which can result in scarring and alar retraction.

The transcolumellar incision is used to connect the bilateral marginal incisions and allows the soft tissues overlying the nasal tip to be elevated in open rhinoplasty. The incision is made just superior to the flare of the medial crura. To prevent linear scar contraction and to facilitate closure, the incision is broken up by using a V, inverted V, or stairstep configuration (Figure 20-15).

Intercartilaginous, intracartilaginous, transfixion, and marginal incisions are commonly used in closed rhinoplasty techniques. The intercartilaginous incision is made at the junction of the upper and lower lateral cartilages in the region of the scroll (Figure 20-16). The incision starts laterally and joins up with a transfixion incision medially. A complete or partial transfixion incision is normally used and provides access to the caudal septum, medial crura, and the anterior nasal spine (Figure 20-17).

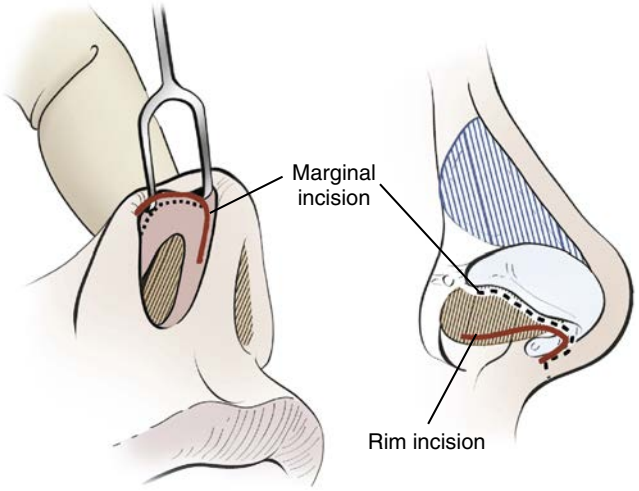


• **FIGURE 20-13** Spreader grafts. Cartilage harvested from the nasal septum can be placed between the nasal septum and upper lateral cartilages in order to widen the angle of the internasal valve and improve nasal breathing. (From Dolan R: Nasal valve and nasal alar dysfunction. In Holt GR, ed: *Advances in rhinoplasty*, Philadelphia, 2000, Saunders.)

A complete transfixion incision is made just caudal to the nasal septum and extends inferiorly through the membranous septum, following the cephalic margin of the medial crura. A partial transfixion incision may also be used and differs only in that it stops at the level of the footpads of the medial crura. Because the attachment of the medial footpads to the septum is not disrupted, less deprojection of the nose occurs. A hemitransfixion incision is not routinely used but is essentially a complete transfixion incision that does not traverse both mucosal surfaces and medial footpads. Access to the nasal septum can be done through a hemitransfixion incision, but delivery of the lower lateral cartilage on the side opposite the incision is more difficult, and asymmetric scarring can distort the shape of the nose.

An intracartilaginous incision is sometimes used in rhinoplasty when delivery of the lower lateral cartilages is not planned (see Figure 20-16). In these situations a cephalic strip is essentially done by placing the incision 3 to 5 mm caudal to the junction of the upper and lower lateral cartilages. This is a technically more difficult procedure because the cartilages are not directly visualized and it is easier to develop asymmetry. The incised lower lateral cartilage is not removed. Some believe that using this incision decreases the likelihood of scarring in the region of the internal nasal valve.

A seldom used incision in rhinoplasty is the Killian incision (Figure 20-18). This incision is useful for gaining access to the septum for isolated septoplasty. The incision is made several millimeters cephalad to the caudal edge of the septum. The incision can be extended onto the nasal floor if needed.



• **FIGURE 20-14** Marginal and rim (infracartilaginous) incisions. The marginal incision *(dotted line)* parallels the caudal edge of the lower lateral cartilages and is commonly used in rhinoplasty. The rim incision *(red line)* follows the contour of the nostril along the mucosa just inside the nostril. A rim incision should not be used because of the problems with scarring and alar retraction. (From Waite PD, ed: *Atlas of the oral and maxillofacial surgery clinics of North America: rhinoplasty*, Philadelphia, 1995, Saunders.)

Tip Plasty

Control of the nasal tip in rhinoplasty is essential in achieving predictable results. The surgeon must respect and preserve tip support in the process of obtaining an esthetically pleasing result. The surgeon must respect the major and minor mechanisms of tip support discussed earlier, so that both structure and function are maintained.[25] Many of the tip supporting structures are violated in the process of skeletonizing the nose.[26,27] Suture techniques or cartilage grafts may be necessary after adjusting the tip for esthetics to maximize nasal tip support. Disregarding tip support can result in nasal tip ptosis or unwanted nasal tip movements as scar contracture occurs during healing.

The skin overlying the nasal tip also will influence the type of procedures performed on the tip. Patients with thick skin may require more aggressive techniques to create changes in the appearance of the tip. It is tempting to reduce the fibrofatty tissue of the nasal tip to enhance changes made to the tip; however, this should only be done in select cases. Excessive thinning can lead to increased scarring and distortion of the tip. In patients with thinner skin, even minor irregularities in the underlying cartilage can result in obvious postoperative deformities. The skin thickness and strength of the cartilages can often be determined preoperatively by simply palpating the nose.

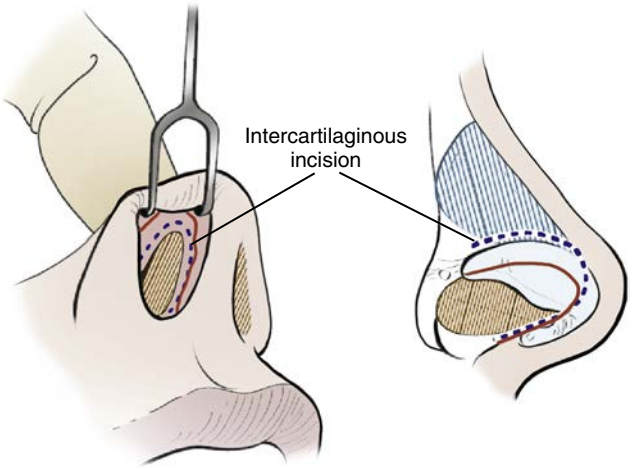
The structure of the lower lateral cartilages is often depicted as a tripod with the medial crura together forming one pillar and the lateral crura acting as the other two

• **FIGURE 20-15** The transcolumellar incision. Various configurations of the transcolumellar incision are used to prevent linear scar contracture and aid in reapproximating the skin at closure. The common configurations include a V, inverted V, or stairstep configuration.

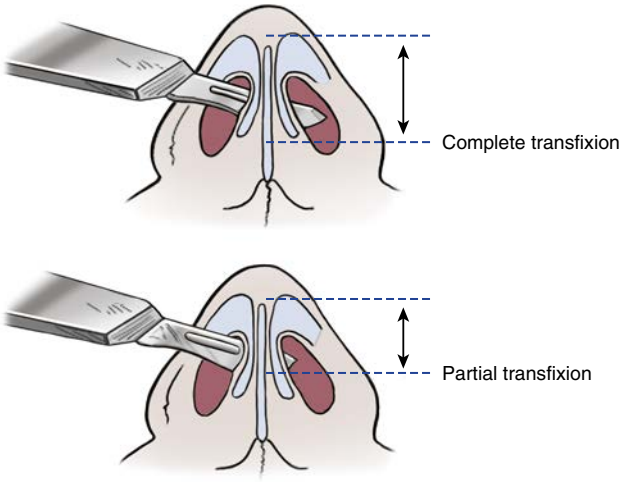
pillars[28] (Figure 20-19). Adjustment to the strength or length of each of these pillars can affect tip rotation and projection. The proposed maneuvers to change the nasal tip should be planned preoperatively.

Tip Projection

A number of procedures can be used to increase tip projection. If the medial crura are significantly divergent, simply suturing them together can result in increased projection.[29]

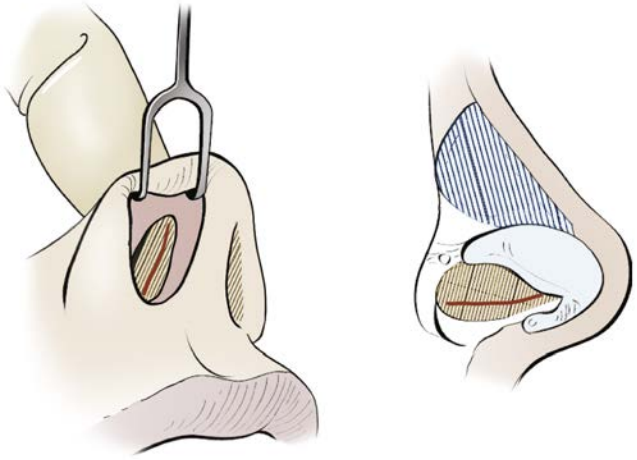


• **FIGURE 20-16** The intercartilaginous and intracartilaginous incisions. The intercartilaginous incision *(blue dotted line)* follows the junction of the upper and lower lateral cartilages in the region of the scroll. The intracartilaginous incision *(solid line)* is made through mucosa and the cephalic portion of the lower lateral cartilages. (From Waite PD, ed: *Atlas of the oral and maxillofacial surgery clinics of North America: rhinoplasty*, Philadelphia, 1995, Saunders.)

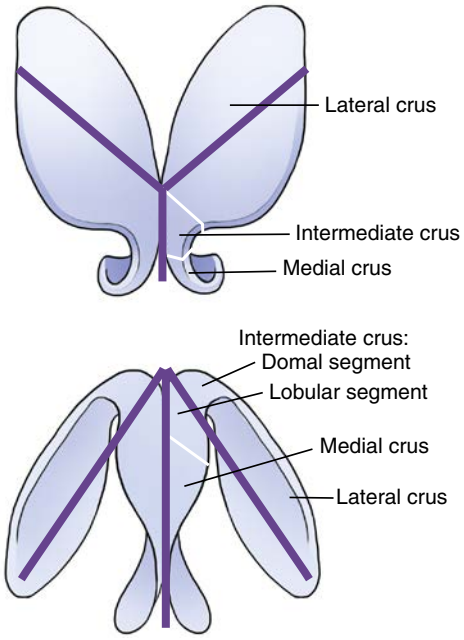


• **FIGURE 20-17** The complete and partial transfixion incisions. The complete transfixion incision is made caudal to the nasal septum, extends through the membranous septum, and detaches the medial footpads of the lower lateral cartilages. A partial transfixion incision stops just short of the medial footpads. (From Koehler JK, Waite PD: Basic principles of rhinoplasty. In Miloro M, ed: *Oral and maxillofacial surgery*, Hamilton, 2004, BC Decker.)

A columellar strut graft can also be placed abutting the nasal spine, and the medial crura can be advanced superiorly with a double skin hook and sutured to the strut. Placing 27-gauge needles through the crura and the strut will assist in stabilizing the graft when suturing (see Figure 20-19); 6-0 Prolene suture on a noncutting needle is used to secure the graft in place.



• **FIGURE 20-18** The Killian incision *(red line)* is a common incision used for septoplasty but is not routinely used for rhinoplasty. The incision is made several millimeters cephalad to the caudal edge of the septum. (From Waite PD, ed: *Atlas of the oral and maxillofacial surgery clinics of North America: rhinoplasty*, Philadelphia, 1995, Saunders.)



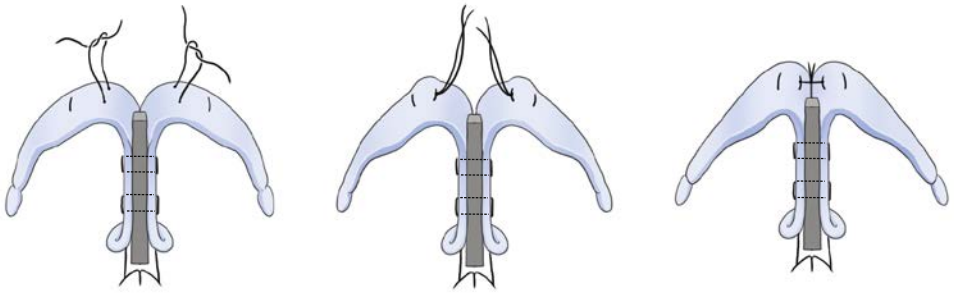
• **FIGURE 20-19** The tripod concept. The lower lateral cartilages act as a tripod supporting the nasal tip. The two medial crura act as one pillar and the lateral crura act as the other pillars of the tripod. Maneuvers that increase or decrease the length or strength of these cartilages will affect nasal tip projection and rotation. (From Koehler JK, Waite PD: Basic principles of rhinoplasty. In Miloro M, ed: *Oral and maxillofacial surgery*, Hamilton, 2004, BC Decker.)

Placing an interdomal suture with a horizontal mattress suture can narrow the nasal tip and when combined with a transdomal suture can also give some increase in tip projection (Figure 20-20). When placing an interdomal suture, the surgeon should be certain to preserve a normal angle of divergence (30 degrees or less) between the intermediate crura in order to maintain two distinct tip defining points. Pinching the intermediate crura together will narrow the tip but will have less esthetic appeal because of a lack of tip definition.[30,31]

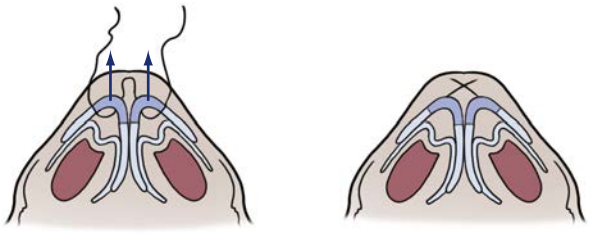
A procedure known as the *lateral crural steal* can be used to increase tip projection (Figure 20-21). A horizontal mattress suture is placed in the lateral crura and advanced to the midline. The intermediate crura now becomes more vertically oriented as the medial crura. This technique will increase the tip projection and rotation; however, it removes the tip defining points and tends to create a single pointed tip, which is not appealing.[32,33]

When significant increases in tip projection are required, cartilage grafting is commonly used.[34] Tip onlay grafts (also called *Peck grafts*) can increase the tip projection by several millimeters. The cartilage can be stacked in layers and sutured in place with 6-0 Prolene. Some surgeons combine this with a columellar strut graft; this has been termed an *umbrella graft*.[35] The shield graft, first described by Sheen, can also be used to increase projection and create better definition to the tip[36,37] (Figure 20-22). A piece of septal cartilage is shaped to form a trapezoid measuring approximately 6 to 8 mm wide superiorly, 5 mm inferiorly, and 10 to 12 mm in length. The edges should be beveled and the corners rounded so that it does not create palpable irregularities. The graft is positioned so that the widest portion forms the tip defining points. The graft is secured at each corner so that it does not rotate. The inferior aspect of the graft overlies the medial crura and can help define the infratip lobule. This graft is helpful when both tip definition and projection are needed. Realize that cartilage grafts can resorb, displace, or distort with time. Suture techniques are generally preferred because of the problems with cartilage grafting.[2,5]

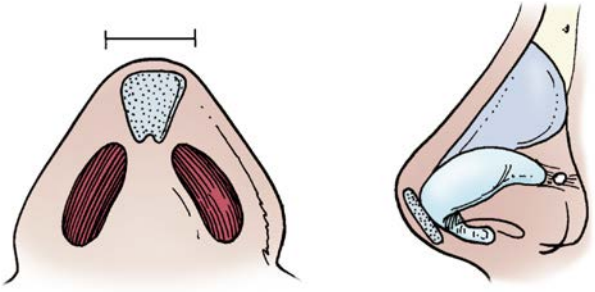
Decreasing tip projection can be done in a number of ways. Simply skeletonizing the nose will decrease the projection slightly. If more deprojection is needed a complete transfixion incision will separate the medial footpads from the membranous septum. This will decrease projection but will also increase tip rotation to some degree. In some cases a prominent anterior septal angle can be reduced. This will decrease tip projection and can also provide better definition to the infratip break.



• **FIGURE 20-20** The columellar strut graft, interdomal and transdomal sutures. Cartilage harvested from the nasal septum can be placed between the medial crura and secured with sutures to provide increased tip support as well as increased nasal tip projection. A transdomal suture is a horizontal mattress suture placed in the dome of the lower lateral cartilages that is used to narrow the nasal tip and better define the most projected portion of the nasal tip. The transdomal sutures can be sutured to one another to further narrow the nasal tip. In cases when tip shape is adequate but narrowing is required, a single suture placed between the domes to bring them closer together can be done; this is termed an interdomal suture.



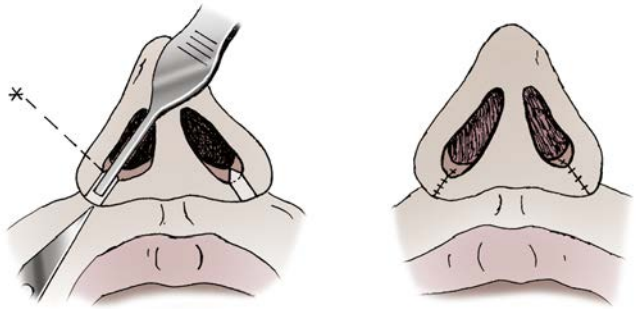
• **FIGURE 21** Lateral crural steal. A horizontal mattress suture placed in the lateral crura which is advanced to the midline can increase nasal tip projection; however, it removes the tip defining points and tends to create a single pointed tip. (From Koehler JK, Waite PD: Basic principles of rhinoplasty. In Miloro M, ed: *Oral and maxillofacial surgery*, Hamilton, 2004, BC Decker.)



• **FIGURE 20-22** The shield graft. A trapezoidal piece of septal cartilage can be sutured in the region of the nasal tip to increase tip projection and better define the tip defining points. (From Taylor CO: Surgery of the nasal tip. In Waite PD, ed: *Atlas of the oral and maxillofacial surgery clinics of North America: rhinoplasty*, Philadelphia, 1995, Saunders.)

If aggressive deprojection is required, the medial crura can be transected horizontally, overlapped, and sutured with horizontal mattress sutures. The same can be done to the lateral crura if the tip needs increased rotation as well. Crural excision maintains the natural shape of the tip at the domes and is therefore preferred to excising segments of the dome and suturing them back together.

Sometimes after significant deprojection of the tip there may be a relative flaring of the alar base and increased columellar show. The alar flaring can be treated with conservative alar base resection; however, if this was not planned preoperatively, it is best to reevaluate this once swelling subsides in several weeks. A minor alar base resection can be done using local anesthesia at a later date if needed in these circumstances (Figure 20-23). The columellar show may need to be addressed by suturing the medial crura posteriorly to the caudal septum and in some cases excising a small strip of the caudal septum. Rarely, a small amount of redundant septal nasal mucosa adjacent to the medial crura needs to be resected.

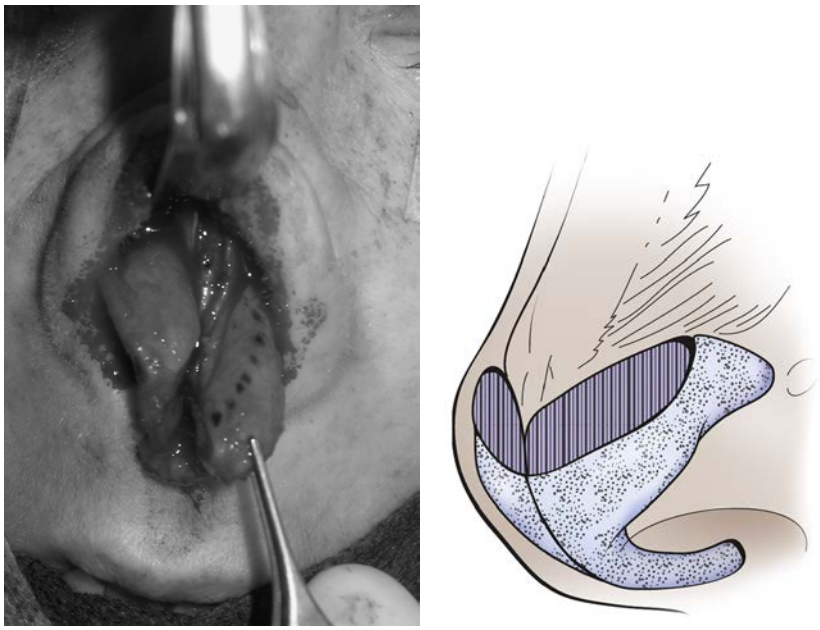


• **FIGURE 20-23** Alar base resection. The excision of 1 to 2 mm of vestibular mucosa and skin at the nostril base can be used to narrow a broad nasal base. (From Taylor CO: Surgery of the nasal tip. In Waite PD, ed: *Atlas of the oral and maxillofacial surgery clinics of North America: rhinoplasty*, Philadelphia, 1995, Saunders.)

Tip Rotation

Understanding the tripod concept and tip supporting mechanisms will allow the surgeon to choose the appropriate technique to adjust tip rotation.

Increasing tip rotation can be done in a number of ways. Simply reducing the dorsal hump of the nose will make the nasal tip appear more rotated. Removing a cephalic strip of cartilage from the lower lateral cartilages will result in increased tip rotation (Figure 20-24). An intercartilaginous incision used in closed rhinoplasty techniques disrupts the scroll and will result in a mild increase in tip rotation. Resecting a small triangular piece of caudal septum near the anterior septal angle will allow the lower lateral cartilages to rotate further. Transecting, overlapping, and resuturing the lateral crura with 6-0 Prolene will effectively shorten the two limbs of the tripod and increase the tip rotation. Maneuvers such as this are aggressive and should be reserved for only select situations. It is generally preferable to use less destructive techniques and preserve the cartilaginous support of the nose. Cartilage grafts, such as the shield graft, can also be used to create the illusion of increased tip rotation. Finally, augmentation of the premaxillary region may give the illusion of increased tip rotation. Premaxillary deficiency is typically seen more frequently in Asian or African American



• **FIGURE 20-24** The cephalic strip. The removal of a complete strip of cephalic cartilage from the lower lateral cartilages will increase nasal tip rotation. It is important to preserve at least 6 mm of width to the lateral crura so that strength of the external nasal valve is not compromised. (From Koehler JK, Waite PD: Basic principles of rhinoplasty. In Miloro M, ed: *Oral and maxillofacial surgery*, Hamilton, 2004, BC Decker.)

patients. The augmentation may be performed with materials such as hydroxyapatite or expanded polytetrafluoroethylene (ePTFE).

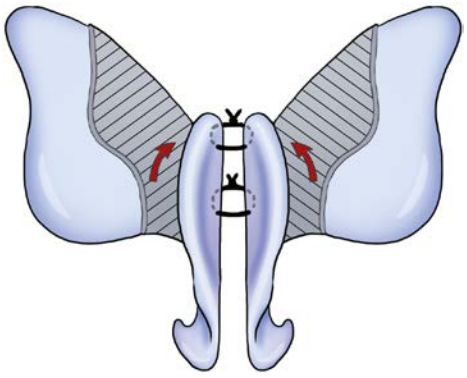
Decreasing tip rotation occurs with many of the techniques described earlier to decrease tip projection. Additional derotation can be done by trimming the caudal septum near the anterior nasal spine or by augmenting the nasal dorsum to create the illusion of decreased tip rotation.

Tip Shape

Preserving or improving the anatomic shape of the nasal tip is an essential portion of rhinoplasty. Some of the early techniques described in tip reshaping involved more destructive methods of cartilage excision. The Goldman tip is an example of such a technique (Figure 20-25). The Goldman tip involves incising the lower lateral cartilage at the junction of the intermediate and lateral crura (this is often termed *dome division*). The medial crura are then sutured together, which results in increased tip projection. The lateral crura are not secured with any sutures and therefore collapse medially. This results in significant narrowing of the nasal tip along with loss of the tip defining points. Additional problems with tip asymmetry, pinched appearance of the tip, and nasal tip ptosis can occur in the long term.[38]

Many rhinoplasty surgeons now try to use more selective cartilage excision techniques combined with suture techniques to improve the shape and position of the lower lateral cartilages. Cartilage grafting technique may also be used to reshape and redefine the nasal tip; however, this can be less predictable in the long term.[39,40]

Cartilage excision from the lower lateral cartilage in the form of cephalic strips is commonly done to allow narrowing of the nasal tip and increase tip rotation. Increased cartilage excision will result in more rotation and tip narrowing but may result in decreased support for the ala. There are three techniques commonly used to modify the shape and strength of the lower lateral cartilages: the complete strip technique, the weakened complete strip technique, and the interrupted strip technique.



• **FIGURE 20-25** The Goldman tip. The Goldman tip is an example of an interrupted strip technique that can radically narrow the nasal tip and increase nasal tip rotation. This technique can result in an overly pinched nasal tip as well as compromise to the external nasal valve.

Complete strip techniques involve removal of a small strip of cephalic cartilage from the lateral crura (see Figure 20-24). Sometimes the cartilage can be further modified by cross-hatching with a scalpel blade to facilitate cartilage reshaping with suture techniques. This is classified as a weakened complete strip technique. These procedures are preferred to the interrupted strip technique because the lower lateral cartilage remains in continuity. An interrupted strip technique involves division of the lateral crura from the dome. The dome division technique is done principally to provide greater narrowing and rotation of the nasal tip. The consequences of an interrupted strip technique can be loss of tip support, alar notching, alar retraction, and alar collapse resulting in external nasal valve obstruction. The Goldman tip technique described earlier is an example of an interrupted strip technique (see Figure 20-25).

To avoid alar collapse on inspiration it is recommended to preserve 6 mm of width to the lateral crura. This number will vary based on the size and shape of the existing cartilage. Some patients exhibit a weak or concave lateral crura and may require some sort of alar batten grafts to provide increased support. Nasal septal cartilage or auricular cartilage sutured to the lateral crura with mattress sutures will correct the collapse in a majority of cases.[41]

Another technique that may be used in the management of external nasal valve collapse is the lateral crural pull up method. This technique involves the placement of a suture in the distal aspect of the lateral crura to a hole drilled in the pyriform aperture. The advantage of this method is that it can be done from an endonasal approach and does not require cartilage harvesting. Long-term data for this technique have not been reported.

A predominant problem in nasal tip plasty is the broad nasal tip. A bulbous nasal tip typically is the result of large, strong, lower lateral cartilages that often have a bidomal configuration. An increased angle of divergence of the medial crura as seen from the basal view may also contribute to a broad nasal tip. In some cases a broad nasal tip can be seen in patients with weak cartilage and thick fibrofatty skin in the nasal tip region. Thick skin with weak lower lateral cartilage is typically seen in Asian or African American patients.

As previously mentioned, there are three principle methods to address shape of the nasal tip: suture modification, dome division (interrupted strip technique), and cartilage grafting.

Suture modification is done after removal of a cephalic strip of cartilage.[31] A transdomal horizontal mattress suture is placed in the region of the intermediate crus to narrow the dome. This is done separately for each dome. If additional narrowing is needed, the transdomal sutures are tied to each other. This interlocked pair of transdomal sutures is termed a *double dome technique* (see Figure 20-20). It is

important to not bring the domes together so tightly that the normal angle of divergence between the intermediate crura is obliterated. The domes should be separated by 1 to 3 mm in order to maintain the tip defining points. Another suture technique is to place an interdomal suture, which can improve tip symmetry and strength as well as decrease the interdomal distance. This involves placement of an interrupted suture in the medial crura 3 to 4 mm inferior to the domes.

The dome division or interrupted strip technique can provide dramatic narrowing in bulbous nasal tips by allowing the lateral crus to assume a more medial position. To decrease the possibility of long-term problems with alar collapse, it is suggested to reapproximate the segments with suture.

Placement of cartilage tip grafts can create the illusion of a narrower tip by changing the placement of the tip defining points. This is best done through an open rhinoplasty approach and may be combined with the suture techniques mentioned earlier.

Open versus Closed Rhinoplasty

Much debate over the preferred method of skeletonizing the nose has occurred.[42,43] There is no evidence that one approach results in more favorable outcomes. It is ultimately up to the surgeon as to which technique he or she is most comfortable with. I use both approaches depending on the situation. For noses requiring minimal tip work but mainly needing dorsal hump reduction, a closed technique is used. For secondary rhinoplasties or tips that require advanced suture techniques or cartilage grafting, an open approach is preferred. I favor the open approach because it provides the best visualization, especially in regard to the nasal tip. If precise closure is done, patients do not find the external incision objectionable.[44]

Open Rhinoplasty

In sequencing the open rhinoplasty the surgeon must first decide whether to perform the tip plasty first and then set the dorsal profile or adjust the dorsum first and then adjust the tip to match the dorsum. Proponents of performing the tip plasty first believe that they have more control of the tip position and that less work may need to be done to the dorsum. I prefer to reduce any humps and set the dorsal profile first before doing the delicate tip work. Tip grafting and suturing can be inadvertently disrupted when doing the dorsum after the tip. Care must be taken if setting the dorsal profile first not to overreduce the dorsum. This is not a problem that is easily corrected. Also, attempting to further reduce the dorsum after osteotomies have been performed can result in avulsion of the nasal bone. Ultimately the decision is made on the basis of the surgeon's preference and comfort with the technique because good results can be achieved either way.

This author's preferred sequence is as follows:

1. Columellar incision
2. Bilateral marginal incisions
3. Skeletonization and exposure of the bone and cartilage
4. Dorsal reduction
5. Dome division if access is needed to the septum for septoplasty or graft harvest
6. Septoplasty if required
7. Turbinate modification if required
8. Lateral nasal osteotomies (micropuncture technique)
9. Tip plasty
10. Alar base modification
11. Closure, taping, and splinting

Anesthesia

I prefer to perform all rhinoplasties with the patient under general anesthesia. Proper local anesthesia is important to decrease surgical bleeding so that precise technique can be performed in addition to providing postoperative pain relief. Using excessive amounts of local anesthesia can distort the tissues, making surgical changes more difficult to assess. Typically 7 to 10 mL of lidocaine 2% with 1:100,000 epinephrine is sufficient. The local anesthesia should be administered in the planned planes of dissection and in the areas rich in blood vessels to provide hemostasis. Before injection I prefer to trim excess nasal hair and place 0.05% oxymetazoline-soaked cottonoids along the septum, middle turbinate, and superior nasal vault. The cottonoids should have excess oxymetazoline squeezed out before placement. There are case reports of flash pulmonary edema related to overdose of topically applied alpha-agonists such as 4% cocaine, 0.25% phenylephrine, and 0.05% oxymetazoline.[45,46]

Local anesthesia is first injected along the caudal edge of the lower lateral cartilage and then along the intercartilaginous junction between the upper and lower lateral cartilages and in the region of the membranous septum. The needle is then directed through the intercartilaginous area along the nasal dorsum, in close approximation to the upper lateral cartilages, nasal bones, and frontal process of the maxilla. A small amount of local anesthetic is deposited in the alar base and infraorbital nerve region. Next, the needle is inserted into the nasal tip and local anesthetic is deposited into the nasal tip and along the columella. Finally, local anesthesia is deposited beneath the mucoperichondrium of the nasal septum on both sides. The turbinates may be injected if turbinectomy is planned. Wait 10 minutes after administering the anesthesia to ensure maximum vasoconstrictive effects.

Incisions and Skeletonization

First, a transcolumellar incision is made. This incision is typically broken up by making an inverted V or stairstep incision.[47] This technique aides in reapproximating the soft tissues at the time of closure and minimizes linear contraction of the scar in the thin columellar tissue. This incision is made with a No. 11 blade after the area is carefully marked

with a surgical marker. The incision should be placed just where the medial footpads begin to flare, approximately midway between the nostril apex and base. An incision made too high or too low becomes easily noticeable. Also the medial footpads provide support for the incision and minimize scar contracture. Ensure that the incision is made perpendicular to the skin so that beveling does not occur. Beveling of the skin edge makes closure difficult and the scar more visible. A properly placed and well closed incision should result in a scar that is not perceivable months after the surgery. The incision is extended onto the vestibular mucosa perpendicular to the medial crura. Be extremely cautious here because the medial crura are just beneath the thin mucosa and can be inadvertently transected.

Next, bilateral marginal incisions are made. This incision is not made along the alar rim as was once used for rhinoplasty surgery. A rim incision violates the tissues in the soft-tissue triangle caudal to the lateral and intermediate crura of the lower lateral cartilage and can result in postoperative scarring and alar retraction. With a 7-mm double skin hook placed at the nostril apex, the ala is retracted superiorly and the caudal edge of the lower lateral cartilage is usually easily visualized. The edge of the cartilage can be felt by gently running the back edge of the scalpel blade across the mucosa. The incision should be made just caudal to the cartilage beginning laterally and extending medially to the apex of the nose. Realize that the incision does not parallel the alar rim; instead it should follow the contour of the cartilage. When the apex of the nose is reached, the skin hooks are moved slightly medially and an index finger is used to push on the tip of the nose to achieve better visualization in this area.

The incision is extended along the very thin mucosa overlying the medial crus approximately 1 mm posterior to the skin of the columella. To make visualization easier, the nose is twisted between the thumb and index finger and no skin hook is used. Extra care should be taken not to injure the medial crura of the lower lateral cartilage. The incision should join up with the previously made transcolumellar incision.

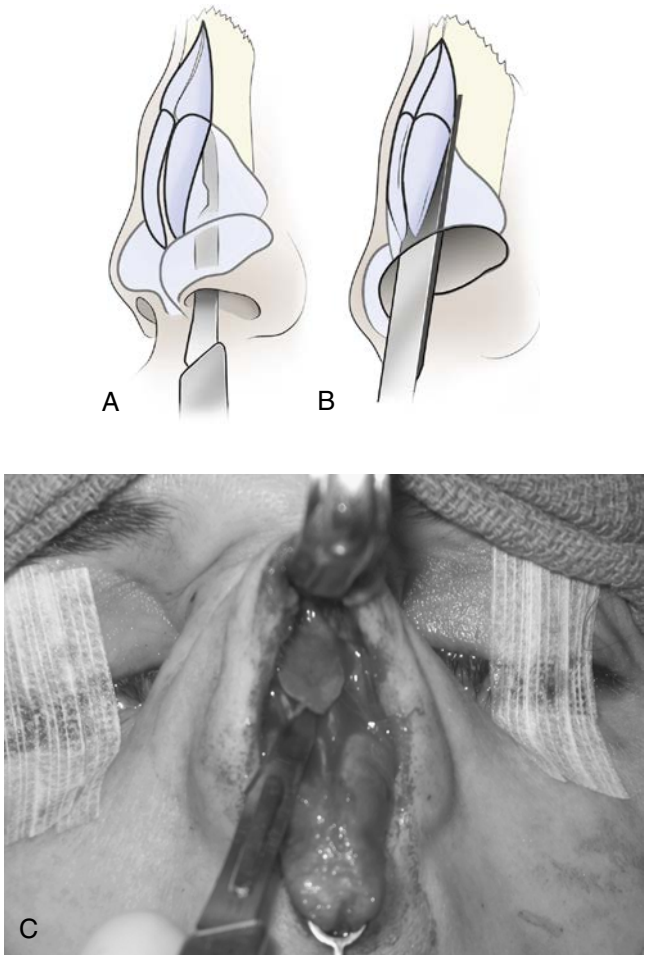
At this point the dissection is begun through the marginal incision to skeletonize the lateral crura of the lower lateral cartilage. Using Converse scissors, dissect under the mucoperichondrium of the cartilage. It is very important to get in the appropriate plane early. Dissection above the perichondrium will result in increased bleeding and scarring. Once the correct plane is established, Stevens scissors can be used to dissect along the upper lateral cartilages to the level of the nasal bones. This retrograde dissection technique is useful in primary rhinoplasty and aids in maintaining the appropriate dissection plane. In revision rhinoplasty it is better to begin elevation of the soft tissues over the columella and nasal tip first because portions of the lateral crus may have been excised or altered in the previous surgery.

After dissecting the soft tissues of the lower and upper lateral cartilages, the soft tissues of the columella and the domes are elevated and joined with the previously made pockets. Converse scissors are used to begin dissection along the vestibular mucosa and a tunnel is created just caudal to the medial crura. Next, a single skin hook is placed at the apex of the inverted V incision and the Converse scissors are used to elevate the columellar skin. Care should be taken not to traumatize the edges of the columellar skin in order to minimize the appearance of the scar postoperatively. When the skin is elevated, small vessels may be encountered that will require cautery. When approaching the intermediate crus, a double skin hook can be placed on the vestibular skin and retracted inferiorly by an assistant. The dissection should join with the previously made pocket, and the lower lateral cartilages should be completely freed from the skin.

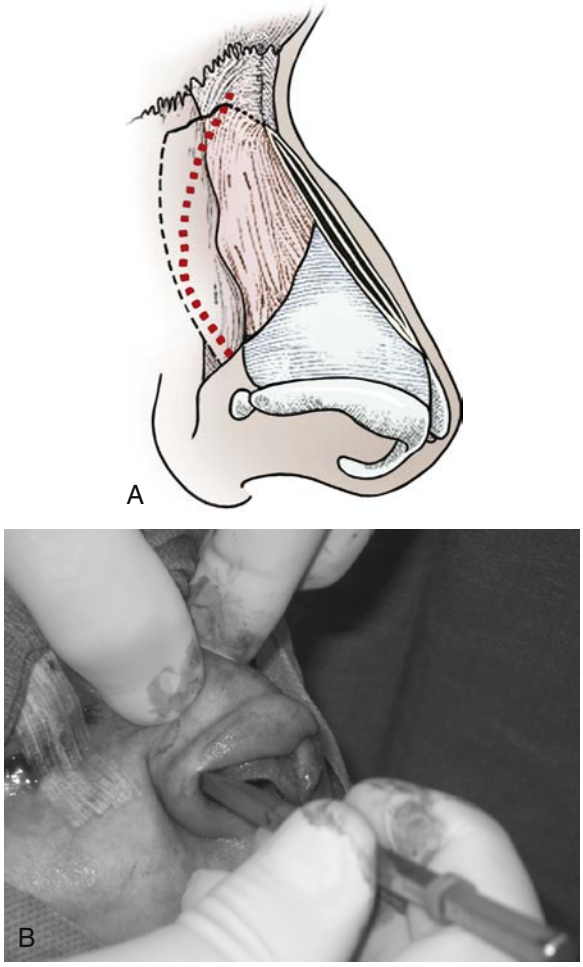
Attention is now directed at elevating the tissues of the nasal dorsum. An Aufricht retractor is placed and the soft tissues should be freed to the junction of the upper lateral cartilages with the nasal bones. The periosteum of the nasal bones should be elevated sharply with a periosteal elevator. Make certain that the dissection does not separate the attachment of the upper lateral cartilages from the nasal bones.

If the dissection is carried out appropriately and adequate anesthesia has been administered, the field should be relatively bloodless. Small vessels may require cautery, and if oozing is persistent, small cottonoids soaked in dilute epinephrine solution can be placed briefly to assist in hemostasis.

At this point the dorsal reduction is performed if it is required.[48] Dorsal humps are primarily cartilaginous but can involve a degree of bony prominence as well. The upper lateral cartilages can be trimmed with a No. 11 scalpel blade and Stephens scissors (Figure 20-26). If there is minimal bony reduction required, the remaining hump is reduced using bone rasps. Care should be taken not to separate the attachment of the upper lateral cartilages with the nasal bones. The surgeon should realize that the skin is thinner in the region of the rhinion and therefore less reduction is needed in this area if a straight profile is desired. Furthermore, because of the thick soft tissues overlying the nasofrontal region, overcorrection is often needed if a deeper nasofrontal angle is desired. Some surgeons prefer to use a guarded handpiece with a burr to reduce this area.[49] Open completion of the dorsal reduction of the profile should be reassessed. The surgeon should take into account any plans for increasing tip projection. If the profile is acceptable and there is no "open roof" deformity in the region of the nasal bones and the bony width is acceptable, no osteotomy of the nasal bones is needed. If the patient has a large osteocartilaginous hump, a No. 11 blade can be used to incise the upper lateral cartilage and dorsal septum to be trimmed and a Rubin osteotome can be placed at the osteocartilaginous junction beneath the partially excised upper lateral cartilages. The osteotome is carefully advanced along the nasal bones. It is imperative to use a sharp osteotome and keep the tip directed slightly superficially. A common error with use



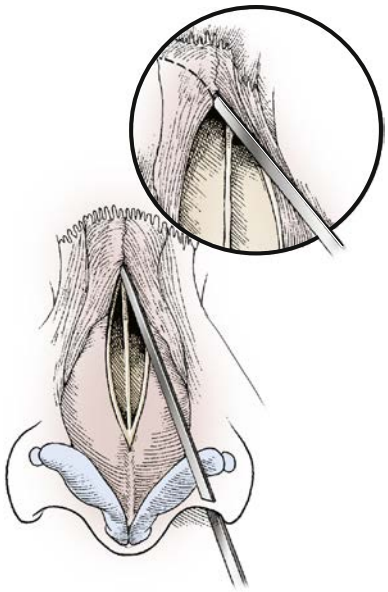
• **FIGURE 20-26** Dorsal reduction. A No. 11 blade can be used to incise the upper lateral cartilages and remove excessive cartilaginous prominence, as depicted in the photograph and in **A**. Reduction of the bony dorsum is then performed using a Rubin osteotome **(B). C,** Rasping of the bony dorsum is an alternative technique for reducing the bony prominence. (From Koehler JK, Waite PD: Basic principles of rhinoplasty. In Miloro M, ed: *Oral and maxillofacial surgery*, Hamilton, 2004, BC Decker.)



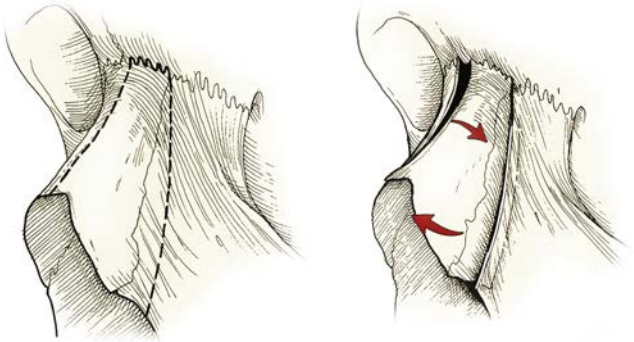
• **FIGURE 20-27** Lateral nasal osteotomies. The *dotted black line* in **(A)** demonstrates a low-to-low lateral nasal osteotomy. The *red dotted line* depicts a low-to-high lateral nasal osteotomy. Note the small triangle of bone preserved in the piriform rim described as Webster's triangle. **B,** demonstrates the use of a 2-mm osteotome to perform a micropuncture osteotomy along the nasal bones. (From Toriumi DM, Hecht DA: Skeletal modifications in rhinoplasty. In Holt GR, ed: *Advances in rhinoplasty*, Philadelphia, 2000, Saunders.)

of a Rubin osteotome is to remove too much bone. If additional bony reduction is required, the rasps may be used. An open roof deformity is common when using this technique, and lateral nasal osteotomies will likely be required. Failure to do lateral nasal osteotomies will leave a flat and unnatural appearance to the nasal dorsum.

There are two principal types of nasal osteotomies: lateral and medial. The lateral nasal osteotomy is used most commonly, and medial osteotomies are usually needed only in cases where the nasal bones are thick and an unfavorable fracture is anticipated.[50,51] The lateral nasal osteotomy begins in a low position, just above the base of the pyriform rim (Figure 20-27). Ideally a small triangle of bone should be preserved at the base of the pyriform, known as *Webster's triangle,* to provide some bony support in the internal nasal valve region. I use a sharp 2-mm osteotome with a micropuncture technique.[52] The osteotome is placed through a stab incision in the mucosa several millimeters above the base of the pyriform aperture. Some surgeons perform the micropuncture technique from an external approach; however, if improper technique or unpredictable scarring occurs, the external incision can be noticeable.[53] The osteotomy is made using multiple perforations along the nasal bone, keeping the osteotome perpendicular to the bone and advancing the osteotome in an interrupted fashion to the region of the intercanthal line. On approaching the intercanthal line the surgeon may decide to keep the osteotomy low (posterior) or high (anterior) on the nasal bones[54] (see Figure 20-27). The typical osteotomy to close an open roof is finished high. A greenstick back fracture is created with digital pressure, and the nasal bone is medialized and the open roof is closed. If the surgeon desires to narrow the nasal width near the intercanthal region, the osteotomy can be completed in a low (posterior) region. The low-low osteotomy is not frequently needed. A medial osteotomy is often needed when a low-low osteotomy is performed, to prevent unfavorable fractures (Figure 20-28). A problem that can



• **FIGURE 20-28** The medial osteotomy. The medial osteotomy is often used in conjunction with a low-to-low osteotomy to prevent unfavorable fracture. (From Toriumi DM, Hecht DA: Skeletal modifications in rhinoplasty. In Holt GR, ed: *Advances in rhinoplasty*, Philadelphia, 2000, Saunders.)



• **FIGURE 20-29** The rocker deformity. An unfavorable fracture that extends into the thickest portion of the nasal bone in the nasofrontal region can result in lateral displacement of the upper portion of the nasal bone when the surgeon attempts to move the nasal bones medially. (From Toriumi DM, Hecht DA: Skeletal modifications in rhinoplasty. In Holt GR, ed: *Advances in rhinoplasty*, Philadelphia, 2000, Saunders.)

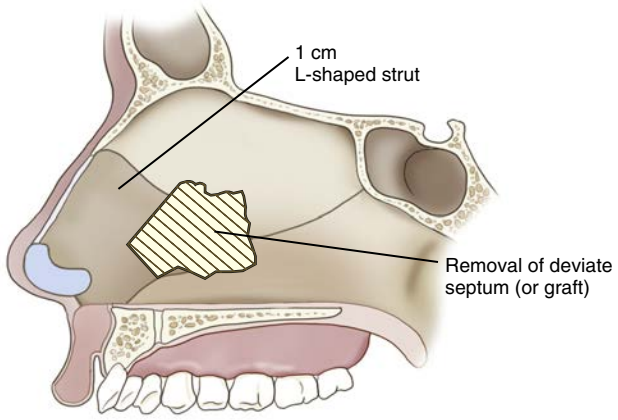
occur if the fracture extends onto the nasofrontal region is known as a *rocker deformity* (Figure 20-29). The thick bone in the nasofrontal region does not mobilize medially and thus creates a fulcrum when the caudal portion of the nasal bone is medialized and results in lateralization of the nasal bones in the intercanthal region. A medial osteotomy is begun on the superior edge of the open roof deformity and is advanced obliquely and laterally. The medial osteotomy prevents uncontrolled greenstick back fractures in thick nasal bones. No further rasping should be performed once osteotomies are completed, because the nasal bones could be avulsed. If irregularities persist through the thin nasal dorsal skin, acellular dermis (Alloderm) can be used to camouflage and is placed on the bone and cartilage.

In some cases, dorsal augmentation is required to correct traumatic defects or previous overresection of dorsum or in ethnic noses with a low dorsum (usually Asian and African American patients). Autogenous materials such as septal, auricular, and rib cartilage; cranial bone; or iliac crest are preferred to alloplastic materials.[55-58] Cartilage grafts can resorb or distort in shape with time. Alloplastic materials include silicone and ePTFE implants. The problem with alloplastic implants is that they can become infected or can extrude years after placement. Careful placement of any dorsal graft is essential because irregularities may be easily seen in the thin skin along the dorsum.[55,59-62]

Attention is now directed to the septoplasty if it is required or septal cartilage is needed. The cartilage can be easily obtained by separating the upper lateral cartilages at the anterior septal angle. This approach to the septum provides the widest exposure and is useful for complex septoplasty or when significant modification to the dorsal septum is required. It is important to ensure that the dissection is beneath the mucoperichondrium to prevent mucosal perforation and increased bleeding. Tears in the mucosa will occasionally occur. A tear on one side of the septum will heal uneventfully as long as the mucosa is reapproximated and intact mucosa remains on the opposite side after the cartilage has been removed. It is wise to elevate the flap on the side of the septum with the least deformity first. The dissection is aided by hydrodissecting the mucosa in a subperichondrial plane with local anesthesia before beginning. The mucoperichondrium is sharply elevated off both sides of the nasal septum with a caudal elevator. Care should be taken when separating the upper lateral cartilages from the dorsal septum. The dissection should extend posteriorly to the ethmoid bone, then inferiorly and anteriorly across the septum-vomer junction. An assistant can retract the lower lateral cartilages inferiorly during this process.

Next, a nasal speculum can be inserted in the pocket on either side of the septum. A sharp caudal elevator or scalpel can be used to incise the cartilage and remove septum for grafting or correcting areas of septal deflection. When removing cartilage it is important to maintain an L shaped strut of cartilage of approximately 1 cm dorsally and caudally (Figure 20-30). If the cartilage is removed before dorsal hump reduction, the surgeon must account for this so that an inadequate dorsal strut does not occur. Insufficient cartilage support can result in a saddle-nose deformity, which can be difficult to correct.

An alternative technique is to divide the domes of the lower lateral cartilages and begin access to the septum from its caudal edge. This technique should be used if grafting is required to lengthen the caudal septum in cases of a retracted or deficient columella or when medial crural strut grafts are indicated to increase tip projection. Realize that dividing the domes significantly decreases the support mechanism for the nasal tip, and if this area is not properly supported with grafts the nasal tip can be deprojected and



• **FIGURE 20-30** Harvesting nasal septum. A portion of the nasal septum can be resected and used for cartilage grafting techniques. It is important to preserve approximately 1 cm of cartilage dorsally and caudally to prevent a saddle-nose deformity. (From Koehler JK, Waite PD: Basic principles of rhinoplasty. In Miloro M, ed: *Oral and maxillofacial surgery*, Hamilton, 2004, BC Decker.)

tip support weakened. Separating the medial crura requires that the surgeon precisely align the cartilage before closure so that the projection of the medial crura is equal and does not result in twisting of the nasal tip.

Some surgeons prefer to combine an open and closed approach. When this is done, the cartilage is harvested from a Killian incision or transfixion incision before beginning the surgical sequence for an open rhinoplasty.

If turbinate modification is required, it can be done at this time. Hypertrophy of the inferior turbinates is the most common cause of nasal airway obstruction. Recognizing the problem preoperatively is important so that it can be addressed and worsened nasal breathing does not occur. Hypertrophy of the turbinates is most commonly due to allergic symptoms. Medical treatment is the mainstay of nasal allergy symptoms. If medical treatment is not successful, surgical treatment can be considered. Enlargement of the turbinates can occur in cases of septal deviation on the side on which the nasal passage is enlarged. If the septum is corrected and the turbinate is not addressed, nasal obstruction can occur.

Many methods have been reported for the management of turbinate hypertrophy including corticosteroid injection, electrocautery, cryosurgery, turbinate outfracture, partial turbinate resection, total turbinate resection, submucous turbinate resection, vidian neurectomy, and laser reduction. The procedure that is the most conservative and that the surgeon feels most comfortable with should be used. I typically use turbinate outfracture or partial turbinectomy. Consideration should be given to the placement of Silastic stents to prevent synechia formation between the turbinate and the septum. The most common complications from turbinate surgery include hemorrhage, atrophic rhinitis, and ozena.

The surgeon can now perform the tip plasty. The techniques described previously are used to increase or decrease tip projection and rotation, and cartilaginous grafts such as a columellar strut for tip support may be used. Spreader grafts placed in the region of the upper lateral cartilages may be needed if the middle vault of the nose needs widening, the upper lateral cartilage becomes avulsed from the nasal bone, or the surgeon is planning on improving the airway in the internal nasal valve[63] (see Figure 20-13). All cartilage grafts should be secured with 6-0 Prolene to prevent displacement.[36,55,64]

At this point the skin is redraped, the esthetics is assessed, closure can proceed. Closure is often neglected at the end of surgery, but it remains a critical part in rhinoplasty. I prefer to close the columellar incision first, followed by closure of the marginal incision. Interrupted 6-0 Prolene sutures with a tapered noncutting needle are used to reapproximate the skin along the anterior and lateral columella. Typically five sutures are placed. The marginal incision is then closed. The first suture should be placed at the apex of the nostril using interrupted 5-0 plain gut sutures. Then close laterally to medially, using interrupted 5-0 plain gut sutures. It is important to take small bites because distortion of the ala can occur if large bites are taken.

If a septoplasty was performed, the septum is closed with a running 4-0 plain gut mattress suture spanning the two sides of the septal mucosa. A Keith needle is used to go back and forth across the septum. The mattress sutures should be started in the caudal septum and then in a clockwise fashion extending posteriorly and returning to the starting point, where the suture is tied. This suture eliminates dead space between the mucosa and prevents septal hematoma. When this technique is used, septal splints are often unnecessary.

Alar base modification is addressed last. The decision to alter the alar base is made preoperatively. However, if there is any doubt about the need for alar base reduction, it is best to postpone this component. Alar base reduction can be easily performed using local anesthesia in the office. The surgeon needs to determine if the nostril needs to be narrowed because of an overly wide nasal passage, the external skin needs to be reduced because of excessive alar flaring, or a combination of both procedures is required. If the size of the nostril is excessive and the ala is not overly flared, a small excision of vestibular skin can be performed. If the nostril sill is flared but excision of vestibular skin will compromise nasal airflow, a conservative excision of skin only just above the crease at the nostril base is performed. The incision should be through skin only and not any deeper. Deeper excision of tissues will increase the likelihood of notching. Also, the incision should not extend far laterally on the alar-cheek junction or the scar will be noticeable. A Weir procedure can be performed to narrow both the nostril size and alar flare. The excision is typically 1 to 2 mm and involves both vestibular mucosa and skin at the nostril base (see Figure 20-23). The incision angles are made more divergent to remove more skin than vestibular mucosa. Precise closure with 4-0 Monocryl deep and 6-0 Prolene on the skin is essential to prevent a noticeable scar.

Closed Rhinoplasty

The main advantage of this technique is the lack of any external scars. To do this technique properly the surgeon should be experienced in rhinoplasty surgery if any significant tip plasty is required. It is much more difficult to do cartilage grafting and suture techniques precisely with this approach.

This author's standard sequence for closed rhinoplasty is as follows:

1. Partial transfixion incision
2. Intercartilaginous incision
3. Septoplasty if required
4. Turbinate modification if required
5. Dorsal reduction
6. Lateral nasal osteotomies
7. Marginal incision
8. Delivery of lower lateral cartilages
9. Tip plasty
10. Alar base modification
11. Closure, taping, and splinting

The sequence begins with a partial transfixion incision. Adson forceps are used to identify the caudal edge of the nasal septum. The columella is then stabilized with the forceps and a No. 15 blade is used to make the partial transfixion incision beginning at the apex of the nostril and extending to just shy of the medial footpads of the medial crura. The blade is passed in the membranous septum just posterior to the medial crura.

Next, a 7-mm double skin hook is placed at the apex of the nostril and lifted superiorly. The junction between the upper and lower lateral cartilages should be identified. An intercartilaginous incision is then made just caudal to the prominence of the upper lateral cartilage, beginning laterally and extending medially to join up with the previously made partial transfixion incision. Converse scissors are used, and the mucoperichondrium of the upper lateral cartilage is identified. Dissection continues in this plane, using Stevens scissors to the nasal bones. With a sharp periosteal elevator the periosteum is then reflected off the nasal bones.

If a septoplasty is required or cartilage is needed for grafting, it is done at this time. The septum is approached from the caudal edge of the septum through the partial transfixion incision. Converse scissors are used to identify the mucoperichondrium. The exposed caudal septum is lightly scored with a No. 15 blade. A large dental amalgam condenser can then be rubbed against the area previously scored, and the perichondrium should easily separate to identify the appropriate plane of dissection. This maneuver is very useful because it is easy to dissect above the perichondrium unknowingly until a mucosal tear or significant bleeding occurs. A caudal and freer elevator is used to elevate the perichondrium off the septum. The elevation sequence should be from the superior caudal septum posteriorly to the ethmoid bone, then continuing inferiorly to the vomer and ending in the inferior aspect of the caudal septum. If wider exposure of the septum is needed, the partial transfixion incision can be extended onto the mucosa of the nasal floor. With a caudal elevator the mucosa of the nasal floor can be elevated, leaving a small band of tissue connected at the junction of the nasal septum and maxillary crest. A nasal speculum can be inserted with one tine in each tunnel, and the tissue in between can be sharply dissected to achieve wide exposure of the septum.[65]

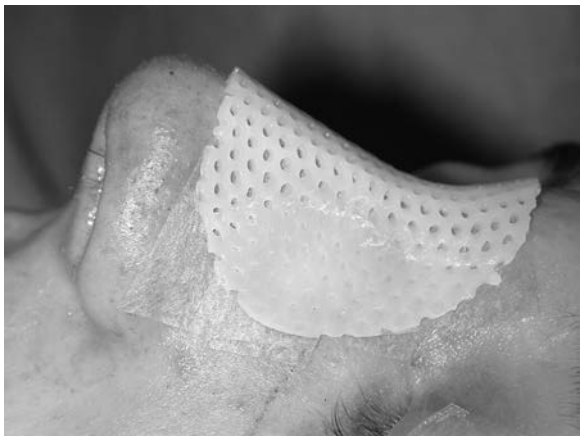
To obtain cartilage for grafting purposes, a Cottle elevator is used to make a cut in the septum at the junction of the ethmoid and vomer bones and the quadrangular cartilage. The elevator should easily cut through the cartilage. A second cut is made at least 1 cm posterior to the caudal edge of the septum, paralleling the previous cut. A freer elevator can now be used to elevate the mucosa off the opposite side of the cartilage. The surgeon should be careful not to perforate the mucosa on the opposite side of the septum. When removing cartilage, care should be taken to maintain a 1-cm strut superiorly and anteriorly. As mentioned earlier, if dorsal reduction is to be done to the nose, this should be accounted for so that insufficient cartilage is not left supporting the nose superiorly. Fomon scissors may be used to make the cuts through the cartilage superiorly and inferiorly. Alternatively, a Ballenger swivel blade can be used. The cartilage is removed with Takahashi forceps. Turbinate modification as described under open rhinoplasty can be done at this time.

After the septoplasty an Aufricht retractor can be inserted, and the nasal dorsum is inspected. Dorsal hump reduction can proceed as described earlier with rasping techniques or osteotomes. The lateral nasal osteotomies are then performed.

Bilateral marginal incisions are then made as described for the open rhinoplasty technique. The incisions begin at the caudal edge of the lateral crus and extend to the area where the medial footpads of the medial crura begin to flare. Converse scissor are then used to identify the perichondrium of the lateral crus. Once the lateral crus is dissected free, the medial crus is dissected and a tunnel is created just in front of the medial crus to join the right and left nostrils. Stephens tenotomy scissors are then used to free the tissue in the area of the domes. The cartilages should be completely freed from the overlying tissues. The Stephens scissors can then be inserted through the intercartilaginous incision and the marginal incision, and the lower lateral cartilage is delivered (Figure 20-31). At this point, cephalic strip and tip plasty techniques can be performed as described earlier. Precise placing and suturing of cartilage grafts is much more challenging with this approach.

The cartilages are replaced into position and the esthetics is assessed. Closure is then performed by first closing the intercartilaginous incisions with interrupted 5-0 plain gut suture. The first suture is placed at the apex of the nostril. Again, it is important to take small mucosal bites so that distortion of the nose or obstruction of the nasal valve does not occur. The marginal incision is then closed with interrupted 5-0 plain gut sutures. If a septoplasty was performed the incision is closed with a running 4-0 plain gut mattress

• **FIGURE 20-31** Delivery of the lower lateral cartilages and cephalic strip. Inserting scissors through the intercartilaginous and marginal incisions will expose the lower lateral cartilage. Once it is exposed, a cephalic strip can be taken.



• **FIGURE 20-32** Nasal dressing. Brown paper tape and a thermoplastic splint placed along the nasal bones and upper lateral cartilages is used for 1 week to stabilize the nasal bones.

suture as described for the open technique. Alar base modification as previously described would be done at this time if needed.

Dressings and Splinting

The patient's first impression after the surgery is very important. A dressing that is asymmetric or sloppy looking may give the patient the impression that the surgery was done poorly. I apply Mastisol adhesive to the nose and place ¼ inch of brown paper tape and a thermoplastic splint. The tape should be neatly cut and placed from the radix to the supratip breakpoint. Additional pieces of tape can be placed in the region of the nasal tip if desired. The thermoplastic splint should cover the region from radix to the supratip, should cover just the nasal bones, and should not extend laterally onto the cheek (Figure 20-32).

Intranasal packs or stents are generally not required. If a turbinectomy is performed or if a large tear is created in the septal mucosa, a silicone stent can be placed to prevent synechiae formation. The stents are secured to each other by passing a 3-0 silk suture through the columella and are usually left in place for 1 week.

Follow-up Care

The patient is seen at 24 hours and again in 1 week, at which time the splints and dressing are removed. The patient is instructed not to blow the nose, so that bleeding is not stimulated.

Patients sometimes use oxymetazoline nasal spray to improve breathing. The patient should be warned not to use the nasal spray for more than 5 days or rebound nasal congestion (rhinitis medicamentosa) may develop. The patient should understand that congestion will be present for several weeks and that only saline nasal spray should be used to keep the mucosa moist and help break up any crusting that develops inside the nose. The patient can gently clean inside the nostril with a cotton applicator and dilute peroxide at 1 week.

The patients should also understand that it will take several months to see the final results of the surgery. Swelling in the region of the nasal tip seems to take the longest to resolve. The patient should be followed long term so that you can truly see the long-term results of various techniques employed. Some of the more destructive techniques to the nasal tip may look good initially but years later may result in an unesthetic appearance.

Complications

Management of late postoperative deformities is outside the scope of this chapter; however, early postoperative problems are discussed. The most common postoperative complication is nasal bleeding, and it is estimated that troublesome bleeding will occur less than 2% to 4% of the time. If nasal bleeding does occur, it usually occurs in a bimodal distribution either in 48 hours from raw mucosal edges or in 10 to 14 days after eschars begin to separate. The patient is instructed to use 0.05% oxymetazoline nasal spray and apply ice compresses. If the patient cannot control the bleeding, the surgeon may need to cauterize the bleeding points or perform nasal packing. Obviously the patient should also be avoiding medications that interfere with bleeding.

Infection is the second most commonly reported complication and occurs in less than 3% of cases. Incomplete removal of debris under the skin flap or presence of a hematoma makes infection more likely. The organisms typically involved are *Staphylococcus, Streptococcus, Haemophilus,* and rarely *Pseudomonas* and *Actinomyces.* Infections were much more common when nasal packing was used. Serious infections can lead to toxic shock or cavernous sinus thrombosis if not recognized and treated.

Hematomas are rare but can be problematic if not identified. Septal hematomas in particular can result in cartilage necrosis, septal perforation, and saddle-nose deformity if not recognized and drained. Septal mattress suturing is a good preventive measure.

CASE STUDY 20-1

This is a 36-year-old man with prominent dorsal hump that is primarily cartilaginous in nature. This is the result of overgrowth of the quadrangular cartilage of the nasal septum. An open rhinoplasty technique was used to reduce the dorsal septum. The nasal tip was deprojected by separating the medial crura from the caudal septum. Harvested septal cartilage was used to place a columellar strut graft to maintain tip support. Transdomal and interdomal sutures were used to better define the nasal tip. The postoperative photos were taken 3 months after the procedure.

CASE STUDY 20-2

This is a 24-year-old woman concerned about a dorsal hump and broad nasal tip. An open rhinoplasty was performed to reduce the cartilaginous and bony dorsal hump. Transdomal and interdomal suture techniques were used to refine the nasal tip.

Rarer problems include tape reactions and skin slough secondary to tight or inappropriately placed dressings. Poor surgical technique with damage to the subdermal plexus could also result in wound problems or skin slough. Allergic reactions to tape or adhesives are easily managed with corticosteroids.

Blepharoplasty

KATHERINE E. DUNCAN, JENNY Y. YU

Introduction

Beer published the first medical illustration of the aging eyelid in 1807.[1] Von Graefe first used the term *blepharoplasty* to describe a case of eyelid reconstruction following a cancer resection.[2] Since then, the blepharoplasty procedure remains one of the most popular surgical procedures for both functional and esthetic reasons. The term *dermatochalasis* can be used to describe both excess skin of the upper and lower lids. This excess is a result of various aging changes. Facial tissues including the eyelids lose elasticity, tone, and volume as we age. Atrophy of collagen contributes to stretching and sagging of the eyelid skin as well as the development of wrinkles. Thinning of the dermis, fat, and musculature can create a hollow appearance. Ligamentous and fascial support structures also stretch over time. Because the eyelids are a central part of the face, dermatochalasis of the eyelids is affected by the dynamics of the surrounding tissue as well.[3,4]

Consider the face in thirds (Figure 21-1). The weakening of the epicranial aponeurosis and frontalis in the upper third of the face contributes to eyebrow ptosis. This in turn worsens the dermatochalasis of the upper eyelid skin. Horizontal laxity of the eyelids can also worsen the dermatochalasis. This is usually due to laxity of the canthal tendons and gravitational descent of soft tissue in the middle third. Weakening of the orbital septum can result in prolapse of the orbital fat pads. All of these changes lead to variations of the dermatochalasis of the upper and lower lids. These changes can affect both the function and esthetics of the eyelids, prompting patients to seek correction.[3]

The term *blepharoplasty* is strictly used as the surgical removal of excess skin and muscle, with and without fat resection. It often is combined with ptosis surgery of the brow and upper eyelids. It is also combined with horizontal tightening of the upper and lower lids. In proceeding with a blepharoplasty, the surgeon must consider the surrounding tissue dynamics in order to achieve a satisfactory outcome for the patient.

Anatomy

Detailed understanding of the eyelid and orbital anatomy is required for successful surgical outcomes. The upper and lower eyelids surround the palpebral fissure and meet at the medial and lateral canthus. The lateral canthus is 2 mm higher than the medial canthus. With the eye in primary position, the margin of the upper eyelid should cover the superior 1 to 2 mm of the cornea while the margin of the lower eyelid is usually within 2 mm of the inferior border of the cornea.[5] The brow cilia should sit at the level of the supraorbital rim, with some gender variations. The lower lid and malar junction should be one continuous plane (Figure 21-2).[3]

The most superficial layer of the upper and lower eyelids is skin. Eyelid skin is one of the thinnest in the body and is devoid of subcutaneous tissue. The orbicularis muscle is immediately under this layer of skin forming concentric circles around the bony rims of the orbit. The orbicularis muscle is the main protractor muscle of the eyelids, responsible for closure of the eyelids and innervated by the facial nerve. The orbital septum is contiguous with the periosteum of the orbit, which delineates the preseptal and postseptal space.[5] Posterior to the bands of orbital septum are the fat pads of the orbit. Fat pads serve as the lubricant allowing for smooth movement of the eyelids and eye. The central and medial fat pads of the upper lid create the volume of the upper lid. Laterally in the upper lid, the two lobes of the lacrimal gland are present. The main retractors of the upper eyelids, the levator aponeurosis and Müller's muscle, are posterior to the fat pads. They are innervated by cranial nerve III and the sympathetic nervous system, respectively. The levator muscle has anterior fiber projections into the skin and orbicularis just above the tarsal plate, and this anatomically marks the lid crease (Figure 21-3). Typically, the lid crease is found 9 to 10 mm above the lid margin, just above the most superior aspect of the tarsal plate. The tarsus, or tarsal plate, is the cytoskeleton structure of the eyelid made up of connective tissue and Meibomian glands. The palpebral conjunctiva is the most posterior layer of the

eyelids continuous with the bulbar conjunctiva, forming the mucosal layer of the ocular surface. The superior tarsal conjunctiva contains an abundant number of goblet cells responsible for forming the mucous layer of the tear film (Figure 21-4).[3,5-7]

The lower eyelid anatomy is similar to the upper eyelid. The lateral, central, and medial fat pads of the lower lid are continuous with the malar fat pad and separated by orbital

• **Figure 21-4** Everted upper eyelid with superior palpebral conjunctiva visible.

retaining ligaments. The tarsal plate of the lower eyelid is only 3.5 to 5 mm tall, compared to 8 to 12 mm in height of the upper lid.[7] The lower eyelid retractors, capsulopalpebral fascia and inferior tarsal muscle, are analogous to the levator and Müller's muscle of the upper eyelid (Figures 21-5 and 21-6).[5]

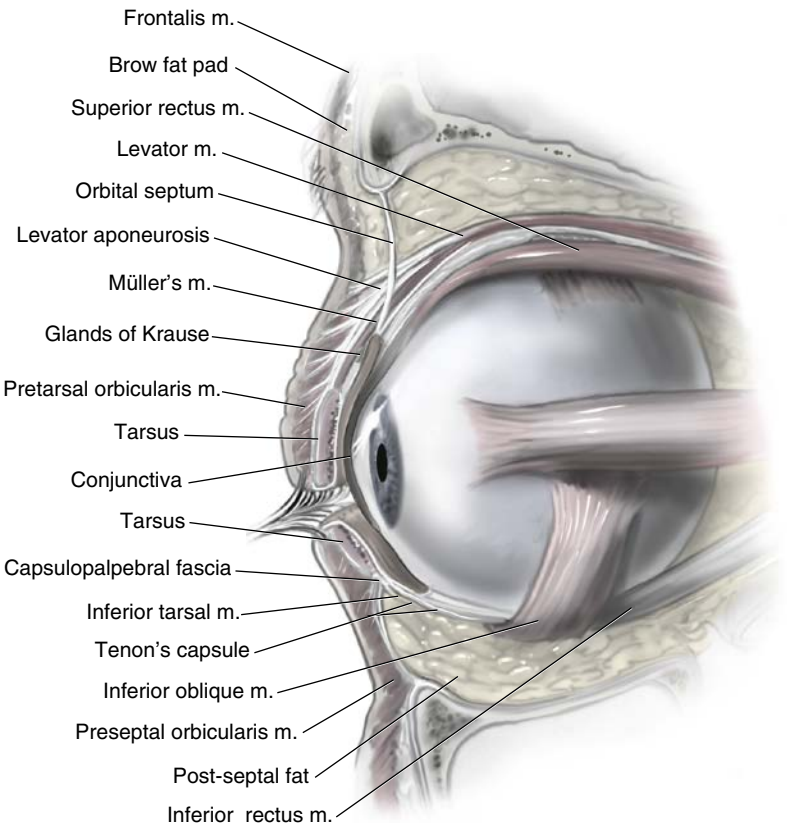
The vascular supply of the eyelids is formed by the anastomoses of the branches of the internal and external carotid arteries. Each eyelid has a marginal arcade located anterior to the tarsal plate 2 to 4 mm from the lid margin. The upper eyelid also has a peripheral arcade just superior to the tarsal plate between Müller's muscle and the levator aponeurosis.[7] The marginal arcade should be avoided during injection of local anesthetics to avoid a hematoma. The venous drainage follows the same pattern (Figure 21-7).

Preoperative Evaluation

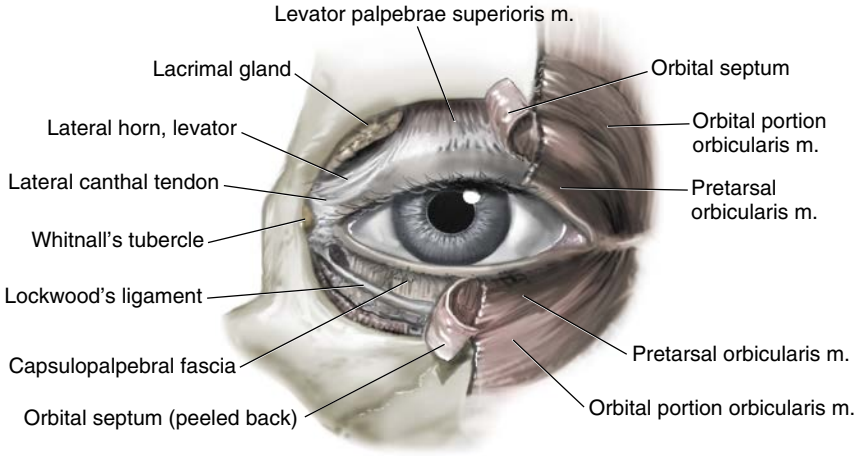
Preoperative evaluation of the patient begins with taking a careful history. It is important to specifically ask about the use of neurotoxin and/or fillers in the history because this can alter the physical examination. Determining the patient's motivations, goals, and expectations for surgery is crucial to the success of any surgical intervention. For example, patients who are interested in restoring function will generally be satisfied with removal of vision-obstructing excess skin only while patients who want to improve their appearance may require a greater amount of skin removal, removal of prolapsed fat, and greater attention to symmetry to meet expectations.[3] It is important to give the patient a clear understanding of what goals and expectations can and cannot be achieved with surgery. Patients with unrealistic self-image or who are not capable of understanding the limitations of the procedure are poor surgical candidates.

Once the patient and surgeon have come to a clear understanding of one another's goals and expectations, a medical history should be obtained that includes a detailed list of all medications. Herbal medications can cause the patient to be more coagulopathic. Patients should be specifically asked about any history of ocular pathology including dry eye.

Examination of the patient should focus on the structure, function, and appearance of the eyelids, eyebrows,

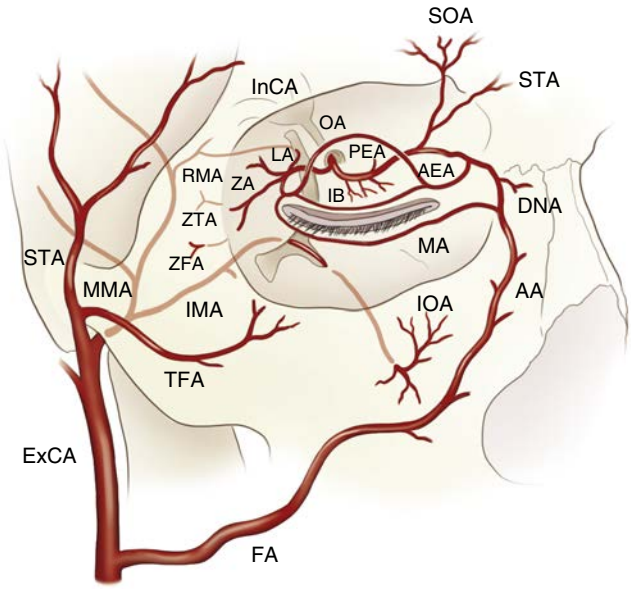


• **Figure 21-5** Anatomic structures of the upper and lower eyelids in sagittal view.



• **Figure 21-6** Anatomic structures of the upper and lower eyelids in coronal view.

and forehead. The position of the eyelid margin should be assessed. If the margin of the eyelid is at or near the pupil, the patient may have visually significant ptosis, typically caused by dehiscence or stretching of the levator aponeurosis, that can be corrected at the time of blepharoplasty. The amount of excess skin of the upper eyelid (dermatochalasis) should be assessed. If skin overhangs the lid margin or sits on the eyelashes of the upper lid it may be visually significant (Figure 21-8). Careful attention should be given to the position of the eyebrows. The normal brow position in men is along the superior orbital rim. In females the eyebrow sits slightly higher than the orbital rim, especially laterally. Descent of the eyebrow position is an age-related change that can be addressed surgically with a brow lifting procedure and can contribute to dermatochalasis. When assessing eyelid and eyebrow position, it is important that the frontalis muscle is relaxed. Patients may compensate for eyebrow and eyelid ptosis by contracting the frontalis muscle, which can lead to subjective complaints of fatigue and heaviness of the eyelids. Attention also should be given to any bulging or prolapse of the fat pads through a weakened orbital septum because this is often a cosmetic complaint from patients



• **Figure 21-7** Arterial supply of the eyelids.

• **Figure 21-8** Dermatochalasis resting on the eyelashes of the upper lid and partially overhanging the eyelid margin.

• **Figure 21-9** Schirmer test is used to quantify tear production. Filter paper is inserted into the inferior fornix and the amount of moisture absorbed by the paper in a specific amount of time is measured.

and can be addressed at the time of blepharoplasty. Finally, examination of the ocular surface for dryness is important because this can be exacerbated by surgical interventions.[4,8] An objective test such as the Schirmer test can assess for quantity of tears present (Figure 21-9).

In contrast to the upper eyelid blepharoplasty, the lower eyelid blepharoplasty is almost always cosmetic because excess skin and fat prolapse of the lower eyelids does not typically functionally impair vision. In assessing a patient for lower lid blepharoplasty, it is important to evaluate amount of excess skin present, the presence of orbital fat prolapse, hollowing at the inferior orbital rim or "tear trough deformity," as well as degree of lower eyelid laxity. Unlike the upper eyelid blepharoplasty, there are multiple approaches to a lower eyelid blepharoplasty and the relative degree of each of these factors influences which procedure should be chosen. Older patients with excess skin typically warrant a transcutaneous lower eyelid blepharoplasty. If lower eyelid laxity is also present, a lower eyelid tightening procedure (i.e., lateral tarsal strip) can be performed at the same time. Patients with minimal excess skin and fat prolapse or tear trough deformity can be approached with a transconjunctival lower lid blepharoplasty with fat excision or redraping.[4]

Operation

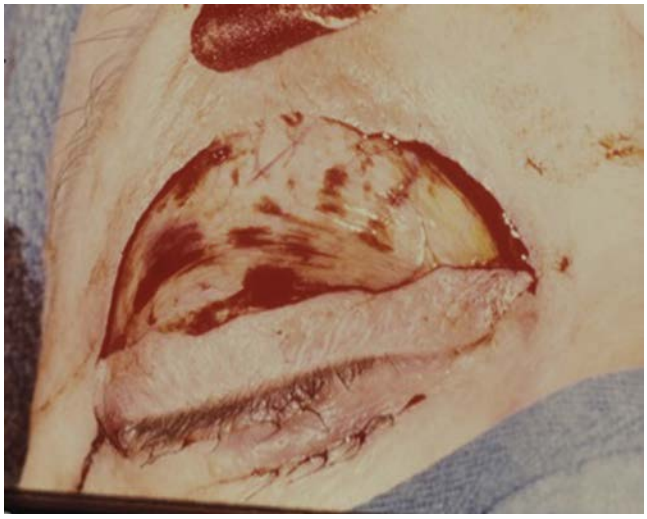
Upper Lid Blepharoplasty

The steps of the basic upper eyelid blepharoplasty are outlined in the following section. Additional procedures involving the correction of ptosis of the eyelids and eyebrows are beyond the scope of this chapter.

1. Measure the position of the lid crease centrally on each side with calipers. Mark the existing eyelid crease. This should fall between 6 to 10 mm above the eyelid margin centrally. If the position of the lid crease is different on each side, choose one crease height and mark symmetric incisions for each eyelid. If the crease is not obvious, manually move the eyelid up and down to better visualize the crease. The lateral edge of the mark should be extended to the orbital rim along a crow's foot crease. Typically, this should be placed 4 to 5 mm above the lateral canthus to avoid webbing. Placement of the incision along the lid crease results in a hidden scar.
2. After the lid crease has been marked, with the eyelids closed, use a smooth fine-tipped forceps to pinch the excess skin. One tip of the forceps will grasp the skin along the marked lid crease while the other end of the forceps is used to grasp the superior extent of the excess skin. Repeat this maneuver at several points along the eyelid and connect the points to outline the upper limit of skin to be removed. Mark this line and connect it with your lid crease marking medially and laterally. A safe zone of skin resection is to preserve a brow-to-margin distance of 15 to 20 mm.
3. Inject subcutaneous anesthetic in the area to be resected, taking care to inject superficially just below the skin.
4. Incise the skin along the marked incision lines with a 15 blade. Some surgeons prefer to use a CO_2 laser or Colorado microdissection needle to incise the skin. In either case, the goal is to make a smooth continuous incision line (Figure 21-10).

• **Figure 21-10** After marking is complete, 15 blade is used to incise the skin.

• **Figure 21-12** The fat pads of the upper eyelid visible beneath the orbital septum.



• **Figure 21-11** Upper eyelid with orbicularis visible after skin removal.

5. Use forceps and iris scissors to excise the marked area of skin, taking care to excise skin only and leaving the orbicularis intact (Figure 21-11).
6. Use cautery to achieve hemostasis.
7. At this point, prolapsed fat may be removed if desired.
   a. The orbicularis and septum are opened with iris scissors or cautery to expose the fat pads.
   b. Gentle pressure on the globe will further prolapse the fat (Figure 21-12).
   c. A hemostat is placed across the base of the prolapsed fat. Great care is taken to avoid any traction on the fat as this can lead to bleeding posterior to the septum. The distal fat is excised and the clamped edge of the fat is then cauterized and released. This can be repeated until a desirable amount of fat has been removed. It is important to note that aggressive fat debulking of the eyelids can result in a hollowed appearance and has generally fallen out of favor. Minimal conservative fat removal is recommended.
8. The skin is then closed with running 8-0 nylon.
9. Apply antibiotic/steroid ointment to the incision and eyes.

Lower Lid Blepharoplasty

The basic transcutaneous and transconjunctival approaches to the lower eyelid blepharoplasty are discussed in the following section. Additional procedures for lower lid tightening and methods of fat redraping are not discussed in detail in this chapter.

Transcutaneous Approach

1. A subciliary skin incision is marked 2 mm below the lower eyelid lashes. The marking is extended inferotemporally along a crow's foot crease at the lateral canthus to the lateral orbital rim.
2. Subcutaneous anesthetic is injected along the marked incision.
3. A traction suture is placed through the lid margin and is used to apply gentle upward traction to the lower lid during the procedure.
4. Incision along the previously marked line is completed.
5. Dissection using iris scissors is carried out inferiorly in a subcutaneous plane to create a skin flap. Dissection is carried out inferior to the extent of excess skin.
6. The orbicularis and orbital septum may be opened with iris scissors or cautery to expose the lower eyelid fat pads. Fat may then be resected as was described in the upper eyelid blepharoplasty or can be redraped over the inferior orbital rim to address any tear trough deformity.[9]
7. The skin flap is then redraped and any excess skin can be excised. It is important to be conservative in the amount of skin resected because this excess resection can cause retraction of the lower eyelid.
8. Close the skin with running 8-0 nylon suture or an absorbable 7-0 chromic suture. Using these microsutures with smaller needles allows for less scarring.

Transconjunctival Approach

1. Transconjunctival injection of anesthetic into the lower eyelid is performed.
2. The lower eyelid is retracted anteriorly to expose the palpebral conjunctiva.
3. Cutting cautery is used to incise the conjunctiva at the lower edge of the tarsal plate, extending the incision through the lower eyelid retractors to the level of the orbicularis.
4. Dissect inferiorly in a plane between the septum and orbicularis to expose the fat pads.
5. The fat pads can then be excised, tightened with cautery or redraped.[9]
6. The conjunctival incision can be closed with 2 or 3 interrupted 7-0 chromic sutures or may be left open after the procedure.

Postoperative Care

Patients are advised to apply antibiotic/steroid ointment to the surgical incisions twice daily for 1 week. Ice therapy is applied in the first 72 hours to reduce postoperative swelling. Patients are instructed to avoid public swimming pools and hot tubs for 1 to 2 weeks. Patients should avoid strenuous activity or bending below the waist for 2 weeks. Nonabsorbable sutures can be removed 7 to 10 days after surgery. Patients should expect postoperative swelling and bruising to persist for up to 3 to 4 weeks after surgery.

Complications

Orbital Hematoma

The most feared complication of eyelid surgery is hemorrhage behind the orbital septum, which can result in an orbital compartment syndrome and vision loss. This complication can be avoided by being judicious with tissue handling to avoid traction of the fat pads. Advising patients to stop anticoagulants or herbal medications that can cause increased bleeding is a must. Severe pain, inability to open the eyelids, and sudden decreased vision are hallmark signs that warrant urgent evaluation of the patient with the possibility of opening the incision for evacuation of the hematoma. Timely recognition and evaluation are crucial in preventing visual loss.

Asymmetry

Asymmetry of the upper lid creases can be avoided by careful and equal marking of the eyelid crease at the beginning of the procedure. Asymmetry of lid height and/or contour usually results from uneven dissection of fat and/or preexisting lid or brow ptosis.

Lagophthalmos

Mild postoperative lagophthalmos (inability to completely close the eyes) is common and typically resolves in the first few days after surgery. This can be managed with lubrication of the eyes. If it is present beyond the first week, it typically can be managed with ointment and massage of the upper eyelids. Persistent lagophthalmos is usually the result of aggressive skin removal or scarring of the orbital septum. Reoperation with lysis of scar tissue and/or skin grafting may be required in severe cases. Conservative skin removal is always preferred because further excision can be performed if needed.

• **Figure 21-13** Postoperative lower eyelid retraction and ectropion.

Lid Malposition

Ptosis of the upper eyelids can occur due to injury to the levator aponeurosis if surgical dissection was carried too deep into the eyelid structures. Gentle handling of the tissue is key. Excessive scarring and wound infections are extremely rare in the eyelids.

Complications of lower eyelid blepharoplasty include lower eyelid retraction, ectropion, and inferior scleral show. These typically occur when there is excessive removal of skin and muscle. Upward massage of the lids can be attempted in the acute postoperative period. However, persistent ectropion and/or retraction may require surgical revision with skin graft (Figure 21-13).

Ocular Surface Irritation and Dry Eyes

As mentioned previously, dryness can be transient in the initial postoperative period. This can be corrected with aggressive use of artificial tears. However, sometimes ocular surface irritation and dryness persist despite good position of the lids. In these situations, it would be appropriate to refer the patient to an ophthalmologist for further evaluation and management.

Conclusion

Blepharoplasty is a versatile procedure that can improve the function and esthetics of the eyelids. It is a relatively simple, low risk procedure that can result in substantial functional and esthetic improvement when performed correctly. Success of the procedure is dependent on a detailed understanding of the eyelid anatomy as well as careful preoperative evaluation and planning. Meticulous surgical technique will allow the surgeon to avoid postoperative complications. It is a procedure that may be easily added to any facial surgeon's armamentarium with consistent effective results.

Forehead and Brow Lift

ANGELO CUZALINA, MANIK BEDI

Introduction

Facial rejuvenation has had a steady increase in popularity over the past 25 years and upper facial procedures rank at the top of facial cosmetics with more than 203,000 blepharoplasties performed in 2015 (number two of all facial cosmetic surgical procedures) and over 40,000 forehead lifts in 2015 (number five of all facial cosmetic surgical procedures). The top minimally invasive cosmetic procedures for 2015 were Botulinum toxin type A (6.7 million) and soft tissue fillers (2.4 million), which were number one and number two, respectively, of all minimally invasive procedures.[92] The desire of the aging population to feel and look rejuvenated has led to new techniques that provide a more youthful and natural appearance and offer faster recovery. Rejuvenation of the upper third of the face is a vital component for proper treatment of the aging face.

Esthetic concerns of the forehead and brow regions affect a wide range of age groups. In contrast to standard lower face and neck rhytidectomies that are more commonly performed on patients older than age 45, cosmetic concerns in the upper third of the face may be evident for patients in their 20s and 30s because of genetic predisposition. In addition, patients who seek upper facial rejuvenation often present with complaints of excessive wrinkling, tired-appearing eyes, and excess eyelid skin. The goal of the facial cosmetic surgeon should be to restore the esthetic balance and a youthful three-dimensional facial topography. The cosmetic surgeon should take time to discuss the patient's goals and realistic outcomes and the conversation should include aging changes that occur in the upper facial region due to sun damage, gravity, bone resorption, decreased tissue elasticity, facial volume loss (deflation), and genetics.

Of all the forehead and brow lift procedures, the endoscopic forehead and brow lift has proved to be the most common and predictable of the facial cosmetic techniques.[1] Patients have benefited from smaller incisions, less morbidity, and rapid convalescence. It is not surprising that in the world of cosmetic surgery, where patients are becoming ever more knowledgeable and demanding, endoscopic procedures are increasingly popular.

The forehead and brow lift is a comprehensive operation and is not just a method used for raising the brows.[2,3] When used properly, it can address not only brow ptosis but also dynamic muscular problems (Figure 22-1). This procedure yields more dramatic facial improvement when properly and selectively combined with other rejuvenation procedures such as fat grafting, skin resurfacing, fillers, neurotoxins, and bone remodeling. Correct diagnosis of age-related changes is critical.

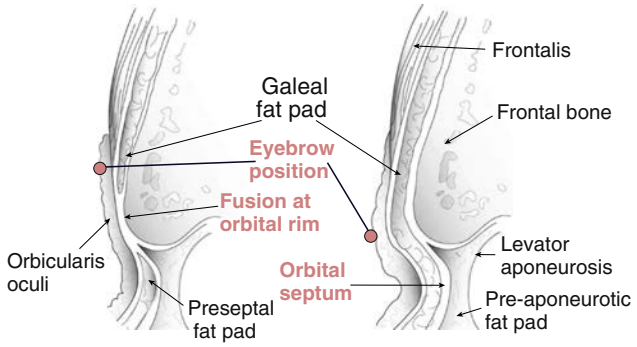
The aging process typically leads to forehead and brow ptosis for almost every patient (Figure 22-2). However, it is necessary to determine whether the ptosis seen around the forehead and brow region is due to a problem with brow position or with upper eyelid laxity, or whether it is caused by the combination of the two. Sometimes, what others may see as ptosis in the lateral brow may actually be fat atrophy that can be better rejuvenated with fat grafting than with lifting of the brow. Still other problems such as dynamic lines produced by muscle activity in the glabellar region and in the forehead itself also must be addressed. Skin texture, variable hairline patterns, bony abnormalities, and asymmetries should be evaluated.

Rejuvenation of the upper third of the face can be one of the most rewarding and fulfilling procedures one can offer to select patients. Specific elevation and correction of lateral hooding, along with a reduction in wrinkles, can result in a natural appearance yet still can impart a tremendous improvement in the patient's overall beauty and youthful appearance. The goal of this chapter is to review upper facial third anatomy and approaches to all forehead brow lift procedures, however, particular attention will be made to the senior author's personal experience of patient's preferred treatment method, the endoscopic forehead and brow lift.

Anatomic and Esthetic Considerations

It is commonly accepted that a youthful forehead represents roughly one third of the overall facial height. In essence, the distance from hairline to glabella is equal to the distance from the glabella to the point at the base of the columella

• **Figure 22-1** The two patients shown are each before and after an endoscopic brow lift. The brow lift is best suited for two primary preoperative issues; wrinkling from dynamic muscular problems and lateral hooding.



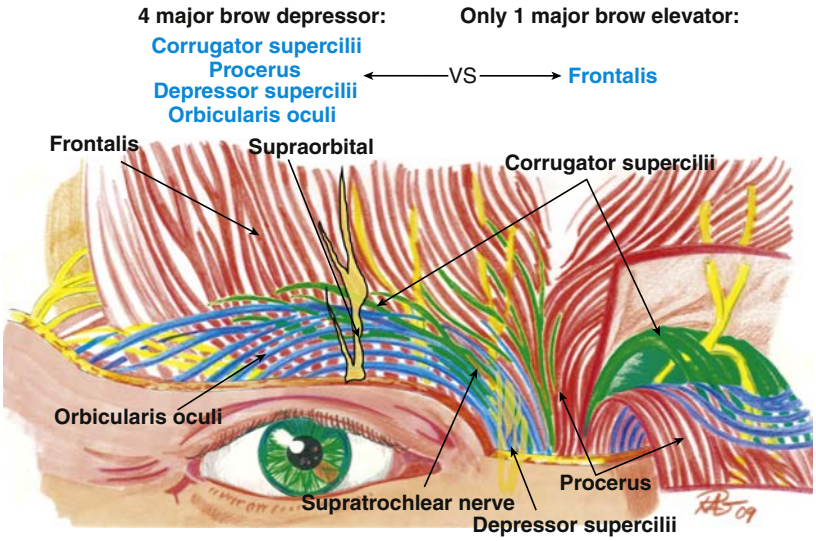
• **Figure 22-2** Cross section through brow near the lateral limbus. Compared to the youthful brow *(left)*, the aging brow *(right)* has loss of volume (including soft tissue and bone), inferior migration of eyebrow below its natural position at the level of the supraorbital rim, collagen and elastic deterioration, and changes in fat volume. The lateral eyebrow segment almost always becomes ptotic earlier in life than the medial eyebrow segment.

(subnasale). A youthful appearing eyebrow is different for men than for women. The female eyebrow should be arched with the peak point of the brow on a sagittal line of the lateral limbus of the eye. The brow itself should be positioned just above the orbital rim, in contrast to a typical male eyebrow, which should lie along the orbital rim in a more horizontal fashion.

The comprehensive anatomy of individual areas has been well described in the literature, often in relation to the specific procedure that is being performed. Therefore, the anatomic discussion can be simplified by separating the specific regions into bone anatomy, muscle and fascial anatomy, vessel and nerve anatomy, and endoscopic anatomy. Each anatomic region will be addressed specifically here so the reader will gain an understanding of surgical anatomy as it relates to the forehead and brow lift.

Bone Anatomy

The highest percentage of bony landmarks for the forehead and brow lift involve the frontal bone, and adjacent parietal bone, zygoma, maxilla, and nasal bones will be at least partially exposed when the procedure is performed. The connections (suture lines such as nasofrontal, zygomaticofrontal, and coronal) are important landmarks because they can be clinically pertinent for limits of dissection and can help the surgeon to know these locations during dissection. Case in point, the fronto-zygomatic suture line is the location at which some surgeons may elect to halt dissection for a basic brow lift. Just posterior and slightly inferior to this suture line is the sentinel vein. This vein is avoided to prevent undesirable bleeding that may complicate the



• **Figure 22-3** Forehead muscles and nerves. The major elevator of the eyebrow and forehead is the frontalis muscle. Several depressor muscles are shown through the cut frontalis: the corrugator supercilii, the procerus, the depressor supercilii, and the orbicularis oculi. Additionally, the close relationship between the depressor muscles of the eyebrow and the supraorbital and supratrochlear nerves is depicted.

procedure. Some surgeons elect to ligate and transect this vein for further tissue release. Knowledge of its location in relation to the adjacent bone landmark is critical. Additional dissection can be performed if mid-face lifting is also considered, or if the patient desires more elevation at the lateral canthal region. Elevation in the subperiosteal plane below the fronto-zygomatic suture into the cheek can be performed for increased lift in the mid-face. Overaggressive dissection into the cheek and around the orbit can create an unnatural "cat eye" appearance if too much tissue is elevated, particularly medially along the fronto-zygomatic suture line and the deep lateral canthus.

The nasofrontal suture line is an excellent landmark to note during dissection. First, dissection needs to proceed only a few millimeters below this suture level onto the nasal bones for adequate release. Second, the paired procerus muscles can be identified here and transection performed if indicated. Third, depending on the point of horizontal transection in this area, the nasofrontal angle location can be altered slightly if desired. Lastly, nasal tip rotation can be achieved if desired, particularly with considerable dissection below the nasofrontal suture line.

Another critical bony landmark is the orbital rim and associated arcus marginalis (this is where the periosteum of the frontal bone fuses with the galea), which limits inferior dissection but must be well visualized and freed of periosteal attachments if the brow and brow fat pads are to be lifted for lasting results. Significant muscle and fascial attachments are also located at the level of the orbital rim medially and laterally. The tenacious temporal fusion line that exists along the temporal ridge is important to identify during dissection; it is equally important for the clinician to know its location preoperatively, so that correct incision placement can be made to facilitate clean dissection under this area. Clean dissection, free of hanging or torn tissues, is critical for adequate endoscopic visualization.[4]

Bony thickness varies in different areas of the skull, and this must be recognized when fixation methods that drill into the skull are used. In addition, venous lakes along the diploe surface of the skull tend to be more centralized around the sagittal suture line, and drilling here should be avoided. Thickness increases posteriorly near the occiput, but screw or bone tunnel fixation here is not required. Caution must be taken to avoid bone penetration near the temporalis muscle in the lateral skull region, where the middle meningeal arteries could be injured. Awareness of average thickness for a given location and of internal anatomy is necessary before drilling into the skull is performed for any reason. The safest site used for bone tunnels or screws for brow lifting is located along a parasagittal line, approximately at the mid-pupil or lateral limbus line and just anterior to the coronal suture.

Muscle and Fascial Anatomy

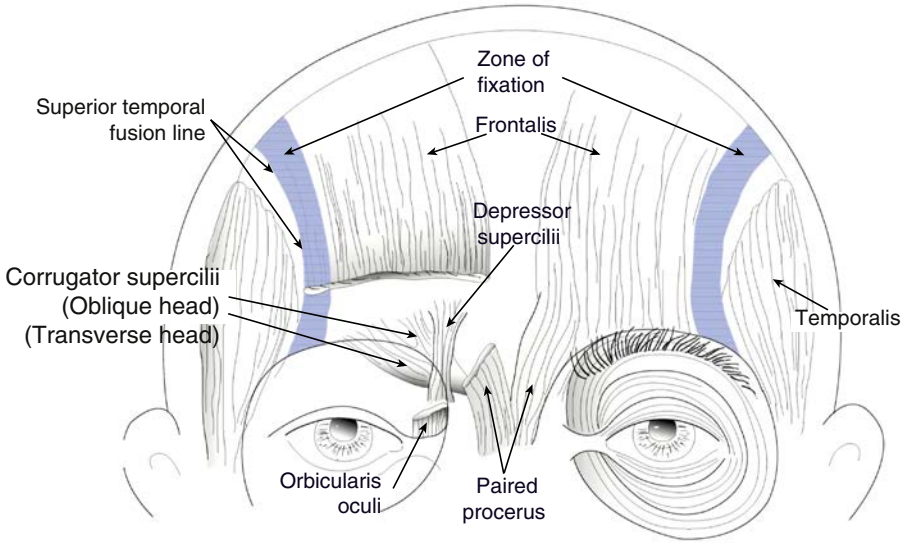
Paired muscles of the forehead and brow region are commonly thought of as elevators and depressors (Figure 22-3). Although the depressors can actually move in an oblique or circular fashion, the only true elevator of the forehead, the frontalis, moves upward to raise the brow. This movement, along with some static tone, maintains brow position and can produce horizontal creases over time. The frontalis muscle originates from the deep galeal plane (galea aponeurotica that connects to the occipital muscle posteriorly).[5,6] It inserts into the orbital portion of the orbicularis oculi muscle inferiorly, and this inserts into the dermis immediately below the eyebrow. Its lateral extension fuses into the dense collection of fascia approximately 1 cm wide, called the *zone of adherence;* this zone runs the length of the superior temporal line and ends inferiorly just above the zygomaticofrontal suture at an attachment of fascia known as the

orbital ligament. These areas are important clinical anatomic regions because freeing the zone of adherence is necessary to achieve good long-term results with lift procedures. Care is required in this region to avoid overzealous stretching and injury to the facial nerve.

The acronym SCALP applies in the forehead for the standard layers: skin, subcutaneous tissue, aponeurosis (the thick galeal fascia), loose areolar (subgaleal) plane, and periosteum. The galeal fascia has simply blended into the frontalis muscle and its midline fascial attachments at the forehead level. This allows sliding movement over the scalp with contraction of the muscle. The frontalis and the galea may be thought of as an extension of the temporoparietal fascia in the temporal region and in the SMAS (superficial musculoaponeurotic system) below the level of the zygomatic arch. The temporoparietal fascia appears somewhat spongy and houses the frontal branch of the facial nerve on its undersurface in the temporal region.

Several other paired forehead and brow muscles thought of as "depressors" are present along the brow and facilitate facial expression. The two most well recognized of these are the procerus and the corrugator supercilii muscles, which are present in the glabella. The procerus muscles are paired superiorly but fuse inferiorly into a single muscle belly that originates on the nasal bones and cartilages. It inserts into the midline intervening medial frontalis muscle fibers and the overlying dermis. The procerus is responsible for depression and frowning between the eyes that often creates a horizontal crease (bunny line) across the upper portion of the nose. The corrugator supercilii muscles are depressors that act obliquely across the glabella and form the classic vertical lines seen during squinting or frowning. These muscles create an "angry" appearance. The corrugator supercilii originates from the frontal bone just above the nasal bones and inserts into the dermis of the medial brow. The corrugator has two heads, the oblique and the transverse, which act in unison to pull the medial brow down and together. Collectively, the paired procerus and corrugator muscles are the main depressors of the medial brow and are the muscles most commonly treated with Botox to help alleviate frown lines in the glabella. These same two muscles are most often transected during an endoscopic brow or forehead lift to achieve a smooth and long-lasting result.

Another depressor muscle of importance is the depressor supercilii muscle, which originates on the frontal process of the maxilla just inferior and superficial to the origin of the corrugator supercilii. It inserts into the medial frontalis fibers and dermis just above the medial brow. The depressor supercilii is important because it is superficial to the corrugator and is easily treated inadvertently with Botox. It is also important because it lies behind the corrugator during a brow lift and can be transected via aggressive dissection through the corrugator muscle. Although a few patients with very low medial brow position may occasionally benefit from this maneuver, it more often causes over-elevation of the medial brow and creates the "surprised" look. Superficial to the depressor supercilii is the orbital portion of the orbicularis oculi, which inserts into portions of the adjacent depressors, the surface of the inferior frontalis, and the dermis below the brow. The orbital portion of the orbicularis muscle originates, to some extent, from the medial canthal tendon and from adjacent bone (Figure 22-4). Deep to all the depressors is the galeal fat pad, which lies directly below the transverse head of the corrugator and helps to reveal the locations of muscular landmarks when it is exposed clinically after transection through the periosteum along the orbital rim.



• **Figure 22-4** The depressor muscles, including the cut edge of the orbital portion of the orbicularis oculi that inserts into portions of the adjacent depressors, are shown here and can be seen anterior to the depressor supercilii. The orbital portion of the orbicularis muscle originates, to some extent, from the medial canthal tendon and from adjacent bone. Separating the plane of dissection into a subperiosteal plane medially and just above the temporalis fascia laterally is the temporal crest with its 1 centimeter "zone of adherence."

Lastly, paired temporalis muscles are located in each temporal fossa, where they originate and then insert onto the coronoid process of the mandible. The importance of these muscles during upper facial rejuvenation is most often related to its overlying temporalis fascia, which can be used to delineate surgical planes and aid in fixation. The temporalis fascia is adherent to the temporalis below and splits into superficial and deep layers in the lower half of the fossa. For consistency, the superficial layer of the deep temporalis fascia describes only that portion of the deep temporalis fascia that is present at the level of the split; the area below is referred to simply as the temporalis fascia, that is, the deep, thick fascial layer seen clinically from the temporal crest down to the zygomatic arch. The spongy temporoparietal fascia, which is superficial to the dense and glossy white–appearing temporalis fascia, houses the frontal branch of the facial nerve within its deep surface.

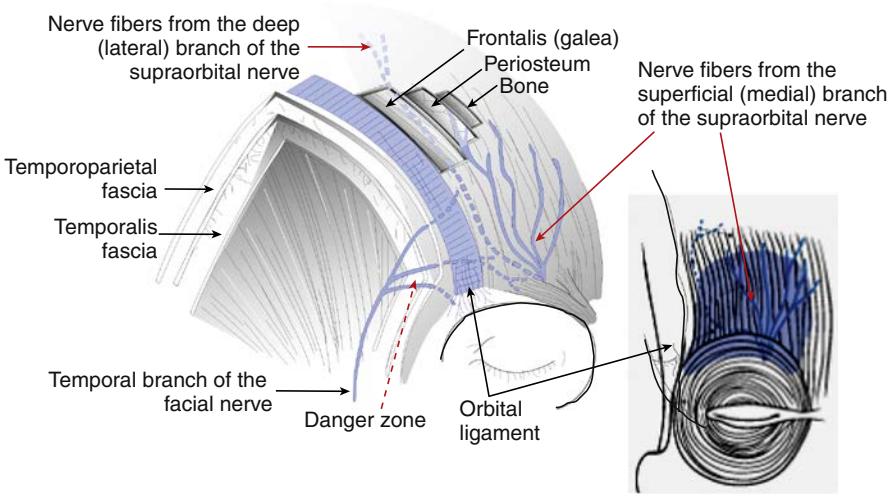
One method of fixation that may be performed during brow lifting involves using suture to fixate the temporoparietal fascia from below a skin incision to the adherent temporalis fascia in a more superior position, to elevate the lateral brow and upper cheek. Some surgeons advocate removing a window of temporalis fascia during this suture fixation procedure and exposing the underlying temporalis muscle in the hope of gaining additional fibrosis and improving fixation longevity.

Vessel and Nerve Anatomy

Perfusion to the upper face and scalp is excellent and comes from multiple sources. Several major blood vessels of the upper face and scalp, including the superficial temporal artery and the facial artery, originate from the external carotid. These give rise to the blood supply in the medial canthal region via the angular artery and in the lateral canthal region via the frontal or anterior branch of the superficial temporal artery. The internal carotid artery branches to the middle meningeal artery and to the ophthalmic artery, which gives rise to the supraorbital and supratrochlear arteries that exit their respective foramina and supply most of the forehead and mid-scalp region. The terminal arterial branches of the upper face have multiple significant anastomoses with adjacent vessels.

Venous drainage of the upper face follows the respective arterial supply, although this pattern can vary. Still, one particular vein that is relatively consistent is known as the *sentinel vein* (medial zygomatico-temporal vein); this vein runs perpendicularly through the temporalis fascia at a location approximately 2 cm lateral or posterior to the lateral canthus. It is clinically significant during open and endoscopic procedures because of the problems that are created by injury to it, such as bruising and impaired visualization. As one elevates the tissues inferior to the zygomatico-frontal suture in the subperiosteal plane, care must be taken to avoid careless dissection laterally, where the sentinel vein can be accidentally torn.

Nerve supply parallels arterial supply to some extent. The supratrochlear and supraorbital nerves, which account for most sensation to the forehead, exit the same foramina or notch as the same named blood vessels. These sensory nerves originate from the first division of the trigeminal nerve. The supraorbital nerve has two divisions after it emerges from the frontal bone: (1) the deep (or lateral) division that supplies the more lateral and posterior portion of the forehead and scalp (Figure 22-5), and (2) the superficial (or medial) division that pierces the frontalis early in its course and runs superficial to the muscle, supplying sensation to the lower forehead and the mid-forehead along the mid-pupil line.



• **Figure 22-5** The supraorbital nerve has two divisions, seen here after they have emerged from the frontal bone. The deep (or lateral) division supplies the more lateral and posterior portion of the forehead and scalp and is the more commonly injured nerve during endoscopic brow lifting. The superficial (or medial) division of the supraorbital nerve pierces the frontalis muscle early in its course and runs superficial to the muscle, supplying sensation to the lower and mid-forehead along the mid-pupil line. It is more commonly injured during a subcutaneous trichophytic brow lift.

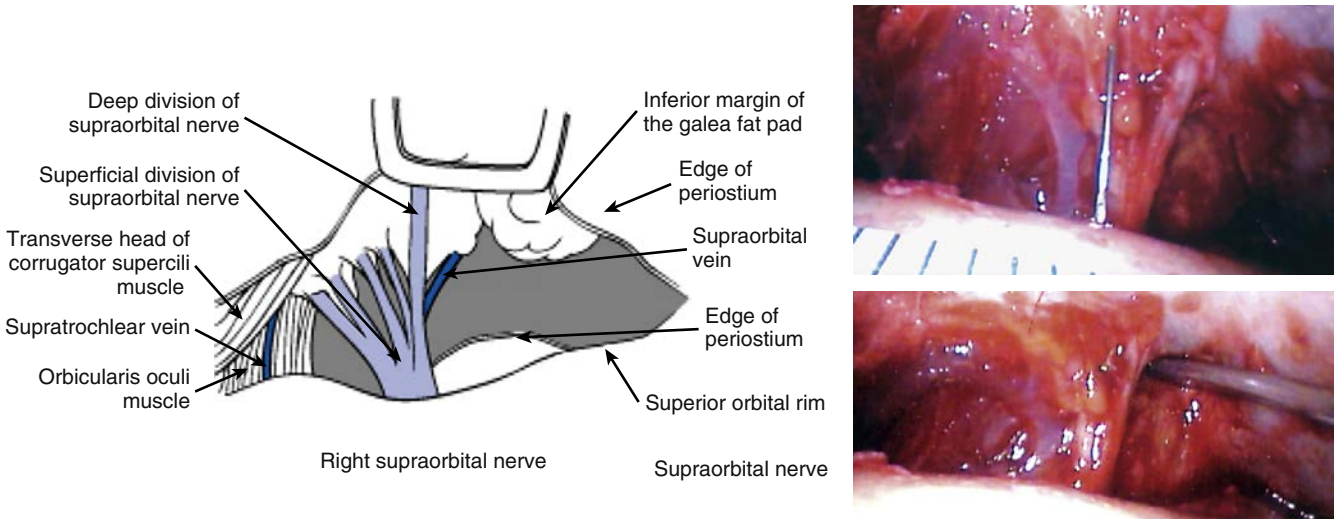
• **Figure 22-6** The supraorbital foramen or notch typically is found within 1 mm of a line drawn in a sagittal plane tangential to the medial limbus, as shown here. This point can be marked on the skin of the brow to give the surgeon a reference point from which the exit point of this important structure and adjacent key muscle groups can be identified. Knowledge of the important anatomic structure allows more aggressive but safe release of tissue, to provide significant elevation in areas such as the lateral third of the brow, as seen here after 18 months.

The bony exit point of the supraorbital nerve is relatively consistent. The supraorbital foramen or notch typically is found within 1 mm of a line drawn in a sagittal plane tangential to the medial limbus (Figure 22-6).[7] This point can be marked on the skin of the brow to give the surgeon a reference point that reveals the exit point of this important structure (Figure 22-7). The deep division has been known to exit as often as 10% of the time from another foramen that may be as high as 1.5 cm above the orbital rim. Therefore, some surgeons advocate that blind (nonendoscopic) inferior dissection from the scalp above should be performed only to within 2 cm of the orbital rims, and that should be followed by endoscopic guidance below this point to decrease the chances of nerve injury.[8-13]

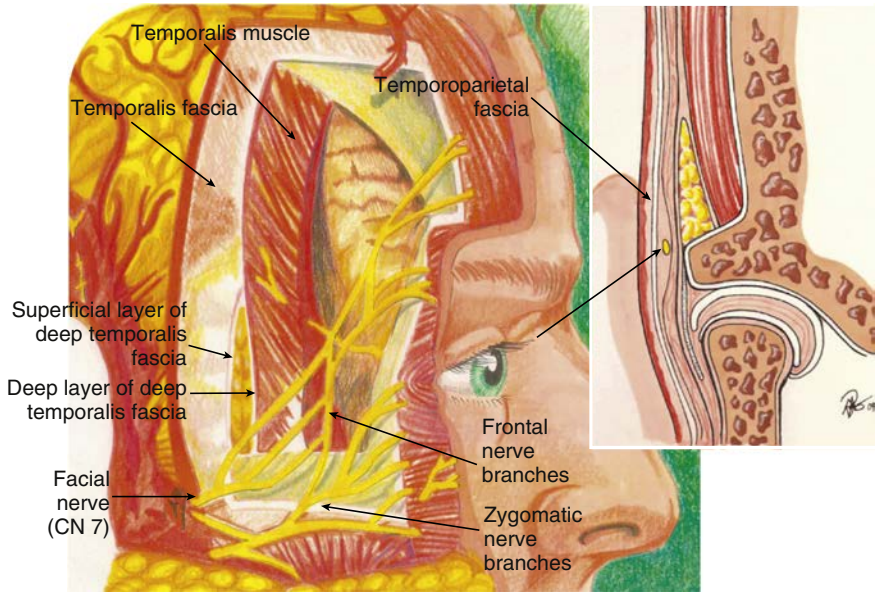
The supratrochlear nerve on each side exits near the orbital rim an average of 9 mm medial to the exit of the supraorbital nerve. The paired nerves supply sensation to the midforehead with some overlap from the supraorbital nerves. Infratrochlear nerves that also originate from division one of the trigeminal nerve exit just below the supratrochlear nerves around the medial orbital rim to supply sensation to the upper nose and the medial orbit. Zygomatico-frontal and zygomatico-temporal nerves originate from the second division of the trigeminal nerve to exit their respective small foramina and supply sensation to the lateral orbit and the temporal regions of the face.

Motor innervation to the forehead and the glabella is supplied by the facial nerve (cranial nerve VII) (Figures 22-8 and 22-9). The frontal (or temporal) branch of the facial nerve supplies the frontalis muscle, the superior portion of the orbicularis oculi muscle, the superior portion of the procerus muscle, and the transverse head of the corrugator supercilii muscle; the zygomatic branch supplies the medial head of the orbicularis oculi muscle, the oblique head of the corrugator supercilii muscle, the inferior portion of the procerus muscle, and the depressor supercilii muscle (Figure 22-10).

The auriculotemporal nerve originates at the third division of the trigeminal nerve; it supplies sensation in front of the ear, to the temporal skin above the zygomatic arch,

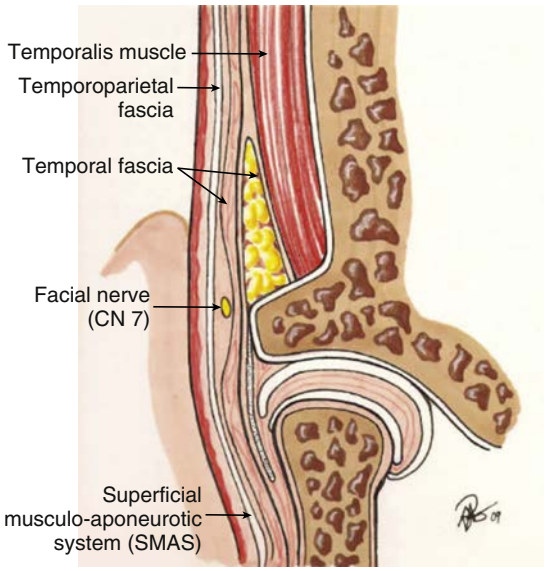


• **Figure 22-7** Right side endoscopic view. A needle can be seen on a right side endoscopic view; it was placed through the skin at a point marked in the sagittal plane tangential to the medial limbus and through the brow skin. This illustrates how accurate this technique is for preoperative identification of the location of the supraorbital nerve.

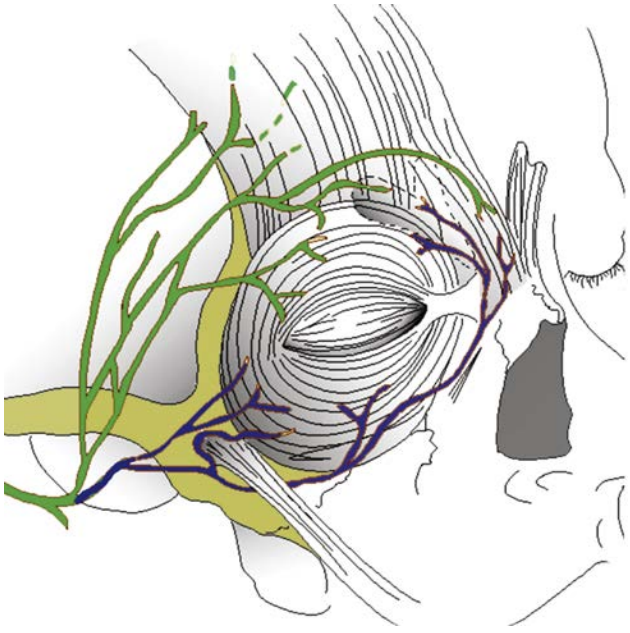


• **Figure 22-8** Motor nerves and fascia of the upper face. Knowledge of the tissue layers overlying the forehead and temple is critical to avoid nerve injury and perform surgery safely. The frontal nerve lies on the deep side of the temporoparietal fascia.

and to the skin that courses along the superficial temporal artery. This nerve may be confused clinically with the frontal branch of the facial nerve during a face-lift or while temporal dissection is performed during brow-lifting procedures.[14-16] It can be distinguished from the facial motor nerve in that this sensory nerve runs within 1 cm in front of the tragus of the ear and parallels the superficial temporal artery. In a 1979 article by Al-Kayat and Bramley the location of the facial nerve's main trunk was described and it was found that it runs no nearer than 1.5 cm below the inferior margin of the bony external auditory meatus and that the most posterior temporal branch of the nerve crosses the zygomatic arch anterior to the bony external auditory meatus at a minimum distance of 0.8 cm and mean of 2.0 cm.[89] A more recent high-resolution MRI study of live subjects measured a minimum distance of 1.7 cm and mean of 2.1 cm.[90] Another anatomic study of interest discussed the facial nerve's path in three dimensions. The study showed that the temporal branch lies in the loose areolar connective tissue layer between the superficial and deep temporal fascia as it crosses the zygomatic arch; it enters the superficial temporal fascia from its undersurface in a consistent region



• **Figure 22-9** Cross section through the temporomandibular joint and zygomatic arch. The temporal nerve runs immediately below the temporoparietal fascia above the arch, which is the fascia continuous with the superficial musculoaponeurotic system below the arch.



• **Figure 22-10** As highlighted in *green,* the frontal (or temporal) branch of the facial nerve supplies the frontalis muscle, the superior portion of the orbicularis oculi muscle, the superior portion of the procerus muscle, and the transverse head of the corrugator supercilii muscle. As highlighted in *blue,* the zygomatic branch of the facial nerve supplies the medial head of the orbicularis oculi muscle, the oblique head of the corrugator supercilii muscle, the inferior portion of the procerus muscle, and the depressor supercilii muscle. Therefore, when these muscles are transected, contraction occurs away from the cut in each direction.

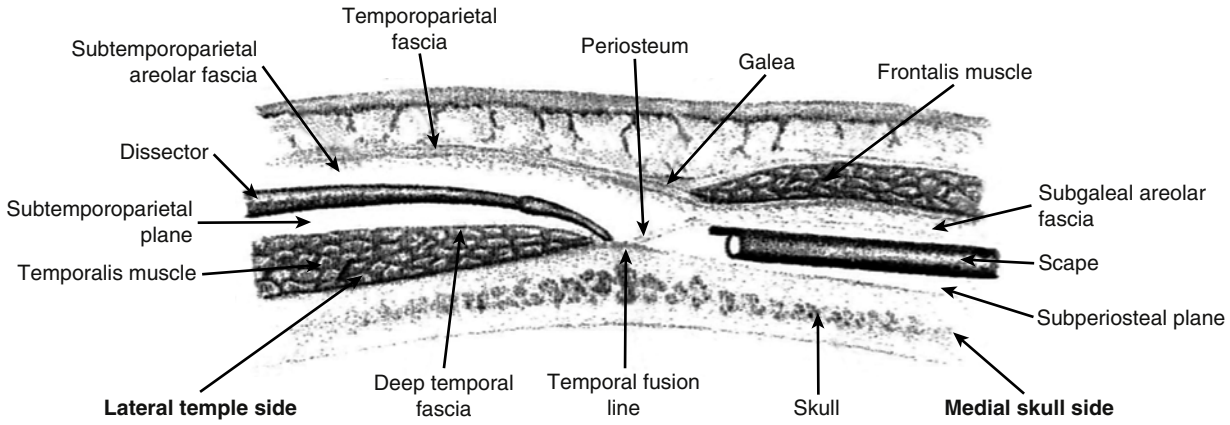
1.5 to 3.0 cm above the zygomatic arch and 0.9 to 1.4 cm posterior to the lateral orbital rim.[91] The frontal branch of the facial nerve typically has already divided into two rami at the level of the arch and into at least four branches by the time it reaches the level of the eyebrow.

Endoscopic Anatomy

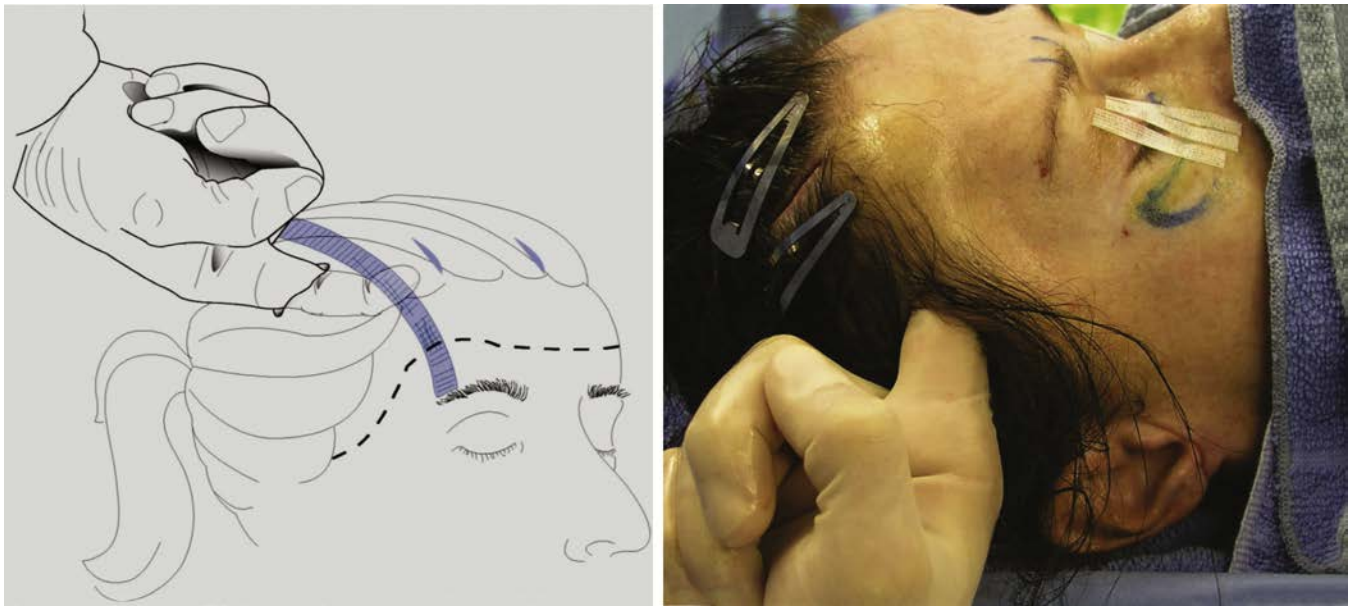
Initial dissection prior to placement of an endoscope must be performed to gain adequate space for the equipment. Early (partially blind and blunt) dissection is performed in the posterior scalp, in the mid-forehead and upper forehead, and in temple regions, leaving endoscopic guided dissection for the inferior forehead, beginning 2 cm above the orbital rim and the zygomatic arch. It is this author's preference to work in a completely subperiosteal plane medial to the temporal crest and in the plane immediately above the temporalis fascia below the temporal line on each side (Figure 22-11). Subperiosteal dissection in the medial forehead helps to prevent injury to the deep or lateral division of the supraorbital nerve, which runs in the subgaleal plane near the zone of fixation. Others begin their dissection in a subgaleal plane in the posterior scalp.[17-32] Regardless of preference, a space must be created in the upper areas of the scalp to allow ample room for placement of an endoscope to aid dissection in the lower forehead near important anatomic structures.

The first anatomic landmark that the surgeon meets early in dissection is the zone of fixation along the superior temporal crest. The upper portion can be released bluntly with the use of finger dissection and/or periosteal elevators. However, the inferior edge of the temporal crest found near the superior-lateral orbital rim usually requires endoscopic guidance for maximum release. Fibers condensed from the periosteum, galea, temporalis, and temporoparietal fascia interlace and fuse to form a zone of adherence at this part of the upper lateral orbital rim, much in the same way that the layers of tissue planes condense at the level of the zygomatic arch (Figure 22-12). A less tenacious zone of adherence is present along the entire temporal crest that can be elevated bluntly at the hairline level and a couple of centimeters below; however, as one approaches the lateral brow, endoscopic guidance and sharp dissection are most often needed for this increasingly adherent tissue plane, which is sometimes referred to as the orbital ligament at the orbital rim (Figure 22-13). The temporal nerve has branches within this ligamentous type of structure just above the brow level, and care must be taken to stay intimately close to the bone and the temporalis fascia to avoid nerve injury. Another fibrous attachment known as the orbicularis-temporal ligament is also nearby; it contains small motor nerve fibers. The orbicularis-temporal ligament represents the decussation of fibers from the temporoparietal fascia and fibers from the temporal fascia that extends laterally, away from the orbital ligament.

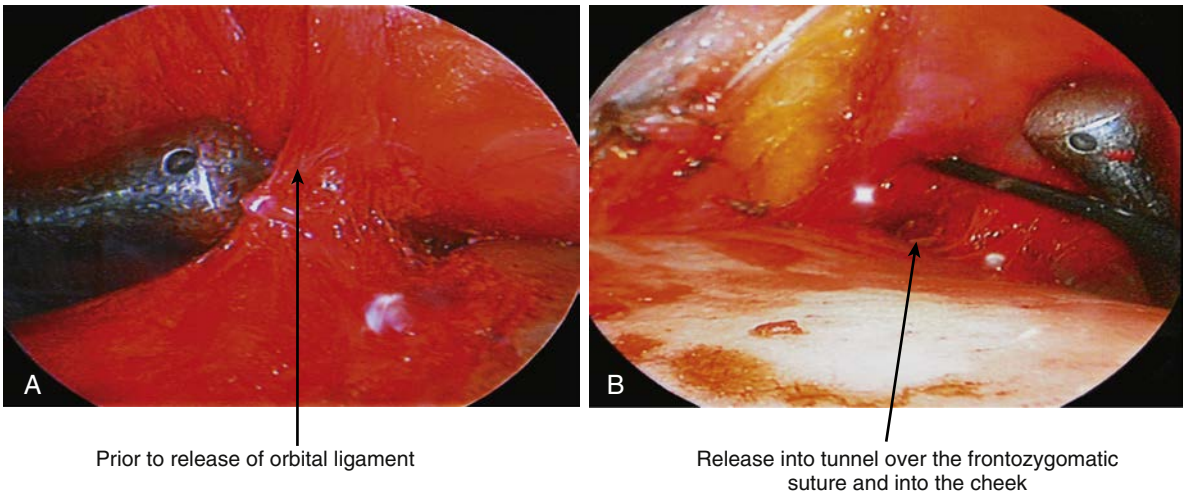
The zone of adherence becomes most firm near the orbital ligament at the orbital rim level; slow, meticulous dissection is required at this point to avoid nerve injury, as well as injury to the sentinel vein, which is located within the orbicularis-temporal ligament approximately 1 cm lateral and inferior to the zygomatico-frontal suture.[33-41] Careful dissection can expose an intact sentinel vein that can be seen piercing



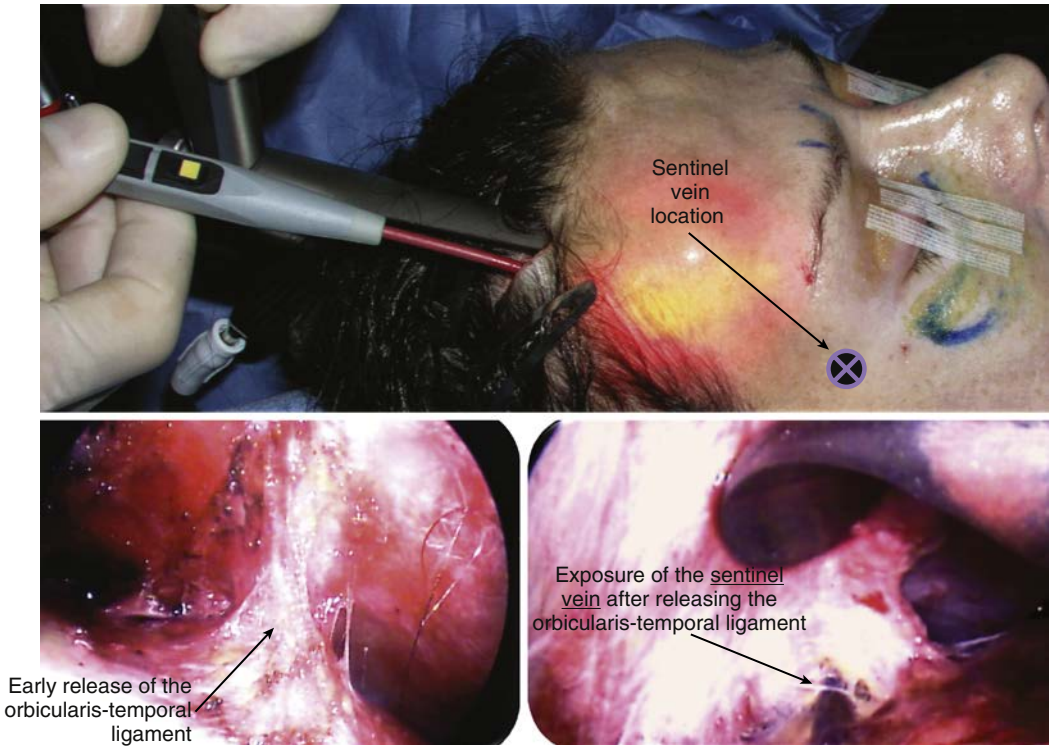
• **Figure 22-11** The temporal incisions can be very helpful as suction ports if the medial ports are too occupied with the endoscope and the cautery device. In this diagram the dissector or suction is in the temporal incision below the temporoparietal fascia and the scope is in the medial (parasagittal) incision in the subperiosteal plane.



• **Figure 22-12** The tenacious zone of adherence along the entire temporal crest can be elevated bluntly at the hairline level and a couple of centimeters below. It is critical when one is performing an "endoscopic" brow lift to elevate from lateral to medial, blunted as seen here to avoid creating a "false" tunnel if dissection is begun from the opposite direction.



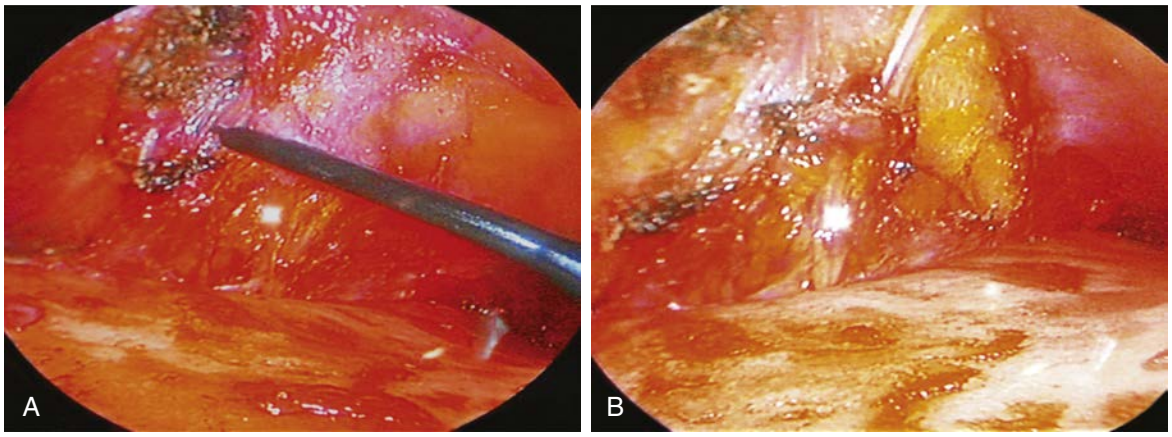
• **Figure 22-13** **A,** The left lateral orbital ligament before release. **B,** The right orbital ligament is shown after partial release immediately lateral to a subperiosteal tunnel created over the frontozygomatic suture and into the cheek.



• **Figure 22-14** Orbital ligament release is critical for adequate brow lift stability. Shown here is the endoscopic release of the orbital ligaments to gain access to the lateral orbicularis oculi. The sentinel vein is at the inferior edge of the ligament and can be cauterized, ligated, or avoided. The vein is typically located 1 cm lateral to the frontozygomatic suture.

through the temporal fascia at a perpendicular angle to enter the temporoparietal fascia above (Figure 22-14).

Dissection medial to the lateral orbital rims in the subperiosteal plane should expose the entire superior orbital rim from each zygomatico-frontal suture. The curvature of the rims then must be visualized so that transection through the periosteum can be made at rim level (arcus marginalis). The nasofrontal suture may not always be seen but can be felt via the periosteal elevator used to elevate tissue into the upper nasal region. During transection through the periosteum across the entire orbital rim, subgaleal fat often is encountered immediately, except when one is working directly behind the supraorbital nerve at the rim level where the deep (or lateral) division of the nerve is closely adherent to the periosteum. Preoperative marking of a point on the brow at a level tangential with the medial iris (limbus)



Initial transection through right corrugator

Release of periosteum higher above SO nerve

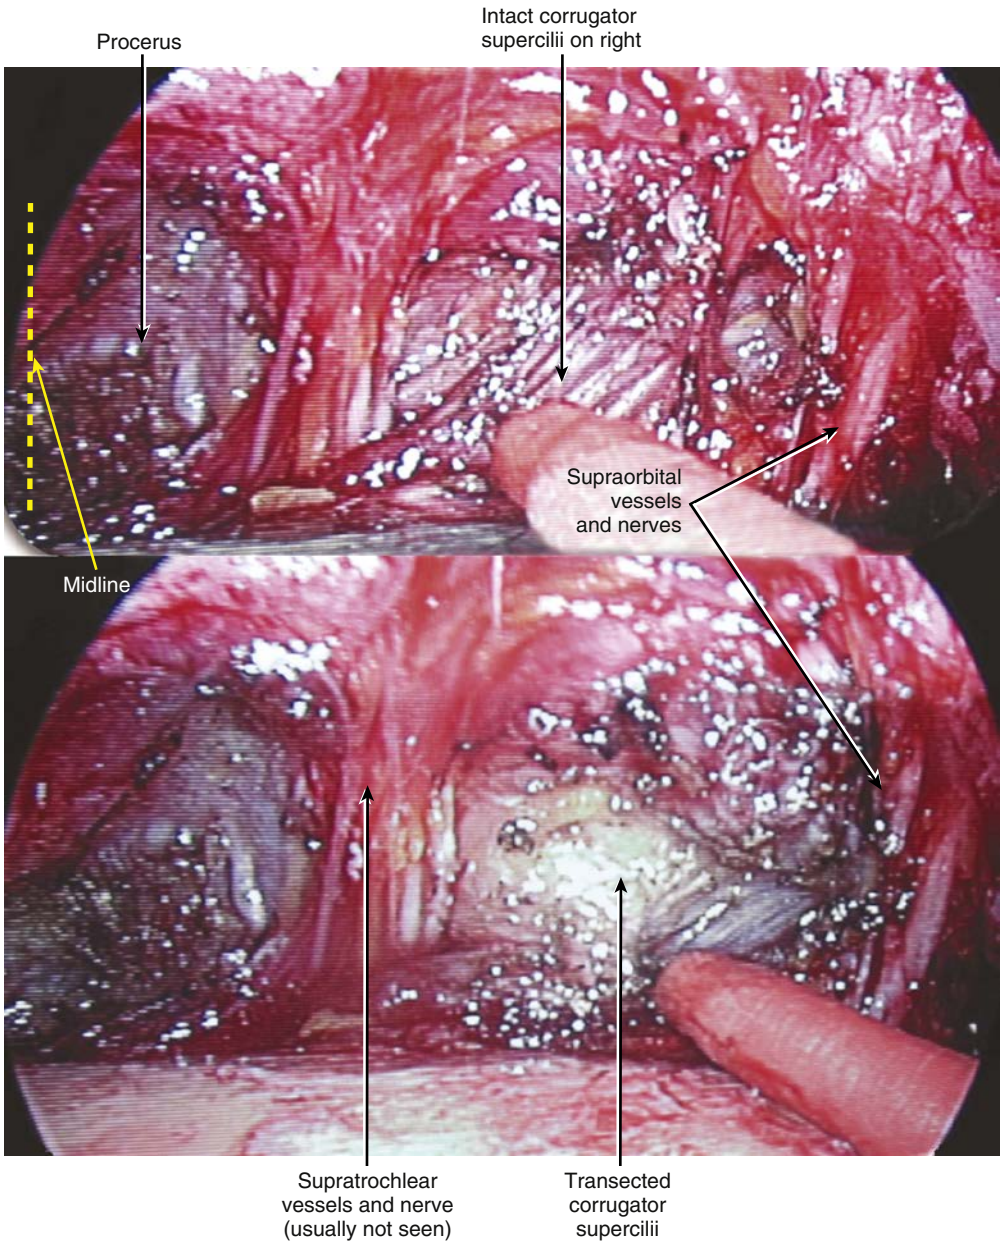
• **Figure 22-15** Periosteal release can be performed 1 to 2 cm above the arcus marginalis at the location of the supraorbital nerve as shown to avoid accidental transection of the base or trunk of the nerve. **A,** Early transection of the corrugator muscle. **B,** Release of periosteum is at the arcus marginalis except in the area of the supraorbital nerve where it is made 2 cm above the orbital rim.

reveals the location of the supraorbital vessels and nerves, so that dissection through the periosteum in this region is performed slowly and superficially to avoid injury to these structures (Figure 22-15). The transverse head of the corrugator supercilii is evident at the orbital rim level behind a portion of the supraorbital vessels and nerves. The corrugator muscle can be transected or partially excised here as well as medially. As dissection proceeds medially, the oblique head of the corrugator is encountered; with transection through this portion of muscle, the supratrochlear nerve and the depressor supercilii muscle may be seen and protected from injury (Figure 22-16). Medially in the glabella, the procerus muscle is seen and is variable in thickness. Care should be used to avoid over-resection in thin patients to prevent an atrophic defect in the glabella caused by excessively aggressive muscle resection. Deeper dissection toward the skin level under the brow will lead to the orbicularis oculi but is not necessary to gain the desired effect, except in the lateral orbicularis, where limited transection may improve lateral brow elevation. Also, transection through the periosteum can be performed at higher levels under the frontalis muscle in the midline but is required only when deep horizontal lines are present. It is important to gain complete release of the retaining lateral ligaments, transection of those muscles that are causing glabellar lines, and adequate separation of periosteum along the orbital rim to attain elevation of the brow and forehead tissues.

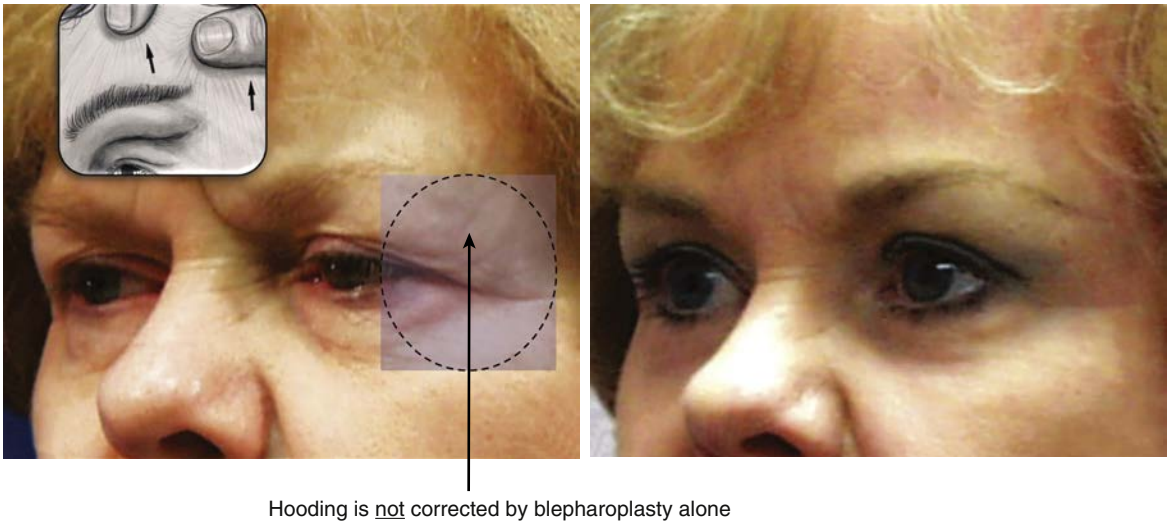
Preoperative Assessment and Treatment Goals

To ensure that a patient will not be disappointed, the clinician must determine whether that patient would benefit from a brow or forehead lift and must select the most appropriate surgical procedure. Four features of the upper third of the face are usually addressed by cosmetic surgeons. One or more of these aspects can be the focus of complaint and thus dictate the treatment goals and surgical approach. The four features are skin quality, rhytides, brow position, and eyelid redundancy/medial fat pat protrusion. Frequently, the novice surgeon may see only horizontal forehead lines as an indication for a brow lift. Unfortunately, this is much less of a problem for most patients than is a low lateral brow position (hooding) or glabellar creasing (Figures 22-17 and 22-18). As was previously discussed, the ideal female brow position is above the orbital rim level laterally and is variable, but on average, it appears 5 to 10 mm above the rim in the lateral one third of the brow. Men require a more straight-up elevation of the entire brow to avoid feminization of their appearance (Figure 22-19). Also, men may benefit from a standard upper blepharoplasty and a local transpalpebral brow lift if brow ptosis is nominal. As with any cosmetic surgery, a risk/benefit decision is made that is good for both the surgeon and the patient. Patients must be educated about the risks and about what can *realistically* be achieved. Even with fairly radical muscle resection and forehead elevation, new dynamic lines often are formed in the upper face and the glabella following surgery. Lateral crow's feet lines caused by action of the orbicularis oculi and by smiling may appear improved following a brow lift that is achieved by unfolding of the muscle; however, these lines are not completely treated by brow lifting alone, and the patient must understand that other treatments such as neurotoxin therapy may be required to manage these particular lines on an ongoing basis.

In addition to brow ptosis and lines in the forehead and glabella, the condition of the patient's skin must be evaluated. Intrinsic skin damage and collagen changes from the effects of sun, age, and smoking cannot be treated by lifting alone. Topical skin care (e.g., Retin A, microdermabrasion, pulsed light therapy, sun block), along with possible surgical resurfacing, must be considered. In general, the forehead can be treated carefully with simultaneous chemical peels

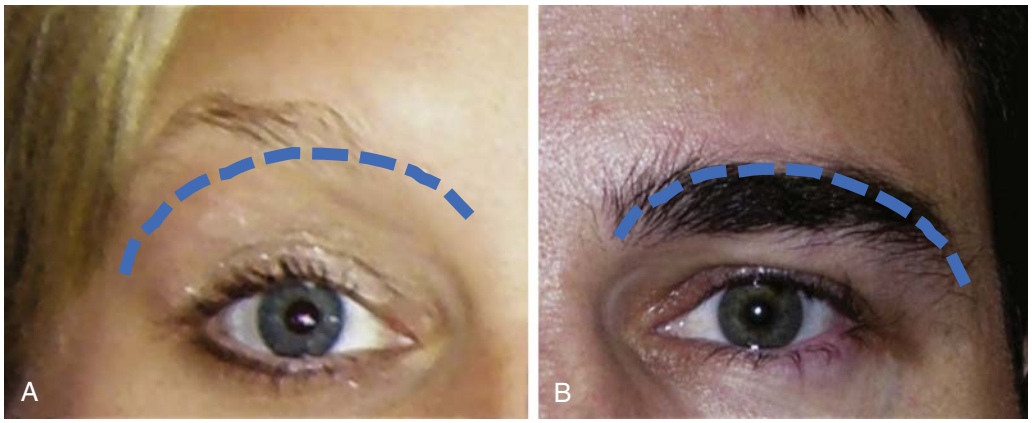


• **Figure 22-16** Right side endoscopic view of the close relation of corrugator supercilii with supraorbital neurovascular bundle and supratrochlear neurovascular bundle (typically not seen). Before transection *(above)* and after *(below).*



• **Figure 22-17** The brow lift is required for maximum esthetics in patients with lateral hooding and heavy dynamic glabellar rhytides. A 55-year-old woman 6 months following a brow lift and simultaneous upper and lower blepharoplasty. Blepharoplasty or brow lifting alone would probably have been inadequate treatment to fully improve the extreme laxity and lateral hooding.

• **Figure 22-18** A brow lift versus a blepharoplasty depends on hooding and lateral brow position. Preoperative and postoperative **(A)** images of a female patient who has relatively good brow position with lateral hooding only and obtained a very nice result from upper blepharoplasty alone. Preoperative and postoperative **(B)** images of a female patient who required both brow lifting and blepharoplasty because of severe lateral hooding and laxity of the eyelid skin after lifting the brow.



• **Figure 22-19** The female eyebrow **(A)** should be arched above the superior orbital rim, with the highest point of the brow on a sagittal line from the lateral canthus, whereas the typical male eyebrow **(B)** should lie at or only slightly above the orbital rim in a more horizontal or uniform arch fashion.

or laser skin resurfacing into the dermal level when brow-lifting procedures are performed, provided that the lifting technique is a subgaleal or subperiosteal technique rather than a subcutaneous lift. As a final point, bony irregularities or hypertrophic bony orbital rims can be evaluated for treatment by means of a cephalometric radiograph or a computed tomography (CT) scan as required. Bony contouring can be performed on a limited basis endoscopically, but major reduction for serious bone hypertrophy such as frontal bossing is best attained through an open (coronal) approach. Bone reduction is limited by pneumatization of the frontal sinus and is best evaluated by CT. Treatment planning for placement of bone tunnels for fixation with brow lifts does not require a preoperative CT scan; however, a standard cephalometric radiograph may reassure the surgeon regarding the thickness of available corticocancellous bone.

Forehead length, hairline adjustment, and other goals of treatment will require the appropriate procedure for rejuvenation of the upper third of the face. The classic coronal lift corrects the eyebrow, forehead, and glabella through a hidden scar in the hairline. Although currently considered to be too large an incision, this technique also moves the hairline

posteriorly and may be inappropriate for patients with a long forehead. Patients with a high hairline/long forehead and eyebrow ptosis may best benefit from the trichophytic technique. This procedure allows the surgeon to shorten the forehead but risks the patient having a visible anterior hairline scar.[93]

Eyebrow asymmetry with or without ptosis can be addressed by using a direct eyebrow lift technique, which has the advantage of a lower incidence of postoperative forehead hypoesthesia. The mid-forehead technique can also be used to raise the eyebrows and correct asymmetry. Both the direct and mid-forehead techniques create a likely risk of a visible scar above the eyebrow or in the mid-forehead, respectively.[94]

The endoscopic forehead and eyebrow lift has gained tremendous popularity because it is minimally invasive in comparison to the coronal and trichophytic operations. Endoscopically, the cosmetic surgeon can correct eyebrow, forehead, and glabellar signs of aging with less hypoesthesia and chance of alopecia. Drawbacks include the need for special instrumentation, a significant learning curve, and minor elevation of the patient's hairline.

As with any surgical procedure, appropriate blood tests and other indicated tests must be performed. The patient should be thoroughly instructed on the critical need to avoid all medications that may cause platelet dysfunction (including aspirin, other nonsteroidal anti-inflammatory drugs [NSAIDs], vitamin E, and many over-the-counter herbal medications) for 14 days prior to surgery.

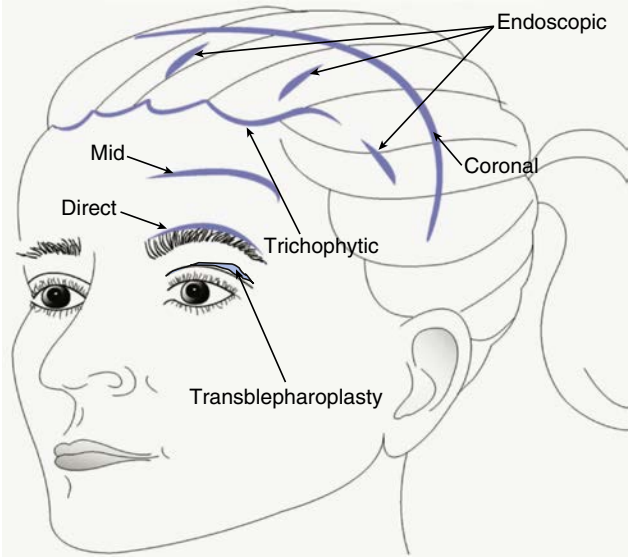
Treatment Approaches and Techniques

The longevity and minimal morbidity associated with endoscopic forehead and brow lift procedures have made this sought after by patients and an invaluable tool for every facial cosmetic surgeon. However, knowledge of the open techniques is still an absolute necessity for becoming comfortable with the endoscopic technique, as with any minimally invasive procedure. The endoscopic approach is not without limitations, and an open procedure may sometimes be needed to correct the patient's specific complaint (Figures 22-20 and 22-21).

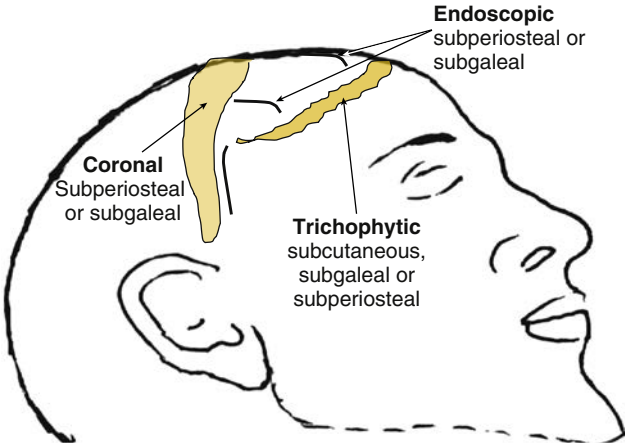
Endoscopic Forehead and Brow Lift Technique

Early attempts at endoscopic surgery began more than a century ago with a crude cystoscope. Nevertheless, modern surgical endoscopy did not gain significant popularity until the 1980s. Endoscopic surgery was begun with upper GI exams, followed by intra-abdominal surgery. Facial endoscopic cosmetic surgery did not really begin until the early 1990s. Yet, over the past 20 years, the endoscopic forehead and brow lift procedure come to be considered by many the state-of-the-art procedure for upper facial rejuvenation. It is predictable and versatile and can be combined with many other techniques. The most notable benefits of the endoscopic technique include smaller scars hidden in the hairline and selective brow elevation without the need for removal of any skin or hair.

Endoscopic techniques require a very dry operating field; thus strict avoidance of medications that can cause platelet dysfunction or excessive bleeding is required, as is proper preoperative injection of vasoconstrictive agents. Prior to administration of anesthesia, five standard photos are taken and the patient is marked while awake and sitting up. After induction of general or IV sedation, the patient is prepped and is injected with local anesthesic with epinephrine. It is the author's preference to administer 1% lidocaine combined with 1:100,000 epinephrine along the entire superior orbital rim, glabella, and lateral orbital rim. Tumescent anesthesia solution (250 mL normal saline mixed with 1 mL 1:1000 epinephrine and 20 mL 2% lidocaine) then is injected into the remaining upper forehead, temple, and posterior scalp. Careful injection into desired tissue planes helps to prevent hematoma formation during injection and allows for a nearly bloodless procedure. Minor shaving of hair along the marked incision lines can be performed if desired immediately before the final prep and drape, but this usually is not necessary.



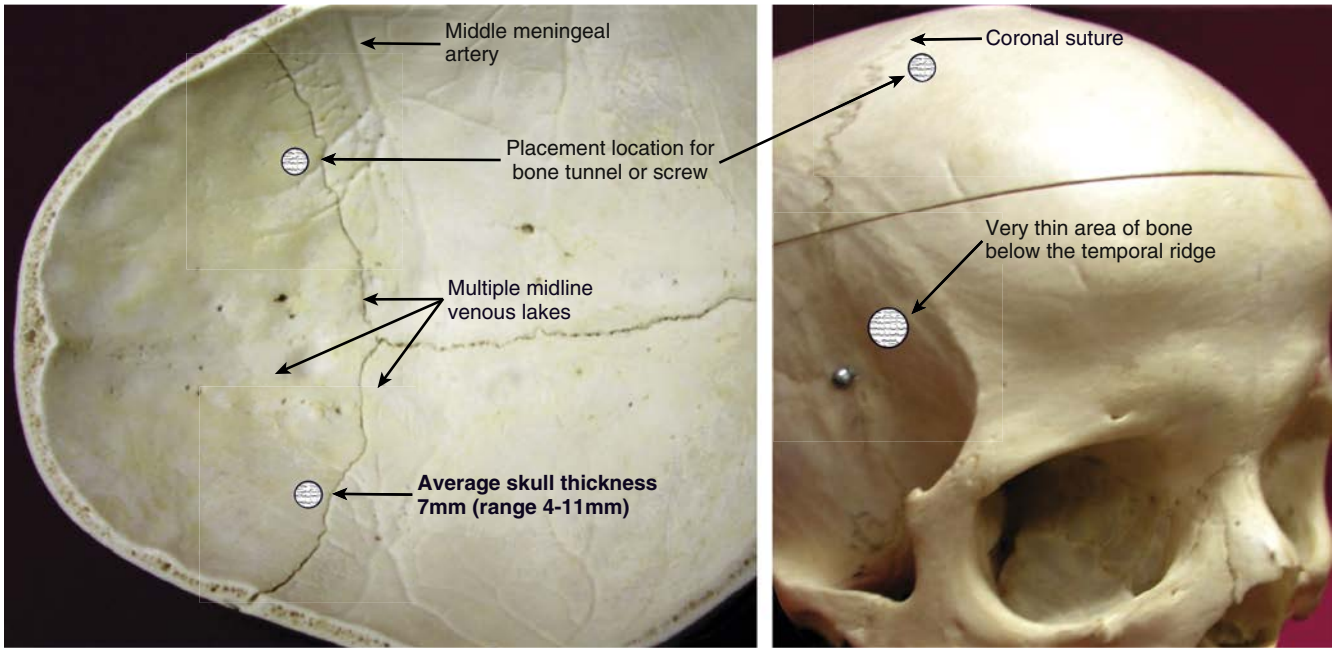
• **Figure 22-20** The different incisions and techniques used during forehead and eyebrow lifting.



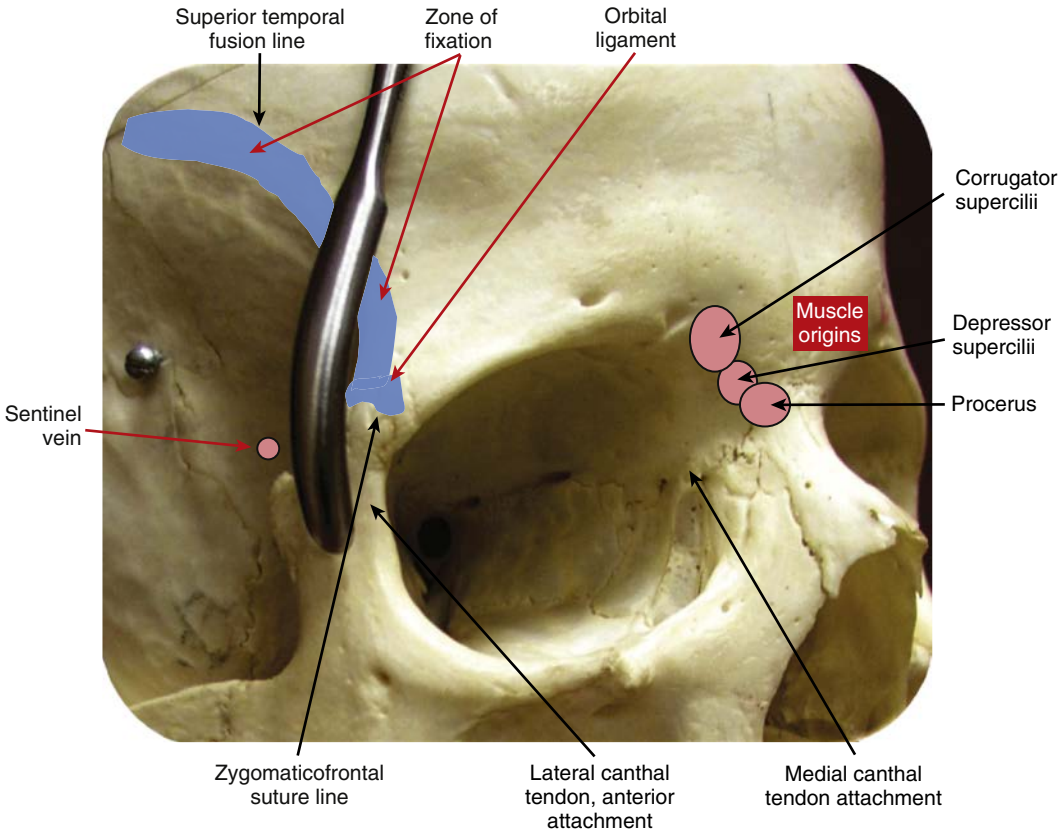
• **Figure 22-21** The different incision techniques and the level of dissection (depth) that can be selected.

The endoscopic technique involves strategic placement of several incisions behind the hairline for access for initial blunt dissection, followed by insertion of the endoscope and the tissue retractor. Other incisions can be used as ports for dissecting tools such as periosteal elevators, electrocautery lasers, tissue graspers, and suction devices. Incision (port) design varies among surgeons. Fixation points usually are placed at these incision sites; therefore, this author prefers to place five separate incisions 3-4 cm in length for easy access and for ideal fixation placement (Figure 22-22). Each of these five begins approximately 1 cm posterior to the hairline. One is placed in the midline of the sagittal plane and two are placed in the parasagittal plane tangential to the lateral third of the brow, where maximum lift is typically desired in females. An incision can be moved slightly more medially for male patients, to attain a more even brow elevation. These three parasagittal incisions are aligned vertically to avoid unnecessary transection of sensory nerves coming from the supraorbital nerves below. The two parasagittal incisions are placed medial to the temporal crest to gain access to skull bone rather than to the temporalis fascia for more secure fixation at this point. It is also important for the clinician to be able to access the subperiosteal plane easily here rather than over the zone of fixation adjacent to the temporal crest, which would make pocket development difficult and would obscure future endoscopic visualization. The location of the parasagittal incision in an area of the frontal bone that is one of the thickest regions combined with a low density of venous lakes helps to prevent accidental intracranial injury during bone tunnel creation or placement of bone screws (Figure 22-23). Finally, two temporal incisions are made—one on each side of the head—for direct access to the thick temporal fascia. These incisions are placed perpendicular to the desired elevation vector from the lateral canthal region. It is a coincidence that the temporal incision ends up paralleling the course of the temporal branch of the facial nerve that is located 2 to 3 cm anterior and inferior to this incision. It also parallels the superficial temporal artery and vein.

• **Figure 22-22** Each of the five incisions for an endoscopic brow lift is typically 3 to 4 cm in length. The three upper incisions are dissected down to bone, and the periosteum is elevated in all directions. One of the parasagittal incisions is shown. No hair is trimmed or removed during endoscopic brow lifting.



• **Figure 22-23** Bone tunnels are one method of fixation. In the median location the average bone thickness is 7.5 mm with a range of 4.7 to 13 mm, however at this location there are many lacuna lateralis (i.e., venous lakes). A parasagittal bone tunnel can be created near the coronal suture where the bone is also thick (average 7.0 mm, range 4.1 to 11 mm) but free of venous lakes and allows safe placement of a shallow tunnel. A secure galeal suture is plicated from the hairline below to the bone tunnel above.



• **Figure 22-24** A smooth and curved periosteal elevator is used to release the periosteum over the superior orbital rims bilaterally, as well as in the nasofrontal area. The dissection should be bimanual while keeping the nondominant hand over the patient's face to control the tip of the elevator. The dissection should be carried laterally over the lateral orbital rim and the zygomatic bone to release the lateral orbital ligament.

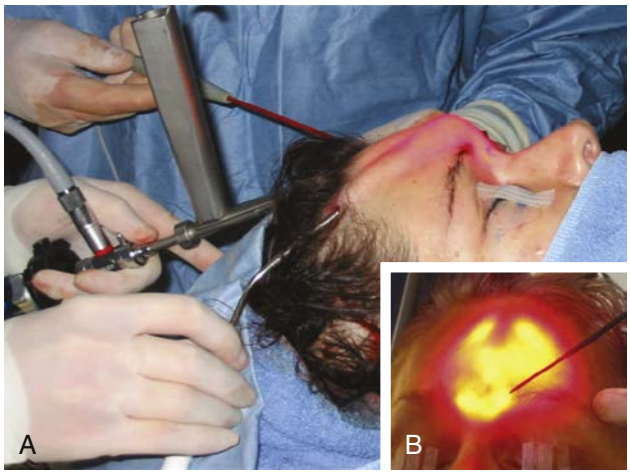
Dissection is performed through the above incisions, down through the periosteum medial to the temporal crest, and down to the temporalis fascia lateral to the crest (some surgeons may elect the subgaleal rather than the subperiosteal medially). Many surgeons, including this author, believe that total subperiosteal dissection medial to the temporal lines rather than subgaleal dissection leads to better fixation and long-term stabilization.[42-60]

Blunt and blind dissection can be carried out after the subperiosteal and subtemporoparietal planes are reached through the five incisions. Finger dissection and long curved endoscopic periosteal elevators are used to elevate the tissue anteriorly to a point 2 cm above the orbital rims and the zygomatic arch. A smooth and curved periosteal elevator is used to release the periosteum over the superior orbital rims bilaterally, as well as in the nasofrontal area. The dissection should be bimanual while keeping the nondominant hand over the patient's face to control the tip of the elevator (Figures 22-24 and 22-25).

Posteriorly, blunt dissection should elevate the temporal tissues to a few centimeters behind the ear, where the temporal fossa becomes self-limiting. Subperiosteal dissection must elevate the scalp at least 10 cm posteriorly but can go back as far as the lambdoid suture. Once these areas have been freed, a connection can be made from the temporal region to the subperiosteal dissection through the upper portion of the zone of fixation at the temporal crest by finger dissection.

• **Figure 22-25** Intraoperative image demonstrating how the subperiosteal dissection is tunneled over the lateral orbital rim into the malar prominence. The elevator is used through a parasagittal incision just behind the hairline. Release below the frontozygomatic suture line into the cheek is critical. The globe is protected at all times.

Avoid blind release of the more inferior portion of the temporal line where the facial nerve crosses because endoscopically guided dissection here will help to prevent nerve injury.[61-63] Breaking through the upper zone of fixation via finger dissection proceeds from the temporal incision toward the medial scalp rather than vice versa, to prevent creation of a false tunnel in the spongy-appearing temporoparietal fascia. False tunnels along the temporal crest create problems



• **Figure 22-26** **A,** The three ports are used in conjunction for ease of movement of the endoscope, the cautery or laser, and the suction cannula. **B,** The *inset* depicts the thin layers of the brow as illustrated by the transillumination from the lighted endoscope. Care must be taken to avoid excess trauma from heat, trauma from retraction, and overzealous tissue thinning.

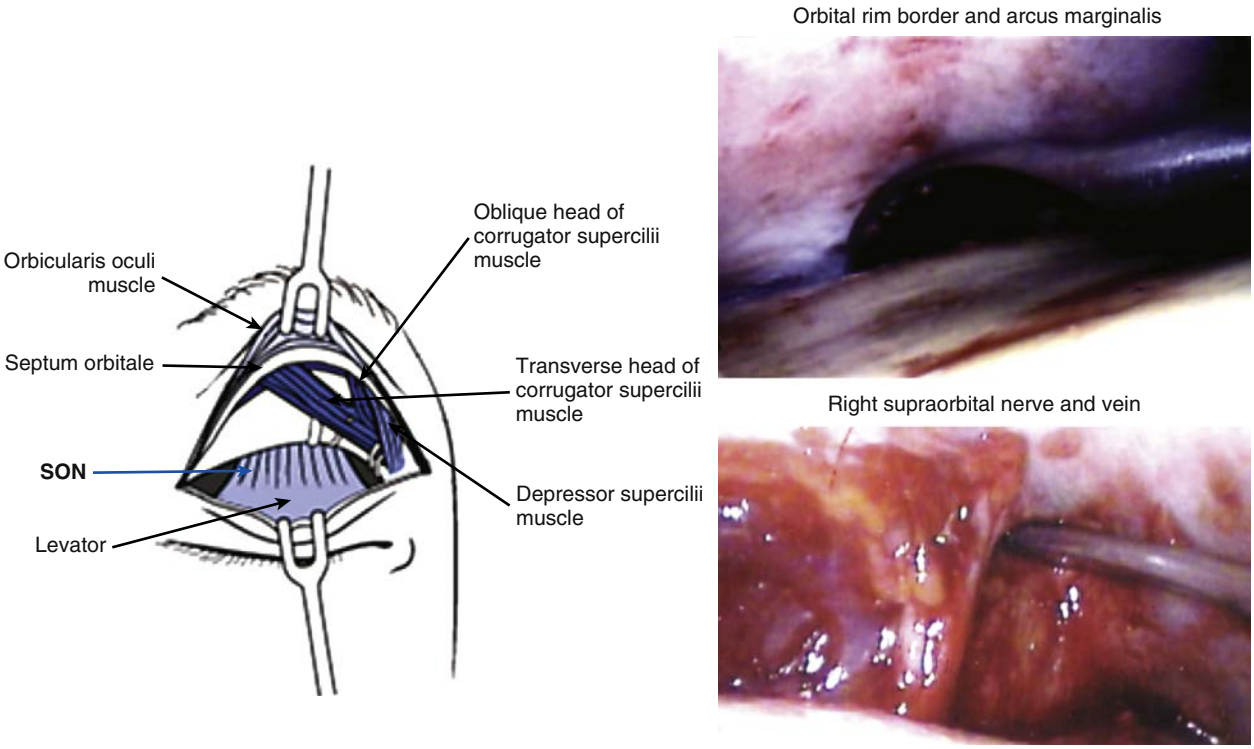
when the endoscope is inserted through the parasagittal port to visualize the lateral forehead. This places the surgeon in a more superficial plane within the temporoparietal fascia and greatly increases the chances of nerve injury. As described earlier, this layer contains the superficial temporal artery and the frontal branch of the facial nerve. The importance of staying directly against the periosteum and temporalis fascia during the initial elevations cannot be emphasized enough.

Following blunt elevation of the scalp from all incision ports, the endoscope is inserted usually through one of the three more medial incisions (Figure 22-26). Poor initial blunt dissection will make the initial endoscopic dissection feel very tight, and care must be taken not to perforate the skin through excessive retraction. Medial dissection is performed down over the nasofrontal suture and the orbital rims under direct endoscopic vision with a curved and smooth rounded elevator to avoid inadvertent tearing of the periosteum. The periosteum may be thin in some patients; a straighter elevator may be used to tear through the periosteum at the level of the rim. However, the entire rolled edge of the orbital rim must be seen, and typically, the periosteum is more precisely incised via needle tip cautery or laser (Figure 22-27). Of course, the area in front of the supraorbital nerves and vessels as described earlier is at a level tangential with the medial limbus and is immediately behind the periosteum; thus cautery dissection must be performed carefully to avoid injury to these structures (Figure 22-28). Cauterization should also be done bimanually because of the relatively small distance that the cautery has to travel to get through the skin, especially in the glabellar area and nasofrontal junction. Periosteum release should be performed 1 to 2 cm above the rim in the area of these nerves to decrease major nerve trunk transection. The three ports are used in conjunction for ease of movement of the endoscope, the cautery, and the suction cannula. The temporal incisions can be very helpful as suction ports if the medial ports are too occupied with the endoscope and the cautery device. With clear and near bloodless dissection at this point, cautious transection can be performed through the corrugator supercilii muscles and the procerus. If unwanted bleeding is encountered and cannot be controlled easily with pinpoint accurate cautery, then pressure should be applied externally over the rim until improved visualization allows for control of bleeding without nerve damage.

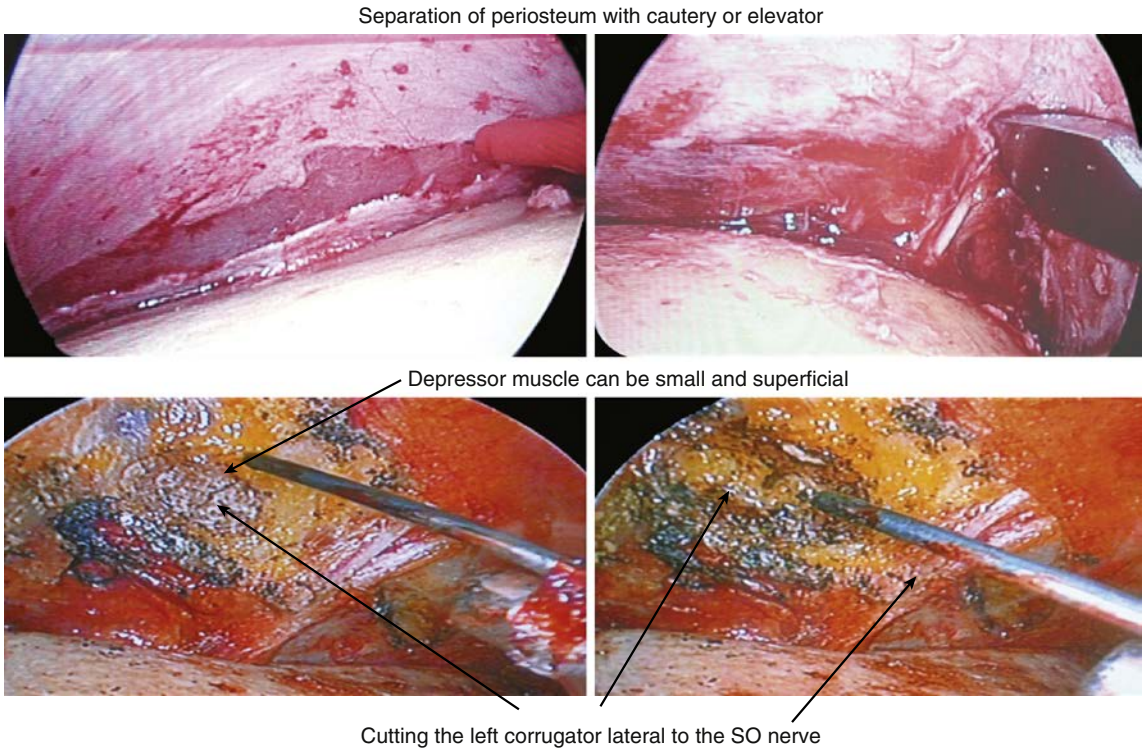
Vertical rhytids in the glabella created by the corrugators can be improved greatly by transection through the corrugator muscles. Likewise, horizontal glabellar lines are treated by transection of the procerus muscle, which creates these particular facial wrinkles or "bunny lines." Subconscious horizontal rhytids can also be treated by appropriate blepharoplasty or brow lift techniques (Figure 22-29). Some surgeons recommend more aggressive surgical avulsion of these muscles with endoscopic biopsy forceps.[64-76] Aggressive muscle removal may lead to more permanent treatment of glabellar lines than is attained with isolated transection only, but this approach should be avoided in most cases because of the increased risk of significant postoperative irregularities and abnormal facial expression. As a rule, patients prefer a more natural appearance with some minor return of frown line expression over risking a bizarre facial expression and glabellar depression from atrophic fibrosis.

Once the periosteum has been completely freed across the orbital rims and appropriate muscles have been treated, the cut periosteal edges are spread apart (periosteal elevators work well for this) by at least 1 cm to facilitate release at the arcus marginalis. Adequate tissue release is critical for significant and long-term brow elevation. Next, the lateral orbital rim must be exposed in the subperiosteal plane after careful release below the zone of fixation and orbital ligament. Dissection must be performed warily along the anterior and inferior aspects of the temporal crest to avoid temporal nerve injury. The dense tissue here that contains the nerve can produce nerve damage through overzealous retraction alone. Staying tightly against the periosteum and the temporalis fascia helps to prevent nerve damage and produces clean and bloodless dissection. Slowly creating a distinct plane of dissection down just past the zygomaticofrontal suture line and avoiding excess retraction helps to prevent unwanted bleeding from the sentinel vein (medial zygomatico-temporal vein). The sentinel vein as previously described in the anatomy discussion need not be sacrificed for a customary endoscopic forehead and brow lift.

Dissection for a standard endoscopic brow lift also need not proceed all the way to the zygomatic arch but can stop approximately 1 cm above this level. If an extended midface lift is planned and elevation of tissue over the zygomatic arch itself is the goal, then dissection must be performed below the superficial layer of the deep temporal fascia above the arch. Abbreviated mid-face lifts performed simultaneously with endoscopic brow lifts may simply be confined to the subperiosteal plane along the lateral orbital rim and are much less risky than a full arch release (Figure 22-30). The

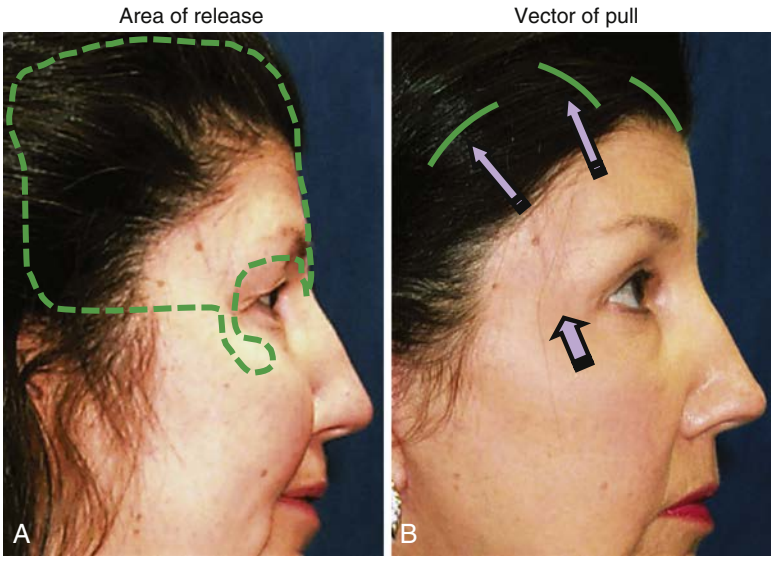


• **Figure 22-27** Right side endoscopic view of the close relation of the supraorbital nerves and the corrugator.



• **Figure 22-28** The photos demonstrate an endoscopic view of the left forehead. Close relationship between the left corrugator muscle and the supraorbital nerve. The belly of the corrugator lies superficial to the supraorbital nerve both medially and laterally. The lateral belly is often more challenging to find and transect compared to the medial belly.

• **Figure 22-29** Dermatochalasis or brow ptosis can lead to constant subconscious frontalis activity that gives rise to deep horizontal forehead wrinkles. The two patients shown had different surgical techniques performed (blepharoplasty in **A** and brow lift in **B**), yet the resulting removal of laxity over the eye caused the patient to subconsciously quit raising the eyebrows and improved the forehead wrinkles. The brow lift patient saw a more profound improvement in these subconscious forehead lines.

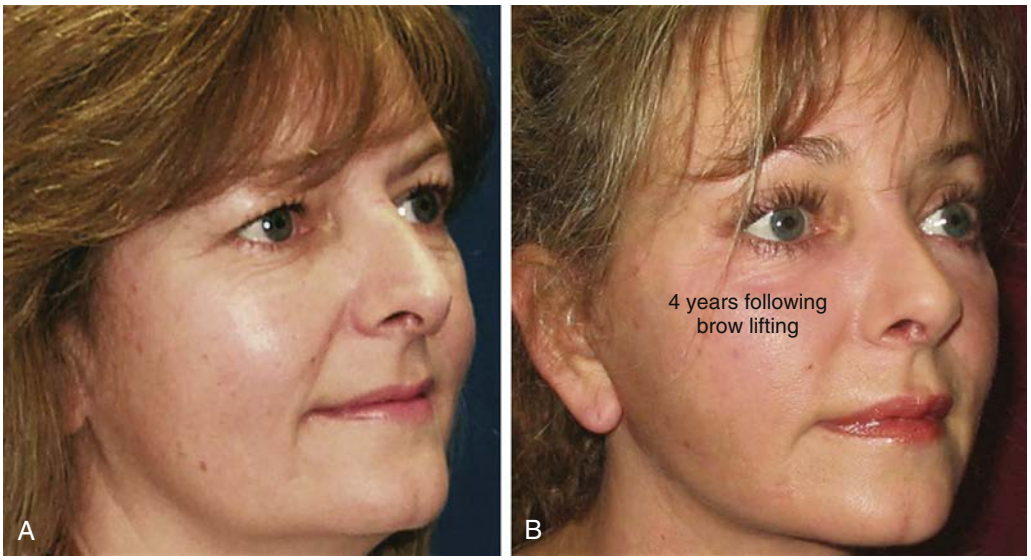


• **Figure 22-30** Before **(A)** and after **(B)** images of endoscopic forehead, brow, and mid-face lift show a lateral view of the area of subperiosteal release and the vector of pull involved in the procedure.

beauty of the classic endoscopic brow lift is its adaptability and the ease with which simultaneous additional procedures can be combined with this eloquent cosmetic surgery. For instance, the temporal incision of an endoscopic forehead lift can easily be extended inferiorly to blend with the preauricular incision from a standard lower face-lift. Also, mid-face lifting (with intraoral dissection) can connect the intraoral subperiosteal dissection over the maxilla and the zygoma to the subperiosteal plane from the endoscopic brow lift through a tunnel near the lateral orbital rim.

After all dissection has been completed, appropriate elevation and fixation are required. Many techniques, such

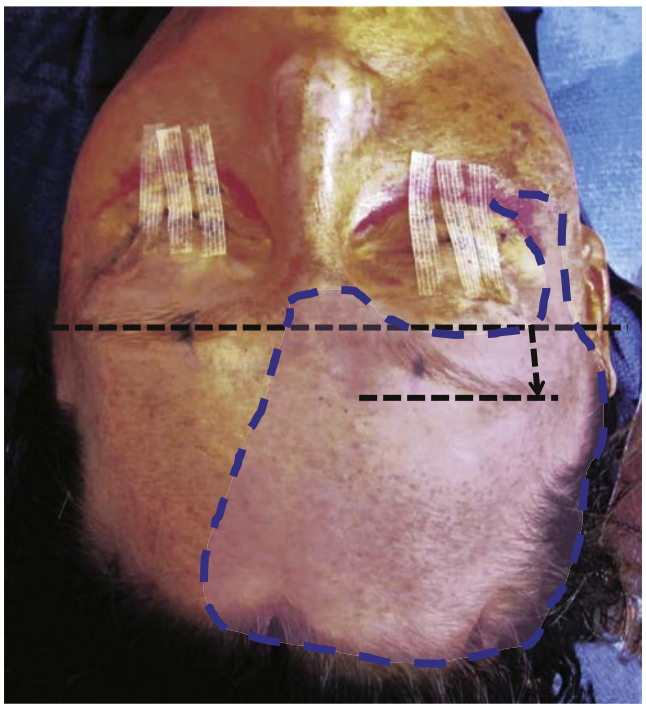
as tissue suture only, bone screws and plates, resorbable screws, bone tunnels, local skin excision, temporalis muscle exposure for added scarification, tissue glue, and tight head wraps, have been described. Regardless of the specific fixation technique chosen, successful long-term fixation is likely dependent on adequate lower forehead tissue release during endoscopic dissection. Failure to adequately release internal forehead tissues will result in relapse in brow ptosis, even with heavy fixation and the appearance of a "nice" lift during surgery (Figures 22-31 to 22-33).



• **Figure 22-31** A 51-year-old woman before **(A)** and 4 years following **(B)** endoscopic brow lift and upper blepharoplasty. Her lid laxity required upper blepharoplasty after elevation of the eyebrows. The long-term results are seen and are most related to proper tissue release versus the type of fixation used.

• **Figure 22-32** **A,** A 55-year-old woman before and 7 years after an isolated endoscopic brow lift procedure. **B,** A 48-year-old woman before and 5 years after endoscopic brow lift combined with a mid-face lift. Both patients have a low hairline along with a very low lateral brow position, which makes them ideal candidates for an endoscopic brow lift.

Once complete internal release of the forehead has been attained, specific lifting vectors for the most pleasing esthetic effect are determined. The lateral one third of the female brow is elevated to the greatest extent, which can be up to 1 cm above the orbital rim. The medial brow should be only slightly above rim level and absolutely below mid-brow and lateral brow levels to avoid a surprised or bewildered expression. Typically, the glabellar region is elevated without the need for midline fixation, which helps to avoid excessive elevation medially. The lateral third of the brow is lifted straight up and can be fixated at the level of the hairline. The galeal tissue is typically secured to bone at this point while the lateral brow is held at the desired height or a few millimeters above the desired level.[77-81] Very little relapse occurs with proper technique—on average, only 1 to 2 mm of lowering after 2 weeks.[1,4,7] Measurements also can be taken with clear circular templates from pupil to brow, to help improve symmetry. Brow position remains very stable following the first few weeks of tissue edema resolution. The time required for complete fixation of the periosteum is not known, but tissue adhesion certainly begins in the first few days after surgery. Various animal studies suggest that a full 12 weeks is required for occurrence of what is called *full histologic periosteal refixation*. An example is the common fixation technique used by many surgeons who place a single transcutaneous bone screw at each parasagittal incision that is removed after only 1 week. The 1-week fixation technique has been used with success for many years. Some suggest that longer bony fixation may provide longer-term retention and less early relapse. Still, long-term fixation appears to be determined most often by proper tissue dissection and release, rather than by a specific fixation technique (Figure 22-34).[1,4,7]

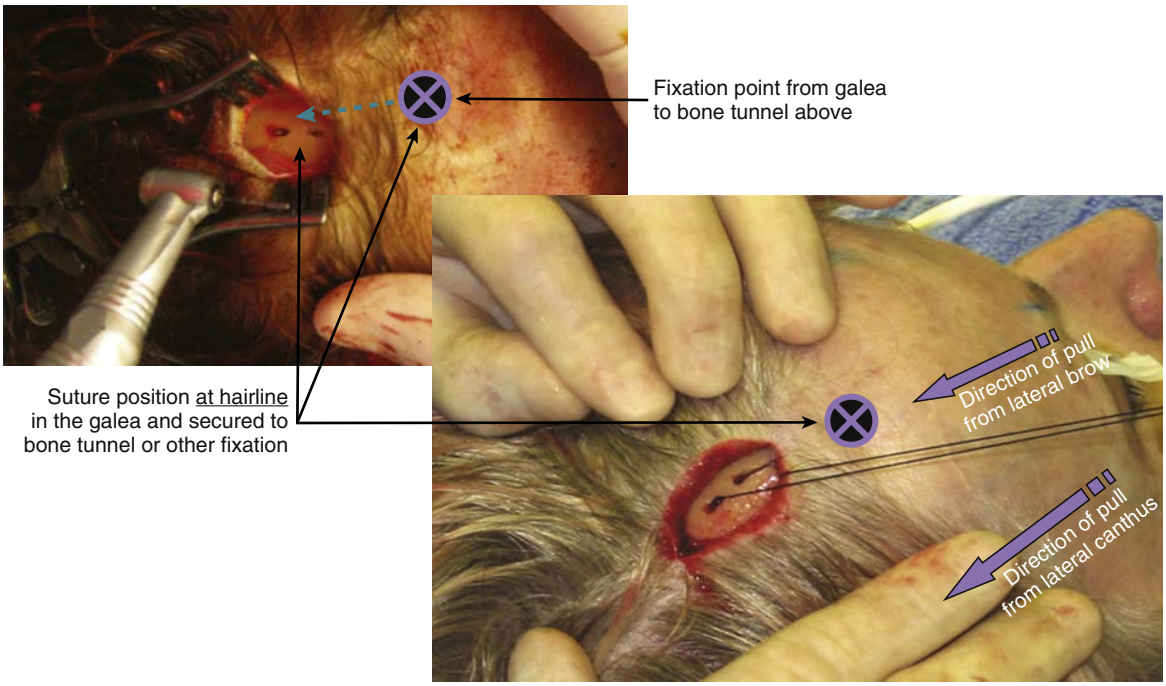


• **Figure 22-33** This image depicts the amount of brow elevation that is achieved on the patient's right side with adequate internal release and transection of the brow depressors. No fixation has been performed on the right side as compared to the untreated left side. The most crucial component of a good long-term result is adequate tissue dissection and proper fascial release rather than any specific fixation technique.

Although many fixation techniques are available, this author prefers bone tunnels at the parasagittal incisions to fixate the galea and the periosteum near the hairline to a bone tunnel created a few centimeters posterior to the hairline under the incision with a single heavy suture such as 0 Nurolon or 0 Vicryl (Figure 22-35). Fixation of the lateral tail of the brow is performed at each temporal incision, where an isolated heavy suture plicates the temporoparietal fascia in a posterior and superior vector to the temporalis fascia. Optional creation of a small window of exposed temporalis muscle in this area may facilitate internal scar formation and fixation. The vector of lift at this outer tail of the brow follows a line drawn at an angle from the outer nasal ala that passes just beside the lateral canthus. The most critical component of long-term result is emphasis on adequate periosteal and ligamentous release along the lateral canthus.

Final closure of hair-bearing scalp incisions can be performed with skin staples alone with excellent scar formation, because no skin is excised and no pressure exists at the incision sites. Redundant tissue (forehead skin) created

• **Figure 22-34** The horizontal line demonstrates the new and stable brow position on a 47-year-old woman following an endoscopic forehead and brow lift procedure combined with a mid-face lift. The patient also had upper and lower blepharoplasty performed along with lower laser resurfacing. The key to a good long-term result is adequate tissue dissection and proper fascial release rather than any specific fixation technique. **A,** Preoperative appearance. **B,** Six days after surgery. **C,** Two weeks after surgery. **D,** Two months after surgery. **E,** One year after surgery. **F,** Five years after surgery. **G,** Eight years after surgery.



• **Figure 22-35** Bone tunnel at right parasagittal incision and suture fixation with a single heavy suture (0 Nurolon or 0 Vicryl). A thick "bite" galea at the level of the hairline is needed to secure the final location of lateral brow elevation. A poor or thin amount of tissue in this single suture could lead to unwanted release and asymmetry a few hours or days later.

by an average of 1 cm of brow elevation is easily distributed evenly over the posterior 10 to 20 cm of elevated scalp, which essentially absorbs or redistributes this excess tissue with few to no signs of bunching, provided adequate posterior elevation of the scalp was performed (Figure 22-36). Because of this phenomenon, the endoscopic forehead and brow lift tends to merely elevate the hairline a very small amount compared with the open skin-excising coronal technique. No drains typically are required for the endoscopic technique (Figures 22-37 and 22-38).

Coronal Forehead and Brow Lift

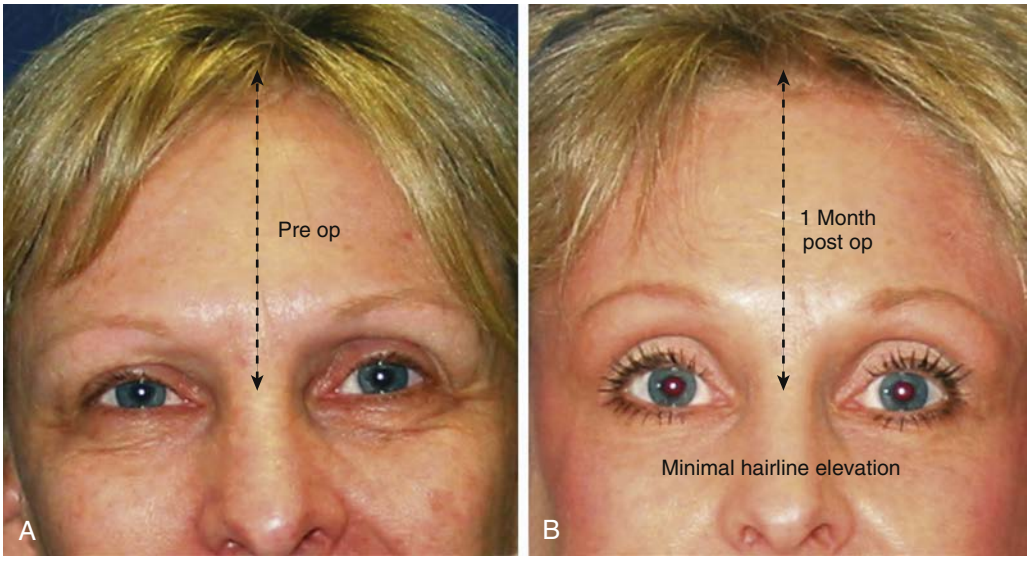
The coronal lift technique involves an incision across the hair-bearing scalp approximately 4 to 5 cm behind the hairline and extending from ear to ear. This line can also be connected to a regular face-lift incision at the superior helical attachment of the ear. Dissection is carried down to the subgaleal or subperiosteal level and elevated to the level of the superior orbital rims and laterally into the subtemporoparietal plane. Correction of any forehead deformity can be addressed with the wide coronal exposure. Deep forehead creases can be reduced with a midline frontalis myotomy, whereas glabellar lines are corrected by transection or resection of the exposed depressor muscles of the eyebrow. Visualization of the supraorbital and supratrochlear nerves is an advantage of this exposure and reduces the risk for injury.

Additionally, bone deformities can be corrected with this approach. This lift can be a great operation for patients with a short forehead (<5 cm), but it can be a significant drawback in those with a normal or long forehead since it elevates the hairline even further. Excision of excess scalp skin is performed after accurate measurement and redraping of the forehead flap. The documented rough estimate is that 2 cm of scalp must be excised for every 1 cm of brow elevation. As mentioned earlier, this approach can be used for access to the mid-face, but care must be taken to not injure the frontal branches of the facial nerve. This procedure exposes an enormous surgical field and can therefore be a great technique for inexperienced surgeons. It should be kept in mind that other than elevation of the hairline, this procedure has an increased risk for alopecia, persistent scalp numbness, longer operative time, and excessive blood loss, and results in a long scar.[47]

Trichophytic and Trichophylic Forehead and Brow Lift

The trichophytic (transfollicular) lift can be the procedure of choice when it is desirable to shorten the forehead or avoid displacement of the hairline (Figure 22-39). A trichophytic (hair loving) incision is made just behind the frontal hairline, whereas a trichophylic incision is made in front of the hairline. A modified version of the trichophytic incision can avoid an unsightly scar by making an irregular incision with an extreme bevel from posterior to anterior beginning 4 to 5 mm posterior to the hairline at an area where the follicular density becomes consistent. The extreme bevel of

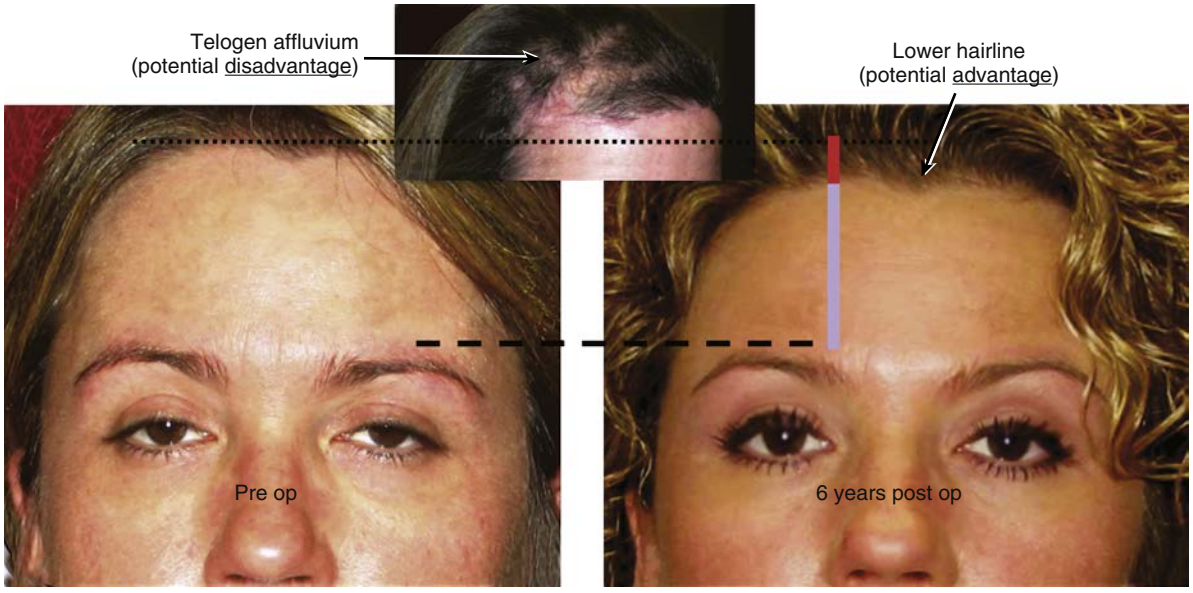
• **Figure 22-36** Images **A** and **B** depict the connected subperiosteal plane of the transblepharoplasty and endoscopic brow lift procedures. Image **C** illustrates the amount of brow lift and skin laxity that can be achieved with adequate release. Forehead flap redundancy disappears by redistribution over the posterior 10 to 20 cm of occipital periosteal elevation. This redistribution accounts for the acceptable minimal raising of the hairline.



• **Figure 22-37** A 53-year-old woman before **(A)** and 1 month following **(B)** an isolated endoscopic brow lift procedure. Hairline elevation can occur following an endoscopic brow lift but is typically minimal, particularly when compared with an open coronal lift, which requires scalp excision and subsequently raises the hairline significantly. No frontalis myotomies are required during the endoscopic procedure.

the incision preserves the hair follicles on the superior flap allowing hair growth both through, and anterior to, the scar postoperatively. This technique allows the same excellent exposure that the coronal method provides and has the ability to lower a high forehead or prevent raising it, although limited lateral dissection is usually encountered. Direct visualization of the brow depressor muscles and the associated nerves is gained as with the coronal exposure. Subgaleal or subperiosteal elevation can be used with this method, although a subcutaneous technique is performed

• **Figure 22-38** A 53-year-old woman 1 week after endoscopic forehead and brow lift *(right)* depicting the typical edema and ecchymosis. This short recovery period is another potential advantage of endoscopic brow lifting techniques.



• **Figure 22-39** The patient shown had a classic trichophytic brow lift without any early problems. However, a potential disadvantage of this procedure is severe alopecia (hair loss) known as telogen effluvium, which developed approximately 2 months following surgery. The patient had complete healing with time. The only treatment was early low-dose steroid injections and minor topical hair growth medication usage. Fortunately, most cases resolve spontaneously. The potential advantage of a trichophytic brow lift is lowering of the hairline. The scar is well hidden and is barely visible at 6 years post op.

more often. Subcutaneous dissection elevates the dermal attachments, releases the deep horizontal creases, and also adds the advantage of reducing posterior scalp sensory loss (Figure 22-40).

The trichophytic and trichophylic methods are ideal for patients with heavy forehead rhytides, low brow position, or a high forehead.[95] However, patients are discouraged by the visible scar and distorted hairline associated with this technique. As a result, most will opt for the endoscopic approach even if it involves raising the hairline.

Direct Brow Lift

A direct brow lift is considered the simplest of the different approaches to raising the eyebrow. An elliptical skin excision is made just above the superior edge of the eyebrow. The authors' preference is to create a beveled incision to allow some hair follicles to grow over the incision. Dissection is continued in a subcutaneous plane to avoid nerve and vessel injury. Electrocautery is then used to excise the ellipse of tissue.

• **Figure 22-40** **A** and **B,** The tricophytic brow lift is an excellent option for patients with a high forehead that requires lowering. The scar fades over months and is hidden by hair. **C,** The *blue line* represents a modified version of the trichophytic incision and involves a beveled incision to cover the scar with hair follicles, as well as creation of a wavy incision to prevent a linear scar. **D,** The *shaded area in yellow* is actual skin excised with the trichophytic technique and the *shaded area in purple* is the area of subcutaneous elevation.

This type of brow lift is simple and can easily be done with local anesthesia. It can also correct brow asymmetry. Its main disadvantage is the potentially visible scar, although for an elderly patient with heavy wrinkles and thick eyebrows, this could be the procedure of choice.[96]

Mid-Forehead and Brow Lift

This technique involves mid-forehead and upper forehead elliptical incisions, with the edges and resultant scar lying inside a horizontal forehead crease. Dissection can be carried down to the corrugator and procerus muscles as indicated and allows skin release with excision of excess skin. This is probably the least used of all techniques, but it should be considered when dealing with an elderly patient who has thin eyebrows and deep horizontal rhytides.[97]

Transpalpebral/Transblepharoplasty Brow Lift

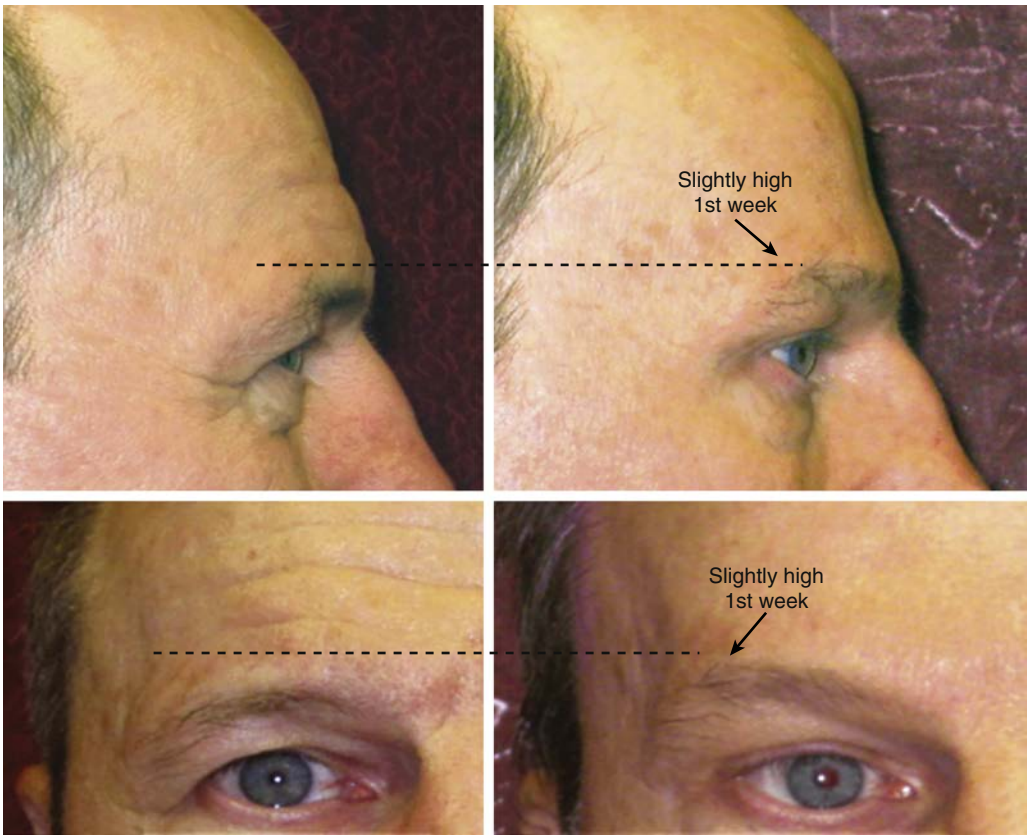
Blepharoplasty can be performed in conjunction with any of the brow lift procedures described if indicated. For example, a simple and direct brow lift can be done through a blepharoplasty incision (see Figures 22-36 and 22-41). Dissection can easily expose the corrugator supercilii, the procerus, and the depressor supercilii, each of which can be transected for elevation of the medial eyebrow and reduction of glabellar lines. However, this approach can only address the lateral brow with a minimal lift (Figures 22-42 and 22-43). The orbicularis oculi can also be treated to address the patient's crow's feet and give the patient "surgical botox" (Figure 22-44).

As mentioned earlier, eyebrow ptosis may be accompanied by dermatochalasis of the upper eyelids, as well as the lower eyelids. Fat pad prominence, orbicularis oculi hypertrophy, and lacrimal gland descent can also make eyelid surgery necessary, with or without forehead and eyebrow lifting. Details regarding eyelid surgery are discussed more extensively elsewhere in this book and should be considered part of one's upper face rejuvenation practice. The supraorbital nerve must be considered with any approach. The location can easily be determined preoperatively.

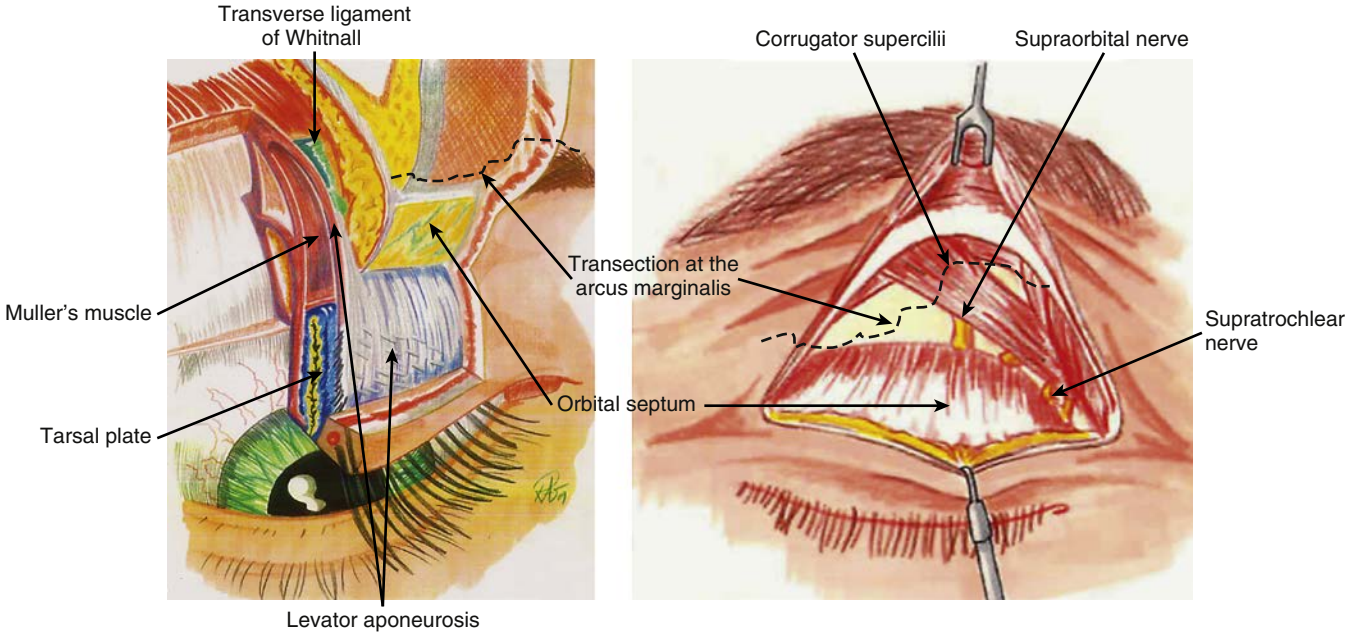
Adjunctive Procedures

Autlogous Fat Transfer

Facial fat grafting is particularly useful for improving orbital and temporal hollowing, as well as for camouflaging infraorbital rim exposure by malar fat ptosis. Facial lipoatrophy is a common finding in patients seeking facial rejuvenation and autologous fat grafting has become a very popular adjunct to facial cosmetic surgery.

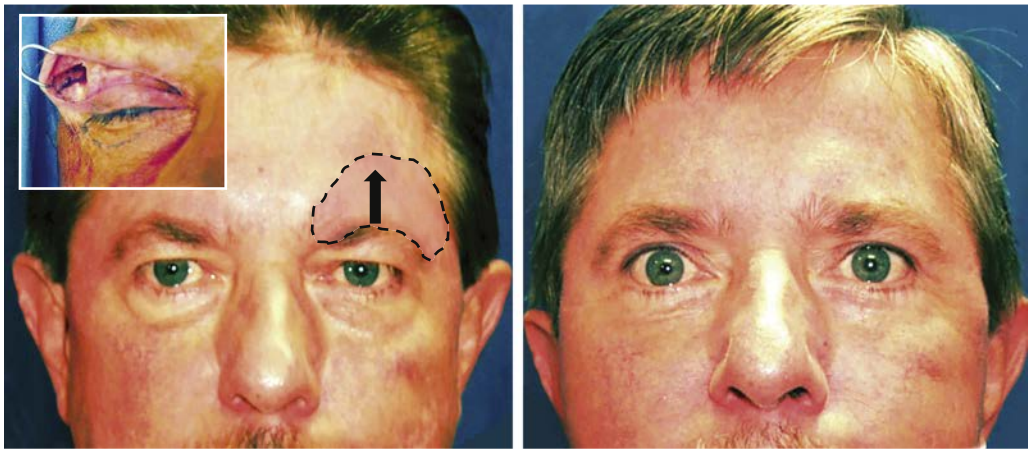


• **Figure 22-41** The male patient shown has classic male pattern baldness and therefore is not an ideal candidate for a typical brow lift. He is shown before and after a combined transblepharoplasty and endoscopic brow lift. His brow position is a few millimeters high at 1 week post op but the position will drop a few millimeters to a more ideal position over the next 6 weeks.



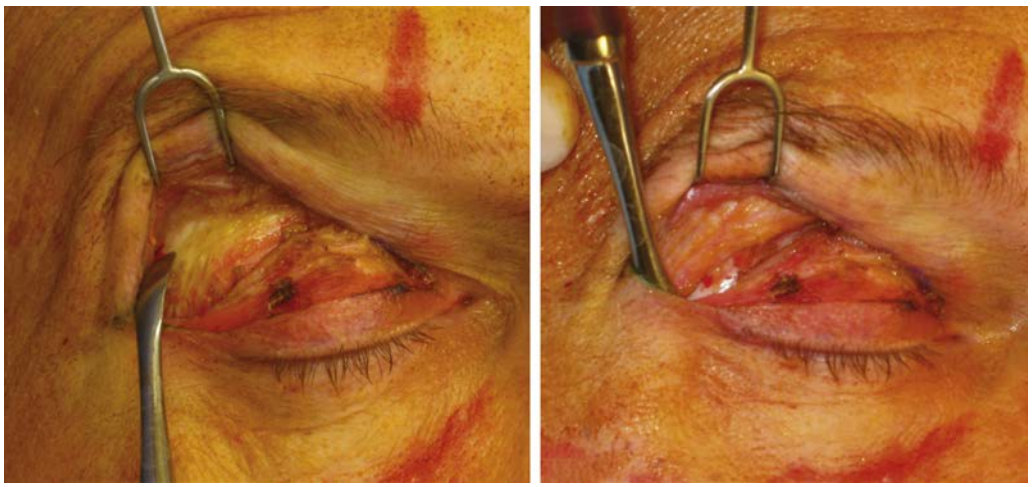
• **Figure 22-42** Right upper eyelid and frontal bone. Release of the corrugator and arcus marginalis can be accomplished from the blepharoplasty incision, but care must be taken to avoid injury to the supraorbital nerve, which runs through the muscle. Transecting periosteum and muscle 1 to 2 cm superior to the arcus in the area of the supraorbital nerve as shown lessens the chance of full nerve trunk injury.

Blepharoplasty with direct brow elevation suture



Blepharoplasty is most appropriate but minor brow elevation helps outcome

• **Figure 22-43** A 57-year-old man shown before, during, and after a transblepharoplasty direct internal brow lift procedure. Despite major release, only a 1- to 2-mm increase in brow elevation should be expected from this simple but limited procedure.



Male transblepharoplasty brow lift

• **Figure 22-44** Release and partial transection of the lateral orbicularis oculi (O.O.) can give the patient "surgical Botox" for the crow's feet. The resection of lateral depressor muscles (O.O.) allows the frontalis to lift the outer brow a few millimeters. The dissection shown extend 1 to 2 cm above the eyebrow along periosteum.

Neurotoxin-Assisted Brow Lift

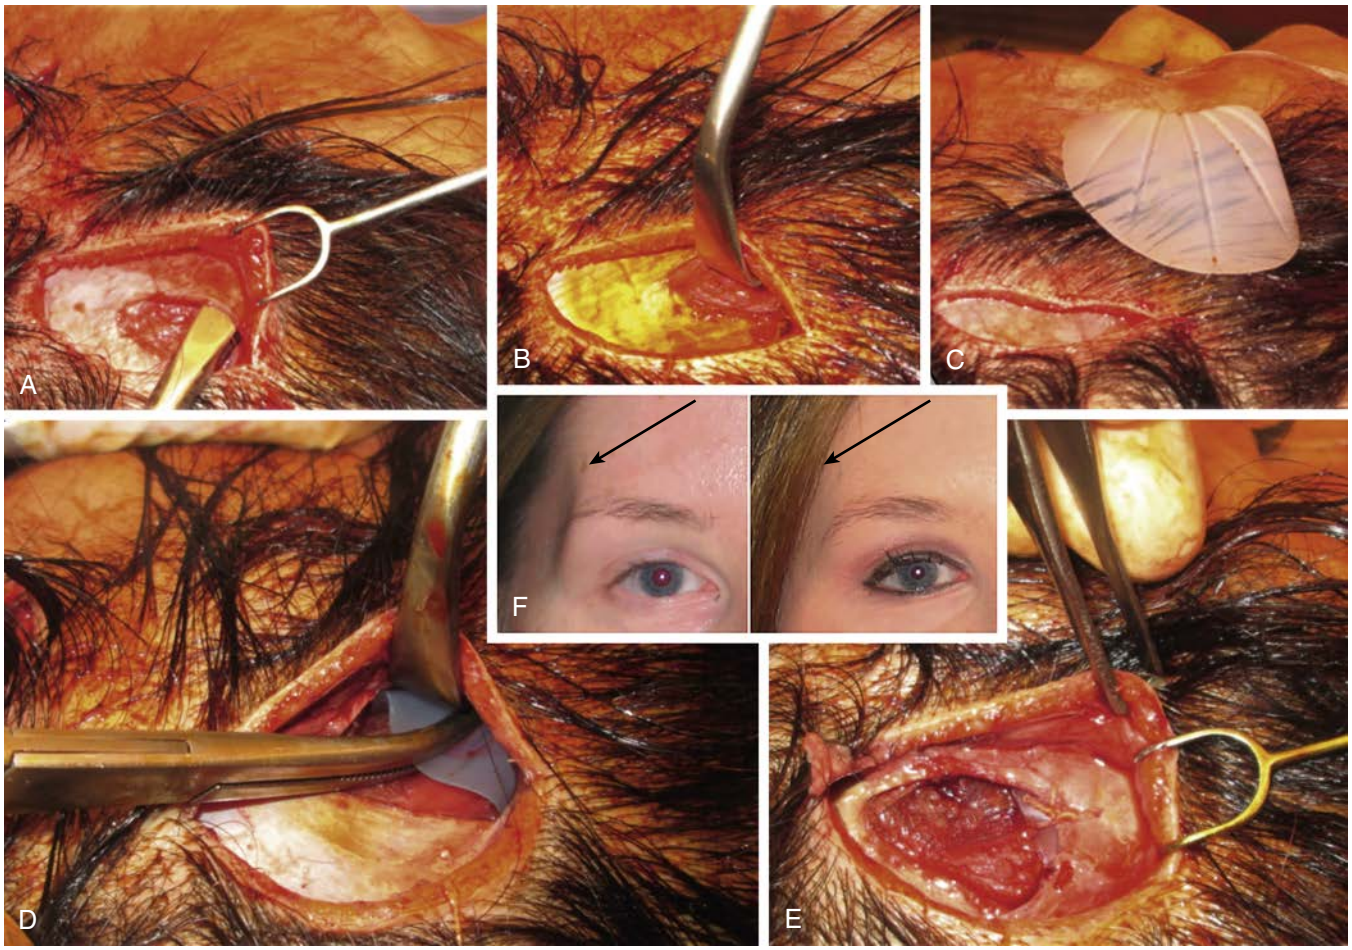
Neurotoxin has proved to be very effective in reducing visible fine lines and wrinkles of the aging face. With regard to the upper third of the face, reduced frontalis activity, glabellar lines, and lateral orbital crow's feet are all particularly exceptional areas to be treated. Focusing the injections on the depressor muscles with subsequent unopposed frontalis elevation can lead to brow elevation, hence obtaining a "chemical brow lift."

The use of neurotoxins has also been theorized to help in stabilizing the forehead flap elevated during forehead lifting. Injecting the depressor muscles 1 to 2 weeks before surgery is thought to reduce depressor muscle activity postoperatively, which allows the forehead to remain lifted and reduces early postoperative relapse.

Temporal Implants

Temporal augmentation procedures with the use of synthetic injectable fillers and autologous fat transfer are popular among patients seeking upper facial rejuvenation. To adequately augment the temporal region a large amount of synthetic filler is typically needed and most will eventually dissolve. Fat grafting can be performed as a longer lasting option, however the longevity can be unpredictable.

Temporal implants are soft, flexible, made of silicone, and offer the patient a permanent correction for temporal hollowing. The implants can easily be placed through an existing temporal incision if an endoscopic approach is being performed. An incision is made in the temporalis fascia and



• **Figure 22-45** Adjunctive procedures such as temporal augmentation can easily be placed through an existing temporal incision. **A,** Creation of a pocket below the temporalis fascia. **B,** An aufricht retractor placed in the pocket. **C,** Solid silicone implant laying over the planned position of the implant just lateral to the orbital rim and above the zygomatic arch. **D,** Placement of the implant into the pocket. **E,** Securing the implant to the overlying fascia to prevent migration with a single 2-0 Vicryl. **F,** Patient with temporal hollowing before and after placement of temporal implants.

a pocket is created from the lateral orbital rim to just above the zygomatic arch. The implant is placed deep to the fascia and superficial to the temporalis muscle. Some surgeons do not secure the implant, however the senior author secures the implant with a single 2-0 Vicryl to the fascia to prevent migration (Figure 22-45).

Skin Care

Laser resurfacing, dermabrasion, or chemical peels can be used as an adjunct to forehead lift surgery. These procedures can be used to even out fine wrinkles and dyschromia of the forehead and periorbital skin.

The senior author's personal experience is to treat patients before any resurfacing procedure with 6 weeks of topical retinoic acid and the addition of hydroquinone for patients with darker skin (Fitzpatrick 3 or higher). Such pretreatment can reduce the risk for post-resurfacing hypopigmentation, hyperpigmentation, and scarring.

Postoperative Care

Following endoscopic forehead and open brow lifting, a compression bandage is applied with a material such as Coban or Coflex. The pressure helps to limit edema and small hematoma formation while possibly improving fixation. Typically, a drain is not required if a very dry field is maintained, making postoperative care very easy. The patient should be instructed regarding limited activity for the first 2 weeks and the use of cold compresses over the eyes and brow. Head elevation is recommended for the first 48 to 72 hours as tolerated. Preoperative avoidance of antiplatelet drugs, careful surgical technique, and immediate postoperative use of cold compresses, elevation, and limited strenuous activity will significantly decrease postoperative healing time.

The patient may have the postoperative dressing removed on postoperative day 1 to allow visual inspection of the surgical site for any problems. A less constrictive Velcro-type

• **Figure 22-46** **A,** Preoperative and postoperative images of a female patient who has relatively good brow position and obtained a very nice result from upper blepharoplasty alone. **B,** Preoperative and postoperative images of a female patient who has a low brow position and was treated with brow lift only with lasting results at 2 years post op.

head wrap then can be used for patient comfort and to allow easy removal for showering, but a dressing is not absolutely required after the first 24 hours. Ensuring a short and comfortable recovery is important for the modern cosmetic surgery patient, who hopes an endoscopic technique will yield results with fewer overall problems than are associated with open techniques. Unfortunately, the release of significant scalp and facial deep tissues continues to produce significant pain that requires narcotic relief for most of the first few days.

The patient is allowed to gently shampoo the hair after 24 hours but must be cautioned to avoid water pressure directly over the incision sites. Each incision then is cleaned twice a day with a dilute peroxide solution, and a thin layer of antibiotic ointment is applied for the first week. Staples can be removed at the end of 1 week. Chemical treatment for hair should be delayed for at least 2 weeks to avoid the possibility of hair loss caused by the harsh chemicals. Hot curling irons or similar devices must be used with caution because areas of scalp anesthesia that may be present for months can predispose a patient to an accidental self-inflicted burn.

Complications

Fortunately, major complications are rare with properly performed endoscopic forehead and brow lifting techniques. Excellent patient selection, diligent preoperative planning, meticulous surgical technique, and thorough postoperative care all are required to limit the chances of complications[82-88] (Figure 22-46). Minor complications can always occur despite a surgeon's best efforts; however, no matter how negligible the problem, the patient must be treated with concern and compassion. The characteristic cosmetic surgery patient is expecting to look better as soon as possible and is not always as tolerant of perioperative problems as a trauma patient might be. Extensive edema and ecchymosis usually are not considered complications, but they warrant appropriate reassurance and even simple suggestions to hasten recovery when feasible. For example, makeup suggestions from a well-trained staff member may greatly improve a postoperative patient's mood after he or she is shown how to better hide unusual ecchymosis.

The overall complication rate for any forehead procedure is low. De Cordier retrospectively reviewed 393 patients who underwent endoscopic forehead lift from 1994 to 2000. The review reported alopecia in one occurrence (0.3%), transient scalp numbness in most patients, 2% with prolonged dysesthesia, and seven patients (2.3%) with a temporary frontal nerve weakness. Forehead hematoma requiring in-office drainage occurred in 3.5% of patients. Seven percent of their patients experienced lagophthalmos, 8% with upper eyelid asymmetry, and 3% with brow

malposition. There was also one patient who had wound dehiscence and one who had a suture abscess.[98] Of all possible problems, permanent facial paralysis or major tissue loss is the most devastating. These particular complications are rare (less than 0.3% and less than that for a standard lower face-lift).

Brow Malposition

Malposition of the brow may occur with any approach to forehead rejuvenation.[99] Too much resection of skin in any open approach or excessive suspension with any procedure may result in lagophthalmos and brow malposition. The risk is increased when simultaneously blepharoplasty is performed. To avoid excessive skin resection during the blepharoplasty the forehead lift should be completed before the eyelid surgery. When lagophthalmos is limited to less than 2 mm there is a decreased risk of dry eye syndrome.[100]

Problems such as corneal abrasions are a matter of great concern to the patient because of the severe pain they produce; these abrasions can be nearly eliminated with proper technique and perioperative attention to detail. For instance, eye lubricant should always be used, and thought should be given to placement of temporary Steri-Strips over the eyelids or a tarsorrhaphy suture to prevent inadvertent scratching of the cornea by gauze, tubing, or other materials during the procedure. All severe pain requires immediate evaluation, and suspected abrasion should be treated with suitable ophthalmic drops for pain, ointments, and with patching of the affected eye for 12 to 24 hours. Minor blurred vision for the first 12 hours due to chemosis and use of ophthalmic ointments is not unusual. Appropriate ophthalmologic consultation is required for persistent or uncontrollable eye pain, persistent dry eye symptoms, or unusual changes in vision.

In one study of 600 patients who underwent combined upper blepharoplasty and open coronal browlift there was no dry eye syndrome, blindness, or globe exposure, and there were only 2 cases of brow asymmetry.[101] In a retrospective study comparing 140 (121 coronal and 19 endoscopic) patients who had either the endoscopic-assisted approach or the open approach there was no significant difference in brow elevation with either approach alone or in combination with blepharoplasty at the 1-year evaluation.[102]

When there is over-elevation of the brow, consideration should be made to performing release of the suspension. When there is under-elevation of the brow it is likely due to inadequate release, fixation, or suspension. This can be treated with revision surgery and ensuring proper release, suspension, or skin excision. Over-resection of the depressor supercilli can lead to medial over-elevation and a "surprised" appearance, which can be avoided by recognition of the anatomy intraoperatively. Minor asymmetries can be improved with strategic placement of neurotoxins (Figure 22-47).

Nerve Damage

Peri-incisional anesthesia is expected and is usually temporary. Direct injury to the nerves is an uncommon occurrence but traction injury (neuropraxia) can occur due to suspension. When neuropraxia injury occurs it may take up to 12 months to completely resolve. In the temporal region the dissection plane is superficial to the superficial layer of the deep temporal fascia and damage to the zygomaticotemporal and auricotemporal nerves (second division of trigeminal) should be minimal.

Knowledge of the facial nerve and its branches is necessary to avoid injury because this results in paralysis and asymmetry of the forehead. In particular, the temporal (frontal) branch is at risk for injury in the temporal lateral dissection. Knowledge of pertinent anatomy is the best way to prevent injury, and meticulous surgical planning will allow facial cosmetic surgeons to avoid nerve damage.

• **Figure 22-47** Images depict why some brow lift patients have a bizarre look from a potential complication of over-elevation of the medial brow. Lateral brow elevation looks attractive on most females but medial brow elevation greater than the lateral brow third creates an odd look for male or female brow lift patients.

Scars

Scarring is of concern with open brow lift procedures and typically results from improper incision design and closure. The unsightly scar may be minimized in open approaches by making an irregular incision with an extreme bevel from posterior to anterior beginning 4 to 5 mm posterior to the hairline at an area where the follicular density becomes consistent. The extreme bevel of the incision preserves the hair follicles on the superior flap, allowing hair growth both through, and anterior to, the scar postoperatively. Scarring and thinning of tissue due to overzealous resection of brow elevators are best managed by dermabrasion or fillers.

Alopecia

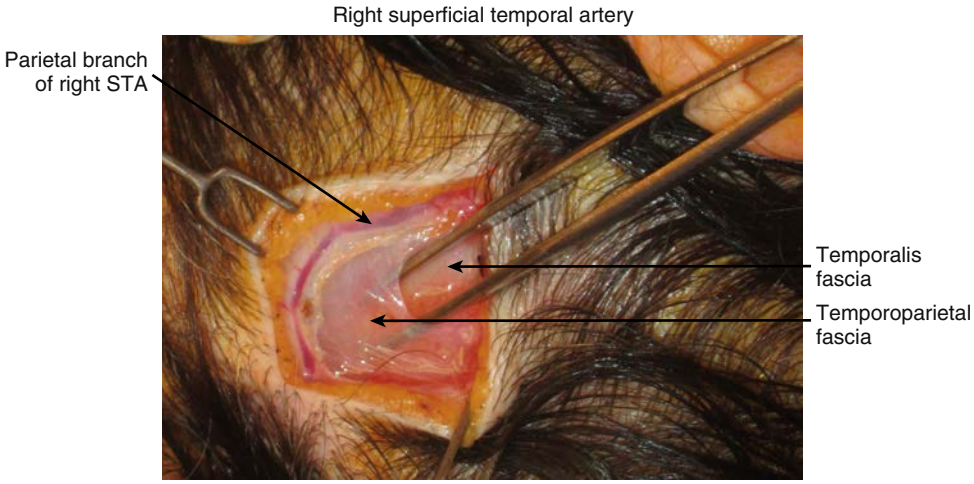
Alopecia can also result from improper incision design and closure, including inappropriate wound tension, rough handling of wound margins, and excessive use of electrocautery. Peri-incisional alopecia can appear as a widened scar; when the scar is visible by the endoscopic approach, the scar can be excised at a later date. Alopecia around endoscopic scars can make them more obvious and scar revision can be performed to improve the scars by excision of the widened scars and close reapproximation of the hair-bearing scalp. As an alternative, follicular unit hair transplants can be placed in the scar.

Acute tellogen effluvium is a rare but known cause of hair loss after brow procedures. Often, the hair follicles in this situation have a club shape and may be found in areas far from the surgical site. The features include diffuse shedding sometimes with accentuated hair thinning, a normal appearing scalp, and a markedly positive pull test. The hair pull test is done by grasping approximately 40 to 60 hairs between the thumb and index finger and applying steady traction (slightly stretching the scalp) as you slide your fingers along the length of the hair. Generally, only a few hairs in the telogen (resting) phase can be plucked in this fashion. Less than 10% is considered normal, whereas greater than this is considered indicative of a pathologic process.[103] Fortunately, telogen effluvium is a self-resolving condition and regrowth can be noted in 3 to 6 months, but cosmetically significant regrowth can take 12 to 18 months (see Figure 22-39).

Bleeding

Excessive bleeding may occur with any approach and may be arterial, venous, or from skin edges. Preoperative evaluation to note blood dyscrasias and patient education on avoidance of agents that cause bleeding will prevent most issues. Injection with a hemostatic agent, ensuring intraoperative hemostasis, and avoidance of injury to the superficial temporal or zygomaticotemporal arteries, supraorbital or supratrochlear vascular bundles, and sentinel vein will decrease postoperative hematomas. If there is slow postoperative bleeding it may be controlled with pressure alone, although hematomas require evacuation, exploration, and control of bleeding (Figure 22-48)

Proper planning, technique, and postoperative care will help to reduce the incidence of complications. Immediate and appropriate treatment, along with sincere concern for the patient's well-being, should help to reduce the chance that a far worse situation may develop.



• **Figure 22-48** The right temporal scalp is shown just above the helix of the ear in a location for a lateral endoscopic port incision or a temporal lift. Two branches of the superficial temporary artery are shown that are seen in the upper temporoparietal fascia. They are one of many sources for hematoma or at minimum a nuisance to a clean operating field.

Summary

An increase in upper facial rejuvenation techniques over the past two decades, led by the use of the endoscope and neurotoxins, has revolutionized the treatment of upper facial aging. Cosmetic surgery treatment of the upper facial third is frequently an essential element for complete facial rejuvenation.[82,83] Matching the diagnosis with the ideal rejuvenation technique(s) is essential for maximum esthetic benefit. Even the best surgical technique can produce inadequate or even poor results if improper patient selection or diagnoses are made; for this reason, the forehead and brow area must be critically evaluated for a wide range of interlacing diagnoses.

Particular skin problems vary with patient age and sex, but gravity remains consistent and nonselective. So, with regard to brow ptosis, the question often is not "Will it occur?" but "When will it occur?" and "How severe will it be?" Lateral brow (hooding) now may be selectively treated endoscopically to achieve a more youthful appearance, often with little down time. Society's idea of beauty at any single moment in time ultimately will guide the patient and surgeon as they choose where the brow should be located rather than merely raising it higher. True or total rejuvenation is complex; it involves multiple modalities and often tissue replacement techniques such as fat grafting. Only time and persistence will prove what best restores youth to the upper face. Forehead and brow lifting, and in particular the endoscopic approach, is merely an elegant surgical tool in a wide surgical armamentarium.

Cosmetic surgery continues to show an exponential rise in popularity. The aging population wants to feel and look more youthful, but nonetheless demands to remain "natural" looking after low morbidity procedures. Today's discernible cosmetic surgery patient is often very knowledgeable on the subject of procedural options and may even insist on a specific technique such as an endoscopic procedure. It is the guidance of a well-trained surgeon and diagnostician that can ultimately produce a happy patient. Also, it is imperative for the surgeon to refuse to provide treatment that is not in the best interest of the patient. Cosmetic surgery is a luxury, and at the end of the day, it is the surgeon's responsibility to provide the patient with the best and safest techniques available to achieve realistic outcomes, whether they are performed open or endoscopically.

Liposuction and Fat Transfer Techniques

HARSHIV J. VYAS, ANDREW M. SOHN, BERNARD J. COSTELLO

Liposuction

Introduction

Over the past three decades, liposuction (e.g., suction assisted lipectomy, suction lipoplasty, fat suction, blunt suction lipectomy, and liposculpture) has advanced significantly. Better understanding of the anatomy, physiology, and metabolism of subdermal fat has led to refinement of surgical techniques, introduction of tumescent anesthesia, and innovations in biomedical technologies, all of which have contributed to enhanced patient safety, superior treatment outcomes, and thus widespread popularity of the procedure. Americans spent more than $13 billion on cosmetic procedures in 2015. Surgical procedures accounted for almost 60% of the total expenditures. Liposuction was noted to be the most popular surgical procedure with almost 400,000 procedures performed nationwide, followed by breast augmentation.[1]

The neck is the most common site treated with liposuction in the craniofacial region. Cervicofacial liposuction refers to a minimally invasive facial rejuvenation procedure that recontours and removes supraplatysmal fat present between skin and platysma. It utilizes a suction assisted technique for fat extirpation from the submental, submandibular, and jowl regions by transcutaneous placement of cannulas at strategic sites. Removal of subplatysmal fat present between platysma and submental musculature is helpful only in isolated cases. Cervicofacial liposuction has become an indispensable tool in the armamentarium of the facial esthetic surgeon for rejuvenation of the aging neck. This chapter focuses on the esthetic applications of liposuction in the cervicofacial region.

History

The first liposuction procedure was described by Schrudde in 1972, which involved a fat excision using sharp uterine curettes. In 1976 Arpad and colleagues used suction for fat removal using blunt hollow cannulas, and shortly thereafter Illouiz developed the technique most resembling liposuction as we know it today. In 1987 the use of tumescent anesthesia as described by Hetter allowed for a more hemostatic approach with good pain control. Ultrasound was added by Scuderi during the same year, and laser assisted liposuction was described in the early 1990s. Other techniques using power, water, or radiofrequency have also been described. No clear data have proven one of these technologies to have a considerable advantage over another, and each has a similar effect.

Fundamentals of Liposuction

Adipose tissue is made up of adipocytes that aggregate together to form lipid lobules. Weight gain within an individual to a moderate level of obesity occurs through lipid accumulation and hypertrophy of individual cells. Average cell weights are ≈0.4 μg and can attain masses up to 1.0 μg. As the individual gains more weight, new fat cells form from mesenchymal stem cells to accommodate the excess lipid accumulation. This hyperplastic adipose deposition is believed to be permanent and "resistant" to subsequent dieting. Even when weight loss regimens are implemented, facial areas such as the submental region are difficult to change. Though exercise programs help to tone muscles throughout the body, it is difficult to strengthen muscles of the face and neck; in addition, toned muscles do not necessarily reduce the amount of superficial adipose tissue.[2] With diet and weight loss, lipid content of cells may be reduced, but the number of adipocyte cells remains constant.[2] After maximal reduction of adipocyte size, the only method to reliably reduce fat content is by excision.[3]

Liposuction effectively decreases the number of adipocytes in two ways:

1. Immediate shearing of fat in contact with the cannula and its extirpation under negative pressure (suction).
2. Gradual necrosis and resorption of surrounding fat over the next 2 to 3 months due to damage to the lipid lobules caused by the to-and-fro motion of the cannula and suction trauma.

Liposuction should thus be viewed as a complement to diet and exercise and not as its replacement.

Tumescent Anesthesia and Its Rationale for Use

The term *tumescent* is etymologically derived from the Latin word *tumere*—to swell. Tumescent anesthesia is a local anesthesia delivery technique that involves the subdermal infiltration of large volumes of a tumescent solution.

Ingredients of Klein's tumescent solution include:

1. 50 mL (500 mg) of 1% lidocaine
2. 1 mL (1 mg) of 1:1000 epinephrine
3. 1000 mL of 0.9% normal saline
4. 10 mL of 8.4% sodium bicarbonate as a buffer

Using the technique of tumescent anesthesia for regional anesthesia, which allows for distribution of the medication over an area that is less likely to be rapidly absorbed, Klein showed that lidocaine doses of 35 mg/kg were safe for liposuction. Prior to that, the recommended maximum dose of lidocaine with epinephrine was considered to be 7 mg/kg of body weight.[4] In most instances, it is not necessary to approach these values for facial liposuction. Higher concentrations of lidocaine (0.1%) are sometimes used for liposuction over sensitive parts of the body such as the periumbilical area, inner thighs, waist, and chest. Elsewhere, a concentration of 0.05% is usually sufficient to provide adequate anesthesia for the procedure.[5] In an average sized patient, 300 to 500 mL of tumescent anesthesia is typically used to anesthetize the neck, jowls, and cheeks. Distention of subdermal tissues with tumescent solution causes elongation and stretching of blood vessels and nerves, potentiating the effects of epinephrine and lidocaine.

Patient Selection and Clinical Considerations

When selecting patients for cervicofacial liposuction, it is imperative to discuss the patient's motivation for surgery, concerns, and expectations. Once the patient's physical status has been deemed appropriate for safe liposuction, the overall body habitus is assessed. Visual criteria for the global assessment of a youthful, attractive neck have been well described.[6] These include a distinct inferior mandibular border, subhyoid depression, visible thyroid cartilage bulge, visible anterior sternocleidomastoid border, and a cervicomental angle between 105 and 120 degrees.

Chung and Williams[2] have suggested a systematic evaluation of the cervicofacial region as follows:

1. Skin condition: Evaluate skin for flexibility, elasticity, firmness, and adherence to the underlying tissues, all of which play a critical role in predicting outcomes. Skin with elastic integrity will more effectively redrape over the underlying liposuctioned contour.
2. Amount and location of fat: Assess the location and amount of fat by palpation. This is best accomplished with the pinch and roll technique. The skin should be palpated or rolled between two fingers to determine the thickness of the skin and fat. In the cervical region, the presence of supraplatysmal fat should be differentiated from subplatysmal fat. With palpation, subplatysmal fat is generally firmer owing to its connective tissue and fibrous content.
3. Integrity of the platysma: Evaluate thickness and laxity of platysma. The presence of platysmal bands at rest indicate that some form of platysmaplasty should be performed for proper rejuvenation of the neck. Furthermore, cervical liposuction may expose occult bands. This may be assessed by having patients strain their neck with their teeth clenched while making a grimace; with this provocative test, platysmal bands due to laxity of the muscular anterior borders may be revealed.
4. Condition of the surrounding skeletal framework: Deficiencies in the surrounding skeletal framework of the cervicofacial region (for example, retrognathia) may significantly affect the results of liposuction.
5. Prominence of surrounding soft tissue structures: Surface anatomy of the submandibular and parotid salivary glands must be taken into consideration. Liposuction in the submandibular region may enhance the appearance of the submandibular glands. Similarly, liposuction of cheek fat may enhance the anterior border of an enlarged parotid gland. Furthermore, patients with heavy masseter musculature may not benefit as dramatically as others from facial liposuction.

The ideal patient for cervicofacial liposuction is one with localized fat deposits without redundancy of skin or platysmal pathosis. The excessive fat deposits may be a result of hereditary predisposition, poor dietary and exercise habits, age, medications, hormones, or weight gain.[2] Skin is more elastic in younger patients, hence removal of localized fat deposits by cervicofacial liposuction can produce an esthetic result. In aging patients, the skin has greater redundancy and liposuction alone cannot achieve desired results. It may need to be combined with other facial rejuvenation procedures such as rhytidectomy, platysmaplasty, or skin resurfacing for a better outcome. Liposuction may also be utilized for contouring adipose tissue in the nasolabial fold and midface region. Due to variability of results at these sites, it is not widely used. Two-dimensional and three-dimensional facial imaging technology is a useful adjunct to diagnosis, treatment planning, and patient education in esthetic surgery.

Preoperative Evaluation

At the time of the preoperative appointment, the surgical objectives, treatment plan, and patient's expectations should be discussed. Past medical history including medications

must be reviewed and updated. A thorough physical examination must be performed. Preoperative and postoperative instructions are given and a written informed consent is obtained. Agents that prolong bleeding, such as aspirin, should ideally be discontinued preoperatively in consultation with the patient's physician. Anticipated recovery time of 1 to 2 weeks following the procedure must be communicated in advance.

Technical Considerations for Surgery

Marking and Incisions

Markings must be made while the patient is in an upright position as significant distortion of soft tissue can occur with the patient in supine position and once tumescent anesthesia is delivered. Key anatomic landmarks such as lower border and angle of mandible, anterior border of sternocleidomastoid, hyoid bone and thyroid cartilage, and proposed incision sites are marked. Depending on the areas that need to be addressed, incision sites can be planned in the following areas: submental (most common), preauricular, postauricular hairline and infralobular. Submental incisions provide access to central cervical liposity while the latter provide access to more lateral regions including the jowls. Placing an incision in the submental crease could lead to the development of a witch's chin deformity. This can be avoided by placing the incision anterior to the crease.

Anesthesia

The procedure may be performed solely using local anesthesia (1% lidocaine with 1:200,000 epinephrine) or under general anesthesia. A microcannula or a spinal needle is used to administer the tumescent fluid in the subdermal plane in a standard radial fashion with an in-and-out motion across the field to be treated. This pretunneling facilitates subsequent suctioning. A wait time of 15 minutes is recommended following administration of the tumescent fluid in order to achieve optimal vasoconstriction and regional anesthesia.

Liposuction Technique

Liposuction may be performed by the "open" (fat removal under direct vision by skin flap elevation) or "closed" (fat removal by blind insertion of a suction cannula in the subdermal plane and its to-and-fro motion) techniques. The closed liposuction technique is described in this chapter, and is preferred by the authors. The supraplatysmal fat compartment forms the majority (44.7%)[7] of the cervical adipose tissue and has a volume of no more than 10 to 15 mL.[8] This region is devoid of any vital neurovascular structures and is the plane in which cervicofacial liposuction is mostly performed. The subplatysmal plane contains the submental vascular plexus and the anterior jugular veins, which pose a significant bleeding risk if violated. Control of bleeding can be challenging due to limited surgical field exposure and visualization. This in turn may place the marginal mandibular nerve at risk if electrocautery is used to control the bleeding.

A wide range of liposuction cannulas of various shapes and sizes are available in the market. Cannulas ranging from 1.5 to 6 mm in external diameter are commonly used for cervicofacial liposuction. A larger sized cannula is preferred in the submental region where greater quantity of fat needs removal. Microcannulas are useful in the cheeks, jowls, and nasolabial folds and near vital structures such as the marginal mandibular nerve because they allow for fine sculpting and contouring. Blunt cannulas that have suction pores/lumen located a few millimeters away from the tip are preferred over sharp tipped cannulas or cannulas with pores at the tip because these are gentler on the tissues.

The negative pressure generated during the vacuum technique is set between 250 and 400 mm Hg, in order to prevent over-resection and destruction of normal adipose architectures, which are the main causes of contour irregularities.[9] Syringe assisted liposuction may also be used in the cervicofacial region. This technique will be discussed in detail later in the chapter. During liposuction, one hand (usually the dominant hand) maneuvers the suction cannula in the subdermal plane while the other hand utilizes tactile sensation to ensure correct placement (location and depth) of the cannula.

The lumen of the suction cannula should be directed away from the skin surface to avoid injuring the subdermal plexus. The cannula is moved in a standard radial fashion with an in-and-out motion, similar to the pretunneling technique used to administer tumescent fluid. This technique preserves a lattice-like connection of lymphatic and neurovascular tissues between the skin and subdermal layers. Suctioning should proceed from deeper to more superficial layers (Figure 23-1).

When addressing the jowls, finesse is needed to avoid skin surface irregularities. Smaller cannula sizes are typically used for fine sculpting. While head extension and lateral rotation of the neck provide appropriate positioning for suctioning the cheek, jowl, lateral neck, and jawline, the marginal mandibular nerve may drop as much as two fingerbreadths below the mandible, become more superficial, and pose a greater risk for nerve injury.[10]

Leaving an intact thin layer of supraplatysmal fat attached to the dermis is recommended to avoid skin contour irregularities. An obvious zone of demarcation between the treated and untreated areas can be avoided by feathering out past the preoperative skin markings.

The end-point of the procedure is determined by the pinch and roll technique as previously described. Only a thin layer of fat should be palpable between the fingers. Healing after liposuction continues for a few months and significant remodeling of the tissues due to fat necrosis and absorption can be anticipated. Hence, it is prudent to remove less rather than more fat.

Primary closure of the incisions is achieved using 5-0 polyglactin and 6-0 polypropylene sutures in a simple interrupted fashion. Open liposuction may be performed in

conjunction with other facial rejuvenation procedures such as rhytidectomy, submentoplasty or chin augmentation to further enhance facial esthetics.

Another option in the management of fat is sometimes used in lieu of or in conjunction with liposuction techniques. In 2015, Kybella (deoxycholic acid) was approved by the FDA for the use in reduction of moderate to severe supraplatysmal submental fat. Deoxycholic acid is a naturally occurring bile acid that aids in several processes such as cholesterol metabolism and the emulsification of fat-soluble vitamins for absorption. Deoxycholic acid has cytotoxic properties that destroy cells via plasma membrane disruption and cell lysis. When injected into fat cells, fat cell destruction occurs by lytic process. This treatment provides a minimally invasive alternative to submental liposuction. Kybella is supplied in 2-mL vials (10 mg/mL) and does not require reconstitution. The average initial treatment is usually 2 to 6 mL (one to three vials) depending on the amount of submental fat. Follow-up treatment can be repeated in 4 to 6 weeks, and a patient can receive up to six treatments. Kybella is indicated for isolated supraplatysmal fat deposits without skin excess. Some of the risks of adverse events include pain at the injection site, swelling, bruising, numbness, erythema, and induration. More serious side effects include injury to marginal mandibular nerve and dysphagia, but are reported infrequently.

• **Figure 23-1** This 29-year-old female had submental liposuction using a standard tumescent technique through a single submental incision. **A** and **B,** Preoperative frontal and lateral photographs; **C, D**, two weeks postoperative frontal and lateral photographs;

• **Figure 23-1, cont'd E, F**, one year postoperative frontal and lateral photographs. In all likelihood, as her skin ages, it may be helpful to consider platysma plication and/or skin excision/face-lift options as skin laxity increases. This case illustrates the difference between skin laxity issues and those due to submental fat deposits.

Postoperative Care

Postoperative care following cervicofacial liposuction involves intermittent ice packs during the first several days and head elevation while sleeping for the first week to decrease postoperative swelling. Patients are instructed to wear a light pressure garment consistently for the first 3 days and then only at night for the next month. Wearing a pressure garment during healing assists with elimination of dead space and holds the skin in the desired position to allow its reattachment to underlying tissues. Strenuous physical activity is avoided for 2 to 3 weeks after completion of the procedure.

Complications

Postoperative complications from cervical-facial liposuction are infrequent and often of a minor nature. Compared with full body liposuction, rapid fluid shifts, hypotension, and significant blood loss are less concerning. Infections are rare, particularly when sound surgical principles are utilized. Although hematomas, seromas, and prolonged postoperative edema are possible, they are quite rare. Small hematomas and seromas respond well to needle aspiration and continuous pressure dressings. Postoperative induration responds well to therapeutic ultrasound treatment. Permanent and/or temporary injury to the marginal mandibular branch of VII or the greater auricular nerve is extremely rare. If this occurs, the event is often temporary in nature. Subcutaneous scarring may occur, but is often related generally to aggressive surgical technique. Sometimes, liposuction can uncover underlying platysmal banding in older individuals. Mild cases can be treated with botulinum toxin A. Platysmaplasty is also an option for more significant deformities. Patients with excess adiposity should be re-treated, but after a waiting period of 4 to 6 months to allow edema to resolve and skin contraction to have mostly finished its course. Postoperative depressions may be treated with a filling agent such as autologous fat injection as described in the next section. As long as suctioning is carried out in the preplatysmal plane, creation of a submental depression or a "cobra deformity" will typically not be a problem. Excess sagging neck skin often results from patient selection issues as these patients would typically have a better result with a skin-tightening procedure.

Fat Grafting

Introduction

Fat grafting is not simply the opposite process of liposuction for those who lack shape and fullness. Volume restoration typically is helpful in completely different areas than the sites of treatment for liposuction. The contemporary conceptual understanding of the physiology of facial aging is that volume depletion along with loss of skin elasticity are responsible for the progressive clinical changes associated with aging. Hollowing of the temporal fossa and the submandibular region, malar fat atrophy, and flattening of the lateral brow due to loss of brow fat pad are some of the manifestations associated with volume depletion in the

aging face. When there is volume loss, treatment of skin redundancy alone can lead to an unnatural facial appearance sometimes seen with face-lifts or blepharoplasties.

Autologous fat transplantation is a minimally invasive facial rejuvenation technique that treats residual soft tissue defects caused by congenital abnormalities, aging, disease, and trauma by restoring facial volume and contour using fat harvested from an autologous source. It may be used as a stand-alone procedure or synergistically along with traditional lifting procedures. When used in combination, the treatment ideology is to use surgical lifts for treatment of skin redundancy and fat grafting for volume rejuvenation. This comprehensive approach often provides optimal and long lasting clinical results characterized by a natural and youthful rejuvenation of the facial complex. Fat transfer to the face was still in the top 10 cosmetic procedures in 2015 with 48,059 procedures performed nationwide, but not nearly as popular as liposuction.[1]

Although the use of fat as a tissue filler dates back a century, results were inconsistent largely due to highly variable resorption. It was not until the 1980s that there was new interest in fat transfer, owing in part to the growing popularity of liposuction. Refinement of surgical technique and a greater understanding of the cellular characteristics of subcutaneous fat led to improved results.

Although there has been a recent surge in the number of soft tissue filling agents in the market and advances continue to be made in the field of biomaterials, autologous fat is still a viable treatment agent. It has several characteristics of an ideal soft tissue filler: for most people it is readily available, is nonallergenic, carries no risk of disease transmission, is well-accepted, and is inexpensive. It is a living tissue that conforms well to the properties of the recipient site and thus may produce a more natural appearance. It is also a preferable choice when large quantities of fillers are required to restore full facial volume, which may not be feasible with synthetic fillers due to expense and the temporary nature of most materials.

Adipose Tissue Biology

An adipocyte is 50 to 150 mm in diameter (as it becomes larger, it dies from ischemia) and the lifespan is several to 10 years in humans.[11] There are various types of cells in subcutaneous adipose tissue, and adipocytes account for only 20% or fewer of the total number of cells.[12] Of this subpopulation of cells, the adipose-derived stem cells (ADSCs) have received significant interest over the past decade, including the biologic behavior of stem cells derived from fat for transfer into other areas for improved healing. ADSCs serve a number of functions and are believed to be a major contributor to the clinical benefits of the graft.

The "cell survival theory," which was first postulated in 1955 and maintains that transplanted adipocytes partly survive once they receive adequate nutrients and remain alive in the recipient site, has now been replaced by the "cell replacement theory," which holds that most adipocytes undergo ischemic death and subsequent replacement with next generation during the first 3 months after fat grafting.[11] Following fat grafting, the grafted nonvascularized adipose tissue loses mass due to the loss of blood supply and the graft is nourished by plasmatic diffusion from the surrounding host tissue for a few days until revascularization occurs. The fate of adipocytes in grafted fat and the long-term postoperative sequence after fat grafting are schematically represented in Figures 23-2 and 23-3.[11]

Patient Selection

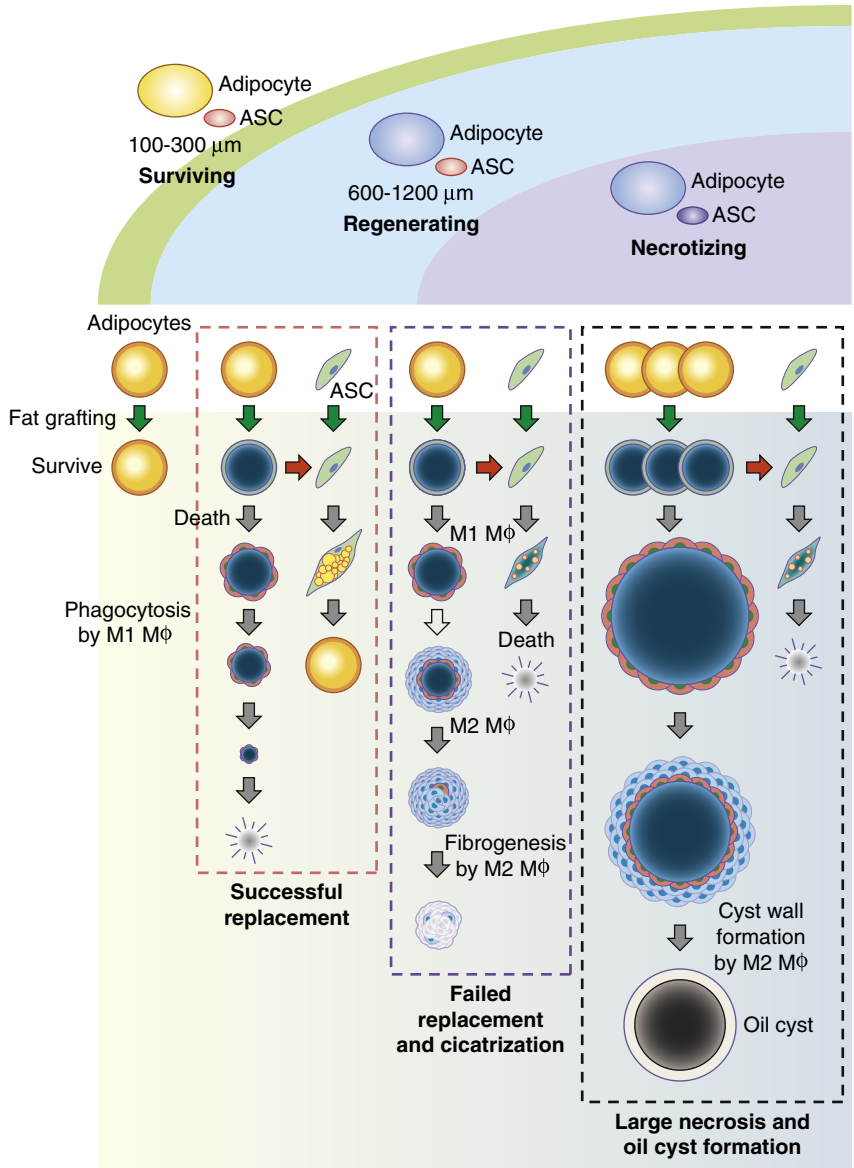
Prior to formulating a surgical plan, it is essential to be fully aware of the patient's medical history and motivation for surgery, and discuss with the patient the expected treatment outcome. Caution must be exercised in patients that are extremely thin because fat stores will be limited. In aging patients that present with significant skin laxity, combining surgical lifts with fat grafting can provide better results in some patients. The overall appearance of the face can be changed significantly with a shift in facial proportions. Patients with more severe deformities such as those seen in Treacher-Collins syndrome, oculoauriculovertebral spectrum, patients with facial lipoatrophy, and those with post-liposuction defects may also be candidates for fat grafting.[13] The surgeon typically reviews past photographs with the patient to demonstrate progressive loss of soft tissue volume and identify the goals of fat grafting. Before and after photographs of other patients can also be used as a tool for educating prospective patients.

Preoperative Evaluation

Preoperative planning is an important key to a successful surgical result and a satisfied patient. In addition to the items discussed earlier in this chapter, a number of additional nuances should be considered. A complete analysis of the cervicofacial complex is undertaken with special focus on regions where volumetric rejuvenation is most effective. These areas include the eyebrow, temple, and upper eyelid in the upper third; lower eyelid, malar and submalar areas, and nasolabial fold in the middle third; and labiomandibular fold, prejowl sulcus, labiomental sulcus, and chin in the lower third.[14] Donor site selection for fat harvesting and anticipated postoperative recovery time of 2 to 3 weeks should be discussed in detail so that active patients can prepare appropriately.

Technical Considerations for Surgery

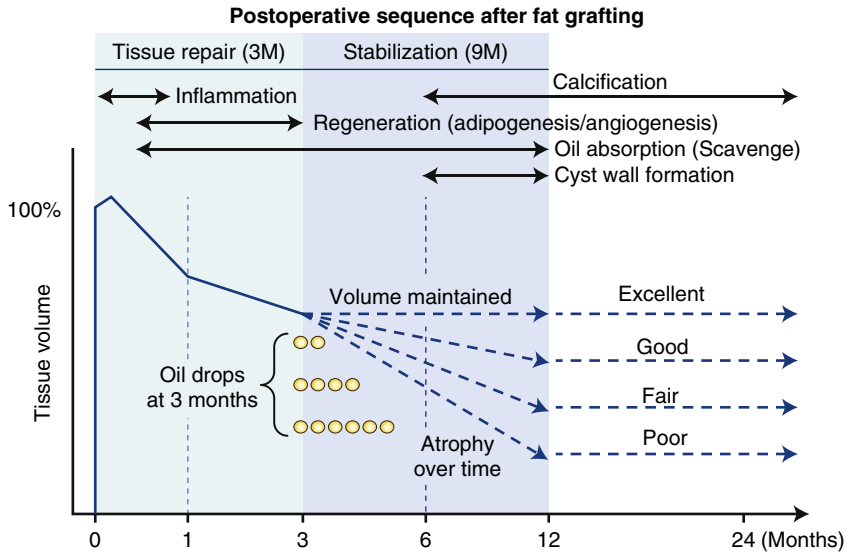
No standardized, universally accepted technical protocol exists for fat grafting. The technique mentioned here is based on the principles described by Coleman and Saboeiro[13] and emphasizes minimally invasive extraction of fat and its centrifugation, followed by injections of micro-particle fat isolates in multiple tissue planes.



• **Figure 23-2** Conclusive schema for the fate of adipocytes in grafted fat. During the first 3 months of adipose tissue remodeling, transplanted adipocytes have differential fates depending on their microenvironments. In this schema, complex cellular events are simplified and the adipocyte fate is categorized into four patterns: survival, successful regeneration, failed regeneration (cicatrization), and oil cyst formation. Cicatrization and oil cyst formation are often not complete at 3 months. The most superficial zone is the "surviving zone," which is less than 300 μm thick. In the surviving zone, both adipocytes and adipose-derived stem cells (ASCs) survive. The second zone is the "regenerating zone," the thickness of which varies (600 to 1200 μm) depending on the microenvironmental conditions. In this zone, adipocytes die but ASCs survive and provide new adipocytes to replace the dead ones. The most central zone is the "necrosis zone," where both adipocytes and ASCs die, no regeneration is expected, and the dead space will be absorbed, be filled with fibrosis, or develop into an oil cyst. (From Mashiko T, Yoshimura K: How does fat survive and remodel after grafting? *Clin Plast Surg* 42(2):181-190, 2015.)

After the complete procedure has been planned, markings of the fat procurement as well as recipient site should be made preoperatively with the patient in an upright position. Small access openings should be placed in areas of skin folds, stretch marks, scars, and hair bearing areas to make them less conspicuous. These markings are done prior to the use of local anesthesia with vasoconstrictor.

The procedure may be performed under general or local anesthesia. Infiltration of 0.5% lidocaine with 1:200000 epinephrine is used to anesthetize the procurement site using a blunt infiltration cannula. The amount of solution infiltrated is typically equal to the amount of fat removed. Current evidence suggests that using tumescent solution at the time of fat graft harvest does not have a detrimental effect on fat graft cell viability and may even enhance viability.[15] Local infiltration of 0.5% lidocaine with 1:200000 epinephrine at the preoperatively determined recipient sites helps with local anesthesia as well as minimizes the risk of



• **Figure 23-3** Long-term postoperative sequence after fat grafting. Adipogenesis after adipocyte death is exerted by activated adipose-derived stem cells (ASCs). Some of the dead adipocytes are replaced with new adipocytes of next generation and the adipogenesis is finished by 3 months (tissue "repair" phase). Dead adipocytes remaining at 3 months are absorbed during the next 9 months (tissue "stabilization" phase). Lipid droplets (dead adipocytes) are absorbed by macrophage phagocytosis, but the absorption is very slow and the absorption period depends on the diameter of the lipid droplets; when the lipid droplet diameter is large, such as 10 mm, the cyst wall is formed before completing absorption and the cyst wall starts to calcify over time. The final volume retention after fat grafting is determined by the rate of successful replacement of adipocytes. If grafted adipose has only small lipid droplets and absorption is finished by 3 months, the volume will not substantially change after 3 months (shown as "excellent"). On the other hand, if many large lipid droplets remain at 3 months, tissue will atrophy between 3 and 12 months (shown as "poor"). (From Mashiko T, Yoshimura K: How does fat survive and remodel after grafting? *Clin Plast Surg* 42(2):181-190, 2015.)

iatrogenic fat embolism due to vasoconstriction of the blood vessels. The maximum dosage of all medications should be considered when planning these procedures, particularly with local anesthetics used in body procedures.

Fat Procurement

Harvested fat remains most viable when there is minimal change in its architecture. Fat should pass intact through the lumen of the cannula during harvesting as well as injection in order for the transplant to be successful. Sites selected for harvesting are usually those where fat is resistant to diet and exercise. In general, the lateral abdomen, posterior hip, back, and lateral thighs are more forgiving and do not have as much potential to wrinkle as the abdomen and medial thighs. In thin patients, small harvests from multiple areas are required. Current data suggest no significant difference in cell viability in adipose tissue removed from four of the most common donor sites: the abdomen, flank, thigh, and knee with handheld syringe aspiration.[15]

Fat procurement is usually done with the patient in a supine position. Symmetry should be maintained when harvesting from bilateral sites. A No. 11 blade may be used to make a small stab incision through which a blunt tipped fat harvesting cannula, usually ranging from 2.1 to 2.4 mm, is passed without friction against the surround skin. Next, a 10-mL syringe is attached to the cannula and the syringe plunger gently retracted by 1 to 2 mL at a time. This limits vacuum barotrauma to the adipose tissue. Although syringe aspiration with low negative pressures is used most often for fat harvest, there is evidence to suggest that no difference exists in cell viability between syringe aspiration and liposuction pump aspiration.[16]

The cannula is advanced in a standard radial fashion with a back-and-forth motion as previously described in the liposuction section of this chapter to maximize fat harvest and minimize contour irregularities. Following the fat harvest, stab incisions are closed primarily using 6-0 nylon in a simple interrupted fashion. The surgical site is then cleaned and a dressing is applied.

Fat Preparation Prior to Grafting

Procured fat is generally not uniform in character and concentration as extracted and some type of processing is necessary to obtain uniform material for injection.[17] Many techniques exist for processing fat, including centrifugation, gravity separation, washing, and filtration. Centrifugation is most commonly used, and is undertaken in a sterile fashion at 3000 rpm for 3 min following which the unprocessed fat separates into three layers: infranatant (blood and lidocaine), central core of fat, and supranatant (oily residue of free fatty acids from ruptured fat cells). The central core of fat, which contains a greater number of adipose cells/mL when compared to the unprocessed fat, is then isolated by decanting the infranatant and supranatant layers. A sponge can be used

to remove any residual oil at the top. Exposure to air should be minimized. Typically, centrifugation retains 50% volume of the unprocessed fat such that for every 10 mL of procured unprocessed fat, the approximate yield of processed fat following centrifugation will be 5 mL. The fat isolate is then transferred to 1-mL syringes in preparation for fat transfer.

Fat Injection

Fat should be injected soon after procurement. Small access openings are created with an 18G needle and 0.7-mm to 1.2-mm injection cannulas are utilized for fat delivery in the appropriate tissue plane. The puncture sites made for access are so small that they usually do not require suturing upon completion of the procedure. It is important to inject fat in small increments. This allows for a larger contact surface area of the injected fat with the recipient tissue, which is critical for adequate nutrition and fat engraftment. In areas that are less forgiving, such as the periorbital region, 0.03 to 0.05 mL is injected per pass. In more robust regions, such as the prejowl sulcus and mid-face, 0.1-mL injections can be performed in each pass.[14] Typically, 20 or more back-and-forth passes in a fan-like manner are made to empty a 1mL syringe. Transferring large globules of fat can result in central necrosis of the mass with subsequent resorption and loss of volume, or cyst formation.[13]

Fat can be placed at different levels to accomplish different effects. For example, grafting fat immediately beneath the dermis can improve the quality of the skin, decreasing rhytids, decreasing pore size, and even reducing scarring. Special care must be taken when placing fat superficially, as irregularities are more apt to be apparent in this plane. This is especially true in areas that have thin skin, such as the lower eyelid. To make changes in the shape of the face or body that relate to the underlying bony skeleton, fat can be placed above the periosteum.[13]

Fat injection should start deep and progress superficially in order to maintain tissue integrity. Injecting from two separate injection sites allows crisscrossing of cannula passes during graft placement, provides smoother fat infiltration, and helps avert a row-of-corn effect that may result if injection is made from one site.[17] Fat should be injected upon withdrawal to avoid iatrogenic fat embolism. Precise positioning of fat increments is important because it is difficult to mold the graft once it has been placed. Similar to liposuction, the operative end-point should always be undertreatment versus overtreatment. On average, 30 to 50 mL of fat is a common amount for a semiconservative full-face fat transfer, with over 60 mL representing a more aggressive strategy.[14] When fat grafting is performed in conjunction with rhytidectomy, it is often most beneficial to inject fat at the beginning of the procedure, before the face-lift has been performed.[17]

Postoperative Care

Minimal active postoperative care is typically required following fat grafting. Placement of sutures, dressings, or drains is not required unless the procedure has been undertaken in conjunction with rhytidectomy. Intermittent cold therapy for the first 48 to 72 hours following surgery may be beneficial to help limit swelling. Head elevation during sleep helps facilitate a decrease in postoperative edema. Minimum manipulation of the surgical sites and avoidance of strenuous physical activity for the first couple of postoperative weeks is recommended. Postoperative swelling as a general rule is proportional to the amount of fat transferred. Swelling and ecchymosis are generally most pronounced around the periorbital and lip regions. Some pain, ecchymosis, and discomfort are also to be expected at the fat harvest site. Two to 3 weeks of limited activity should be discussed with the patient preoperatively. Additional time off from work may be necessary in some cases as postoperative edema, although resolving, can persist for 3 to 4 months. Retreatment is typically deferred until 6 months to allow for postoperative volumetric changes to stabilize.

Complications

Complications from fat transplantation are rare and rarely are they significant. One of the more common issues is overtreatment, particularly in the infraorbital and periorbital areas. Small fat cysts may form; however, this can be avoided by injection of the micro aliquots of fat. Fat hypertrophy can occur with significant weight gain. Nodules can form from placing the fat too superficially. Nodules and calcifications can be treated with intralesional steroid (10 mg/mL), ultrasound, massage, and, rarely excision. Infection is another possible complication, even in the setting of preoperative antibiotics.

The propagation of emboli from an intravascular injection is the most significant complication. This risk can be decreased through the use of small blunt cannulas for fat injection. Injection should be initiated after the cannula has been checked with an aspiration technique to note its position outside of the lumen of a vessel. Other maneuvers that can minimize this risk include retrograde filling, low injection pressure, and avoidance of fat transfer into previously traumatized tissue. Disruption of the blood supply to the skin is rarely an issue, but can occur. If blanching of the skin occurs, the surgeon can apply nitropaste to the area, place the patient in Trendelenburg position, and massage the area until blanching resolves and skin flush returns. Lastly, muscle dysfunction may temporarily occur with injection of fat into the muscle.

Botulinum Toxin and Facial Chemical Peels for Skin Enhancement

FAISAL A. QUERESHY, ANDREI MARECHEK

"Not for Wrinkles—Botulinum toxin type A has been promoted for use as a wrinkle remedy. Apparently, some practitioners have been injecting the substance to ease wrinkles by weakening face muscles. In a November 18, 1994, Federal Register notice, the FDA denounced the promotion of such unapproved use as 'an egregious example of promoting a potentially toxic biologic for cosmetic purposes.' "[1]

Botulinum Toxin

Botulinum toxin, or Botox, was first described as a lethal "sausage toxin," and is an extremely effective injectable neuromodulator that has changed the way providers approach cosmetic procedures. The Food and Drug Administration of the United States (FDA) first approved use of Botox for cosmetic purposes for use in the glabellar region in 2002. Today, Botox is FDA approved for cosmetic use in reduction of glabellar and lateral canthal lines. Additionally, Botox has been approved for numerous noncosmetic procedures. Botulinum toxin type A is currently commercially available in three formulations in the United States: OnabotulinumtoxinA known as Botox (Allergan, Inc., Irvine, CA), Abobotulinum toxin A known as Dysport (Ipsen Limited, Slough, United Kingdom), and Incobotulinum toxin A known as Xeomin (Merz Pharmaceuticals, Greensboro, NC). Rimabotulinum toxin B is the established name for botulinum toxin type B, which is commercially available as Myobloc or NeuroBloc (Solstice Neurosciences Inc./Eisai Co., Ltd.)

History and Pharmacology

Botulinum toxin is an exotoxin produced by the obligate anaerobe *Clostridium botulinum*. *Clostridium botulinum* is a spore-forming, gram-positive rod found in the soil. The exotoxin is an A-B neurotoxin, or type III toxin, that consists of two polypeptides. Part A causes the action of the toxin, and part B binds to the host cell. Of all natural toxins, botulinum toxin is the most potent. Multiple serotypes of the toxin—A, B, C1, C2, D, E, F, and G—are produced by bacteria. Of these serotypes, A is the most potent. Types A, B, and E are the most likely causes of human disease, while toxins C and D do not appear to affect the human nervous system.[2] The toxin binds to the presynaptic neuron of the neuromuscular junction via presynaptic cholinergic receptors. The toxin is then internalized into the cell and acts by cleaving components of protein complex SNARE that is normally responsible for exocytosis of acetylcholine. This results in inhibition of acetylcholine release and therefore a neuromuscular blockade and flaccid paralysis. The different serotypes of botulinum toxin differ by site of cleavage of the SNARE complex.

This toxin causes the disease botulism, which is a form of food poisoning. The disease was first noted and described by Justinus Kerner between 1817 and 1822 when he noticed an association between consumption of blood-sausages and food poisoning,[3] hence the name "Botulus," which is Latin for "sausage." Symptoms of the disease usually occur within a day or two. Nausea is followed by blurred vision, muscle weakness, and, finally, respiratory or cardiac failure. The disease is rare today because nitrites added to food prevent the growth of bacteria. Heating will destroy the toxin, but not the spores. The toxin will not form in highly acidic foods.[4] In adults, competing bacteria prevent formation of the toxin by ingested bacteria. In infants, competing microorganisms have not been established. Many cases of infant botulism have been reported after honey ingestion, so it is recommended that children younger than 1 year of age not be fed honey.

Botulinum toxin itself was first isolated and was associated with *C. botulinum* by Van Ermengem.[3] Therapeutic purposes of the toxin were not investigated until the 1970s. Use of Botox for reduction of facial lines was reported in 1992. It is currently used for many conditions in which relaxation of muscles will provide the desired result. Glabellar and canthal lines, overactive bladder, urinary

incompetence, headaches, limb spasticity and dystonia, axillary hyperhidrosis, blepharospasm, and strabismus are examples of the conditions for which botulinum toxin is an FDA-approved treatment.

Preparations

Botox or Botox Cosmetic (botulinum toxin type A) is supplied in 50- and 100-unit vials.[5] One unit is the median lethal dose (LD50) in mice. The estimated LD50 for a 70-kg human is 2800 units. The calculation of units is specific to each brand and cannot be compared with another product. The vial contains vacuum-dried toxin, human albumin, and sodium chloride. Botox is reconstituted with sterile saline. Nonpreserved saline is recommended, although some authors have used preserved saline,[6] and others have recommended addition of 1% lidocaine.[7] Various amounts of diluent may be used; common dilutions are shown in Table 24-1.

The package insert recommends that unopened vials of Botox should be stored at 2° C to 8° C for up to 24 months, and that reconstituted Botox should be stored under the same conditions and used within 4 hours. However, multiple studies have suggested that reconstituted BT-A can be safely used within 2 weeks.[8] A typical dose of Botox for the treatment of glabellar furrows is 20 units, and 12 units for lateral canthal lines (each side). Results are seen within 1 to 2 days, with increasing intensity noted in the first week.[5]

Dysport (botulinum toxin type A) is supplied in 300- or 500-unit vials as a lyophilized powder that must be reconstituted. Other constituents include human albumin and lactose. Although initially marketed in Europe, the U.S. FDA approved the use of this agent in 2009. The dose range for the treatment of glabellar furrows is 40 to 60 units.

Xeomin (botulinum toxin type A) is supplied in sterile 50 units or 100 units lyophilized powder that also must be reconstituted. The dose range for treatment of glabellar furrows is 20 units.

Myobloc (botulinum toxin type B) is supplied as a sterile liquid. Each vial contains toxin, human albumin, sodium succinate, and sodium chloride. Three different sizes are available: 2500 units (0.5 mL), 5000 units (1.0 mL), and 10,000 units (2.0 mL). The dose range for the treatment of glabellar furrows is 1800 to 3500 units. Myobloc is not FDA approved for cosmetic use, but several studies have shown its effectiveness.[9-11] Myobloc (pH 5.6) is more acidic than Botox (pH 7.2), and its duration of action is shorter. Botulinum toxin type B can be effective in patients who develop a tolerance to type A toxin, and it may have a faster onset of action.

TABLE 24-1 Botox Dilution Table

Vial	Diluent Added	Resulting Dose (Units per 0.1 mL)
100 Unit	2.5 mL	4.00 Units
50 Unit	1.25 mL	4.00 Units

Uses in Facial Cosmetics

Botox, Dysport, and Xeomin have been approved for cosmetic treatment in the United States. Although all three products are approved for treatment of glabellar lines, only Botox is approved for treatment of lateral canthal lines; any other use is considered off-label. More and more uses are being identified and have been described in peer-reviewed journals.[12-14]

Glabella

Treatment of glabellar furrows focuses on the corrugator supercilii and procerus muscles. Contraction of the corrugators and to a lesser degree the medial orbicularis oculi and the depressor supercilii produces vertical lines between the eyebrows. Contraction of the procerus produces horizontal lines over the bridge of the nose. The package insert for Botox Cosmetic recommends five injections of 0.1 mL (20 units total), with two injections into each corrugator and one into the procerus. Higher or lower doses can be used in keeping with the muscle strength of individual patients (Figure 24-1). In general, higher doses are needed for male patients. It is recommended that injections not be made closer than 1 cm to the orbital rim because of concerns about diffusion causing ptosis (Figure 24-2).

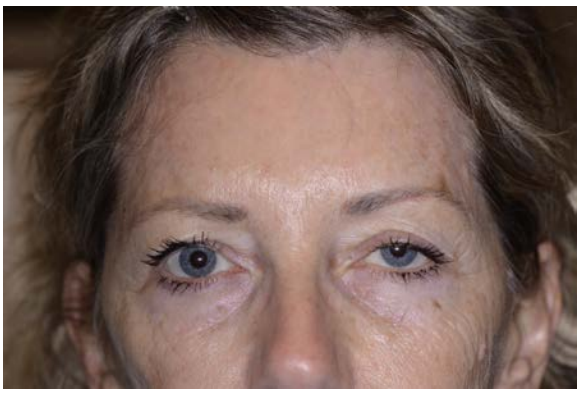
• **Figure 24-1** **A,** Glabella pretreatment. **B,** Glabella post treatment.

Forehead

The frontalis muscle produces horizontal forehead lines. The frontalis muscle has two bellies that are separated more superiorly than inferiorly. Injecting into the central tendon will have some effect because of diffusion but will not be as effective as injecting into the muscle itself. Evaluation of the patient to determine whether the frontalis is being used to elevate a ptotic brow is necessary prior to treatment. Unless a combination of procedures is planned, reduction of forehead lines with the result of brow ptosis should be avoided. The amount of Botox used will vary widely depending on the desired results. Relaxation of the entire frontalis muscle usually is not the goal. The lateral frontalis muscle is avoided to prevent brow ptosis. In the more medial area, slight relaxation is usually enough to decrease lines without completely paralyzing the muscle.

Crow's Feet

Lateral canthal lines are caused primarily by contraction of the lateral orbicularis oculi muscles. Contraction of the zygomaticus major can cause lines in the lower lid/upper cheek. As with the glabella, injections should be made 1 cm away from the orbital rim. If the zygomaticus major is to be injected, the patient should be warned that this could affect the smile line. Typically, a dose of 6 to 12 units is used on each side (Figure 24-3).



• **Figure 24-2** Ptosis following Botox treatment.

• **Figure 24-3** Botox treatment of crow's feet deformity.

Nasolabial Folds

Relaxation of the levator labii superioris alaeque nasi can decrease the depth of the medial nasolabial fold and has been used by some practitioners for treatment of excessive gingival display, or the "gummy smile."[12] This, however, can cause significant changes in upper lip animation, thus necessitating a thorough discussion with the patient prior to treatment. The dose used is 2.5 to 7.5 units per side.

Upper Lip

Perioral rhytides are caused by contraction of the orbicularis oris. These wrinkles often are addressed through resurfacing procedures or filler materials. These procedures can reduce the appearance of the rhytides but do not address the underlying cause. Doses of 2 to 6 units given at several injection points or use of the threading technique[15] will slightly relax the muscle. Care must be taken because higher doses can cause lip incompetence.

Chin

Dimpling of the chin can be improved by injection of the mentalis. This technique also has been used to correct abnormal contraction following chin implant or genioplasty. With mentalis dysfunction following surgery, deeper placement with a higher dose may be required. Doses range from 2.5 to 12.5 units for dimpling of the chin. Care should be taken to avoid the lip depressor muscles because, as with the upper lip, lip incompetence can result.

Neck

Hypertrophic platysma muscle banding is a frequent complaint among aging female patients. Patients with this condition can be treated surgically, but good results can be obtained with the use of Botox in patients without significant skin excess. Doses of 5 to 20 units per band injected directly into the muscle band usually will reduce both active and relaxed platysmal bands (Figure 24-4).

Treatment Technique

The patient should be evaluated with the risks and expected outcomes explained. A consent form should be reviewed and signed and preoperative photographs taken. The skin should be prepared with an alcohol swab. Application of topical anesthetic or ice may be desired by some patients. Having the patient flex the muscles planned for treatment will guide the injection. For the glabella, the patient should be asked to frown; for the forehead, the patient should be asked to raise the eyebrows; and for crow's feet, the patient should be asked to smile or squint. Botox should be prepared to the desired dilution and drawn into a syringe. Use of a ½-mL insulin syringe with a marking at each 0.01 mL allows for easy measurement of units of Botox based on dose (see Table 24-1). Botox should be injected directly into the muscle. Activating the muscle has been shown to increase uptake of Botox. Botox will diffuse to other areas to some degree. This effect is increased by massage and the use of higher volumes.

• **Figure 24-4** **A,** Neck pretreatment. **B,** Neck 1 week post treatment.

Some authors recommend massaging areas such as the forehead to disperse the toxin locally.[16] This should be avoided in areas where dispersion will lead to undesirable results, such as near the orbits. Following the procedure, some recommend no activity for several hours. Others recommend that the patient should remain upright. Effects are usually seen within 24 hours, and the intensity will increase to full effect within a week. Effects of the medication last for about 3 to 4 months, but with regular treatment, the effects often can last much longer. This may be due to atrophy of the treated muscles or to changes in habits.

Contraindications and Adverse Effects

As with all cosmetic procedures, patients who have unrealistic expectations should not receive Botox. Patients who may be allergic to any of the components, such as patients with allergies to cow milk, should not receive Botox. Botox is a category C drug that is not recommended during pregnancy. It is not known whether Botox is secreted in breast milk. Patients with neuromuscular disorders (amyotrophic lateral sclerosis, myasthenia gravis, Eaton-Lambert syndrome) may be extremely sensitive to systemic effects, especially dysphagia. Drugs that interfere with neuromuscular transmission (curare, lincosamides, polymyxins, quinadine, magnesium sulfate, anticholinesterases, succinylcholine) may potentiate the effects of Botox.[5]

Patient complaints of pain during injection vary widely. The use of topical anesthetic or ice can reduce the discomfort. The area of injection is often tender to palpation for a few hours afterward. Swelling is usually minimal and is localized to the sites of injection. Ecchymosis can occur. Care should be taken to avoid small vessels, especially in the lateral canthal area. It is best for patients to avoid aspirin, NSAIDs, and any other medication or herbal supplement that has anticoagulant properties for a week or longer prior to Botox injection.

Other local complications of Botox result from unintended relaxation of specific muscles or excessive relaxation of the treated muscle. Ptosis of the upper eyelid can occur if Botox diffuses to the levator palpebra superioris. This condition can be treated with apraclonidine 0.5% eyedrops, which, as an alpha-adrenergic agonist, stimulates the sympathetic Müller's muscle to contract producing 1 to 2 mm of eyelid elevation. Brow ptosis can occur if the frontalis muscle is over-relaxed. Diplopia can result if Botox diffuses into the orbit affecting the extraocular muscles. If diplopia is significant, an ophthalmology consultation should be obtained, and consideration may be given to injecting the antagonist of the affected muscle. Otherwise, these conditions will resolve as the medication loses its effects over 3 to 4 months.

Cheek or lip ptosis can occur when Botox is used in the mid-face. Lip incompetence can occur when Botox is used periorally. Careful placement of small volumes can prevent these problems. Patients occasionally complain of excessive elevation of the lateral brow (the "Spock" look) following treatment of the glabellar or forehead region. This condition is easily treated without ptosis of the brow by placing 2 units in the hyperactive area. Systemic reactions may include nausea, fatigue, and rashes. Dysphagia has been reported following treatment of cervical dystonia. In some cases, placement of a gastric feeding tube is required. Death following aspiration pneumonia has been reported.

With long-standing deep rhytides, some patients may not see a significant decrease in facial lines, even with relaxation of intended muscles. Other patients will develop antibodies to botulinum toxin A, causing a lack of effect. A meta-analysis reported 0.49% of 2240 patients exhibited seroconversion. A complete lack of response to treatment was only seen in 3 of the seroconverted patients.[17] Higher doses or more frequent intervals may be more likely to cause antibody formation. Substituting Myobloc (type B) for Botox (type A) can overcome patient resistance.

Chemical Peels

Chemical peeling (chemabrasion, chemosurgery, or chemexfoliation) is a skin resurfacing procedure by which caustic materials are used to remove layers of the epidermis and dermis in a controlled manner. New epidermal growth is stimulated, resulting in improved texture and even pigmentation. Healing following a chemical peel is a result of epithelial migration from adnexal structures.

History

Caustic preparations for peeling procedures using sour milk (α-Hydroxy acid) to aesthetically improve the skin were first

described in 1550 BC by ancient Egyptians. Dermatologists began using chemical peels in the mid-1800s to treat freckles and melasma, but publications about these procedures were rare until mid-century. Early publications often discussed the phenol peel, but other chemicals were also used.[18,19] As interest in chemical peels increased, various formulations were created and modified.

Indications

Chemical peeling alone or as an adjunctive procedure is indicated to treat actinic keratoses and fine rhytides, hyperpigmentations, shallow depressed scars, and acne. Some of these indications may be better treated by other means, such as resurfacing with dermabrasion or lasers or use of medications. Chemical resurfacing is best for patients with white skin, that is, Fitzpatrick classification types I to III. Type I patients always burn and never tan. Type II patients tan only with difficulty and usually burn. Type III patients tan but sometimes burn.

Contraindications

Patients with darker skin colors, including Fitzpatrick classification types IV thru VI, may have a higher incidence of complications if they receive chemical peels. Type IV patients rarely burn and tan with ease. Type V patients tan very easily and very rarely burn. Type VI patients tan very easily and never burn. These patients must be warned of the higher incidence of pigmentary changes, hyperpigmentation, hypopigmentation, and irregular pigmentation. Pigmentary changes also can occur in patients who are taking estrogens for hormone replacement therapy or for birth control. Systemic retinoid use can lead to post-treatment scarring. If a patient has taken retinoids in the previous year, treatment should be delayed. Although acne can be treated with superficial chemical peels, deeper peels can exacerbate acne. Acne should be controlled with antibiotics prior to resurfacing. A history of herpes labialis is not a contraindication to treatment because all patients should be given prophylactic antivirals, but active sores should be allowed to heal prior to treatment. It is important to review the expected outcomes with the patient, and what is achievable given the technique being utilized. If the patient's expectations do not correspond with expected results, the procedure should not be performed.

Depth of Peel

Superficial peels affect to the depth of the stratum granulosum of the dermis or into the papillary dermis. Medium-depth peels reach the upper reticular dermis, and deep peels reach the mid-reticular dermis. The depth of peel is evaluated on the basis of skin appearance. A peel into the papillary dermis will appear as a light frost with a pink background. The frost is caused by coagulation of proteins, and the pink background is provided by blood vessels of the papillary dermis. As the peel proceeds into the upper reticular dermis, the white frost will become a solid sheet. In the mid-reticular dermis, the white frost begins to turn gray.[20] Selection of appropriate depth of peel is critical to achieve desired results. Deep peels, although very effective, can have a high risk of complications such as scarring or hypopigmentation. Superficial peels, on the other hand, are less effective but offer a low chance of complications. Medium-depth peels are between these two depths.

Peeling Agents

Alpha-hydroxy Acids

Glycolic, lactic, citric, and tartaric acids are naturally occurring alpha-hydroxy acids. Glycolic acid, which is derived from sugar cane, is commonly used for superficial peels. It is used at various strengths. Low concentrations are used in home care systems and in skin conditioning programs in preparation for deeper peels. Higher concentrations are used alone or in combination with other peeling agents. After the acid has been applied and left in place for a minute or two, it must be diluted with water or neutralized with sodium bicarbonate.[21]

Jessner's Solution

Jessner's solution is a keratolytic that can be used by itself for a superficial peel or in combination with trichloroacetic acid (TCA) for a medium-depth peel. It contains 14% each of resorcinol, salicylic acid, and lactic acid in ethanol. Multiple applications are used to provide the desired depth of peel. Neutralization or dilution is not necessary.

Trichloroacetic Acid

TCA is used for superficial and medium-depth peels. Concentrations from 10% to 35% are used for superficial peels. In combination with Jessner's solution, 35% TCA will achieve a medium-depth peel. Fifty percent TCA has been used for medium-depth peels, but this is associated with increased scarring and pigmentation changes. TCA is a keratocoagulant that is self-neutralizing. Additional TCA may be applied after time is allowed for the first application to neutralize. This is done until an even frost is achieved at the desired depth.

Phenol

Phenol is a keratolytic that results in a deep peel. The Baker-Gordon formula for a phenol peel consists of 3 mL 88% phenol, 2 mL distilled water, 8 drops of Septisol soap, and 3 drops of croton oil. The Baker-Gordon formula allows for deeper penetration than would be achieved with pure phenol (88% in solution) by itself. This is so because pure phenol causes immediate keratocoagulation, which blocks deeper penetration. Phenol is rapidly absorbed and is partially metabolized by the liver and excreted by the kidneys. In addition to causing hepatic and renal toxicity, phenol can cause cardiac arrhythmias. Patients should be evaluated preoperatively to rule out hepatic, renal, or cardiac deficiencies. To minimize toxicities, one esthetic unit at a time is treated. Preoperative, intraoperative, and postoperative hydration with intravenous fluids is used to decrease renal toxicity.

Continuous cardiac monitoring is necessary during and for 2 hours after the procedure.

Preparation

Skin can be prepared for resurfacing procedures with topical tretinoin or glycolic acid for 4 to 6 weeks. Both allow for increased penetration by decreasing the thickness of the stratum corneum. Tretinoin also will increase the rate of reepithelialization. Hydroquinone may decrease the incidence of post-treatment hyperpigmentation.

All patients who undergo resurfacing procedures should receive prophylactic antivirals to prevent herpes simplex virus activation. Acyclovir or valacyclovir is started one day preoperatively and used for at least 7 days postoperatively. Antibacterial prophylaxis with cephalexin or an equivalent, and antifungal prophylaxis also may be considered.

Patients should be warned about what to expect as they recover from the chemical peel. For 7 to 10 days following a chemical peel, desquamation of the skin will progress. Patients may become alarmed if they are not prepared for their own appearance or for the length of time needed for recovery.

Procedure

The anesthesia used is based on the depth of peel and patient desires. Intravenous sedation with propofol works well for chemical peels because of its duration of action. Topical anesthetics may reduce the predictability of the depth of peel. Local anesthetic blocks can be used while avoiding epinephrine if a phenol peel is used.

The patient's skin should be prepared with a degreasing agent. Septisol, acetone, or alcohol may be used to degrease the skin. The peeling agent then is applied to each esthetic unit. The patient is observed for skin changes that may indicate that the planned depth has been reached (Figure 24-5). Neutralization is used if required by the peeling agent.

A fan directed at the patient's face will provide some comfort as the patient recovers. Cool wet sponges may help once the procedure is complete. Some recommend applying topical anesthetic after the procedure.

Postoperative Care

Analgesics usually are not necessary following superficial or medium-depth peels. Petroleum jelly, A&D ointment, or Complex Cu3 should be applied to the peeled area. Tape dressings have been used, but an occlusive dressing of petroleum jelly is almost as effective.[22] Petroleum jelly is easier to remove and allows observation of the wound. The patient is instructed to gently clean the area several times a day to remove peeling skin and to prevent crust formation. The ointment then should be reapplied. Peeling skin should not be pulled or rubbed off because this increases the risk for infection and scarring. Once reepithelialization is complete, the patient may return to the pretreatment facial care regimen. Makeup may be used, and sunscreen should be worn.

• **Figure 24-5** Application of Obagi Blue facial peel.

Complications

Pigmentary changes occur more often in patients with darker skin tones and with deeper depth of peel. Application of bleaching agents such as hydroquinone to hyperpigmented areas works well in diminishing these areas. No reliable treatment for hypopigmentation is known.

Scarring is more likely with deep peels or in patients who develop postoperative infection. Scarring is more likely to occur in skin overlying a bony prominence or in patients who have undergone concurrent procedures. Scars can be treated with massage, topical or intralesional steroids, silicone gel sheeting, or flashlamp pulsed dye laser.

Erythema should be expected in the weeks following a chemical peel. This can be hidden with makeup once epithelialization is complete. Prolonged erythema can be treated with topical steroids or flashlamp pulsed dye laser.

Infections can be avoided with the use of appropriate prophylactic antimicrobials. If an infection does occur, early diagnosis and treatment are necessary to avoid scar formation.

Milia can occur following a chemical peel. This condition is easily treated by unroofing the keratin-filled structure with a blade or a needle and expressing the contents.

Summary

Botox has been shown repeatedly to be a safe and effective way to reduce facial lines caused by muscle action. It can be used alone or as an adjunct to other facial cosmetic procedures.

Chemical peels represent one option for skin resurfacing. Although laser resurfacing has increased in popularity and the use of phenol has decreased due to safety concerns, chemical peels are an ever-evolving technique. Chemical peels are a cost-effective way to reduce facial rhytides and improve pigmentation.

Otoplastic Surgery for the Protruding Ear

TODD G. OWSLEY, TINERFE J. TEJERA

Introduction

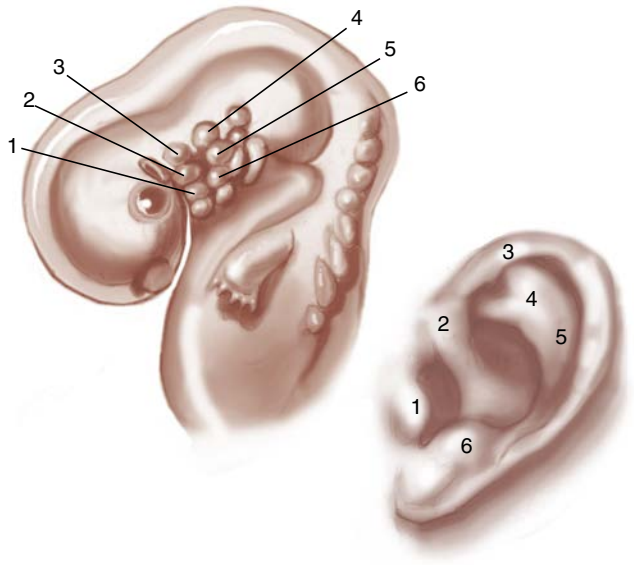
Auricular deformities, particular prominent ears, are a common congenital anomaly affecting nearly 5% of the white population. Children with auricular deformities are likely to experience ridicule by their peers. Prominent ears, commonly referred to as prominauris, can be predictably treated before children enter school, thus avoiding the emotional trauma caused by ridicule. Whereas cosmetic surgery is performed primarily in the adult population, otoplastic surgery is performed primarily on children and can be an invaluable service for the patient and satisfying for the surgeon.

Numerous publications have described the correction of auricular deformities. The surgeon must understand the history of these various techniques to develop a predictable and successful method of addressing the problem of prominent ears. Dieffenbach is credited with the first otoplastic technique to correct a prominent auricle in 1885. Ely, in 1881, authored the first case report describing correction of prominent ears in a 12-year-old boy who was being teased at school. Since that report, more than 170 surgical techniques have been described in the literature for the correction of prominent ears.

When clinically evaluating the facial complex, the ears often are overlooked. If protruding ears are present, reduction otoplasty as an adjunctive or isolated procedure can be predictably performed, often with satisfying results. A thorough understanding of the embryology and development of the human auricle, along with the resultant external anatomy of the ear, is of paramount importance in developing a reliable technique to deal with common auricular deformities.

Embryology of the Auricle

Malformations of the auricle are common, occurring in 1 in 12,500 births. They can occur alone or in combination with a syndrome affecting the head and neck structures. The embryogenesis of the auricle exemplifies in miniature the precise and logical progressions characteristic of the developing human form. The external ear development during the third to twelfth weeks of embryonic life is complex. The precursors to the auricle present from days 36 to 38 of intrauterine life, developing first from the first branchial groove where the first (mandibular) and second (hyoid) branchial arches are present (Figure 25-1). Both arches give rise to the auricular hillocks, often referred to as the auricular tubercles of His. Hillock numbers 1, 2, and 3 arise from the caudal border of the mandibular arch, and numbers 4, 5, and 6 are formed from the cephalic border of the hyoid arch. The auricular hillocks present in their most prominent and characteristic form by intrauterine day 41. During this same stage, the groove between the mandibular and hyoid arches (hyomandibular groove) widens and deepens by the increased growth of the hillocks. This groove eventually forms the external auditory canal and concha. By days 43 to 45, the hillocks have migrated and coalesced to form the



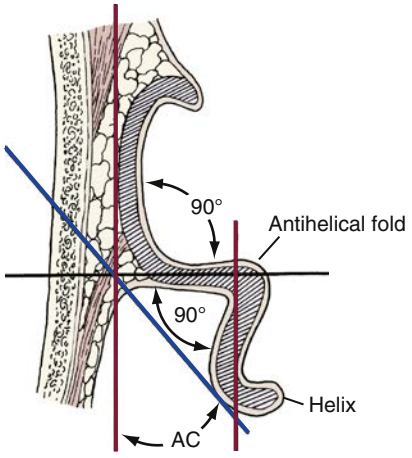
• **Figure 25-1** Development of the auricle from the first and second branchial arches.

auricle. During this union the mesenchyma of the hyoid arch increases substantially relative to the mandibular arch to contribute 85% of the external adult ear. Hillocks 2 and 3 from the mandibular arch lose their individuality and fuse to form the helical crus. Later, hillocks 4 and 5 from the hyoid arch merge and alter their configuration as they give rise to the helix and antihelical fold. Hillock 1 remains prominent and becomes the tragus, and hillock 6 becomes the antitragus.

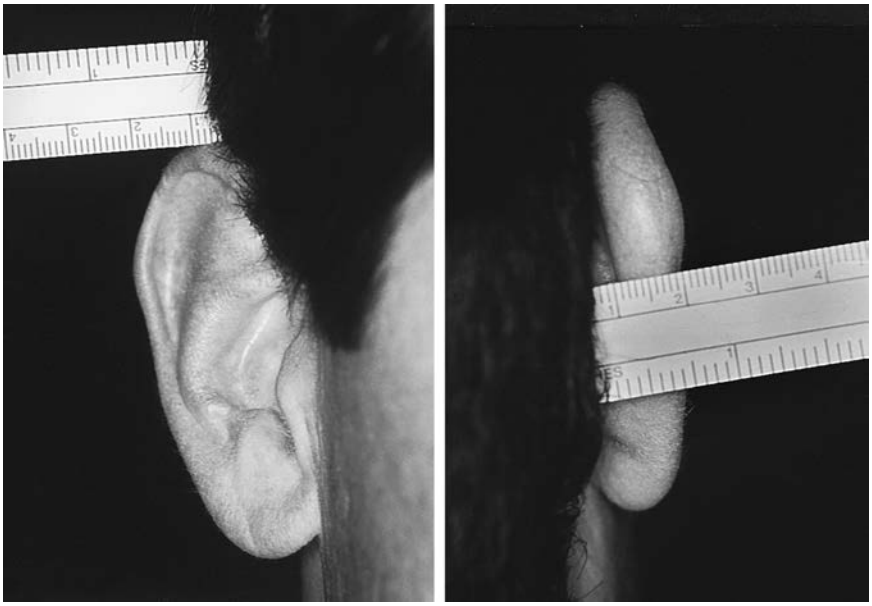
Surgical Anatomy

The majority of the growth of the pinna is completed by an early age. The average child has 85% of ear development completed by age 3 years. The ear is nearly fully grown by the age of 7 to 8 years. Ear height continues to grow into adulthood, but the width and distance of the ear from the scalp change little after 10 years of age. Of note, a person's two ears often vary in size and shape from each other. The average adult ear is approximately 6.5 cm in length and 3.5 cm in width. In the "normal" ear, the auricle lies between horizontal lines drawn from the upper rim of the orbit and the nasal spine. The normal posterior wall of the conchal bowl is set at an angle of approximately 90 degrees to the mastoid. A second 90-degree angle is formed at the antihelical fold and is called the scapha-conchal angle. These two angles, in combination with the curvature of the helix, set the auricle adjacent to the scalp at approximately 25 to 35 degrees, forming the auriculocephalic angle (Figure 25-2). When correcting prominent ears, three important anatomic "pearls" can be used intraoperatively to assess the final result: (1) the helical rim should be seen just lateral to the most lateral presence of the antihelix from the frontal view; (2) the distance measured between the helical rim and the mastoid area is slightly less than 2 cm; and (3) the distance between the skull and the uppermost aspect of the helix is approximately 1 cm (Figure 25-3).

The auricular cartilage is a unique, intricately shaped, and delicate structure with multiple elevations and depressions that provide both skeletal support and form to the adult ear. The cartilage of the auricle is a single piece of yellow (elastic) fibrocartilage with a complicated relief on the anterior, concave side and a smooth, posterior, convex side. Cartilage thickness is fairly uniform throughout. The cartilage is covered on both surfaces by a thin, firm, adherent layer of perichondrium. The anterior lateral surface of the cartilage is covered with fine, thin skin, closely adherent to the cartilaginous framework. Subcutaneous fat is practically nonexistent, but a diffuse



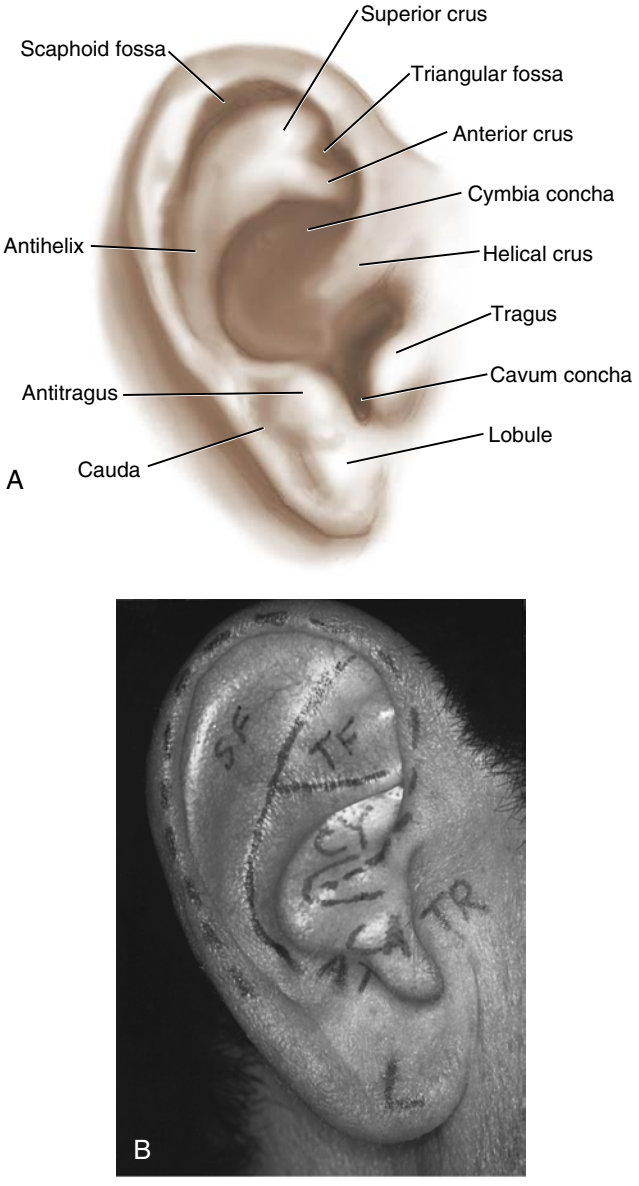
• **Figure 25-2** An axial section at the level of the helical crus demonstrates the ideal auriculocephalic angle *(AC)* of 30 degrees. (Modified from Tanzer RC: Congenital deformities. In Converse J, editor: *Reconstructive plastic surgery, vol 4,* ed 2, Philadelphia, 1977, WB Saunders.)



• **Figure 25-3** Anatomic "pearls" that are useful intraoperatively.

subdermal vascular plane exists that supports flap viability. The posterior surface of the cartilage framework is draped with less-adherent skin that contains two layers of fat and a larger subdermal plexus of arteries, veins, and nerves.

A helical border terminates anteriorly in a crus that lies almost horizontally above the external auditory meatus. The antihelix crowning the posterior conchal separates and diverges into both a superior and an anterior crus enclosing the triangularis fossa. Between the helix and the antihelix lies a long, deep furrow called the scapha. The conchal cavity, composed of the cymba (superior) and cavum (inferior) concha, arises from the floor, which is at least 1 cm deeper than the overlying tragus and antitragus. The inferior tip of the helical cartilage is referred to as the cauda, and extending from this inferiorly is the lobule, which hangs without any skeletal framework (Figure 25-4).



• **Figure 25-4** **A** and **B,** Anatomy of the external ear.

Blood Supply

The arterial blood supply to the ear is principally derived from two main branches of the external carotid artery: the superficial temporal artery and the posterior auricular artery. The superficial temporal artery emerges from the parotid capsule 1 cm in front of the ear deep to the veins and below the anterior auricular muscle. It gives off the superior, medial, and inferior branches, supplying the anterior and anterolateral surface of the auricle. The posterior surface is dominantly supplied by the posterior auricular artery, which travels parallel to the postauricular crease upward, crossing below the great auricular nerve and under the posterior auricular muscle. Awareness of this relation is important to avoid damage to the artery or nerve during surgery. The posterior auricular artery gives off three branches—superior, medial, and inferior—that provide a greater volume of blood to the postauricular ear than its anterior counterparts. These same vessels perforate the auricular cartilage over a large surface of the anterior ear and anastomose with the branches of the superficial temporal artery. The external ears have a tremendous blood supply, allowing multiple surgical approaches and salvage of the ear after traumatic avulsion.

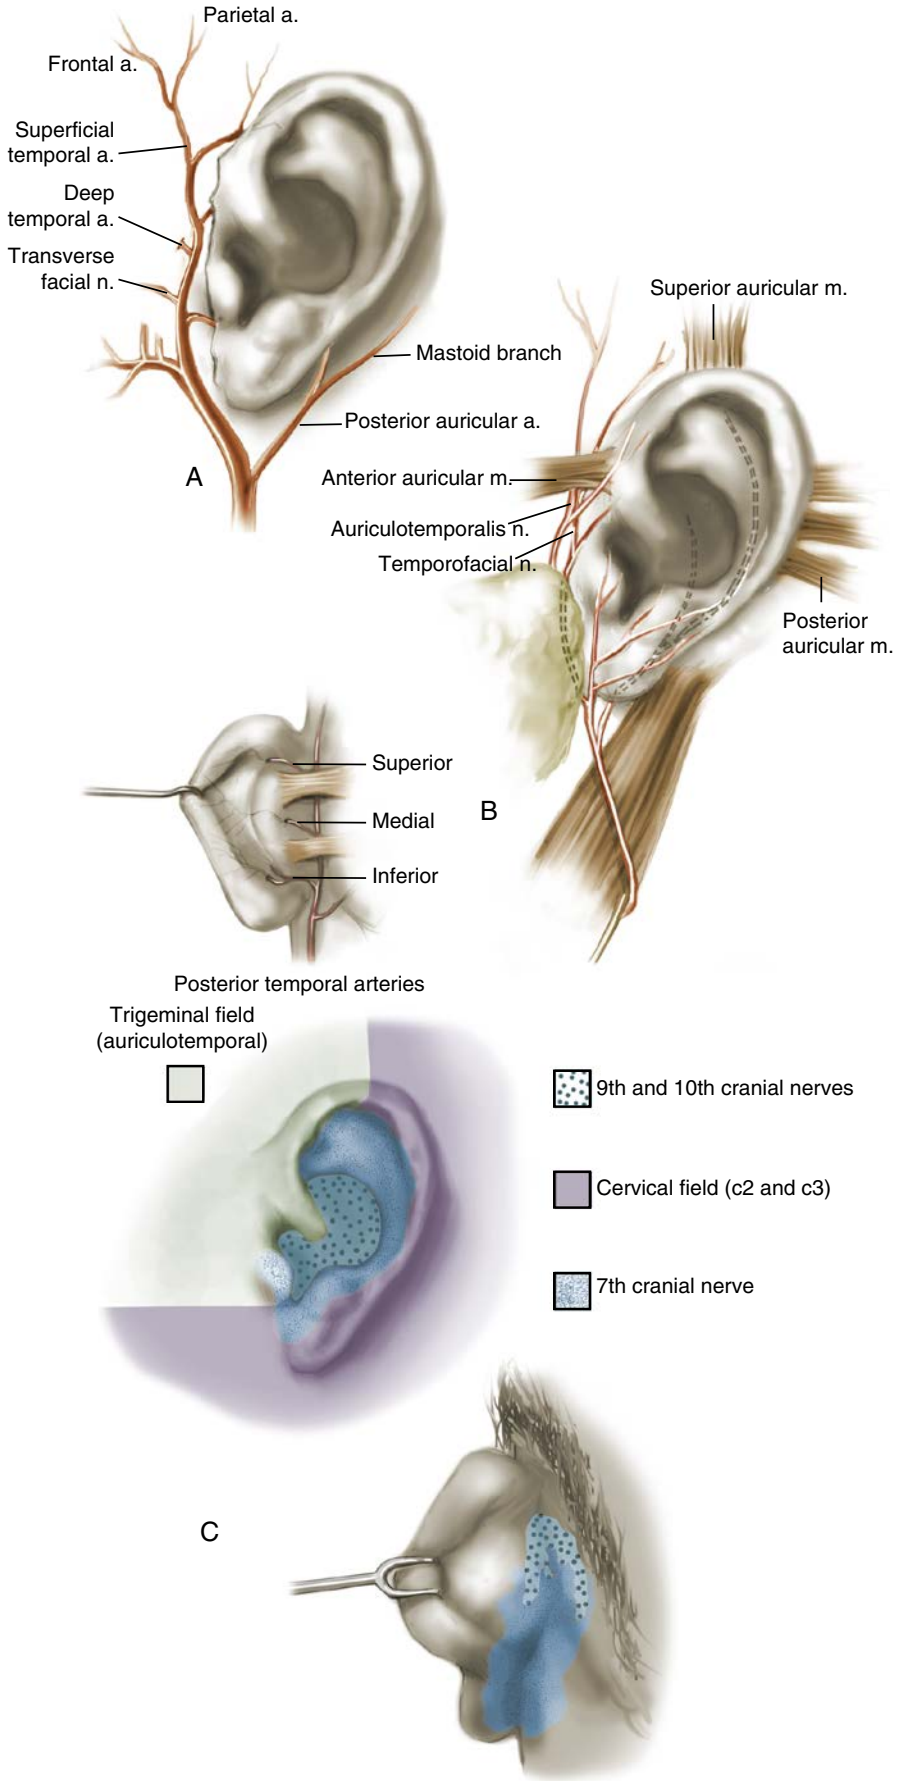
Venous drainage of the ear by way of the complementary veins is into the external jugular vein. Lymphatic drainage is into three surrounding areas by way of the complex and extensive network of lymphatic vessels.

Nerve Supply

The sensory nerve supply is primarily from the anterior and posterior branches of the great auricular nerve. The nerve is an important surgical landmark, traveling 8 mm posterior to the postauricular crease. When dissecting in this area, care must be taken to avoid damage to the nerve, which can result in near complete anesthesia to the ear. Less-important contributions to sensation are made by the auriculotemporal and lesser occipital nerves to the conchal cavity and external auditory meatus (Figure 25-5, *B*). Regional anesthesia of the auricle is readily accomplished by instilling anesthetic solution along its base anteriorly and posteriorly (Figure 25-6). Supplemental anesthesia may be needed at the posterior wall of the external auditory meatus supplied by the auricular branches of the vagus nerve (nerve of Arnold).

Congenital Deformities

Ear deformities are common and variable because of the complex embryologic engineering that takes place in the development of the auricle, as previously described. Many classification systems of ear deformities have been attempted. Tanzer classifies congenital ear defects, correlating embryologic development with a surgical approach for correction of the deformity. Marx has a well-accepted classification system subdividing microtia into three groups according to severity. Rogers simplifies classification of congenital ear defects, dividing them into four groups



• **Figure 25-5** **A,** Arterial blood supply. **B,** Nerve supply. **C,** The cutaneous innervation of the ear on the anterior and posterior aspects. The areas may overlap and vary with each individual.

• **Figure 25-6** Technique to provide regional anesthesia of the auricle.

according to various stages of arrested development: microtia, lop ear, cup ear, and protruding ear. In this chapter, the term *protruding* is used to refer to any ear that is more prominent than is considered normal. Classifying other congenital abnormalities and their corrections is beyond the scope of this chapter.

In patients with protruding ears, two major deformities individually or in combination account for the majority of abnormalities. Several lesser deformities can accentuate the abnormality as well. The most common deformity seen is a poorly developed antihelical fold, which can involve both the superior and the anterior crura. This eliminates a definition between the conchal cavity and scapha, resulting in the lateral projection of the upper portion of the helix. The second abnormality seen is the formation of excessive conchal cartilage, in particular the posterior conchal wall. This causes significant protrusion of the auricle. Both abnormalities causing the protruding auricle to some degree is not an uncommon finding.

Other deformities include a protruding earlobe and irregularities along the helix, including an unrolled margin of the helical rim and an anteromedially displaced insertion of the postauricular muscle. Of importance, this last deformity often is bilateral and can be associated with ossicular deformities and a hearing deficit.

Precise recognition of the cause or causes of the protruding ear obviously is crucial in formulating the surgical technique to correct the abnormality.

Surgical Correction

Indications and Timing

Perhaps the most important indication for surgical correction of prominent ears is to eliminate the psychosocial effects of the ear defect. Macgregor has documented the irreversible social and psychological consequences of facial anomalies, especially of the ears. Ridicule by peers begins as early as age 4 to 5 years, during development of the body image concept. This leads to problems with social adjustment, self-image deficit, and ultimately behavioral disorders. Therefore most patients present at an early age for surgical correction. The elective correction of protruding ears is recommended starting at approximately age 5 years according to the literature. This then becomes one of the most common elective procedures performed in young children. The next most represented group are adults in their fourth decade of life. This finding may be attributable to a national trend toward more cosmetic procedures being performed among adults in general.

Techniques

Many otoplasty techniques described in the surgical literature are similar and have evolved over an 80-year experience. Many techniques address only the conchal hypertrophy without mention of the antihelical fold. The described techniques generally can be subdivided into suture-only techniques, cartilage-splitting or cartilage-weakening techniques, or a combination of the two.

Furnas described his suture-only technique for correction of prominent ear deformity in 1968. It consists of a postauricular approach, removing the vestigial posterior auricular muscle and its ligament down to the underlying mastoid fascia. Two to three nonresorbable sutures are placed through the conchal cartilage and mastoid fascia and tightened to the new, retracted position of the ears. This is still a commonly used technique to set back the ears in patients with conchal hypertrophy alone. Problems associated with this technique have been relapse attributable to cartilaginous "memory" and irregularities created in folding the conchal floor. Another problem is displacement of the conchal bowl anteriorly, creating stenosis of the external auditory canal.

The Converse-Wood-Smith technique is used to correct and create an antihelical fold with a cartilage cutting and suture method. Several full-thickness cuts through cartilage are placed in the scaphoid fossa. The cartilage is then folded on itself, described as "tubing," and permanent horizontal mattress sutures are placed, forming the new antihelical fold. Excessive conchal cartilage can be addressed with a cartilage incision added at the rim of the bowl to reduce the bowl and retract the ear. A new antihelical fold is formed, but at the expense of sharp cartilaginous ridges seen through the thin anterior auricular skin.

Following are three techniques addressing the two fundamental abnormalities in protruding ears that have produced consistent, satisfying cosmetic results with low

recurrence rates. The Davis method addresses the protruding ear caused by a hypertrophic posterior wall of the conchal bowl, and the Mustardé method is used to create a new antihelical fold (Figure 25-7). The Farrior method addresses both the conchal bowl and the antihelical fold as one technique. The refinement of other abnormalities, such as a prominent earlobe, also is discussed.

Davis Method

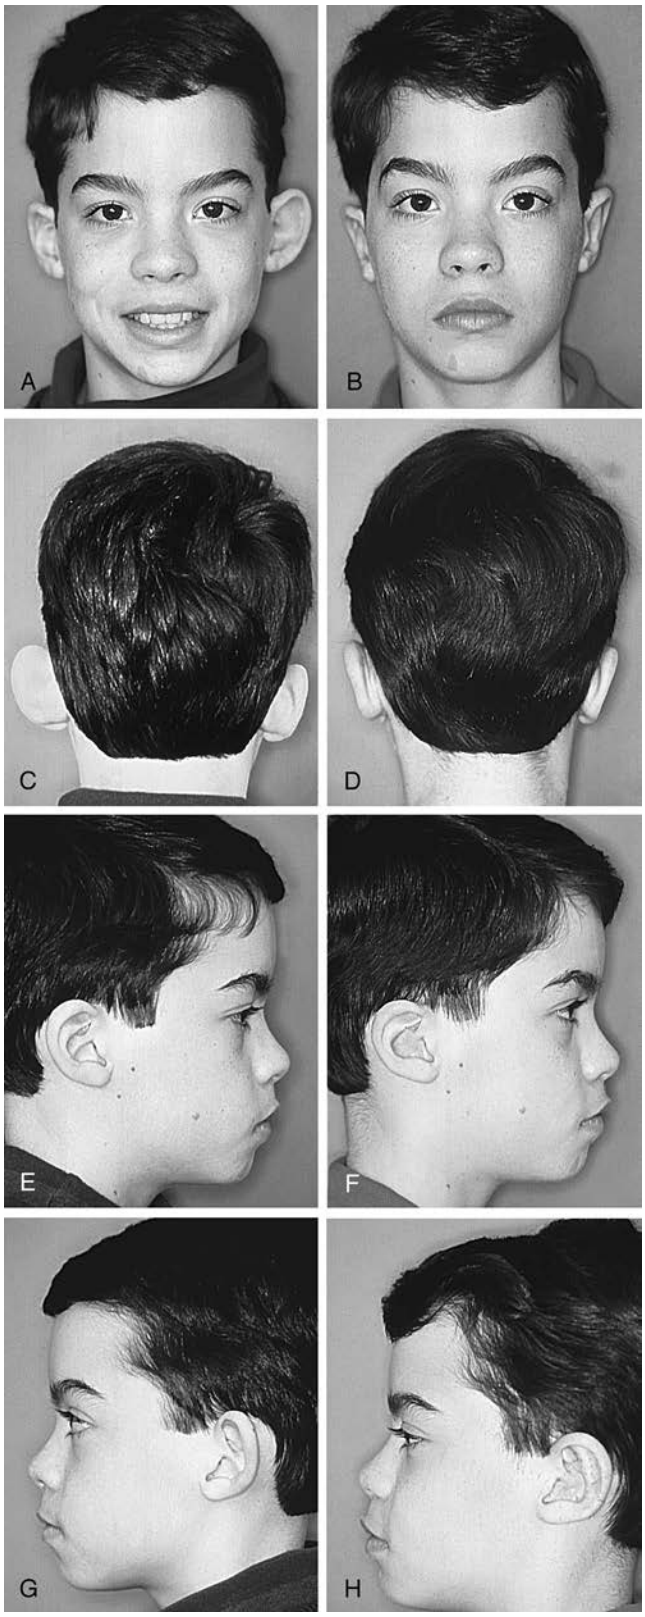
The Davis method, used for the correction of conchal hypertrophy, is a cartilage excision technique performed in a stepwise fashion.

Marking the Cartilage Excision

The area of cartilage to be removed is initially marked on the skin of the anterior surface of the conchal bowl. Methylene blue transfixion tattoos are preferred to mark the posterior surface of the conchal cavity. The line lies just below the lower crus border, carries forward into the cymbal fossa, and continues around as an "arrowhead" to preserve a well-defined helical radix. The tracing should continue forward against the posterior edge of the external auditory canal. From that location, it curves posteriorly into the cavum concha, continuing to the posterior conchal wall, leaving 8 mm of posterior conchal wall height measured from the scapha-conchal junction. This should complete the circle, which should appear as a kidney bean shape, including the entire conchal bowl. The exact height of the posterior wall is important and must be individually measured for each case (Figure 25-8, *A* to *C*).

Removal of Skin and Cartilage

Before beginning the actual surgical procedure, local anesthesia is used for hydrodissection of the tightly adhered anterior auricular skin along the conchal bowl. This simplifies the dissection of cartilage from the overlying skin. The concha is exposed through a postauricular elliptic skin excision. The ellipse is only wide enough to remove the predicted excess skin produced with ear retropositioning. Closure of the incision should be passive. This area is predisposed to hypertrophic or keloidal scarring when closed under tension. After removing the postauricular skin, the conchal cartilage is visualized along with the previously placed tattoo marks. The marks are used as a guide for incising through the cartilage, taking care to avoid perforation of the anterior skin. The dissection is then carried to the anterior conchal cartilage surface subperichondrially. The hydrodissection, along with use of a small, sharp Freer elevator (EDLO S.A. Produtos Medicos, Canoas, Brazil), allows separation between the skin and cartilage. The cartilage is removed, including the entire conchal bowl, with the exception of the 8 mm left along the posterior conchal wall. The ear is then passively placed on the mastoid surface, and the new projection of the helical rim is observed and carefully measured. Any defective prominence can be

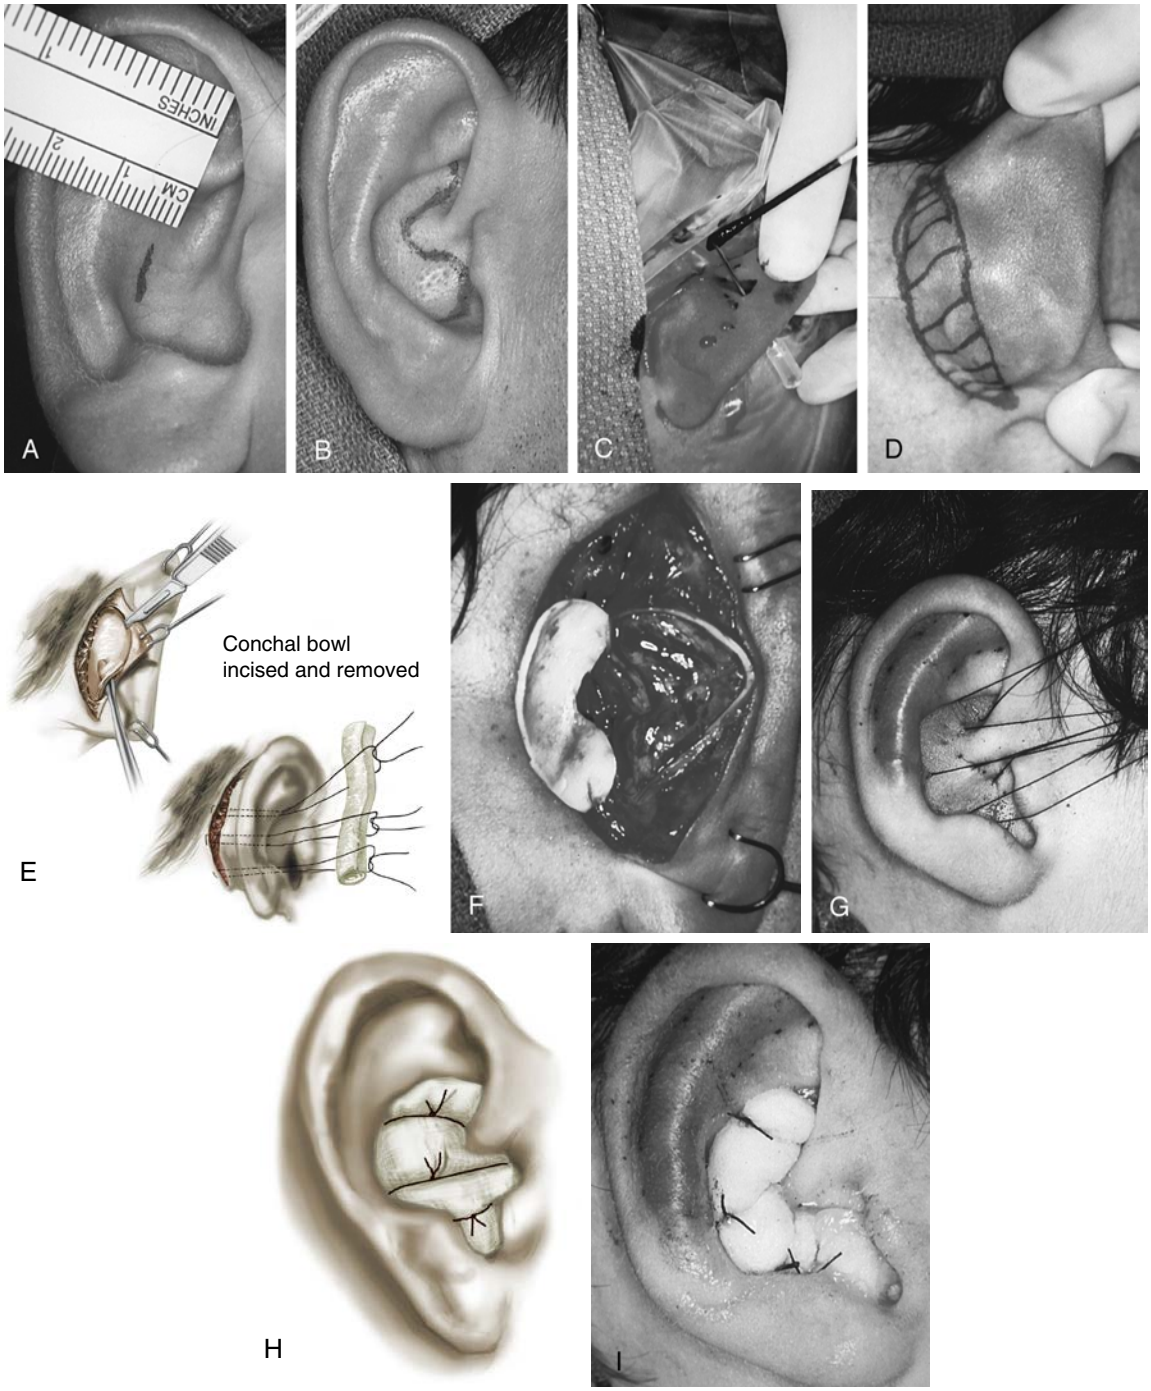


• **Figure 25-7** **A** to **D,** Preoperative and postoperative photographs of a 9-year-old boy who presented for correction of protruding ears. His diagnosis was conchal hypertrophy involving the right ear and a combination of conchal hypertrophy and lack of antihelical fold formation involving the left ear. The Davis method was used to correct the right ear, and the Davis and Mustardé techniques were used on the left ear. **E** and **F,** Lateral views of the right ear demonstrating a natural-appearing, deepened conchal bowl. **G** and **H,** Lateral views of the left ear demonstrating a new antihelical fold and a deepened conchal bowl.

revised with further cartilage removal. The postauricular muscle and underlying connective tissue are removed down to the underlying mastoid fascia to allow passive skin draping of the conchal floor, producing a natural-appearing, deepened conchal bowl. Any excessive postauricular skin can be removed at this time (Figures 25-8, *D* to *F*).

Ear Fixation

The ear is fixed in the new position with three to four mattress transfixion sutures of 3-0 silk, which perforate the skin anteriorly, anchor deeply into the postauricular muscle stump, and pass back through the anterior skin. The mattress sutures are then gently tied over a dental cotton roll that has been moistened with a triple-antibiotic ointment



• **Figure 25-8** Davis method. **A,** Marking the height of the posterior conchal wall that will remain. **B,** Marking the conchal bowl to be excised. **C,** Transferring the marking to the underlying cartilage with methylene blue. **D,** Initial amount of skin to be removed in an elliptic fashion. **E** and **F,** Postauricular view of excised cartilage. **G** to **I,** Through-and-through fixation sutures anchored to the postauricular muscle and mastoid fascia used to secure the cotton bolster. (*E* and *H,* Reprinted from Davis JE: Prominent ears, *Clin Plast Surg* 5:475, 1978.)

and placed into the cymbal and caval fossa, making sure to place one end of the cotton roll into the external auditory canal to avoid postoperative stenosis. The sutures and cotton roll hold the ear in place during healing, stretch and flatten the skin uniformly over the conchal floor, and give depth to the conchal bowl. The postauricular incision is then closed in a running fashion with a resorbable suture, leaving a small opening inferiorly for drainage. The cotton roll dressing is left in place for a minimum of 2 weeks for optimal healing (Figure 25-8, *G* to *I*).

Mustardé Method

The Mustardé method, first described in 1959, is indicated for a prominent ear with a poorly formed or absent antihelical fold. This cartilage weakening technique relies on precisely placed horizontal mattress sutures, creating a new antihelical fold. It rarely is performed alone and commonly is used in combination with the Davis method.

Marking the Antihelical Fold

The scapha is folded back against the underlying scalp by applying digital pressure on the superior helical rim, which creates an antihelical fold. The crest of the fold is marked with a surgical marker. To prepare for placement of the mattress sutures, marks are placed parallel to the crest at least 7 mm apart to avoid creating too narrow of a fold. The lateral marks placed on the skin are transferred to the underlying cartilage with a hypodermic needle dipped in methylene blue (Figures 25-9, *A* and *B*).

Dissection and Cartilage Weakening

Local anesthetic solution is infiltrated along the scaphal fossa beneath the anterior auricular skin, hydrodissecting the skin from the underlying cartilage. This is to facilitate the anterior dissection and mattress suture placement. The postauricular skin is then removed in a fashion identical to that described for the Davis method. After identifying the marks placed on the posterior surface of the scaphoid cartilage, a Freer elevator is passed through a small horizontal incision created through the cartilage at the most inferior aspect of the new antihelical fold. The anterior auricular skin is dissected from the underlying cartilage, corresponding to the crest of the new antihelical fold. Through the tunnel dissected along the anterior surface of the cartilage, the body of the new antihelical fold is weakened to facilitate folding and to remove the inherent memory. Many methods have been described, but cartilage weakening can be adequately performed with Adson Brown forceps (KMedic, Kenosha, Wis.), a nasal rasp, or a dermabrader with a small diamond fraise (Figures 25-9, *C* to *E*).

Suture Placement

Nonresorbable, horizontal mattress sutures (4-0 Mersilene [Ethicon Endo-Surgery, Inc., Cincinnati, Ohio]) are placed. All sutures are placed through the medial perichondrium, cartilage, and lateral perichondrium, being careful not to include the anterior skin. The sutures should be placed perpendicularly across the antihelical fold so that upon tightening, a well-rounded antihelical fold will be created. The sutures are tightened under direct observation and adjusted accordingly to form the new antihelical fold (Figures 25-9, *F* and *G*).

Dressing

The dressing is important and is placed to provide adequate pressure to obliterate dead space and avoid postoperative hematoma formation. A carefully layered dressing is placed over the anterior and opposing posterior surfaces of the scaphoid region with a quarter-inch petrolatum gauze, followed by 4- by 4-inch fluffs, held secure with a pressure-type facial dressing (Figures 25-9, *H* and *I*).

Farrior Technique

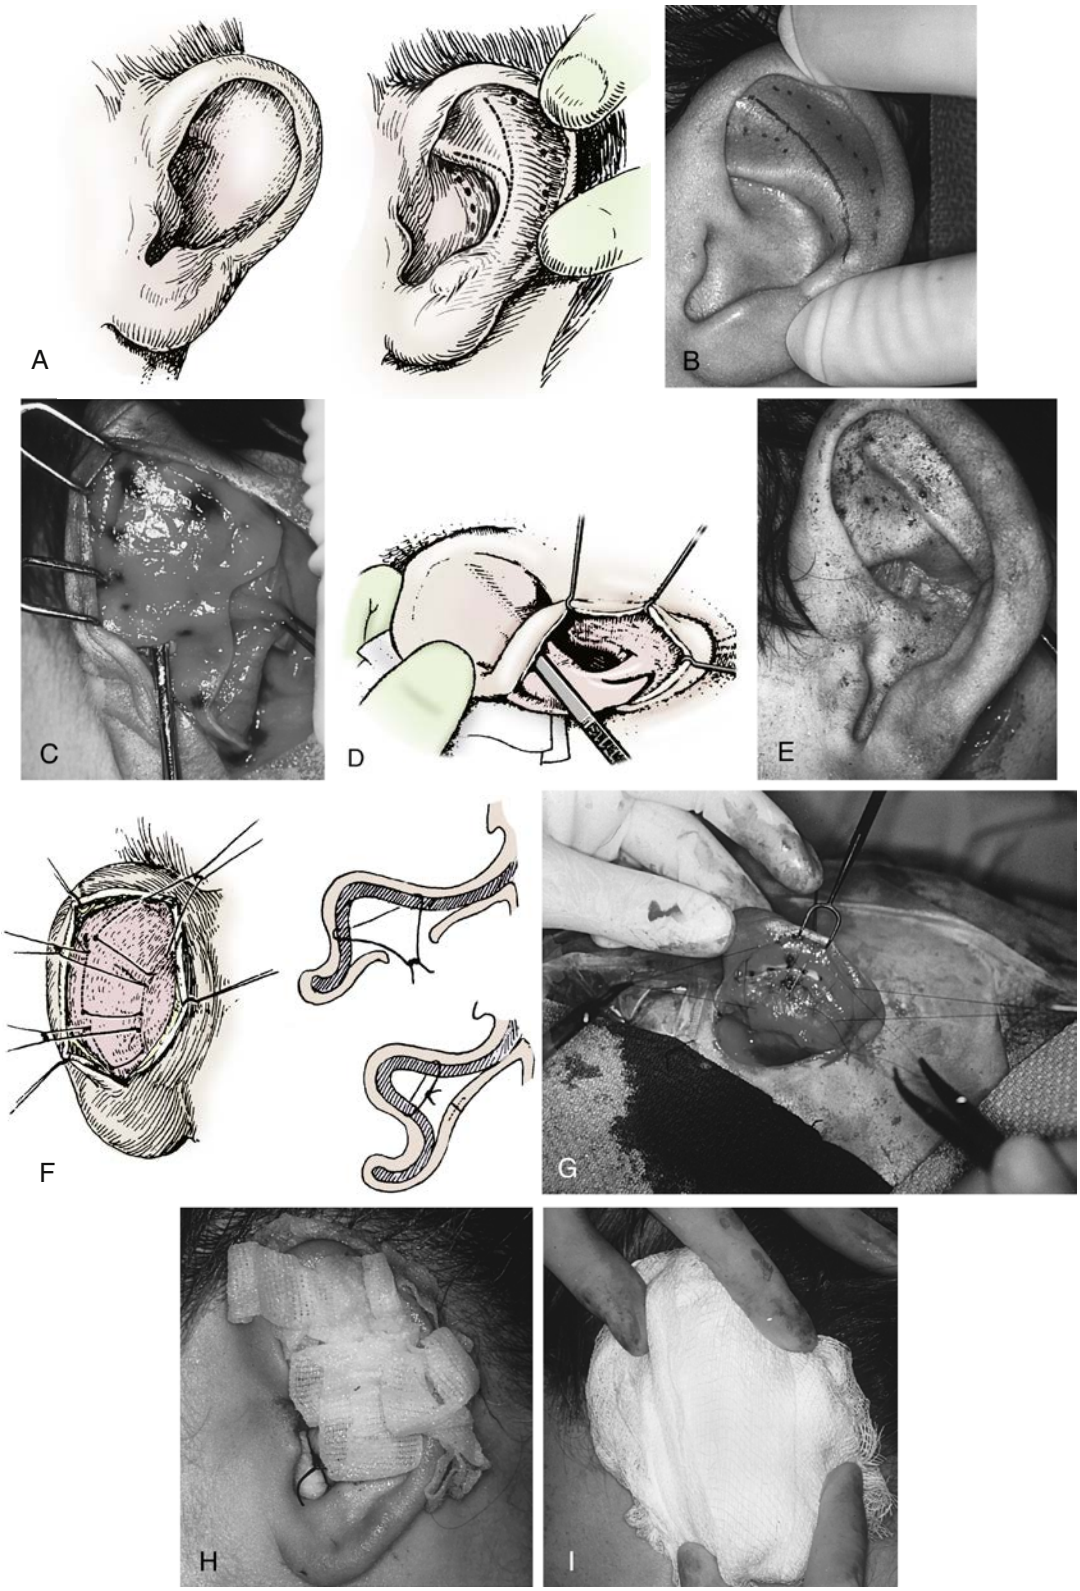
The Farrior method was first published in 1959 and is one of the first surgeries that used components of both suture and sculpting techniques. It works well for patients with large, protruding lop or cup ears. Local anesthetic is provided. An elliptical dumbbell excision of skin is drawn with a surgical marker on the postauricular skin. The amount of skin to be removed is in direct proportion to the amount of antihelical correction. All the corrections are performed through this incision, including the cartilage cutting and suture techniques. Each maneuver is then performed in a stepwise fashion, with the simplest methods used first to try to achieve the designed contours.

The antihelical fold is first reduced with mattress sutures alone, similar to the Mustardé method, but placed along a weakened antihelical fold with scoring incisions. Care should be taken to not place the scoring incisions along the triangular fossa and interior crus, which would change the shape of these two anatomic landmarks. If a deep conchal bowl is the cause of ear prominence, then conchal reduction is performed. Farrior reduced the conchal bowl at the conchal rim rather than remove the entire bowl, like Davis, and then placed conchal mastoid sutures with 4-0 Mersilene (Figure 25-10).

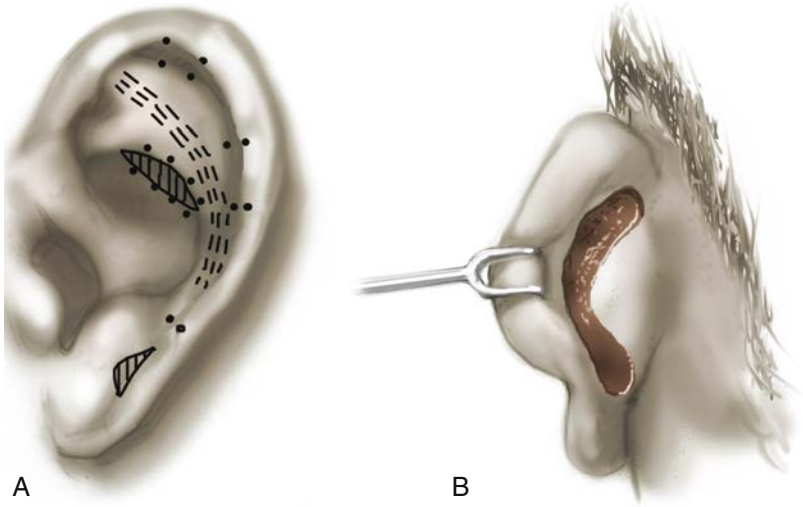
Because most protruding ears involve both antihelical and conchal excess, several maneuvers are required, including conchal reduction, cartilage scoring, and suturing, all in a stepwise fashion. In addition, an elliptical dumbbell of skin is removed and sutured together, completing the reduction. If the superior third is still prominent, more work is required in the scaphoid region. This is done by extending the horizontal mattress sutures in a parallel fashion into the superior crus and sectioning the anterior inferior crus, causing a pillar effect. The closure of skin incisions and dressing are identical to the Davis and Mustardé methods.

Correction of a Protruding Earlobe

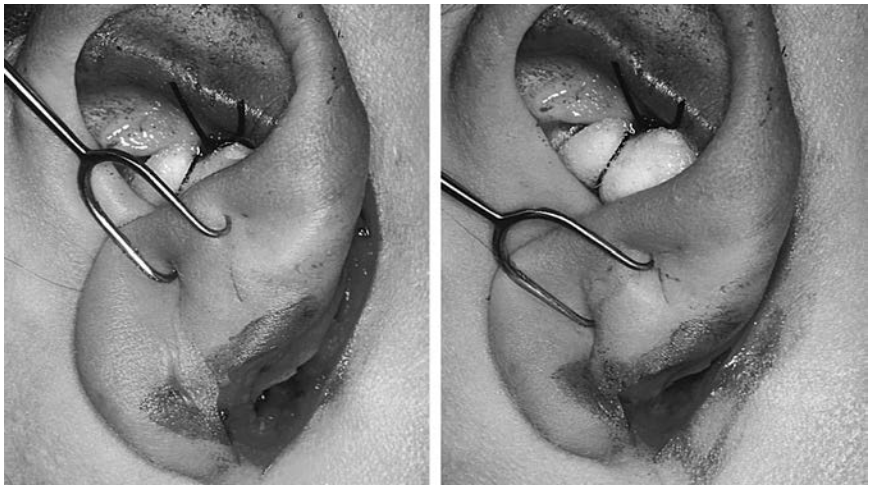
A protruding earlobe often accompanies a protruding ear. If so, it must be simultaneously identified and corrected. If



• **Figure 25-9** Mustardé technique. **A** and **B,** Creating and marking the desired antihelical fold by folding back the helix with distal pressure. Lines, parallel to the crest of the fold, are marked and transferred to the underlying cartilage and used for suture placement. **C** to **E,** Dissection of the scaphoid fossa beneath the anterior skin for weakening the cartilage and creating the desired antihelical fold. **F** and **G,** Placement of the horizontal mattress sutures to create a new antihelical fold. **H** and **I,** Placement of petrolatum gauze and fluffs as an important pressure dressing. (*A* and *F* Reprinted from LaTrenta GS: Otoplasty. In Rees TD, LaTrenta GS, editors: *Aesthetic plastic surgery,* ed 2, Philadelphia, 1995, WB Saunders. *D,* Modified from Stenstrom SJ, Heftner JL: The Stenstrom otoplasty, *Clin Plast Surg* 5:467, 1978.)



• **Figure 25-10** **A,** Maneuvers in the Farrior technique. This technique requires more cartilage scoring, and the cartilage is removed as needed at the superior rim of the conchal bowl and cauda helicis inferiorly. This preserves more of the cavum concha cartilage compared with the Davis technique. **B,** Notice the elliptical excision of the skin is superior to the posterior auricular crease. This gives better access to the antihelix and aides in retracting the severely protruded helix.



• **Figure 25-11** Marking of skin to correct protruding lobule. Areas marked are excised in a fishtail fashion and closed.

the lobule of the ear protrudes, an extension of the posterior auricular incision is drawn with a surgical marker in the shape of a V onto the earlobe. Finger pressure on the freshly marked lobe, compressing it to the mastoid skin, produces a mirror image imprint forming a W-shaped (fishtail) portion of skin to be excised. After this portion is excised and hemostasis is achieved, closure is accomplished with 4-0 plain gut suture. The two V-shaped incisions are brought together, reducing the protruded state of the lobule (Figure 25-11).

Complications

The incidence of complications after reduction otoplasty is quite low. Calder and Nassan concluded that experienced surgeons had a complication rate of 9%. Inexperienced otoplasty surgeons had a mean complication rate of 20%. Most of these complications were minor, specifically suture extrusion and repeat protrusion of the superior third. The major complications to be avoided are infection and keloid formation. Immediate complications include pressure necrosis from an overly tight dressing, infection, and hematoma formation. Delayed complications include hypertrophic and keloid scar formation, recurrence of the ear deformity, neurosensory deficits, and unesthetic results.

Hematoma

Postoperative hematoma formation, with an incidence of 2% to 4%, is the most common problem and requires immediate and aggressive intervention. It is most often

related to inadequate hemostasis achieved at the time of surgery. Other factors in hematoma formation include an overly tight wound closure without drainage at the base of the wound, postoperative trauma, hypertension, and a preexisting bleeding dyscrasia. Persistent pain beneath the dressing or significant bleeding through and around the dressing suggests hematoma formation and demands prompt inspection. The presence of a hematoma is indicated by a tense and bluish swelling beneath the auricular skin, most often in the retroauricular space. Management includes suture removal, blood clot evacuation, hemostasis, and repeated closure of the wound with a large pressure dressing reapplied. Large doses of antibiotics are advisable to prevent perichondritis. If this problem remains untreated it can result in fibrosis, perichondritis, and cauliflower ear deformity.

Perichondritis

Wound infection in otoplasty occurs in the early postoperative period and usually is a sequel to an undetected or inadequately treated hematoma. Symptoms include pain, erythema, fever, and possibly discharge. Treatment includes high doses of antibiotics after appropriate wound cultures. Common bacteria include *Staphylococcus aureus, Escherichia coli,* and *Pseudomonas aeruginosa.* Adequate drainage is achieved by opening all sutures and carefully irrigating necrotic debris from the wound. All correction sutures must be removed and the cosmetic deformity addressed at a later date. The complication can be devastating, causing massive cartilage destruction and severe deformity, even with aggressive therapy. Prophylactic antibiotics have not been scientifically proved to be beneficial, but they often are used in the preoperative and postoperative periods to avoid this devastating complication. *Pseudomonas* infections can be the most devastating of all, and the authors recommend coverage with dual antibiotics, including quinolone and a cephalosporin after surgery.

Keloid and Hypertrophic Scar Formation

The closure line of the skin incision in the postauricular region is susceptible to scar formation, most commonly seen in younger patients and patients with deeply pigmented skin. Keloid formation, one of the most frustrating of all postoperative complications, requires aggressive therapy. In the early stages of keloid formation, intralesional triamcinolone acetonide 40 mg/mL is injected weekly until regression or significant improvement is evident. Most hypertrophic scars improve with steroid infiltration, but some keloids can progress into significant unesthetic lesions. Low-dose radiation, although potentially dangerous, may provide the only effective means of control of some keloids. More advanced lesions require surgical excision combined with radiation and delayed skin grafting of the irradiated area, with final aid from intralesional triamcinolone. The risk can be minimized by ensuring that the skin incision is passively closed.

Aesthetic Complications

Inadequate correction of the ear deformity is the most common untoward result of otoplasty and often is more obvious to the surgeon than to the patient. Calder and Nassan described at least one complication or residual deformity in 16.6% of all patients who underwent otoplasty with all techniques. Recurrence of the ear deformity is a more common complication of reduction otoplasty but is less likely to happen after excising a portion of the cartilage as well as a segment of skin, as described in the Davis method. Depending on sutures alone for correction carries a greater risk of recurrence. Messner and Crysdale concluded that with time a substantial loss of correction can be expected with most patients. This is not true with the reliable methods described earlier.

"Telephone" Ear Deformity

"Telephone" ear deformity occurs when the root of the helix and the ear lobule remain protruded while the middle half, or third, of the ear is set back against the head. This is more common in a large ear with a wide scapha. The incidence has been reported to be 3%. Reverse telephone ear reveals a pronounced conchal bowl with respect to the lower and upper poles. These deformities can be avoided by carefully checking the position of the helical root, the upper helical rim, and the lobule at the completion of surgery.

Scaphal Buckling

Scaphal buckling or a transverse fold can develop in the Mustardé technique. This deformity can be avoided by placing the horizontal mattress sutures closer together where the scapha is widest and performing adequate anterior scoring or weakening.

Narrowed Meatus

A constricted external auditory meatus can occur if the conchal bowl is rotated anteriorly when setting the ear back in any technique in which the conchal bowl is not excised. This problem is eliminated in the Davis method, in which the floor of the conchal bowl is excised. Care also must be taken in placing the inferior end of the cotton roll bolster dressing into the external auditory canal to avoid stenosis.

Summary

Reduction otoplasty carries few complications and can provide satisfying results for both the patient and the surgeon in the majority of cases. As in all cosmetic procedures, proper patient selection is imperative. Accurate preoperative assessment of the individual deformities and the appropriate choice of a surgical correction minimize unfavorable esthetic results. The single greatest cause of unfavorable results in this procedure is inaccurate diagnosis.

The surgeon must understand the normal external anatomy of the ear and learn to recognize the pathologic characteristics of the abnormal ear. Having accurately assessed the deformity, the surgeon must be familiar with the various surgical approaches available to correct them. Finally, a working knowledge of the potential complications of otoplasty, their prevention, and treatment is necessary.

Facial Implants in Cosmetic Surgery

FAISAL A. QUERESHY, SUMIT K. NIJHAWAN

Introduction

Facial implants offer a novel minimally invasive treatment option the cosmetic surgeon can offer to patients to address certain complaints. However, the surgeon must be fully competent with not only the surgical technique necessary to achieve a desired outcome, but also with the properties, risks, and benefits of the material being used. It is imperative for the surgeon to have excellent technique and to be attentive to the relevant anatomy. Management of patient expectations is perhaps the single most important factor in predicting outcomes in cosmetic surgery. A detailed discussion with emphasis on the patient's reasons for seeking surgery must be entertained. A treatment plan that will address these concerns should be tailored. If expectations are unreasonable or a plan is tailored that does not attend to the patient's concerns, the surgery may be a failure prior to the first incision.

There are several red flags that should alert the surgeon to potential problem patients. One approach to this concern is the use of the acronym SIMON (*s*ingle *i*mmature *m*ale *o*ver-expectant *n*arcissistic), which was described by Gorney to identify potential problem patients.[1] Additionally, those patients with a large psychological component should be approached with caution. Patients with a small degree of deformity with a large emotional concern do not make good surgical candidates.

Gunter identified 13 red flags that identify a potential problematic patient with possible psychological issues. These include (1) minimal disfigurement, (2) identity problem of sexual ambivalence, (3) delusional view of body image, (4) unrealistic life change as a result of surgery, (5) confused motives for wanting surgery, (6) history of poor relationships, (7) unresolved grief or current crisis, (8) older neurotic man overly worried about aging, (9) paranoid thoughts, (10) history of dissatisfaction from multiple physicians, (11) sudden dislike for one's anatomy, (12) hostile attitude toward authority figures, and (13) present misfortunes blamed on appearance.[2,3] For patients that do present with alarm signs, time must be taken to educate the patient about the surgery, and redirect the patient to more appropriate outcomes. If the patient continues to stipulate unrealistic outcomes, or if constant redirection to realistic outcomes is needed, then this is a poor surgical candidate.

Body dysmorphic disorder (BDD) is defined as a distressing and impairing preoccupation with an imagined defect in a normal appearing person. The preoccupation must cause a significant distress or functional impairment, and the symptoms cannot be better accounted for by another mental disorder. Though any part of the body can be scrutinized by the patient, focus is on facial flaws in the majority of the cases. These patients display habits such as frequent mirror checking and constant need and requests for reassurance. Further, there is a high level of prevalence of other psychiatric illnesses in these patients. According to Allen, BDD is relatively common, with prevalence predictions ranging from 1.9% in the general population to 12% in psychiatric outpatients.[4] The majority of patients with BDD seek nonpsychiatric therapies, and if treated with surgery these patients do not improve their psychiatric diagnosis. Indeed, it may worsen. The surgeon should identify these patients when possible, and refrain from surgery.

Once an appropriate surgical candidate has been identified, it is important to listen to the patient's concerns. It is often easy to offer the patient a treatment plan based on the anatomic variations the patient may have, but that does not address the patient's primary concern. A plan should be rendered that addresses the patient's complaints and that the patient is comfortable with. This plan should be formulated through a collaborative effort with the patient.

Several tools can be utilized to help with this collaborative discussion. The most important educational tool may be preoperative and postoperative pictures of patients that have undergone the same procedures and have consented to have their pictures shared. Other forms of preoperative aids that can be beneficial for review during this discussion include image modifying software. It should be noted that such projections should only be used as visual guides, and no guarantees can be made of the final product. A document from the patient should be reviewed and signed, acknowledging that projected results are not guaranteed.

Finally, consideration should be given to measuring facial features in proportions, because the facial structures must be taken as a whole. The facial structures, including skin, musculature, and the bony support, all work in harmony and must be taken as a whole in relationship to the rest of the face rather than studied alone. Altering the position or function of one structure will have an impact on the neighboring structures. This is a lesson learned from orthognathic surgery, and a combination of procedures often works best in providing optimal results.

CASE STUDY 26-1

Redundant Skin, Small Chin

This 57-year-old woman presented for discussion of surgical options with complaints of a deficient chin. The patient was also concerned with the "turkey neck" appearance of her neck (Figure 26-1; see Figure 26-5 for postoperative results).

When evaluating any patient from a lateral view, one must consider the relation of the face in a vertical and anterior/posterior direction. Facial beauty relates to balance and harmony in size and volume in all three dimensions.

Four major points of protrusion exist when viewing the profile of the face: the forehead/brow, malar prominence, nose, and chin. These eminences provide topographic changes that give definition to the face. These changes are found as creases, folds, and depressions.

Photographs of this patient clearly show an anterior posterior deficiency of the lower one third of her facial profile, with a convex facial profile. However, the vertical dimension is appropriate. Further evaluation reveals platysmal banding and submental lipomatosis. Further, there is excessive skin redundancy and laxity with drooping of the jowls. A tailored treatment plan to restore facial balance is chin augmentation, rhytidectomy, and platysmaplasty. Simply attempting to restore facial proportions with a chin augmentation would yield insufficient results because the patient's profile reveals a lack of definition due to the redundancy of her skin. Further, the level of platysmal banding and submental lipomatosis would mask the planned chin augmentation if not addressed.

Many surgeons have published landmarks that have proven to be successful for them when planning for chin advancement (Table 26-1). If a lateral cephalometric radiograph is available, a reliable method of measuring anterior-posterior chin position is referred to as the holdaway ratio (Figure 26-2). On the lateral cephalometric radiograph, a line is drawn from the nasion to the B point (the NB line). The distance from this line perpendicularly to the most labial aspect of the lower first incisor is then compared to the distance from this line, perpendicularly, to pogonion. Ideally, this ratio should measure 1:1 to 1:1.5. Many times, thick soft tissue may mask the bone, or the proper imaging may not be available to perform the holdaway ratio measurement. It may be desirable in this case to perform an evaluation based on the patient's clinical soft tissue profile. Dr. Ricketts is credited with development of the E-plane, or esthetic plane, to aid in evaluation. The E-plane is simply a line drawn from the nasal tip to the soft tissue pogonion. Though there is variation among different ethnic groups, for a Caucasian face, the upper lip should fall approximately 4 mm behind this line, and the lower lip should reside 2 mm behind the plane.

• **Figure 26-1** The patient presents for evaluation of her deficient chin and "turkey neck." **A,** Frontal view of the patient in repose. **B,** Profile view of the patient. In addition to the deficient chin, note the banding at the platysma that gives a general lack of definition to the lower facial third and neck.

CASE STUDY 26-1—cont'd

Redundant Skin, Small Chin

It is prudent to note that the maxilla and mandible must be orthognathic to use this evaluation for determination of chin projection. Additionally, care must be taken to ensure that the nasal tip projection is not either deficient or excessive when evaluating the chin position with this method. If the maxilla and mandible are both orthognathic and projection of the nasal tip is appropriate, the desired E-plane can be drawn on the patient's profile view to yield an esthetic position of the chin (Figure 26-3).

Different surgical options for chin augmentation should be considered, such as an osteotomy for a genioplasty with

TABLE 26-1 Different Analyses Determining Chin Position

	Rish technique	A line to Frankfort horizontal is created tangential to the anterior edge of the lower lip vermilion border. This line marks the desired chin projection.
	Merrifield Z-angle	A line is created through the pogonion and the most anterior point of the upper lip vermilion border. The angle this creates with the Frankfort horizontal should be 80 ± 5 degrees.
	Legan's angle	One line is projected through the glabella and subnasale, and a second line is projected through the subnasale and the pogonion. The ideal angle created between these two lines is 12 ± 4 degrees.
	Zero meridian of Gonzales-Ulloa	A line through the nasion perpendicular to the Frankfort horizontal is created. The pogonion should be within 5 mm of this line. Slight (≤5 mm) retraction of the pogonion from this line is more acceptable in women. Retraction of the chin less than or equal to 1 cm is deemed first-degree retraction, 1 to 2 cm is second-degree retraction, and greater than 2 cm is third-degree retraction. First- and second-degree retractions are treated with implants. Third-degree retraction is best treated with maxillofacial surgery.
	Goode's method	A perpendicular line is created from the Frankfort horizontal through the alar-facial crease. The ideal chin position is at or just anterior to this line.

CASE STUDY 26-1—cont'd

Redundant Skin, Small Chin

TABLE 26-1 Different Analyses Determining Chin Position—cont'd

	Calhoun and Gibson (lower facial triangle)	A triangle is defined by the tragion (consistent with the superior margin of the external auditory canal [EAC]), subnasale, and the chin defining point (determined by centering an arc at the tragion with a radius that allows the arc to be tangential to the chin). The points T, S, and C are used; the ideal facial profile has a TC/TS ratio of 1.15:1.19, and an S angle of 88 to 93 degrees. This analysis should be used only if the lower facial profile was subjectively not well balanced.
	Peck and Peck	Accounts for facial height and anterior projection. The nasal angle is from the tragion to nasion and nasal tip (normal is 23.3 degrees). The maxillary angle is the tragion through nasal tip and labral superioris (14.1 degrees). The mandibular angle is from the tragion through the labral superioris and pogonion (17.1 degrees). The facial angle is the angle created by a line from the tragion through the midpoint of the line from the nasion through the pogonion (102.5 degrees). The line from the nasion to labral superioris, through the aforementioned line from the tragion, yields the maxillofacial angle (5.9 degrees). Nasal maxillary angle is from the tragion with a line drawn between the nasal tip and the labral superioris (106.1 degrees).
	Holdaway	The "harmony" line or "H line" is from the pogonion through the most prominent portion of the upper lip. The angle between this projection and a line between the pogonion and the nasion is called the "H angle." The ideal H angle is 10 degrees; the higher the angle, the more retrusive the chin.
	Powell and Humphreys	Uses the "esthetic triangle" and is based on the ideal profile of a nasofrontal angle of 115/120 degrees (male/female), a naso-facial angle of 36/36 degrees, a nasomental angle of 130/130 degrees, and a mental-cervical angle of 80/85 degrees.
	Stambaugh	Line tangential to the anterior point of the vermilion of the upper and lower lips in contact. Chin should meet this line in men (±2 mm) and be 2 to 3 mm behind this line in women (±2 mm). Vertical height of the maxilla and mandible is considered when evaluating the patient for chin augmentation. If a short mandible itself is short relative to the rest of the face, augmentation may accentuate lower lip eversion. If the maxillary height is disproportionately small, augmentation of the mentum can accentuate a deep sublabial crease.
	Zide Quick Analysis of the Chin (QUAC)	Anatomically based. Looks at (1) lip eversion, (2) the anterior teeth, (3) chin pad thickness, (4) labiomental fold depth and height, and (5) dynamic chin pad motion with smile.

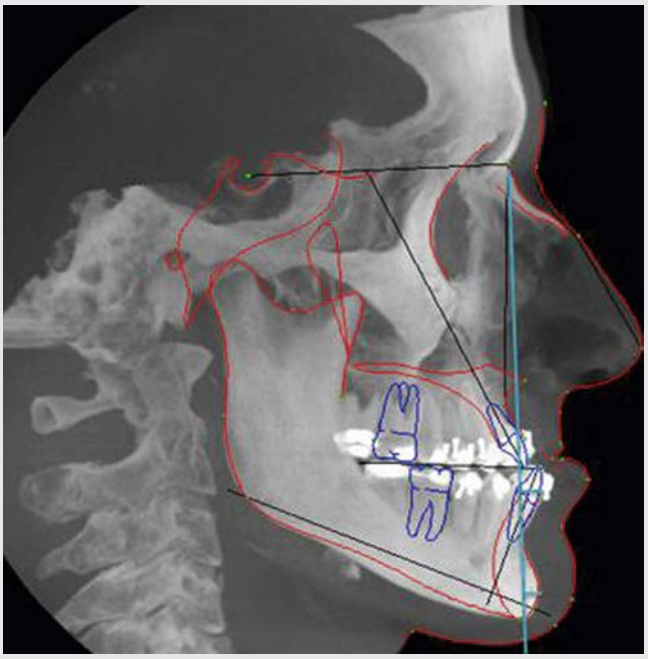
CASE STUDY 26-1—cont'd

Redundant Skin, Small Chin



• **Figure 26-2** An example of the holdaway ratio. A line, shown in light blue, is made from nasion to B point. The perpendicular distance from this NB line is measured to the most labial portion of the lower first incisor and to pogonion. Ideally, this ratio should be 1:1 to 1:1.5.

rigid fixation compared with an alloplasty to augment the chin. Per Wilford, a 60% to 75% soft tissue change with osseous augmentation in the anterior-posterior dimension can be expected.[5] Stripping of periosteum from the inferior border of the mandible may minimize soft tissue change. An 80% to 85% soft tissue change can be seen in the anterior-posterior dimension with alloplastic augmentation. Vertical augmentation results in a 1:1 soft tissue change for both alloplastic and osseous augmentation. Different alloplastic materials are available for this type of procedure. Though the incision has been described either extraorally or intraorally for alloplastic implants, most advocate an extraoral approach when possible to maintain sterility.

Factors in choosing augmentation materials include the specific properties and limitations of the implant materials and the site for implantation. According to Adams, consideration must be given to several factors when considering the alloplastic material being used. These include material density, ability to be sculpted, the degree of associated tissue reaction, the degree of migration, resorption, the incidence of infection, and extrusion rates.[6,7] When deciding on the density of the material to be used, as a general rule, bone is best replaced with firm materials whereas soft tissues are best augmented with less dense materials. Soft, more porous materials are much more difficult to remove in case of infection. The site of augmentation is just as important. Silastic may work well for rigid areas such as the chin, but has been associated with extrusion when used for nasal augmentation. Another

• **Figure 26-3** Use of the E-plane for evaluation of chin projection. Note that for proper evaluation with this method, the maxilla and mandible must be orthognathic, and the nasal tip projection should be appropriate. **A,** The E-plane line is drawn, shown in black. Notice that the lower lip is touching the line, and the upper lip is only 2 mm behind the line, indicating a deficient chin. **B,** The same patient is shown after alloplastic chin augmentation. Notice a more appropriate relationship of the upper and lower lips to the E-plane with the chin in correct projection.

Hydroxyapatite

commonly used alloplastic material, porous polyethylene or Medpor (Stryker Global, MI) has several favorable properties. Niechajev showed that in a 16-year history with 118 implants placed, Medpor showed favorable characteristics including tissue in-growth and vascularization, biocompatibility, ease of contouring, fixation flexibility, and a bony feel.[8-11] In this series complications included implant extrusion in two nasal augmentation cases and infection in three cases. Medpor has been used for augmentation in rhinoplasty, as well as chin augmentation and malar augmentation.

Synthetic alloplastic materials can be broadly categorized into carbon-based polymers, non-carbon-based polymers, aliphatic polyesters, metals, and ceramics (Box 26-1). Among the most popular facial implants used today is the silicone implant (Silastic, Dow Corning Corp., Midland, MI). This is an inert non-carbon-based polymer that becomes encapsulated by the host. It is popular because of its soft and flexible consistency and, most important, its nonporous composition.

Infection that may develop usually can be treated with a course of antibiotics, and some porous implants such as Medpor may need complete removal to be treated effectively. In general, 1×10^5 bacteria are needed to cause clinical manifestations of an infection.[12] In the environment of a foreign body, this number is greatly reduced. Antibiotic coverage should be considered both peri-operatively and postoperatively. The implant should be soaked in antibiotic solution before replacement.

Alloplastic chin augmentation may be advocated over genioplasty for several reasons (Box 26-2). A genioplasty is more invasive, and there is a prolonged recovery associated with increased swelling in the postoperative course. Further, there is an increased risk to the lingual periosteum and musculature. Although there is concern for resorption, as previously stated, resorption can be limited by limiting the stripping of the periosteum. Further, there is greater risk of altered vitality of the anterior dentition with a genioplasty, with greater associated paresthesia. Further, there may be increased notching of the inferior border. A further indication for an alloplastic implant over a genioplasty is a low mental foramen that may make an osteotomy difficult.

Advantages for genioplasty over alloplastic augmentation include lower infection rates, more versatility (better for cases of asymmetry), less bone resorption, and more useful in cases with change in vertical dimension (Box 26-3).[13] Additional indications for a genioplasty include younger individuals to limit bony resorption from implants. Also, if more than 4 to 6 mm of augmentation will be necessary, an osteotomy may be indicated because larger implants may be associated with increased complications. Further indications for a genioplasty include failure of previous alloplastic implants, hyperactive chin musculature which may cause displacement of an alloplastic implant, or a patient with labial incompetence and labial strain, which may place excessive forces on an implant and lead to increased resorption.

Though an alloplastic chin implant can be placed by an intraoral approach or through an incision proximal to the submental crease, the extraoral approach is advocated to limit infection. Both options are effective and have their benefits and limitations (Boxes 26-4 and 26-5). The patient described in this case benefited from submental liposuction, cervicoplasty, rhytidectomy, platysmaplasty, and alloplastic chin augmentation (Figure 26-4). The final postoperative pictures show the patient with an appropriate projection of the chin, along with more neck definition (Figure 26-5).

• BOX 26-2 Advantages and Disadvantages of Alloplast

Advantages

Easily reversible
Quicker recovery time
Less painful
Less chance of paresthesia
Can address pre-jowl sulcus
Can be used on patients with low mental foramina

Disadvantages

Overaugmentation
Lateral limb malposition
Greater concern for infection
Extrusion (rare)
Bone resorption

• BOX 26-3 Advantage and Disadvantages of Genioplasty Osteotomy

Advantages

Can change vertical dimension
Better for asymmetry

Disadvantages

Deeper anesthesia
More equipment and hardware
Painful, more dissection
Greater risk of IAN injury
Risk to dental roots
Overaugmentation
Longer surgery time

Note the augmentation in projection of the chin, along with the lack of platysmal banding.

CASE STUDY 26-2

Sunken In, Aging Face

A 47-year-old female presented for evaluation, asking for dermal fillers. Clinical examination demonstrated significant facial atrophy, particularly under the malar prominences, in the areas of the cheeks and nasolabial folds. Further, the patient was seen to have fine vertical rhytids of the upper lip, and thin upper and lower lips (Figure 26-6; postoperative, Figure 26-7). In such a case, it is important to redirect the patient. Given the significant fat atrophy to both her cheeks, dermal fillers alone would be inappropriate and would not address the patient's concerns. In such circumstances, malar implants would also be inappropriate because the actual malar projection is adequate. An abdominal fat transfer along with Restylane injectable filler was recommended to the patient.

Because there is no concern with biocompatibility in autologous transfer, fat makes for a very good filler material (Box 26-6). Additionally, this is generally a safe procedure with minimal morbidity and relative surgical ease, with few drawbacks. Kaufman and colleagues offer a review on several considerations when considering autologous fat transfer. Though fat transfer has been performed as injectable grafts since the 1920s, it has gained popularity since 1990. The popularity of this procedure reflects an increase in body lipocontouring. Though there has been some concern regarding the long-term viability of this procedure, the published literature reflects reasonable success with the procedure.[14-16]

Though conclusive studies differentiating between different donor sites are largely lacking, the abdomen serves as the most commonly used donor site. During the harvest, high vacuum extraction is discouraged because it may result in adipocyte rupture. Several authors have described the harvest technique with 3-mm cannulas using a curetting motion with a 10-mL syringe to obtain globules of fat. Prior to harvest, infiltration of a tumescent solution may be performed to help achieve hemostasis and help break up fat globules. Different authors describe different concentrations, but the mixture used for this case was 50 mL of 1% lidocaine solution, 1 mL of 1:1000 epinephrine, and 12.5 mL of 8.4% sodium bicarbonate in 1 L of normal saline.

After harvest, the fat must be prepared for transfer in a centrifuge. A typical protocol is to centrifuge aspirated fat at 3000 rpm for 3 minutes to separate fat aspirate from oil, blood, and other contaminants. It has been reported that up to 50% of fatty tissue undergoes cytoplasmic lysis upon exposure to air. Although this is debatable, attempts should be made to minimize prolonged storage prior to transfer. Some literature is also available on addition of growth factors to enhance fat viability, though there appears to be little clinical evidence of such measures. It is generally accepted that fat survival is based on the proximity of transfer to a blood supply. Therefore, many authors describe a "fanning out" technique while injecting

Sunken In, Aging Face

• **Figure 26-6** **A,** Frontal. **B** and **C,** ¾ views. In addition to the fine vertical rhytids around the peri-oral region, notice the sunken appearance in the right and left cheeks.

CASE STUDY 26-2—cont'd

Sunken In, Aging Face

• **Figure 26-7** The patient originally presented in this case shown 4 days postoperatively in **(A)** frontal and **(B)** ¾ view. Notice the augmentation of the infra-orbital and peri-alar area. Also, there is much more definition with a slight decrease in the peri-oral rhytids. The ecchymosis seen is normal 4 days post-surgically. The patient was satisfied with her result, but understands that a degree of lipoatrophy is expected.

• BOX 26-6 Advantages and Drawbacks of Autologous Fat Transfer

Advantages

Biocompatible
Semipermanent
Stem cells found in fat can lead to increased skin rejuvenation
Can address two areas at once (lipo-excess and lipodystrophy)

Disadvantages

Requires local or regional anesthesia
More surgically invasive
Second surgical site
May have longer healing time
Unpredictable longevity

to maximize the surface area of fat that is in contact with vascularized tissue.

Studies have found that within 6 months, aspirated fat grafts have lost up to 60% of their original weight, compared to 1% of fat loss using an excisional technique. Hence, consideration must be given to over-injecting in anticipation of this atrophy. Other complications of this procedure include fat hypertrophy and fat emboli, but these are rare.

The patient presented in Figure 26-7 benefited from an abdominal fat transfer to the peri-alar region as well as the cheeks and infraorbital region, as well as Restylane injectable filler to the peri-oral region. The patient was very satisfied with the immediate result. However, the patient is well aware of the expected fat atrophy, as patients must be counseled of this in the preoperative visit. As a result, patients undergoing this procedure should be made aware of further surgeries that may be needed in the future.

CASE STUDY 26-3

Malar Cheek Implant

• **Figure 26-8** A 73-year-old patient presents to discuss surgical options for her facial rhytids.

A 73-year-old woman presented stating that she doesn't like her wrinkles and wants to discuss surgical options (Figure 26-8). A bird's-eye view shows very flat malar eminences (Figure 26-9). When the face is assessed in a front view it can be considered a triangle, with the corners as the chin and zygomatic eminence (Figure 26-10). An attractive face often has well-defined corners of the triangle and hence a well-proportioned chin and cheekbones. Malar implants can be a valuable adjunct to facial cosmetic surgery. It is suggested that the zygomatic prominence should be located 2 cm inferior to and 1.5 cm lateral to the lateral canthus of the eye. There are several other methods of assessing proper malar projection (Table 26-2). This landmark should aid not only in evaluation of the malar region, but also in planning proper augmentation.

The treatment plan for this patient was a rhytidectomy, cervicoplasty, laser skin resurfacing, submental liposuction, lower blepharoplasty, and malar augmentation. Though the patient's main complaints were facial rhytids when she presented, a combination of the above mentioned procedures gave the patient the harmony required and the result she desired while addressing her chief complaint. The rhytidectomy, cervicoplasty, submental liposuction, and laser resurfacing helped remove excessive skin and addressed her concern of facial rhytids. However, the dramatic change was highlighted by the augmentation of her zygomatic eminence to give her a harmonious result.

Though there may be different incisions used for placement of malar implants, an intraoral Keen incision is very popular. If sterility is to be maintained for other procedures being performed, as in this case, the malar implants should be placed either prior to prepping the patient, or after the sterile portion of the procedure is complete. If there is excessive redundant tissue and verification of placement of the implant position will be difficult, the implants are best placed after the skin excision is performed in the rhytidectomy. If this will not be an issue, as in this case, the implants can be placed prior to the sterile procedures and can help guide the amount of skin excision. A subperiosteal pocket must be created that extends to the infraorbital rim and over the zygomatic arch and includes the lateral wall of the orbit. Attention should be made to not violate the infraorbital neurovascular bundle and to stay subperiosteal, particularly lateral to the orbit, to avoid the temporal branch of the facial nerve. The implant should be soaked in gentamycin solution before its placement intraorally. Fixation with monocortical screws helps prevent against migration.

Postoperatively, the patient was very satisfied. Her chief complaint of facial rhytids was addressed not only by removal of excessive skin with the rhytidectomy, but the skin was further tightened with laser resurfacing. The dermatochalasia was addressed by the lower blepharoplasties. The cervical banding was addressed with the submental liposuction and

CASE STUDY 26-3—cont'd

Sunken In, Aging Face

• **Figure 26-9** A bird's-eye view shows very flat malar eminences.

platysmaplasty. The malar augmentation helped bring harmony to the patient's facial proportions by giving her adequate malar projection that she lacked prior to surgery (Figure 26-11).

An advantage to the malar implant is that it is easily reversible. Though results are often pleasing, there may be several reasons that warrant removal. According to Yaremchuk, approximately 10% of malar implants are removed or replaced because of improper implant shape, size, or position, and other reasons may include infection, dehiscence, and impingement on the infraorbital neurovascular bundle.[17-21] If an implant has been in for some time, a fibrous capsule may form around the implant that may make mobility and removal of the implant troublesome. After removal, a secondary placement of a malar implant may be attempted if desired.

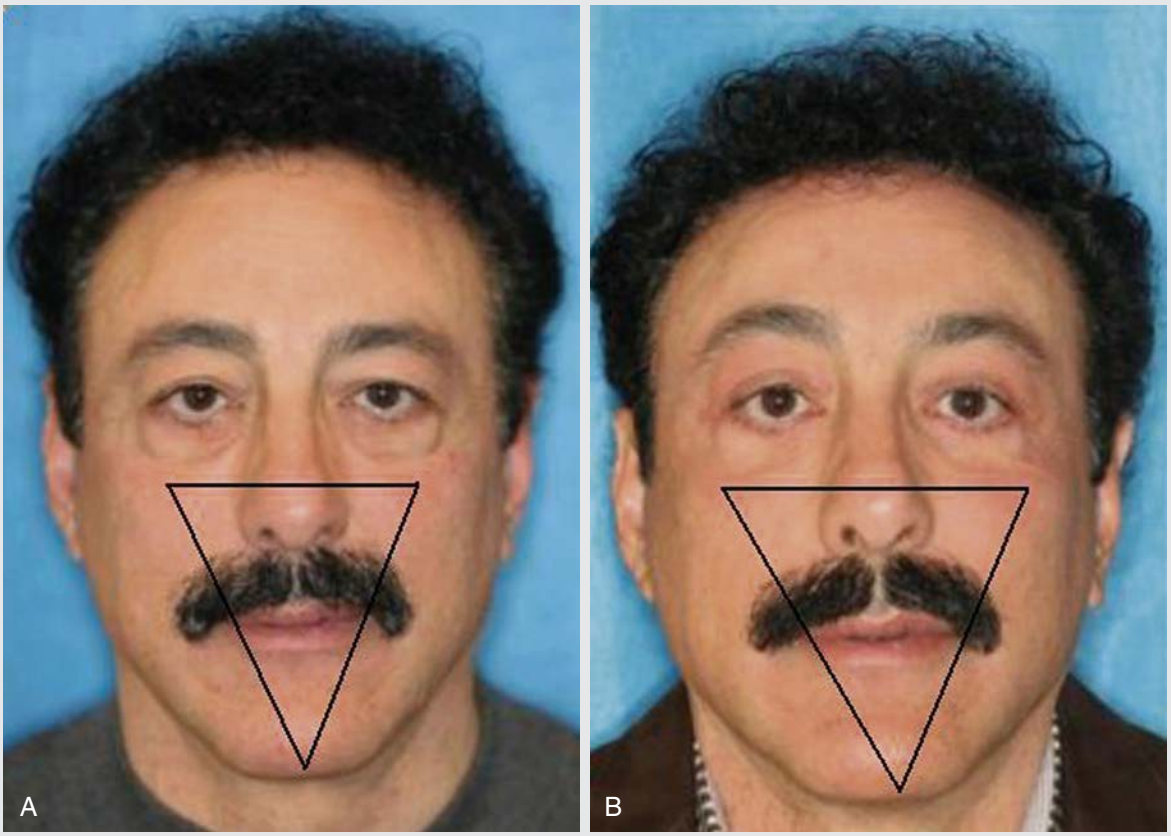
CASE STUDY 26-3—cont'd

Sunken In, Aging Face



• **Figure 26-10** An attractive face has well defined corners of the triangle from the chin to the zygomatic eminence. **A,** A patient with malar insufficiency is assessed from the frontal view. There is a lack of malar prominence, and the facial triangle is imbalanced. **B,** More symmetry in the facial triangle is seen after malar augmentation.

TABLE 26-2 Analyses for Malar Implants

Hinderer[29]	From the frontal view, draw a line from the lateral commissure of the lip to the lateral canthus of the ipsilateral eye and another line from the tragus to the inferior edge of the nasal ala. The area posterior and superior to the junction of these two projections should be the most prominent area of the malar eminence.
Powell et al[18]	Draw a vertical line through the middle of the face, then bisect the segment between the nasion and the nasal tip with a line that curves gently upward to the tragus on both sides. Draw a line from the inferior ala to the lateral canthus and another line, parallel to this one, from the lateral oral commissure toward the ear. The intersection of the curvilinear horizontal line and the line from the oral commissure marks the point where the malar area should be most prominent.
Silver and Guilden[21]	If the malar prominence in the true lateral projection is >5 mm posterior to the nasolabial groove, then a deficiency in the malar area exists. Silver describes the malar prominence triangle. To create this triangle, draw a Frankfort horizontal line across the face in frontal projection and a parallel line that bisects the upper lip. Then draw a perpendicular line through both of these lines and through the lateral canthus. The intersection of the vertical line and the line through the upper lip defines point A. Create a line from point A through the medial canthus and then a second line from point A toward the temporal area, but at the same angle from the vertical that was created by the projection from point A through the medial canthus. This creates the malar prominence triangle with the base being the Frankfort horizontal and the apex being point A. Silver advises that the implant should be placed several millimeters below the Frankfort line.
Schoenrock[25]	On an oblique view (27 to 35 degrees of rotation from the frontal view) in natural head position, a line drawn through the lateral canthus and the mentum should reveal the "width" of the malar eminence. This is said to be approximately 3 to 7 mm in the average person.

CASE STUDY 26-3—cont'd

Sunken In, Aging Face

• **Figure 26-11** The patient initially presenting in the case is seen postoperatively. **A,** The frontal picture demonstrates a marked improvement with tighter skin. The platysmal banding and goose neck have been addressed with cervicoplasty. **B,** The malar implants augment the result by providing proper projection of the face giving an esthetic, harmonious result.

CASE STUDY 26-4

Fillers: Injectable Implant Materials

• **Figure 26-12** A 78-year-old female presents for fillers in her upper lip and nasolabial fold.

A 78-year-old female presented with a desire to have fillers in her lips and nasolabial folds (Figure 26-12). The patient had undergone multiple cosmetic procedures in the past, including a rhytidectomy, upper and lower blepharoplasties, and collagen fillers every 18 to 24 months. Some of the most commonly used fillers include hydroxylapatite products (Radiesse-Merz Aesthetics, North America) and hyaluronic acid products (Restylane-Galderma, TX, and Juvederm-Allergan, CA). Collagen products, such as Zyderm (Allergan, CA) and Zyplast, were more popular for use in the 1980s.

Fillers can be categorized by the depth of implantation (i.e., superficial upper and mid-dermis, deep dermis, and subcutaneous levels), the longevity of correction (i.e., temporary, semipermanent, and permanent), allergenicity, and composition of agent. Collagen and hyaluronic acid are biodegradable and last from 4 to 9 months. Patients are sometimes dissatisfied due to the short-lived effects of the filler. Collagen is a major structural component of the dermis, and comprises 70% of dry skin. Type I comprises 80% to 85% of the collagen encountered. Loss of collagen results in skin fragility and wrinkles. Aging and UV light accelerate this process. Drawbacks of collagen fillers include the risk of hypersensitivity reaction. The response can be seen as early as 6 hours after treatment, and can last up to 4 weeks. A positive skin test disqualifies the patient for treatment with bovine collagen, and two negative skin tests are advocated prior to placement of the filler. A reaction, if it occurs, typically resolves within 4 to 24 months. When injecting bovine filler, the depth of infection should be into the dermis to avoid beads and cysts. CosmoDerm and Cosmoplast are bioengineered human collagens that were FDA approved in 2003. These lack the risk of skin hypersensitivity, and hence require no skin testing. Further, there is less bruising than with hyaluronic acid. CosmoDerm may be placed superficially and is the filler of choice for peri-orbital wrinkles and smoker's lines above the top lip. Drawbacks of bioengineered collagen include expense and limited longevity.

Hyaluronic acid (HA) has been very widely used in the last few years. It is nonimmunogenic, with longer duration (6 to 12 months), and is reversible with hyaluronidase. The two main categories include animal derived (Hylaform) and bacteria derived (Restylane and Juvederm). Drawbacks of hyaluronic acid include bruising, swelling, lumps, and acneiform eruptions. Rarely, there can also be arterial occlusion, which is thought to occur from swelling of the HA implant, causing vascular compromise. If vascular compromise occurs, treatment must be prompt. According to Narins et al. hyperbaric oxygen, if used in an appropriate time interval, can be used to reverse effects of vascular compromise.[22,23]

CASE STUDY 26-4—cont'd

Fillers: Injectable Implant Materials

• **Figure 26-13** Injection of Juvederm to melolabial and perioral rhytids. Notice the dramatic change in the depth of rhytids in the postoperative picture *(right)*, as compared to the preoperative picture *(left)*.

Hyaluronidase takes effect over 24 hours, but does not have the instant effect desired. Restylane, which lasts 6 to 9 months, has a good safety profile, and its stiffness makes it an ideal material for deep wrinkles and nasal tip support. Juvederm has the advantage of a smooth consistency with a broad range of particle sizes, which allows for a uniform distribution. Juvederm XC includes lidocaine and allows for a more comfortable injection (Figure 26-13).

Semipermanent fillers last for 1 to 3 years and include products such as Radiesse and Sculptra. Radiesse was FDA approved in 2006. It stimulates cutaneous cells to generate focal foreign body reaction and neocollagenesis, which slows the degradation of the product. It is a radiopaque material that can be visualized on radiographs. Benefits of this filler include that it can be combined with other fillers and is very pliable. Disadvantages include that it is not reversible like HAs. Also, it doesn't contain anesthetic and requires a large-bore needle for injection due to its high viscosity. The use of topical or regional anesthetic is recommended. Implantation to superficial and mobile wrinkles is discouraged due to palpable and visible white papules that may develop. Sculptra is not a true filler. It promotes the production of new and organized collagen into the dermis and is a dermal stimulator, so results are not seen until about 4 weeks after surgery.

Permanent fillers are very popular outside of the United States due to their lower cost. Their use requires a skilled and experienced practitioner because the results may be permanently disfiguring. Examples include Artefill, which was approved in 2006 for correction of nasolabial folds. Artefill is composed of synthetic microspheres and cow-derived collagen.

The patient in Figure 26-14 had Radiesse injected into bilateral malar regions, including the nasolabial folds and melolabial folds. Note that the injection should be kept deeper in the dermal layer to avoid noticeable superficial papules. After injection, the area should be massaged to ensure an even distribution.

• **Figure 26-14** **A,** Radiesse, a semipermanent filler, is injected in the dermal layer in the nasolabial fold. Superficial injection is discouraged due to visible and palpable papules that may develop. **B,** After injection, the area is massaged to ensure even distribution.

CASE STUDY 26-5

Lip Implants

Per Segall, assessment of the patient desiring lip augmentation should include evaluation of the lip height and length, and the vermillion arch. Any asymmetry should be noted, along with presence of peri-oral rhytids. As patients age, there is a loss of lip volume with some effacement of the vermillion border.[24] A discussion should revolve around patient expectations. Pictures of both the patients and any magazine cutouts are excellent tools in evaluating patient desires and discussing realistic expectations. Following a thorough assessment, patients may be offered various treatment modalities, which include fillers, free fat grafts, and lip implants.

For years the most common permanent alloplast material used in the lip was polytetrafluoroethylene implants, or Gore-Tex[25] (W. L. Gore & Associates, Newark, DE) and the hollow, more expensive Soft Form implants (Allergan, Inc.). Newer on the market is Advanta (Atrium Medical Corporation, Hudson, NH), which is a dual-porosity implant created with hopes of less migration and more softness. These materials are not without limitations. In a highly animated area such as the lips, exposure of the implant is possible, and infection is a risk when introducing a foreign body. The most common complaint regarding these implants is their susceptibility to becoming hard and palpable.

Recent strides have been made in creating a better lip implant. The VeraFil implant (Evera Medical, Foster City, CA) has gained FDA approval for soft tissue augmentation around the eyes. In Europe is it being used as a lip implant known as FulFil. This is a saline-filled implant in a silicone capsule and with a thin polytetrafluoroethylene outer shell. An implant length and diameter are picked and the implant is inserted into the lip deflated, with a small access hose at the end. The implant is then injected with saline to inflate. The volume of saline can be adjusted clinically to an appropriate amount. A limitation of this implant is that it cannot be altered in length intraoperatively. Doing so would likely perforate the silicone outer shell.

When determining the size of the needed implant, Niamtu[26] recommends proper pre-operative assessment including obtaining pictures of the patient in the upright position with frontal, obilque, and lateral repose photographs, as well as full smile, pucker, and mouth wide open pictures. Erring on the side of an implant that is too short rather than too long is better to minimize the risk of extrusion. Local anesthesia is infiltrated in the mucobuccal fold, and small incisions are made bilaterally. Implant placement in the lip depends on the patient's needs and desires; if a person's concern is wrinkles in the white portion of the lip, it is placed slightly higher. The majority of implants are placed within a pocket created at the wet-dry border in the subdermal plane. This gives the lip the popular "full-rolled out" appearance. It is advocated to soak the implant in antibiotic solution prior to delivery. Meticulous technique is essential to ensure that the implant sits symmetrically in the muscular layer of the lip.

According to Segall,[24] disadvantages of the lip implant include graft palpability, and visibility if placed too superficially. This is most visible on full patient animation. Other complications include risk of graft migration, extrusion, foreign body granuloma formation, and infection.[24,27,28] Should a complication arise, implants can be removed, but there is a risk for scarring or lip asymmetry after removal.

Summary

Many advances have been made in the field of cosmetic surgery. Surgeons always strive to give patients the most esthetic, natural result with minimal risk. The everlasting pursuit of youth and beauty keep inspiring surgeons, patients, and manufacturers to push the envelope in terms of what is possible. Facial implants have in many ways revolutionized this never-ending pursuit. As newer materials and techniques continue to be utilized to provide the best outcomes, it is imperative for a cosmetic surgeon to always be at the forefront of knowledge. As different materials become available, it is important to understand the different physical properties of the materials, how the materials behave differently, potential adverse outcomes and limitations, and the latest published experience.

Cosmetic surgery can be one of the most challenging and rewarding disciplines. Knowledge of anatomy, the ability to identify appropriate surgical candidates, knowing limitations, and having excellent surgical skills are all factors that play a role in patient outcomes. Though facial implants have revolutionized cosmetic surgery, the ultimate success of a procedure has, does, and will always rest in the hands of the surgeon.

Orofacial Embryogenesis: A Framework for Understanding Clefting Sites

KATHLEEN K. SULIK

Introduction

This chapter explains human facial morphogenesis in an attempt to establish a framework for understanding the genesis of orofacial clefts. To facilitate this, illustrations created in the 1940s based on 3D reconstructions of histologic sections of human embryos as well as more recent scanning electron micrographs are presented and described. These images show the complex morphology of the developing human face, an appreciation of which is essential to interpreting experimental and clinical data regarding the genesis of both commonly occurring and unusual orofacial clefts. Of note, a majority of the multiple cleft sites, as defined by Tessier,[1] correspond to the interface of morphologically distinct regions or growth centers of the embryonic face and can be readily related to failures of their growth, fusion, or merging.

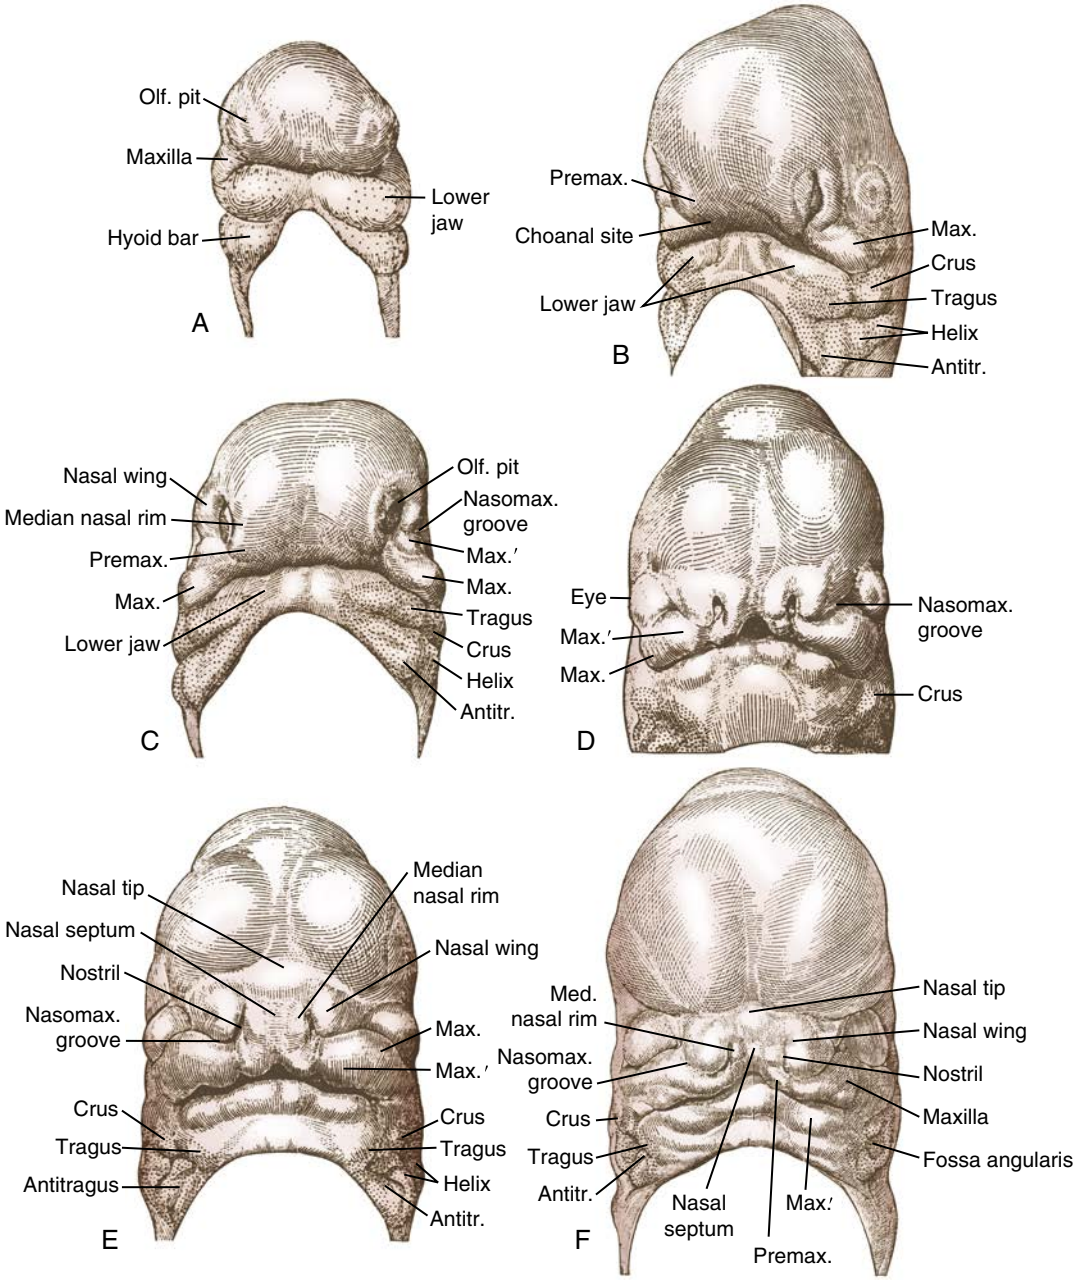
Extensive discussion of the contributions and interactions of various cell types to yield the facial growth centers and result in their appropriate development is beyond the scope of this chapter. For this information, the reader is encouraged to examine relevant review articles.[2-4] Furthermore, this chapter is not intended to provide a comprehensive survey of known genetic factors and environmental influences that shape the face and can result in clefts. With knowledge in this arena growing at a rapid rate, reference to both reviews [5-11] and databases of teratogens, genes, genetic disorders, and gene expression patterns for human beings and pertinent animal models is recommended (e.g., Online Mendelian Inheritance in Man: http://www.ncbi.nlm.nih.gov/omim, Edinburgh Mouse Atlas Project: http://www.emouseatlas.org/emap/home.html, and Mouse Genome Informatics: http://www.informatics.jax.org).

For obvious reasons, only a fraction of existing knowledge regarding normal and abnormal craniofacial embryogenesis is derived from examination of human embryos. Therefore extrapolations from descriptive and experimental studies of a broad spectrum of mammalian and nonmammalian species have been, and continue to be, common. Avian and rodent models have proven to be particularly informative. In this chapter the orofacial morphogenesis of these two species is compared with that of the human being, providing supportive evidence and new clues regarding the developmental basis for a variety of clefts.

Complexity of Human Facial Morphogenesis

The developing face is most commonly described as being composed of tissues associated with the frontonasal prominence and the bilateral first pharyngeal (also known as visceral or branchial) arches. The frontonasal prominence surrounds the forebrain, and from it bilateral medial and lateral nasal prominences (also known as swellings or processes) form. The forehead, nose, philtral component of the upper lip, a portion of the upper alveolar ridge, and the primary palate develop from these portions of the embryo. The remainder of the face typically is described as arising from the first pharyngeal arches, each of which is composed of a maxillary prominence that forms the upper jaw and a mandibular prominence from which the lower jaw is derived. As illustrated and discussed in this chapter, this rather simplistic description of embryonic facial morphology is not complete and offers an inadequate framework on which to interpret clinical findings and new developmental investigations.

Although typically oversimplified when referenced in texts, a key embryology resource regarding human facial embryogenesis is a 1948 publication by G.L. Streeter.[12] Selected images from this source are reproduced in Figure 27-1. These drawings, created by J.F. Didusch from reconstructions of histologic sections, show human embryos ranging from 32 to 44 days after conception. Streeter described the developing face as being composed of a number of facial swellings (prominences) that reflect centers of growth. As shown in Figure 27-1, *A,* the primordia of the maxilla



• **Figure 27-1** Drawings made by J.F. Didusch of human Carnegie stages (Streeter's horizon) 14 (32 days; **A**), 16 (37 to 40 days; **B** and **C**), 17 (41 to 43 days; **D** and **E**), and 18 (44 to 46 days; **F**) from reconstructions of the face. *ANTITR.,* Antitragus; *HYOID BAR,* pharyngeal arch II; *MAX.,* maxillary growth center; *MAX'*, supplementary maxillary growth center; *MED. NASAL RIM,* medial nasal prominence (MNP); *NASOMAX. GROOVE,* nasomaxillary groove; *NASAL WING,* lateral nasal prominence (LNP); *OLF. PIT,* olfactory pit; *PREMAX,* premaxillary center (globular process of His). (Reprinted from Streeter GL: Developmental horizons in human embryos: age groups XV, XVI, XVII and XVIII, being the third issue of a survey of the Carnegie Collection, *Contrib Embryol Carnegie Inst Wash* 32:133-203, 1948.)

and lower jaw are apparent as separate swellings prior to the appearance of the frontonasal prominence–associated swellings that will surround the olfactory pits. Regarding the tissue from which the lower jaw forms, Streeter noted that in addition to a median groove, lateral and transverse grooves are present, indicating multiple growth centers for this region of the developing face. In addition to forming the lower jaw, tissues of the lateral and caudal surfaces of the mandibular bar (i.e., first pharyngeal arch) were noted to contribute to the formation of the external ear, in particular the tragus and crus. From the hyoid bar (i.e., the second pharyngeal arch), the helix and antitragus of the ear form (see Figure 27-1, *B* to *F*).

Streeter's description of the growth centers that form the upper jaw include bilateral maxillary centers with a "characteristic subdivision" that he labeled MAX′ (see Figure

27-1, *C* to *F*). Each of the MAX′ subdivisions is more rostrally positioned than the associated main maxillary centers (MAX) and are located adjacent to the developing frontonasal prominence. As the tissues of the frontonasal prominence develop, bilateral olfactory pits become apparent when growth centers termed the nasal wings (lateral nasal prominences [LNPs]) develop to form their dorsolateral boundaries, and medial nasal prominences (MNPs) arise at their medial rims. Growth centers located at the oral cavity (ventral) end of each medial nasal rim, but that are discrete from the nasal rim, are destined to form the premaxilla. Streeter noted that these growth centers could be termed the intermaxillary or incisive centers. They also are known as the globular processes of His. Most textbook descriptions currently do not distinguish the premaxillary (PREMAX) centers from the MNPs. Bilateral closure of the upper lip involves contact of the PREMAX with the MAX′ center and the ventral aspect of the LNP (LNP′) on each side of the developing face. Lip closure normally occurs during the sixth week of human gestation, when the embryo appears as shown in Figures 27-1, *D* and *E.*

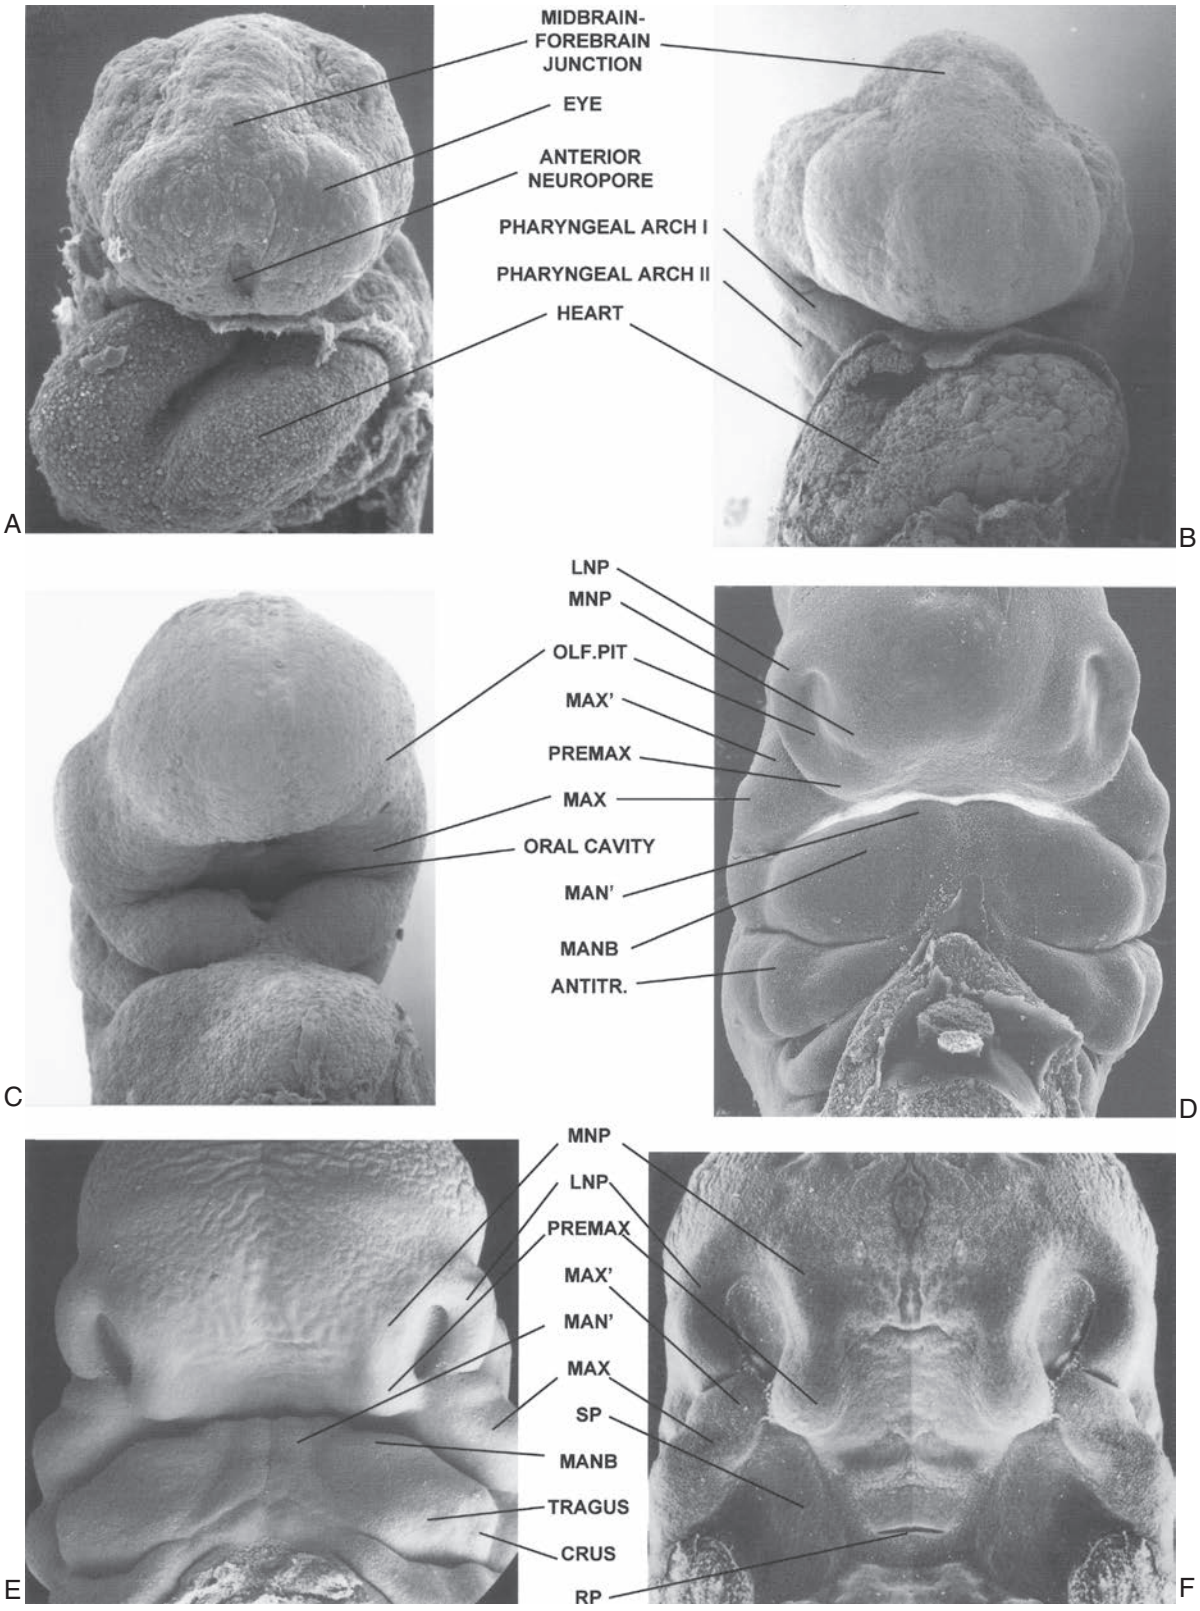
Streeter's work was extended in 1985 by Hinrichsen[13] in a detailed report heavily based on scanning electron micrographs illustrating human facial morphogenesis. Figures 27-2 and 27-3 include four images from Hinrichsen's work, with the remainder prepared by this chapter's author as part of the Necker collection (Necker Children's Hospital, Paris, France; see also https://embryology.med.unsw.edu.au/embryology/index.php/Scanning_Electron_Microscopy). These scanning electron microscopic images of human embryos complement those of Didusch's drawings, revealing a more complex array of facial growth centers than commonly recognized.

Micrographs in Figure 27-2 show frontal views of the faces of Carnegie stage 11 (see Figure 27-2, *A*), 12 (see Figure 27-2, *B* and *C*), 16 (see Figure 27-2, *D* and *E*), 17 (see Figure 27-2, *F* and *G*), and 18 embryos (see Figure 27-2, *H* and *I*): stages present at 24 to 25, 26 to 27, 37 to 40, 41 to 43, and 44 to 46 days after fertilization, respectively. An image of a 9-week-old fetus also is shown (see Figure 27-2, *J*). At the earliest stage shown, the anterior neuropore is completing its closure, a process that results in separation of the forebrain neuroepithelium from the surface epithelium of the frontonasal prominence (see Figure 27-2, *A*). The developing eyes, which are evaginations from the forebrain, are seen at this time as bulges raised on each side of the developing upper midface. By 26 days, the site of the anterior neuropore is no longer apparent (see Figure 27-2, *B*). Over the course of the next few days, the bilateral sites of the olfactory pits, around which the nose forms, become notable (see Figure 27-2, *C*; also see Figure 27-1, *A*). As shown in Figure 27-2, *C,* the first pharyngeal arches, from which the lower jaw develops, initially have a deep median groove between them. By the time the embryo enters its sixth week of development, although a median groove is still present, the tissue bridge connecting the bilateral first arches is much wider (see Figure 27-2, *D*).

As also shown in Streeter's work, in the developing lower jaw a shallow furrow separates the bulk of the first arch tissue from what appears to be a supplementary mandibular growth center that is the progenitor of the mentum. In this chapter, this tissue is termed MAN′. Another first arch growth center that can be identified at this time appears to correspond to the region of the future body of the mandible (MANB). Between 37 and 40 days of development, the first arch–derived external ear growth centers (auricular hillocks) become evident (see Figure 27-2, *D* and *E*). Confirming Streeter's findings, an obvious supplementary maxillary growth center (MAX′, see Figure 27-2, *D* and *F*) adjacent to the most ventral portion of the LNP (LNP′), as well as distinct MNP and PREMAX centers, also are present at this stage of development. On the side of MAX′ opposite LNP′ is the bulk of the MAX. Removal of the lower jaw, as has been done in the embryo shown in Figure 27-2, *F*, shows that a major portion of MAX extends into the oral cavity, forming the secondary palatal (SP) shelves. This view also allows visualization of Rathke's pouch (RP), the progenitor of the anterior pituitary gland.

By the end of the sixth week, the lip should be closed bilaterally while a median groove between the PREMAX centers remains (see Figure 27-2, *G*). Also by this time the six auricular hillocks from which both of the external ears form can all be seen. They comprise a large portion of the first and second pharyngeal arch tissue. Other prominent first arch components are MAN′ and the MANB. These mandibular subsegments also are apparent early in the seventh week of human gestation (see Figure 27-2, *H*). At this time the PREMAX centers have merged in the midline. While the contour of the upper lip thus becomes smoother, at this stage in development the bilateral sites of union between the MAX′ and PREMAX remain apparent (see Figure 27-2, *I*). By the beginning of the fetal period, epithelial plugs fill the nostrils, and the forming vermillion border of the upper lip is notable (see Figure 27-2, *J*). In addition, the hard palate is closed as a result of the union of the SP shelves with each other as well as with the PREMAX-derived primary palate (PP).

Scanning electron micrographs of the lateral aspects of the head and neck of a series of human embryos ranging from 24 to 53 days of gestation are shown in Figure 27-3. From days 24 to 25 of development, the cranial end of the human neural tube completes its closure. This is evident in the three Carnegie stage 11 embryos shown in Figure 27-3, *A* to *C.* The embryo in Figure 27-3, *A,* still has a widely open forebrain; the rim of the forebrain of the embryo in Figure 27-3, *B,* has curved medially; and only a small anterior neuropore remains in the embryo shown in Figure 27-3, *C.* As previously noted, the frontonasal prominence is that part of the developing face associated with (surrounding) the forebrain. Just caudal to the forebrain/frontonasal prominence region in all the Carnegie stage 11 embryos is a distinct maxillary growth center. And caudal to the developing maxillary region of the developing face is the first pharyngeal arch. As shown in Figure 27-3, *D* to *G,* during the



• **Figure 27-2** Scanning electron micrographs of faces of human embryos at Carnegie stages 11 (24 to 25 days; **A**), 12 (26 to 27 days; **B** and **C**), 16 (37 to 40 days; **D** and **E**), 17 (41 to 43 days; **F** and **G**), and 18 (44 to 46 days; **H** and **I**) as well as an early fetus (9 weeks; **J**). *ANTITR.,* Antitragus; *LNP,* lateral nasal prominence; *MAN′*, supplementary mandibular growth center; *MANB,* mandibular body; *MAX,* maxillary prominence (growth center); *MAX′*, supplementary maxillary growth center; *MNP,* medial nasal prominence; *OLF. • **Figure 27-2, cont'd**

fifth week of development the first pharyngeal arch has a proximal and distal segment. The distal segment of the first pharyngeal arch appears to correspond to the lower jaw as well as the tragus and crus of the external ear, whereas the proximal segment contributes to the anterior aspect of the helix of the external ear as well as the zygomaticotemporal (ZT) portion of the face (see Figure 27-3, *I*).

Between 28 and 32 days of gestation (Carnegie stages 13 and 14; see Figure 27-3, *E* and *F*), bilateral olfactory placodes become evident features of the frontonasal prominence as the LNPs and MNPs begin to form. Just posterior to the LNP, the lens pit can be seen. In addition, the trigeminal ganglion creates a bulge located proximal to the first arch and the MAX. As previously noted—and as shown at low and high magnification in Figure 27-3, *G*, 27-3, *H* respectively—by stage 16 (37 to 40 days) MAX′ is evident as a maxillary prominence subsegment. Also at this stage the LNP has two distinct growth centers, one of which (LNP′) is more ventral and abuts the upper portion of MAX′. The PREMAX center abuts the lower portion of MAX′. As development progresses through the sixth week (see Figure 27-3, *I* and *J*) and as discussed by Hinrichsen,[13] MAX′, LNP′, and PREMAX unite bilaterally to close the upper lip. Figures 27-3, *I* and *J* also illustrate the first pharyngeal arch growth centers evident in the sixth week. These appear to correspond to the region of the mentum (MAN′); MANB and ramus (MANR); the ZT; and the segments of the external ear that include the tragus, crus, and the anterior segment of the helix. The three auricular hillocks of the second pharyngeal arches also can be seen. The most ventral of these forms the antitragus, whereas the others contribute to the helix. As the embryonic period ends, the contours of the face become relatively smoother as the numerous distinct facial growth centers become much less obvious (see Figure 27-3, *K*).

With the lower jaw of late embryonic and early fetal period fetuses removed, the roof of the oronasal cavity and the forming palate are readily observed (Figure 27-4). At the end of the embryonic period the oronasal cavity roof is characterized by a posteriorly positioned remnant of Rathke's pouch (see Figure 27-4, *A* and *B*) and a more anteriorly positioned nasal septum (NS), lateral to which the posterior openings to the nasal cavity are located. Anterior to the NS are the PREMAX centers. In addition to contributing tissue to the philtral region of the upper lip, they form part of the upper alveolar ridge and the PP. The remainder of the palate, the SP shelves, including the soft palate, is derived from the

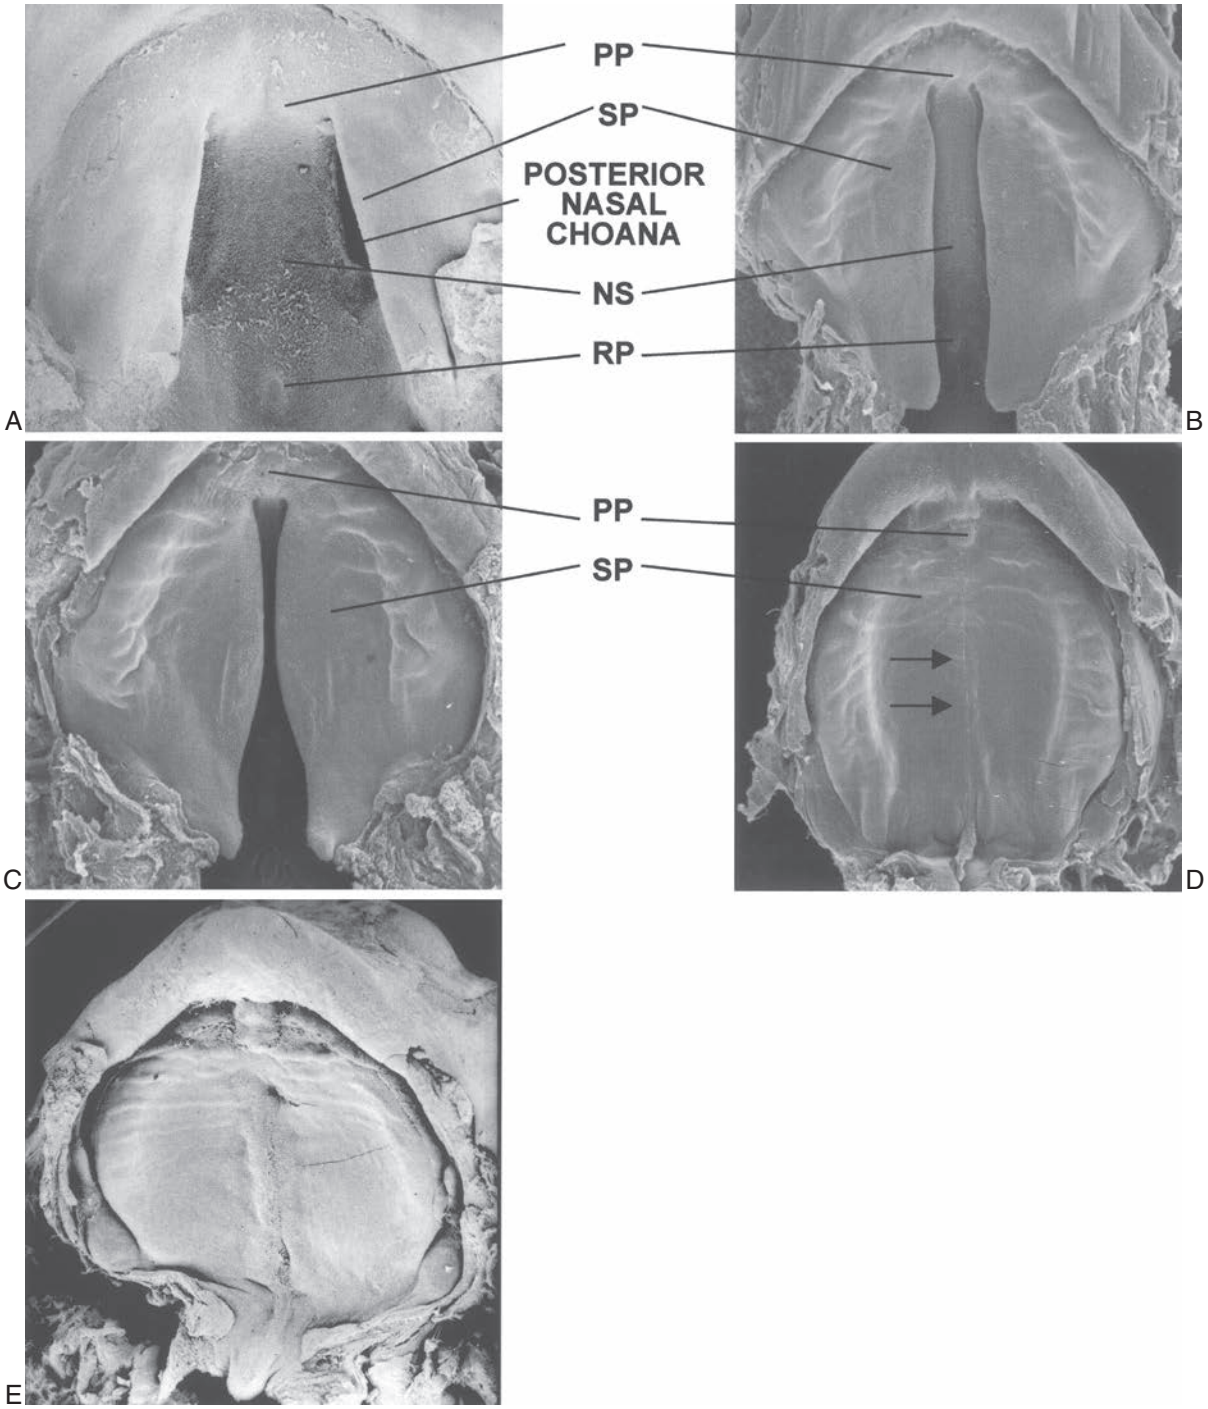
• **Figure 27-3, cont'd**

maxillary prominences, including an anterior contribution that appears to be from MAX′. Both MAX and MAX′ also contribute to the upper alveolar ridge. As the fetal period begins, the SP shelves become approximated in the midline (see Figure 27-4, *C*). Fusion proceeds both anteriorly (rostrally) and posteriorly, with closure being complete in the ninth week (see Figure 27-4, *D*). Union of the SP with the PP and NS also occurs early in the fetal period.

Insights from Studies of Facial Morphogenesis in Chicks and Mice

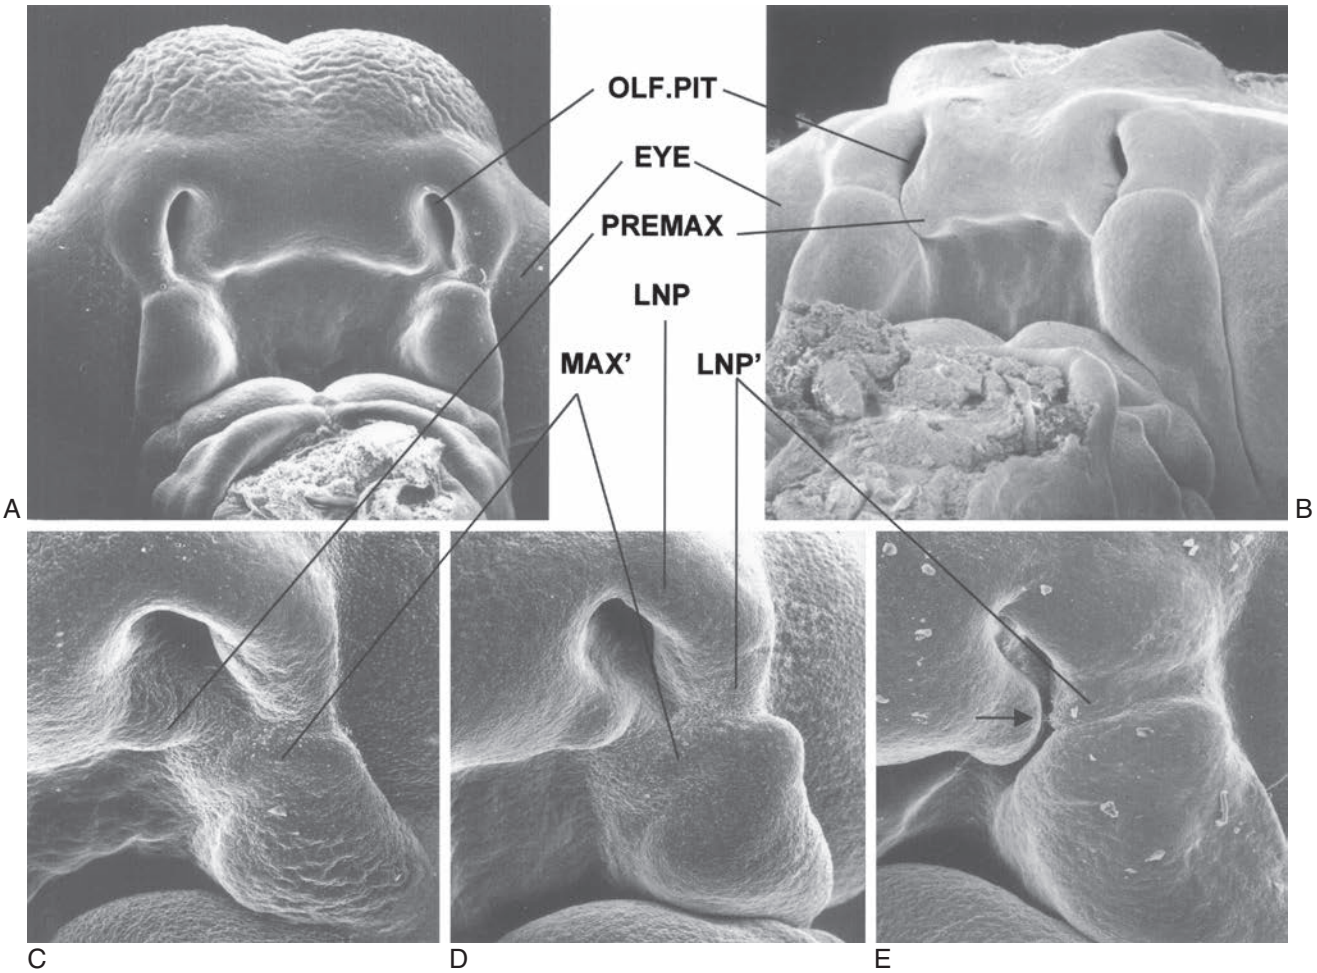
Results of more recent studies involving scanning electron microscopy, cell fate mapping, and analyses of gene expression patterns in model systems have provided additional insights regarding the complexities of normal and abnormal craniofacial embryogenesis.[3,4,10,14-16] In some cases



• **Figure 27-4** Scanning electron micrographs of the roof of the oral cavity illustrate the human hard and soft palate at late embryonic (stage 23, approximately 55 days; **A**) and early fetal periods (week 9, **B** to **D**; week 10, **E**). *NS,* Nasal septum; *SP,* secondary palate; *PP,* primary palate; *RP,* site of Rathke's pouch. *Arrows* indicate fusion seam.

the new findings are contrary to commonly held views. Excellent examples include experimental results regarding the genesis of the maxillary prominences. The maxillary prominences are classically considered to be the dorsal part of the first pharyngeal arch. However, dye-based fate mapping studies in chicken embryos have shown that this is not accurate.[17] Consistent with the morphologic features as described for human embryos, a major portion of each maxillary prominence has been shown to be a separate structure that arises cranial (rostral) to the first pharyngeal arch. In addition, different molecular codes have been identified for the cranial (rostral) versus the caudal aspects of the maxillary prominences, that is, portions of the developing upper jaw that appear to correspond to MAX′ versus MAX and/or POSTMAX. More specifically, in the chick, when the maxillary prominence begins to form during Hamburger and Hamilton (HH) stage 18 to the time that the embryos reach HH stage 24 (when development corresponds to approximately 30 to 40 days in the human being), retinoic acid receptor β is restricted to the cranial (rostral) aspect of the maxillary prominences. These cranial cells give rise to more distal parts of the upper beak, and the caudal cells of the maxillary prominences form more proximal facial structures. As shown in Figure 27-5, between HH stages 24 and 26, when development corresponds to 37 to 43 days in the human being, the chick maxillary prominences have morphologically distinct portions that appear to correspond to MAX′, MAX, and POSTMAX in the human being. The MNPs and LNPs also each have morphologically distinct growth centers (MNP and PREMAX, and LNP and LNP′, respectively). As clearly shown in Figure 27-5, *E,* in the chick normal lip closure begins with fusion between LNP′ and the PREMAX segment. Later, the PREMAX segment also joins MAX′.

Like avian embryos, the mouse has proven to be an excellent experimental model for embryogenesis studies. The usefulness of the chick is largely attributable to its accessibility for grafting and labeling experiments, whereas for mice the extensive genetic information and tools now available for modifying and identifying sites of gene expression have been invaluable. A factor that somewhat diminishes the usefulness of the mouse as a model for the



• **Figure 27-5** Scanning electron micrographs of 4½- to 5-day-old chick embryos at HH stages 24 (**A**, **C** to **E**) to 26 **(B).** *LNP,* Lateral nasal prominence; *LNP′*, supplementary lateral nasal prominence growth center; *MAX′*, supplementary maxillary growth center; *MNP,* medial nasal prominence; *OLF. PIT,* olfactory pit; *PREMAX.,* premaxillary center.

study of normal and abnormal orofacial embryogenesis, however, is that in this species the various growth centers and contours of the developing face are not as readily defined morphologically as in the human and chick. For example, at the time of neural tube closure in the mouse, a distinct maxillary growth center is not observed (Figure 27-6, *A* and *B*), whereas it is in the human (see Figure 27-3, *C* and *D*). And although a hint of distinction is seen between the MAX′ and MAX (see Figure 27-6, *D* and *E*), this is not as clear as in the human and chick. This also

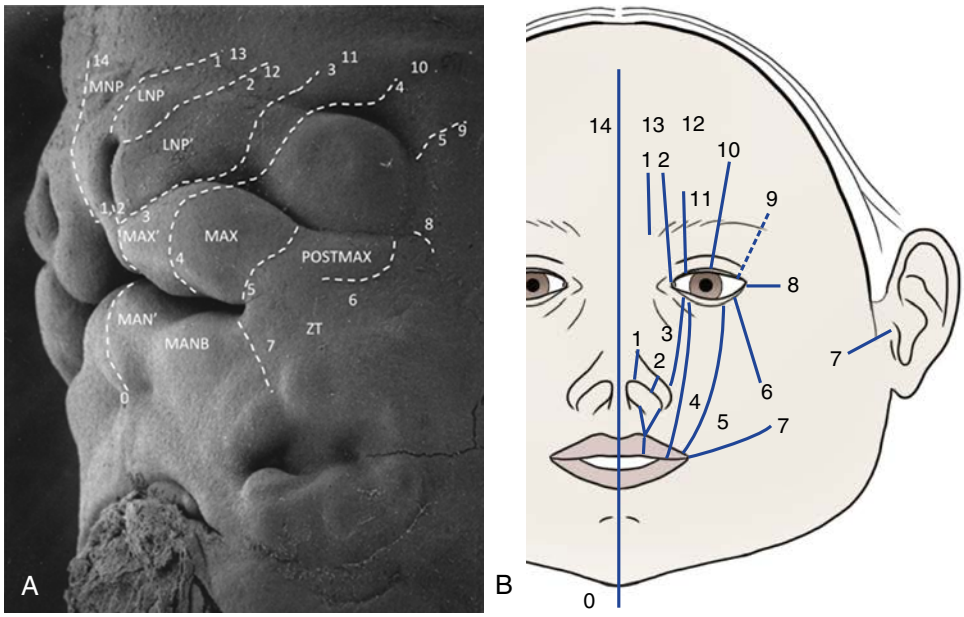
is true for the distinction between the mouse MNP and PREMAX, LNP and LNP′, and the various subcomponents of the first pharyngeal arch. As in the human and chick, lip closure entails union between the PREMAX segment, LNP′, and MAX′ (see Figure 27-6, *G* and *I*). Also as in the human, the NS, with which the secondary palatal shelves fuse to separate the oral and nasal cavities, extends posteriorly only as far as the posterior extent of the choanae (compare Figures 27-4, *I* and 27-6, *I* and *J*). Also notable is that the NS is composed of bilateral growth centers. As in the human, union of the SP shelves occurs after that of the segments of the lip and requires elevation of the palatal shelves to a position above the tongue (see Figure 27-6, *K* and *L*).

Orofacial Clefting Sites

Knowledge of the various facial growth centers is key to understanding the basis for the sites of both commonly occurring and unusual facial clefts. Figure 27-7 illustrates the apparent relation between the facial growth centers of a 6-week human embryo and the craniofacial clefting scheme developed by Tessier.[1]

Notable in the Tessier classification scheme is that the midline has two different cleft numbers: 14, which extends through the forehead and 0, which is at the level of the mid-face and mandible. Cleft 0, which designates median facial clefts, is unique in that it represents two quite different phenomena. One involves a median split between



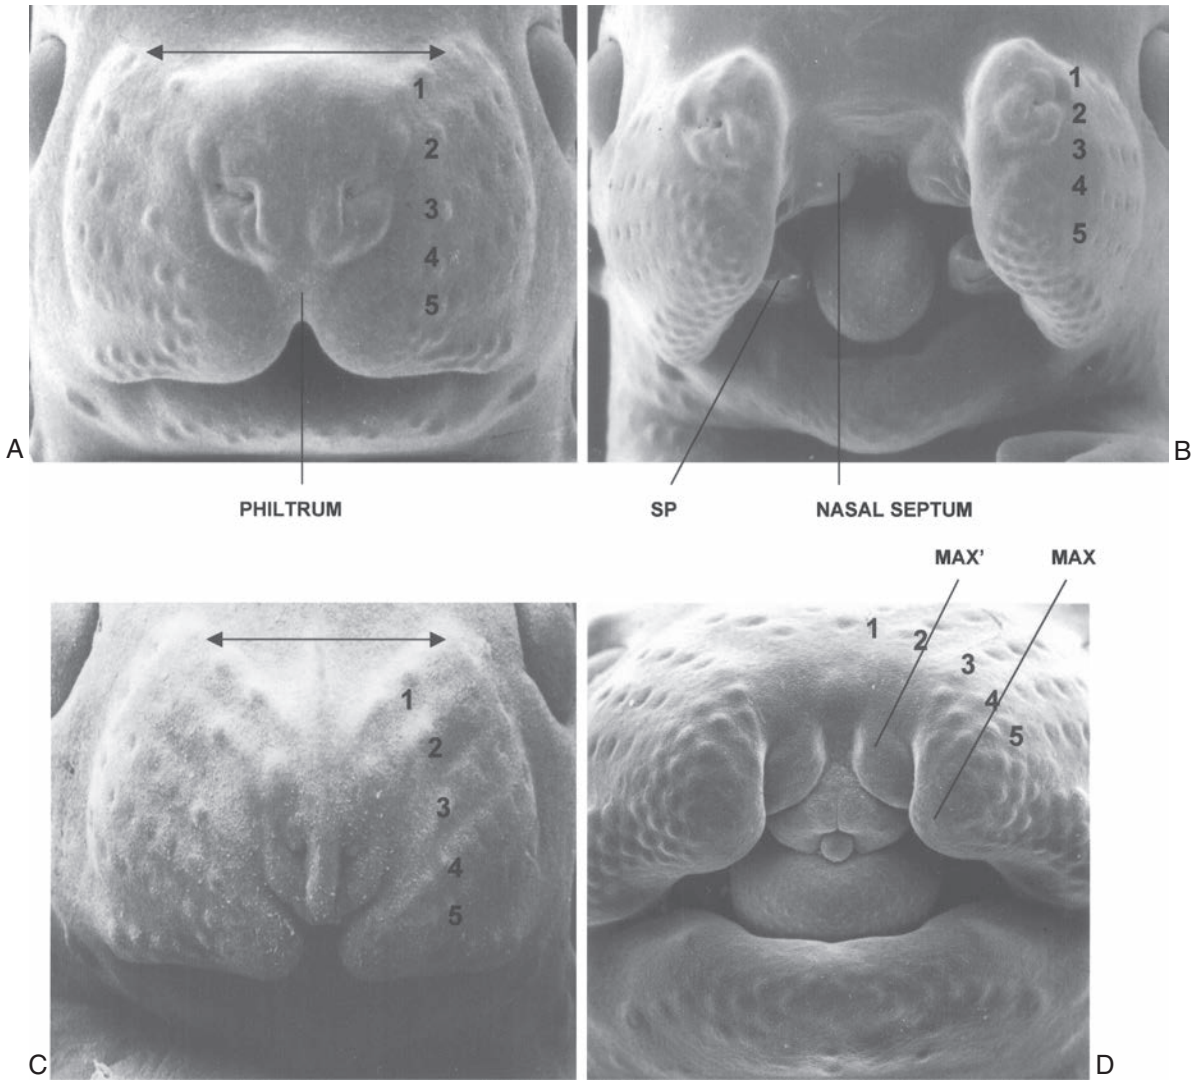
• **Figure 27-7** Furrows between facial growth centers, most of which remain visible in the 7 week old human embryo shown in (**A**) are correlated to the position of Tessier's numbered facial clefts (**B**). (Reprinted from Tessier P: Anatomical classification facial, cranio-facial and latero-facial clefts, *J Maxillofac Surg* 4:69-92, 1976.)

the bilateral MNP and PREMAX centers as well as the NS and typically is accompanied by hypertelorism. As in the mouse fetus that has this type of defect (Figure 27-8, *B*), although a wide midline cleft is present, all the elements of the nose and upper lip are present and are proportionally normal.

The other type of median midfacial cleft involves hypotelorism with a spectrum of reductions in the tissues of the nose and PREMAX region. This is the spectrum of holoprosencephaly.[18] At the mild end of the spectrum is reduced size of the PREMAX centers and the MNPs. This is exemplified by a mouse fetus shown in Figure 27-8, *C*, that has too little tissue between the two nostrils and has a single, merged MNP. The median tissue loss is noted by the abnormally close proximity of the whisker follicles of the maxillary prominences. In addition, the PREMAX centers are absent in this fetus so that a central cleft is present between the two maxillary prominences. The cleft does not extend into the nose. A more severe manifestation of central midfacial tissue loss is illustrated in Figure 27-8, *D*. This fetus has no nostrils. All MNP-, PREMAX-, LNP-, and LNP″-derived tissues that should immediately surround the nostrils did not form. This is evidenced by the fact that the whisker follicles of the two maxillary prominences meet in the upper midline of the snout instead of being widely separated. Also illustrated in Figure 27-8, *D*, is that the upper two rows of whisker follicles are associated with MAX′, whereas the other three rows are MAX associated.

As illustrated in Figure 27-9, new insights regarding nonmedian clefts of the upper lip also are provided by examination of mouse fetuses. Although, as previously noted, the various facial growth centers of mouse embryos before and at the time of normal lip fusion are not readily defined, examination at later stages of individuals that have complete or incomplete clefts of the lip validates their presence. Comparison of the normal early fetal-stage mouse nose and upper lip with those with clefts of the lip confirms the following: (1) MAX′ and LNP′ are distinct entities that normally fuse with the PREMAX center (see Figure 27-9, *C*); (2) MAX′ may fuse with the PREMAX center even though LNP′ does not (see Figure 27-9, *B, left*); and (3) normal lip formation entails overlap of the lateral aspects of the PREMAX centers and the ventral portion of MAX′ by MAX (see area of normal PREMAX overlap indicated by *dashed lines* in Figure 27-9, *C*).

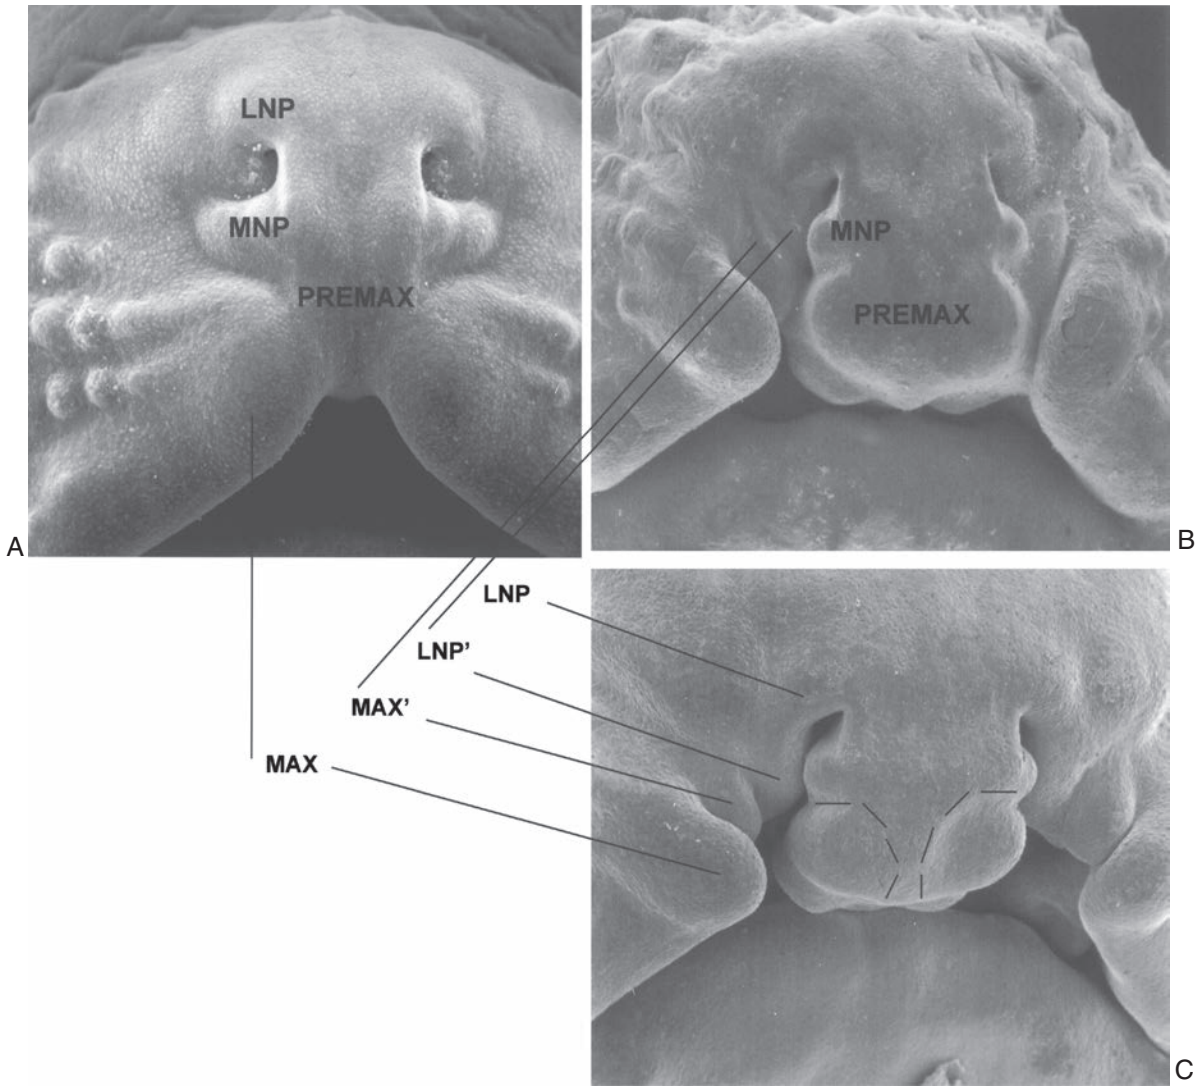
Tessier's type 1 cleft includes a cleft of the lip in the region of the philtral ridge along with a cleft through the ala that extends through the dorsum of the nose. This clearly represents failure of union between the medial (the PREMAX and MNP) and lateral (MAX′, LNP, and LNP′) components of the upper midface. The defect in the lip that occurs in type 1 is comparable to that in the type 2 cleft. In the latter, however, although hypoplasia of the ala nasi is present, true notching is not. Type 2 cleft is that typically seen in isolated cleft lip cases, corresponds to the clefts shown in Figure 27-9, *C*, and results from failure of the PREMAX and MNP to unite with LNP′ and MAX′. In both types 1 and 2 the alveolus is involved, with the cleft in the position of the maxillary lateral incisor. While this tooth is commonly entirely missing, when present the primary maxillary lateral incisors are found in three distribution patterns as follows: (1) one lateral incisor located distal to the alveolar cleft, (2) one lateral incisor located mesial to the alveolar



• **Figure 27-8** Comparison of normal **(A)** and abnormal mouse fetuses with type 0 clefts. The fetus in **B** is hyperteloric, whereas those in **C** and **D** are hypoteloric. *MAX,* Maxillary prominence; *MAX′*, supplementary maxillary growth center; *NS,* nasal septum; *SP,* secondary palate. *1* to *5,* Rows of MAX whisker follicles; *double-headed arrow,* separation between the maxillary hair follicles.

cleft, and (3) the presence of two lateral incisors with one tooth on each side of the cleft.[19] In individuals with type 2 clefts, including those with Simonart's bands, one maxillary lateral incisor located distal to the cleft is most common and the least common situation is one maxillary lateral incisor located mesial to the cleft.[20, 21] That a lateral incisor may be found lateral to the cleft has been difficult to reconcile with the generally accepted premise that all of the upper incisors originate in tissues of the PREMAX. This idea has, however, been challenged by Wei et al.,[22] who examined nonhuman primate embryos and suggested that the lateral incisors instead originate within the maxillary prominences and then undergo a medial shift in position, and by Horokova et al.,[19] who, in examining human 6- to 8-week-old embryos, determined that the upper lateral incisor epithelium originates from both maxillary and PREMAX tissues. It is now quite clear that the maxillary component of the upper lateral incisor is a MAX′ derivative.

In type 3 cleft the lip defect is in the region of the typical cleft lip, but the cleft does not extend deep into the tissue. As opposed to types 1 and 2, the alveolar defect is between the lateral incisor and the canine. The type 3 cleft defect appears to involve primarily the union of the lateral incisor–bearing MAX′ with the canine-bearing MAX center. A defect of this type is shown at right in Figure 27-9, *B.* In type 4 cleft, alveolar involvement also is between the lateral incisor and the canine, but the accompanying cleft in the lip is located between the philtral ridge and the commissure of the mouth rather than at the position of the philtral ridge. A defect of the type shown at left in Figure 27-9, *B*, is expected to result in a type 4 cleft. It represents a wide separation between the MAX′ and MAX centers. The presumed MAX deficiency that underlies the type 4 defect would be expected to result in reduced size of the secondary palatal shelves and subsequently a cleft of the secondary palate. Cleft palate is, indeed, a type 4 component.



• **Figure 27-9** Scanning electron micrographs of the nose and upper lip of mouse fetuses at gestational day 13 to 14. Normal morphology is shown in **(A);** a type 3 cleft is shown on the right and a type 4 cleft is shown on the left in **(B);** bilateral complete type 2 clefts are shown in **(C).** *LNP,* Lateral nasal prominence; *LNP′*, supplementary lateral nasal prominence growth center; *MAX,* maxillary prominence; *MAX′*, supplementary maxillary growth center; *MNP,* medial nasal prominence; *PREMAX.,* premaxillary center. *Dashed lines,* Area of MAX overlap.

The position of the type 5 cleft, which extends as a furrow between the corner of the mouth and the junction of the middle and lateral third of the lower eyelid, is readily delineated in the 6-week-old human fetus. This furrow separates the MAX from the POSTMAX of the embryonic face. A deficiency involving the POSTMAX and/or ZT growth center would presumably yield a type 6 cleft, which is similar to that typically found in Treacher Collins syndrome.

The type 7 cleft, which extends from the corner of the mouth to the ear, presents with abnormalities of the mandibular ramus, coronoid, and condyle along with absence of the zygomatic arch. This cleft is at a position that corresponds to that of an obvious furrow present between the proximal and distal portions of the first pharyngeal arch of Carnegie stage 16 human embryos (see Figure 27-3, *G*).

The proximal border of the first arch appears to correspond to the position of the type 8 cleft. This cleft involves the lateral bony wall of the orbit and is considered to be the first of the "northbound" clefts. As illustrated in Figure 27-7, that the remainder of the northbound clefts have southbound counterparts strongly supports a segmental origin for the upper facial structures. More specifically, the mesenchymal cells comprising the MNP, LNP, LNP', MAX', and MAX facial growth centers likely originate at early developmental stages from the dorsal midline as discrete (neural crest cell) populations that are arranged in rostro-caudal segments. Intervals between these segments appear to correspond to the clefting sites described by Tessier.

Summary

Along with reference to the early literature, appreciation of the complexity of facial morphogenesis has been facilitated by the availability of a developmental series of scanning electron micrographs of human embryos as well as commonly used experimental animals. Examination of human, mouse, and chick embryos has allowed recognition of the existence of comparable facial growth centers across these three species. In some cases the overt appearance of a particular center in one species has allowed recognition of its more subtle counterpart in another. A clear example of this is the MAX′ segment, which had been noted in human embryos by Streeter in histologic reconstructions and is obvious in scanning electron micrographs in both human and chick embryos but is not that obvious in mice. Consideration of this growth center as a distinct entity of the developing face has provided a developmental context for understanding the genesis of a variety of clefts of the lip. This, along with awareness of the form and location of the numerous other growth centers of the developing face, provides a developmentally based rationale for Tessier's classification scheme.

Acknowledgments

Thank you to Dr. Timothy A. Turvey for his critical reading of this chapter and The National Institute on Alcohol Abuse and Alcoholism for its generous grant support.

Comprehensive Management of Facial Clefts

BERNARD J. COSTELLO, RAMON L. RUIZ

The comprehensive treatment of cleft lip and palate deformities requires thoughtful consideration of the anatomic complexities of the deformity and the delicate balance between intervention and growth. Comprehensive and coordinated care from infancy through adolescence is essential to achieve the best outcome, and surgeons with formal training and experience in all the phases of care must be actively involved in the planning and treatment.[1-3] Specific goals of surgical care for children born with cleft lip and palate include:

- Normalized esthetic appearance of the lip and nose
- Intact primary and secondary palate
- Normal speech, language, and hearing
- Nasal airway patency
- Class I occlusion with normal masticatory function
- Good dental and periodontal health
- Optimized psychosocial development

Successful management of the child born with a cleft lip and palate requires coordinated care provided by a number of different specialties, including oral and maxillofacial surgery, otolaryngology, plastic surgery, genetics and dysmorphology, speech-language pathology, orthodontics, pediatric dentistry, and prosthodontics.[4] In most cases care of patients with congenital clefts has become a subspecialty area of clinical practice within these different professions. In addition to the primary cleft repairs in infancy, treatment plans routinely involve multiple treatment interventions to achieve the above goals staged throughout childhood. Because care is provided over the entire course of the child's development, coordinated and long-term follow-up is essential under the care of these different health care providers.

The formation of interdisciplinary cleft palate teams has served two key objectives of successful cleft care: (1) coordinated care provided by all the necessary disciplines, and (2) continuity of care with close-interval follow-up of the patient throughout periods of active growth and ongoing stages of reconstruction. The best outcomes are achieved when the team's care is centered on the patient, family, and community rather than a particular surgeon, specialty, or hospital. The idea of having an objective team that does not revolve around the desires of one particular individual or discipline is sometimes impeded by competitive interactions between surgical specialties. Historic battles over surgical domains between surgical specialties and economic factors contribute to these conflicts and negatively affect the work of the team. Healthy team dynamics and optimal patient care are achieved when all members are active participants, when team protocols and referral patterns are equitable, and when the needs of the child are placed above the needs of the team or individual members. Treatment should be based on the surgeon's formal training and experience instead of specialty identity.

The surgical reconstruction of clefts requires that the surgeon undertaking this important work maintain a contemporary cognitive understanding of the complex malformation itself, the varied operative techniques used, facial growth considerations, and the psychosocial health of the patient and family. This chapter presents the overall staged reconstructive approach for repair of cleft lip and palate from infancy through the time of skeletal maturity as well as a discussion of the surgical procedures involved in primary cleft lip and palate repair. Controversies in cleft repair, secondary revision procedures, bone graft reconstruction of the cleft maxilla, and orthognathic surgery for cleft-related dysmorphology are discussed in later chapters of this text.

History of Cleft Lip and Palate Repair

The history of cleft lip and palate care has always been closely linked to dentistry and oral and maxillofacial surgery. The birth of what is now the American Cleft Palate-Craniofacial Association is strongly rooted in dentistry, and its further

development has always had various aspects of the dental profession at its heart.

The first documented cleft lip repair was performed in 390 AD on a patient who later became the governor general of several regions in China, although nothing is known about the actual surgeon.[5,6] Jehan Yperman is believed to have been the first to describe unilateral and bilateral cleft lip repair.[6,7] The first diagrammatic representation of cleft lip repair and cleft palate obturator use is credited to Ambrose Pare in the fourteenth century.[6,8] Much later, the first documented successful cleft palate repair was performed by a dentist, Le Monnier, in 1766 in Paris.[6,9] The concepts of cleft lip and palate repair have evolved from straight-line repairs to a variety of techniques using various cutbacks, triangles, and Z-plasties.[6-14] During the 1950s Asensio, an oral and maxillofacial surgeon from Guatemala, developed a novel technique for cleft lip repair that involved the rotation of the philtral segment inferiorly and advancement of the lateral segment medially with a quadrangular flap. Although he used this approach in Guatemala throughout the 1950s, he did not report it until later.[15,16] Ralph Millard described his classic rotational advancement technique in the mid-1950s, and his concepts changed cleft repair forever.[17,18] Millard is credited with perhaps the most important technical development related to cleft lip repair, and today the majority of surgeons use his original technique or some close modification of it.

In the mid-nineteenth century, Hullihen,[19] recognized as the father of American oral and maxillofacial surgery, published a treatise on comprehensive care of cleft lip and palate deformities. Another pioneer, Truman Brophy, was the professor of oral surgery and dean of the Chicago College of Dentistry and contributed greatly to the care of many patients with clefts. Brophy[20] published a text detailing his experiences with the management of various malformations of the mouth and their surgical repairs, including the details of cleft repair. One of his pupils was Chalmers Lyons, who started a residency program in oral surgery at the University of Michigan in 1917.[20] Lyons developed the largest cleft practice in America and contributed extensively to the literature.[20]

Many of the concepts related to interdisciplinary care with a cleft plate team were introduced by Robert Ivy, an oral and maxillofacial surgeon who later became dually qualified in plastic surgery.[20] Ivy trained in both dentistry and medicine at the University of Pennsylvania. After his training in dentistry, Ivy further developed his interests in maxillofacial surgery as an assistant to his uncle, Matthew Cryer, who was a professor in oral surgery at the University of Pennsylvania. Robert Ivy became interested in clefts during his training as the first dental intern at Philadelphia General Hospital. His interests in maxillofacial injury led him to serve in France in World War I as an assistant to Vilray Blair. After the war, Ivy and Blair's collaboration resulted in two landmark publications by Ivy, *Essentials of Oral Surgery* and *Fractures of the Jaws*. Through work with his state representatives in Harrisburg, Pennsylvania, he was able to start the first cleft palate clinics in Lancaster, Pittsburgh, Philadelphia, Erie, and Scranton, which provided interdisciplinary care to children in those regions for cleft lip and palate deformities. When Reed Dingman put forth a resolution of the American Society of Maxillofacial Surgeons condemning oral and maxillofacial surgeons practicing in the hospital setting, Ivy resigned his membership and sent a letter of protest in support of his dental colleagues to the organization that he helped build.[20]

In the 1950s the concept of primary or early bone grafting of the cleft maxillary defect was introduced by Schmid.[21] Although the concept initially was met with enthusiasm from a number of surgeons, primary bone grafting eventually was abandoned because of unfavorable outcomes. During the decades that followed, the negative skeletal, dental, and growth-related consequences of primary bone grafting became better understood.[22,23] During the early 1970s an oral and maxillofacial surgeon, Phillip Boyne, was the first to publish his favorable outcomes using autogenous particulate bone grafts for reconstruction of the cleft maxilla/alveolus later in childhood during the mixed dentition rather than earlier in life.[24] Although Boyne's work and results represented a landmark discovery in the field of cleft reconstruction, cleft palate teams were slow to integrate his approach into their treatment protocols because of the negative associations that lingered after the days of primary bone grafting. Today Boyne's principles of secondary bone grafting represent the standard approach for most of the world's cleft centers.[24,25]

Orthognathic reconstruction of the patient with cleft deformities has been discussed by many authors.[26-36] Early techniques limited some surgeons' options to procedures centered on mandibular setback.[37] During the 1970s, the use of total maxillary osteotomy was pioneered by Bell.[38] His novel ideas provided oral and maxillofacial surgeons with an understanding of the biologic basis for maxillary osteotomy, described the vascular supply that allowed the procedures to be safely performed and, as a result, incorporated the Le Fort I osteotomy into modern practice.[38] Since that time a number of technical refinements have been described for use of the Le Fort I osteotomy specifically in the cleft patient. Much of this work has been done by two of Bell's former pupils, Fonseca and Turvey,[39] who went on to make substantial contributions to the skeletal reconstruction of patients with clefts. Another dually qualified oral and maxillofacial surgeon, Posnick, has published the most complete descriptions of surgical technique modifications for patients undergoing mid-facial advancement in the absence of prior bone graft reconstruction and his extensive experiences with the long-term stability of mid-facial advancement after correction of various types of cleft deformities with orthognathic techniques.[26-30] Distraction osteogenesis has gained recent popularity for correction of mid-facial hypoplasia but has yet to show significant advantages over traditional techniques for the majority of patients.[32,33,40-42] Jeffrey Posnick's influence during this time was magnified substantially by training a number of fellows in the United

States to comprehensively treat cleft and craniofacial dysmorphology, develop these techniques, and teach them at major academic centers in North America. Other fellowship programs that have followed his model and mentorship have flourished, developing the subspecialty and making it a key aspect of successful training in oral and maxillofacial surgery programs.

Comprehensive and coordinated care has become more prevalent across the world, involving many different types of specialty care for children with clefts. Evidence-based care is a key aspect of care and a practical reality, with pooled data and continued research worldwide. The days of performing procedures purely based on a particular surgeon's clinical experience are passing. Posnick, Shaw, Long, Lohmander, and others have provided comprehensive, succinct, and evidence-based discussions on the topics of cleft lip and palate reconstruction from infancy through adolescence that are beginning to take hold in the form of treatment protocols.[26] Dentistry and the specialty of oral and maxillofacial surgery have had significant roles in analyzing data and putting forth new standards of care. These efforts as well as craniofacial training programs associated with oral and maxillofacial surgery departments have helped solidify the role of oral and maxillofacial surgery in the comprehensive care of patients with clefts.

Embryology

To understand the goals of lip and palate repair from an anatomic standpoint, the cleft surgeon must have an appreciation for the failure of embryogenesis that results in clefting. Critical points in the development of the fetus occur when the fusion of various prominences creates continuity and form to the lip, nose, and palate. Anomalies occur when the normal developmental process is disturbed between these components. Each prominence is composed of ectomesenchyme derived from neural crest tissue of the mesencephalon and rhombencephalon. Mesoderm also is present within these prominences as mesenchymal tissue. The prescribed destiny of each of these cells and tissues is controlled by various genes to alter the migration, development, and apoptosis and form the normal facial tissues of the fetus. At the molecular level many interdependent factors exist, such as signal transduction, mechanical stress, and growth factor production, that affect the development of these tissues. Currently only portions of this complex interplay of growth, development, and apoptosis are clear.

At approximately 6 weeks of human embryologic development the median nasal prominence fuses with the lateral nasal prominences and maxillary prominences to form the base of the nose, nostrils, and upper lip. The confluence of these anterior components becomes the primary palate. When this mechanism fails, clefts of the lips and/or maxilla occur. At approximately 8 weeks' gestation the palatal shelves elevate and fuse with the septum to form the intact secondary palate. When one palatal shelf fails to fuse with the other components, a unilateral cleft of the secondary palate occurs. If both palatal shelves fail to fuse with each other and the midline septum, a bilateral cleft of the palate occurs.

Fusion occurs when programmed cell death (apoptosis) occurs at the edges of the palatal shelves. The ectodermal component disintegrates and the mesenchyme fuses to form the intact palate. Soon after this the anterior primary palate fuses with the secondary palate and ossification occurs. If failure of fusion occurs with any of the above components at any point, a cleft of the primary and/or secondary palates occurs. Clefts may be complete or incomplete based on the degree of this failure of fusion.

Genetics and Etiology

Clefts of the upper lip and palate are the most common major congenital craniofacial abnormality and are present in approximately 1 in 700 live births.[43] Although inheritance plays a role, cleft lip and palate is not considered a single-gene disease. Instead, clefts are thought to be of a multifactorial etiology with a number of potential contributing factors. These factors may include chemical exposures, radiation, maternal hypoxia, teratogenic drugs, nutritional deficiencies, physical obstruction, and genetic influences. One prevailing theory relates the process of clefting as a point when multiple factors come together to raise the individual above a threshold, at which time the mechanism of fusion fails.[44,45] Multiple genes have been implicated in the etiology of clefting.[46-48] Some of these genes include the *MSX*, *LHX*, *goosecoid*, and *DLX* genes. Additional disturbances in growth factors or their receptors that may be involved in the failure of fusion include fibroblast growth factor, transforming growth factor, platelet-derived growth factor, and epidermal growth factor. Promotor genes that influence this potential are identified and the knowledge base is refined at a pace that is quicker than comprehensive texts can allow. The reader is encouraged to update their understanding with the latest published literature and online resources that provide near real-time reporting of this information.

Clefts of the lip occur more commonly in males than in females.[49] In addition, left-sided cleft lips are more common than right-sided cleft lips, and unilateral cleft lips are more common than bilateral cleft lips.[50] Bilateral clefts of the lip are most often associated with clefting of both the primary and secondary palates. Cleft palate alone is seen in approximately 1 in 2000 live births, an incidence similar in all racial groups.[51] Significant differences in the prevalence of clefts exist when specific ethnic and racial populations are examined. For example, African Americans have a birth prevalence that is less common than the total population, and Asians tend to have a higher prevalence.

In the majority of cases unilateral cleft lip and palate is an isolated nonsyndromic birth defect not associated with any other major anomalies.[43,52,53] By comparison, a much

greater proportion of patients with an isolated cleft palate have an associated syndrome or sequence.[43,53] Some of the more common syndromes seen in this group include Stickler, van der Woude, and DiGeorge syndromes. Early diagnosis is important because functional issues may arise early in life and go unnoticed. For example, patients with an isolated cleft palate should be evaluated early by an experienced pediatric ophthalmologist to evaluate the possibility of Stickler syndrome. Patients with Stickler syndrome may have ocular abnormalities that lead to retinal detachment. In an otherwise healthy-appearing child these findings may be difficult to diagnose, so early visual loss may go unnoticed. In many cases long-term genetic follow-up is necessary to make a definitive diagnosis and provide genetic counseling.

The chances of a recurrence of clefting within a family depend on many factors, including family history, severity, gender, degree of relationship to the affected individual, and the expression of a syndrome. Predicting the inheritance patterns of families with a history of cleft lip and/or palate can be complicated. A skilled geneticist or dysmorphologist is best equipped to make these determinations based on pedigree analysis and genetic testing. Because most clefts are sporadic, the chances of a family having another child with a cleft after having a child with a unilateral cleft lip and palate in which no family history of clefting is present is approximately 2% to 4%. The chances are higher if additional family history is present or if the cleft is bilateral.[54,55] The nature of any genetic influence will have an effect on the presence of a cleft. Such is the case in patients with autosomal-dominant syndromes such as Stickler syndrome, in which 50% of the children may express the syndrome if one of the parents carries the altered gene.

Classification

The typical classification system used clinically to describe standard clefts of the lip and palate is based on careful anatomic description. Clefts can be unilateral or bilateral; microform, incomplete, or complete; and may involve the lip, nose, primary palate, and/or secondary palates (Figure 28-1). The presentation of clefts is extremely variable, and the individual repairs are custom tailored to achieve the best symmetry and balance. More severe facial clefting is most commonly described by using Paul Tessier's orbitocentric system of numbering (Figure 28-2).[56] Other systems are based on embryologic fusion planes, but these are cumbersome to use in routine clinical practice.[57]

Prenatal Counseling

Recent advances in imaging have revolutionized prenatal care and maternal-fetal medicine. Ultrasound images of clefts of the lip currently can be visualized at approximately 16 weeks of gestation.[58-60] Diagnostic images of the palate are more difficult to acquire, making the correct prenatal diagnosis of a cleft palate less predictable. Anterior palatal structures may be visualized by using sagittal and coronal views, but this currently requires the latest technology and a skilled ultrasonographer with experience performing this type of study.

When the diagnosis of cleft lip is made during pregnancy, the family can be referred to an experienced surgeon for a prenatal discussion. A prenatal consultation provides an excellent opportunity to explain the diagnosis, review the different stages of cleft lip and palate reconstruction that may be necessary, and prepare the parents for practical considerations such as feeding a child with a cleft palate. This gives the family the opportunity to ask questions, calm fears, and learn about feeding techniques that will be important during the first week of life for their baby. Parents are empowered with this new knowledge, and the preparations made during a prenatal consultation allow them to anticipate the delivery of their baby with a greater comfort level regarding the necessary care of the infant during the early postnatal period. The family is then referred to a cleft and craniofacial team to begin a more thorough interdisciplinary approach.

Critical to this process is consultation with a geneticist or dysmorphologist to discuss the issues associated with the birth and the possibility of other associated deformities. Additional testing may be warranted to evaluate the possibility of associated deformities, syndromes, or sequences that could affect the birthing process. Exceptionally skilled ultrasonographers can visualize airway development and other abnormalities that may require early intervention with fetal surgery, exit procedures, extracorporeal membrane oxygenation, or surgical airway management (tracheotomy) at the time of delivery. Magnetic resonance imaging often is helpful in determining the more definitive morphology and helping guide the need for intervention early in life.

In some medical centers fetal diagnosis and treatment teams are in place to deal with issues associated with various deformities diagnosed in the prenatal period. These teams foster a cohesive environment in which information is exchanged through consultation. Much like the environment of a cleft and craniofacial team, families can get the best information available to consider their baby's treatment decisions with an interdisciplinary care model that is patient (mother and fetus), family, and community oriented.

Feeding the Child With a Cleft Palate

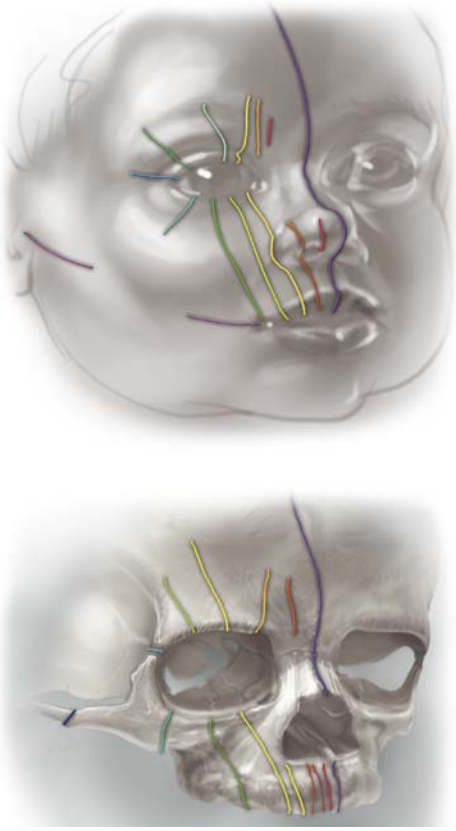
Children born with isolated cleft lip can feed quite well and even have the opportunity to breastfeed in most instances. However, infants with cleft palate can have difficulty feeding because of the inability to form an adequate seal between the tongue and palate to create sufficient negative pressure to suck fluid from a bottle. Nasal regurgitation and inefficient handling of secretions and foods also may

• **Figure 28-1** Cleft lips come in a variety of configurations; each repair must be customized to establish the most normal morphology. **A,** Microform left unilateral cleft lip only, not requiring primary repair. **B,** Minor left incomplete unilateral cleft lip only. **C,** Left incomplete unilateral cleft lip and palate with a Simonarts band. **D,** Wide left complete unilateral cleft lip and palate.

be observed during early development. Specialized nipples and bottles are necessary to improve feeding immediately after birth. The most useful devices combine oversized nipples with reservoir spaces and large openings, a squeezable bottle to push fluid into the nipple assembly, and a one-way valve that allows the bolus of fluid to pass from the bottle to the nipple only to minimize the amount of work the child must perform to feed. These include a variety of nipples with reservoirs that collect a variable volume of liquid that can be expressed more easily when sucking is inefficient or not possible. Bottles that can be squeezed to allow manual flow of liquid to the infant are helpful for improving feeding. No single bottle and nipple combination works better than another; trials with a variety of types using different techniques are helpful to optimize feeding early in life.

Close attention to weight gain is critical for these children. In general, in 24 hours each infant should ingest approximately 2 to 3 ounces of milk for each pound of weight. Feeding sessions should last no longer than 35 minutes because longer sessions are fatiguing and burn more calories than the baby can consume. Infants should be weighed at least weekly on the same scale, preferably at the pediatrician's office.

The subject of breastfeeding an infant with a cleft palate is controversial, with some practitioners encouraging the practice and others strongly opposed to it. Breastfeeding a newborn has clear advantages, including passive



• **Figure 28-2** Complex facial clefts can be classified according to Tessier's original orbitocentric system of numbering. Clefts may involve all tissue planes, including skin, mucosa, bone, teeth, muscle, brain, peripheral nerve, and other specialized tissues.

immunologic contribution of the mother to the child in the form of secretory immunoglobulin A and an experience that enhances bonding between the mother and child during such a critical period.[61,62] At the same time the infant's inability to create negative oral pressure often makes successful nursing difficult, if not impossible. Exclusively breast-fed infants with severe dehydration and failure to thrive are relatively common because of these difficulties. This is especially a concern in infants with a wide cleft of the secondary palate, a condition in which breastfeeding may not be possible. The authors' approach with regard to breastfeeding in the presence of a cleft palate is to use a combined protocol that includes intermittent feeding with the use of a specialized bottle and attempts at nursing. Breast milk may be pumped for use with the specialized nipple and bottle that will provide the nutritional and immunologic benefits desired. This also allows the parents to keep a more quantitative record of how many ounces have been ingested over the course of the day; this normally is difficult with breastfeeding alone. At the same time, the mother and baby are not deprived of an opportunity to incorporate breastfeeding into the daily regimen. This approach obviously requires rigorous documentation of the child's weight, consultation with a lactation consultant and infant feeding specialist, and frequent follow-up evaluations through the surgeon and pediatrician.

TABLE 28-1 Staged Reconstruction of Cleft Lip and Palate Deformities

Procedure	Time Frame
Cleft lip repair	After 10 weeks
Cleft palate repair	Age 9-18 months
Pharyngeal flap or pharyngoplasty	Age 3-5 years or later based on speech development
Maxillary/alveolar reconstruction with bone grafting	Age 6-9 years based on dental development
Cleft orthognathic surgery	Age 14-16 years in girls, 16-18 years in boys
Cleft rhinoplasty	After age 5 years, but preferably at skeletal maturity; after orthognathic surgery when possible.
Cleft lip revision	Anytime once initial remodeling and scar maturation is complete, but best performed after age 5 years

Treatment Planning and Timing

The timing of cleft lip and palate repair is controversial. Despite a number of meaningful advancements in the care of patients with cleft lip and palate, a lack of consensus exists regarding the exact timing and specific techniques used during each stage of cleft reconstruction. Surgeons must continue to balance the functional needs, esthetic concerns, and the issue of ongoing growth carefully when deciding how and when to intervene. In no other type of craniofacial surgical problem is the issue of early surgery's effect on growth more apparent than in the treatment of cleft lip and palate deformities. The decision to manipulate the tissues of the growing child surgically should not be made lightly and should consider the possible growth restriction that can occur with early surgery. Nevertheless, many patients with congenital deformities benefit from surgical intervention based on functional or psychosocial reasons. Understanding the growth and development of the craniofacial skeleton is critical to the treatment planning process.[33] In many cases waiting for a greater degree of growth to occur is advantageous unless compelling functional or esthetic issues are present that cannot or should not wait.

Because of the many different treatment philosophies, the timing of treatment interventions varies considerably among cleft centers. Therefore producing a timing regimen that everyone agrees on is difficult. Each stage of surgical reconstruction and the suggested timing based upon the patient's age are presented in Table 28-1. Special considerations may alter the sequencing or timing of the various procedures based on individual developmental, functional needs, or esthetic needs. Significant differences exist worldwide regarding the timing of different repairs. As of yet, timing of repair cannot be guided by truly definitive outcome research.

Cleft lip repair generally is undertaken at some point after 10 weeks of age. Waiting until the child is 10 to 12 weeks of

age allows enough time for a complete medical evaluation of the patient so that any associated congenital defects affecting other organ systems (e.g., cardiac or renal anomalies) may be revealed. The surgical procedure itself may be easier when the child is slightly larger and the anatomic landmarks are more prominent and well defined. Historically, the anesthetic risk-related data have suggested that the safest time for surgery in this population of infants could be outlined simply by using the "rule of 10s." This referred to the idea of delaying lip repair until the child was at least 10 weeks old, 10 pounds in weight, and with a minimum hemoglobin level of 10 mg/dL.[63,64] Today more sophisticated pediatric anesthetic techniques, advances in intraoperative monitoring, and improved anesthetic agents have all resulted in the ability to provide safe general anesthesia much earlier in life.[65] Despite this ability, no measurable benefit exists to performing lip repair before 3 months of age.[64,66,67] Some surgeons have advocated that lip repair be carried out in the first days of infancy based on the idea of capitalizing on early "fetal-like" healing. Unfortunately, these hoped-for benefits have not been observed, and problems with excessive scarring and less-favorable outcomes have been encountered.[68-70] Children may have more scarring at this early age, and their tissues are smaller and more difficult to manipulate. Consequently the esthetic outcomes may be worse if surgery is performed at an earlier age; because no clear benefits exist for earlier repair, the recommendations for repair remain at approximately 3 months of age.

Cleft palate repair usually is performed at approximately 9 to 18 months of age. In deciding the timing of repair the surgeon must consider the delicate balance between facial growth restriction after early surgery and speech development that requires an intact palate. Most children require an intact palate to produce certain speech sounds by 18 months of age. If developmental delay is present and speech will not likely develop until later, then the repair can be delayed further. Little evidence suggests any benefit to palate repair before 9 months of age.[71-73] Repairs before this time are associated with a much higher incidence of maxillary hypoplasia later in life and show no additional improvements in speech. For these reasons most surgeons perform primary palate repair at approximately 9 to 18 months of age.

As these children continue to develop, a significant percentage will have inadequate closure of the velopharyngeal mechanism (velopharyngeal insufficiency [VPI]) even after successful palate repair, which may produce hypernasal speech.[74] These children usually are diagnosed at 3 to 5 years of age when a detailed speech examination can be obtained by a skilled speech pathologist. When VPI is shown to be consistent and caused by a definable anatomic defect, surgery often is helpful. A pharyngeal flap or sphincter pharyngoplasty may be used to treat VPI, with the goal of improving closure between the oral and nasal cavities and reducing nasal air escape during the production of certain sounds. In some select cases, palate repeat repair may be considered with a two-flap palatoplasty or double-opposing Z-plasty technique.

Approximately 75% of patients with any type of cleft have clefting of the maxilla and alveolus.[24-26] Bone graft reconstruction of this site is performed during the mixed dentition before the eruption of the permanent canine and/or the permanent lateral incisor. The timing of this procedure is based on dental development and not chronologic age. On the basis of work by Boyne, most surgeons reconstruct this area during the mixed dentition before eruption of the permanent canine. Earlier reconstruction of this area has been associated with a high degree of maxillary growth restriction, requiring orthognathic correction later in life in a much higher percentage of patients.[22,24] The gold standard for reconstruction in this area is autogenous bone from the anterior iliac crest. Cranial bone, rib, tibia, symphysis of the mandible, zygoma, and allogeneic bone have all been studied, but none has been shown to be appreciably better than the iliac crest.[26,75,76]

Orthognathic reconstruction of maxillary and mandibular discrepancies is performed at 14 to 18 years of age based on individual growth characteristics.[26-36,38] This is done in conjunction with orthodontics before and after surgery. However, in some cases of severe maxillary hypoplasia, early Le Fort I osteotomy may be performed to optimize facial esthetics and occlusion with the supposition that revision osteotomies will likely be necessary. These early osteotomies may complicate later treatment. Early orthognathic maxillary advancement is reserved for the most severe dysmorphology, and in most cases the authors prefer standard orthognathic techniques timed in the standard fashion.[31-33] Attempts at using distraction osteogenesis have been associated with a higher complication rate than standard orthognathic techniques.[32,42,77] However, this remains an option for exceptionally large advancements or other indications.

As with the timing of other interventions, lip and nasal revision is best reserved for after the majority of growth is complete. Most of the lip and nasal growth is complete after age 5 years. Lip revision may be considered just before school begins, at approximately 5 years of age or later. However, this may be performed earlier if the deformity is severe. Nasal revision is performed after age 5 years because most of the nasal growth is complete by this time. If orthognathic reconstruction is likely, then rhinoplasty usually is best performed after orthognathic surgery because maxillary advancement improves many characteristics of nasal support. When nasal deformity is particularly severe, rhinoplasty can be considered earlier even if orthognathic surgery is expected. Multiple early revisions of the lip or nose should be avoided so that excess scarring does not potentially impair ongoing growth.

Cleft Lip and Palate Repair

Presurgical Taping and Presurgical Orthopedics

Facial taping with elastic devices may be used for application of selective external pressure and may improve lip and nasal position before the lip repair procedure. In the authors'

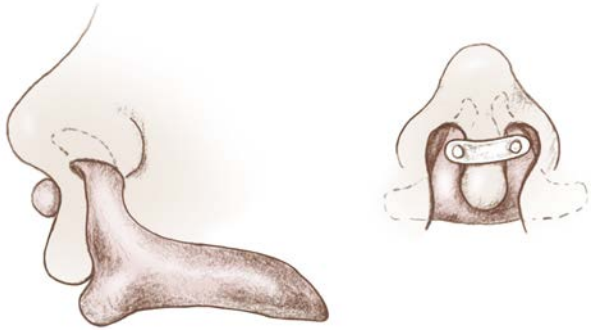
opinions these techniques often have greater impact in cases of wide bilateral cleft lip and palate in which manipulation of the premaxillary segment may make primary repair technically easier. Although one of the basic surgical tenets of wound repair is to close wounds under minimal tension, attempts at improving the arrangement of the segments by using taping methods have not shown a measurable improvement.[78-80]

Some surgeons prefer presurgical orthopedic (PSO) appliances rather than lip taping to achieve similar goals.[81,82] PSO appliances are composed of a custom-made acrylic base plate that provides improved anchorage in the molding of lip, nasal, and alveolar structures during the presurgical phase of treatment (Figure 28-3). Although the use of appliances probably allows an easier surgical repair, clinical evidence is lacking to demonstrate any measurable improvement in esthetics of the nose or lip, dental arch relation, tooth survival, or occlusion of the patient. Studies have looked at the dental arch relations and other outcomes in patients who have infant presurgical orthopedic devices, and no improvement was seen.[83,84] In addition, no long-term improvement in speech outcome has been demonstrated in patients who had PSOs.[85] Furthermore, concerns regarding potential negative consequences of these types of appliances have been raised.[86] PSOs also add significant cost and time to treatment early in the child's life. Many appliances require a general anesthetic for the initial impression used to fabricate the device. Frequent appointments are necessary to monitor the anatomic changes and periodic appliance adjustment.

The Latham appliance was popular for expanding and aligning the maxillary segments of the patient with a cleft palate.[87] It is a pin-retained device inserted into the palate with acrylic extensions onto the alveolar ridges. A screw mechanism is then used to manipulate the segments as desired. The Latham appliance used with gingivoperiosteoplasty has been shown to be associated with significant growth restriction of the mid-face when used in infancy to approximate the segments for repair.[86] Children who have had Latham appliances have been shown to have significant mid-facial growth restriction in adolescence 100% of the time, whereas children who have not had the Latham appliance have mid-face hypoplasia 25% to 35% of the time.[42,80,86]

The Grayson nasoalveolar molding appliance has become popular with some centers in attempts to manipulate the segments without pin retention before lip and nose repair (see Figure 28-3). The nasoalveolar molding appliance is adjustable by removing or adding acrylic and manipulating protrusive elements that attempt to mold the nasal cartilages. This device attempts to align the alveolar segments, lip structures, and nasal cartilages to optimize repair. Unfortunately, the hoped-for advantages of this appliance have not been realized. In addition, no long-term data are available regarding growth in the craniofacial skeleton after using this protocol. The limited short-term data that are available cannot be extrapolated to determine the ultimate outcome on growth, function, or esthetics. Many surgeons use gingivoperiosteoplasty in conjunction with the PSO, using limited flaps to close the alveolus cleft during the primary repair of the lip or palate. Many surgeons who use this appliance in conjunction with their primary lip repairs perform a gingivoperiosteoplasty in attempts to have bone form at the alveolus. This is more easily performed with the segments aligned in close proximity because the flaps are small.[82] Experiences with similar techniques in the 1960s involving primary bone grafting had poor results regarding growth.[22,23] Subsequent studies have confirmed the high incidence of growth restriction in this population. In addition, no convincing, long-term, objective data have shown improvement in either lip or nose esthetics.

In their current state, no convincing and validated evidence exists that any of the PSOs offer an improved outcome in esthetics, function, or growth in patients with cleft lip and palate. Coupled with the fact that appliances are time consuming and have a high cost of fabrication and utilization, advocating their uniform use is difficult. As with other interventions considered for patients with clefts, costly and unproven interventions should be avoided, although they may prove to be helpful in select cases.[88] A subset of more severe clefts may benefit from the devices. Perhaps long-term data will be forthcoming and positive to help determine which patients may benefit from PSO appliance treatment.



• **Figure 28-3** Frontal and lateral views of the Grayson nasoalveolar molding appliance showing the nasal projections that theoretically help mold the nasal cartilages and maxillary segments into a more appropriate configuration before repair.

Lip Adhesion

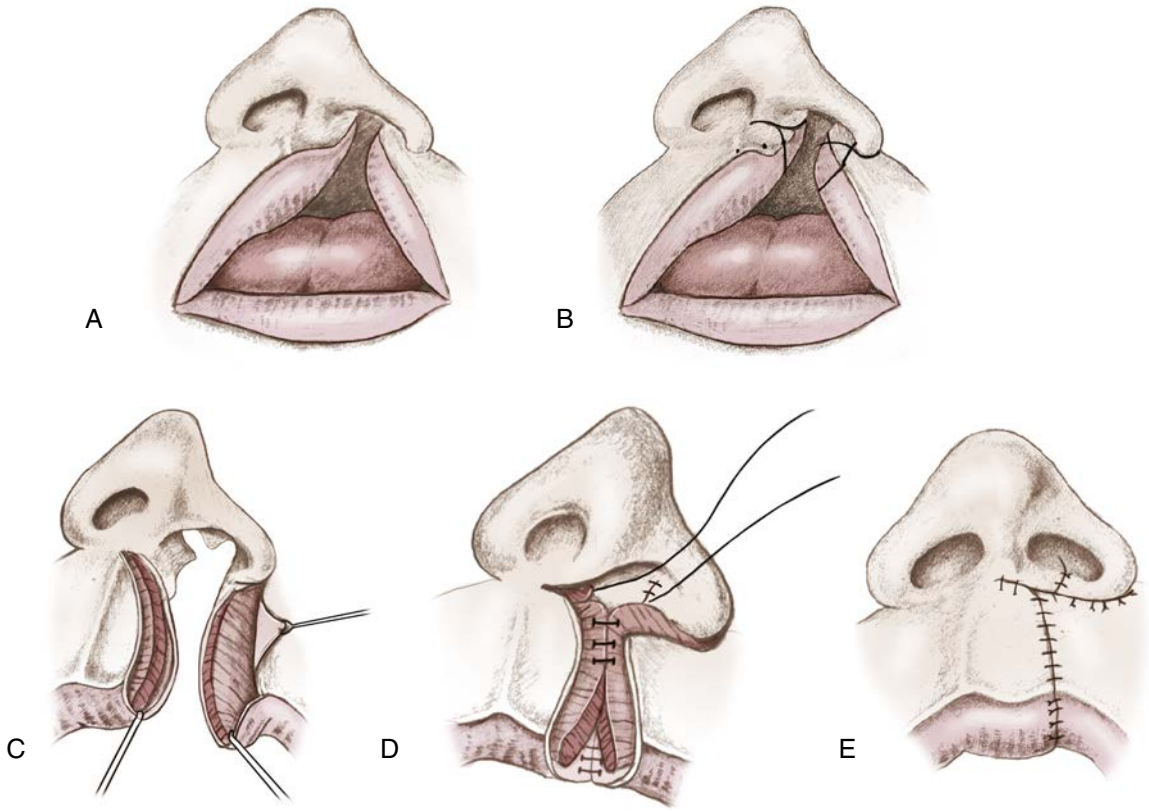
Some surgeons attempt to surgically approximate the segments of the cleft lip before definitive lip repair in an attempt to achieve a better relation of both the lip structures and the dental arches.[89-91] This is achieved by advancing small flaps of tissue across the cleft site. Some surgeons advocate the use of this technique in wide bilateral clefts, but it rarely is performed in unilateral cases. The lip adhesion usually is completed at 3 months of age. In most cases this will convert a wide, complete cleft into a wide, incomplete cleft because the scar eventually will be excised from the cleft site, recreating a similar wide deformity. The definitive lip repair is

then completed 3 to 9 months later by excising the scar and reapproximating the remaining lip structures. Furthermore, at the second procedure the tissue to work with when performing the definitive repair usually is less supple. As with most endeavors in cleft surgery, repeated early interventions tend to complicate later refinements because of excessive scarring. In general, adequate mobilization of the flaps in one stage will make tension-free skin closure possible in most cases without the need for taping, presurgical orthopedic appliances, and/or lip adhesion.

Primary Unilateral Cleft Lip Repair

Unilateral clefts of the lip and nose present with a high degree of variability; thus each repair design is unique (see Figure 28-1).[26,92] The repair technique preferred by the authors for cleft lip and nasal deformities is shown in Figures 28-4 and 28-5 and usually is performed after 10 weeks of age.[17,18,26,63] The basic premise of the repair is to create a three-layered closure of skin, muscle, and mucosa that approximates normal tissue and excises hypoplastic tissue at the cleft margins. Critical in the process is the reconstruction of the orbicularis oris musculature into a continuous sphincter. The Millard rotation advancement technique has the advantage of allowing each of the incision lines to fall within the natural contours of the lip and nose. This is an advantage because achieving mirror-image symmetry in the unilateral cleft lip and nose is difficult with the normal side immediately adjacent to the surgical site. A Z-plasty technique such as the Tennison-Randall repair may not achieve this level of symmetry because the Z-shaped scar is directly adjacent to the linear nonclefted philtrum (Figure 28-6). Achieving symmetry is more difficult when the rotation portion of the cleft is short compared with the advancement segment. A functional muscle reconstruction utilizing the perinasal musculature may be considered in conjunction with this, or most any other lip and nose repair technique.

Primary nasal reconstruction may be considered at the time of lip repair to reposition the displaced lower lateral cartilages and alar tissues. Several techniques are advocated,



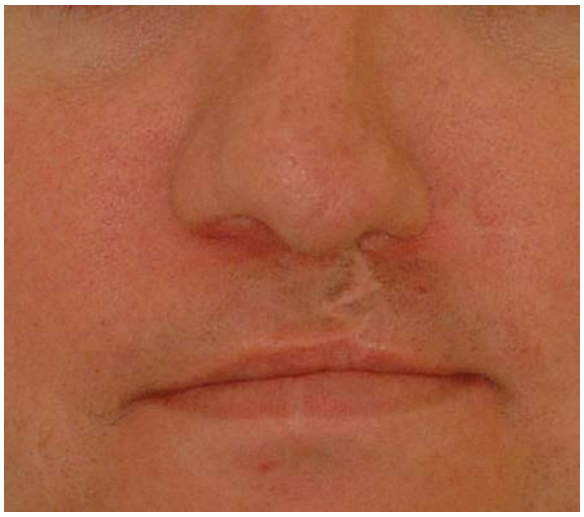
• **Figure 28-4** **A,** Complete unilateral cleft of the lip highlighting the hypoplastic tissue in the cleft site not used in the reconstruction. Note the nasal deformities typical in the unilateral cleft, including displaced lower lateral nasal cartilages, deviated anterior septum, and nasal floor clefting. **B,** The typical markings for the authors' preferred repair, highlighting the need to excise the hypoplastic tissue and approximate good vermilion and white roll tissue for the repair. **C,** Once the hypoplastic tissue has been excised, the three layers of tissue are dissected (skin, muscle, and mucosa). Completely freeing the orbicularis oris from its abnormal insertions on the anterior nasal spine area and lateral ala is important. Nasal flaps also are incorporated into the dissection to repair the nasal floor (not shown). **D,** The orbicularis oris muscle is approximated with multiple interrupted sutures, and the vermilion border/white roll complex is reconstructed. The nasal floor and mucosal flaps are approximated. **E,** The lateral flap is advanced and the medial segment is rotated downward to create a healing scar line that will resemble the natural philtral column on the opposite side. The incision lines are hidden in natural contours and folds of the nose and lip.

and considerable variation exists regarding the exact nasal reconstruction performed by each surgeon.[93,94] The primary nasal repair may be achieved by releasing the alar base, augmenting the area with allogeneic dermal grafts, or even performing a formal open rhinoplasty. Because lip repair is performed at such an early point in growth and development, the authors prefer minimal surgical dissection because of the effects of scarring on the subsequent growth of these tissues. McComb described a technique that consists of dissecting the lower lateral cartilages free from the alar base and the surrounding attachments through an alar crease incision.[93,95-97] This allows the nose to be bolstered and/or stented from within the nostril to improve symmetry.

Primary Bilateral Lip Repair

Bilateral cleft lip repair can be one of the most challenging technical procedures performed in children with clefts. The lack of quality tissue present and the widely displaced segments are major challenges to achieving exceptional results, but superior technique and complete mobilization of the tissue flaps usually yields excellent esthetic results

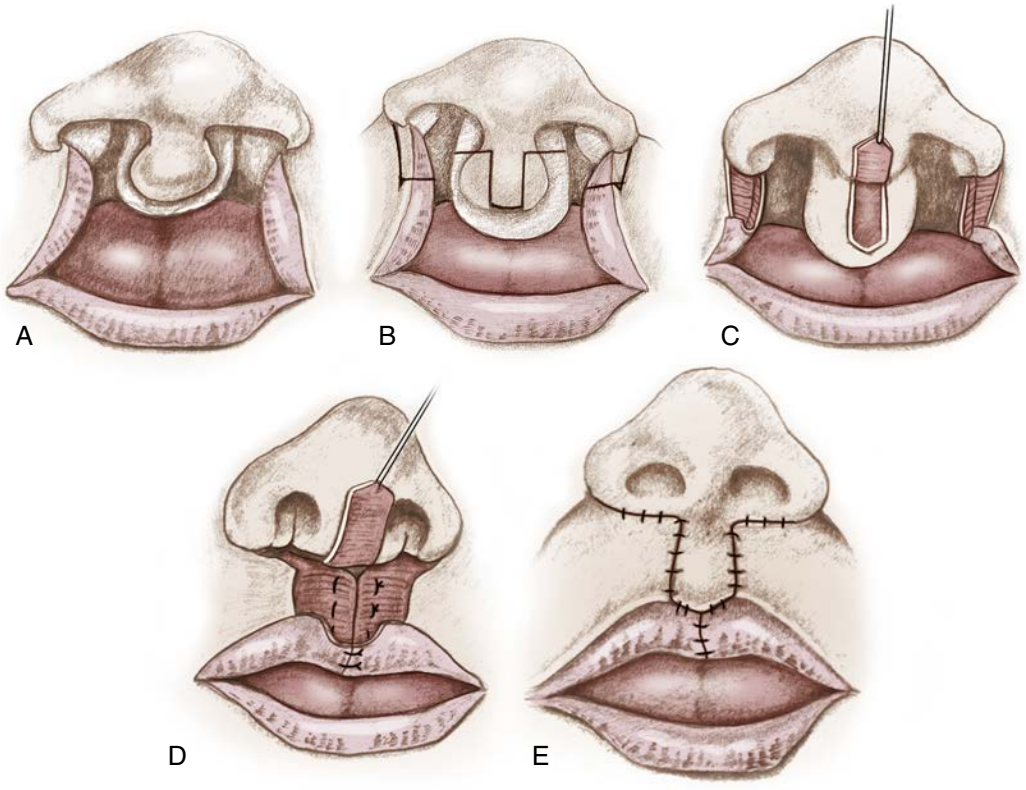
• **Figure 28-5** **A,** Three-month-old child with a right-sided incomplete unilateral cleft lip. Note the short philtrum near the midline that must be rotated downward to avoid notching and improve symmetry. **B,** Nine-month-old boy after the rotation-advancement repair of his cleft lip and nasal deformities. **C,** The same child in part **B** 2½ years after his cleft lip and nasal repairs. **D,** And at ten year follow-up without any revision of the original repair.



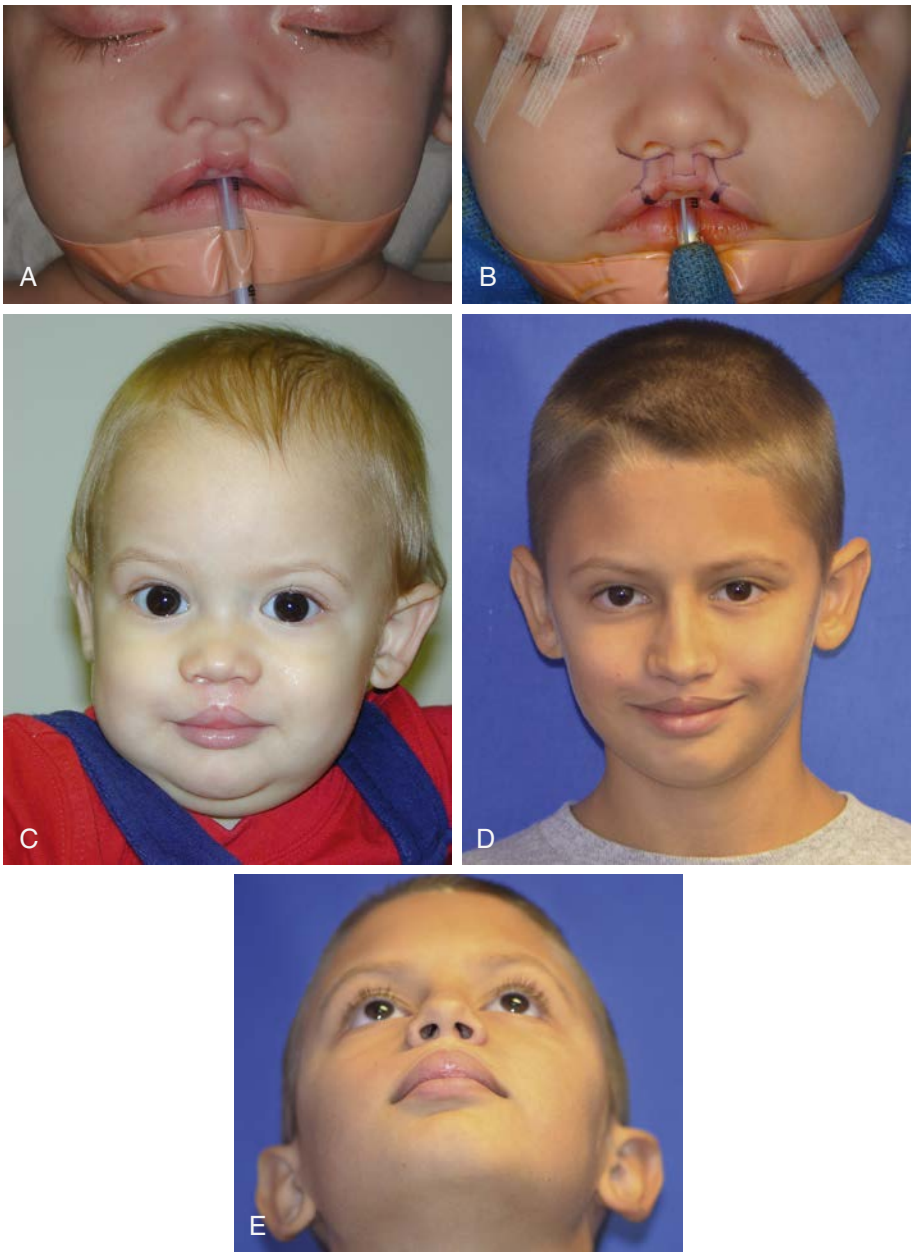
• **Figure 28-6** A typical scar that may result from a Z-plasty lengthening repair. Although the length and symmetry of the lip is good, an unnatural contour can occur because of the Z shape of the closure.

(Figures 28-7 to 28-10). In addition, the columella may be quite short in length, and the premaxillary segment may be significantly rotated. Adequate mobilization of the segments and attention to the details of using only appropriately developed tissue will yield excellent results even in the face of significant asymmetry.

Some surgeons have used techniques to lengthen the columella surgically and preserve hypoplastic tissue with banked fork flaps.[98,99] Early and aggressive tissue flaps in the nostril and columella areas do not look natural after significant growth has occurred and result in abnormal tissue contours. Although surgical attempts at lengthening the columella initially may look good, they frequently look abnormally long and excessively angular later in life (Figure 28-11). Revision of these iatrogenic deformities is difficult, and some of the contour irregularities cannot be adequately revised. If the hypoplastic tissue is excised and incisions within the medial nasal base and columella are avoided, the long-term esthetic results usually are excellent.



• **Figure 28-7** **A,** The bilateral cleft of the lip and maxilla shown is complete and highlights the nature of hypoplastic tissue along the cleft edges. The importance of the nasal deformity is evident in the shorter columella and disrupted nasal complexes. **B,** Markings of the authors' preferred repair, with an emphasis on excision of hypoplastic tissue and approximating more normal tissue with the advancement flaps. **C,** A new philtrum is created by excising the lateral hypoplastic tissue and elevating the philtrum superiorly. In addition, the lateral advancement flaps are dissected into three distinct layers (skin, muscle, and mucosa). Nasal floor reconstruction also occurs in conjunction with these advancement flaps. **D,** The orbicularis oris musculature is approximated in the midline with multiple interrupted and/or mattress sutures. This is a critical step in the total reconstruction of the functional lip. No musculature is present in the premaxillary segment, which must be brought to the midline from each lateral advancement flap. The nasal floor flaps are sutured at this time as well. The new vermilion border is reconstructed in the midline with good white roll tissue advanced from the lateral flaps. **E,** The final approximation of the skin and mucosal tissues is performed, leaving the healing incision lines in natural contours of the lip and nose.



• **Figure 28-8** **A,** Presurgical appearance of the incomplete bilateral cleft lip of a 3-month-old boy. **B,** Surgical markings for excision of the hypoplastic tissue and the planned creation of a new philtrum. Advancement flaps from the lateral lip segments bring good white roll to the midline by small cutbacks. **C,** The same child at 1 year of age after the repair of his bilateral cleft lip. **D** and **E,** The same child at age 13.

The authors prefer a primary nasal reconstruction that can be performed in a similar fashion to the technique described by McComb.[100] This allows release and repositioning of the lower lateral cartilages and alar base on both sides without aggressive degloving of the entire nasal complex. Other open rhinoplasty techniques have been suggested that use direct incision on the nasal tip or prolabial unwinding techniques.[100-103] As with most early maneuvers, aggressive rhinoplasty at this time may incur early scarring that affects growth potential of the surrounding tissues, making revision more difficult and long-term esthetics less than ideal. Good results can be achieved with a number of different techniques.

Cleft Palate Repair

The term *primary palate* is used to describe the anatomic structures anterior to the incisive foramen (e.g., the alveolar ridge, maxilla, piriform rim). The term *secondary palate* refers to structures posterior to the incisive foramen. Therefore, when surgeons refer to the initial or primary cleft palate repair, they are in fact describing the closure of the secondary palate structures, which include the hard palate, soft palate, and uvula. The structures of the embryologic primary palate are reconstructed later in childhood during the cleft maxillary/alveolar bone graft procedure.

• **Figure 28-9** **A,** Presurgical appearance of a bilateral cleft lip and palate with significant asymmetry and rotation of the premaxillary segment. Note the nasal asymmetry and bunching of the orbicularis oris laterally. **B,** The same child at 14 months of age. No presurgical molding or taping was utilized in this case.

Cleft palate repair during infancy has two main goals: (1) the water-tight closure of the oronasal communication involving the hard and soft palate, and (2) the anatomic repair of the musculature within the soft palate, which is critical for normal creation of speech. The soft palate, or velum, is part of the complex coupling and decoupling of the oral and nasal cavities involved in the production of speech. When a cleft of the soft palate is present, abnormal muscle insertions are located at the posterior edge of the hard palate. Surgery must be aimed at the release of abnormal muscle insertions, not simply closing the palatal defect. Muscle continuity with correct orientation should be established so that the velum may serve as a dynamic structure.

The exact timing of repair of a palate cleft is controversial. In general, the velum must be closed before the development of speech sounds that require an intact palate. On average this level of speech production is observed by approximately 18 months of age in the normally developing child. If the repair is completed after this time, compensatory speech articulations may result. Repair completed before this time allows the intact velum to close effectively, appropriately separating the nasopharynx from the oropharynx during certain speech sounds.[104-107]

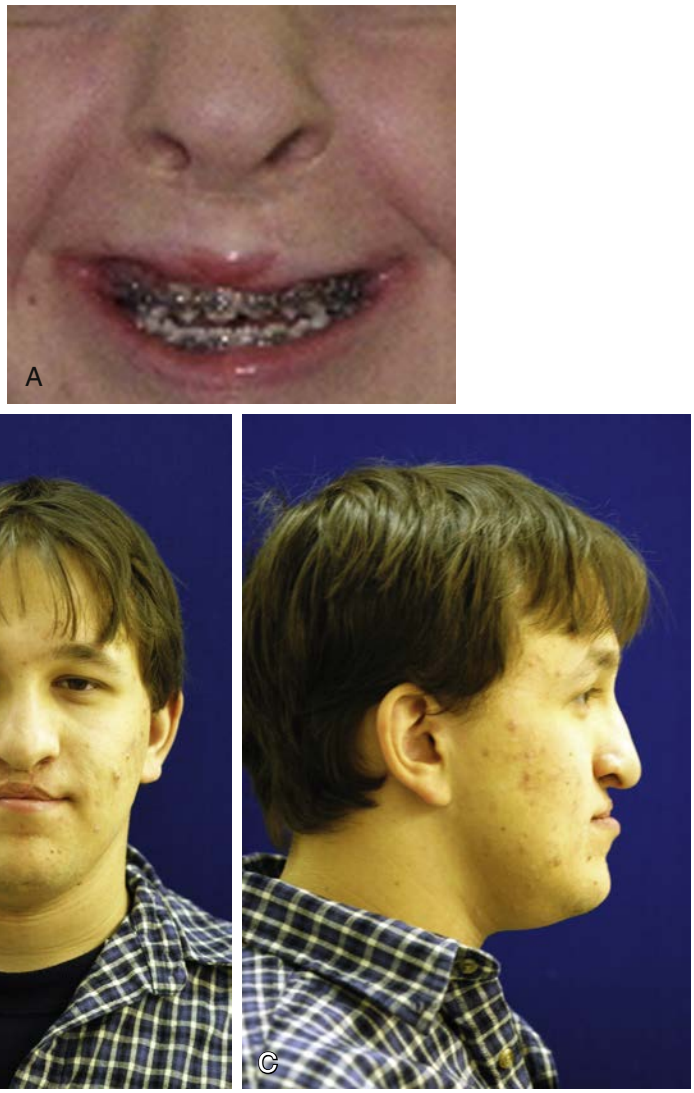
In patients with a cleft palate, concerns for normal speech development frequently are balanced with the known biologic consequences of surgery during infancy; namely, the problem of surgery during the growth phase resulting in maxillary growth restriction.[33,72,73,108] When repair of the palate is performed between 9 and 18 months of age, the incidence of associated growth restriction affecting the maxillary development is approximately 25%.[31,33,109-111] If repair is carried out earlier than 9 months of age, severe growth restriction requiring future orthognathic surgery is seen with greater frequency.[22,26,31,33,109,112-114] At the same time, proceeding with palatoplasty before 9 months of age is not associated with any increased benefit in terms of speech development, so the result is an increase in growth-related problems with an absence of any functional benefit.[115,116] When using only chronologic age, carrying out the operation during the 9- to 18-month timeline seems to best balance the need to address functional concerns such as speech development with the potential negative impact on growth. To date no rigorous clinical trial has examined what is likely the most critical factor in dictating the exact timing of cleft repair—the individual child's true language age—because it is difficult to measure adequately. In cases in which significant developmental delay is present, surgery should be delayed because speech formation is not yet an issue and benefit in terms of growth of the maxilla is likely. Delaying palatal closure is relevant in situations in which the cleft palate is associated with other complex medical conditions, neurodevelopmental delay, complex craniofacial anomalies, and/or the presence of a tracheotomy.

Another approach used to balance speech issues with growth-related concerns is to stage the closure of the secondary palate with two operations. In general, this involves the repair of the soft palate early in life as an initial step followed by closure of the hard palate later in infancy with or without the use of an obturator. The idea is that timely repair of the soft palate, which is critical for speech, is accomplished, whereas hard palate repair with mucoperiosteal stripping is delayed until growth is further along.[117,118] Although this technique is not advocated by the majority of surgeons in the United States, some surgeons may believe that repairing the hard palate later may offer the advantages of less growth restriction, easier repair of larger clefts, and less chance for fistula formation. No convincing definitive data exist to favor this approach over a single-stage repair, but the practice is continued by some centers when evidence suggests some benefit—particularly

• **Figure 28-10** **A,** Presurgical frontal view of a wide bilateral cleft lip and palate with significant asymmetry and lack of columella length. **B,** Presurgical left lateral view of a wide bilateral cleft lip and palate with a protrusive premaxillary segment. Note the short columella length. **C** and **D,** The same child at 10 months of age after repair of her bilateral cleft lip and palate. No presurgical taping or orthopedic appliances were used.

regarding growth. In contrast, most North American speech-language pathologists prefer closure of the palate as a single operation.[117]

Cleft palate reconstruction requires the mobilization of multilayered flaps to reconstruct the defect because of the failure of fusion of the palatal shelves. In general, when the initial palate closure is performed, this refers to closure of the tissues posterior to the incisive foramen. This is done in a layered fashion by first closing the nasal mucosa and then the oral mucosa. Because the main function of the palate is to close the space between the nasopharynx and oropharynx during certain speech sounds, the surgeon also must reconstruct the musculature of the velopharyngeal mechanism. The musculature of the levator palatini is abnormally inserted and invested within the tissue near the posterior aspect of the hard palate. The musculature therefore must be de-inserted and reconstructed in the midline to create an adequately functional velum.[26,119] Therefore the soft palate is closed in three layers by approximating the nasal mucosa, levator musculature, and the oral mucosa. The hard palate portion is closed in two layers by using nasal mucosa flaps and then oral mucosa flaps. Both the hard and soft palate repairs must be done in a tension-free manner to avoid wound breakdown and fistula formation. Adequate mobilization of the flaps during the dissection is

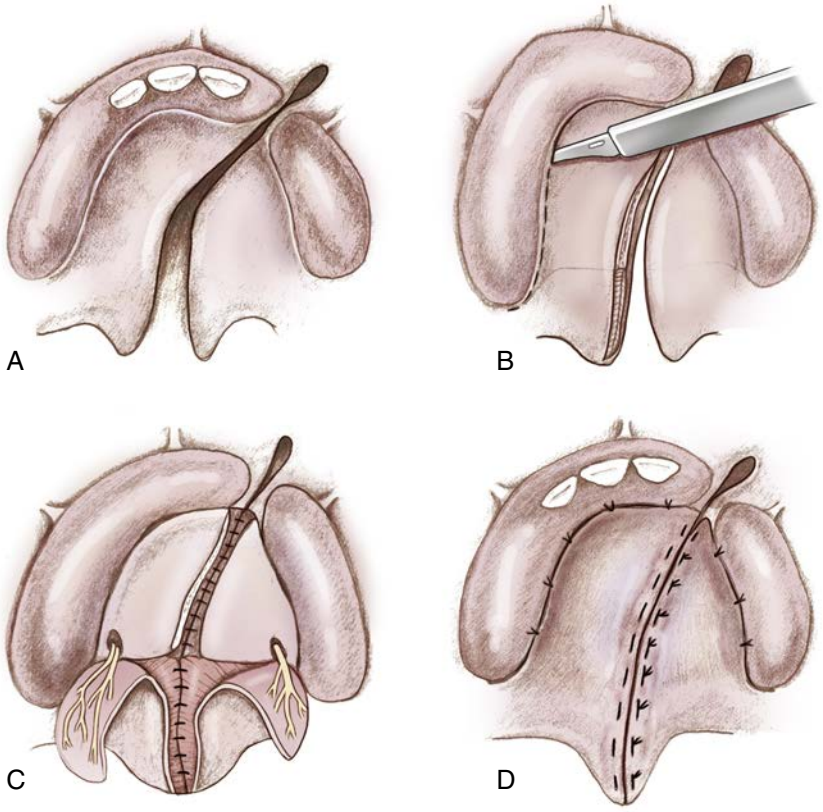


• **Figure 28-11** **A,** Frontal view of a teenage girl who had undergone columella lengthening and banked fork flaps during her initial repair and attempts at secondary rhinoplasty by another surgeon before orthognathic surgery. **B,** Frontal view of a patient who underwent columella lengthening and banked fork flaps during his initial repair. **C,** Lateral view of the patient from **B** with a columella that is long and has a tip oriented downward.

essential to achieve tension-free closure. At times some surgeons may elect to incorporate vomer flaps or acellular dermal matrix into the repair if mobilization of the lateral flaps to the midline is difficult.

Many techniques have been described for repair of the palate, and the controversies among these techniques are described later in this text.[120-127] The Bardach two-flap palatoplasty uses two large, full-thickness flaps that are mobilized with layered dissection of the soft palate and brought to the midline for closure (Figure 28-12).[26,120] This technique preserves the palatal neurovascular bundle as well as a lateral pedicle for adequate blood supply. The von Langenbeck technique is similar to the Bardach palatoplasty but preserves an anterior pedicle for increased blood supply to the flaps.[26,121] This technique also is successful in achieving a layered closure but may be more difficult when suturing the nasal mucosa near the anteriorly based pedicle attachments. The authors do not favor push-back techniques because they may incur more palatal scarring, restrict growth, and do not show a measurable benefit in speech.

Another common technique is the Furlow double-opposing Z-plasty, which attempts to lengthen the palate by taking advantage of a Z-plasty technique on both the nasal mucosa and the oral mucosa (Figure 28-13).[26,124-127] This technique can be effective at closing the palate but has been reported by some to have a higher rate of fistula formation at the junction of the soft and hard palates, where theoretical lengthening of the soft palate may compromise the closure.[26,128-133] Some surgeons use interpositional acellular dermal matrix at the time of primary repair to combat this complication.



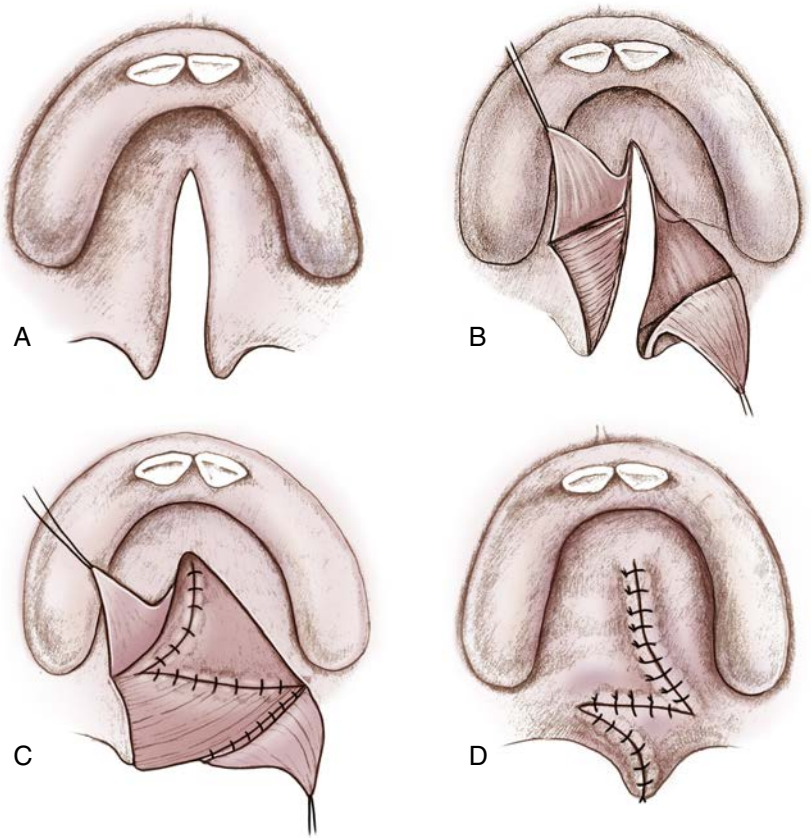
• **Figure 28-12** **A,** Unilateral cleft of the primary and secondary palates is shown with the typical involvement from the anterior vestibule to the uvula. **B,** The Bardach palatoplasty technique requires two large, full-thickness mucoperiosteal flaps to be elevated from each palate shelf. The anterior portion (anterior to the incisive foramen) of the cleft is not reconstructed until the mixed dentition stage. **C,** A layered closure is performed in the Bardach palatoplasty by reapproximating the nasal mucosa. The muscle bellies of the levator palatini are elevated off their abnormal insertions on the posterior palate. They are then reapproximated in the midline to create a dynamic functional sling for speech purposes. **D,** Once the nasal mucosa and musculature of the soft palate are approximated, the oral mucosa is closed in the midline. The lateral releasing incisions are quite easily closed primarily because of the length gained from the depth of the palate. In rare cases, in very wide clefts a portion of the lateral incisions may remain open and granulate by secondary intention.

No benefit has been convincingly demonstrated with any particular repair technique when looking at dental arch form, speech outcome, feeding, or any other functional variable. At this point in our understanding, surgeons often consider their own experiences and training when repairing clefts because definitive data suggesting that one repair is preferable over another are lacking.

In very wide clefts some surgeons advocate considering a pharyngeal flap at the primary palatoplasty procedure to assist in closure because revision palatoplasty is sometimes unsuccessful in eradicating fistulas. Those who use this technique usually perform it in extremely wide clefts and do so quite selectively. This allows the central portion of the closure to be filled with posterior pharyngeal wall tissue, making the closure of the nasal and palatal mucosa easier. Patients with Pierre Robin sequence or Treacher Collins syndrome may have exceptionally wide clefts that are difficult to close with no tension, and this technique may be considered for them. The drawbacks of using a pharyngeal flap during the repair of the palate include an increased risk for complications such as bleeding, snoring, obstructive sleep apnea, and hyponasality.

Complex Facial Clefting

Clefting of the facial structures other than the typical nasolabial region is rare and often presents difficult challenges to the reconstructive cleft surgeon. Therefore consideration should be given to referring patients with complex facial clefting to surgeons with experience in this particular area. Comprehensive interdisciplinary care is important to achieve the best results, including involvement of neurosurgery, ophthalmology, orthodontics, speech pathology, and other members of the craniofacial team. Some interventions such as eye lubrication may be necessary within hours after birth, and accurate prenatal diagnosis of severe facial clefting is helpful in planning for early care.



• **Figure 28-13** **A,** Complete cleft of the secondary palate (both hard and soft) is shown from the incisive foramen to the uvula. **B,** The Furlow double-opposing Z-plasty technique requires that separate Z-plasty flaps be developed on the oral and then nasal side. Note the cutbacks creating the nasal side flaps, highlighted in blue. **C,** The flaps are then transposed to theoretically lengthen the soft palate. A nasal side closure is completed in the standard fashion anterior to the junction of the hard and soft palate. In general, this junction is the highest area of tension and can be difficult to close. This contributes to the higher fistula rate in this type of repair at this location. **D,** The oral side flaps are then transposed and closed in a similar fashion, completing the palate closure.

The etiology of the various facial clefts may be related to failure of embryologic fusion, physical obstruction in fetal life, association with an encephalocele or tumor, amniotic bands, or other anatomic disruptions during fetal life.[55] The majority of complex facial clefts are sporadic events not related to a single-gene disease. Many complex facial clefts involve the orbit, and the classification system most often used is orbitocentric in design (see Figure 28-2). Tessier[56] described a numbering system for facial clefting phenomena to make description and surgical planning more easily discussed. Other systems exist but have a more cumbersome nomenclature.[57]

Primary repair of severe facial clefts often is more difficult than even the most difficult standard bilateral clefts.[134-136] Although mobilization of the lip and nose structures is rather straightforward, the closure of clefts in the orbital region can be challenging because of the lack of eyelid and adjacent tissue for advancement and/or rotation. Revision surgery is the norm in this group and may include a skilled ophthalmologic surgeon early in the process for the best functional and esthetic results.

The staged reconstruction of these types of severe facial clefts is similar to the more common cleft lip and palate protocols. However, several functional issues are present in patients with complex facial clefting that require more immediate attention. For example, patients with large Tessier 7 clefts may have problems with retaining food in their oral cavities because of the discontinuity of the orbicularis oris (Figure 28-14). This may prompt early repair and reestablishment of the orbicularis oris musculature for functional concerns.

For patients with orbital clefts, a skilled pediatric ophthalmologist should evaluate the child early to avoid severe corneal abrasion and desiccation. Immediate lubrication of the globes is necessary to prevent severe, irreversible corneal damage until eyelid structures can be mobilized to cover the globe adequately. Early after birth, tarsorrhaphy stitches can be used to gain adequate closure of the lids for corneal protection. Ignoring the need for eye protection may result in severe corneal scarring that may cause blindness and prompt consideration for corneal transplantation. Corneal transplantation in infants often is not successful but is possible in patients with severe orbitofacial clefts. Another concern is the support of the globes at the orbit floor that may be involved in some facial clefts. The timing of orbital

• **Figure 28-14** **A,** A 2-month-old boy with a Tessier 7 left facial cleft associated with craniofacial microsomia (Kaban type IIb), congenital ear anomalies, a lateral tongue cleft, and a left-sided epibulbar dermoid. **B,** The same child 8 months after the primary repair.

reconstruction depends on the functional needs of the cleft area in each patient. These are some of the concerns present in complex facial clefting, and a customized treatment plan must be formulated for each patient.

Outcome Assessment

Decision making in cleft care should involve evidence-based research and a critical look at outcomes. Unfortunately, little evidence-based research is available to guide clinicians through the many treatment protocols for cleft care.[113] Although the clinical experience of the surgeon certainly has value, this must be integrated with a constant review of evidence-based research. Enthusiasm by a surgeon or a particular group of surgeons regarding a specific intervention because of personal experiences may help popularize that intervention, but typically little outcome data support its use. Too frequently the long-term results are not forthcoming, and the treatment regimen may still persist. Unfortunately some of the treatment protocols used today are based on the poor outcomes and mishaps of previous surgeons rather than regimens chosen as a consequence of published evidence of the actual success of a particular treatment. The United Kingdom and other European centers have collaborated to pool data and provide more meaningful assessments of outcome.[137,138] The continued study should help teams understand interventions and their potential consequences in greater detail. The Americleft project attempts to evaluate the North American data in a similar way, and the published outcomes do resemble those seen in Europe.[138-158]

In addition, the pressures of a costly health care system have made treatment decision questions even harder to investigate than ever before.[88] A need to understand the outcome differences of various treatment philosophies will be critical to help determine which protocols will be most beneficial to the patient without extending valuable health care resources on unproven or ineffective methods. For this reason, among many others, the need to abandon unproven and unnecessary interventions has never been greater. Outcomes studies based on results such as appearance, facial growth, occlusion, patient satisfaction, and psychosocial development are all critical in this process. Surgeons involved in the care of patients with clefts must critically review the literature on a regular basis and not be tempted by poorly evaluated techniques popularized by clinical reports.

Summary

The comprehensive care of patients with clefts requires an interdisciplinary approach that demands precise surgical execution of the various procedures necessary to treat cleft deformities effectively. Long-term follow-up with the interdisciplinary team is an essential component of this process. Furthermore, clinicians experienced in the comprehensive interdisciplinary care of patients with clefts are best equipped to deal with these concerns. The treatment of patients with cleft and craniofacial deformities should be free of bias and demand team care that is patient, family, and community oriented. Only in this fashion can the overall treatment be optimally successful. This type of care maximizes the patient's ability to grow into adulthood and succeed in life without focusing on his or her deformity.

Repair of the Unilateral Cleft Lip: A Comparison of Surgical Techniques

RAMON L. RUIZ, BERNARD J. COSTELLO

Introduction

Cleft lip, with or without involvement of the palate, is a common malformation affecting approximately 1 in 700 live births in North America.[1,2] When a cleft involves at least the lip and alveolus (primary palate), a complex, three-dimensional (3D) malformation is the result. Distortions of the skin, underlying musculature, mucosal membranes, underlying skeletal structures, and dentition are present. The goals of unilateral cleft lip and nasal repair include the creation of an intact upper lip with adequate vertical length and symmetry, repair of the underlying muscular structures with normal function, and primary correction of the associated nasal deformity. Posnick has described the surgical objectives of unilateral cleft lip repair as "the creation of a structure directly adjacent to its mirror image located in the most conspicuous area of the human body."[3]

The first techniques used for the repair of unilateral cleft lip primarily involved a straight line closure of the defect.[2,4] Modifications involving the use of a quadrangular flap offered advantages over these initial techniques.[4,5] The Tennison technique was described in 1952 and involved the use of a triangular flap and vertical repositioning of the Cupid's bow area.[6] Millard[7] subsequently described the rotation and advancement flap technique, which is recognized as the most important technical development in the repair of the unilateral cleft lip and nasal deformity. Today most surgeons in North America and throughout the world use the Millard technique or some close modification of it.

Every cleft surgeon has a favorite technique for the repair of a unilateral cleft lip. In Parts I, II, and III of this chapter, experienced cleft surgeons provide an overview of three popular approaches used in the contemporary surgical treatment of unilateral cleft lip malformations: (1) the rotation and advancement flap technique, (2) the Tennison triangular flap repair technique, and (3) the functional approach to cleft lip repair.

Timing of Cleft Lip Repair

Early protocols describing the staged reconstructive approach to cleft lip and palate deformities referred to the "rule of tens" as a general guideline for the exact timing of the initial lip repair. Surgery was delayed until the child was at least 10 weeks of age, weighed at least 10 pounds, and had a hemoglobin level of at least 10 g/dL.[8,9] These guidelines initially were designed to minimize anesthetic morbidity and mortality in infants. Although contemporary anesthesia practices and pharmacologic agents would safely allow earlier surgery, cleft lip repair during the early neonatal period rarely is undertaken because no measurable benefit exists to performing lip repair before the infant is 10 to 12 weeks old. Today most North American cleft lip and palate programs continue to delay the initial surgery for cleft lip repair until the child is 10 to 12 weeks of age.[3] This largely is because the hoped-for advantages of early lip repair have not been scientifically proven or documented in the world surgical literature. Proponents of surgery during the neonatal period often have referenced the "scar-less" healing associated with fetal development,[9] with the idea being that if surgery is undertaken early in the neonatal period, then "fetal-like" physiology may still be present and the child will have less scar formation at the surgical site. Unfortunately, these benefits have not been observed, and problems with excessive scarring and less-favorable outcomes have been encountered.[3,4] Neonates may have more scarring at this early age, and their tissues are smaller and more difficult to manipulate. Another potential rationale for early surgery is the psychosocial benefit of immediate repair. Again, scientific evaluations have

failed to establish any psychosocial benefit or improved bonding between the mother and child as a result of early cleft lip repair.[4,10]

Description and Comparison of Surgical Techniques

Rotation and Advancement Flap Technique

A key technical component of the rotation and advancement flap technique described by Millard is the creation of a horizontal, back-cut incision within the superior region of the lip near the base of the columella. This allows downward rotation of the central lip to create adequate lip length and provides the needed downward rotation of the Cupid's bow region. The Tennison procedure, in contrast, allows downward repositioning of the lower third of the lip and Cupid's bow.

When the vertical lip incision and horizontal back cut are carried out, a segment of skin along the base of the columella is created and referred to as the C-flap. This C-flap is a portion of excess skin within the medial superior lip/prolabial area that can be used as part of the nasal sill repair or incorporated into the medial lip segment to create additional length.

The advancement flap refers to the lateral lip segment that is advanced into the defect during the repair. The lateral lip segment is prepared by creating a vertical incision with excision of hypoplastic tissue and identification of the orbicularis muscle, undermining of the overlying skin, and creation of releasing incisions within the maxillary vestibule. In addition, a horizontal incision along the alar base allows adequate mobilization so that the leading edge of the flap is advanced for closure of the defect.

Repair of a unilateral cleft lip and nasal deformity with a rotation and advancement flap technique involves the rotation of the medial lip segment downward, release of abnormal insertions involving muscular and cartilaginous structures, advancement of the lateral lip segment, and repair of the three tissue layers (mucosa, muscle, and skin). The popularity of the Millard rotation and advancement flap technique is a result of a number of distinct advantages, including the ability to normalize the position of Cupid's bow and create lip length while positioning the vertical lip scar within the natural line of the philtral column. This approach uses all the prolabial skin to create adequate vertical dimension of the lip. The procedure may be applied to a wide spectrum of cleft malformations with consistent success. In addition, the rotation and advancement flap technique offers the surgeon significant flexibility so that intraoperative adjustments can be made.

Theoretic disadvantages of the rotation and advancement flap technique are most likely encountered in cases of wide cleft defects. One challenge is an insufficient lip length in cases of severe, complete cleft defects. Subsequent wound contracture along a vertical scar may shorten the lip further. Over the years, modifications and refinements to the original procedure have been made by Millard and others to address these potential problems.[11-14]

Tennison Triangular Flap Technique

Unlike the rotation and advancement flap technique described by Millard, the Tennison lip repair technique uses a back cut placed at the bottom of the central lip within the philtral skin along the white roll.[6,15] The defect created in this region is then repaired with a full-thickness triangular flap elevated within the lateral lip segment. This incision placed along the inferior aspect of the philtral column allows downward movement of the Cupid's bow but does not allow inferior displacement (i.e., vertical lengthening) of the entire lip segment to the same extent as the Millard procedure.

Compared with the Millard rotation and advancement flap procedure, the Tennison technique has a number of theoretic advantages. The procedure allows a significant amount of vertical repositioning of the Cupid's bow with a relatively easy maneuver (horizontal incision parallel to the white roll). Proponents of the procedure also argue that the triangular design avoids the problem of wound contracture and lip length shortening encountered with the vertical philtral column scar seen in the rotation and advancement flap operation. Lastly, the tendency to excise too much tissue along the nasal sill and end up with a smaller nostril on the cleft side is decreased with the Tennison procedure.

The most prominent criticism of the Tennison technique relates to the horizontal back cut along the white roll into the philtral column to allow downward rotation of the Cupid's bow. The disadvantage is the placement of a horizontal incision and resultant scar across the philtrum. Surgeons who routinely use the Tennison procedure try to minimize the resultant scar by controlling how far the horizontal incision is extended across the philtrum. The idea is to extend the horizontal incision to the midline only and not to the contralateral philtral column. Another potential pitfall associated with the Tennison repair is the fact that it is more technique sensitive. Specifically, flaps are designed with calipers to measure incision lengths based on numerous anatomic landmarks. Once the flaps are elevated, little opportunity is available for change in design and, in fact, many surgeons describe a point of no return during the procedure in which little or no modification is possible. This stands in sharp contrast to the rotation and advancement flap technique, which allows intraoperative adjustments of the repair. Later in this chapter, the author makes an excellent suggestion: to begin a Tennison repair by first developing all incisions and flaps on the medial aspect of the cleft defect. This allows the surgeon an opportunity to reevaluate the defect intraoperatively and create any final modifications in the lateral flap.

Functional Cleft Lip Repair: The Delaire Philosophy

The theory of a functional matrix that drives facial development is well described in the orthodontic and surgical literature.[16] This concept is that the growth of dentofacial and skeletal components is shaped by the surrounding soft tissue (e.g., skin, muscle) matrices. This important developmental

principle also is at the center of the functional cleft lip repair. Facial clefts disrupt functional muscular fields or musculoaponeurotic units during fetal development. These abnormally positioned soft tissue elements cause disruption of subsequent development of underlying skeletal and cartilaginous structures. In a cleft of the upper lip, specific muscle groups, including the orbicularis oris, transversalis nasi, levator labii superioris, alaeque nasi, zygomaticus, and levator anguli oris, are all involved by the cleft defect, are malpositioned, and have abnormal insertions within the surrounding bony anatomy. Over time, abnormal position and function affect form so that these abnormal muscle insertions and positions lead to a secondary hard tissue deformity.

In a series of publications, Delaire[17-20] was the first to propose a surgical approach for the correction of cleft lip and palate centered around the proper anatomic repositioning of underlying musculature and aponeurotic attachments. Delaire described a system of several muscular sphincters or rings in relation to the nasal and oral structures.[21] His work led to the philosophical approach that the cleft surgeon must reestablish the normal position of these muscular units that comprise the functional matrix of the face so that normal function and growth patterns are created. The idea is to reposition the muscle aponeurotic system and establish an equilibrium to the action of the nasolabial musculature. More recently, Carstens[22] has elaborated on this functional matrix repair with particular emphasis on the embryologic origin of the soft tissue and muscular elements being repaired.

In practical terms, this philosophy of functional repair translates into key differences in the surgical procedure compared with the rotation and advancement flap and Tennison triangular flap procedures. First, subperiosteal dissection is used as part of the functional repair technique. Subperiosteal dissection allows aggressive mobilization of musculoaponeurotic elements and the lower lateral cartilages of the nasal complex. A theoretic advantage of subperiosteal dissection is that less disruption occurs to the blood supply of the muscles being reoriented. This concern for the meticulous preservation of blood supply also is carried over into the incision and flap designs used for functional repair. Surgeons carrying out functional repairs often avoid the use of back cuts across the skin of the columella base and eliminate or minimize horizontal incisions along the lateral alar base to avoid any degree of interruption in blood supply.

Summary

The contemporary armamentarium of the cleft surgeon includes a number of surgical procedures and technical refinements that have evolved over the past 60 years.[4,13] In the three parts that follow, specific attention is given to three popular treatment approaches used in the initial repair of the unilateral cleft lip and nasal malformation. The authors provide an overview of general principles and theoretic advantages and disadvantages. The first of these descriptions covers the Millard rotation and advancement flap technique, which remains the most popular procedure used for the repair of the unilateral cleft lip. Although less popular in the United States, the Tennison triangular flap technique frequently is used in cleft programs worldwide. The description of the Tennison procedure provides a concise review of the technique, an overview of the advantages of the procedure, and a number of clinical examples provided by a world authority on the subject. A review of functional cleft lip repair provides an overview of the philosophical principles advanced by Delaire for the creation of a normalized functional matrix during cleft lip repair. Common to all three approaches is an emphasis on the importance of careful incision design, adequate muscle repair, and attention to primary repair of the associated nasal deformity. The objective of this section of the text is to provide a review of these contemporary principles relevant to the reconstruction of cleft lip. A detailed understanding of a broad range of surgical techniques from which to choose ultimately will provide the cleft surgeon with the greatest likelihood for success.

PART 1: ROTATION AND ADVANCEMENT FLAP TECHNIQUE FOR UNILATERAL CLEFT LIP REPAIR

KEVIN S. SMITH

The asymmetry of the unilateral cleft lip and palate is a complex, multidimensional deformity. Refinements in the surgical approach for the reconstruction of this congenital defect have evolved over time. The rotation and advancement flap technique for cleft lip repair probably is the most widely used operative procedure for the unilateral cleft lip. This cleft lip repair technique was first introduced in 1955 by Millard.[23] The markings and measurements used for the Millard rotation and advancement flap procedure are straightforward and allow the incorporation of intraoperative adjustments during the operation. With this "trim as you go" technique, superior results are routinely achieved.

The objectives of unilateral cleft lip repair include (1) approximation of cleft edges without loss of natural landmarks, (2) repositioning of the cupid's bow into a normal position, (3) placement of incisions and scar along natural lines, (4) muscle repair and alignment, (5) balancing of the alar bases, and (6) an equal columella bilaterally.[24] In combination, these goals address the asymmetry inherent with both incomplete and complete clefts involving the lip and primary palate. Specific components of orofacial cleft deformities involving the lip and alveolus (primary palate) include (1) a muscle continuity defect, (2) vertical deficiency of the lip on the affected side, (3) deficiency of the nasal structures on the ipsilateral side, (4) lower position of the dome of the nasal ala on the ipsilateral side, (5) possible short columella, and (6) an underlying skeletal deformity characterized by a dental crossbite and poor bony foundation on which the nasal labial structures rest.[25]

Although the use of the Millard rotation and advancement flap technique yields consistently favorable results,

some questions have been posed regarding its limitations when applied to wide, unilateral cleft lip defects. The specific potential pitfall when used in wide cleft defects is that the resultant lip repair is vertically short, with insufficient lateral lip vermilion. Modifications to the Millard technique have been made to address this problem better. These refinements have included inferior cutaneous flaps and the white roll flap, which is a small, triangular interdigitation just above the vermilion.[26,27] These modifications were added because of observations by several surgeons that the rotation was inadequate and that significant whistle-type deformities occurred after basic Millard rotation advancement flap.

Another option in cases of wide cleft lip and palate defects is the use of a lip adhesion procedure as an initial phase of surgery. This is performed early during infancy, and the subsequent, definitive lip repair procedure with a rotation advancement technique is delayed for several months. The lip adhesion involves a simple two-layer (lip skin and mucosa) repair of the lip that converts a wide, complete defect into an incomplete, more-narrow defect over time. In addition to narrowing the cleft gap, a theoretic advantage of the adhesion procedure is the secondary molding of cleft maxillary segments into a more anatomically favorable position before final lip closure and/or palate repair. Some authors prefer the use of presurgical orthopedic devices, such as the Latham appliance, with or without a lip adhesion. This provides more aggressive repositioning of the skeletal elements in the hope of simplifying the lip repair surgery and maximizing esthetic results.[28,29] Although the combination of a lip adhesion and Latham device makes the eventual lip repair more easily performed, a negative effect on subsequent mid-facial growth often occurs. More recently, the use of nasoalveolar molding techniques has grown in popularity. Presurgical nasoalveolar molding is applied to improve the position of maxillary segments and idealize soft tissue contour and position before initial lip and nasal repair. The use of nasoalveolar molding in the cleft lip and palate patient is discussed in greater detail in Chapter 31.

During the 1940s and 1950s, the late Dr. Oscar Asensio of the Hospital Centro Infantil de Estomatologia in Antigua, Guatemala, was simultaneously developing a technique involving a modification of the rotation and advancement flap procedure. Asensio's operation for the repair of the unilateral cleft lip is significant in that it allows for the creation of significant vertical dimension while preserving lateral vermilion.[30] Asensio, an oral and maxillofacial surgeon, described in English his technique for rotation and advancement flap at the American Association of Plastic Surgeons meeting on June 25, 1973.[30] At that time he had operated on more than 548 clefts. In the years before that, Asensio was confronted with a significant number of wide cleft lip malformations not being repaired in Guatemala. His technique proved to be useful in cases in which patients had large defects and the adjuncts of lip adhesion and presurgical orthopedic appliances were not readily available. His son, Dr. Rodolfo Asensio, trained in pediatrics and oral and maxillofacial surgery, continues his father's work in Antigua to this day. Together, both Asensios have repaired more than 3000 clefts. These procedures typically are performed under local anesthesia and sedation.

Presurgical Care

If nasoalveolar molding, lip taping, or pin-retained orthopedic (Latham) treatments are planned, they should be initiated during the second to fourth weeks of life. Impressions are made and used in the fabrication of the appliances. The preferred technique for lip taping is to use a type of occlusive wound care dressing on the skin so that the tape will not touch the skin. The dressing is applied with a skin adhesive, and any lip taping materials are then adhered to the dressing. This ensures minimal skin irritation of the infant during the taping procedures. As with the nasoalveolar molding and Latham-type devices, lip taping is time consuming and relies on compliant parents. Nasoalveolar molding can be accomplished in the wide unilateral cleft lip, and the author's personal experience has revealed that this technique is simpler and less costly than the Latham-type appliance. Another benefit of nasoalveolar molding is that it does not appear to have the negative effect on mid-facial growth observed with the use of the Latham device.

Description of Surgical Procedures

Millard Rotation and Advancement Flap Technique

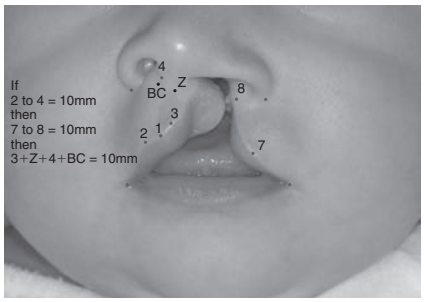
The rotation and advancement flap technique described by Millard is the most frequently used repair by cleft surgeons worldwide. Most surgeons add their own preferences and modifications to this technique depending on the specific cleft deformity (complete, incomplete, etc.) and individual patient's anatomy.

Figure 29-1 demonstrates the classic anatomic landmarks used in the Millard procedure. Those points are identified to make initial measurements and achieve anatomic alignment of specific soft tissue elements. To preserve maximal soft tissue, initial incisions are followed by paring of tissue elements as the procedure continues.[24]

• **Figure 29-1** Anatomic landmarks used for the Millard and Asensio rotation and advancement flap techniques. Identification of these key points is initially performed; they are the basis of measurements used for flap creation and alignment of soft tissue elements.

Three key technical principles of the Millard rotation and advancement flap procedure are as follows:

1. The rotation of the cleft edge of the noncleft side is the most important principle to understand and perform to obtain adequate vertical height at the cleft philtral ridge. This is accomplished by the measurement between the base of the columella (point 4) and the Cupid's bow on the noncleft side (point 2). This distance equals the total length of the incision made on the cleft edge of the noncleft segment, from point 3 to the base of columella (point Z) and including the back cut (BC). A bent wire is sometimes used to confirm this distance. The wire is used to represent this curvilinear incision with the back cut included (Figure 29-2). Additional height can be obtained in the area of the cleft by making a white roll flap incision at the area of point 3. When used, this usually is a 1- to 2-mm incision to allow increased rotation of the vermilion segment.
2. The vertical height of the lateral lip segment on the cleft side must be developed to a length equal to the rotation segment. If the distance between point 7 and point 8 is insufficient, tissue is pared away laterally in the area of point 8 to increase the vertical dimension until it equals the measured distance on the rotated side. If a white roll flap is to be used at the vermilion border, it should be developed when these cuts are made just above point 7 (area *F* in Figure 29-3). The final incisions are demonstrated in Figure 29-3. The C-flap can be used to create a nasal floor repair or incorporated into the noncleft side to increase the amount of rotation and length.
3. The third principle critical to the Millard procedure is that of muscle dissection and reconstruction. The orbicularis oris must be identified and isolated separately from the overlying skin and mucosa. The muscle should be freed several millimeters into the lip element on either side so that anastomosis of the lip muscle can be accomplished as a distinct layer of the repair (Figure 29-4).



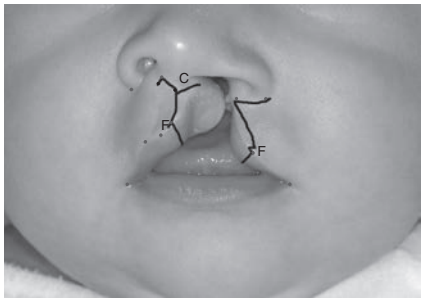
• **Figure 29-2** Markings and measurements used for the Millard-type rotation and advancement flap cleft lip repair. *Points 1, 2,* and *3* represent the outline of Cupid's bow. *Point 4* represents the base of the columella. *Point Z* is the lateral base of the columella on the side of the cleft. *Point BC* represents the extent of the back cut. In measuring for a Millard-type closure, the distance from *points 2 to 4* will equal the curvilinear cut that goes from *points 3 to Z to 4* and then to *BC*. That total distance will also be equivalent to the measurement from *points 7 to 8.*

Intraorally, closure of the wide cleft lip requires the vestibular incision on the cleft side; in wide clefts this incision occasionally must be extended superiorly into the nasal cavity, almost to the point of the inferior turbinate. This tissue has been undermined in the supraperiosteal plane to allow adequate advancement of tissue on the cleft side.

Asensio Technique for Rotation and Advancement Flap

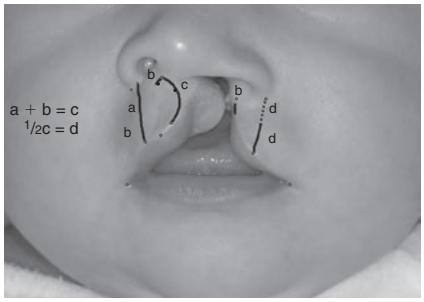
The general principles of this closure for unilateral cleft lip defects are quite similar to the Millard rotation and advancement flap technique. The primary modification made in the Asensio procedure involves the excision of a soft tissue segment from the lateral advancement flap to create additional length while preserving vermilion tissue. The Asensio technique is defined specifically by the initial measurements and markings and requires little refinement once the incisions have been made. Elements of the landmarks, markings, and surgical steps for the Asensio technique are as follows:

1. Anatomic landmarks within the alar base, Cupid's bow, and lip segments are marked on each side (see Figure 29-1) in identical fashion as for the Millard procedure. Landmarks are identified and key white roll points are marked. On the lateral side, the end of the distance from the white roll point at the leading edge of the advancement flap is measured to the commissure for comparison with the contralateral side.

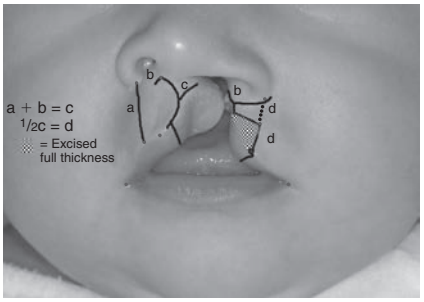


• **Figure 29-3** The final incision design for the Millard-type rotation and advancement flap closure. The C-flap can be placed into the base of the columella or into the nasal sill region. *F* represents possible back cuts for additional lengthening with the use of a white roll flap above the vermilion border.

• **Figure 29-4** Intraoperative view of the lateral advancement flap dissection. The center forceps are holding the well-defined orbicularis oris muscle. Defining and joining the two sides of the muscle is of utmost importance in cleft repair.



• **Figure 29-5** Measurements and markings for the Asensio technique. Rotation length is again determined by measuring the distance from the alar base to the white roll point on the noncleft lateral Cupid's bow. *Line b* is the back cut distance and *line c* is equal to a ±1 b. One half of *line c* will become the distance of *line d.*



• **Figure 29-6** The final incision design for the Asensio technique (excluding intranasal incisions). The *patterned area* is the area for full-thickness excision. White roll flaps can be included in the design if needed. Note *line a* is not an incision, but rather only one of the original measurements.

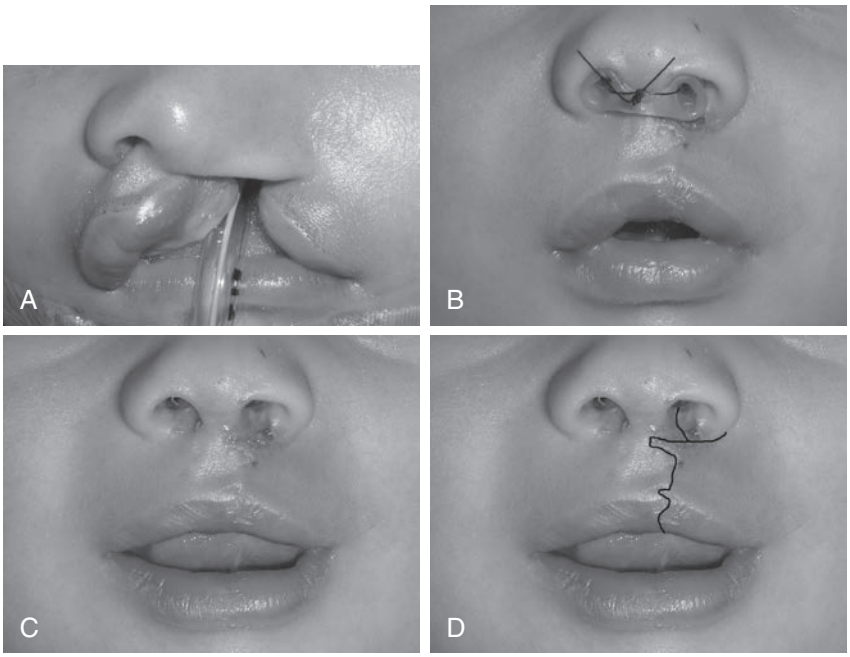
2. The distance of the height of the ala to the lip is now measured on the noncleft side. This distance is labeled *distance a* and is called the alar height. Add 1 to 3 mm to *distance a* depending on the size of the patient's lip: 1 mm for an infant, 2 mm for a child, and 3 mm for an adult. This small additional measurement is referred to as *distance b* and is used to calculate the length of the back cut. Next, the addition of *distances a* and *b* equals the length of the incision labeled *distance c* in Figure 29-5. *Distance c* is then measured in a curvilinear manner from the Cupid's bow to the columella and marked. In addition, the *distance b* measurement is added for the back cut. These markings are similar to those used in a Mallard-type rotation advancement.
3. On the lateral lip element, distance of *line c* is then divided in half and used to calculate the length of a new incision *line d.* Putting one point of a compass at the previously marked alar base, an arc is swung using *line d* as the radius. After putting one point of the compass at the end of the white line, another arc is drawn using *d* (½ the length of *c*) as the radius, where these arcs intersect (see Figure 29-5). This establishes the length of the lateral lip after the incisions are created. This ensures that the length of the lateral, advancing lip segment will match the length of the rotation side. After this point has been marked, the quadrilateral flap is drawn, with the width of the leading edge equal to the length of *distance b,* as illustrated in Figure 29-6. The termination of the superior border of the quadrilateral flap goes to the outer edge of the ala. The lower edge of the quadrilateral flap goes to the point where the arcs met. Note that the area shaded in Figure 29-7 represents a full-thickness excision of the lateral lip advancement flap. If a white roll flap is to be used at the vermilion border, it can be developed during the final stages of the procedure.

• **Figure 29-7** The final result of left complete cleft lip repair for the patient seen in Figure 29-6, using an Asensio technique. The photograph was taken 1.5 years after surgery.

Nasal Reshaping

In addition to rotation and advancement flap maneuvers and careful muscle reconstruction, cleft surgeons must address the abnormal position of the lower lateral nasal cartilages in the cleft patient. Once adequate mobilization of the advancement flap has been accomplished, mobilization of the nasal cartilages on the affected side must be performed to release cartilaginous structures from their abnormal attachments to the underlying piriform rim. McComb[31] described lower lateral nasal cartilage lifting during initial cleft lip repair. The technique is relatively simple and involves careful dissection between the lower lateral cartilage and cutaneous elements. These structures may be approached through the columellar and lateral alar incisions. Once the cartilage has been thoroughly dissected free of the skin, intranasal splinting techniques can be used to hold the cartilages in a more normal anatomic position. The technique originally was described using bolsters and sutures and lifting the suture transcutaneously superiorly on the nose with another bolster on the skin.

The author's preferred technique involves the use of silicone nasal formers. They are available in a multitude of



• **Figure 29-8** Clinical photographs of a patient with a wide, unilateral, complete cleft of the lip and palate. Initial lip repair was performed with a rotation and advancement flap procedure with the Asensio technique. **A,** A wide cleft defect before closure. **B,** One week after surgery, the patient shows good healing of the lip closure, and silicone nasal stents are still in place. **C,** Stent removal reveals maintained nostril shape and healing nasal floor. At this stage good symmetry has been achieved. A good wound care regimen, as described in text, is vital. **D,** Line drawing of the Asensio technique incision design used in this patient.

sizes, can be sutured in place, and remain intact during the initial phase of postoperative healing. Care must be taken to observe for wound dehiscence and mucosal ulceration intranasally. The use of silicone nasal molding devices also requires extra care on the part of the family in that the devices need to be cleaned and irrigated on a regular basis with saline and a syringe with a catheter. Infants are obligate nasal breathers, so the nasal stents must be kept free of dried mucus and blood. Nursing staff and parents must understand the proper technique in cleaning these stents before discharge.

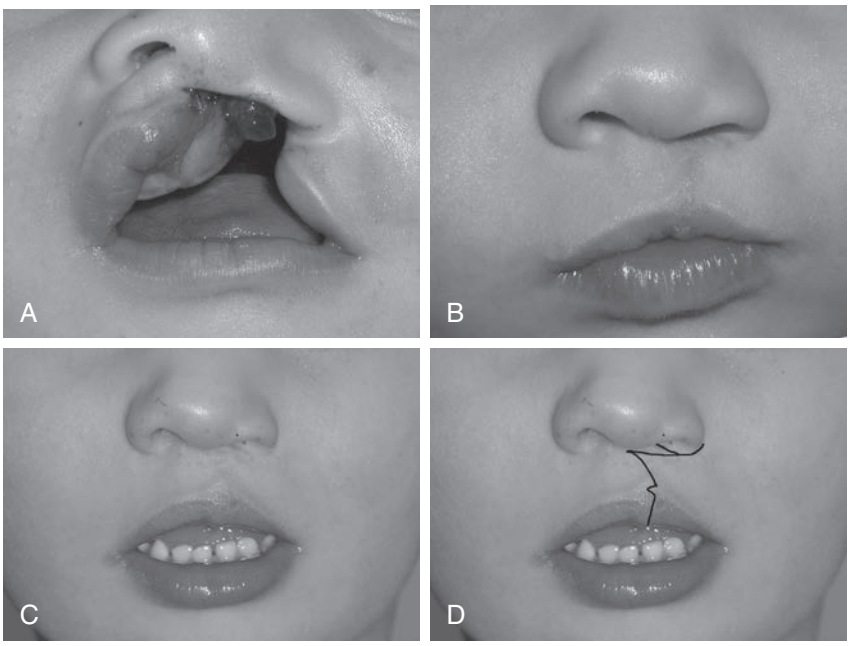
Postoperative Care

In addition to nasal bolsters or stents, a lip dressing is applied with skin adhesive lateral to the incisions and ¼-inch sterile tape as a simple coverage for the wound. This taping over the lip segments also provides support for the completed lip repair. If good muscle and subcutaneous closure have been accomplished, a Logan's bow or other device is not necessary. The infant may need to have arm restraints postoperatively, but generally these can be discontinued at 2 weeks. At 1 week after surgery the nasal stents can be removed. The sterile tape dressing over the lip usually lasts 3 to 5 days or can be removed at the first postoperative visit 1 week after surgery. Any minor scabbing present can be removed with dilute hydrogen peroxide for daily wound care over the course of the next week. In addition petroleum jelly can be applied to the wound to help soften any scabbing.

At postoperative week 2, definitive wound care must begin. This wound care regimen can include massage with vitamin E oil with a two-finger technique, in which one finger is placed inside the lip and one finger is outside, as much as the infant can tolerate. Once the vitamin E oil has been massaged into the skin, a silicone gel material is placed over the wound. This is accomplished twice a day with gentle cleaning with mild baby soap before the massages. This twice-daily regimen should be continued for 4 months.

Summary

The rotation and advancement flap technique remains the most popular surgical approach for the repair of the unilateral cleft lip deformity (Figures 29-8 and 29-9). The principles as described by Millard are easily applied and allow modification of the lip repair procedure depending on specific patient anatomy and the configuration of the cleft defect.



• **Figure 29-9** Clinical photographs of a patient with a wide, unilateral, complete cleft of the lip and palate. Initial lip repair was performed with a Millard rotation and advancement flap procedure. **A,** A wide cleft defect before closure using the Millard rotation and advancement flap technique. Note the presence of a natal tooth within the cleft. **B,** Six-month postoperative result for the Millard-type cleft repair; the family was diligent in postoperative wound care, massage, and the use of silicone scar gel. **C,** Eighteen-month postoperative results. Note increased nasal asymmetry and some elevation of the vermilion. Child may require minor revision of the nose and vermilion around school age. **D,** Line drawings of the Millard technique used in this patient.

PART 2: SURGICAL CORRECTION OF UNILATERAL CLEFT LIP WITH TENNISON—RANDALL TRIANGULAR FLAP TECHNIQUE

RAFAEL RUIZ-RODRIGUEZ

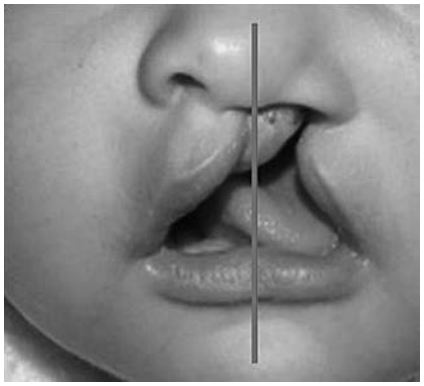
The management and specific surgical technique used for the correction of the unilateral cleft lip deformity remains a controversial topic among cleft surgeons. Several different operative techniques are used, each with distinct theoretic advantages when compared with the others. The evolution of most techniques began with an ancestral straight-line closure.[32] Later, a quadrangular flap technique was described by Hagedorn and modified by Le Mesurier.[33-35] These prominent pioneers were trying to build an artificial Cupid's bow through the insertion of a quadrangular flap inside the philtrum.

Two techniques described during the mid-twentieth century remain popular choices for cleft lip repair today. In 1952 Tennison[36] described a triangular flap technique that was subsequently modified by Randall and Hagerty in 1958.[37,38] In 1957 Millard described a rotation advancement flap technique.[39] Common to all these techniques were two primary goals: (1) the preservation of anatomic structures present, even in the deformed lip, and (2) anatomic repositioning of lip segments into a more natural position. For example, the Cupid's bow is present but is displaced toward the noncleft side and rotated superiorly into a position that is oblique to the horizontal facial plane. Worldwide, a majority of surgeons use one of these two popular techniques, often with specific modifications based on the reconstructive needs of the patient and surgeon preference.

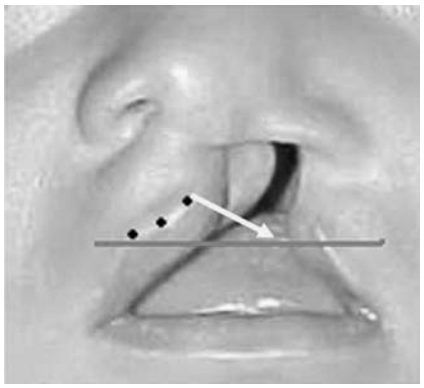
In 1952 Tennison[36] described his stencil method, in which he "preserved" the Cupid's bow and used a segment of wire to develop the surgical measurements. In the same year Cardosa[40] emphasized Tennison's main idea, which was the preservation of the Cupid's bow. He also recommended the use of a caliper instead of a wire. This idea was supported by Randall, Hagerty, and Cronin, each of them making some small and personal modifications.[37,38,41]

In contemporary practice, most experienced cleft surgeons would likely agree that the key to a successful cleft lip repair is the management of the Cupid's bow. The principles and objectives of cleft lip repair rely on the fact that the philtrum is abnormally displaced from the midline (Figure 29-10) and that the Cupid's bow is rotated superiorly, sometimes almost perpendicular to the horizontal plane. In crafting the surgical technique, the adequate mobilization of the philtrum toward the midline and the downward rotation of the Cupid's bow must be considered (Figure 29-11). In this manner, a normal lip is created in both vertical and horizontal dimensions.

When considering surgical maneuvers aimed at lowering the vertical position of the Cupid's bow, an incision within the philtrum provides adequate inferior rotation of the highest point of the bow (peak of the bow on the cleft side of the lip) to establish normal position. This incision creates a soft tissue



• **Figure 29-10** An unrepaired, left, complete unilateral cleft lip deformity. Note the significant displacement of the philtrum away from the midsagittal plane. The Cupid's bow is asymmetric and rotated superiorly on the cleft side. The degree of superior malposition can be so severe that the Cupid's bow is almost perpendicular to the horizontal plane.



• **Figure 29-11** A successful surgical repair must reposition the Cupid's bow inferiorly and toward the midline.

• **Figure 29-12** The Tennison procedure uses an incision from the mucocutaneous junction, along the white roll, to the middle of the philtrum to carry out downward rotation of the Cupid's bow.

• **Figure 29-13** In the Millard rotation and advancement flap procedure, a curved vertical incision is created from the base of the columella to the mucocutaneous junction. This creates downward rotation of the entire central lip.

space or defect that must be filled with a soft tissue flap from the advanced lateral segment. Tennison's technique accomplishes this goal by making a perpendicular incision along the white roll from the mucocutaneous junction to the middle part of the philtrum. The resultant defect is then occupied by a triangular flap from the lateral segment (triangular flap technique) (Figure 29-12). In contrast, the Millard rotation and advancement flap technique achieves the necessary inferior rotation of the central lip by creating a curved incision from the base of the columella down to the mucocutaneous junction, filling the space with the leading edge of the lateral lip segment. The procedure is given its name because of the downward rotation of the central lip to create adequate vertical length and advancement of the lateral flap to close the defect (Figure 29-13).

Tennison Technique versus Millard Rotation and Advancement Flap for the Correction of Unilateral Cleft Lip

The Tennison technique has a number of advantages, but the most important one is the versatility of the procedure, which may be applied for the repair of a broad range of clefts from incomplete to wide complete deformities. It is the author's point of view that a Millard rotation and advancement flap procedure, in cases of wide clefts with severe rotation of the Cupid's bow peak, does not permit enough downward rotation of the peak. This results in a deficient vertical lip length on the affected side. This is also the reason why Millard described his Millard II technique, in which he added modifications that included a back-cut incision at the base of the columella, allowing more downward rotation of the Cupid's bow.[42-44] In addition, Millard's technique could leave a long, straight scar from the base of the columella to the white roll, which can develop an undesirable vertical retraction, making the lip even shorter. Another disadvantage is the creation of a nostril that is smaller than the normal side. The main use of the Millard technique at our center is for more-narrow cleft defects in which a large downward rotation of the peak is not required.

One challenging aspect of the Tennison operation is the highly technique-sensitive design that requires precise measurements at the beginning of the procedure and allows little deviation intraoperatively. This is in sharp contrast to the Millard technique, which actually permits modifications during surgery. In fact, surgeons may believe that there is a point of no return during the Tennison operation in which no modifications of the original design can be made. Therefore a miscalculation during the initial design can lead to poor results in the end: a lip that is either too short or too long. This problem mostly occurs as a result of

inappropriate planning and an incorrect design rather than a poor technique.

Most surgeons who do not routinely use the Tennison procedure cite the unfavorable position of an incision that invades the philtrum with the triangular flap. This undesirable component of the Tennison repair may be minimized by modifying portions of the incision over the philtrum. Despite this concern, the Tennison technique allows repair of large cleft malformations quite easily. In wide cleft defects, a large amount of downward rotation of the Cupid's bow peak is required. If a Millard procedure is used for the repair of a wide cleft, many surgeons suggest performing a lip adhesion before attempting the definitive repair. In this manner, a complete wide cleft initially is converted into an incomplete cleft. This additional surgical step does not necessarily help the patient's esthetics or feeding, and it requires an additional general anesthetic exposure. In these cases, the cleft can be nicely repaired by the Tennison technique, with acceptable results in the majority of the cases.

Surgical Planning and Markings

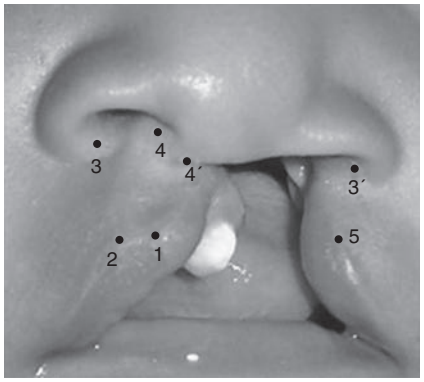
Surgical repair typically is undertaken when the patient is approximately 10 weeks old. The procedure is performed under general anesthesia with oral endotracheal intubation. The first consideration is placing the endotracheal tube in the midline in a rest position to avoid any lip displacement toward one side, which might lead to inaccuracies in the design. Once the endotracheal tube and the patient's head are secure, the surgeon is positioned at the head of the operating table. A fine surgical skin marker is used to mark the selected anatomic landmarks carefully on the cleft side of the defect; these landmarks are illustrated in Figure 29-14 and listed in Table 29-1.

In the original description by Tennison, a measurement was made from the commissure of the lips to the peak of the Cupid's bow on the normal side. This measurement was then directly transferred to the cleft side. This maneuver generally is avoided now because the deviated, abnormal position of the philtrum distorts this measurement, and its use is likely to result in an incorrect horizontal length for the repaired lip on the cleft side.

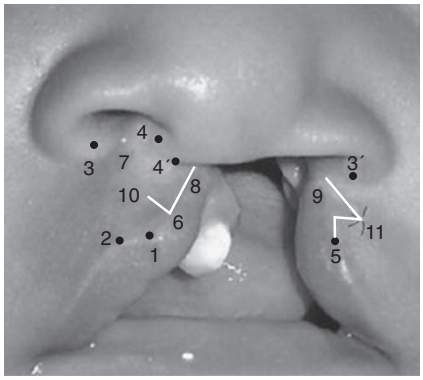
The landmarks on the noncleft side are initially marked, and some are then used to measure and transfer markings onto the cleft side. After these measurements are transferred, the incisions are designed. A horizontal incision within the philtral region and a triangular flap within the lateral segment are then designed (Figure 29-15). This is done by creating a straight line from the base of the columella on the cleft side to the peak of Cupid's bow; a back cut is then created that extends into the philtrum. Calipers are used to measure the vertical and horizontal components of this line, and the dimensions are used to craft the triangular flap on the lateral lip segment. Although the sequence of markings and measurements used are different from previous descriptions, the author believes this sequence allows an easier understanding of the procedure. In addition, proper closure of the nasal sill requires that the incisions described be extended along the inside of the nose to the septum on the medial side and up to the lower turbinate mucosa on the lateral side. These incisions ultimately are used in combination with vestibular-releasing

TABLE 29-1 Anatomic Landmarks

Landmark	Location
1	Lowest (central) point on the Cupid's bow
2	Peak of Cupid's bow on the noncleft side
3	Base of the ala on both sides
4	Base of the columella on both sides
5	Specific white roll point on the cleft side, where the vermilion begins to diminish; represents the peak of Cupid's bow



• **Figure 29-14** Initial identification of key anatomic landmarks used in the repair of the unilateral cleft lip and nasal deformity. Points include the center of Cupid's bow (marked *1*), peak of Cupid's bow on the noncleft side (marked *2*), alar bases (marked *3*), base of columella (marked *4*), and peak of Cupid's bow on the lateral cleft side (marked *5*).



• **Figure 29-15** Incision design for the Tennison technique. A *straight line* is marked from *points 8 to 6*. From the junction of this line with the white roll, a horizontal line will be extended within the philtrum. This will end at landmark *10*. To determine how long this incision will be, the distance between landmarks *7* and *2* and *8* to *6* must be measured. The difference between those two measurements determines the incision length inside the philtrum. Calipers are used to measure the distance from *points 6 to 10*; by placing the tip of the caliper on *point 5*, an equilateral triangle will be created on the lateral side.

incisions to allow adequate mobilization of the anatomic structures and release of cartilaginous and soft tissue structures from abnormal bony insertions (Figure 29-16).

To achieve good surgical results, we must consider the severity of the cleft as well as the deviation from normal of all the anatomic structures that form the lip, such as the nasal mucosa excess and the depressed paranasal area from the misalignment of the maxillary process (Figure 29-17).

Surgical Technique

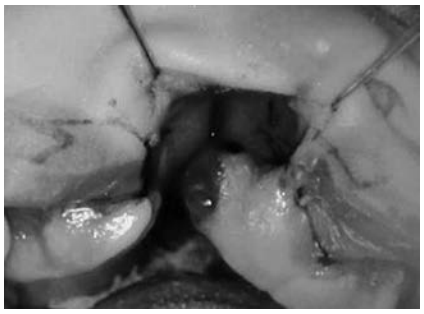
After the incision design is finalized (Figure 29-18), the borders of the cleft and the maxillary vestibule are injected with 0.5% of lidocaine with 1:100,000 epinephrine. The author recommends that the surgeon never inject before designing the repair because the infiltration of anesthetic fluid distorts the anatomy of the cleft.

• **Figure 29-16** Continuation of the incisions along the base of the nose, septal mucosa, and mucosa of the lower turbinate. In addition, vestibular releasing incisions allow adequate mobilization and repositioning of lip segments.

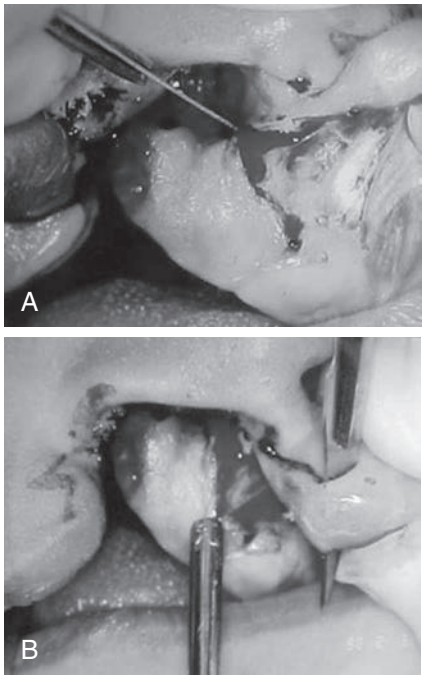
The author's preferred approach is to begin with the vestibular and nasal sill incisions on the medial side of the cleft defect and then proceed outward toward the skin incisions. Supraperiosteal dissection is carried out, followed by the creation of incisions on the skin of the medial side. The author strongly recommends starting on the medial side of the cleft defect because the extent of lowering and position of Cupid's bow can be evaluated and modifications to the original design can still be made. If modifications are required, the incision from points 6 to 10 can be made larger or smaller, and the size of the triangular flap from the lateral side can be modified as well. The initial dissection is carried out to create the floor of the nose. The skin incisions are started with a No. 15 blade and completed with a No. 11 blade (Figure 29-19).

After the initial incisions are created, dissection along the medial aspect of the cleft is undertaken (Figure 29-20). This involves dissection of the muscle from its abnormal insertions at the anterior nasal spine up to the tip of the nose, careful not to touch the nasal cartilage. Damage of the cartilages at this age will produce a lack in growth. The muscle will be dissected off from the labial mucosa as well as from the skin to avoid tension at the time of suturing. The muscle is removed by sharp dissection because no fascia layer is at this level and the main goal is to reorient the muscle to create a normal function and mimic the lip. After the muscle is

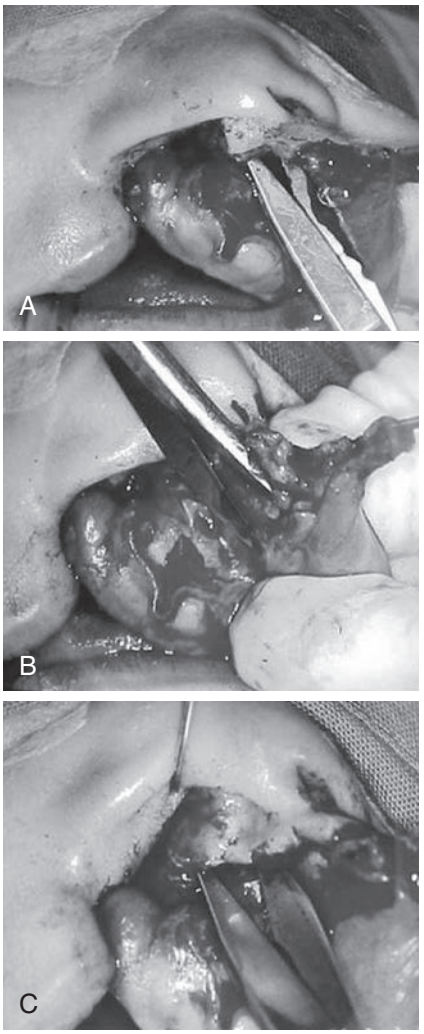
Note the deviation of Cupid's bow. In addition, the 3D malformation includes malpositioned skeletal segments, excess nasal mucosa, asymmetry of the paranasal regions, and abnormal insertions of soft tissue structures on the piriform rim.



• **Figure 29-18** Markings for the repair of a right unilateral cleft lip. Measurements and incision design are finalized before anesthetic containing vasoconstrictor is administered.



• **Figure 29-19** Initial incisions and dissection are focused on the medial aspect of the cleft defect. **A,** Skin incisions are started with a no. 15 blade and completed with a no. 11 blade (**B**). Care is taken to bevel the blade toward the midline to preserve as much usable tissue as possible.

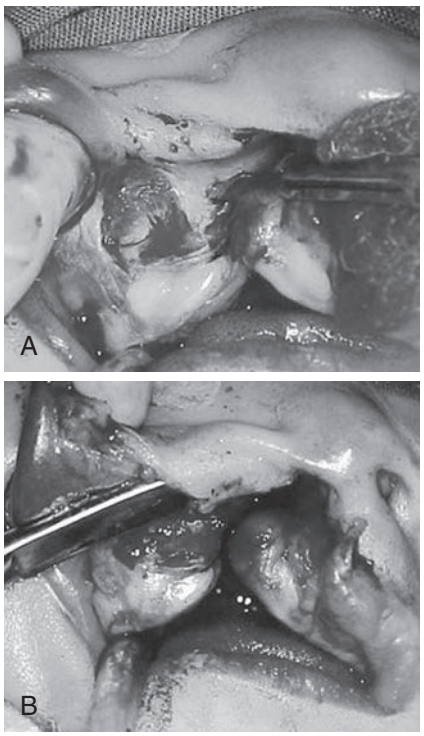


• **Figure 29-20** Dissection of the medial side of the cleft defect with a Tennison technique. A, Separation of the muscle from the overlying skin and labial mucosa. **B,** Sharp dissection to free the orbicularis oris muscle so that normal muscle orientation can be established. **C,** Dissection along the septal mucosa. Meticulous care is taken to avoid damaging the septal cartilage.

completely freed, dissection of the mucosa from the septum will take place, with the surgeon being aware of the high risk of damaging the septum cartilage if a deep dissection in that area is made.

After initial dissection of the medial side is complete, the lateral side incisions are created. On the lateral side supraperiosteal dissection from the sulcus up to the lower turbinate is carried out. The lip is freed and displaced toward the midline. The dissection of the muscle is continued from its abnormal position at the base of the ala to a more normal orientation. Next, the alar cartilage is freed from the nasal skin and from the nasal mucosa to allow it to conform in its new position (Figure 29-21). Better results are obtained by using a silicon conforming splint within the operated nostril during the healing phase. Once the dissection inside the nose is completed, the nasal floor is evaluated and approximated to obtain closure without tension (Figure 29-22). A final check of all the components of the repair, including adequate downward rotation of the Cupid's bow, mobilization of the lip toward the midline, and symmetry of the nostrils, is performed.

Closure of the lip and nasal components is then carried out (Figure 29-23). Suturing the floor of the nose as posterior as possible is performed with 4-0 Vicryl (Ethicon, Inc., New Brunswick, NJ). The muscle is sutured next with 4-0 or 5-0 Vicryl sutures, depending on the width of the cleft and the tension that could exist. Careful suturing is performed while placing the muscles oriented in a horizontal position. Next, "key sutures" of the skin are placed with 6-0 nylon. These anatomic landmarks include the corner of the triangular flap and the white roll points. The remainder of the closure is completed with 6-0 or 7-0 nylon on the skin and 5-0 chromic gut at the end the vermilion border and oral mucosa.



• **Figure 29-21** Lateral dissection. **A,** Vestibular incisions are made and dissection is carried out along the base of the nose and lower turbinate mucosa. **B,** Alar cartilage is freed from nasal skin, mucosa, and abnormal bony insertions.

• **Figure 29-22** Evaluation of the nasal floor before closure.

Summary

Although the Tennison technique remains popular in Asia, Europe, and Latin America, few surgeons in United States are in favor of this useful procedure. The most common complaint associated with the Tennison repair is related to the creation of an incision that invades the philtrum with the triangular flap. At the author's institution, more than 25 years of surgical experience has demonstrated that both techniques, with or without modification, offer distinct advantages and some disadvantages (Figure 29-24). A critical analysis of results must include evaluation of the following: (1) the proper horizontal repositioning of Cupid's bow, (2) symmetry of the nostril and alar base, (3) labial tubercle on midline and a vermilion border with proper fullness, (4) adequate lip length and symmetry, (5) proper nasolabial angle, (6) adequate paranasal fullness, (7) adequate labial projection, and (8) good projection of the nasal tip. Application of the Tennison technique gives the surgeon an opportunity to achieve each of these outcome objectives.

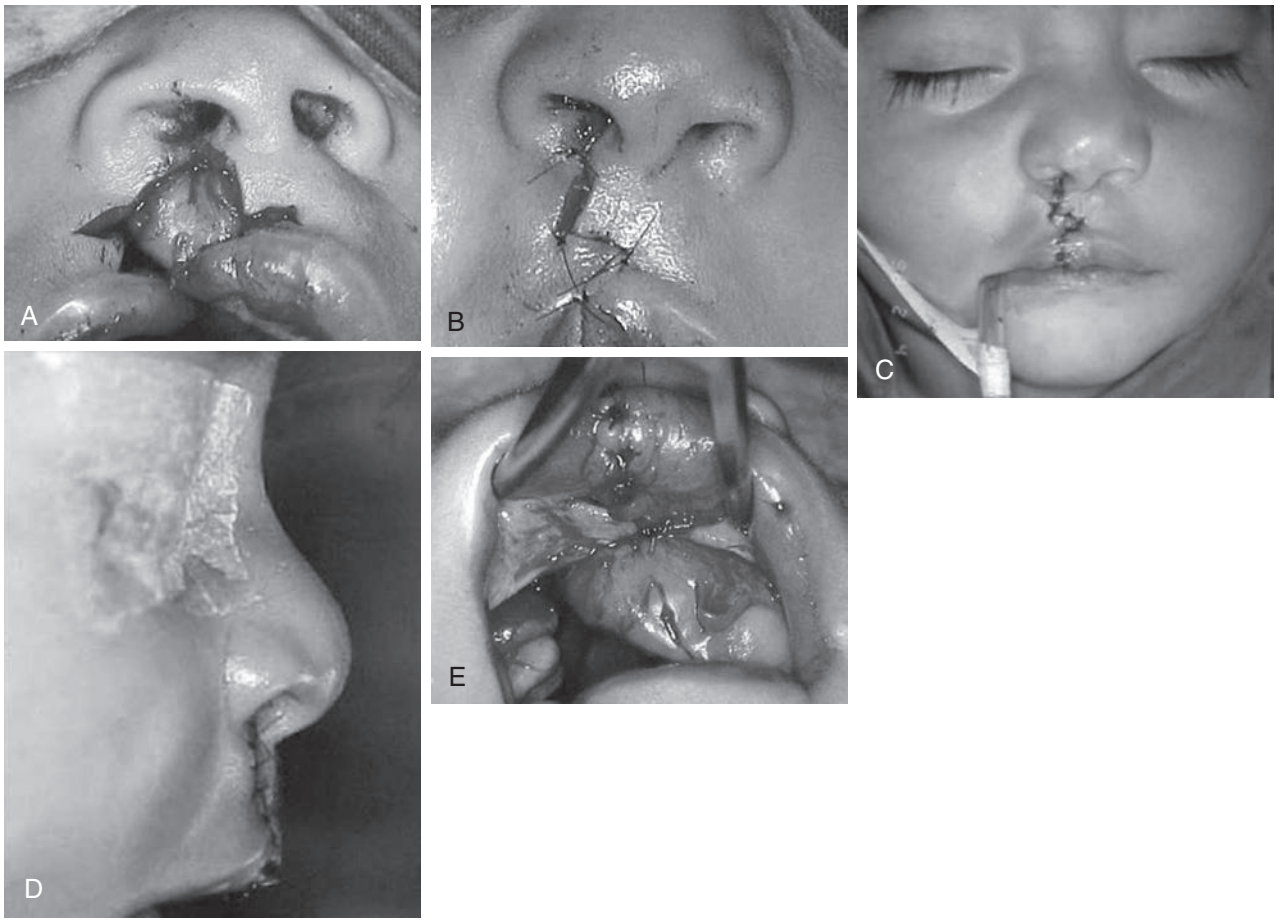
An interesting observation is the fact that surgeons who are familiar with the rotation and advancement flap technique often are unfamiliar with the technical details and potential applications of the triangular flap technique. In contrast, surgeons who routinely choose the Tennison approach as their first choice in repairing wide cleft defects usually are quite familiar with the Millard procedure and often apply it for smaller facial clefts. The author believes a working knowledge of both procedures gives the cleft surgeon the flexibility of selecting the best operative treatment for each patient based on the specific cleft malformation.

PART 3: FUNCTIONAL CLEFT LIP REPAIR

BRUCE B. HORSWELL AND IMAD E. SHAMI

Functional cleft lip and nasal repair is a concept of reconstruction based on basic anatomic and developmental arrangements, which in the orofacial region are key for normal growth, function, and appearance. The application of this concept for the surgical repair of orofacial clefts was first proposed and subsequently investigated by Delaire et al.[45-50] over the course of almost 3 decades. They noted that a cleft of the labiomaxillary region disrupted important functional musculoaponeurotic fields beginning in early fetal development and that this disruption exerted maladaptive influences on associated cartilaginous and skeletal structures. The observations of many clinicians point to the deleterious effects of muscular disinsertions around the cleft and the necessity for total muscular reorientation at the time of primary cheilorhinoplasty to provide a normal functional matrix from which proper form and development can take place, as proposed by Moss.[51]

The facial anatomic field concept, which derives from basic embryologic units and determines the consequent maldevelopment in the cleft deformity, is well articulated by Carstens[52] and Schendel.[50] In essence, clusters of programmed neuromeric cells may be adversely affected by an event in utero (e.g., hypoxia), resulting in a deficient state of cells (reduced numbers or volume) or giving rise to misprogrammed cells that do not participate normally in subsequent cellular differentiation and lead to the development of a cleft. This translates into disrupted and displaced tissue elements within the orofacial region—principally the developing muscle envelope around the nasal, lip, and palatal regions. Underlying skeletal structures follow suit and become displaced and hypoplastic. Muscle function is stimulatory to the underlying bone, and if proper muscle reconstruction is not undertaken the piriform rim, nasal floor, and anterior maxilla remain deformed and hypoplastic. The disrupted muscular envelope and individual muscles must



• **Figure 29-23** Closure of the lip and nose. **A,** Preliminary suture to evaluate the nostril and nasal base. **B,** Initial sutures at key anatomic landmarks. **C** and **D,** Frontal and profile views of the final closure. **E,** Closure of the vestibule and lip mucosa.

be identified, mobilized, and properly reoriented in repair to provide a functional matrix environment—hence the term functional matrix repair.[52]

Cleft Model and Repair

Delaire et al.[45-50] have described the orofacial musculature as being arranged in circumferential musculoaponeurotic slings or sphincters around the nose and oral cavity. The disrupted and displaced muscles are schematically demonstrated in Figure 29-25.

Each of these muscles is joined to its counterpart through aponeurotic attachments or indirectly by the *orbicularis* outer sleeve. In the cleft condition, the transversalis and levator (alaeque and labii) heads are disinserted superiolaterally. This results in the elongated, thinned, and slumped ala of the nose and abnormal retraction of the lip segment (Figure 29-26).[53] At the perioral region, the orbicularis muscle takes an oblique lateral course, which is accentuated in the cleft condition.[54] It further displaces the musculoaponeurotic layer inferoposteriorly because nothing tethers it to its counterpart in the sling. As a result, the facial midsagittal and transverse axis are deviated to the noncleft side. Such distortion is difficult to overcome unless complete muscle mobilization and proper alignment take place at the primary repair. A nonfunctional repair, as noted in Figure 29-27, does not eliminate the influence of abnormal muscular position on subsequent skeletal development. The result is disruption of normal lip and nasal alar growth. The 3D computed tomography scan reveals associated skeletal dysmorphology involving the hypoplastic piriform rim on the affected side.

In concert with proper muscle repair, the lower lateral cartilage on the cleft side must be freed through selective dissection to allow the soft tissue repair to rearrange the cartilaginous elements. This occurs as the reconstructed muscular sling (principally the levators and transversalis) brings with it the overlying and underlying nasal and vestibular skin, respectively.[53] Muscular contraction (levators, transversalis), constriction (deep orbicularis), and depressor action (myrtiformis) further enhance soft tissue development and form.[55] In fact, Park and Ha[54] emphasize the necessity of proper orbicularis sleeve microdissection and reorientation for the lip to achieve fullness in form and natural function. Bony stimulation and deposition take place when under the positive muscular influences, which results in a more balanced and symmetric skeleton.[55,56]

• **Figure 29-24** Clinical photographs of children before and after undergoing unilateral cleft lip repair with the Tennison technique.

Principles of Functional Repair

Carstens[52] comprehensively defines the principles of a functional matrix repair as postulated by Delaire. They are summarized as follows:

1. Understand the embryologic facial developmental fields and units that give rise to lip, nasal, and maxillary structures.
2. Maintain vascular pedicles to the columella, nasal, and musculoperiosteal envelope through subperiosteal dissection.
3. Identify and correct pathologic muscular displacements and distortions.
4. Realign muscles to their proper insertions or counterparts and hold them there.
5. Attempt to remove abnormal vectors of force on the soft tissue envelope and underlying skeleton.

Lip Incisions

The technique of functional cleft repair is described in the next section. Refer to Figure 29-28 for cutaneous lip and nasal incisions. Several popular skin incision techniques may be used through which access to the underlying musculoaponeurotic units can be gained; however, many surgeons favor modifications of the rotation advancement

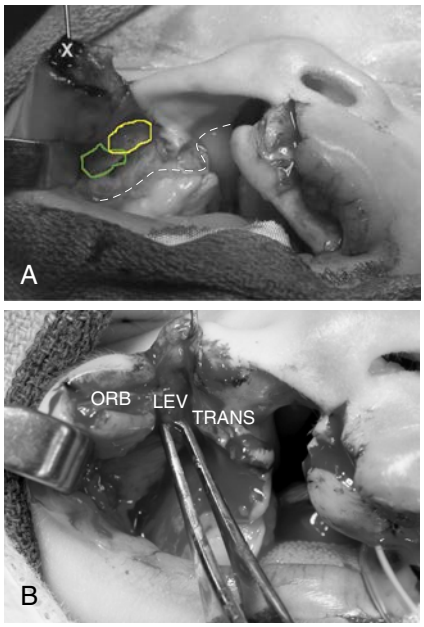
• **Figure 29-28** Schematic of cutaneous and intranasal, and intraoral incisions.

approach,[57] as does this author. Incisions into the oral cavity, principally on the buccal vestibule, and intranasally must respect vascular pathways. To preserve blood supply to the maxillary vestibular mucosa and underlying periosteum, the incision carried along the alveolar segment should remain on the alveolus but away from dental follicles. In the medial nose, the external lip incision should not create a back cut across the columella skin to maintain the small nasal twigs, the terminal branches of the anterior ethmoid arteries. The incision then runs superior and posterior to the columella skin just caudal to the medial crus of the lower lateral cartilage. This affords access to the intermediate crus and lower dome for dissection from their soft tissue envelope.

The cleft lip segment incision (advancement side) runs superiorly from a point on the white roll that corresponds



• **Figure 29-29** Intraoperative photo of muscle dissection, identification, and mobilization. in location and length to the prolabial segment. As this incision approaches the fixed ala intranasally, it runs up and over the inferior turbinate to create an adequate advancement of the nostril floor. Through this incision and in a subperiosteal plane, the entire musculoaponeurotic field (including its component levators and transversalis, as shown in Figure 29-29) can be mobilized and repositioned. Subperiosteal dissection preserves the vascular supply to the muscular components. A circumalar, transverse incision at the nasal base to create adequate mobility of the lateral nasal segment often is not necessary. If performed, this incision should be conservative to preserve the natural ala-lip junction.

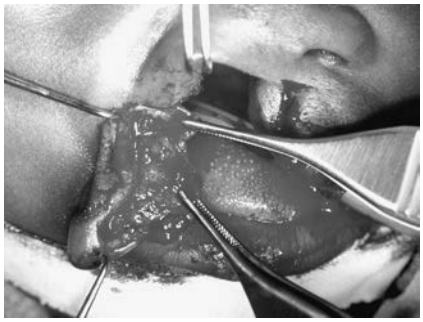
Nasal Dissection

An important component of functional repair is correction of the nasal cartilaginous displacement and distortion. The muscular base around (levators and upper transversalis) and under (transversalis nasalis, myrtiformis or depressor nasii) the ala contributes to lower nasal form and development. The lower lateral cartilage requires dissection from its soft tissue envelope with proper repositioning. This key component of primary cleft nasal repair was first advocated and successfully confirmed by McComb[14] and later corroborated by others[58-60] as being a safe and necessary procedure during primary repair to address the nasal deformity.

Access to all the lower cartilage is gained through the columellar base on the prolabial segment and laterally through the advancement incision. Small, curved tenotomy scissors gently introduced under the skin and hugging the crura



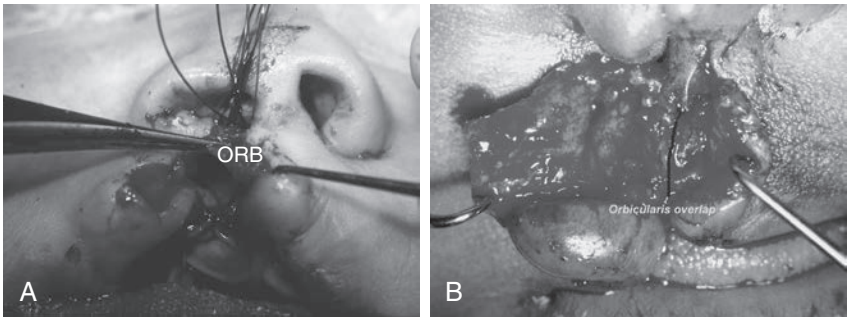
• **Figure 29-30** Intraoperative photo of muscle bundle identification (transversalis) with traction to confirm muscle insertion for proper repositioning.

allow skin dissection. Great care is necessary to avoid incising the cartilage or piercing the skin. The domal cartilage can be accessed through both the medial columellar and lateral ala incisions. If necessary, a small infracartilaginous incision inside the rim can be performed for more complete domal access and dissection. Lastly, to accommodate narrowing of the nasal tip and coaptation of the medial crura, small stab incisions in the vestibular mucosa can be made through which a horizontal mattress (through-and-through) suture can be passed in a buried fashion.

Closure

Once dissection is completed, soft tissue closure may begin. Muscle repair requires identification of each component by careful microdissection into the soft tissue. Haphazard muscle bundles initially are encountered, but after several millimeters the muscle heads can be identified and confirmed by traction—a dimpling of the overlying skin signals that the appropriate muscle component is grasped (Figure 29-30). The first muscle sling is the nasal floor component of myrtiformis and transversalis nasalis, which are approximated with one or two horizontal mattress sutures (4-0 or 5-0 permanent or slow-absorbing suture) secured to the contralateral area in the anterior nasal spine. The levator heads are then sutured across and on top of the nasal spine region; this will result in slight overcorrection and narrowing of the nostril sill but will resist the tendency of tissue memory relapse (Figure 29-31). Final muscle repair involves overlapping the orbicularis sleeves and placing everting sutures to recreate a philtral ridge. When proper muscle repositioning is accomplished, the skin and mucosa follow. The subdermal layer is coapted with 5-0 horizontal mattress sutures. Simple 5-0 or 6-0 fast gut sutures or tissue glue (cyanoacrylate) can be applied to obtain a very fine closure. Wound support tapes are placed for several weeks. The initial overcorrection and "pout" obtained with thorough muscular repair eventually assumes a more natural form under animation and time and results in a balanced lip and nose.

To facilitate nasal form, nostril stents are placed using either red rubber catheters fashioned to nostril size or commercially available soft Silastic stents (Dow Corning



• **Figure 29-31** **A,** Muscle repair in midline on the anterior nasal spine with orbicularis *(ORB)* sleeve dissection. **B,** Orbicularis overlap with schematic horizontal mattress sutures placed to indicate overcorrection to recreate the philtral margin and lip fullness.

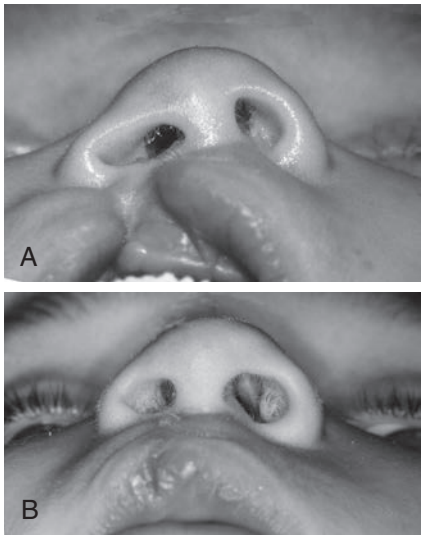
Corp., Midland, MI). The author prefers to use anatomically fashioned stents that are then sutured over supportive bolsters (petrolatum gauze) at the nasal tip and septum (Figure 29-32). Two to three layers of support tape are placed on the skin to protect it from pressure necrosis under the bolsters, which are removed at 2 weeks. The stents are maintained either through septal sutures for another 4 weeks or worn passively and taped in place. Figures 29-33, 29-34, and 29-35 illustrate preoperative unilateral cleft lip and palate cases and postoperative results after functional repair and before any secondary procedures.

Review of Studies Examining Functional Repair

Moss[52] first advanced the concepts of facial form and development based on functional matrices. He described anatomic models that gave rise to developmental tissue fields representing future facial structures. The clinical benefits of cleft reconstruction based on the embryologic development of facial elements were initially advanced by Delaire et al.[45,46,48,49] He and others performed functional cheilorhinoplasty based on developmental anatomy and described subsequent facial growth and development over time. [49,50,53,55,61]

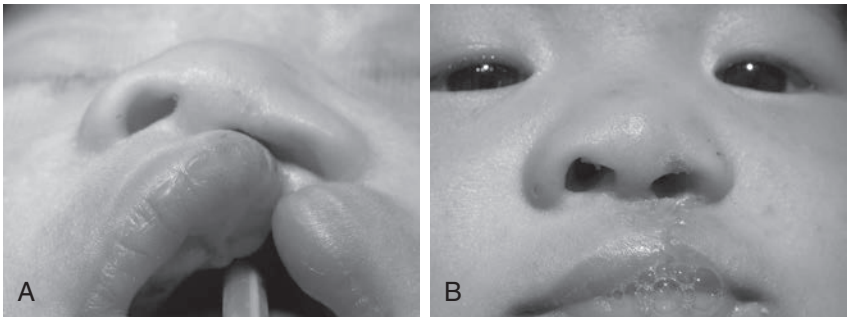


• **Figure 29-33** **A,** Preoperative photo of 2-month-old with right, incomplete, unilateral cleft lip and palate. **B,** Postoperative photo of same patient at 5 years. Note nasal projection, alar symmetry, and lip fullness.

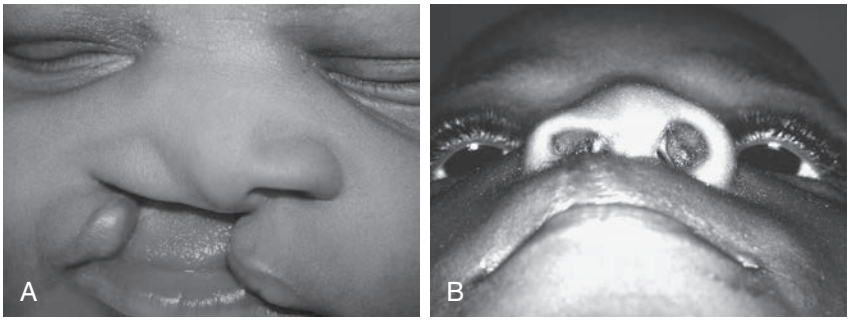
Nasal symmetry and projection were noted to be improved in children who underwent a comprehensive functional repair.[62] Apparently the nasal osteocartilaginous framework is stimulated by proper musculature function, providing forward vectors of growth and symmetrical alignment at the alar bases.[53] Direct stimulation of periosteum through muscle attachment and function is believed to contribute to osteogenesis of the underlying nasomaxillary bone. [46,49,52,61]

Lip balance and function are widely recognized to depend on proper muscle repair, specifically the orbicularis.[54,63] However, an important muscular element to the superficial sleeve of the orbicularis is the insertion of the levators at its outer aponeurosis.[63] This insertion is disrupted in the clefted lip, and when corrected in repair exerts a positive influence on ultimate lip form and balanced function. Studies have demonstrated preoperative and improved postoperative responses of muscles under function that suggest a physiologic benefit from proper muscle repair.[64]

At the histologic level, Schendel[50,56] documented this positive relation between muscles when he observed a limited



• **Figure 29-34** **A,** Preoperative photo of 2-month-old with left unilateral cleft lip and palate. **B,** Postoperative photo of same patient at 2 years.



• **Figure 29-35** **A,** Preoperative photo of newborn with right unilateral cleft lip and palate. **B,** Postoperative photo of child at 3 years.

reordering of muscle fiber orientation and design after repair. After cleft lip repair, a pattern of denervation followed by reinnervation of the muscle bundles has been observed, further substantiating the physiologic benefits of functional repair.

Summary

Functional cleft lip repair involves the total identification and mobilization of the nasolabial muscular elements: levators, transversalis nasalis, and orbicularis muscles. These muscular compartments are accessed through cutaneous and mucosal incisions that provide cosmetic results and include proper tissue fields and vascular pedicles that are developmentally based, thus reestablishing the proper functional model. Subperiosteal dissection is performed to mobilize the musculoaponeurotic elements, and muscle coaptation is then performed in a stepwise fashion to create the proper functional nasolabial muscular sling.

Nasal cartilage dissection also is performed during primary repair to facilitate the restoration of a functional matrix. This is achieved through selective columellar, alar, and rim incisions by which total lower lateral cartilage dissection and repositioning can be undertaken. Careful tissue support through placement of wound tapes, nasal stents, and bolsters is key to preserving the functional matrix during initial healing.

When these steps are observed during primary cheilorhinoplasty, function can proceed as normally as possible in the cleft condition and give rise to an improved nasolabial and maxillary complex in both development and appearance.

Cleft Palate Repair

MICHAEL JASKOLKA, WILLIAM CURTIS, PAUL KLOOSTRA, GERARDO P. ROMEO, PAMELA M. GALLAGHER

TWO-FLAP PALATOPLASTY

MICHAEL JASKOLKA, WILLIAM CURTIS, PAUL KLOOSTRA

Introduction

The goal of repairs of the cleft hard and soft palate is to provide separation of the oral and nasal cavities with the creation of a functional velopharyngeal mechanism. Ideally, this should provide for normal speech and hearing, uninhibited growth, and ideal occlusion and avoid hindering psychosocial development. In the ideal scenario there would be a theoretic benefit to a single operation to achieve these goals without the creation of iatrogenic disease.

The optimal sequence of care is controversial. Although not for a lack of effort, high-level evidence is limited in the context of the management of the cleft palate. Significant barriers exist and begin with the variable management of the cleft lip; when present in conjunction with a cleft of the palate, the results of treatment are inexorably tied together. Although not specifically addressed in this section, variations in the severity of presentation, timing of repair, presurgical orthopedic management, and technique of cleft lip repair all set an uneven foundation upon which the treatment of cleft palate must be based and measured. The remaining barriers to quality study include a high level of patient anatomic variability, inconsistencies regarding classification and terminology, nonstandardized methods of evaluation, data collection and outcome assessments, treatment sequences that vary by institution, and techniques that vary by surgeon. Meaningful conclusions are made more elusive due to limited patient volumes at many centers and the need for longitudinal study over a period of many years, ideally until after skeletal maturity is reached.

The weakness of the literature leads to a lack of consensus regarding almost every aspect of the care of patients with cleft palate. It is likely that no single "optimal sequence" of care exists because each patient presents with a unique condition and considerations. An understanding of the relevant considerations associated with surgical repair of the cleft palate should be combined with proficiency in both the available literature and proficiency in various techniques to allow each practitioner to make educated decisions for individual patients and provide a tailored approach.

History

Cleft palate repair has evolved over time from the work of many preceding surgeons. Innumerable procedures have been trialed; some have been discarded while others have been modified and stood the test of time. The following is a summary of key advancements leading to current concepts, from simple mucosal approximation, through successful closure of the hard palate, attempts to lengthen the soft palate, to true functional reconstruction of the clefted velum.

The first endeavors to close the congenitally clefted palate consisted of simple approximation of raw mucosal surfaces. M. le Monnier, a French stomatologist, was the first cited to have achieved mucosal closure by suture approximation followed by cautery in 1766.[1,2] In the early 1800s subsequent surgeons including Carle Von Graefe, Philibert Roux, and John Warren all made advances in technique and instrumentation, focusing on the mucosal closure of the cleft palate; together they forged the field of cleft palate surgery.[3]

Johann Dieffenback, a student of von Grafe, introduced the lateral relaxing incision in 1829. He was succeeded by Bernhard von Langenbeck whose work with subperiosteal dissection and periosteal osteogenesis was extended to the hard palate.[4] Von Langenbeck's technique involved pairing of the cleft margin, lateral relaxing incisions, subperiosteal dissection, preservation of the greater palatine neurovascular bundle, and allowed for closure of both the hard and soft palate in a single operation.[2,3,5]

As palatal closure was being achieved more reliably, the focus of palatoplasty shifted towards the creation of a functional palate. Multiple maneuvers were proposed to medialize and lengthen the soft palate. Christian Billroth, in 1889, recommended fracturing of the hamulus to mobilize the soft palate without injuring the muscle.[2,3]

In 1920 Hugo Ganzer, a dentist and prominent contributor to the field of facial plastic surgery, described the closure of the hard palate in a V-Y fashion, posteriorly displacing the hard palate mucosa. Of note, he was also the first to recommend incising the cleft margin, rather than excising the edges.[6,7]

In 1924 Franz Ernst observed the nasopharynx of the cleft patient to be enlarged and recommended that as a component of palatal repair, the pharynx should be narrowed. He recommended dissection within a theoretic space medial to the pharyngeal constrictor to gain mobility of the soft palate.[6]

Victor Veau published over 500 cases in his textbook *Uranoplasty* in 1931. His publication directed attention to the use of the V-Y pushback, vomer flaps for nasal mucosal closure, and more important, to the "indispensible" suture repair of the "cleft muscle" of the soft palate.[6]

Janusz Bardach reported the most recent popular modification of the hard palate closure in 1967. He described the extension of von Lagenbeck's relaxing incisions to the anterior edge of the cleft margin and the subsequent creation of two axially patterned full-thickness mucoperiosteal flaps based on the greater palatine neurovascular bundle. This design, termed the "2-flap" allows for greater access to the nasal and velar soft tissues.[8]

In 1969, Otto Kreins first coined the term "veloplasty," and echoed Braithwaite as to the importance of isolated muscular reconstruction of the soft palate. Kreins' veloplasty involved severing the medial tensor tendon from the hamulus, disinsertion of the velar musculature from the posterior hard palate, and blunt dissection to release the levator veli palatini from the pharyngeal constrictors. He cautioned against separating the muscles from the nasal mucosa for fear of nasal mucosal necrosis.[9]

Through the 1970s and 1980s the effectiveness of intravelar veloplasty (IVV) was debated with the report of various techniques.[10-12] The current state of IVV has convincingly demonstrated improved speech when carried out in a complete or aggressive fashion with release of the periosteal sheath of the greater palatine neurovascular bundle, transection of the medial portion of the tensor tendon, anatomic dissection of the levator, retrodisplacement into the middle of the soft palate, with approximation or overlap for the creation of appropriate tension.[13,14]

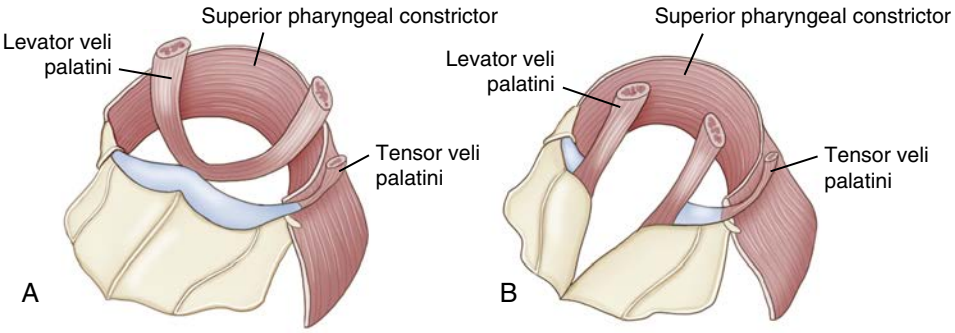
Anatomy

Understanding the contrast between the normal and aberrant anatomy of the cleft palate is paramount for appropriate reconstruction.

The hard palate consists of the primary and secondary palates. The primary palate, also referred to as the premaxilla, contains the alveolus and the maxillary incisors bordered posteriorly by the incisive foramen. Posterior to this point, the secondary palate is formed as a result of the fusion between the maxillary and palatine bones with the midline vomer.[15]

The soft palate and associated musculature is termed the velum and functions as a valve, hinging at the posterior surface of the hard palate in a superoposterior direction to form a seal with the posterior and lateral pharyngeal walls. It functions to separate the oral and nasal cavities during speech and swallowing.[16] Velopharyngeal closure is achieved primarily through the action of the levator veli palatini in combination with the superior pharyngeal constrictor.[16,17] The velum consists of multiple distinct layers as approached during palate surgery. The oral mucosa is adherent to a dense layer of minor salivary glands and fibrofatty tissue. This layer is thicker at the midline and tapers laterally. The confluence of muscles is then encountered below the minor salivary glands. Finally, a thin fascial layer is formed from an extension of the oral and nasal periosteum of the hard palate, which is covered with the thin delicate nasal mucosa.[18]

The musculature of the intact, non-cleft velum consists of a single intrinsic muscle, the muscularis uvula, and multiple extrinsic muscles: the palatoglossus, palatopharyngeus, tensor veli palatini, and levator veli palatine. The palatoglossus creates the anterior pharyngeal arch as it ascends from the posterior tongue to the palate and inserts into the palatal aponeurosis.[16,17,19] The palatopharyngeus is a flat muscle arising from the lateral pharyngeal wall and the greater horns of the thyroid cartilage of the larynx.[17] It creates the posterior pharyngeal arch as it extends superiorly and medially into the soft palate where it splits with fibers running parallel to the anterior and posterior portion of the levator veli palatini. Some of the muscle fibers insert into the aponeurosis, others into the uvula, but the majority of the fibers unite with the contralateral palatopharyngeus to form a loop.[19] The palatopharyngeus and palatoglossus, along with the tongue, form the oropharyngeal sphincter, which is more consistently utilized in swallowing than in speech production.[16,17,19] The tensor veli palatini ("tensor") is a thin, broad, and flat muscle arising from scaphoid fossa at the base of the medial pterygoid plate of the sphenoid bone and lateral margins of the eustachian tube cartilage, descending from the base of the skull toward the soft palate in parallel with the eustachian tube.[16,20,21] Upon separating from the inferior aspect of the eustachian tube, the tensor is flat and nearly vertical and ends in a tendon that wraps around the hamulus, the most inferior portion of the medial pterygoid plate. The tendon extends medially into the velum and contributes to the formation of the palatal aponeurosis at the posterior aspect of the posterior nasal spine.[22] The tensor functions to open the eustachian tube during swallowing and yawning, allowing pressure equalization and drainage of the middle ear. The levator veli palatini is, possibly, the most important muscle of normal velopharyngeal closure. The levator descends from the petrous portion of the temporal bone and the junction of the cartilaginous and bony segments of the eustachian tube, extending anteriorly, medially, and inferiorly, along the inferior and posterior aspect of the eustachian tube, just posterior to the tensor veli palatini. The levator is tube-shaped at the inferior aspect of the eustachian tube, and becomes flat as it enters the soft palate. Some fibers extend anteriorly toward the hard palate, others posteriorly into the uvula, though the majority unite with the contralateral levator to create a

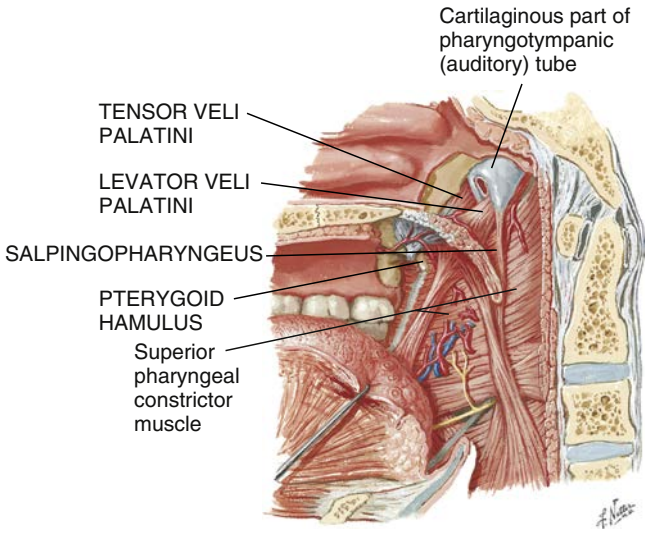


• **Figure 30-1** **A,** The key anatomic components of the normal palatal and velopharyngeal anatomy are displayed, including the intact posterior hard palate and vomer, levator and tensor sling, and superior pharyngeal constrictor which forms the posterior portion of the velopharyngeal valve. **B,** The key anatomic components of the abnormal palatal and velpharyngeal anatomy associated with cleft palate are displayed, including the hard palate defect and absent vomer, division of the levator sling, and abnormal insertion of the tensor.

sling in the middle 40% to 50% of the soft palate.[23] The entire course of the levator muscle can be visualized in an oblique coronal view, demonstrating its sling-like nature and its function for suspending, elevating, and retracting the palate toward the posterior pharynx.[16-19]

The superior pharyngeal constrictor is a thin muscle with multiple origins, resulting in multiple discrete muscle bundles including the glossopharyngeus, mylopharyngeus, buccopharyngeus, and pterygopharyngeus. These muscle bundles extend posteriorly to unite along the pharyngeal raphe. The superior pharyngeal constrictor may participate in the velopharyngeal mechanism by providing posterior and lateral pharyngeal wall movement, though this is not consistent across all individuals.[16]

In contrast to the previously described anatomy found in non-cleft individuals, a variety of configurations are seen with clefts of both the hard and soft palate. A cleft of the secondary palate typically results in a bony deficiency at or adjacent to the midline and has an associated soft tissue deficiency. This varies from subtle posterior osseous notching to a complete dissociation of the palatal shelves. Disjunction of the vomer from the hard palate is also common and, at times, can be complete.[15] Along with the disruption of the midline hard and soft tissue anatomy, the orientation and functionality of the soft palate musculature is also abnormal. The levator veli palatini, palatoglossus, and palatopharyngeus aberrantly attach to the posterior hard palate, and the tensor veli palatini inserts onto the hard palate, maxillary tuberosity, and pterygoid process[16] (Figures 30-1 and 30-2). The pharynx is also abnormal, with an increase in width and depth.



• **Figure 30-2** Cross-sectional view of the normal palatal and velopharyngeal anatomy demonstrating the positions of the palatoglossus, palatopharyngeus, musculus uvulae, superior pharyngeal constrictor, and their relationships to the levator muscle and its attachment to the Eustachian tube. Surgical Technique

Soft Palate

Proper surgical repair should involve functional reconstruction of the velar apparatus and can be accomplished by surgically creating a more anatomically correct form. Straight line repair incorporates "radical" or "complete" intravelar veloplasty (cIVV) and double opposing Z-plasty (DOZP) techniques, which are the two most prominent techniques employed for velar reconstruction in North America, with almost identical frequency.[24] Although different in surgical execution, the goals are similar: complete release, retroposition, and reconstruction of the levator muscle sling.

The "straight line repair" refers to the design of flaps and final orientation and appearance of a straight line scar in the midline of the palate when this approach is used. Incorporation of the cIVV with this technique is not mandatory but it is becoming more universally accepted that it improves success with regard to construction of a functional velum when included with straight line repairs. In contrast to DOZP, which produces a lengthened soft palate by design, the cIVV only does so by incorporating "push-back techniques." Straight line repair with cIVV, though, may create a more correct anatomic reconstruction. Both approaches

variably demonstrate excellent outcomes in the literature, but superiority of one technique is yet to be determined.

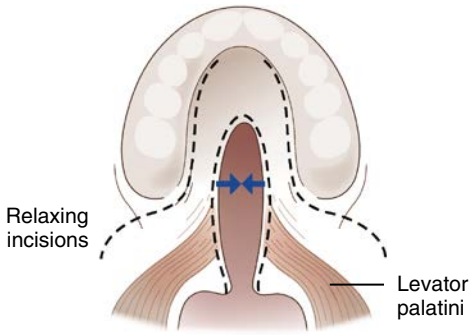
Hard Palate

The closure of the hard palate may be considered independently from reconstruction of the velum. Marginal incisions are used in all cases with varying amount of subperiosteal dissection. In theory, the addition of lateral incisions, stripping of the palatal periosteum, and creation of denuded areas of bone raise concerns for growth restriction. The competing consideration is that the use of additional incisions allows for less tension across the midline closure, mobilization of the neurovascular pedicle, and improved access to the soft palate to facilitate appropriate levator release and reorientation.

The narrow incomplete cleft may be closed without any lateral incisions. However, the majority of complete unilateral and bilateral palatal clefts will require additional dissection. Bipedicled flaps (von Langenbeck) provide theoretical improvement in vascularity to the palatal tissues, but have no definitive positive impact on wound healing as measured by fistula or dehiscence rate when compared to unipedicled flaps. The VY push-back design is also commonly employed with the purported advantage of increasing soft palatal length at the expense of the creation of a transverse area of denuded bone at the anterior portion of the palate. The advantage of increased palatal length has not been demonstrated without the creation of a nasal surface defect, although the worry of restricted AP maxillary growth has also not been definitively demonstrated as compared to other procedures when performed using the same sequence at the same patient age. Lastly, the "two-flap" repair popularized by Bardach is the most flexible technique, especially in the wide complete cleft. Although lateral areas of denuded bone are often created, the flaps are traditionally sutured back to the same anterior position in an attempt to completely close the palate up to the lingual surface of the alveolus. The concern here is the stripping of the entire hard palate and the resulting growth disturbance in the anterior and transverse dimension. Again, this has never been definitively demonstrated in the literature to be more severe as compared to other techniques.

Surgical Technique

Endotracheal intubation with the use of an oral RAE placed in the midline is advocated. Preoperative antibiotics and steroids may be administered by the anesthetic care team. The patient is then positioned with the neck in extension through the use of a shoulder roll and extension of the head of the bed. A horseshoe headrest may be used if desired. Special care must be taken in patients with Down and velocardiofacial syndromes due to the potential risk of cervical spine instability. A mouth gag of the surgeon's choice, most commonly a Dingman, is applied for exposure and tongue retraction with care being taken to avoid endotracheal tube compression. Periodic release of the gag is common because it may help to limit postoperative tongue edema.



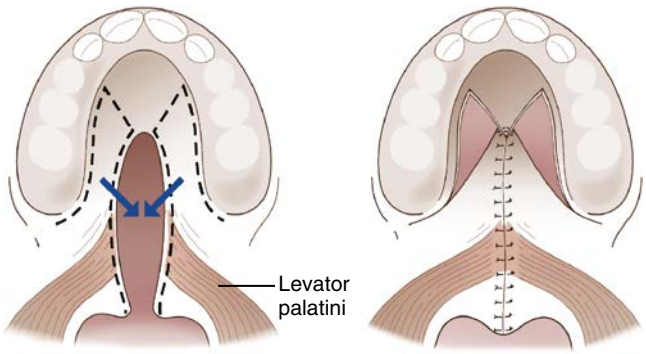
• **Figure 30-3** The von Langenbeck palatoplasty. Lateral releasing incisions are fashioned such that bipedicled mucoperiosteal flaps may be mobilized medially in tension-free fashion.

The procedure begins with placement of a throat pack. Surgical markings are made and local anesthetic with vasoconstrictor is given via infiltration for hydrodissection and tumescence of the soft palate to facilitate incisions. Additional aliquots of injectable saline may also be used to improve soft tissue turgor.

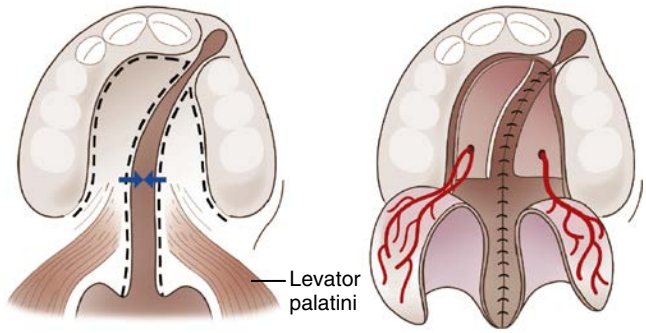
Initial incisions are made along the margin of the cleft beginning from the anterior extent of the soft palate through the tip of the uvula. The oral and nasal mucosa are split at their intersection. A modification employed by some is the demucosalization of the very medial tip of the uvula prior to the initial incision to facilitate later closure. Dissection of the soft palate is limited at this point to the creation of an oral layer just below the mucous glands and a nasal-muscle layer. Incisions are then carried towards the anterior hard palate. A beaver blade can be utilized if desired, particularly in the incomplete cleft. The marginal incision is often placed slightly more towards the oral mucosa to facilitate adequate closure of the nasal layer.

If desired, lateral releasing incisions are made from just posterior to the tuberosity and extending anteriorly. The incisions are started with a knife and approximately 5 mm of attached gingival height is maintained on the palatal aspect of the dentition; they are then carried to bone with use of electrocautery at an angle to avoid injury to the greater palatine vessels. If bipedicled flaps (von Langenbeck) are intended, the incisions are terminated prior to turning medially toward the cleft margin (Figure 30-3). If unipedicled flaps are intended with a V-Y in mind, the anterior releasing incision is then carried at a sharp angle back toward the anterior edge of the cleft on each side (Figure 30-4). If unipedicled flaps are intended for a two-flap design, the incisions are carried to the anterior cleft margin (Figure 30-5).

When utilized, hard palate mucosal flaps are elevated in a subperiosteal plane from anterior to posterior and lateral to medial. The greater palatine neurovascular bundle is identified and protected as the flap is elevated off of the posterior edge of the hard palate. Dissection is completed circumferentially around the neurovascular bundle, posterior to the



• **Figure 30-4** The Veau-Wardhill-Kilner push-back palatoplasty. Full-thickness mucoperiosteal flaps are elevated and "pushed back" in V-Y fashion to lengthen the reconstructed velum. Note the areas of the hard palate denuded and left to heal by second intention.



• **Figure 30-5** The Bardach two-flap palatoplasty. Two axially patterned, full-thickness mucoperiosteal flaps are elevated, providing excellent visibility to the nasal side closure and velar musculature for its reconstruction.

hard palate and laterally along the hamulus. In the wide cleft, additional maneuvers such as further dissection along the medial aspect of the pterygoid plate, division of the tensor tendon, dissection into the space of Ernst, scoring of the periosteal sheath surrounding the neurovascular bundle, and foraminal ostectomy to release the neurovascular bundle may all aid in mobilizing the tissues of the palate for tension-free closure. In-fracturing of the hamulus is also utilized by some, but is not considered a necessity.

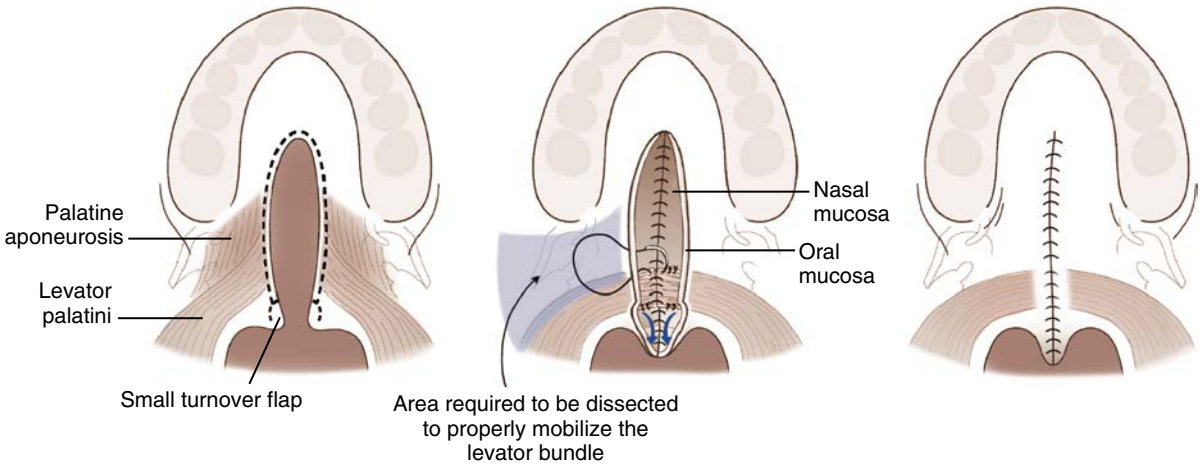
The nasal mucosa is then elevated from the medial margin of the hard palate. Once in the subperiosteal, a curved freer is used to elevate the tissues off of the nasal surface of the palate up to the lateral wall of the nasal cavity. Careful assessment of cleft width and available soft tissue is then used to decide if vomer flaps are indicated to form the nasal layer. If so, additional local anesthetic is injected. In the unilateral complete cleft palate, the incision is made at the junction of the oral and vomerine mucosa. In the bilateral complete cleft palate, the incision is made directly on the base of the vomer. If additional release is required, posteriorly placed lateral extensions can be made.

Closure is begun at the uvula with a single interrupted 4-0 Vicryl suture that is left uncut on slight tension. A horizontal mattress suture may then be used to approximate the next portion of the uvula. The nasal mucosal layer is then closed in an interrupted technique to minimize shortening, with the knots everted onto the nasal surface. Once the hard palate is reached, a running suture may be employed. Vomer flaps are incorporated at this point as necessary and help to reconstruct the posterior choanae and set the position of the velum.[25]

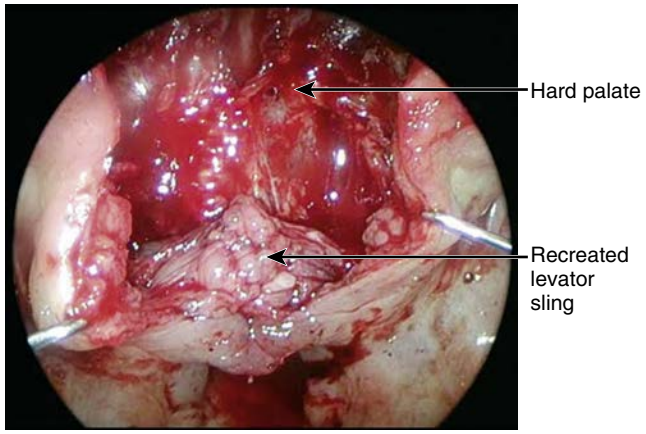
A complete intravelar veloplasty as described by Sommerlad[14] can now be performed beginning with sharp dissection of abnormally arranged muscles from the nasal mucosa and the posterior aspect of the hard palate. The mucosal layer is identified by its bluish hue. Sharp tenotomy scissors under loupe magnification, and steady counter-traction with a single skin hook placed in the oral mucosa flap facilitate this dissection. The dissection begins several millimeters lateral to the midline sutures of the nasal layer and is carried laterally along the posterior edge of the hard palate. The aponeurosis of the tensor tendon is divided and a portion of fibrous tissue remaining with the levator and palatopharyngeus muscles is lightly grasped to facilitate the remaining sharp and blunt dissection from the superior pharyngeal constrictor allowing for further release and posterior medial displacement. The muscles are approximated in the midline with 5-0 PDS horizontal mattress sutures, but may require some amount of overlap to establish appropriate tension of the reconstructed sling due to their increased length and laxity.[26] If appropriately positioned, the levator bundles should lie approximately half of the distance from the hard palate to the uvula, and can be secured to the underlying nasal mucosa with a suture to prevent migration[17,23] (Figures 30-6 and 30-7).

In the extremely wide cleft, or in the case of significant nasal mucosal tears, additional reinforcement of the hard and soft palate junction may be desired. This can be accomplished with acellular dermal matrix or with a pedicled vascularized buccal fat graft, both of which add an additional layer in the area most susceptible to breakdown and fistula formation (Figure 30-8). An additional benefit of using fat pad advanced and secured between the hard palatal shelves and the muscles of the velum sandwiched between oral and nasal mucosa is obliteration of dead space and aid in maintaining retroposition of the repaired musculature.

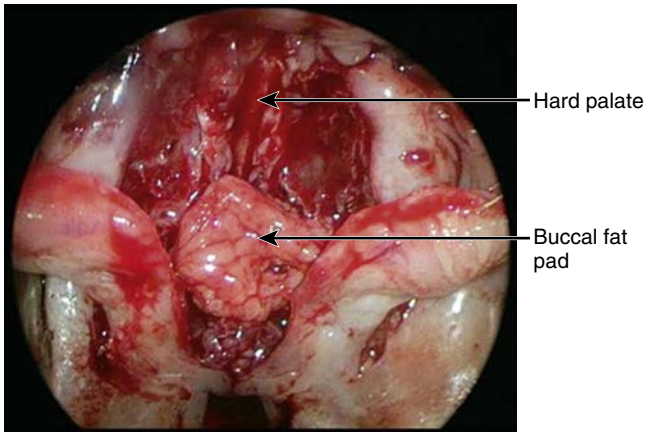
The oral layer is then closed in the midline with 4-0 Vicryl mattress sutures at the hard and soft palate junction, and intermittently to establish eversion of the edges of the wound. Intervening 5-0 Vicryl simple interrupted sutures can supplement closure. Once approximated in the midline, the lateral edges of the hard palate flaps may be suspended to the unelevated anterior and lateral alveolar mucosa with interdental sutures maintaining a tension-free midline closure. The throat pack is removed and the stomach evacuated with a suction catheter. A 2-0 silk traction suture can be placed through the tongue and secured extraorally for use in the unlikely event of postoperative airway obstruction. Full liquid diet, preferably by cup or valveless sip cup, is appropriate and most patients are observed overnight. Additional doses of IV antibiotics and steroids may be administered. Once the patient is successful in resuming adequate oral



• **Figure 30-6** Intravelar veloplasty after Sommerlad. A more extensive dissection of the levator bundles into the space of Ernst is accomplished, permitting the tension-free, transverse reorientation and retropositioning of the levator veli palatine to at least the middle third of the velum.



• **Figure 30-7** Appropriate reconstruction, alignment, and position of the levator musculature within the middle of the soft palate in relation to the posterior border of the hard palate



• **Figure 30-8** Demonstration of the application of a pedicled buccal fat pad graft during primary palatoplasty. This technique is employed to minimize the risk of fistula formation at the hard and soft palate junction, obliterate dead space, and create a more supple velum.

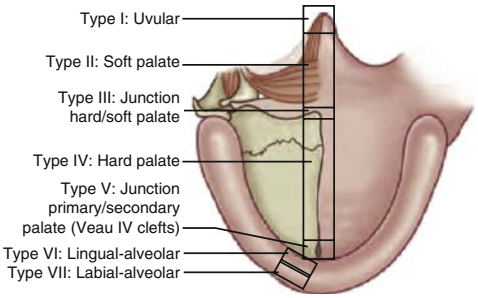
intake and absence of airway embarrassment is confirmed, the traction suture is removed and the patient is discharged, often on the next postoperative day. A full liquid or purée diet is instructed for 3 weeks. Arm restraints may be used by some surgeons early in healing, but are not a requirement unless requested by the family.[24,27]

Outcomes

Objective evaluation of outcome is likely the most ideal way to rate success in cleft care. As mentioned previously, there are significant barriers to the publication of level one evidence supporting an ideal cleft palate repair method. However, the literature is replete with lower level evidence studies and manuscripts and the practicing surgeon should be familiar with that information. Outcomes are often discussed in terms of fistula rates, audiologic and otologic function, speech, dental/occlusal relationships, and growth.

Fistulae

One of the primary goals of palate repair is the separation of the oral and nasal cavities; as a result, postoperative fistula rates have become a parameter of success. A fistula technically may form anywhere along the repair, but is more common at the junction of the hard and soft palate.[27] Although seemingly straightforward, the literature is again difficult to interpret, largely because of inconsistent terminology. The Pittsburgh Fistula Classification System (Figure 30-9) is an example of one attempt to standardize categorization by specific location. When considering the incidence of fistulae it is important to make the distinction between a true fistula and a residual cleft. Cohen and colleagues have recommended defining a fistula as a failure of healing or breakdown of the primary surgical repair.[28] Therefore, a communication in the region of the alveolus after primary palatoplasty that was never repaired should be considered a



• **Figure 30-9** The Pittsburgh Fistula Classification System. (From Smith DM, Losee JE: Cleft palate repair, *Clin Plastic Surg* 41:189-210, 2014.)

residual cleft.[14] Lastly, not all fistulae are clinically significant and their presence may not lead to symptoms such as nasal regurgitation, halitosis, mucosal irritation, and hypernasal speech.

The reported incidence of fistula occurrence following primary palatoplasty ranges from <1% to 70%[14,28,29,30] with a recent systematic review reporting an 8.6% fistula rate.[31] Little controlled research has been performed to evaluate the effect of the palate repair technique on the incidence of fistula. Cohen reported a 43% incidence utilizing a VWK repair, and only 22% with a von Langenbeck repair.[29] Emory reported no significant difference in the rate of fistula between the Bardach two-flap palatoplasty (8%) and the von Langenbeck repair (15%).[32] To contrast Cohen's published fistula rates, Andersson reported a 4% fistula rate, and Sommerlad reported a 15% rate with a modified von Langenbeck repair, while Aslam reported a 5.6% rate and Salyer reported a 10% rate with the Bardach two-flap palatoplasty.[14,25,28,31]

Confounding variables beyond technique are likely to play a role and include cleft type and severity, patient age, syndromic diagnosis, and surgeon experience.[28,29,33,34] There is general consensus that cleft type and severity correlate with the rate of fistulae following cleft palate repair.[28,29,35] Sommerlad reported a 12% fistula rate in isolated cleft palate, 14% in unilateral cleft lip and palate, and 35% in bilateral cleft lip and palate.[14] Less clear is the impact of age at the time of repair as some report a decrease in fistula rate with an increasing age at the time of repair while others report no change.[25,28,33,34,36] A similar controversy exists in regard to the correlation between syndromic diagnosis and the incidence of fistulae.[36] These findings are likely to relate to which syndromes were included. Last, and perhaps most important, individual operator experience and skill set should not be ignored, with volume often cited as a meaningful surrogate marker for skill. Emory and colleagues demonstrated that the surgeon completing >60% of the cleft palate procedures at their institution had a significantly lower rate of postoperative fistula formation,[33] while Andersson and colleagues reported on more than 50 surgeons over 40 years at their institution, reporting a significant difference based on surgeon volume when a cleft involved both the hard and soft palate. However, the rate of postoperative fistulas dropped dramatically for surgeons who had performed more than five palatoplasties.[28]

Otologic/Audiologic

Chronic otitis media (OM) characterized by effusion and conductive hearing loss is found in almost all infants with cleft palate. The proposed etiology is eustachian tube dysfunction secondary to anatomic and functional abnormalities. Although the natural history is such that these conditions are likely to improve over time they are extremely prevalent during the toddler years, which are critical for speech and language development.[37]

Audiologic and ENT evaluation are an important component of the multispecialty care of children with cleft palate and are meant to identify abnormalities with the goal of providing early treatment to facilitate speech and language development. A combination of cleft palate repair and ventilation tube placement has been shown to lead to normalization of eustachian tube function in approximately 90% of patients over time.[38] In this vein, ventilation tubes are often placed prophylactically at the time of cleft lip or cleft palate repair; others base their decision on findings of recurrent OM, effusion, and sustained hearing loss. Ideally, treatment protocols should allow for the appropriate development of speech and language as well as the prevention of short- and long-term otologic and audiologic conditions such as unnecessary surgery, tympanic perforation, cholesteatoma, and permanent hearing loss.

Otologic and audiologic outcomes are difficult to measure because eustachian tube function is not immediately improved following palatoplasty. Surrogates for function that are followed over time include tympanometry studies, hearing testing, number of ear procedures, and associated complications. However, as with the other outcome measures, it is difficult to control for age at the time of placement, uniformity of evaluation and testing, long-term follow-up, and type of cleft.

The impact of the cleft palate repair technique may be improved with the use of a muscle reconstruction technique.[39,40] Specific comparisons between the use of IVV as versus the DOZP have demonstrated contradictory results without clear superiority of a specific technique.[41-43]

Speech

A child with an unrepaired cleft palate, or one that has been repaired without the creation of an adequately functioning velopharynx, will likely acquire a speech deficit. This is often due to a combination of velopharyngeal dysfunction (VPD) and compensatory misarticulation. VPD is a general term indicating failure of the velopharyngeal mechanism to properly separate the oral and nasal cavities; it is characterized by hypernasal resonance, inappropriate nasal air emissions, and poor speech quality.[44,45] VPD is divided into velopharyngeal insufficiency due to structural inadequacy, velopharyngeal incompetence due to limited function despite structural

integrity, and velopharyngeal mislearning due to inappropriate function during speech despite normal structure.[45] Compensatory misarticulation is rooted in the attempt to simulate typical phonemes through atypical methods. A common example is the use of the vocal cords to generate sufficient pressure to generate plosive phonemes (i.e., /p/), termed a "glottal stop."[46] A similar, but distorted sound is generated leading to poor intelligibility that becomes worse with connected speech.

The speech and language pathologist is essential in the evaluation and treatment of articulation and resonance disturbances. Assessment is generally composed of perceptual speech evaluation as well as objective testing such as nasometry, pressure flow, video fluoroscopy, and nasopharyngoscopy.[47-49] The perceptual speech examination attempts to standardize assessment but is dependent on the perception and interpretation of the observer. It is also limited by other components necessary for normal speech such as hearing, neurocognitive development, and anatomic variability in the nasal, oral, and pharyngeal tissues. Early research identified the bias of surgeons and the inability of the lay ear to identify specific speech errors, as well as poor inter-rater reliability between speech language pathologists.[50] Higher level studies such as Eurocleft and Americleft[51-53] attempt to control for some of these limitations. Despite its shortcomings due to subjectivity, the speech language assessment provided by trained speech professionals is a heavily used tool for individual assessment, tracking progress and directing therapy in most centers.

Objective testing is often used to aid in the diagnosis of VPD, track clinical progress, and provide research applicable data. Nasometry provides a measure of nasal acoustic energy that is compared to normative values and reported as a "nasalance" score. Dynamic video fluoroscopy provides multiple views of the pharyngeal mechanism during function; it allows for measurement, but is associated with radiation exposure.[54] Pressure flow testing measures intraoral pressure as compared to airflow through the nose and provides an estimate of the size of the velopharyngeal orifice.[55,56] Nasopharyngoscopy is a qualitative exam that provides visualization of the velopharynx during function. Interpretation of findings is subjective in nature but endoscopy is useful in aiding decision making for secondary surgical interventions.[55,57,58]

Speech outcomes are difficult to assess, and ultimately most use a measure of "intelligibility" and rates of secondary speech surgery to determine success or failure. Many times, errors of articulation and abnormal resonance in the presence of an inadequate velar mechanism are "lumped together" in casual discussion of speech intelligibility, but they are clearly different and require distinct approaches to management.

When discussing VPI, referral for subsequent speech surgery such as revision palatoplasty, sphincteroplasty or pharyngeal flap surgery, are used as surrogate markers for the presence of VPI following initial interventions. However, not all patients that develop VPI undergo surgical treatment. Furthermore, the criteria for recommending secondary speech surgery are not uniform between centers. The ideal surgical technique should provide adequate palatal length and intact muscular function for proper speech production.

Initially the V-Y pushback was described in attempt to lengthen the palate as compared to the von Langenbeck repair, but its impact on speech has been questionable. In 1975, Krause retrospectively reported on 267 patients after transitioning from von Langenbeck to the Veau-Wardill-Kilner (VWK) technique. Pharygneal competence was improved from 56% to 74%, but the results were confounded by the reduction in age at time of palatoplasty from 3 to 2 years old.[59] Another classic study reviewed 64 children, controlling for age and type of cleft (Veau type I and II), failed to show any difference in palatal length, soft palate mobility, perceptual speech exam, or nasal air emissions between the two techniques.[51] Others have reported no significant difference in the rate of secondary pharyngoplasties performed, ranging between 15% and 45%.[59-62]

The management of the soft palate has evolved from simple adhesion to the contemporary goal of complete anatomic reconstruction of the musculature. This emphasis has come from prior cadaveric studies[17,19] and more recently anatomic and functional characterization by MRI.[63] The efficacy of "veloplasty" as published by Kreins has been debated with regards to the development of normal speech. In 1989, Marsh published a nonrandomized prospective study of IVV. Their results demonstrated no difference with regard to perceptual speech scores at 3 years of age with a 30% velopharyngeal dysfunction rate and 10% requiring secondary speech surgery.[12] These results seemed to reinforce the findings of previous less robust studies.[64] This conclusion has been challenged with the hypothesis that incomplete dissection and retrodisplacement of the soft palate musculature was to blame. In 1995, Cutting published an anatomic basis for a more complete dissection and included a series of 111 palate repairs with 5-year follow-up and a secondary speech surgery rate of 6.3%.[13] Sommerlad published a similar, but independently developed, technique referred to as "radical" IVV with a 15-year cohort study of 442 palatoplasties and 10 years of follow-up. He reported a secondary speech surgery rate, commonly between 5 to 10 years after surgery, of less than 10%, and 4.6% when looking at the most recent 10 years in isolation.[14] The critical importance of a complete IVV continues to be reported in the literature and has been widely adopted by cleft surgeons performing straight line palate repair.[65,66]

The ideal timing of palatoplasty in relationship to speech development is still debated. Early surgery is thought to benefit speech development at the expense of more pronounced growth restriction.[67-69] In general, speech develops through a predictable sequence with a transition from vocal play to babbling between 6 to 12 months of age.[70-72] From the perspective of proper speech development, it would make sense that palatal closure should be directed by one's phonologic development. A retrospective review of 40 children after

palatoplasty revealed that children with less than a 5-word vocabulary at the time of surgery demonstrated significantly better articulation and resonance at 3 years.[73] Practically, the timing of repair tends to be based on chronologic age with 94% of palatal repairs performed in the United States between 6 and 15 months, and 74% between 6 and 12 months of age.[24] Ysunza completed a prospective study of 76 patients randomized to repair at 6 and 12 months old. Although VPI rates were similar at 4 years, phonologic development was better in those treated at 6 months old with a lower rate of compensatory misarticulations, and reported no difference in maxillary growth.[74] Dorf and Curtin reviewed compensatory misarticulation rates in children undergoing cleft palate repair before or after 12 months of age. Only 10% of children treated before but 86% of those treated after 1 year of age developed compensatory misarticulations.[72] Repair beyond 1 year has been associated with poorer rating of speech intelligibility.[75,76] The benefit of early palatoplasty appears to diminish when the age of surgery falls below 6 months with the literature providing conflicting conclusions.[74,77-79]

Cleft severity appears to be inversely correlated to surgical outcomes with bilateral cleft lip and palate consistently demonstrating the worst speech.[26,61,80] Counterintuitively, those with an isolated cleft palate are also found to have a high rate of secondary velopharyngoplasty, ahead of unilateral cleft lip and palate.[25,61] Some suggest this is due to the absent attachment of the vomer that may maintain palatal length.[59,61] The existence of undiagnosed syndromes in those with isolated cleft palate may also contribute.

Growth

Normal mid-facial growth is paramount to facial function and esthetics and is measured by vertical facial height, projection, and occlusion.[81] Deposition at the anterior surface of the transverse palatine suture provides maxillary length and projection. Bilateral deposition at the midpalatal suture provides maxillary width, with more posterior activity. Vertical height develops through appositional growth at the hard palate and alveolus.[82] The maxilla is suggested to obtain additional projection and vertical height as vomerine growth bodily displaces the maxilla anteriorly and inferiorly.[83]

Effective research evaluating growth in the cleft population is challenging due to the accumulation of treatment effects and the extended follow-up necessary to evaluate outcomes beyond skeletal maturity. When maxillary growth is assessed by cephalometric analysis, the current standard, caution should be exercised as anterior maxillary landmarks such as ANS and A point are commonly distorted by asymmetric muscular insertions and may result in a false representation of a longer and more anteriorly positioned maxilla.[84-86]

Growth disturbance in complete unilateral cleft lip and palate is characterized by a short maxilla in height, length, and projection. The mandible is also generally smaller with a steep mandibular plane, anterior-posterior occlusal discrepancy, and a short cranial base.[87,88] The growth disturbance in isolated cleft palate also demonstrates a reduced maxillary and mandibular projection and size, but to lesser extent and less of an anteroposterior occlusal discrepancy, and a normal base of skull length.[88] In contrast, the dental arch in bilateral cleft lip and palate following primary lip repair demonstrate a wider posterior arch width and an anterior arch length shorter than those with unilateral cleft lip and palate.[90]

The ultimate facial form of those with cleft lip and palate is inexorably tied to the treatment of the cleft lip and alveolus. Such interventions include cheiloplasty associated with maxillary retrusion,[91] aggressive presurgical orthopedics leading to collapse of the dental arch,[68] and gingival periosteoplasty or primary bone grafting associated with a short anterior arch length, severe inclination of the lesser segment, and poor occlusal relationships.[68,92-95]

The poor maxillary projection of the cleft population has frequently been attributed to iatrogenic injury.[89,96-98] In 1949 Graber called attention to the grossly impaired maxillary growth seen at that time, reporting a correlation between maxillary retrusion and collapsed maxillary arches with the extent of scarring and multiple palatal procedures.[99] Ross and colleagues have supported this view, reporting that all palatal repairs inhibit maxillary length, posterior height, and projection.[82] While soft palate repairs impact posterior maxillary growth and transverse width to variable degrees, hard palate repair techniques and timing tend to have the most significant effects on mid-facial retrusion.

The Veau-Wardill-Kilner push-back has received criticism for inducing excess scar tissue and impairing maxillary and occlusal development when compared to the von Langenbeck and two-flap techniques.[62,82,95,100,101] Although reports and opinions have been presented to favor the von Langenbeck or the two-flap palatoplasty technique, neither has consistently lead to superior results.[62,82,90-92,102] Reports have also demonstrated significant interoperator variability, suggesting that other factors influence results. Following the philosophy of limiting dissection and extent of denuded bone, and reducing scar tissue formation, additional modifications in the form of refraining from fracturing the hamulus, reducing mucosal stripping, and limiting the extent and location of relaxing incisions have been recommended.[37,101,103,104]

Staged repair of the soft and hard palate defects is one approach to limiting poor mid-face growth in people with cleft palate defects. Popularized by centers in Europe, delay of repair of the hard palate cleft has gained significant commitment from some centers throughout the world.[105,106] Interestingly, Bardach and colleagues impressed with published results visited and examined a small, random subset of Schweckendiek's patient population, confirming growth results but observing poorer speech outcomes than initially reported.[8] Various other publications in support of single-stage techniques have reported suboptimal speech results with staged protocols and so, while a staged protocol is still practiced by

some centers,[107] 96% of centers in North America adhere to a single-stage method according to recent survey.[24]

As demonstrated in the Eurocleft and Americleft data, improved occlusal development is obtained when palatoplasty is delayed.[68,95] The results of other studies, however, have been variable regarding the ideal timing of palatoplasty.[108-111]

In Europe the classic approach to staged repair is being supplanted in some centers by a different approach. A vomer flap is used to achieve nasal side hard palate closure at the time of lip repair, followed by subsequent repair of the soft palate before the occurrence of any significant speech development. Although early repair of the soft palate is associated with favorable speech development, the long-term impact on maxillary growth has yet to be clearly determined.[75,112]

Comparison with the DOZP

A recent survey of the American Cleft Palate Craniofacial Association reported an equivalent percentage of surgeons perform two-flap with IVV (45%) and DOZP (42%).[24] Similar outcomes are reported utilizing each procedure by experienced surgeons with impressive case volumes although high quality evidence supporting one procedure over the other is limited.

The largest prospective randomized trial to date comparing the two procedures reported improved speech with the DOZP when using hypernasality as the outcome measure (82% vs. 71%) whereas the fistula rate was significantly higher (23% vs. 14%).[77] Significant surgeon variability was identified.[113] Audiologic and otologic outcomes were similar at 5 to 6 years of age and other outcomes have yet to be reported.[44]

Conclusion

Repair of the cleft palate involves layered closure of the hard palate and functional reconstruction of the soft palate with straight line repair and complete intravelar veloplasty or double opposing Z-plasty techniques. A simultaneous repair of the hard and soft palate between 9 and 15 months of age is the most common approach in the majority of U.S. centers with no significant difference in utilization of straight line techniques or DOZP. This sequence appears to demonstrate acceptable outcomes with regard to speech and growth. Low published rates of fistulae formation are common with straight line techniques. Regarding middle ear disease, neither straight line or DOZP techniques have proven superior. Similarly, superiority of straight line techniques or DOZP techniques with regard to growth restriction are unlikely to be related to the generalities of straight line technique and most likely depend more on timing of repair and individual techniques of the operator as they relate to extent of dissection, areas dissected, and creation of excessive scarring.

Only through standardization of patient evaluation, data collection, and long-term outcomes assessments will multicenter studies be able to clarify many of the unanswered questions related to cleft palate repair. Ideally though, care should maximize speech outcomes, promote middle ear health, limit facial/dental growth restriction and associated mid-face retrusion, and do so with a minimal number of interventions so as to limit negative psychosocial impact on affected people and their families.

DOUBLE OPPOSING Z-PLASTY

Gerardo P. Romeo

Prior to the use of the double opposing Z-plasty technique various modifications of straight line repairs had been utilized to treat cleft palate deformity.[114-118] Results with eliminating oral and nasal communication were highly acceptable; however, achieving velopharyngeal competence and proper speech was less predictable. The desire for velar lengthening resulted in various publications of "push-back" style techniques.[114-116] For a great while, though, the abnormal musculature of the soft palate was not meaningfully addressed during palatoplasty. Satisfactory consistent and reproducible speech results were not commonplace during this time. A technique for dissection and repositioning of the inappropriately positioned palatal musculature via intravelar veloplasty (IVV) by Kriens was published in 1969 and conceptually changed the evolution of palate repair techniques.[119,120]

The usefulness of Z-plasty to increase the length of a linear wound or scar band has long been known; however, publication of techniques incorporating it into palatoplasty did not begin until the 1970s.[121] In 1976 Dr. L.T. Furlow developed and began using a new technique for cleft palate repair that both increased velar length and appropriately addressed the soft palate musculature via a "double opposing Z-plasty." His main intent was to improve speech outcomes and velopharyngeal function while limiting negative growth effects.[122,123] His first public presentation of the technique came in 1978.[124] His technique successfully incorporated the dissection of palatal musculature from abnormal skeletal insertions and reorientation into proper position, conceptually similar to IVV, but incorporated it into the design and elevation of bilateral mucosal flaps for Z-plasty, both repairing the defect and increasing velar length.

Technique

A Dingman mouth gag is utilized for this procedure. The patient is positioned on the operating table in supine position. Use of a shoulder roll with the neck slightly extended is helpful. The hamulus of the medial pterygoid is palpated and serves as the important landmark. Surgical markings are made and anesthetic solution containing a vasoconstrictor is injected. As originally described, the posteriorly based myomucosal flap of the oral side is made on the patient's left for the right-handed surgeon as a matter of convenience for proper dissection. The technique is described in

this orientation in this chapter, but may be mirrored if so desired.

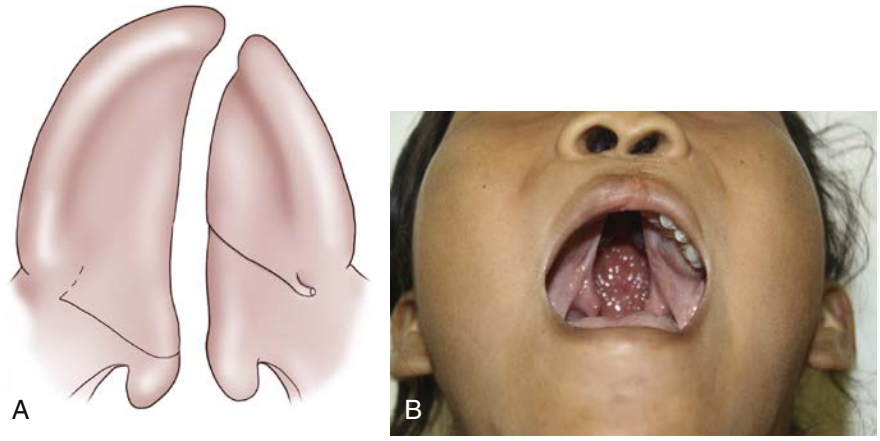
The first marking is made slightly beyond the posterior border of the hard palate in the mucosa of the soft palate, leaving a small cuff for suturing on the patient's left. The mark extends from the hamulus to the midline cleft approaching the junction of the hard and soft palate. The cleft will serve as the central limb of the Z-plasty and is marked at the junction of the nasal and oral mucosa. On the opposite side, the anteriorly based flap is marked beginning with the central limb left at the junction of nasal and oral mucosa and extending posteriorly to the base of the uvula. From the uvula, a straight line is drawn across the soft palatal oral mucosa to the right hamulus (Figure 30-10). The Dingman retractor is now "let down" to avoid prolonged tongue ischemia, reperfusion injury, and the resultant complications that have been reported while waiting for the vasoconstrictive effects of the anesthetic solution.[125,126] This should be repeated periodically throughout the procedure.

A 15c blade mounted on a No. 7 surgical blade handle is used. The first incision is made in the midline cleft at the junction of the oral and nasal mucosa on the patient's left side to the tip of the uvula. Traction of the uvula is maintained with a traction suture or surgical forceps. The incision is made from the anterior extent of the hard palatal cleft to the uvula. The lateral limb of the Z-plasty is then incised on the patient's left through mucosa only until the first incision is met in the midline. Anteriorly, the palatal shelf and posteriorly the muscle layer are identified. The posteriorly based palatal flap is elevated so that the muscle layer is freed from the nasal mucosa and maintained attached to the oral mucosa, incorporated into the flap.

Laterally, the dissection proceeds until the palatal aponeurosis is encountered and it is incised to the hamulus. Careful dissection with blunt technique using a freer or periosteal elevator ensues to mobilize the musculature posteriorly. A useful modification of technique described by the surgeons at the Children's Hospital of Philadelphia involves fracture of the hamulus and extended dissection into the space of Ernst to aid in posterior mobilization of the flap and ability to advance flaps across the midline.[127] With much of the flap elevated, the tensor palatini tendon becomes visible as it crosses the hamulus. Its muscle fibers abnormally insert at the palate. In the original technique, the tendon is not disturbed. Some postulate that maintenance of the integrity of the tensor tendon is necessary for eustachian tube function post repair, while others perform tenotomy to increased mobilization of the flap.[128,129]

As originally described, a periosteal elevator is now used to address the cleft of the hard palate. This dissection extends in the subperiosteal plane to the alveolus. This allows for relaxation of tissue from the palatal vault, many times without lateral relaxing incisions. Avoiding releasing incisions was postulated by Furlow to limit maxillary growth effects. Presently though, multiple modifications are described using various relaxing incisions as well as elevation of von Langenbeck and/or Bardach style flaps.[124,127,128,130] Some surgeons prefer to dissect the hard palatal flaps immediately after initial incisions as it facilitates developing the flaps in the appropriate layers rather than at this stage in the surgery.

Attention is then directed to the opposite side where the oral anterior-based mucosal flap is developed. The incision again begins at the oral/nasal junction in the cleft at the midline from the anterior-most extent of the hard palatal cleft. Incision extends posteriorly to the tip of the uvula, exposing the hard palatal shelf anteriorly (partial elevation of palatal mucoperiosteum aids in defining the proper plane of dissection) and the palatal muscles between layers in the soft palate. From the base of the uvula, the incision is carried anterolaterally toward the hamulus. Again, this flap does not incorporate palatal muscles. The point of the flap at the base of the uvula is elevated developing a plane of dissection between the palatal muscles still attached to nasal side mucosa and the oral side minor salivary glands. The oral side mucosa of the hard and soft palates remain continuous after completion of dissection on either side. Traction



• **Figure 30-10** Z-plasty incisions. The cleft serves as the central limb of the Z-plasty on both sides. The Lateral limbs of the Z-plasty end at the pterygoid hamulus. Notice the lateral limb of the anterior based flap begins at the base of the hemi uvula. (From Furlow LT Jr: Cleft palate repair by double opposing Z-plasty, *Plast Reconstr Surg* 78:724-736, 1986.)

sutures are placed to position oral side flaps and nasal side flaps can then be marked as a mirror image of the oral side.

Elevation of the posterior based nasal side myomucosal flap (on the patient's right in this case) is completed with surgical scissor or blade and extends toward the hamulus ending at the eustachian tube (Figure 30-11). Leaving a small cuff of tissue at the muscle attached to the nasal side mucosa at the hard palate will aid in suturing later. The aponeurosis is again incised when encountered laterally, as was the previous side. Blunt instrument dissection is again used to mobilize the flap and palatal muscles attached to the nasal side mucosa posteriorly. Attention now returns to the patient's left side. The nasal side anterior based flap is then developed, sharply incising from the base of the uvula to the eustachian tube on the left. The four flaps are then ready for reorientation and suturing. A vomer flap can be developed at this time for nasal side closure if necessary. Rotation of flaps and closure using resorbing sutures now begins.

The two hemi uvulae are tacked together. The tip of the anterior based nasal side flap on the left is rotated anteriorly across the cleft and inset with a single suture into the resultant crotch of the nasal side posteriorly based flap on the right near the eustachian tube while the right side flap (containing the palatal muscles) is rotated posteriorly. The rotation will bring the palatal musculature of the right side posteriorly based flap across the cleft for inset near the eustachian tube on the left and is secured in position with suture. The flaps, now reoriented and lying in proper position are then sutured together with knots toward the nasal side (Figure 30-12). Both synthetic and natural resorbing sutures that maintain strength for approximately 1 to 2 weeks are sufficient and should ideally be mounted on a tapered needle. Nasal side repair is now complete and oral side closure ensues. The point of the anterior based flap on the patient's right is rotated and secured across the cleft near the hamulus while the left side flap is rotated posteriorly. The left side

posterior based flap is now secured across the cleft at near the hamulus. Mattress sutures are then used for oral side closure, to achieve proper eversion while avoiding tension at the suture line (Figure 30-13).

Speech

Supporters of this technique often site increased velar length, establishment of a competent velar mechanism, and successful speech outcomes. Radiologic evidence has confirmed increased velar length and bulk as well as successful reconstruction and repositioning of an intact velar sling in a more correct position.[131,132]

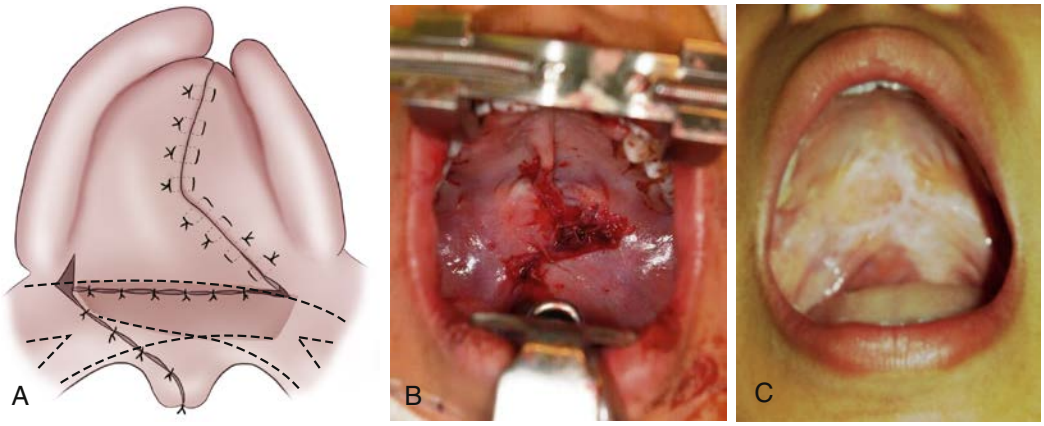
Dr. Furlow first reported on 22 children. His VPI incidence prior to this was ≈48% using a von Langenbeck technique without IVV. With his new technique, 18 were free of velopharyngeal insufficiency (VPI) and 2 had "very mild" VPI as determined by speech pathologist. This marked a significant, predictable improvement.[122]

The group from the Children's Hospital of Philadelphia (CHOP) warrants mention when discussing the double opposing Z-plasty. The surgeons of that institution adopted the technique very early on and are in part responsible for its evolution and wide utilization. Their initial experience was actually published 1 month prior to Dr. Furlow's reporting on 106 patients and using a modified technique. Similarly, they too described an improvement in VPI as compared to their prior experience. They reported having used the surgery in patients with submucous cleft palate as well as a revision technique for VPI following primary palatoplasty. Subsequent publications from that institution continue to support excellent results.[124,127] A 30-year retrospective experience using a modified technique in 869 patients was published in 2013.[128] Of all analyzed patients, 72.5% had competent or borderline competent mechanism and 21.5% with borderline incompetence but intelligible speech using Pittsburgh weighted speech scale as an outcome measure. Only 8% of patients overall required a secondary pharyngeal surgery. This is the largest single institution volume of patients reported in the literature to date and the results are both consistent and encouraging.

Other retrospective institutional publications are in support of similar speech outcomes with the Furlow technique.[133] Additionally, some comparisons between Furlow and straight line techniques without IVV suggest superiority of the Furlow technique.[134,135] However, a small retrospective analysis comparing Furlow versus straight line repair without IVV failed to show any statistically significant difference in outcome.[136]

A retrospective single surgeon comparison between outcomes with Furlow palatoplasty versus straight line palatoplasty *with* IVV demonstrated a trend toward poorer speech score outcomes in the IVV group but the difference was not statistically significant. The rate of a necessary salvage procedure for VPI, however, was far superior in the Furlow group (8% vs. 29% in the IVV group) and showed statistical significance suggesting superiority by that measure of success.[137] A limitation of this study design, though, is that a single surgeon may not be equally skilled in the two techniques as may be suggested by the VPI rate following IVV being quite high when compared to the strongest reported outcomes from other institutions/individuals for that procedure.[138,139]

A large, high level, prospective study of 467 patients by Williams also claims superiority of the Furlow technique versus a straight line repair technique utilizing intravelar veloplasty with regard to velopharyngeal function.[140] That study used a cul-de-sac test of hypernasality and a mirror test of nasal air emission as a primary measure of velar function and combined that with a four-point hypernasality scale to rate resonance as a secondary measure during patient interactions with the speech and language pathologist. The cul-de-sac test showed a statistically significant advantage of the Furlow technique: however, none of the



• **Figure 30-13** **A,** Oral side flaps are now rotated and secured, successfully rotating the abnormal musculature from the patient's left side to span the cleft in an appropriate posterior position. There is overlap of the muscles of both posterior based flaps and a lengthened soft palate at the conclusion of the surgery. Everted, tension free closure is of paramount importance. **B,** Immediate post-op. **C,** Six month follow-up same patient. other results—while suggestive of an advantage—proved statistically insignificant.

Versatility

While initially developed as a technique for primary repair for cleft palate, usefulness for a variety of indications has emerged. Surgical management of VPI in submucous cleft palate (SMCP) and as a revision procedure for postsurgical VPI in an attempt to avoid pharyngeal flap or other pharyngeal speech surgeries is gaining favor. Avoidance of a P-flap in management of VPI is appealing due to high potential for development of postoperative snoring, obstructive sleep apnea,[141,142] and possible overcorrection resulting in hyponasal speech. Retrospective data suggest success rates with the Furlow technique may be no different statistically than P-flap in some patients.[143] Additionally, prospective data suggest a clear advantage of Furlow palatoplasty over P-flap with regards to developing OSA.[144]

There are multiple groups that have used Furlow palatoplasty techniques for surgical management of VPI in patients with SMCP, including that data in analysis along with all other cleft subtypes with satisfactory results.[124,127,128,131,133,142,143,145,146] Others, though, have examined specifically VPI of the patient with SMCP excluding other cleft subtypes. Chen retrospectively examined 30 patients with VPI due to SMCP managed with a Furlow technique and reported achieving a competent velopharyngeal mechanism and normal resonance in 29 of them with no complications. Importantly, there were multiple specific inclusion criteria with regards to VP gap size in relation to age as well as response to biofeedback speech therapy preoperatively that were used to select patients for Furlow palatoplasty. The significance of those criteria on outcomes, though, is unclear and was never verified independently.[147] In a 10-year retrospective by Seagle successful outcomes in 83% of cases was reported with the Furlow technique in SMCP associated VPI. The highest rate of success was seen in patients with velopharyngeal gaps of 8 mm or less.[148] A small prospective study by Abdel-Aziz was published in 2012. In it, 15 patients with SMCP and VPI that was not improved with prior speech therapy were managed with the Furlow technique. Thirteen of the 15 had complete velopharyngeal closure on postoperative nasopharyngoscopy as well as statistically and clinically significant speech improvement with no incidence of hyponasal speech.[149]

Use of the Furlow palatoplasty for VPI after a failed surgical attempt rather than a pharyngeal surgery is also proving useful, though distinct data examining it as a revision procedure separating it from VPI associated with SCMP are scarce. A prospective paper by Deren examining the Furlow technique as a revision technique after Veau-Wardill-Kilner palatoplasty with VPI confirms effectiveness. Eight of the 27 patients had normal resonance and no nasal escape postoperatively and 10 had normal resonance with mild nasal escape or no nasal emission but mild hypernasal resonance. The remaining 33% were considered failures, but still had signs of improvement relative to preoperative assessment.[150]

The presence of a syndromic diagnosis is considered a confounding variable when evaluating outcomes of palatoplasty and is variably excluded from data sets. While not a true syndrome, Pierre Robin sequence is also often excluded from data and lumped into the syndromic category. The data sets that do include syndromic diagnoses tend to show little difference in success rates between syndromes and sometimes show success rates inferior to outcomes compared to "non-syndromic patients."[151-153] A prospective evaluation, however, examining Furlow palatoplasty for surgical VPI management that included "syndromic patients" in outcomes analysis showed no statistically significant difference in velopharyngeal insufficiency outcomes between those that did and did not carry a syndromic diagnosis (an exception being patients with 22q11 deletion syndrome). Carrying a diagnosis of velocardiofacial syndrome has been shown to be particularly troublesome as it is consistently difficult to correct VPI.[146,153]

Furlow palatoplasty, however, is not the only revision palatoplasty option for addressing VPI. Two-flap repair with aggressive intravelar palatoplasty using intraoperative magnification has a high rate of achieving velar competence and satisfactory speech improvement.[154] A head to head comparison of these techniques specifically for management of VPI as a revision does not exist to date, though a small series by Afrooz suggests that Furlow palatoplasty might be more effective than two-flap palatoplasty with IVV in patients with some syndromic diagnoses diagnosed with occult submucous cleft palate.[152] This series, though, was relatively small and retrospective.

Growth

With regards to growth, little information following Dr. Furlow's early comments in his publications exist. The large prospective study from the University of Florida Craniofacial Center and the University of São Paulo Hospital for Rehabilitation of Cleft Lip and Palate in Bauru, Brazil, provided growth charts for babies born with deformities, but it failed to present the objective long-term growth data about the effect of different techniques used for initial cleft lip and palate repair on subsequent facial growth to date as was once hoped.[155] Meaningful growth data require follow-up until skeletal maturity of the craniofacial skeleton, making these studies highly difficult to complete and rarely undertaken. With much variability between surgeons and centers in technique and age at time of repair, attributing growth effects to the technique of the soft palate repair alone would be difficult. In addition, with the possible exception of transverse width of the hard palate following repair of the soft palate,[156] it is most likely that growth of the mid-face is affected more by scarring of structures forward of the soft palate with severity relating more to age, technique of hard palatoplasty, and extent of dissection on the alveolus at the time of repair.[117,157-160]

Ear Health

Eustachian tube dysfunction in patients with cleft palate is well documented, often requiring close otologic follow-up and care. Dr. Furlow initially described achieving 70% normal hearing in his cleft patient population postoperatively with only 5 of 20 patients having a mild hearing loss. He attributed this to the nasal Z-plasty incisions ending immediately adjacent to the eustachian orifices.[122] It should be noted that no division of the tensor tendon was discussed in his original paper. In contrast, a retrospective study from Güneren published in 2000 found no difference between Furlow and VWK push-back in terms of eustachian tube function and presence of postoperative serous otitis media.[161] While stating that there were no modifications of the Furlow technique, there was no comment on whether or not the tensor tendon was divided in this study. A paper by Antonelli published in 2010 prospectively looked at ear outcomes in patients treated with Von Langenbeck vs. Furlow and found no difference in outcomes.[162] Whether or not tensor tendon tenotomy has an effect on hearing outcomes or eustachian tube function is not clear at present. Regardless, it appears that Furlow outcomes are no worse than other methods in this regard.

Limitations and Complications

Fistula

In his first publication of the technique, Dr. Furlow described difficulty with a wide U-shaped cleft. It is widely accepted today that the widest clefts may not be repairable with the Furlow technique because the length gained from Z-plasty is at the expense of width by design. Fistula formation is a known complication of all methods of palatoplasty with highly variable rates of occurrence in the literature.[163] Fistula rates with the Furlow technique, however, are cited as being increased relative to 2-flap techniques.[140,164-167] Various modifications have been described to address this. The use of releasing excisions, for example, has been associated with a lower incidence of fistula in addition to other modifications of technique.[140]

The use of acellular dermis in both primary palatoplasty and fistula repair has been shown to aid with lowering fistula rates.[167-169] Levi published an extension of a previously utilized concept in straight line repairs that incorporates buccal fat pad into Furlow palatoplasty both to combat fistula formation and to cover large areas of denudation of the hard palate.[170] Bindingnavele[171] described islandization of the hard palatal mucoperiosteal flaps while maintaining integrity of greater palatine artery pedicle to decrease tension of final closure and optimize mobilization. This technique compared to Furlow without islandization showed a statistically significant benefit of islandization to decrease rate of fistula formation.[171]

Gupta published a paper incorporating buccal myomucosal flaps for very wide unrepaired clefts in mature adult patients.[130] Oyama, focusing on growing babies, published a mucosal adhesion technique for staging palatoplasty in growing patients where wide clefts were converted to narrower ones that are more amenable to Furlow technique with tension-free closure. Results in this small series were effective in narrowing the width of palatal cleft over time with limited detrimental growth effect, though the series was small and follow-up short.[156]

Teaching

Another perceived limitation of the Furlow technique is that it is difficult to learn and teach. Comprehension of the procedure only from text or diagram is difficult. Various attempts at techniques to aid in the learning process have been published.[172,173] A paper by Losken, though, showed that surgical participation in the technique by a novice operator can still result in good outcomes when strict criteria are maintained in patient selection.[174] From experience, observing the live procedure just one time quickly clarifies many of the uncertainties of concept for the novice surgeon. Technical skill develops with repetition.

Summary

The double opposing Z-plasty technique commonly referred as the Furlow technique has proven to be a useful and effective technique in palatal reconstruction. One should remember though that "the Furlow" does not describe a single operation as multiple variations and modifications exist. Therefore, the available literature should be taken with the proverbial grain of salt when considering translation into one's practice. It is, of course, only a hammer in the metaphoric tool belt of the cleft surgeon and one must remember that not all patients are nails. While supporters of the technique would like to prove complete superiority over all other methods, it should be remembered that literature exists that supports some of those claims but an equivalent body of literature either refutes them or shows equivalent outcomes to straight line techniques, typically, with IVV. Because so many difficulties exist in creating a bias-free body of literature that accounts for all of the multiple variables in cleft care, it is important to familiarize oneself with all of the available literature and recognize that, like most techniques, there are instances where use of this technique will be ideal and others where use of many of the other techniques would also prove effective. Ideally, with experience, the cleft surgeon will recognize the utility of this procedure and utilize it for its strengths in appropriate situations. Surgeons should constantly examine their own outcomes in a systematic, objective way and not be wary of changing old habits for new methods in search of better outcomes.

TWO-STAGE PALATAL REPAIR

GERARDO P. ROMEO, PAMELA M. GALLAGHER

The growth problems encountered in patients surgically treated for cleft lip and cleft palate have long been recognized and are well described. Mid-face retrusion, distortion

of dentoalveloar structure, and abnormal posture and position of the mandible have been long accepted as the most commonly occurring abnormalities associated with cleft palate repair.[175-182] One approach developed in the attempt to minimize the mid-facial growth restriction has been to "stage" the repair of the palatal defects.

Staged repair of the palate, sometimes called delayed repair of the hard palate, refers to separation of the veloplasty from the surgical repair of the cleft hard palate, classically termed uranoplasty, into distinct procedures at differing points in growth and development. The rationale behind this technique is to minimize any unnecessary growth restriction associated with the surgical repairs of the hard palate while facilitating the development of normal speech by creating a functional soft palate. Ideally, veloplasty might occur before compensatory speech errors and poor habits develop early in life. While the technique is not as popular in the United States as is single-stage palate repair, in which the velum and hard palate are repaired in a single operation,[183] it has a long-standing history of use in various centers throughout the world. Like all other aspects of surgical care of patients born with clefts, the approach has both supporters and critics with variable levels of literature available supporting claims made by both.

Origins

In the context of the time period in which this approach originated, severe mid-facial growth restriction, the resultant cosmetic deformities, and malocclusion were nearly impossible to correct meaningfully. Orthognathic surgery, particularly of the maxilla, was in its infancy, therefore, one must remember that the two-staged repair was born from necessity.

The concept for the technique was initially presented by Gillies and Fry in 1921.[175] Recommendations were for soft palate repair utilizing a technique that involved division of the soft palate and aberrant musculature from the hard palatal shelves, retropositioning of the velum to gain length posteriorly, and repair of the soft palate and musculature across the cleft in the midline. The remaining cleft of the hard palate was then managed with a removable obturator prosthesis. The concept of delaying the repair of the hard palate until a later point in time was mentioned, but in fact, the recommendation of the author was not to repair the hard palate at all.[184] The approach failed to gain popularity initially but the concept gained support later after being re-introduced in 1951 by H. Schweckendiek in Europe and later by Slaughter and Pruzansky in the United States.[185,186]

A landmark publication in 1978 by W. Schweckendiek detailed a 25-year retrospective report on the patients that had been treated using the staged surgical protocol developed by his father. The soft palate was repaired in the first year of life in straight line fashion utilizing lateral releasing type incisions. This was followed by lip repair approximately 3 weeks later. The hard palate was not repaired until middle to late adolescence (12 to 14 years of age). The residual hard palate defect was not obturated until eruption of the permanent incisors and first molars, if at all. The results were compelling in that transverse and AP maxillary growth was excellent with harmonious occlusion and satisfactory speech outcomes were reported by the surgeon.[187]

Various centers began to explore staged repair as a viable alternative at this point in history. Ultimately though, publications highlighting compromised speech outcomes and questioning the extent and significance of benefits to growth began to accumulate[188-191] and the approach failed to maintain a stronghold in most centers in the United States.

Various staged protocols have been developed and utilized since the initial description in 1921. The only commonality shared by all of them is that the hard and soft palate defects are repaired at differing points in time. This fact makes review and meaningful comparison of the literature challenging. Additionally, the overwhelming majority of available literature on the topic is retrospective and riddled with biases.

Many variations exist under the blanket term of "staged" or "delayed hard palate" repairs and meaningful generalizations are nearly impossible to make with any degree of accuracy. For simplicity, when discussing staged approach to palate repairs, the implied definition involves velar repair in the first year of life up until 18 months, optional use of an obturator both before and after velar repair, and hard palate repair in the preschool or early school age though, to be clear, this is not a strict definition nor is it universally accepted.

Optimal Timing and Technique

Staged repair and the question of its utility is more a series of individual questions regarding optimal techniques and timing of different aspects of care rather than a single question with a single answer. With that, it would seem that a single generalization regarding usefulness of the technique that can be applied to all patients and centers cannot exist. Therefore, it makes sense to examine some of the individual aspects of staged repair and their history via the literature en route to a meaningful attempt at drawing some conclusions.

Velum

Early in it's history, the first protocols involved repair of the velum anywhere from the first year of life to 3 years of age.[175,185,186] As focus shifted from minimizing growth restriction to the importance of developing ideal speech, the age at which velar repair occurs has steadily shifted towards earlier in life,[192-194] with benefits being reported when velar repair occurs at the first signs of the development of canonical babble.[194] Literature regarding timing of repair both as single and staged repair typically recommends repair occur before 18 months,[195] ideally between 9 and 12 months,[194] and perhaps as early as 3 to 6 months of age,[196,197] with the most commonly accepted practice being that individual speech development should dictate optimal velar repair for speech rather than any specific chronologic age.[194,198] Blanket

application of these suggested parameters regarding timing, however, is not suggested because the recommendations were made in the specific context of the studies from which they were derived. For example, there may be no perceivable benefit to very early palatoplasty in cases of definitive one-stage repair utilizing double opposing Z-plasty techniques,[199] but in instances where specific staged palatoplasty techniques incorporating very early velar repairs that limit dissection of the hard palate and healing of extensive areas of denuded hard palate secondarily are avoided, highly acceptable speech outcomes using delayed hard palate repair techniques have been confirmed. In literature published from the center in Göteberg, Sweden, for example, the staged technique utilized which incorporates very early repair of the velum using a specific, standardized technique described by Liljia,[200] main tenets of which included limiting dissection of the hard palate to the most posterior edge and minimizing remaining denuded areas to heal by secondary intention after repair, has resulted in highly encouraging phonation of consonants, absence of glottal substitutions, and excellent velopharyngeal function.[196,201] One should always keep in mind though, that many techniques are used in the repair of the soft palate with a seemingly endless number of variations, so it is not clear that applying conclusions between studies would apply to all, or any, other techniques. For example, selectively utilizing the timing of repairs discussed above with techniques for velar repair that incorporate an extensive hard palatal dissection or other techniques that result in an extensive amount of denuded hard palatal bone to heal via secondary intention or neglect to provide a meaningful reconstruction of the soft palate musculature may result in a compromise of either speech, growth, or both. There have been numerous publications that show, however, that high level speech results and preserved maxillary growth can be achieved in staged approaches that utilize both double opposing Z-plasty techniques and two-flap repairs with intravelar veloplasty.[202-207] The common theme in all of these techniques is limited dissection of the hard palate and minimal to no denuded bone left to heal by secondary intention.

Maxillary Obturator Appliance

Prior to Velar Repair

Obturator prostheses provide a mechanical barrier separating the oral and nasal cavities while the cleft defect is present. The use of these appliances both before velar repair and afterwards while waiting for hard palate repairs has been described in the literature. Some centers advocate use of a prosthesis to aid in feeding and phonation and to promote harmonious positioning of dentoalveolar segments, at times using it along with nasoalveolar molding techniques, prior to lip (and velar) repair. At the present, the overwhelming majority of the appliances are passive given the growth restriction seen previously with active appliances.[208] While some literature has suggested that use of a passive obturator in infancy may initially aid in speech development, it has not been shown to translate into a sustained benefit with age, with differences no longer appreciable by age 6 years.[209,210] With regard to use of passive style obturators prior to velar repair, multicenter trials have failed to show a definitive long-term benefit with regard to speech development, feeding, and long-term cosmetic outcomes and they may actually increase care burden and cost unnecessarily for some children and their caretakers.[211-214] It should be noted, however, that use of passive appliances prior to veloplasty have never been shown to be harmful to the patient or compromise outcomes and therefore are not necessarily contraindicated.

Following Velar Repair

Use of an obturator appliance after velar repair and before hard palate repairs is another area of controversy within the staged approach and is commonly described throughout the literature. The goal of use of the prosthesis after veloplasty, similarly to when used prior to repair, is to provide mechanical separation between the oral and nasal cavities for facilitation of feeding and speech production. Some utilize an appliance for all patients between velar and hard palate repairs. Some never utilize an appliance while others allow for selective use in some circumstances where difficulties with speech or feeding become overwhelming for the patient and caretakers. Centers that advocate usage often claim facilitation of speech and feeding[187,195] while others report that they are unnecessary with many children achieving satisfactory speech (with obvious limitations based on the residual hard palate defect) without them so long as intensive speech therapy is accessible.[187,195,196,201]

In the instances where appliances are utilized, most are passive, some are removable, and some use pin retention. The specific effect of the obturator both with regard to speech and influence over growth and long-term effects on occlusion are sparse in the literature. Some are of the opinion that pin retention of the obturator is associated with increased growth restriction and often cite a report by Holland and colleagues to support that sentiment. However, it should be appreciated that the protocol described in that center at the time involved placement of serial obturators replaced for "optimal fit." Additionally there was an excessively high rate of fistula formation in that report and the majority of patients underwent multiple revision procedures to the palate as well as a significant number of speech related surgeries in the pharynx.[215] Therefore, suggesting that the observed growth restriction was due to the staged approach itself and/or pin retention of the prostheses alone rather than the increased number of surgeries and scarring in those patients may not be accurate. Furthermore, hard palate collapse after veloplasty has long been appreciated to occur spontaneously and there has never been a study examining if pin retention versus no retention results in collapse of any further significance compared to veloplasty without postoperative use of an obturator. Although it is possible that fixed obturators may impede growth there is no high level evidence to support this claim at this time. It would be just as reasonable to assume that pin retention may actually prevent more collapse than a removable appliance without pin retention or no prosthesis at all. Until a meaningful comparative study

examining this becomes available, however, the use of a passive palatal obturator either with or without pin retention is equally acceptable, as is the decision to not use an appliance between velar and hard palate repairs so long as the patient tolerates whichever approach is selected.

Uranoplasty

The age and style of hard palate repair is also variable with ranges reported anywhere between 15 months and young adulthood with numerous variations of surgical techniques being utilized. Similarly to the timing of velar repair, the age at which the hard plate repairs occur has become younger and younger with time with no single age universally accepted as "ideal" in an attempt to limit aberrant speech and minimize growth restriction. Gillies delayed hard palate repair indefinitely.[1] Later publications delayed repair until skeletal maturity in the teenage years with excellent growth results.[187,189] As time went forward, repairs were completed earlier still between the ages of 6 and 10 years, again with excellent long-term growth results.[195,201,216,217] When both growth and speech outcomes were compared in children that had repairs earlier still at 3 to 5 years of age, again, no significant difference regarding both speech and growth were evident when compared to longer delays in hard palate repair (between 6 and 10 years of age).[218-221] As a result, this range of approximately between 3 and 5 years of age is highly acceptable, though some reports describe even younger ages for repair.[197]

While, typically, two-flap techniques for mucoperiosteal repair of the hard palate cleft have been the most common methods examined, many variations with regard to flap design, extent of dissection, and techniques to obliterate dead space or provide coverage of denuded areas are included in the literature. The true extent of these modifications is poorly examined in the context of staged repairs but it is likely that they have the most potential for impact if hard palate repairs are completed very early in life, in which case avoidance of excessive scarring and avoidance of leaving denuded areas to heal by secondary intention are advisable.

Though not a new technique, one of the most significant variations in recent history relating to staged hard palate repair, and steadily gaining popularity, is the use of a single-layer vomer flap and complete avoidance of oral side mucoperiosteal dissection. In some reports this occurs simultaneously with lip repair and separate from velar repair, which would qualify it as a staged technique. In others, it is incorporated during repair of the velum (which would be considered a single-stage technique). Many reports suggest favorable speech and growth, though not all have a sufficient length of follow-up to make definitive generalizations.[221-225]

Supporters, Critics, the Literature, and Conclusions

The benefits reported by supporters of the staged technique both historically and currently remain consistent. The main advantage is a decreased incidence of iatrogenic growth restriction, particularly in terms of anterior-posterior projection.[175,185-187,189,195,197,202-205,216-220,226,227] Second, there is a decrease in the size of the residual hard palate cleft following soft palate repair which has often been reported to facilitate repair of the hard palate at the subsequent operation and, in the best of circumstances, achieve spontaneous functional closure of the hard palate. With this, the resultant proximity of the palatal shelves limits the amount of hard palate dissection necessary to complete surgical closure thereby facilitating hard palate repair using oral side mucoperiosteal flaps.[186,187,206] Dental arch form and relationships, typically aided by orthodontic treatment, have also been shown to develop more similarly to those of people born without cleft deformity. This in turn has been associated with a decreased need for orthognathic surgery in many publications.[205,216,217] Last, and of at least equal significance, is that the construction of a functional vellum in the first year of life allows for achievement of highly acceptable speech over the long term albeit with specific protocols and often requiring intensive speech therapy.[196,201,221]

Critics of the technique most often cite poor speech outcomes as the greatest drawback to utilizing staged approa ches.[189-191,215,217,228] The types and severity of speech disturbances vary between publications, but the overwhelming majority of reports discuss articulation errors and substitution errors, followed by velopharyngeal incompetence/insufficiency. There is great difficulty, however, in making generalizations from these publications for a multitude of reasons. First, much of the literature is historic and occurred before proper attention was paid to the dissection and reorientation of velar musculature. This is a significant confounder when staged historic protocols that are then compared to more recent data sets which do incorporate those techniques. Second, the age range at which velar repairs occur is very broad both across and within individual publications, sometimes occurring as late as 3 years of age. This would clearly conflict with the modern understanding of the benefits of having velar repair occur prior to 18 months, likely best between 9 and 15 months of age and dictated by individual speech development. Therefore including children that were repaired at 12 months with children repaired at 24 months or even 36 months, as has been reported, would skew the results. The use of obturator prostheses is also highly variable and may create speech related biases in a way that is not clearly understood. For example, is it appropriate to compare identical surgical protocols with regard to timing and technique if one requires use of an obturator at birth and continued until hard palate repair to one that does not use an appliance at all or to one that introduces the appliance at 5 or 5 years of age, after much compensatory speech has developed? Examples such as these illustrate "apples to oranges comparisons" in the literature which are often used to bolster the sentiment of those that believe that staged repairs are not viable options. Additionally, there is no scarcity of publications that have relied on surrogate markers such as number of velar revisions or number of pharyngeal flap procedures to describe

incidence of VPI without description of objective criteria, if any were used, to determine the diagnosis or clear indication for the procedure(s). This use of surrogate markers does not necessarily translate into useful data, but many generalizations have been made citing literature that contains them.

Regarding speech assessment in many publications, one should take note of the fact that very few centers validate intra- and inter-rater reliability. Some publications do not necessarily represent objective assessment while blinded to the relevant details that would provide bias (which can be achieved, for example, by rating deidentified high level recordings rather than live patients) and there is a true scarcity of speech publications that are completed by speech professionals that do not have a direct affiliation with the operator or parent institution (which makes the reliability of an already subjective specialty even harder to guarantee). However in recent history, great efforts have been made at attempting to make this the common standard for high level speech related publications. Currently, the centers that are publishing speech data and making the strongest attempts to eliminate or account for biases and confounders tend to support that specific staged approaches can result in excellent growth advantages while achieving very high level speech outcomes long term, albeit with intensive speech therapy. Those publications examine specific protocols over long periods of time and make great efforts to rate speech as objectively as is possible by incorporation of rater blinding and calibration. In addition, compensatory speech problems are examined in a sophisticated manner in which different types of substitutions are not grouped together. Rather they differentiated from one another and considered in the context of the anatomic limitations presented in the individual patients. For example, a velar compensatory sound in a patient with an open hard palate and intact velum is different from a glottal substitution (which is more difficult to correct with speech therapy) and so they warrant different consideration. While some centers would simply group both into the category of "an error" they potentially have very different potential for successful correction after the anatomy is corrected to where the velar sound, for example, can now be created appropriately at the ridge of the intact alveolus. This highly sophisticated approach has helped to clarify that a generalized diagnosis of "poor speech" is insufficient and that in context and with time staged approaches can lead to very high levels of both intelligible speech and preserved growth over the lifetime of the patient.[196,201,216,219-222]

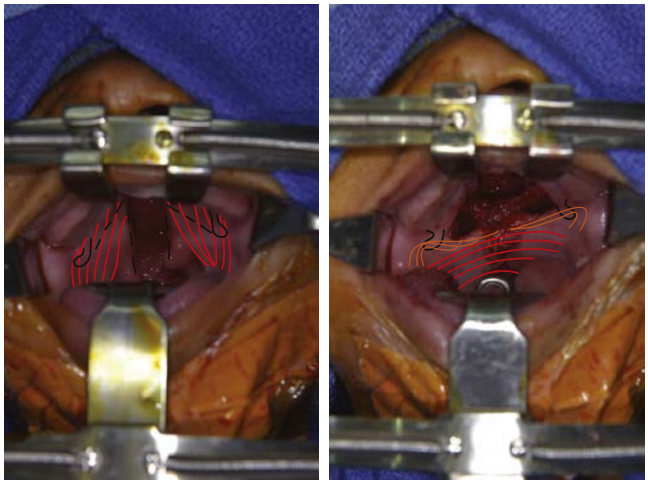
The second most common claim of those who are in opposition to staged techniques is that the growth restrictions encountered in one-stage repairs are not significantly different from growth observed with two-stage techniques.[215,229] Those publications tend to share common shortcomings. Sometimes the growth data are not evaluated after skeletal maturity (though this has also been the case in some of the supportive literature) and therefore, potentially, do not represent a valid final outcome measure. Most commonly though, confounding variables such as excessive numbers of surgical procedures, use of surgical techniques that are known to be associated with excessive growth restriction, and the secondary effects of variations in other phases of care (i.e., primary bone grafting, secondary bone grafting, and variations of lip and nasal surgery techniques) are overlooked when drawing conclusions and making generalizations. While it is completely true that some staged techniques can result in significant growth restriction depending on the specific details of timing and techniques utilized, this should not be applied to "staged repairs" as a whole. Many publications have examined the most sound techniques—those that have made great efforts to avoid needless dissection of the hard palate and avoid leaving denuded areas to heal by secondary intention, and that control for additional variables that are introduced by way of the additional phases of care—and they almost universally show advantages in mid-facial growth by delaying hard palate repair.[230]

Conclusions

Staged palatoplasty in the modern era is seemingly becoming less popular, especially in the United States, though the trend may begin to change as centers that utilize vomer flap for nasal side only repairs report outcomes over time. There are enough supportive data, however, that illustrate that the growth benefits of some of the more classic staged repair approaches can be superior to some single-stage techniques with regard to avoiding excessive mid-face growth restriction and still achieve highly acceptable speech outcomes over the long term, so long as individual techniques and timing are true to the published protocols and the patients have access to adequate speech therapy. If a staged protocol is to be used, ample support exists in support of velar repair between 9 and 12 months of age dictated by speech development. In the hands of some surgeons and with some protocols, velar repair can be successful as early as 5 to 7 months and perhaps as late as 15 to 18 months depending, again, on individual speech development of the patient. Multiple techniques can be used successfully for velar repairs in stages, as long as velar musculature is appropriately addressed, very limited dissection of the posterior hard palate occurs, and little to no denuded maxilla remains exposed to heal by secondary intention. While widespread benefits of preoperative obturator appliances when compared to use of no appliance are not necessarily supported by some objective measures in the literature, they do little harm, if any, and may provide significant benefits to some patients, perhaps in terms of avoiding development of some compensatory misarticulations and in ease of feeding depending on when in development they are introduced. The decision to use an obturator after velar repair while awaiting hard palate repair has also been shown to be unnecessary, particularly in speech production; but, again, passive appliances, removable or pin retained, tend to be highly convenient and well tolerated by the patient and have not been proven to do any harm. Repairs of the hard palate can occur anywhere between 18 months and 8 years

of age, with literature that has examined patients beyond skeletal maturity demonstrating excellent growth results with no perceivable compromise in results in the range of 3 to 5 years of age. There is a true possibility that hard palate repair can occur earlier in the life of the child as long as specific approaches/techniques are adhered to (i.e., use of a vomer flap only), but it is premature to utilize this time frame routinely, particularly with repairs that involve oral side mucoperiosteal flap repair of the hard palate. There is little if any negative effect from delaying hard palate longer if so desired, though it is not necessary. In order to optimize growth, maxillary and alveolar cleft bone grafting procedures should not be combined with the earliest of hard palate repairs. However, bone grafting may be incorporated into the hard palate repair as long as the child is in the early mixed dentition at the time of uranoplasty.

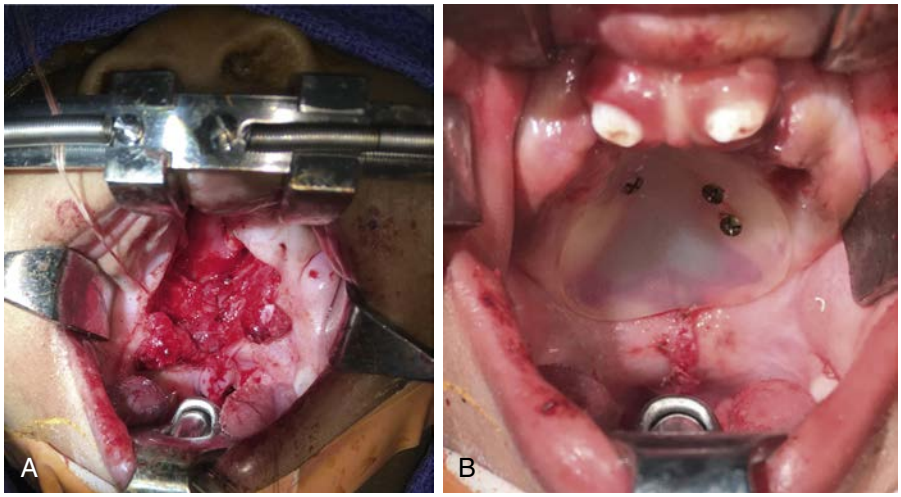
The author's personal sentiment is that the concept of staging should not be forgotten or archived in history while there are still so many questions left to be answered. Efforts should be made in individual centers to examine if incorporation of these techniques might help to improve the long-term outcomes of some of their patients, particularly if mid-face retrusion and long-term cosmetic goals are not being met. Well designed prospective studies should then be conducted to attempt to clarify any of the many controversies that exist regarding the specifics of timing and technique. While there is no standardized, universally accepted staged protocol, with the data currently available and with understanding of the strengths and limitations of those studies, delayed hard palate repair techniques can achieve excellent results with regard to mid-facial growth, decrease the need for orthognathic surgeries for a significant number of patients and result in very good speech.



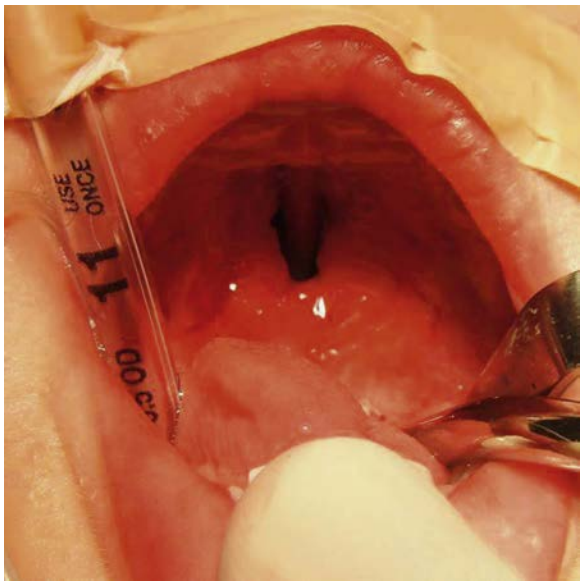
• **Figure 30-14** A variation of a straight line technique, similar to that initially described by Gilies, which additionally incorporates intravelar veloplasty, and avoids dissection of the hard palate. The result is a retropositioned velum with intact musculature. In some variations, the retropositioned nasal side flap is fixed to a small posteriorly based vomer flap (not illustrated in this instance) to help in maintaining retroposition. A maxillary obturator prosthesis may now be inserted with or without pin retention according to protocol.

Our Center

With the available data in the current literature, our center continues to utilize a staged technique for some patients. The approach involves lip repair completed between 3 to 6 months of age with advancement and rotation flap techniques. Most children receive presurgical nasoalveolar molding in the months leading up to lip surgery. Velar repair, usually with a double opposing Z-plasty or with a technique similar to the technique originally described by Gillies for the widest of cleft palates, is completed between 9 and 12 months of age (Figure 30-14). A single, passive palatal obturator appliance, retained with screws, is inserted intraoperatively immediately upon completion of velar repair under the same general anesthetic and remains in place from this point forward until the repair of the hard palate (Figure 30-15). There is no attempt to replace or refit the prosthesis as the child grows. In some instances, hard



• **Figure 30-15 A,** Intraoperative view following nasal side repair and intravelar veloplasty, oral side flaps retracted. **B,** Immediate post-operative view after oral side closure and insertion of maxillary prosthesis.



• **Figure 30-16** Image of palatal defect following removal of pin-retained palatal obturator prosthesis immediately prior to hard palate repair by two-flap mucoperiosteal flap technique. Note proximity of palatal shelves and low level mucosal inflammation which is typically seen with this use of a prosthesis. (Courtesy Dr. Pamela Gallagher)

palate repair is dictated by loosening or loss of the obturator. Otherwise, the obturator is removed at the time of hard palate repair around 3 to 4 years of age. Figure 30-16 illustrates the appearance of the healed velum (note the narrowed hard palatal cleft and the areas posterior to the hard palatal shelves that have healed in by secondary intention) after removal of the obturator prosthesis and immediately prior to repair of the hard palate. Anecdotally, there is a very high level of satisfaction in both practitioners and patients utilizing this approach with regard to cosmetics, functionality, and speech within our center. Data collection is ongoing regarding long-term outcomes.

Presurgical Infant Orthopedic Treatment for Patients with Cleft Lip and Palate

LINDSAY A. SCHUSTER, PEDRO E. SANTIAGO

Introduction

This chapter reviews oral-facial cleft incidence and etiology, cleft versus non-cleft anatomy, historical background of presurgical infant orthopedics, and current presurgical infant orthopedic treatment options with a focus on nasoalveolar molding (NAM).

Cleft Incidence and Etiology

Oral-facial clefting occurs in approximately 1:690 births, with the prevalence of those affected by both cleft lip and cleft palate being 5.6 per 10,000 births.[1] The prevalence of cleft lip and palate also varies among different ethnic groups, with children of African descent having the lowest prevalence and those of Native American descent being one of the highest reported. Males are reported to have a higher prevalence of clefts involving the lip or lip and palate, whereas females have a greater prevalence of clefts of the palate only. It is reported that approximately 70% of those affected by both clefting of the lip and palate are nonsyndromic.[2]

The etiology of orofacial clefts is multifactorial with genetic, environmental, and teratogenic considerations. Some genes implicated in animal models of clefts include: sonic hedgehog gene, TGF-α variants, TGF-β-3 and IRF-6.[3] Medications, such as anti-seizure medications and retinoic acid, have been associated with orofacial clefts. Maternal factors associated with clefts include folate deficiency, smoking, excessive alcohol use,[3] stress, maternal obesity, occupational exposures, ionizing radiation, and infection.[4]

The severity of clefting varies widely within the basic unilateral, bilateral, complete, and incomplete descriptors. Clinically, there are over 240 possible combinations of cleft lip with or without cleft palate.[5] In addition to the disruption to intraoral and perioral anatomy, the nasal anatomy is significantly affected in cleft patients.

Presurgical Infant Orthopedics

In a newborn affected by a cleft lip and palate, treatment to mold the affected oral, perioral, and nasal anatomy in preparation for the primary surgical repair is known as *presurgical infant orthopedics (PSIO)*. This treatment takes place in the first few months of life with the goal of lessening the severity of the cleft deformity and normalizing anatomic relationships in preparation for the primary lip/alveolar/nose surgery.

The utilization of extraoral traction to the cleft anatomy dates back to 1686, when Johan Philip Hofmann described a head cap attached to horizontal laces across the lip to relieve tension on the newly surgically repaired cleft.[6] Dating from a similar technique used by Desault in 1790, various iterations of extraoral strapping, taping, and intraoral alveolar approximation were used to lessen the cleft severity prior to surgical repair.[7] The era of modern PSIO therapy dates to 1950 when McNeil utilized a series of passive intraoral acrylic plates to mold the intraoral cleft anatomy sequentially.[8] This technique has been modified by various practitioners throughout subsequent years. In 1975 Latham and Georgiade described a presurgical orthopedic technique in which they utilized an intraoral appliance retained by pins surgically placed in the alveolus to approximate the cleft segments in a short period of time.[9] This technique is commonly known as the Latham appliance. Randall described a surgical alternative known as a lip adhesion.

This is a two-stage surgical procedure: initially, the lip adhesion surgery, a temporary attachment of the lip segments, is performed with the goal of decreasing the alveolar cleft gap prior to definitive surgical repair.[10]

It is important to note that these treatment therapies address the intraoral and extraoral cleft deformity, but do not attempt to treat the nasal deformity. In 1988, an article by Matsuo et al. presented the concept of preoperative molding of the cleft nasal cartilage with silicone tubes.[11] This moldability of neonatal cartilage, due to circulating maternal estrogens and resultant increase in hyaluronic acid, was known to this group through their work in molding of the neonatal ear. In addition to moldability related to maternal estrogens, it is postulated that cartilaginous molding stimulates immature chondroblasts, producing an interstitial expansion.[12] As a novel evolution in presurgical orthopedic appliance design, in 1993 Grayson introduced nasoalveolar molding (NAM), a technique that combines the intraoral molding of the alveolus and perioral/lip anatomy with the earlier work of molding the cartilage of the nose.[13] NAM represents the first presurgical orthopedic appliance to address the cleft lip, alveolar, and nasal deformity in preparation for primary surgery.

During the last decade, the nasoalveolar molding technique has gained popularity around the world with many teams adapting such therapy in their protocols. There have been more than 120 articles and chapters written on the subject. In the United States and Canada, 71% of centers reported using some form of presurgical molding before bilateral cleft lip surgery, with nasoalveolar molding being the most popular at 55% of those using PSIO.[14] Another study cites that at least 71% of cleft surgeons of the American Cleft Palate Craniofacial Association use NAM occasionally.[15] In 2010 it was reported that 37% of U.S. cleft teams offered nasoalveolar molding to their patients.[16]

Presurgical infant orthopedics produces notable reduction of the alveolar and labial cleft gap. Nasoalveolar molding addresses the nasal cartilaginous deformity improving nasolabial symmetry and esthetics.

Nasoalveolar Molding

In 1997, Grayson and Santiago described the NAM protocol for patients born with a cleft lip and palate.[17] The main goal for this therapy is to normalize the cleft skeletal, cartilaginous, and soft tissue anatomic relationships. This normalized anatomy provides the surgeon with the most optimal anatomy to perform the primary lip, alveolus, and nose surgery, minimizing the need or extent of secondary surgical revisions.

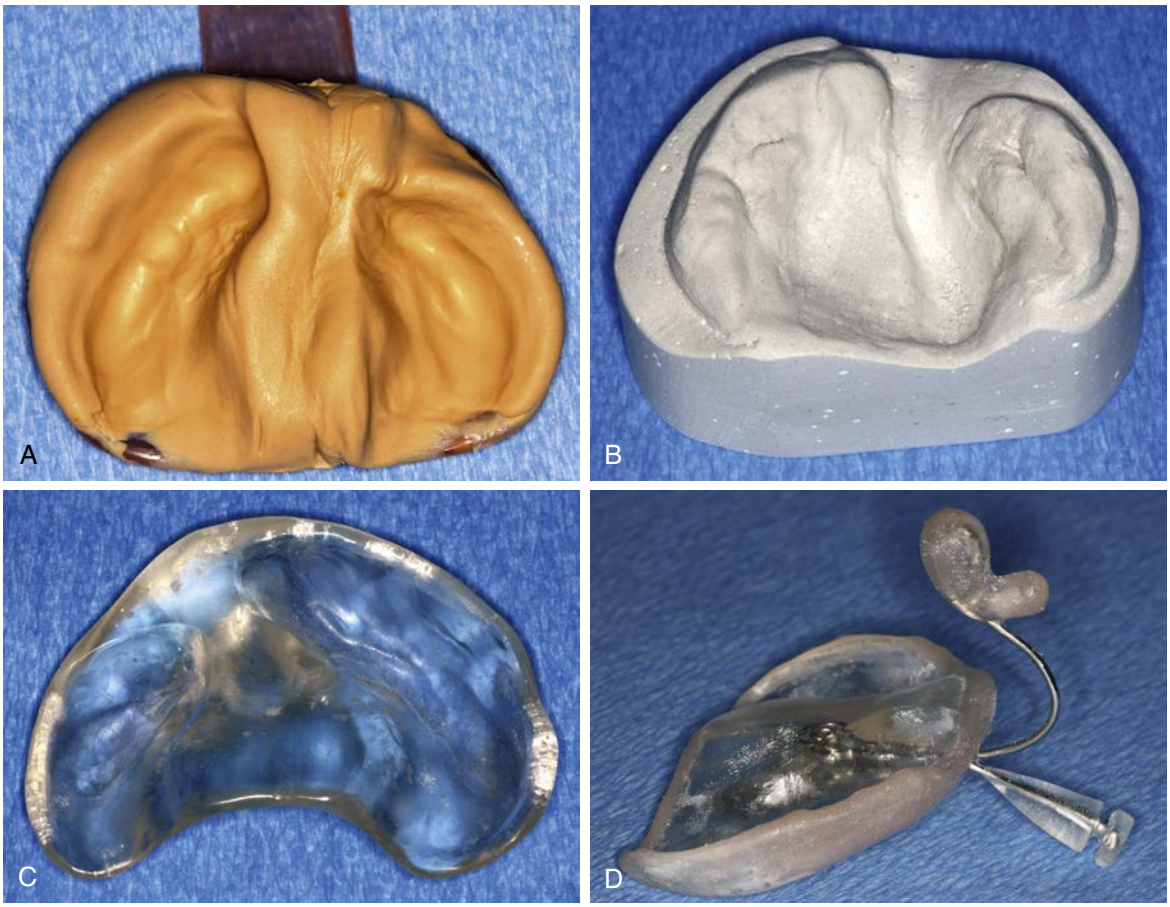
NAM objectives include: (1) approximate the alveolar processes into a normalized U-shaped arch form, (2) approximate the lip segments, (3) lessen the nasal deformity (through cartilaginous molding and columellar lengthening). Short-term studies (4 months to 1 year)[18-20] and long-term studies (4.5 to 9 years)[21,22] indicate that NAM significantly improves nasal symmetry over surgery alone.

Close approximation of the alveolar segments by means of the alveolar molding plate facilitates incorporation of gingivoperiosteoplasty (GPP) into the surgical protocol. GPP is the closure of the soft tissue alveolar segments performed in conjunction with primary lip and nose surgery. Santiago et al.[23] have shown a 60% reduction in the need for a secondary alveolar bone graft procedure in cases where a combined approach of presurgical infant orthopedics and a gingivoperiosteoplasty was performed. This combination was less expensive than a traditional protocol (lip repair, primary nasal repair, and secondary alveolar bone graft).[24] It is important to note that GPP is a technique-sensitive procedure with varying surgical results. Furthermore, it is a separate therapeutic option from NAM, associated with its own risks and benefits.

If presurgical infant orthopedics is elected, the consultation process may start prenatally upon diagnosis of a cleft on ultrasound. While detection rates on 2D ultrasound vary greatly (9% to 100%), 3D ultrasound detection rates are much higher, detecting 100% for cleft lip and 86% to 90% for cleft lip and palate.[25] The National Birth Defects Prevention Study (1998-2004) reported that prenatal diagnosis was made in 33.3% of their 978 cases of CL/P.[26] If prenatal consultation is not a possibility, it is important that the initial consultation and clinical exam take place within the first weeks of life for optimum treatment efficacy. If nasoalveolar molding is offered by the team, this consultation is an important opportunity to talk to the parents about treatment alternatives, risks/benefits of treatment, the basic processes of treatment, and especially to gauge the parent's ability to comply with home care and attendance at weekly or biweekly adjustment visits. Treatment is initiated as soon as possible to take advantage of the moldability of tissues, especially the cartilage of the nose, given the short post-natal period of circulating maternal estrogens that facilitate tissue pliability.

After the informed consent discussion with the infant's caregivers, an intraoral mold (utilizing a polyvinyl siloxane material) of the infant's mouth is taken by the orthodontist and the surgeon (or other practitioner who is able to manage a potential medical emergency) (Figure 31-1, *A*). Though complications with impression are rare, it is important that trained clinicians are available to monitor and manage the infant in case of any signs of breathing difficulty or distress. The impression is utilized to create a stone cast (see Figure 31-1, *B*) reproduction of the infant's intraoral anatomy and fabricate the hard acrylic intraoral plate (see Figure 31-1, *C*).

Adjustments to the appliance are made at weekly or biweekly appointments. A sequence of subtractions and additions of hard and soft acrylic, in conjunction with facial tapes and orthodontic elastics for retention and force application, incrementally mold the alveolar segments toward



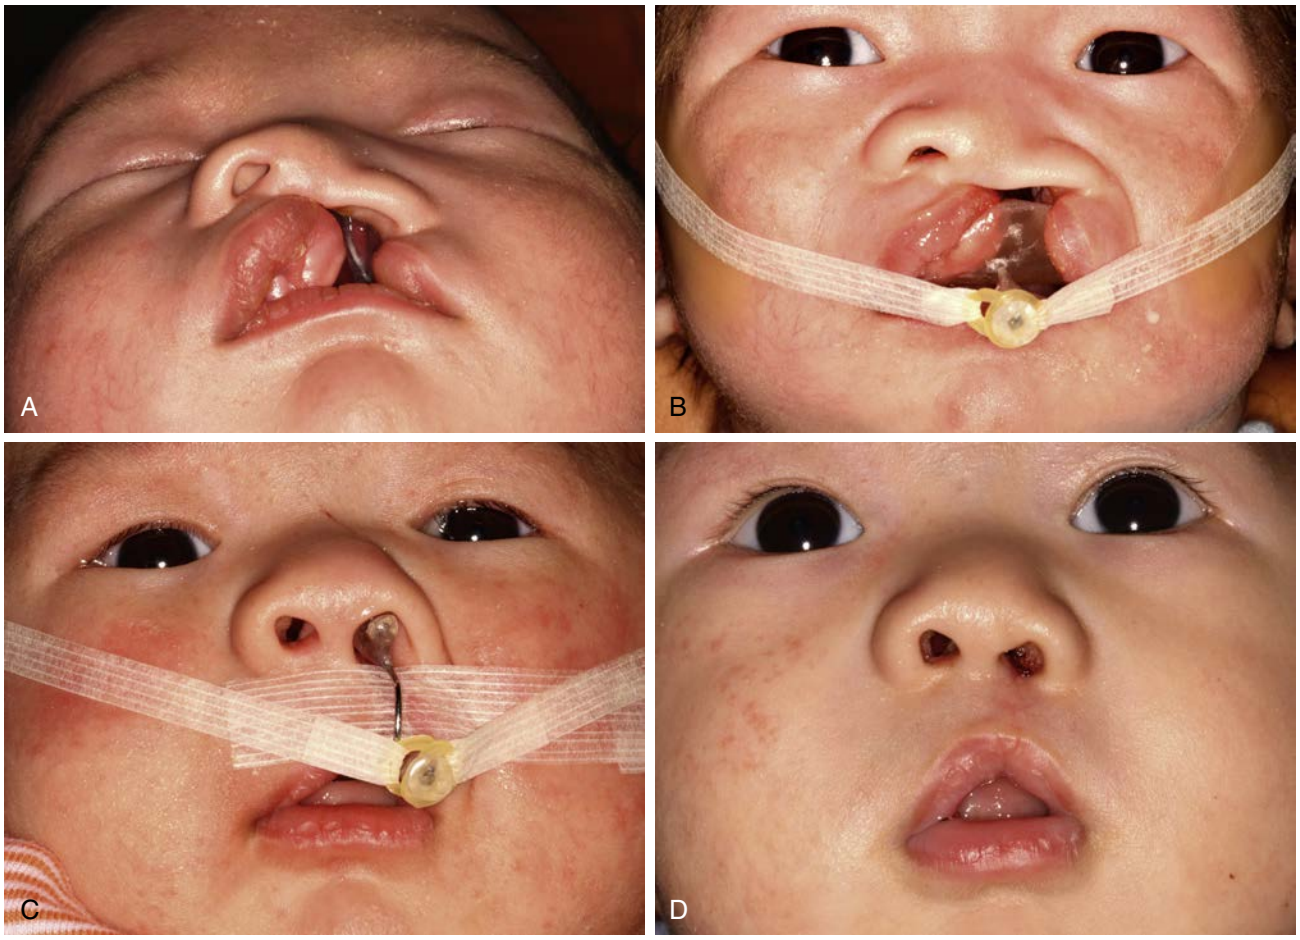
• **Figure 31-1** In the process of making the NAM appliance, a PVS impression is taken of the infant's mouth **(A),** a stone cast made from this impression **(B),** and a hard acrylic intraoral plate is fabricated **(C).** A nasal stent is added to the plate to address the nasal deformity, once the alveolar segments are in close approximation **(D)**.

each other. At each visit, special care and attention must be directed to evaluation of the intraoral and extraoral soft tissues for any signs of irritation. If the alveolar segments are properly aligned, the goal is a contiguous "U" shaped arch form, comparable to the arch form in an infant without a cleft. This arch form promotes optimal labial approximation and allows for gingivoperiosteoplasty, should the infant's surgeon elect this procedure. Improper molding vectors can lead to a maxillary collapse with a "T" shaped relationship of the greater and lesser segments in unilateral clefts, and a "V" shaped relationship in bilateral clefts, with the premaxilla being blocked out anteriorly due to inadequately expanded lateral segments. Once the segments are within 3 to 4 mm of each other, a nasal stent is added (see Figure 31-1,*D*) to mold the distorted nasal cartilage. Total treatment time typically takes place over 3 to 4 months in patients with unilateral clefts[27] and approximately 5 to 6 months in bilateral cases.[28]

Treatment success is very reliant on excellent compliance. Missed appointments and removal of the plate by the infant are common challenges to treatment. As previously discussed, the informed consent process is an important opportunity to communicate the time commitment of weekly (or biweekly in some cases) adjustments and dedication to homecare of the appliance. If the infant is removing the plate, gloves or arm restraints (in older patients) may be used to discourage dislodgement of the plate.

Correcting the Unilateral Cleft Deformity

The anatomy of a patient with clefts of the lip, alveolus and palate can be described by anatomic location, laterality, and degree of clefting (Figure 31-2, *A*). In a patient with a unilateral cleft, the skin of the labial anatomy of a cleft lip is vertically deficient on one side (with cupid's bow being less distinct and the philtrum being shorted on the affected side) and the underlying orbicularis oris muscle is not continuously attached. Rather, this muscle is attached at the cleft margin or nasal base. The continuity of the alveolar bone and gingiva is disrupted by the cleft. The nasal anatomy is significantly affected: the columella is shorter on the cleft side and deviated from an anterior-posterior projection, with the base towards the non-cleft side and the portion near the tip towards the cleft side. The nasal tip is flattened and bent towards the non-cleft side. The lateral cartilage is displaced posteriorly, inferiorly, and laterally on the cleft side. The alar base is widened and



• **Figure 31-2** The unilateral alveolar, labial and nasal cleft defect severity **(A)** is addressed through use of the NAM plate **(B),** accessory transverse lip taping and nasal stenting **(C)** to normalize anatomy in preparation for the primary surgical repair. NAM improves nasolabial symmetry and esthetics **(D)**.

caudal septum and anterior nasal spine deviate towards the non-cleft side (see Figure 31-2, *A*).

After the impression and intraoral plate fabrication process described above, the plate is delivered and the caregiver is taught how to care for the appliance, including the extraoral facial taping (see Figure 31-2, *B*). The extraoral activation system consists of two Steri-strip tapes individually folded inside the lumen of separate orthodontic elastics. The elastics are attached to the retentive "button" that is an extraoral projection from the molding plate and the Steri-strips are then extended laterally to the cheeks and fixed to a protective "base tape." During active movement of the greater segment towards the lesser segment, the tape and elastic construct is typically more active on the side towards the intended movement (lesser segment side). In addition to the external taping forces, the plate is modified at weekly adjustments with additions of soft acrylic and removal of hard acrylic to incrementally mold the cleft alveolar segments toward each other. A transverse lip tape may be incorporated at any point during treatment to provide an external force to approximate the lip segments, greater and lesser alveolar segments and further facilitate alignment of the nasal base and columella toward the mid-sagittal plane (see Figure 31-2, *C*).

Once the alveolar segments approximate to about 4 mm, a nasal stent is added to the system (see Figure 31-2, *C*). The nasal stent is made out of an orthodontic wire carefully bent into a gooseneck shape and is attached to the anterior flange of the oral molding plate with hard acrylic. The most superior part of the wire is bent into a kidney bean shape with superior and inferior lobes and is covered with a hard acrylic core surrounded by soft acrylic. This kidney bean shaped acrylic is positioned inside the nose with the superior lobe positioned in the nose immediately lateral to the columella, supporting the nasal dome on the cleft side. The inferior lobe is external to the nostril. The cleft-side cartilage of the nasal dome is lifted by the stent to achieve normal elevation and symmetry, moving the cartilage's apex from a lateral position to a superior/anterior position. The nasal stent is adjusted

• **Figure 31-3** The bilateral cleft anatomy is characterized by labial soft tissue and cartilaginous nasal deformities **(A)** and alveolar and palatal defects **(B)**.

at the weekly visits to shape the cartilaginous dome and medial and lateral crura into a more normalized anatomy.

The goal of the nasal and alveolar molding is proper alignment of the nasal cartilages, columella, lip, and alveolar segments to optimize surgical correction (see Figure 31-2, *D*).

Correcting the Bilateral Cleft Deformity

In the bilateral complete cleft lip, alveolus, and palate patient, the orbicularis oris and vertical soft tissue anatomy of the lips are also discontinuous. The vertical deficiency of tissue occurs lateral to the prolabium, a midline lip structure that does not contain a muscular component. Cupid's bow, columellar, and philtral structures are obliterated. Similar to the effects of clefting of the soft tissues lateral to the prolabium, the clefts of the alveoli are lateral to a bony midline structure called the premaxilla. This premaxilla is often protruded and deviated to one side. The lateral nasal alae are distorted, with horizontally oriented nostrils and a wide alar base (Figure 31-3).

The goal of presurgical nasoalveolar molding in patients born with bilateral cleft lip and palate is to lessen the severity of the nasal deformity (lengthen the deficient columella, reduce the alar base width, reshape the distorted lateral cartilages) and align the alveolar segments. As in the unilateral deformity, the molding plate is fabricated from a stone cast made from a polyvinyl siloxane intraoral impression. The bilateral plate has two anterior acrylic extensions or buttons to which the facial tapes are attached for retention and activation. The first stage of treatment consists of weekly acrylic modifications of the intraoral molding plate and differential forces on the elastic/Steri-strip taping system to centralize the everted premaxilla, expand the lateral segments, and retract the premaxilla. As the alveolar segments approximate each other and form a more normalized U shaped alveolus, two nasal stents are incorporated into the anterior rim of the molding plate and enter the nasal apertures as described in the unilateral section (Figure 31-4, *A*). The nasal stents shape the distorted cartilages and create tissue-expanding forces that reposition the lateralized apex of the nostril superiorly and anteriorly to support the nasal dome. The nasal stents, in combination with a surgical tape applied to the prolabium and attached inferiorly to elastic orthodontic rubber bands anchored on the plate's acrylic buttons, create tissue-expansion forces that elongate the columella (see Figure 31-4, *B*). Additionally, a horizontal columellar band made of soft acrylic may also be attached between the inferior lobes of the nasal stents to provide an additional expansion force across the columella. The intraoral plate and extraoral nasal stents are periodically adjusted over a period of 5 to 6 months to attain the goal of normalized anatomy. This provides the reconstructive surgeon with an optimal starting point for surgical repair (see Figure 31-4, *C* and *D*).

Nasoalveolar molding has been shown to be an adjuvant therapy to the primary surgical repair:

1. The controlled presurgical alignment of the cleft alveolar and lip segments and reduction of the nasal deformity reduces tension on the surgical repair and may reduce the extent of the primary lip and nasal surgery required.
2. The presurgical closure of the alveolar gap provides the surgeon with the option to perform a gingivoperiosteoplasty at the time of lip closure.
3. Columella lengthening in the patient with a bilateral cleft eliminates the need for secondary surgical columella elongation and the resultant lip-columella junction scar.
4. When used in conjunction with primary surgical repairs, NAM therapy allows for a single initial surgical procedure to address the lip-nose-alveolus complex and its deformity. Through reduction of the residual deformity, additional surgical revisions may be avoided.

• **Figure 31-4** **A,** The NAM plate for bilateral cleft treatment consists of two acrylic extensions or buttons and bilateral nasal stents that support the nasal dome and shape the nasal cartilages. **B,** Utilizing a prolabium tape, which is attached inferiorly to the buttons, produces an additional columella-lengthening force. **C** and **D,** The plate and nasal stents are modified at weekly visits over a period of approximately 5 to 6 months to provide the surgeon with a reduction in the initial anatomic distortions and optimized starting point for the surgical repair.

Summary

In a newborn affected by a cleft lip and palate, treatment to mold the affected oral, perioral, and nasal anatomy in preparation for the primary surgical repairs is known as *presurgical infant orthopedics (PSIO)*. This treatment takes place in the first months of life with the goal of lessening the severity of the cleft deformity in preparation for initial lip/nose reconstructive surgery. There are multiple techniques available with variable degrees of success in reducing the cleft deformity. Options include lip taping, the pin-retained Latham appliance, and nasoalveolar molding. The surgical alternative, lip adhesion, is another option routinely elected by some cleft centers. Although most presurgical infant orthopedic techniques are effective in reducing the alveolar and labial cleft gap, NAM is the only therapy that addresses the cartilaginous nasal deformity improving nasolabial symmetry and esthetics. While the caregiver of an infant who is born with a cleft experiences heightened anxiety, NAM and the consequent frequent contacts with the treatment team before surgery, is shown to reduce anxiety and increase a sense of empowerment for the caregivers.[29,30] The scientific literature, shows that there is significant evidence supporting NAM's effectiveness as a treatment for newborns with a cleft lip and palate.

Evaluation and Management of Speech Disorders for the Patient with Cleft Palate

DAVID J. ZAJAC

This chapter provides an overview of speech characteristics, evaluation techniques, and management approaches for the patient with repaired cleft palate with or without cleft lip. The intended audience is oral and maxillofacial surgeons, speech-language pathologists (SLPs), and other health care professionals who have basic knowledge of both cleft conditions and the anatomy and physiology of the vocal tract. The chapter begins with a discussion of the multiple causes of speech disorders among patients with cleft palate. Multiple causes are emphasized, as most textbooks tend to focus on velopharyngeal dysfunction as the cause of speech disorders and neglect the contribution of other structural factors. Next, core speech characteristics of individuals with repaired cleft palate and velopharyngeal dysfunction are described. Both perceptual and instrumental assessment techniques of speech and velopharyngeal function are then reviewed. The chapter concludes with an overview of the role of secondary surgery, prosthetics, and behavioral approaches to treatment.

Etiology of Speech Disorders in Individuals with Cleft Palate

Although SLPs have traditionally focused on inadequate function of the velopharyngeal mechanism as the primary cause of speech problems in individuals with cleft palate, other factors are also involved. It is well known that alveolar and dental anomalies associated with clefts of the primary palate contribute to speech disorders.[1-4] In addition, because eustachian tube dysfunction and otitis media are almost universal in children with cleft palate, the deleterious effects of conductive hearing loss on speech acquisition must be considered.[5-8] Finally, it must be emphasized that children born with cleft palate are not immune from developing other speech problems during childhood such as phonologic disorders, apraxia of speech, and stuttering. Relative to the last, Dalston and co-workers, however, reported that for unknown reasons, the prevalence of stuttering among children with cleft palate is actually lower than expected.[9] Regardless, the point to be made is that children with cleft palate are a challenge relative to the diagnosis of speech problems that might result from multiple causes. Clearly, differential diagnosis of the underlying cause of speech problems is essential if appropriate treatment recommendations are to be made.

Velopharyngeal Dysfunction

The primary goal of surgical repair of clefts of the secondary palate is to restore the muscular integrity of the velopharyngeal structures to enable normal speech development.[4,10] Although the timing of palate repair varies greatly across institutions, current consensus for initial palate surgery of infants in the United States appears to be 9 to 12 months of age. If a cleft of the primary palate is involved, definitive correction of the alveolar defect is delayed until the child is approximately 8 to 9 years of age and is in mixed dentition. Typically, review of studies indicates that the success rate for surgical repair of clefts involving the secondary palate is appropriately 70% to 80%.[11]

For the child born *without* cleft palate, we expect that by 3 to 4 years of age he or she will naturally acquire vowels, nasal consonants, and stop-plosive consonants. In English, stop-plosives are articulated primarily at three locations in the oral cavity: bilabial for /p/ and /b/, lingual-alveolar for /t/ and /d/, and lingual-velar for /k/ and /g/. By the time a child is 7 to 8 years of age, we expect that the entire phonetic inventory of English—including fricative and affricate consonants—will be mastered. Conversely, for a child born with a cleft of the secondary palate, the phonetic inventory

may consist of only vowels, nasal consonants, and vowel-like consonants (e.g., /w/ and /j/) at 3 years of age if palatal surgery was not successful. In addition, as described later, some children with cleft palate may develop pharyngeal and/or glottal articulations in an attempt to compensate for velopharyngeal dysfunction. Table 32-1 lists the stop, fricative, and affricate consonants that are likely to be affected by velopharyngeal dysfunction. As illustrated, inadequate velopharyngeal function has the potential to affect a majority of English consonants.

In addition to congenital clefts of the secondary palate, velopharyngeal dysfunction may occur in children because of congenitally deep nasopharynx; obstructing tonsils and/or adenoids; and neuromotor problems such as dysarthria and/or apraxia. Diagnosis and management decisions that involve children with repaired cleft palate, therefore, need to take possible co-existing factors into consideration.

Dental and Alveolar Anomalies

When clefts involve the primary palate, structural anomalies involving the teeth and alveolar ridge are likely to occur. Missing and/or supernumerary teeth are often found in and around the cleft site. Maxillary collapse and resulting posterior crossbites are common. Oral-nasal fistulas may also occur, especially during maxillary expansion as part of orthodontic treatment. Even in cases of isolated clefts of the secondary palate, there may be alveolar and/or palatal morphologic anomalies that occur as the result of growth restriction due to surgical repair. In addition, clefts of the secondary palate are often associated with syndromes and/or sequences such as Pierre-Robin, which may directly cause dental malocclusion. Although alveolar and dental anomalies have long been noted to affect speech production, surprisingly, the extent of the impact of these structural problems on speech intelligibility has not been systematically investigated.[1,4] Table 32-2 lists the consonants that are likely to be affected by alveolar and dental anomalies. As illustrated, a majority of consonants are produced by bringing the lips and tongue into contact with the teeth, alveolar ridge, and hard palate.

Other Causes

Because of the disruption of velar morphology caused by palatal clefting, infants with cleft palate are prone to a sequence of eustachian tube dysfunction, development of otitis media with effusion (OME), and mild to moderate conductive hearing loss.[5,12] Indeed, the prevalence of OME in children with cleft palate has been reported to be more than 95%.[6-8] Roberts and Clarke-Stein identified three ways in which persistent OME might disrupt normal development of speech and language.[13] First, reduced hearing acuity might result in inaccurate encoding of perceptual information. Second, prolonged hearing reduction might impair a child's ability to discriminate linguistic information, characterized by low perceptual saliency (e.g., morphophonemic markers). Third, illnesses associated with OME might "restrict or alter the child's interactions with people and objects in the environment," thus reducing available opportunities for speech and language learning. Although these disruptions have obvious face validity, available research has indicated an equivocal relationship between the occurrence of early conductive hearing loss as a consequence of OME and subsequent development of speech and language in children *without* cleft palate.[14-24]

In contrast to children without cleft palate, only a few studies have investigated the impact of conductive hearing loss on speech acquisition in children with cleft palate. Hubbard, in a retrospective study, reported that articulation scores were better in a group of children with cleft palate who received early and aggressive ear care as compared with a group of children with cleft palate who did not receive early ear care.[25] Broen and colleagues studied infants with and without cleft palate longitudinally to age 30 months.[26] These investigators reported that hearing levels of the infants

Affricates					ʧ ʤ	

accounted for significant differences on cognitive and developmental measures between the cleft and noncleft groups. Clearly, additional research is needed to gauge the impact of early hearing loss as a result of OME in children with repaired cleft palate.

Finally, we know that approximately 6% to 10% of children without cleft palate will require speech therapy for idiopathic or functional articulation disorders.[27] In addition, developmental neuromotor disorders such as apraxia of speech may occur in children and can dramatically reduce speech intelligibility. Obviously, children born with cleft palate are not immune to such speech disorders. Indeed, relative to children with velopharyngeal dysfunction who also have velocardiofacial syndrome, Kummer and colleagues (2007) reported an increased prevalence of apraxia of speech.[28]

Speech Characteristics of Individuals with Cleft Palate

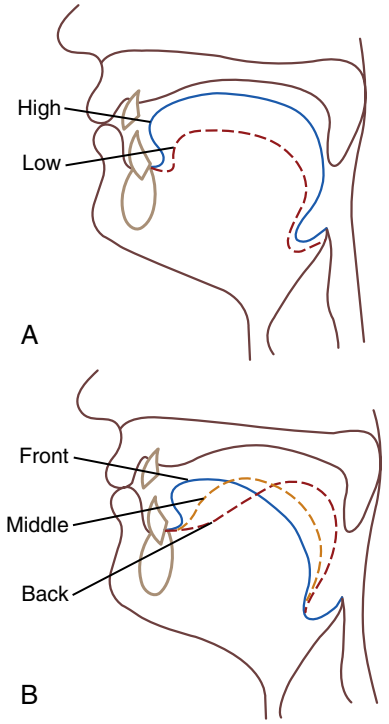
After initial palate repair, approximately 20% to 30% of children will exhibit speech characteristics that reflect inadequate velopharyngeal function. These characteristics include hypernasal resonance during vowel production, nasal air emission (visible and/or audible) during consonant production, and reduced oral air pressure during consonant production. These speech characteristics are often referred to as *obligatory* symptoms because they naturally occur in the presence of inappropriate oral-nasal coupling. In addition, children with velopharyngeal dysfunction may alter tongue placement for articulation of consonants. These misarticulations are referred to as *compensatory (or maladaptive)* behaviors in that they are learned in response to inadequate velopharyngeal closure.

Resonance Imbalance

Resonance is a complex perceptual phenomenon associated with vowels and voiced consonants. It occurs due to acoustic excitation of the air-filled cavities of the upper vocal tract, primarily the pharynx, oral cavity, and nasal passages. In English, speakers *without* cleft palate will produce vowels and oral consonants with nearly complete separation of the oral and nasal cavities as illustrated in Figure 32-1. This is accomplished by elevation and retraction of the soft palate and sphincter-like closure of the upper pharyngeal walls. The primary resonating cavities, therefore, are the pharynx and mouth. During production of the nasal consonants (/m/, /n/, and /ŋ/) and vowels that precede or follow a nasal consonant, the soft palate will relax and lower to some degree. Nasal resonance, therefore, will be perceived during these speech sounds. The primary determinants of normal nasal resonance during nasal consonants and adjacent vowels are (1) the physical characteristics of the nasal cavities such as volume and cross-sectional area, and (2) the temporal extent of velar lowering before and after nasal consonants (i.e., anticipatory and carryover nasalization), respectively. In addition, some normal nasal resonance may occur during production of nonnasalized vowels and voiced oral consonants owing to the extent that the air mass in the nasal cavity is excited even in the presence of complete velopharyngeal closure. This phenomenon—sometimes referred to as *sympathetic vibration*—is determined by a complex interaction between the fundamental frequency of the speaker and the physical characteristics (mass and stiffness) of the elevated soft palate.[29,30]

For a speaker with repaired cleft palate who has incomplete velopharyngeal closure, inappropriate acoustic coupling of the oral and nasal cavities will occur and result in a hypernasal resonance imbalance during production of vowels and voiced, nonnasal consonants. The degree of the perceived hypernasality will be determined primarily, but not exclusively, by the physical extent of the coupling of the oral and nasal cavities. As noted previously, both temporal characteristics of nasalization and physical characteristics of the velum also may contribute to hypernasality. Indeed, even if a speaker with repaired cleft palate achieves complete velopharyngeal closure, it is possible that resonance may be hypernasal owing to physical changes in the velum caused by surgery (e.g., increased stiffness due to scarring).

Finally, it must be noted that some speakers with repaired cleft palate may exhibit primarily hyponasality or mixed hypernasality and hyponasality. Hyponasality will



• **Figure 32-1** Illustration of normal velopharyngeal closure during vowel production. **A,** Velar and tongue positions for high and low vowels. **B,** Velar and tongue positions for front, middle, and back vowels. (Adapted from Skolnick ML, Cohn ER: *Videofluoroscopic studies of speech in patients with cleft palate,* New York, 1989, Springer-Verlag.)

occur during production of nasal consonants and adjacent vowels when the nasal cavities are obstructed. The location of the obstruction may be posterior and include hypertrophied tonsils and/or adenoids or anterior and include deviated septum, hypertrophied turbinates, and/or a collapsed nasal vestibule.

Nasal Air Emission

Nasal air emission (or escape) is distinct from hypernasality both in perceptual features and affected speech sounds. Nasal escape refers to the visible or audible loss of air through the nose that accompanies stop-plosives and/or continuant consonants. Audible nasal escape may be brief when it accompanies stop-plosives (confined to the closure phase of the consonant) or relatively prolonged when it accompanies continuants such as /s/. Although audible nasal escape may occur during both voiced and voiceless consonants, it is most salient during production of voiceless sounds. This occurs because voiceless sounds are typically produced with higher levels of intraoral air pressure than voiced sounds.[31] Unlike hypernasality, the presence of nasal air escape always implies the direct physical coupling of the oral and nasal cavities at some location (i.e., at either the velopharynx and/or a fistula at some point along the palate). Although hypernasality and nasal escape may co-occur, each may occur without the other.

Because of the complex nature of audible nasal escape and anatomic variability among speakers, it is not unexpected that there have been numerous and at times somewhat confusing descriptions of nasal air emission reported in the literature. Peterson-Falzone and co-workers described "audible" nasal air escape as the sound that is produced when one "forcefully exhales through the nose."[4] They further describe a severe form of audible nasal air emission that they term "nasal turbulence." This arises from extra noises due to increased "intranasal or velopharyngeal resistance." The extra noises may occur due to either tissue vibration and/or displacement of mucus pooling in a constriction. Kummer and co-workers refer to nasal turbulence as "nasal rustle" and attribute it to bubbling of secretions within a small velopharyngeal port.[32] Zajac and colleagues, however, suggested that the distinctive quality of nasal turbulence (or rustle) was due to tissue vibration at the velopharyngeal port.[82] Regardless, Kummer makes the excellent point that clinicians need to be aware that the presence of nasal turbulence (or rustle) typically indicates a relatively small velopharyngeal opening.

Finally, audible nasal air emission may occur in the presence of normal velopharyngeal closure as part of learned nasal fricatives. This is often referred to as phoneme-specific nasal emission (PSNE). Nasal fricatives are characterized by complete occlusion of the oral cavity with exclusive shunting of airflow through the nose to produce turbulence and frication. The frication can be produced either posteriorly at the velopharyngeal port or anteriorly at the nasal valve. Nasal fricatives can be substituted for any of the fricative, sibilant, and/or affricate sounds. During production of stop-plosive sounds, velopharyngeal closure is complete. Because nasal fricatives are used by children both with and without palatal anomalies, these errors are most likely learned, perhaps due to conductive hearing loss during early acquisition of fricatives. Therefore, behavioral speech therapy, not surgery, is the treatment option. Zajac provides a discussion of nasal fricatives and PSNE with audio examples from children both with and without cleft palate.[34] Behavioral techniques to address nasal fricatives are discussed later.

Reduced Intraoral Air Pressure

When velopharyngeal inadequacy exists, not only will nasal air escape occur during the closure phase of stop consonants, but the oral release burst during the plosive phase will be reduced in intensity owing to the loss of air pressure through the nose. In severe cases, an oral stop may sound more like a nasal consonant (e.g., "bat" may sound like "mat").

Articulation and Intelligibility

The prevalence of articulation errors in children with repaired cleft palate is high. Based on a review of the literature, Peterson-Falzone and co-workers concluded that approximately 75% of preschool children with repaired palate exhibit some type of articulation disorder.[4] Estimates were as high as 90% in some studies.[35] Given that multiple causes may be involved, these findings should not be surprising. As a comparison, the overall prevalence of functional articulation disorders among children without cleft palate is generally estimated to be 6% to 10%.[27]

Children with cleft palate and velopharyngeal dysfunction have been described to exhibit a variety of compensatory misarticulations.[1,4] As noted by Peterson-Falzone and colleagues (2010), compensatory articulations were historically considered to consist of glottal stop and pharyngeal fricative substitutions for oral consonants.[4] A shift in articulatory constriction to a location inferior to the velopharyngeal sphincter was considered to occur in response to velopharyngeal inadequacy in order to preserve manner of production. Philips and Kent[36] succinctly defined compensatory articulations as: "… behaviors that are thought to be learned and habituated [automatized] for productions of speech sounds when, due to VPI, normal productions cannot be achieved."

Given that velopharyngeal inadequacy results in an obligatory reduction in oral air pressure associated with stop consonants, it is not surprising that glottal substitutions may occur.[37] Sherman and colleagues reported that children with cleft palate primarily substituted glottal stops for voiceless stops—which require greater oral air pressure than voiced stops.[38]

In addition to "gross" compensatory errors such as glottal stops and/or pharyngeal fricatives, there are additional articulations typical of speakers with repaired cleft palate. Using both perceptual and radiographic techniques, Trost described the middorsum palatal stop, the posterior nasal fricative, and the pharyngeal stop.[33] The middorsum palatal stop was described as a substitution for alveolar and/or velar stops. It is produced with the dorsum of the tongue making contact with the palate in approximately the location for production of /j/. Perceptually, it was described as a cross between /t/ and /k/ or between /d/ and /g/, depending on voicing. The posterior nasal fricative was identified as a substitution for sibilant sounds. As noted earlier, it is produced with oral occlusion that forces air through a small velopharyngeal constriction. The pharyngeal stop was identified as a substitution for velar stops /k/ and /g/. It is produced with the base of the tongue making contact against the posterior pharyngeal wall.

The middorsum palatal stop is produced anterior to the velopharyngeal sphincter. It is problematic, therefore, to attribute its function as a compensatory response to velopharyngeal inadequacy. Hoch and colleagues noted the frequent co-occurrence of anterior oronasal fistulas (ONFs) and middorsum palatal stops in children with repaired cleft lip and palate.[39] Accordingly, they attributed the occurrence of the middorsum palatal stop to "anterior palatal defects." Similarly, Kummer stated that middorsum palatal stops might occur in response to malocclusion and/or dental crowding in the oral cavity, two frequent consequences of unrepaired alveolar clefts.[1] Indeed, several studies have noted that palatalized articulations were associated with physical narrowing of the anterior palate.[2,84]

Whereas several investigators have suggested that the middorsum palatal stop is a frequently occurring misarticulation in children with cleft palate, its effect on speech intelligibility is largely unknown.[40-42] Both trained and untrained listeners cannot consistently identify middorsum palatal stops as distinct from examples of /t/ and /k/ produced by children with repaired cleft palate.[42] Although an identification task is not the same as intelligibility, middorsum palatal stops "may reduce the intelligibility of the individual's speech by neutralizing the place contrast."[42]

Although articulation and intelligibility are often used as synonymous terms, intelligibility as a construct supersedes articulation. Kent has defined intelligibility as "the degree to which the speaker's intended message is recovered by the listener."[43] Therefore intelligibility is dependent on the speaker, the situation, and the listener. Many of the early studies that investigated intelligibility in children with repaired cleft palate employed transcription or write-down techniques.[11,44-46] In general, these studies indicated (1) clear differences in intelligibility between subjects with and without cleft palate, (2) a tendency for articulation and intelligibility scores to be correlated (especially errors involving stop consonants), and (3) a tendency for intelligibility and velopharyngeal function to be correlated.

Vocal Dysfunction

Voice disorders in individuals with clefts of the palate are often reported in the literature.[47-51] Hoarse vocal quality, reduced loudness, deviant and/or restricted pitch range, and tense or strained qualities are some of the commonly observed vocal aberrations. These studies have also reported a high prevalence of organic voice disorders among individuals with cleft palate as compared to speakers without cleft palate. McWilliams and co-workers used nasoendoscopy to examine 32 children with repaired cleft palate who had hoarse vocal quality.[48] These investigators reported that 72% of the children exhibited vocal fold nodules. Marks and co-workers reported that perceptual symptoms of dysphonia were evident in 34% of 102 speakers who were evaluated for suspected velopharyngeal dysfunction.[49] Similarly, D'Antonio and colleagues reported that 41% of 85 speakers with velopharyngeal dysfunction exhibited either perceptual symptoms of dysphonia and/or laryngeal anomalies.[50] As a comparison, voice disorders typically occur in no more than 6% of the general population.[27]

The high prevalence of voice disorders among speakers with velopharyngeal dysfunction is often attributed to compensatory changes in respiratory and/or laryngeal behaviors. Because nasalization of sound results in attenuation of acoustic energy, a speaker with inappropriate oral-nasal coupling will have to increase intensity to achieve a given level of loudness. One way to increase intensity is to use increased laryngeal resistance during voicing. The available evidence relative to laryngeal resistance among speakers with cleft palate, however, is equivocal. Whereas Zajac reported similar levels of laryngeal resistance in children with and without cleft palate, a study performed by Guyette et al reported that children with cleft palate and incomplete velopharyngeal closure exhibited higher levels of laryngeal resistance than children with cleft palate and complete velopharyngeal closure.[52,53]

Some speakers with velopharyngeal dysfunction may actually reduce loudness. McWilliams and colleagues refer to this phenomenon as "soft voice syndrome" and suggest that it is an attempt to mask perceptual symptoms of hypernasality and/or nasal air escape.[11] Finally, clinicians should also be aware that vocal hoarseness will effectively mask hypernasality in many patients with repaired cleft palate. Careful attention, therefore, should be paid to patients with hoarseness.

Perceptual Evaluation Procedures

It is often said that the ear (and eye) of the SLP is the most important tool relative to diagnosis of speech problems in individuals with repaired cleft palate. The use of instrumental techniques as described later in this chapter is secondary to perceptual assessment and is used to objectively document the severity of dysfunction and/or to guide treatment approaches (e.g., type of secondary palatal surgery). The primary objective of the clinician as part of perceptual

assessment is to determine the adequacy of velopharyngeal function for normal speech production. To do so, the clinician must obtain an adequate sample of conversational and elicited speech to detect the presence of obligatory and/or compensatory speech behaviors.

Nostril Pinch Test

A relatively simple procedure to help the clinician determine if hypernasality is present is the nostril pinch test.[54] The speaker is instructed to prolong a vowel such as /i/ both with the nostrils open and with them closed. If velopharyngeal closure is adequate, there will be little change in resonance from the open to closed states. A perceptual shift to more oral resonance with the nostrils occluded is an indication of incomplete velopharyngeal closure. For some patients with inadequate velopharyngeal closure, the shift in resonance may approach a cul-de-sac quality. This is a muffled, nasal-like quality that occurs because of the blockage of the anterior nose. As described by Kuehn and Henne, the nostril pinch test may also be used to detect the presence of hyponasality in speakers with cleft palate.[54] Hyponasality is a reduction in normal nasal resonance during production of nasal consonants. It may occur as a result of posterior obstruction by enlarged tonsils and/or adenoids or anterior obstruction due to a collapsed nasal vestibule, deviated septum, and/or hypertrophied turbinates. To detect hyponasality, the speaker is instructed to produce words containing nasal consonants such as "mama" with the nostrils both open and closed. If no nasal obstruction is present, then a definite shift to hyponasal resonance should occur with the nostrils occluded.

Nasal Emission Testing

A relatively simple technique can also be used to detect the inappropriate escape of nasal airflow during oral consonant production. The clinician holds a small mirror or detail reflector beneath the nostrils of the speaker during production of syllables and sentences that contain nonnasal consonants (Figure 32-2). If velopharyngeal closure is complete, then no visible fogging of the reflector will occur except perhaps at the very beginning and end of the utterance. Visible nasal escape at the start and end of an utterance is normal and is caused by the movement of the velum during transitions from breathing to speaking and from speaking to breathing, respectively. Clinicians must also be cautious regarding speaking rate during nasal emission testing. If a speaker uses a relatively slow rate with respiratory pauses between words, then normal nasal escape may occur at the onset and offset of each word owing to movement of the velum as noted previously.

Nasal emission testing can also be used to detect nasal obstruction. If reduced or absent nasal airflow occurs during production of nasal consonants, then some degree of obstruction and hyponasality will likely be present. Typically, it is best to start nasal emission testing during production of nasal consonants to rule out obstruction before testing for nasal escape during nonnasal consonants.

• **Figure 32-2** Detail reflector to test for nasal obstruction during breathing and nasal air emission during speech.

• BOX 32-1 Respiratory and Speech Stimuli to Determine Nasal Obstruction and Velopharyngeal Dysfunction During Nasal Emission Testing

Stimuli to Determine Nasal Obstruction

- Quiet breathing with lips closed
- Repetition of /mi/ and /ma/
- "Mama made some lemon jam"

Stimuli to Determine Velopharyngeal Dysfunction

- Repetition of /pi/ and /pa/
- Repetition of /si/ and /sa/*
- Repetition of /ki/ and /ka/†
- "Papa plays baseball"
- "Sissy sees the sky"
- "Lucy likes lollipops"

*May indicate phoneme-specific nasal emission.
†May indicate patent anterior ONF.

Finally, nasal emission testing might be useful to determine if an anterior ONF is symptomatic for speech. This is done by systematically varying production of anterior and posterior stop consonants and observing the resulting pattern of nasal air emission. As indicated by Kuehn and Henne, if an ONF is lingual to the alveolar ridge, then during production of syllables containing /p/, nasal air escape will occur if the ONF is patent.[54] If, however, during production of syllables containing /k/, nasal air emission is absent, then the source of the nasal air escape can be attributed to the anterior ONF. Obviously, this assumes that velopharyngeal closure is complete. Box 32-1 presents respiratory and speech stimuli used by this clinician during nasal emission testing to rule out nasal obstruction, detect the presence of nasal air escape resulting from velopharyngeal dysfunction, and detect the presence of nasal air escape possibly caused by an anterior ONF or learning (i.e., PSNE).

Perceptual Rating Scales

Once global decisions are made regarding the presence or absence of hypernasality and nasal air emission, various types of rating scales may be used to indicate the perceived level of severity. Most commonly, the equal-appearing interval (EAI) scale is used with varying numbers of intervals.[11] In its most simple form, a four-point EAI scale is used to represent normal (0), mild (1), moderate (2), or severe (3) hypernasality. Five-, seven-, or nine-point EAI scales can also be used. Obviously, as more intervals are used, reliability of judgments within and across clinicians becomes more problematic. EAI scales can also be used to judge the severity of nasal air emission, vocal symptoms such as hoarseness and breathiness, and, as discussed later, articulation and speech intelligibility.

Articulation Testing

As part of the clinical evaluation, the SLP will use a standardized test of articulation to describe speech errors and document the speaker's level of impairment relative to a reference sample of speakers. Any of the commercially available articulation tests are adequate for this purpose (e.g., Arizona Articulation Proficiency Scale 3, Fisher-Logemann Test of Articulation Competence). Typically, the SLP will use transcription symbols based on the International Phonetic Alphabet to describe articulation errors such as substitution, omission, addition, and distortion of targeted speech sounds. In addition, when evaluating a speaker with repaired cleft palate, it is important for the clinician to use special diacritic transcription symbols that provide a further level of phonetic detail regarding distortion of sounds such as dentalization, palatalization, and/or the presence of audible nasal air escape.

Intelligibility Assessment

Some authors have advocated the use of rating scales to evaluate intelligibility in speakers with cleft palate given that write-down or transcription techniques were too time-consuming.[55] Apparently, this advice was well heeded, as revealed by a recent survey of the literature compiled by Whitehill.[56] Based on a review of 57 published articles between 1960 and 1998, Whitehill reported that 63.2% employed "crude" estimates of intelligibility or EAI scaling procedures, whereas only 14% used transcription methods. In addition, it was noted that only three of the reviewed studies used predictive analysis techniques in an attempt to explain underlying intelligibility deficits.

Hodge and Gotzke described a single-word intelligibility test to identify underlying phonetic contrasts that contribute to speech intelligibility in English-speaking children with repaired cleft palate.[57] The study evaluated 15 children between the ages of 3 years, 5 months and 6 years, 7 months. Only 5 of the children studied, however, had repaired cleft palate; 10 children were controls. Hodge and Gotzke obtained 3 indexes of speech intelligibility: (1) a global index based on 100 consecutively transcribed utterances from spontaneous speech, (2) a closed-set (i.e., multiple choice) single-word intelligibility score, and (3) an open-set (i.e., orthographic write down) single-word intelligibility score.[57] The closed- and open-set tests included up to 124 words that reflected various phonetic contrasts known to be problematic for children with cleft palate. The recorded words of the children were presented to groups of listeners who were instructed to either select the word they heard from a list of words (closed set) or simply write down the word they heard (open set). Hodge and Gotzke reported a high correlation between spontaneous speech intelligibility scores and scores obtained from the open-set task (r=0.88).

Zajac and co-workers developed a computer-mediated, 50-word intelligibility test designed for young children with cleft lip and palate.[83] Adult listeners used orthographic transcription to determine the percentage of words correctly identified for each child. Zajac and colleagues reported that the test was valid and reliable and appeared to be a good instrument to conduct multicenter outcome studies of speech intelligibility.

Instrumental Assessment Techniques

Although perceptual assessment of velopharyngeal function in patients with repaired cleft palate is considered the gold standard, Peterson-Falzone and colleagues indicate that a "comprehensive" evaluation of velopharyngeal function must include both perceptual and instrumental assessment techniques.[4] As noted earlier, instrumental assessment is ideally suited to complement perceptual judgments of severity and/or to suggest specific surgical interventions. At times, however, objective instrumental assessment may override perceptual judgments. This may occur because of the ability of instruments to isolate and focus on a specific aspect of behavior without influence from competing factors. It is well known, for example, that auditory perception of speech can be influenced by visual stimuli (e.g., the McGurk effect).[58]

Instrumental techniques to assess velopharyngeal function can be conveniently categorized as direct and indirect.[59] Direct techniques are those that provide actual visualization of the structures of interest; indirect techniques are those that show some effect of the structures of interest. Summarized in the following sections are some of the more commonly used direct and indirect instrumental techniques to assess velopharyngeal function.

Direct Techniques

Lateral Still Cephalometry

Lateral still cephalometry produces a radiograph obtained in the lateral view while a speaker sustains a nonnasal phoneme. Also called a "phonating cephalograph," it allows assessment of the extent of velar contact to the posterior

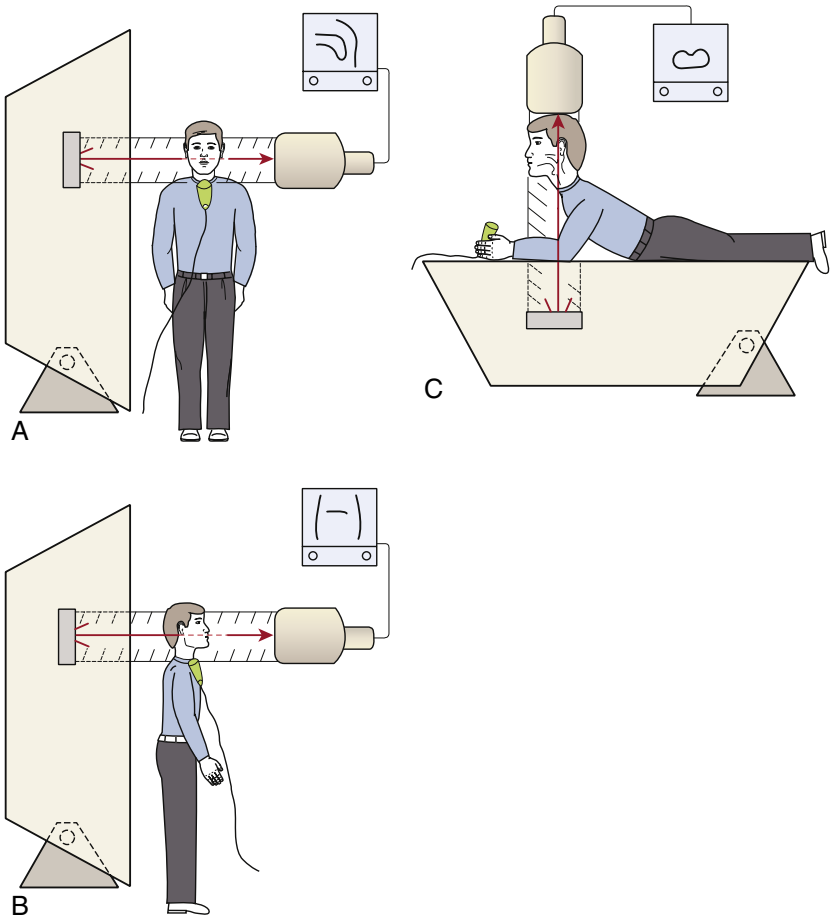
pharyngeal wall. The speaker is simply instructed to prolong a vowel such as /i/ or a continuant such as /s/ while the radiograph is taken. Examination of the radiographic film allows assessment of the length of the velum, depth of the nasopharynx, and level and extent of velopharyngeal closure. As summarized by Moon, subjective and/or objective interpretation of the lateral cephalograph is possible.[59] Although obtaining measurements from lateral cephalometric radiographs is a relatively straightforward technique and provides important information, a significant disadvantage is that only a single two-dimensional view of the velopharyngeal structures is obtained.

Multiview Videofluoroscopy

As its name implies, videofluoroscopy overcomes the disadvantage of lateral cephalometry by providing multiple views of the velopharyngeal mechanism. This technique provides a comprehensive radiographic assessment of both velopharyngeal and oral structures and functions by obtaining a systematic series of audio-video images while the patient speaks and drinks barium. As described by Skolnick and Cohn, the patient is assessed during the following sequence of activities (Figure 32-3): (1) speaking in lateral view without barium contrast, (2) swallowing barium in lateral view, (3) speaking in base view after barium is instilled into the nostrils, (4) speaking in frontal view after barium contrast, and (5) speaking in lateral view after barium contrast.[60] The lateral view with barium contrast allows assessment of velar length, depth of the nasopharynx, and dynamic movement of both the velopharyngeal and lingual structures during production of nasal and nonnasal phonemes. The base view allows assessment of lateral pharyngeal wall movement and shape of velopharyngeal closure (circular, coronal, or sagittal) during speech. The frontal view allows assessment of lateral pharyngeal wall movement relative to the level of velar elevation. By synthesizing the multiple views, the clinician is able to gain a "three-dimensional" impression of the ability of the patient to achieve velopharyngeal closure.

Video Nasendoscopy

During nasendoscopy, a flexible fiberoptic endoscope is inserted through the nasal cavity to record the dynamic movements of the velopharyngeal structures during speech production. The scope is connected to both a light source and a video camera. A microphone is used to record the speech signal along with the video images. During a typical assessment, the patient is instructed to breathe quietly,



• **Figure 32-3** Illustration of patient positioning for multiview videofluoroscopy. **A,** Lateral view. **B,** Frontal view. **C,** Base view. (Adapted from Skolnick ML, Cohn ER: *Videofluoroscopic studies of speech in patients with cleft palate,* New York, 1989, Springer-Verlag.)

swallow, and produce words and sentences that contain nasal and nonnasal segments. Similar to videofluoroscopy, nasendoscopy provides important diagnostic information regarding velopharyngeal function. In addition, it can provide useful information to prosthodontists relative to the design and fitting of palatal obturators (see the later discussion of prosthetics).

Several disadvantages of the use of nasendoscopy must be mentioned. First, it is invasive and typically requires the use of a topical anesthetic and/or vasoconstrictor. Children, especially those with nasal deformities resulting from clefts of the primary palate, may not tolerate the procedure well. Second, the view of the velopharyngeal mechanism is essentially limited to the nasal aspect of the velum and the superior-posterior pharyngeal wall. This means that velopharyngeal function may be difficult to discern if closure occurs at a more inferior level. Third, similar to videofluoroscopy, results from nasendoscopy are largely subjective in nature. In an attempt to overcome this limitation, a multidisciplinary group of clinicians formed a working group to develop standards for reporting results.[61] This group devised a rather complicated system of rating velopharyngeal closure based on the relative contributions of the velum and posterior and lateral pharyngeal walls. Based on recent studies reported in the literature, however, there does not appear to be widespread acceptance of this reporting system.

Indirect Techniques

Pressure-Flow Method

The application of aerodynamic principles to the study of the velopharyngeal mechanism during speech production was pioneered by Warren and DuBois.[62] Their procedure has come to be known as the *pressure-flow method*. Essentially, it requires the placement of small-bore catheters into one of the nostrils and behind the lips to detect differential oral-nasal air pressure and the placement of a flow tube into the remaining nostril to obtain nasal airflow. During production of oral consonants such as /p/, the size of the velopharyngeal gap can be estimated using a derivation of Bernoulli's principle.

Figure 32-4 illustrates the clinical application of the pressure-flow method. The pressure catheters are connected to calibrated differential air pressure transducers. The airflow tube is connected to a calibrated, heated pneumotachograph and air pressure transducer. The speaker simply repeats a train of /pi/ syllables with the oral catheter held behind the lips. Based on measurements of oral air pressure (P_o), nasal air pressure (P_n), and nasal airflow (V_n), estimates can be made of the cross-sectional area of the velopharyngeal port during production of /p/ using the following equation:

$$A = V_n/K[2\,(P_0 - P_n)\,/D]^{1/2}$$

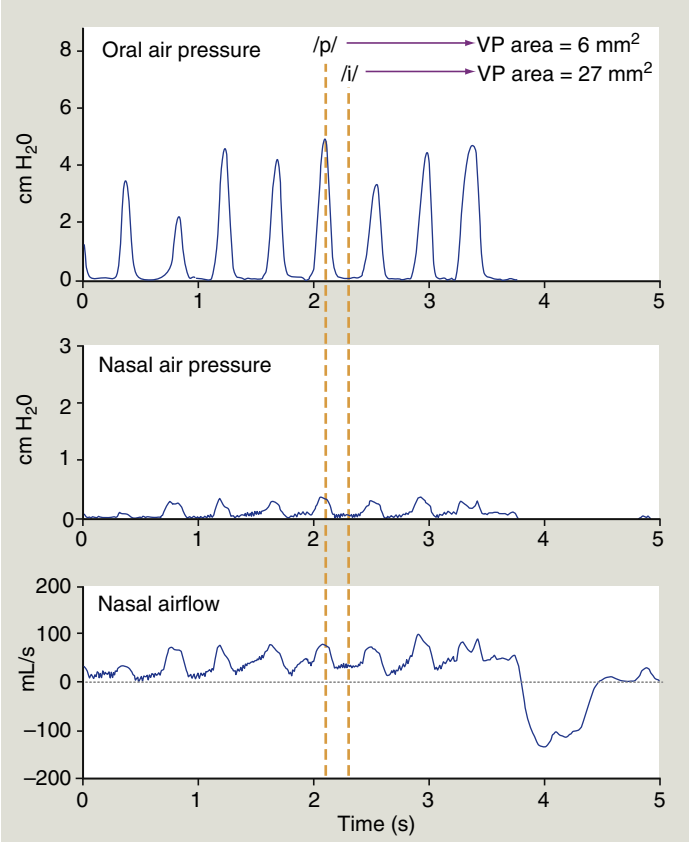
where A is area in square centimeters, V_n is nasal airflow in milliliters per second, k is a constant (0.65) used to correct for turbulent airflow, P_o is oral pressure in dynes per square centimeter, P_n is nasal pressure in dynes per square centimeter, and D is the density of air (0.001 gm/cm^3). Both hardware and software are commercially available to obtain pressure-flow measurements and calculate velopharyngeal area (Microtronics Inc., Chapel Hill, NC).

• **Figure 32-4** Placement of oral pressure catheter, nasal pressure catheter, and nasal airflow tube during pressure-flow testing.

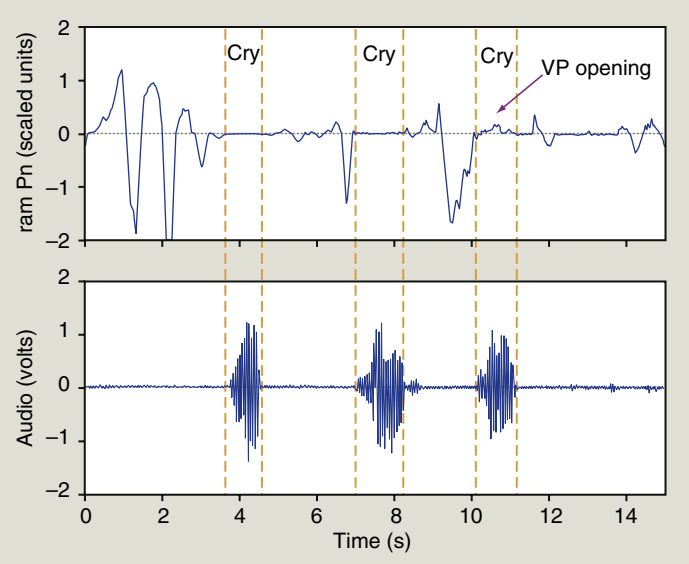
Figure 32-5 illustrates pressure-flow information from a 12-year-old boy with a repaired cleft lip and palate who repeated the syllable /pi/ eight times. Typically this utterance should be produced with complete velopharyngeal closure and no indication of nasal air pressure or flow. As revealed in the figure, however, there is evidence of consistent escape of nasal airflow during both the /p/ and /i/ segments. Perceptually the boy's speech was characterized by mild to moderate hypernasality and visible nasal air escape. Estimated velopharyngeal orifice area during the /p/ segment was approximately 6 mm^2. Estimated velopharyngeal area during the vowel segment, however, was approximately 27 mm^2. This difference is expected based on production demands of consonants (closed or constricted oral cavity) versus vowels (open oral cavity). It needs to be noted, however, that estimates of velopharyngeal orifice size during production of vowels are typically not obtainable owing to relatively low (or absent) levels of oral air pressure.

Normative data using the pressure-flow method have been reported by Zajac.[63] For speakers without cleft palate, estimates of velopharyngeal orifice size during production of syllables such as /pi/ are typically under 1 mm^2, which reflects essentially complete closure. During plosive sequences such as /mp/ in the word "hamper," velopharyngeal orifice size is typically under 3 mm^2 and rarely exceeds 5 mm^2 in speakers without cleft palate.

Thom and colleagues described the use of nasal ram pressure (NRP) as an index of velopharyngeal closure in infants during production of cries and vocalizations.[64] Six infants without cleft palate were studied longitudinally between 2 and 6 months of age. NRP was detected by inserting a double-barreled cannula connected to a pressure transducer into the nostrils of the



• **Figure 32-5** Example of oral air pressure *(top)*, nasal air pressure *(middle)*, and nasal airflow *(bottom)* during repetition of the syllable /pi/ by a 12-year-old boy with velopharyngeal dysfunction.



• **Figure 32-6** Example of nasal ram pressure *(top)* and audio *(bottom)* of a 13-month-old infant obtained 4 months after palate repair. Nasal breathing is evident before the distress cries. First and second cries show velopharyngeal (VP) closure; third cry shows an open VP port.

infants. A lapel microphone recorded cries and vocalizations. The study revealed that velopharyngeal closure occurred during cries beginning at 2 months of age. Velopharyngeal closure during vowel-like vocalizations, however, tended to increase as a function of age. The study suggested that this technique may hold promise in the early diagnosis of velopharyngeal dysfunction in infants with cleft palate after surgical repair. At the UNC Craniofacial Center we have begun to investigate infants by obtaining NRP after cleft palate repair. Figure 32-6 illustrates NRP and audio of a 13-month-old infant obtained 4

• **Figure 32-7** Placement of Nasometer head-mounted microphones to determine nasalance.

months after surgery. As shown, the NRP data suggest that this infant exhibited velopharyngeal dysfunction during the third cry. We are currently collecting longitudinal data on a group of infants with repaired cleft palate and hope to determine the clinical utility of this promising new procedure.

Nasometry

The Nasometer uses two microphones to detect nasal acoustic energy in relation to oral acoustic energy produced during voiced speech sounds. Precursors to the Nasometer, Tonar (The Oral-Nasal Acoustic Ratio) and Tonar II, were originally developed by Fletcher.[65,66] Currently the Nasometer is commercially available from Kay Pentax Corporation (Lincoln Park, NJ). A similar device, called the OroNasal mask system, is available from Glottal Enterprises (Syracuse, NY). The output of the Nasometer is a measure called *nasalance*. It is calculated as the ratio of nasal acoustic energy to oral-plus-nasal acoustic energies and expressed in a percentage:

$$\%\,\text{Nasalance} = \text{Nasal intensity}/(\text{oral} + \text{Nasal intensity}) \times 100$$

Clinical use of the Nasometer is illustrated in Figure 32-7. Two microphones are separated by a metal plate that serves as a sound barrier. A head harness positions the sound barrier to rest on the upper lip beneath the nose. The top microphone detects nasal acoustic energy, and the bottom microphone detects oral acoustic energy. The outputs of each microphone are band-pass filtered at 350 to 650 Hz, digitized to a computer, and percent nasalance is calculated and displayed. Nasalance statistics such as means, standard deviations, maximums, and minimums can be calculated. Typically speakers are instructed to read a passage devoid of nasal consonants (the "Zoo" passage) and sentences loaded with nasal consonants. As indicated later, speakers with normal resonance typically do not exhibit nasalance scores that exceed 32% during reading of the Zoo passage. For nasal sentences, normal speakers typically do not exhibit nasalance that falls below 50%. In addition, MacKay and Kummer have provided nasalance norms for children based on repetition of consonant-vowel syllables.[67]

Percent nasalance appears to be a fairly sensitive predictor of perceived hypernasality and hyponasality. Dalston and coworkers, for example, reported that nasalance scores of 32% or greater during reading of the Zoo passage had a sensitivity of 0.89 and a specificity of 0.95 in identifying speakers with at least mild hypernasality.[68] In a separate study Dalston's group further reported that nasalance scores of 50% or less during reading of sentences loaded with nasal consonants had a sensitivity of 0.48 and a specificity of 0.79 in identifying speakers with perceived hyponasality.[69] The authors noted that the relatively low sensitivity increased to 1.0 when speakers who exhibited audible nasal emission during voiceless consonants were omitted from analysis. The latter finding highlights a limitation of the Nasometer in that audible nasal air emission tends to inflate nasalance scores.

The Nasometer is a popular clinical tool that is helpful in the diagnosis of speakers with resonance imbalance. Although the basic concept of the Nasometer is valid, the reader should be cautioned relative to several aspects of its use. First, the actual sound separation between the oral and nasal microphones is limited. In practice, this means that 0% nasalance does not occur during production of sounds when the velopharyngeal mechanism completely separates the mouth from the nose. Likewise, 100% nasalance typically does not occur during nasal consonants. Second, although nasalance scores are intended to reflect voiced speech segments, the Nasometer is also sensitive to nasal turbulence that may occur during voiceless consonants. This may inflate nasalance scores and, as indicated earlier, reduce sensitivity relative to perceptual characteristics of speech. Finally, because the Nasometer uses two microphones, there may be subtle mismatches in the microphone sensitivities as a function of frequency response. Indeed, users of both the original Tonar and the current Nasometer have been cautioned relative to this possibility.[70,71] If mismatches in microphone sensitivity exist, then discrepancies in nasalance scores may occur as a function of different Nasometer units, and comparisons across centers may be problematic. Based on published and unpublished studies, this writer suggests that clinicians tolerate at least a range of plus or minus 7% when comparing a patient's nasalance score with published norms owing to possible differences in microphone sets.[71]

Management of Velopharyngeal Dysfunction

Treatment of velopharyngeal dysfunction after primary palate repair is typically considered if communication abilities of an individual are impaired and/or if the speech of the individual calls undue attention to itself, causing social stigma. Physical management via secondary surgery or

prosthodontics is typically recommended for obligatory symptoms such as hypernasality and/or nasal air escape. In some cases, primarily when obligatory symptoms are mild and/or inconsistent, behavioral therapy approaches may be tried.

Secondary Surgery

Surgical approaches to correct velopharyngeal inadequacy include creation of a posterior pharyngeal flap, sphincter pharyngoplasty, and palatal lengthening. As indicated by Sloan, pharyngeal flaps and sphincter pharyngoplasty are perhaps the two most commonly used procedures.[72] During pharyngeal flap surgery a superiorly based flap of the posterior pharyngeal wall is released and sutured to the velum. This creates a midline obstruction across the nasopharynx. During production of nonnasal speech sounds, velopharyngeal closure is achieved by medial displacement of the lateral pharyngeal walls against the flap. At the UNC Craniofacial Center, pharyngeal flaps are typically recommended for relatively large, circular-shaped velopharyngeal gaps when some degree of lateral pharyngeal wall movement is observed during multiview videofluoroscopy and/or nasendoscopy. An obligatory side effect of a posterior pharyngeal flap is increased resistance during nasal breathing. In some cases, if sleep apnea occurs, the flap can be surgically divided.

A sphincter pharyngoplasty involves the release of two muscular flaps from the posterior faucal pillars, with surgical attachment to the posterior pharyngeal wall. As its name implies, this procedure attempts to achieve velopharyngeal closure by facilitating normal sphincter-like movement. At the UNC Craniofacial Center, sphincter pharyngoplasty is typically recommended for relatively small, coronal-shaped velopharyngeal gaps. Although some clinicians believe that sphincter pharyngoplasty is less likely to cause airway impairment as compared with a pharyngeal flap, recent evidence has not shown an advantage of sphincter pharyngoplasty based on objective sleep study data.[73]

Recently some surgeons have begun to use palatal lengthening as a secondary procedure to correct velopharyngeal inadequacy. As indicated by Kuehn and Henne, this procedure may be indicated if initial palate surgery did not successfully reconstruct the velar musculature (i.e., the "velar sling").[54]

Speech Appliances

In some cases a recommendation may be made for obturation of a velopharyngeal defect by a speech appliance rather than surgical correction. Typical cases may include patients in whom (1) the velopharyngeal gap is large and/or there is limited movement of structures, (2) perceptual symptoms of velopharyngeal dysfunction are severe, and/or (3) other medical conditions contraindicate surgery.[74] As indicated by Leeper and co-workers, the recommendation for prosthodontic management is largely determined by the age and oral condition of the patient.[74] Young children who may not tolerate and/or comply with procedures and individuals with poor oral hygiene and/or missing teeth are not good candidates.

Speech appliances may also be used to obturate anterior defects such as ONF in either the alveolar or palatal regions. At the UNC Craniofacial Center we often recommend an anterior speech appliance for young children who have a large alveolar fistula but are not yet ready for bone grafting procedures. These appliances, which often can be fabricated from acrylic material during a single visit, function to provide a stable target area for learning alveolar consonants as part of speech therapy.

Finally, palatal lift appliances are sometimes recommended for patients who exhibit velopharyngeal incompetency as a result of neuromotor involvement (e.g., velar paralysis). In these cases the function of the appliance is not to obturate but to elevate and hold the velum against the posterior pharyngeal wall during speech production.

Behavioral Approaches

SLPs are well trained not to attempt speech therapy in patients with velopharyngeal dysfunction when the cause is structural and the symptoms are strictly obligatory (i.e., hypernasality and/or audible nasal escape). Unfortunately, SLPs are not well trained to treat articulation issues in these patients. Compensatory misarticulations are learned behaviors that can be corrected only by speech therapy. As indicated by Golding-Kushner, SLPs can intervene with a patient even before secondary surgery if the goal is to correct faulty placement of articulation.[75] In this situation the SLP may need to use a clip to occlude the nose and prevent nasal air escape while allowing the patient to focus on learning correct oral placement. Obviously, once the nasal clip is removed, the patient may exhibit audible nasal air escape and/or revert back to using compensatory misarticulations. A competent SLP who is aware of the structural defect and the goal of therapy, however, may shorten the duration of articulation therapy needed once secondary surgery is done. In addition, Golding-Kushner advocates that speech therapy may actually be necessary before surgery in some patients with pervasive glottal stops who exhibit little or no velopharyngeal movement.[75] In these patients the goal of therapy is to stimulate some degree of velopharyngeal movement in order to determine the extent of dysfunction and make appropriate surgery recommendations. Golding-Kushner describes step-by-step techniques for establishing correct articulation in children who exhibit compensatory misarticulations.

In some cases, an SLP may attempt to intervene with a patient who exhibits mild and/or inconsistent obligatory symptoms of hypernasality and/or audible nasal air escape on a trial basis. These patients may benefit from procedures that are meant to increase the extent of velopharyngeal

closure—assuming that the patient is capable of achieving better closure—and/or to mask the perceptual consequences of symptoms. One technique is the practice of words that contain nasal-plosive sequences such as "hamper" with increased loudness or stress on the plosive segment. Extra effort will naturally increase activation of the velar and pharyngeal muscles and perhaps result in better closure. McHenry, for instance, reported improved velopharyngeal closure in patients with dysarthria when they were instructed to increase vocal effort.[76] A similar approach is to simply instruct the patient to speak with exaggerated articulatory movements of the lips, tongue, and jaw. By overarticulating, the speaker may also increase vocal effort, but, more important, will shift resonance to a more open oral cavity. A shift to oral resonance may effectively mask nasal resonance even without a change in velopharyngeal closure per se.

The SLP must use caution with either of these procedures in that obligatory symptoms of hypernasality and/or nasal air escape may actually increase as a result of increased effort. Indeed, as noted previously, some speakers may use a soft voice to avoid perceptual symptoms. If increased loudness and/or overarticulation results in worsening of perceptual symptoms, then behavior therapy should be discontinued and surgical intervention considered.

Somewhat contradictory to the previously described approaches, Kummer recommends "quick and light" articulatory contacts as a behavioral strategy to reduce audible nasal air escape.[1] This approach has theoretic merit in that any reduction in oral air pressure will reduce the driving pressure that generates nasal air flow. In addition, Gaylord and Zajac reported that children with repaired cleft lip and palate produced the alveolar stop-plosives /t/ and /d/ with longer stop gaps compared with children with cleft palate only.[77] We speculated that the cause of these temporal differences might relate to reduced oral sensation in the children with alveolar defects. Regardless of the cause, this finding indirectly supports the use of "quick" articulatory contacts in that the time for audible nasal air escape to be perceived will be reduced.

Kuehn and colleagues have recently described the theory and approach to a novel behavioral therapy that uses continuous positive airway pressure (CPAP) during speech.[78-80] The therapy program consists of an 8-week schedule of speech exercises that use CPAP applied to the nasal cavity. Both speaking time and magnitude of CPAP are systematically increased over the 8-week period. The goal of the program is to "train" the velopharyngeal structures to achieve closure in the face of increasing levels of resistance provided by the CPAP. Speech stimuli consisting of disyllables that contain nasal-plosive sequences are used. The nasal-plosive sequences are assumed to maximize resistance during the period of velopharyngeal closure (i.e., during the transition from the nasal to the plosive segment). Although the approach is based on sound scientific principles, limited success in reducing perceived hypernasality in children who had repaired cleft palate has been reported.[80] In addition, it is not clear that "resistance" is actually maximized during the closing phase of the nasal-plosive sequences that are recommended as speech stimuli. Weaver, for example, reported that both oral and nasal mask pressures were essentially equal during the /mp/ sequence of nonsense syllables when positive nasal air pressure was applied.[81] Differential nasal pressure (i.e., velar "resistance") was generated only once velopharyngeal closure was actually achieved.

Finally, speech therapy is the indicated treatment for cases of PSNE. As discussed previously, although this phenomenon mimics velopharyngeal dysfunction, it is actually a learned misarticulation that is characterized by oral occlusion and nasal direction of airflow (i.e., production of nasal fricatives). The goal of therapy is to eliminate the oral stopping. As indicated by Kummer, once this is achieved, the nasal fricative is spontaneously eliminated.[1] An efficient technique to eliminate PSNE is to instruct the child to produce /t/ with exaggerated oral release that naturally becomes an /s/. Nose occlusion may be used initially to help break the cycle of oral stopping and nasal emission.

Management of the Cleft Maxilla

GERARDO P. ROMEO, BERNARD J. COSTELLO

Clefting of the maxilla and alveolus occurs due to a failure of fusion of several key components of the facial structures during the first trimester of pregnancy and typically includes components of the maxillary processes, median nasal process, and palatal shelves.[1] When one or several of these components fail to fuse, a variety of clefts and associated deformities are seen. Each multitissue defect requires appropriate attention in reconstruction for optimal outcome and, ideally, should be based on growth and the iatrogenic potential for growth restriction, functional needs and esthetic concerns, patient impact with regard to psychosocial development, and overall care burden for the patient, and at times family and other caregivers.

There are multiple goals of reconstructing the cleft of the maxilla. The most basic goal is to eliminate oral and nasal communication and to establish normal anatomic boundaries of the oral and nasal cavities to support proper deglutition and speech. Unification of the cleft maxillary segments into a continuous osseous structure (especially important with bilateral cleft deformity) and establishment of intact alveolar bone to support proper development and eruption of teeth are the other primary goals. Finally, the esthetic results for the reconstructed and repaired facial deformities can be optimized with proper management of the osseous maxillary defects beneath as skeletal augmentation in the way of bone grafting has been shown to provide many favorable changes to the facial esthetic, specifically in the area of the cleft lip and nose.[2,3,4,5]

One could imagine that the best theoretic surgical solution might be a single-stage correction of all abnormalities as early as possible. This would circumvent many, if not all, of the complexities associated with cleft care regarding feeding, speech development, growth of the facial skeleton, and avoidance of a number of stressors during psychosocial development. Unfortunately though, this idea does not translate to a reality as both single-stage and early age correction, even in utero, yield little if any benefits of clinical significance and cause extensive disruption of facial growth or other problems. Single-stage and very early corrections do not account for well-understood concepts in facial growth, namely that surgical scarring has high potential for growth restriction and that growth of the facial skeleton is not uniform and varies in rate and extent between subunits over childhood and adolescence. Although there are studies that suggest speech advantages are worthwhile with these approaches,[6,7,8] long-term growth follow-up does not extend the point of facial skeletal maturity. Keeping in mind the most basic concepts of craniofacial growth, it is clear that the severity of iatrogenic growth restriction would not become evident until maturity. Despite this, the centers that cite the "advantages" of using this approach fail to publish late growth data or convincing arguments based on data that show measurable improvements.

As with most aspects of cleft care, a number of controversies exist regarding timing, technique, and reconstructive materials utilized in management of the maxillary osseous cleft defect. This chapter will provide a background and foundation for management, address some of the controversies, and discuss the surgical techniques believed to be most sound by the authors.

History and Surgical Options

The first documented reconstruction of the osseous maxillary cleft defect is attributed to Anton Freiherr von Eiselsberg in 1901. The extraordinary case involved a 19-year-old female born with bilateral cleft lip and palate who had undergone multiple surgical attempts at treatment with poor results. She was found to have a large residual fistula of the palate, velar incompetence, and a flat broadened nose. She was reportedly so unhappy with her state of repairs that she agreed to reconstruction of her defect by sacrificing her left little finger.[9] The extremity of this case illustrates just how sensitive affected people can be to poor long-term results.

Interestingly, outcomes evaluation regarding restorative techniques and graft options for maxillary cleft reconstruction over time has helped shape the general approach to cleft care worldwide into the current state. Examination of the differing opinions in the literature highlights the progression of technique and the current focus on long-term evaluation of outcomes and limited growth restriction as a key focus to achieve balance between esthetics and function long term.

Surgical treatment of the maxillary osseous defect during the early life of the patient can be achieved with gingivoperiosteoplasty (GPP) and primary bone grafting. GPP, first presented by Skoog in the 1960s, is often completed during infancy simultaneously with initial repair of the cleft lip.[10,11,12] The modern form of the technique has evolved to incorporate use of orthopedic devices, such as those described by Latham and later Grayson,[13,14] preoperatively to approximate misaligned cleft palatal segments. Then, oral and nasal side flaps are developed, resembling secondary grafting techniques to be discussed later, in such a way that following reorientation and closure, the oral and nasal cavities are completely separated from one another by two intact layers spanning the osseous defect. The cleft gap is now lined with periosteum on both the oral and nasal sides and bleeding is promoted to stimulate spontaneous formation of bone. The published results are mixed with respect to amount and quality of bone to be provided at the cleft site for eruption of the permanent dentition (i.e., the canine and lateral incisor).[15,16] A significant percentage of patients will still require grafting at a later date prior to the eruption of the permanent teeth due to insufficient bone volume. Significant growth restriction and maxillary hypoplasia have been seen when utilizing this technique, although it is still heavily favored in many centers. Several reports have confirmed this concern.[16,17] While there is no scarcity of literature claiming that growth results are no worse when compared with other methods, most fail to follow patients through skeletal maturity. A paper by Sobocki in which Skoog was the senior author has suggested that growth as measured by cephalometrics is not significantly worse than secondary bone grafting techniques. However, the authors acknowledge that the incidence of clinically significant anterior crossbite/skeletal malocclusion as identified by a validated method is higher with GPP.[18]

Primary bone grafting was introduced prior to GPP in the 1950s by Schmid.[18] The concept initially was met with enthusiasm from a number of surgeons and was widely used in the 1960's.[19-29] During the decades that followed, many negative skeletal, dental, and growth-related consequences of primary bone grafting became better understood and primary bone grafting eventually fell out of favor.[16,20,30-32] Conceptually, primary bone grafting shares many similarities to GPP with the exception that a graft material is placed into or spanning the cleft gap rather than allowing the cleft defect to regenerate bone spontaneously. By definition, primary bone grafting must occur before two years of age.[33] The classic technique utilizes autogenous rib as the graft material because it is readily available in the age group, can be harvested with modest complications, and regenerates spontaneously.[34,35] The goal at the point of introduction of the technique was mainly to unify the cleft segments because it was postulated that unification with a site of normal growth could limit the progressive flattening of the lip and nose and address the osseous notch. However with significant detrimental growth effects, growth characteristics of the rib that did not correspond satisfactorily to craniofacial growth, and lack of success in avoiding an additional secondary graft for the majority of people treated this way,[36] focus shifted away from this approach in pursuit of better outcomes.

During the early 1970s Phillip Boyne was the first to publish favorable outcomes using autogenous particulate bone grafts for reconstruction of the cleft maxilla and alveolus later in childhood during the mixed dentition rather than earlier in life.[22] This was the dawn of the era of secondary bone grafting. Secondary bone grafting is divided into early secondary (between 2 and 5 years of age), secondary (between 5 and 16 years of age) and late secondary (older than 16). Although these early definitions based on chronologic age are still recognized, the central tenet of successful secondary bone grafting is that procedural timing is actually based on developmental age, specifically dental rather than chronologic. Although Boyne's work and results represented a landmark discovery in the field of cleft reconstruction, cleft palate teams were slow to integrate the approach into their treatment protocols because of the negative associations that lingered after the poor outcomes experienced previously with primary bone grafting.

Boyne's principles of secondary bone grafting have become the standard approach for most of the world's cleft centers because they result in decreased limitations of growth and successfully address the numerous goals of reconstruction of the cleft maxilla.[20-22] Secondary bone grafting prior to the eruption of the relevant permanent dentition remains the most commonly performed protocol[20-22,37] and is the favored protocol of the authors.

Procuring bone graft from the iliac crest, cranium, symphysis, or another autologous location has been the standard for reconstruction of this site since Boyne's initial descriptions. Several key factors are considered when selecting the ideal time for grafting, namely anatomic considerations, concepts of dentoskeletal growth and development, and the potential for complications both at the site of reconstruction and the graft donor site.

Dental Considerations

Abnormalities of the dentition associated with cleft lip and palate have long been recognized to be encountered with a higher frequency when compared to noncleft cohorts and is another area where the surface defect conceals other abnormalities below. The most commonly encountered abnormalities of dentition are hypodontia, hyperdontia, abnormal location and transposition, dental rotations, variability of tooth size and anatomy, delayed formation and eruption, and increased risk and incidence of dental caries. Typically, teeth adjacent to the cleft are most affected. The permanent lateral incisor is the most susceptible to abnormality, however, teeth distant to the cleft and even in the opposing jaw have been found to be variably affected at rates higher than in noncleft people. Caries incidence and eruption delay, on the other hand, tend to affect the entire dentition. Some of the specific abnormalities and teeth affected vary across cleft subtypes as well as between primary and permanent dentitions.

The formation and eruption of permanent teeth is typically delayed in patients with cleft lip and palate. This may occur in both jaws and can range anywhere from 4 months and 10 months on average.[38,39] Caries risk and incidence has also been shown to be more severe in people with cleft lip and palate relative to the noncleft population. This holds true for both primary and adult dentition, may have a genetic association, and has been validated by meta-analysis.[40,41]

Hypodontia is the most commonly cited dental anomaly in cleft lip and palate patients. In noncleft patients, the incidence of hypodontia is variable across studies and populations, roughly 3.4% to 9.6%.[42-44] With the exception of third molar teeth, congenital absence of the mandibular second premolar and maxillary lateral incisor are the most commonly missing teeth in noncleft patients.[45]

The incidence of hypodontia in people born with cleft lip and/or palate is significantly higher—roughly 7 times the noncleft population—and has been reported as high as 77%, but also varies between studies and populations examined.[38,46-54] The permanent lateral incisor on the cleft side is most frequently missing, up to 50% of the time.[38,48,55] More rarely, the cleft side central incisor may be missing, but incidence may be closer to that of the general population,[50,53,54] though incidence of size and shape abnormality is clearly higher than that seen with the general population.[56,57] The permanent canine is rarely reported as missing but may be transposed with the first premolar tooth on the cleft side up to 8.5% of the time.[50,54,58] The primary lateral incisor is congenitally missing with less frequency than is the permanent tooth.[48,49] Abnormalities in the primary dentition do not translate directly to the permanent dentition, so the abnormality in one is not necessarily seen in the other.[38,48,49,59] The incidence of cleft site hypodontia varies for the different cleft subtypes but it is commonly reported that incidence increases with severity of the cleft (i.e., complete UCLP has higher risk than incomplete cleft lip only).[38,60]

When the lateral incisor is not congenitally missing, it is usually located distal to the cleft both in the primary and permanent dentition.[48,49,61] Additionally, when it is present, it is commonly of abnormal size or shape and can be of limited use to the patient long term, often requiring extraction.[58,61]

As for hypodontia distant to the cleft site, incidence, while not as high as at the cleft site, is higher than is seen in noncleft cohorts and is reported from 21% to 49%.[38,46,49,61,62] The mandibular second premolar, the noncleft-side lateral incisor, and the second maxillary are the most likely teeth to be absent outside of the cleft site. The incidence of distant site hypodontia is highest in patients with complete cleft lip and palate deformity versus incomplete, cleft lip only, or isolated cleft palate patients.[63-65] In the case of the isolated cleft palate, the mandibular second premolars, maxillary second premolars and maxillary lateral incisors are the most likely affected and range in reported incidence from 23% to 56% for second premolars to as high as 59% for maxillary lateral incisor.[47,66-68]

The presence of supernumerary teeth is the second most frequently encountered cleft site dental anomaly. The incidence of supernumerary teeth in the general population is reported as roughly 0.2% to 3%.[64,69,70] It is more common to see supernumerary teeth in the adult versus the primary dentition of noncleft patients, and the most common supernumerary tooth is the mesiodens.[71]

Supernumerary teeth are seen with higher frequency both with syndromic diagnosis and/or as a feature of cleft lip/palate.[67,70] The incidence of supernumerary teeth in people born with cleft lip and cleft lip and palate ranges in reports from 1% to 42% for permanent teeth and up to 60% in the primary dentition. The highest incidence is seen in cleft lip only, less so in cleft lip and palate deformity and rarely, if ever, in isolated cleft palate.[48,49,64,72-75]

Cleft site supernumerary teeth have been postulated to be the result of fragmentation of the dental lamina due to the presence of the cleft.[46,49] Cleft deformity, though, is the result of failure of fusion rather than destruction of an already fused area. For that reason this remains a questionable explanation. The idea that perhaps there are two areas of odontogenic potential on each side of the cleft and failure of fusion of the frontonasal and maxillary processes keeps those areas from coming into contact and fusing themselves during embryonic development is another commonly accepted explanation. The result is variable success of each of those areas individually giving rise to a viable tooth bud.[59] This theory intuitively might seem more logical as by this reasoning, many of the dental anomalies in cleft patients are simply explained: If both germs are viable, a supernumerary tooth develops along with the lateral incisor. If one side fails, a single incisor develops, and depending on which one is successful in giving rise to a viable tooth bud dictates the position of the resultant tooth relative to the cleft. Lastly, if both are nonviable, congenital absence and hypodontia is the result. Tooth abnormalities, both associated with cleft lip and palate and not, have been shown to have varying degrees of genetic and environmental influences and share, in some cases, homeobox gene mutations similar to those seen in cleft lip and palate.[65]

Knowledge of these dental abnormalities will aid in proper treatment planning for these patients. Hypodontia, for example, has been found to be associated with an increased need for orthognathic surgery at skeletal maturity, particularly when the edentulous cleft side lateral space is managed with canine substitution.[76,77] Therefore incorporation of dental implant into the treatment plan of the patient may prove useful in some instances because this has been shown to work well in the cleft population.[78,79] The presence of supernumerary teeth may be associated with crowding, delayed eruption and impaction of neighboring teeth, root resorption, and nasal eruption patterns, all of which can contribute to malocclusion directly or by extension, and must be considered during the secondary bone graft.[80,81] Additionally, the delayed eruption patterns common to cleft

Appreciate the appropriate amount of orthodontic/orthopedic expansion in preparation for the grafting procedure.

lip and palate must be considered when planning for the most basic treatments such as serial extractions for facilitation of tooth eruption in appropriate instances to the timing of presurgical and expansion and secondary bone grafting procedures.

Timing of the Grafting Procedure

Most commonly, grafting of the maxillary cleft occurs during the 6- to 10-year age range, and qualifies as secondary grafting (rather than early or late). However optimal timing relies on knowledge of dental development and the abnormalities associated with the dentition of cleft patients rather than simply chronological age.

Most commonly, the timing of graft placement is based upon having one-half to two-thirds root formation of the permanent canine on radiographs as the permanent lateral incisor is often missing. Should a lateral incisor be present and of good morphology, then the surgeon may consider performing the secondary bone grafting to the maxilla and alveolus targeting development and eruption of the lateral incisor. Because the lateral incisor erupts earlier than the canine, failure to establish continuity of the alveolus prior to eruption may compromise its periodontal health.

Early secondary bone grafting may be considered if the central incisor is bordering the cleft because this may provide more adequate periodontal support to that tooth (Figure 33-1). Some literature supports this technique as the periodontal outcomes have been reported to be improved.[82] No randomized or controlled studies have shown this to be an improved protocol in a comparative fashion over grafting based on canine development. The bone retention and bone heights have been shown to be quite good in the initial reports from those that favor this approach, but comparative studies are lacking.

Another important factor in deciding the optimum time frame for the secondary grafting procedure is the ability to perform Phase I orthodontic expansion of the maxilla utilizing a quad helix or similar appliance in preparation for the surgical procedure. The presence of fully erupted permanent maxillary first molars is favored by some to provide anchorage for the orthodontic expander rather than utilizing primary teeth or a soft tissue–based appliance. Appliances that provide force directly via the palatal shelves may affect the blood supply of the flaps utilized during the surgery and

create a significant hygiene problem, causing inflammation of the flaps typically used for closure.

Presurgical Orthodontic Considerations

Phase I orthodontic expansion is necessary in most cases involving palatal clefting behind the incisive foramen to coordinate the arches prior to grafting. Maxillary expansion after grafting typically does not work effectively due to lack of a palatal suture. Bone grafting effectively solidifies the transverse dimension such that preoperative expansion becomes very important to help optimize the chances for arch compatibility at skeletal maturity. Having the transverse dimension expanded appropriately preoperatively can minimize the chances for crossbites and perhaps, long term, the need for segmental osteotomies of the maxilla. There are some practitioners, however, who will expand the immature bone graft similarly to concepts exploited in distraction osteogenesis early after the grafting procedure upon healing of the oral soft tissue.

The choice for an expander is often dictated by the shape of the arch, the available teeth for orthodontic anchorage and the compliance of the patient and caregivers. In general, a banded expander such as a Hyrax or quad helix is appropriate. Tissue-based and bonded expanders are less desirable because hygiene access is suboptimal and they can be difficult to remove. Typically it is helpful for the expander to be removed at the time of, or just prior to, the surgery. This allows for optimal access and complete control of the palatal flaps and closure of any residual fistula or unrepaired cleft posterior to the alveolus. The expander or another transpalatal retention device can be replaced postoperatively to retain the transverse width. The loss of transverse dimension is generally a slow process rather than a quick one, so allowing for soft tissue healing and resolution of patient discomfort will not compromise the expansion.

A common pitfall is avoidance of complete expansion of the maxilla prior to grafting with the theoretic concern that the cleft would be too large for the surgical closure. Conversely, it is much easier to mobilize the various flaps involved and repair the nasal mucosa with maximal expansion. Minimal anterior expansion can make it difficult to place sutures in the nasal mucosa in certain clefts. As such, maximal preoperative expansion is recommended and improves surgical access. Oral-side flaps are typically not that difficult to mobilize, even in large defects.

Bilateral clefts may require additional Phase I orthodontic expertise because the premaxillary segment is typically protrusive and often asymmetric relative to the other components of the maxilla, as well as the mandible. It is important to take the premaxillary segment out of occlusion with the lower arch utilizing presurgical phase I orthodontic/orthopedic techniques to avoid motion of this segment after grafting. Motion of the premaxillary segment while under function often causes a nonunion of the segments. A palatal splint may be placed after the graft is completed and may be used to minimize force on the anterior segment and protect the graft from occlusal trauma.

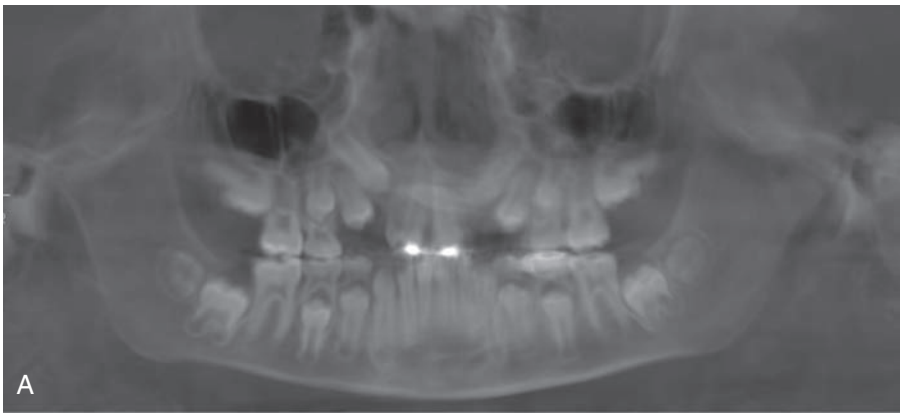
If primary, supernumerary, or non-restorable teeth are present in the cleft site, then decisions regarding optimal timing for extraction must be made. A consideration should be made for presurgical extractions with healing time prior to the definitive bone grafting procedure when the teeth are severely compromised by disease and/or if there is a paucity of available mucosa for surgical manipulation. Alternatively, teeth can be removed at the time of grafting, but for clefts that may be difficult to close there is an advantage to allowing secondary intention healing to occur at the extraction sockets for additional gingiva to be utilized during the repair. In the case of impacted supernumerary teeth, diligent efforts at identification and localization prior to the bone graft procedure can yield significant gains. Incorporating removal into the bone grafting procedure can avoid secondary surgical extraction procedures that would come at the expense of the previously placed bone graft (Figure 33-2).

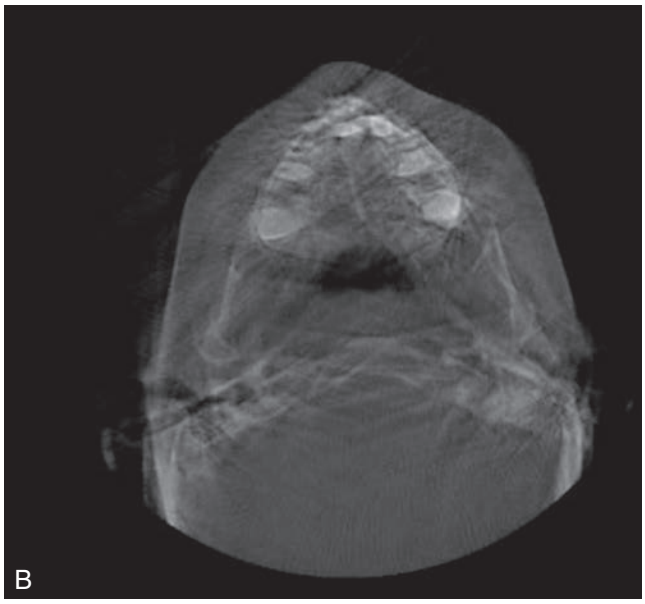
Technique

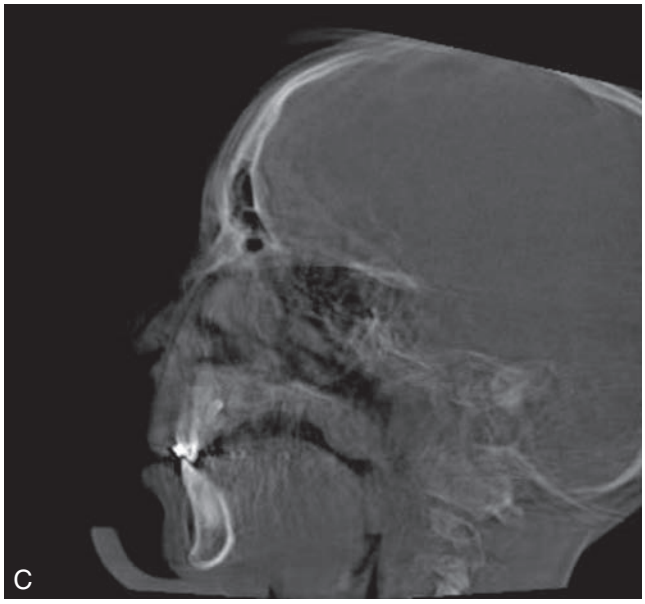
The osseous defect of the secondary palate that does not extend to the primary palate or alveolus is typically not reconstructed in isolation because it would provide little benefit to the patient. Techniques for augmentation of defects of the alveolus that are incomplete and have no osseous discontinuity resemble the techniques utilized for augmentation of post-traumatic areas or edentulous areas that are the result of caries or periodontal disease and will not be discussed here at length. The only comment with regards to inadequacies of bony volume of the alveolus that have continuity is that grafting should be utilized only to provide for sufficient bone for sound orthodontic movement of teeth and should wait as long as possible until that time. If long-term management, however, involves space maintenance for a dental implant at maturity, bony augmentation should follow principles in existence for preparation/augmentation of hypotrophic ridge that is not related to a congenital cleft, including both method and timing, specifically waiting for skeletal maturity prior to augmentation and dental implant placement.

For "notched" defects isolated to the alveolus without osseous discontinuity, eruption of primary teeth alone should be sufficient for gaining appropriate vertical dimension. Surgical manipulation of any kind in this scenario where only crestal height is deficient, especially early in life, will introduce scar tissue that may be unnecessarily detrimental to vertical growth of the alveolus and negatively influence tooth eruption.

For osseous continuity defects of the maxilla and maxillary alveolus that are associated with complete clefts of the lip and premaxilla or cleft lip and palate, the following secondary bone graft techniques are appropriate and often ideal. Approximately 75% of patients with a cleft have a need for reconstruction of the maxilla and alveolus.[20-22] Despite successful lip repair and closure of the hard and soft







• **Figure 33-2** An orthopantomogram **(A)** and axial **(B)** and sagittal **(C)** sections of a cone beam CT illustrating a completely impacted supernumerary incisor. The patient had previously been grafted successfully and now presents after being referred for removal of the impacted tooth. Note the coronal radiolucency associated with the impacted tooth. Removal of the tooth may result in nasal communication and raise the risk for fistula formation, and requires careful closure after removal of the tooth

palates during infancy, a residual nasolabial fistula and bony cleft defect that involves the alveolar ridge, maxilla, and piriform rim will remain by design.[20,21]

The visible cleft is obviously only the surface deformity and varies considerably in severity and presentation between patients. Defects in the deep tissues, regardless how subtle on the surface, are always present in congenital orofacial clefts. The osseous maxillary defect and associated dental abnormalities present with cleft lip and palate are highly variable from patient to patient.

Often, the osseous defect of the maxilla, particularly in the context of dental care or rehabilitation, is referred to as "the alveolar cleft." It is rare, however, that only the maxillary alveolus is cleft. Therefore describing all cleft defects that involve the maxillary alveolus simply as an "alveolar cleft" fails to appreciate that, in the greatest majority of patients, the osseous defect may compromise portions of the primary and secondary palate, the nasal floor, the pyriform rim, and the anatomy of the maxillary sinus walls, which in turn supports facial and nasal contours. A well planned and executed bony reconstruction of the cleft maxilla, therefore, in addition to constructing continuity of the alveolus and establishing a favorable environment for development and sound eruption of teeth associated with the cleft site, should address all of the affected areas.

Techniques can be separated for discussion based on whether the surgeon utilizes broad advancement flaps or pedicled mucosal flaps to rotate into larger defects with subsequent gingival reconstruction. The techniques can also be discussed in terms of unilateral or bilateral cleft types. In general the reconstruction of the maxilla and alveolus is performed in one step—whether the cleft is unilateral or bilateral. Staged grafting for bilateral clefts has been described where one side is addressed individually so as to create a situation where the second side can be grafted using techniques that resemble those for a unilateral osseous cleft. The defect in bilateral clefts, though, is continuous from side to side. Often, the septum is undescended and no clear

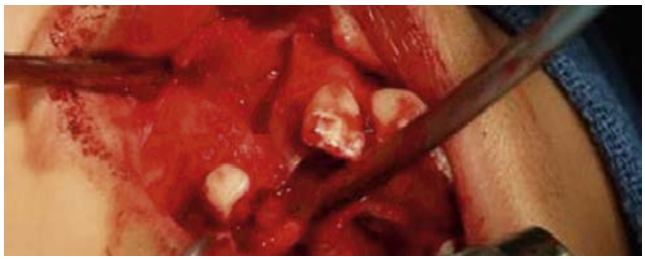
division is present from one side to the other in the area of the incisive foramen. This concept therefore is, perhaps, anatomically misguided.

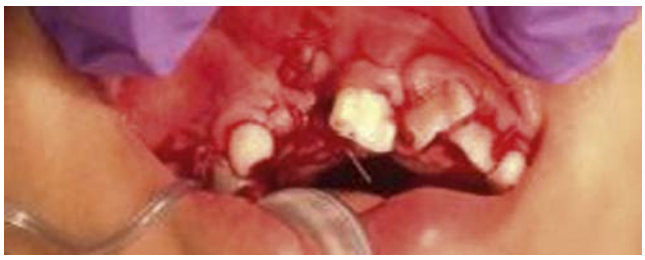
Unilateral Reconstruction

Broad advancement flap techniques are often utilized to close small and large defects in the alveolus and maxilla. These techniques involve making crestal incisions along the gingival crevices with low posterior release of the buccal flap that will allow for a sliding advancement of the gingival flap toward the defect (Figure 33-3). Palatal side dissection involves dissection and elevation of full-thickness bardach-style flaps. The residual unrepaired cleft is then dissected in a partial-thickness fashion by completely separating the nasal mucosal from the oral mucosa. Establishment of a watertight mucosal lined nasal floor will provide periosteal continuity at the roof of the osseous defect and the appropriate wound bed for placement of the bone graft material. Experienced surgeons will recognize that a well-repaired nasal floor from the primary lip and nose reconstruction is quite helpful in facilitating this dissection during the bone grafting stage. Inadequate attention to the mucosal tissues beyond the nasal sill during the primary closure will make subsequent dissection of the two distinct flaps of oral and nasal mucosa exponentially more challenging in this area and can limit the space available for graft placement at the piriform rim at this phase of treatment.

Once the flaps are developed and mobilized, the nasal side flaps are secured to one another with mattress sutures. Some amount of prior dissection up the piriform rim and septum to mobilize these nasal flaps is helpful in achieving tension-free repair. Posterior dissection and repair of the nasal floor mucosa should extend well into the palatal defect, as far back as is necessary to close any residual fistulas or unrepaired cleft (Figure 33-4). Cancellous bone is then placed into the defect to reconstruct everything anterior to the incisive foramen region, including the piriform rim. This will provide support to the nasal floor and the nasal root at the piriform rim. Despite appropriate primary lip and nose repairs, the nasal root is usually inferiorly positioned and deficient in anterior-posterior projection on the cleft side with a broad, flattened appearance of cleft side nares. The oral mucosa is then closed in a tension-free manner over the bone graft material. A four-way stitch is typically placed between the two palatal flaps and the two anterior/buccal flaps to provide gingiva at the crest of the alveolar ridge area. Resorbable suture material is used on a small tapered needle of medium circumference. Eversion is of paramount importance and proper attention should be directed at the superior aspect of the residual cleft in the buccal vestibule as this is a common area for residual fistula after repair (Figure 33-5).



• **Figure 33-4** Maxillary cleft defect following complete dissection and nasal side closure; now prepared for placement of the bone graft.

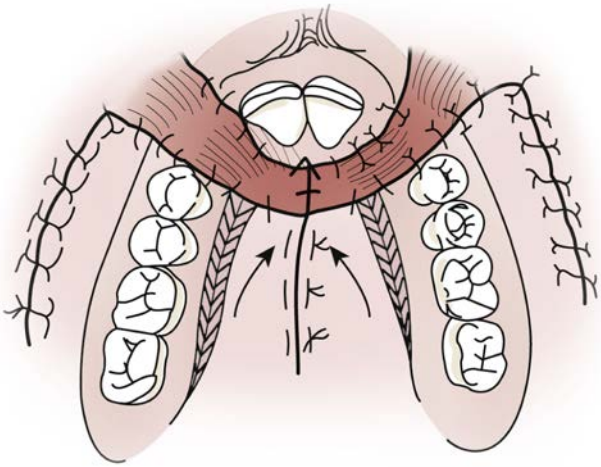


• **Figure 33-5** Maxillary cleft defect following oral side closure. Note wound eversion and tension free closure. Close attention to repair of the oral-nasal communication at the peak of the cleft in the vestibule following graft placement is important to minimize fistula formation in this area. Anterior nasal floor closure is also important in minimizing this risk.

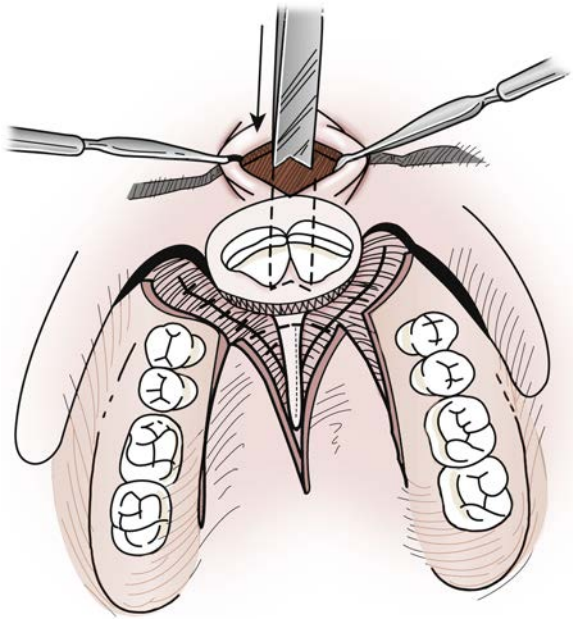
An alternative to this technique is to bring in a mucosal finger flap from the vestibule above the mucogingival junction with limited dissection of the soft tissues in close proximity to the cleft. These are random pattern flaps that can easily be sewn to the posterior aspect of the oral side closure on the palate to fill larger defects with little to no tension. However, these flaps do not provide keratinized gingiva to the alveolar crest, and a separate graft or periodontally focused procedure may be necessary to augment the gingiva and provide keratinized tissue at the alveolar crest. For sound periodontal health of teeth, keratinized gingiva must be present circumferentially around them. Mobile, nonkeratinized mucosa around teeth will eventually result in periodontal disease and tooth loss.

Bilateral Maxillary and Alveolar Reconstruction

The techniques for the bilateral cleft are similar to those used with unilateral clefts with several modifications. In



• **Figure 33-6** Illustration of a bilateral cleft maxillary defect utilizing buccal finger flaps for closure of oral side defect. This alternative technique is helpful in unilateral or bilateral cases when the defects are larger and may be more difficult to close with a limited flap technique.



• **Figure 33-7** Illustration of a bilateral cleft maxillary defect dissection to avoid de-vascularization of the pre-maxilla. A midline vertical incision may be placed anteriorly to gain access to the cartilaginous septum if necessary. While premaxillary setback is not advocated by the authors, this technique can be utilized to facilitate access in rare occasions.

many cases, tissue tends to be more limited and mobilization of those tissues can be technically challenging, especially at the posterior aspect of any remaining palatal fistulas and the incisive foramen region. Some surgeons prefer to use mucosal finger flaps from the vestibule to allow for easier oral side closure of the defects similar to the techniques used in the limited flap technique described previously (Figure 33-6). Also, the premaxillary segment requires an adequate blood supply for proper healing, and this comes from the anterior vestibule. Therefore, the incision design does not extend to the tissues of the anterior vestibule so as to not devascularize the premaxilla (Figure 33-7). Complete nasal and oral closure is necessary to avoid formation of persistent communications and to support the bone graft. This is typically most difficult in the incisive foramen region but can be facilitated by adequate orthodontic expansion. This area is difficult to access when the premaxilla is posteriorly displaced into the crowded palatal shelves and septum. Wide orthodontic expansion helps provide adequate space for use of septal flaps and flaps along the posterior aspect of the premaxilla.

Immobilization of the premaxilla is another concept of vital importance to promote successful bone grafting and elimination of oral and nasal communication with avoidance of postoperative fistula formation. A splint is often employed to provide additional stabilization and avoid occlusal trauma to the premaxillary segment. Mobility of the segment, no matter how limited, increases the risk for infection and graft failure. In some cases, a screw can be used to fixate the premaxillary segment to the palatal shelf similar to a lag screw technique. Because the screw must be placed between the central incisor roots without impinging the root structures and engage the palatal shelf, the method is highly technique sensitive. The authors prefer to use orthodontic stabilization and/or an occlusal splint rather than screw fixation because it is straightforward, highly predictable, and avoids the need for removal of the screw.

Reconstructive Materials

The most widely accepted standard for use in this reconstruction is autogenous bone from the anterior iliac crest. Cranial bone, rib, tibia, symphysis of the mandible, zygoma, and allogeneic bone have all been studied, but none has been shown to be appreciably better than the iliac crest.[3,20,21,32,37,83-90]

The type of bone graft material utilized most often for cleft reconstruction is cancellous bone from the anterior iliac crest. Other common sites include cranium, rib, chin, zygoma, tibia, posterior iliac crest, and allogeneic products. Most of the comparative studies show that iliac crest is superior to other procurement sites.[3,20,21,32,37,83-95] The iliac crest graft is predictable and causes very little morbidity with the proper technique. Some surgeons will procure a cortical piece of bone from the medial crest beneath the cartilaginous cap for use as a nasal floor insert to be wedged into position at the piriform rim.[82] Additional cortical onlay grafting is sometimes completed along the anterior surface of the maxilla, particularly at the piriform rim laterally or inferiorly, and then placed with one or several fixation screws. Considerable care is necessary to avoid injuring developing teeth if this technique is utilized in this age group. Additionally, while immediate and short-term results are very good with facial surface onlay grafts, resorption over time means that they are short lived. This technique is best suited for older individuals undergoing late secondary grafting or for augmentation prior to placement of dental implants.

Cranium can also be an effective graft material. It is used less often, however, due to variable and highly limited cancellous bone content and the need to morselize the cortex into usable form to fill the defect appropriately. Additionally there are concerns with potential morbidity and risk for violation of intracranial structure. Furthermore, surgeon familiarity with partial-thickness procurement of cranium is less when compared with iliac crest harvest.

Posterior iliac crest is preferred by some surgeons, usually due to the greater amount of bone that can be procured and a belief that pain may be less debilitating compared with an anterior approach. While posterior iliac crest does offer a greater volume of bone, the cleft defect typically requires between 2 and 5 cc of compressed bone on average for an adult defect,[96] and less volume is typically necessary in children. This approach is less commonly used when compared with anterior iliac crest due to the need for repositioning and the subsequent chance for accidental extubation. It might be considered if an abnormally large defect requires increased graft volume or as a matter of convenience if the patient is positioned prone for an adjunct procedure (i.e., dermal harvest of the gluteal region). CT scan may be useful in predicting defect volume.[96]

Rib grafts have some advantageous when completing primary bone grafting techniques because they readily available and a reasonably straightforward harvest when compared to other sites in children of very young age.[35] However, harvest can leave significant scarring on the chest wall and occasionally breast bud injury leading to breast deformities in female patients. Additionally, the bone quality of rib graft is less desirable than that of iliac crest. Therefore, when the risk of intraoperative complications is combined with potentially long-lasting postoperative complications and no advantage over the bone procured from the ilium, rib has limited utility.

Chin, ramus, tibia, and zygoma typically do not offer a favorable amount of graft material for complete reconstruction in this age group, but may be useful options in some older patients undergoing late secondary bone grafting or in preparation for placement of a dental implant. Tibial bone grafts are of limited use in children due to theoretic risk for growth restriction when harvest inadvertently crosses into the epiphyseal plate or the knee. Limited bone volume and inherent qualities of the cancellous bone also limit utility.

Allogeneic bone outcomes have not exceeded those of autogenous materials in any of the well-designed studies. Some data may suggest though that combining it with autologous graft has a similar outcome to autograft alone.[92] Surgeons will occasionally mix allogeneic bone putty or other similar materials for advanced handling capabilities with autogenous bone or with recombinant proteins to enhance the process.[17,95] Presently, the authors do not endorse this as routine practice except in rare situations and would advise against utilization of bone morphogenic protein (BMP) until further studies in children are available.

Recently, an interest in BMP use has prompted some limited reports of successful bone regeneration, but this has yet to be published in a comprehensive clinical trial. The product is not approved by the United States Food and Drug Administration for use in children and it may have growth restriction implications based on its effect on sutures in animal models as well as recent reports of its use in early childhood.[17,91]

Several other adjuncts are often utilized to assist in the closure and healing at the site. Most are not well studied, but are anecdotally claimed by some surgeons to facilitate success in certain instances. Collagen membranes have been used as a barrier membrane underneath the oral or nasal mucosa. These are typically resorbable, made from bovine collagen, and can be sutured into position in conjunction with the flaps. They are used as an adjunct to avoid early graft exposure should the mucosal quality of tissues be compromised during healing. Decellularized dermal matrix grafts have also been described, but the authors do not favor this technique because it is not reliable in the area of the alveolus. Anecdotally, any exposure to the oral cavity greatly increases the risk for infection, wound breakdown, and graft loss.

Despite the clear strengths of autogenous iliac crest for osseous maxillary reconstruction, there is no arguing that elimination of a donor site without compromising outcomes would be desirable. The use of allografts, either alone or in combination with autograft or BMP, have had mixed results but successes do not resemble those for autogenous sources.[92,95] Tissue engineering on the other hand may show promise. With limited cases showing outcomes similar to autologous graft, including osseous continuity of appropriate volume and even spontaneous eruption of teeth through the graft site, without secondary donor site morbidity, this may become a viable method in the near future.[97-100]

Postoperative Considerations

Most patients have only minor discomfort associated with iliac crest bone grafting and benefit from a local injection of a long-acting local anesthetic at the end of the procedure during the initial recovery period. Some advocate for the use of embedded catheters for long-term delivery of local anesthetic in the donor site. Although there has been some research directed at proving the utility of this approach[101] it has not proven necessary in the opinion of the authors when a limited dissection with careful tissue handling is utilized as most patients are discharged from hospital on oral pain medications and controlled pain on postoperative day number one.

A modified diet consisting of liquids is recommended for two to three weeks. A splint is used for bilateral clefts and is typically removed several weeks after the grafting procedure (on average between 3 and 6 weeks) once the bone has sufficiently consolidated. Gentle tooth brushing should be performed by properly instructed caregivers postoperative day number one with great care to avoid direct contact with the graft site for several days. Chlorhexidine solution and systemic antibiotics may be helpful for avoidance of infections

of the oral cleft site. Infections at the maxillary alveolus are rare when using iliac crest bone graft, but may be encountered. Conservative irrigation and very limited debridement combined with topical and systemic antibiotics may salvage treatment and prevent complete loss of the graft. Preoperative optimization of dentition and periodontium may help minimize unfavorable results.[102]

Complications at the donor site are rare in children. Iliac crest grafts can rarely be associated with a variety of complications including a loss of sensation in the region due to the lateral femoral cutaneous or cutaneous branches of the subcostal nerve being injured.[103-106] Rarely, if a large cortical graft is taken, fracture can occur. This is rare in children, but is seen more commonly in adults. Proper attention to osteotomy design and anatomic landmarks can minimize this risk. If rib or cranium is chosen, then local anatomy typically dictates the potential complications such as pneumothorax or intracranial injury/bleeds respectively. Cortical and corticocancellous grafts taken from the mandible can be associated with sensory disturbances of the trigeminal system.[106,107]

Infections at the graft procurement site are rare and typically involve skin flora. Risk is minimized with stringent sterile technique and single-dose preoperative prophylactic antibiotic with appropriate floral coverage. Hematoma is a risk and can be minimized with assertive local measures and ensured hemostasis prior to wound closure. Seromas may occur but are also rare in children. If encountered, both may require drainage procedures.

If complete graft loss occurs due to any reason, other options for reconstruction exist. Repeat bone grafting is reasonable after allowing for an appropriate amount of time for infection to be completely resolved and maturation of oral soft tissues. Another option involves simultaneous bone grafting and fistula closure during Le Fort I osteotomy, if the patient requires orthognathic surgery at skeletal maturity.[108,109] And finally, in people that do not have a severe skeletal malocclusion and no need for an orthoganthic surgery and have had repeated failures with prior bone grafting attempts due to an abnormally large osseous cleft, distraction osteogenesis of the alveolus has shown some favorable results.[110,111]

Summary

Management of the cleft maxilla is an important part of reconstructing the patient born with a cleft of the lip and palate. While the main focus of this area of reconstruction involves techniques that will re-establish osseous continuity beneath the surface tissue defects, the means by which that is achieved remains, like all things in cleft care, controversial. Secondary bone grafting with autologous anterior iliac crest is favored by the authors due to predictable outcomes and sound support from existing literature. Nuances of the techniques used in primary lip, nose, and palate repairs can either greatly facilitate or extensively hinder subsequent reconstruction of the osseous maxillary cleft defect when utilizing secondary bone grafting techniques.

The educational background of the oral and maxillofacial surgeon as both a dentist and surgical subspecialist is ideal for guiding treatment planning and surgical care in the team setting, particularly at this phase of care. In-depth understanding of the dental abnormalities frequently seen in patients with cleft lip and palate will allow the oral and maxillofacial surgeon to better formulate comprehensive treatment plans with other members of the cleft and craniofacial team, particularly the dental specialties. Therefore mastery of the nuances of both skeletal and dental findings in this population is a requirement.

After proper planning, successful surgical execution relies on recognition of the extent of the anatomic abnormalities and proper attention to their reconstruction at all stages. In the case of the cleft maxilla, by combining knowledge of skeletofacial and dental development with time-tested surgical techniques and treatment regimens, high-level outcomes with regard to fistula closure, speech and deglutition, eruption and support of healthy dental structure, and optimized facial esthetics can be a reality for these patients. Proper care demands that those involved not only master the concepts behind the craft, but more importantly, constantly examine outcomes with an objective eye so as to improve in ways that will best serve the patient and not any individual surgeon, team, or institution.

Cleft Orthognathic Surgery

PAUL S. TIWANA, TIMOTHY A. TURVEY, RAMON L. RUIZ, BERNARD J. COSTELLO, NEERAJ H. PANCHAL

Introduction

The presence of mid-face deficiency in the patient with cleft deformities remains a challenging clinical problem. Maxillary hypoplasia in the cleft patient is almost always the direct biologic consequence of prior surgical intervention. The surgical repair of the lip and/or palate during infancy, although critical for esthetics and speech development, produces scarring that affects subsequent maxillary growth. The soft tissue envelope surrounding the midface is further violated during bone grafting of the cleft maxilla, possible palatal fistula repairs, and other revision procedures. The scarred soft tissue envelope can also create difficulties at the time of skeletal corrective surgery and with long-term stability after maxillary advancement.

From a historical perspective, patients with mid-face deficiency secondary to facial clefting were often ignored. If the deficiency was extreme, surgical intervention usually was offered in the form of mandibular setback. This did little to address the underlying skeletal problem and frequently had the potential to negatively affect the posterior airway. Only with the development of new surgical techniques, a better understanding of the biologic principles of revascularization, and improvements in instrumentation has the patient with mid-face deficiency secondary to facial clefting benefited functionally and esthetically from surgical correction.[1-28]

Although mid-facial deficiency and class III malocclusion may be the most obvious components of the deformity seen in cleft patients, the dysmorphology is actually more complex. Critical examination of most patients with facial clefts reveals deficiencies of the paranasal, nasal, infraorbital, and maxillary regions. This suggests that the deficiency is not confined to the level of the alveolus and basal bone but extends to involve the entire maxilla and adjacent bones. Understanding that facial clefts involve all tissue layers in the region is critical for effective skeletal surgical planning. The presence or absence of a class III malocclusion has been used in most studies to report the incidence of mid-face deficiency in cleft lip and palate. Ross estimated that 25% of patients with unilateral facial clefts have a class III malocclusion with a degree of mid-face deficiency that warrants surgical correction.[4] However, as discussed earlier, more stringent criteria must be applied to correctly determine the presence and severity of mid-face deficiency in association with cleft lip and palate.

Maxillary deficiency in the presence of facial clefting also results in negative functional consequences on the patient's speech, nasal respiration, sinus function, olfaction, and hearing. Severe mid-face deficiency in cleft lip and palate can also contribute to exorbitism and eyelid dysfunction. From an esthetic standpoint, the deformity can be associated with malar and infraorbital deficiency, lack of nasal tip projection, and deficient upper lip support. The stigmata characteristic of patients with facial clefts are not inherently due to the cleft itself but are caused by the insult of growth potential and surgical scarring in the mid-face. The result is often both a maxillary *deficiency* and a maxillary *deformity*. Therefore, if improvement of esthetic deficits as well as relief of malocclusion are the goals of mid-face advancement, the surgeon must appropriately address the need for maxillary advancement and bone graft contouring of the deficient facial skeleton for soft-tissue support and reconstruction of structural defects.[28]

Presurgical Evaluation

The presurgical workup for cleft lip and palate patients follows a path similar to that of the regular dentofacial deformity population, with a few exceptions. Accurate dental models with a centric bite and facebow transfer, facial and oral photos, facial measurements, and lateral cephalometric and Panorex x-ray films are necessary for both populations. In the cleft patient, obtaining periapical films, an occlusal film, or alternatively a computed tomography (CT) scan that demonstrates the detailed anatomy of the cleft regions and adjacent tissues is helpful. This additional information provides guidance to the surgeon regarding bony anatomy,

blood supply, and periodontal status of the adjacent cleft dentition. Importantly, information must be gained from the patient's surgical history regarding previous operations. The surgeon must take into account not only the type of operations, but also what effect a particular type of cleft procedure may have on the current treatment plan. For example, the presence of a pharyngeal flap not only portends issues with intubation during anesthesia, but also informs the surgeon of the potential difficulty that may be encountered with mobilization intraoperatively. Of particular interest to the surgeon is the type of procedure used for palatoplasty. Certain methods of palatal repair (e.g., palatal island flap) can alter the vascular pedicle necessary for the maxilla to survive down-fracture and mobilization. The physical examination itself is important and yields information regarding the presence or absence of palatal fistulas and the pattern of scarring in the oral mucosa, lip, and palate. Evaluation of the intranasal anatomy such as the septum and inferior turbinates should also be performed. The septum is usually deflected, and obstructed nasal breathing is a common complaint. Le Fort I osteotomy in most circumstances provides ideal access to these structures when intranasal surgery is indicated.

Timing of Surgery and Psychosocial Considerations

Surgical correction of the mid-face deficiency secondary to facial clefting is ideally performed when the patient is both psychologically and biologically mature enough to undergo the procedures. As with most patients, surgery to correct mid-face deficiency in the facial cleft population most prudently occurs after the facial bones have reached skeletal maturity. This improves the predictability of the surgery and decreases the risk of outgrowing the surgical correction. This consideration should always be a component of the informed consent process.

In some instances proceeding with surgery before the completion of facial growth can be considered, especially for those patients with psychosocial comorbidities. Critical to proceeding under these circumstances is the understanding of the patient and parents that additional or repeat surgery may be required once facial skeletal maturation is complete if the patient outgrows the correction. The postoperative course for facial skeletal surgery has become more benign because rigid fixation eliminates the need for intermaxillary fixation, steroids control swelling, antibiotics reduce infection, and the use of hypotensive anesthesia and recombinant erythropoietin dramatically reduced the need for homologous blood transfusion. Despite these advances, the decision to proceed with early surgery should not be taken lightly or be made for the convenience of an impatient surgeon or orthodontist.

Another biologic consideration that affects the timing of surgery is the eruption of the permanent dentition. Delaying surgery until after the eruption of the permanent maxillary canines and second molars minimizes the risk of injury to the teeth during osteotomy. Impacted wisdom teeth (third molars) can be safely removed during the osteotomy, and their presence should not delay surgery. In fact, removing them during the osteotomy reduces the number of surgical procedures the child may undergo.

Improvement of self-concept and self-image in cleft patients almost always follows surgery to address facial skeletal disproportion. This must not be overlooked when considering the timing of surgery. Improving facial balance by surgical correction of disproportion often results in dramatic and favorable changes. The patient and family often perceive these changes positively. In addition, as the procedure is likely the penultimate correction of the cleft deformity, a sense of achievement is usually felt by the patient and family after years of effort directed at multiple dental and surgical procedures. In contrast, a few patients with dependency directed at their facial stigmata may respond differently to surgical treatment. This is difficult to determine preoperatively, and the involvement of a psychologist familiar with children with facial deformities can be invaluable in these instances.

As with any patient with a congenital facial malformation, cleft patients are psychologically different from most patients with acquired facial deformities.[29] The congenital nature of the deformity requires multiple psychologic adjustments with every procedure. Many cleft patients are acquainted with the disappointment after soft tissue procedures aimed at reducing lip scarring and correcting nasal asymmetry. For still others, unrealistic expectations may accompany corrective skeletal surgery. These patients should be identified early through complete cleft team evaluations and referred for counseling preoperatively.

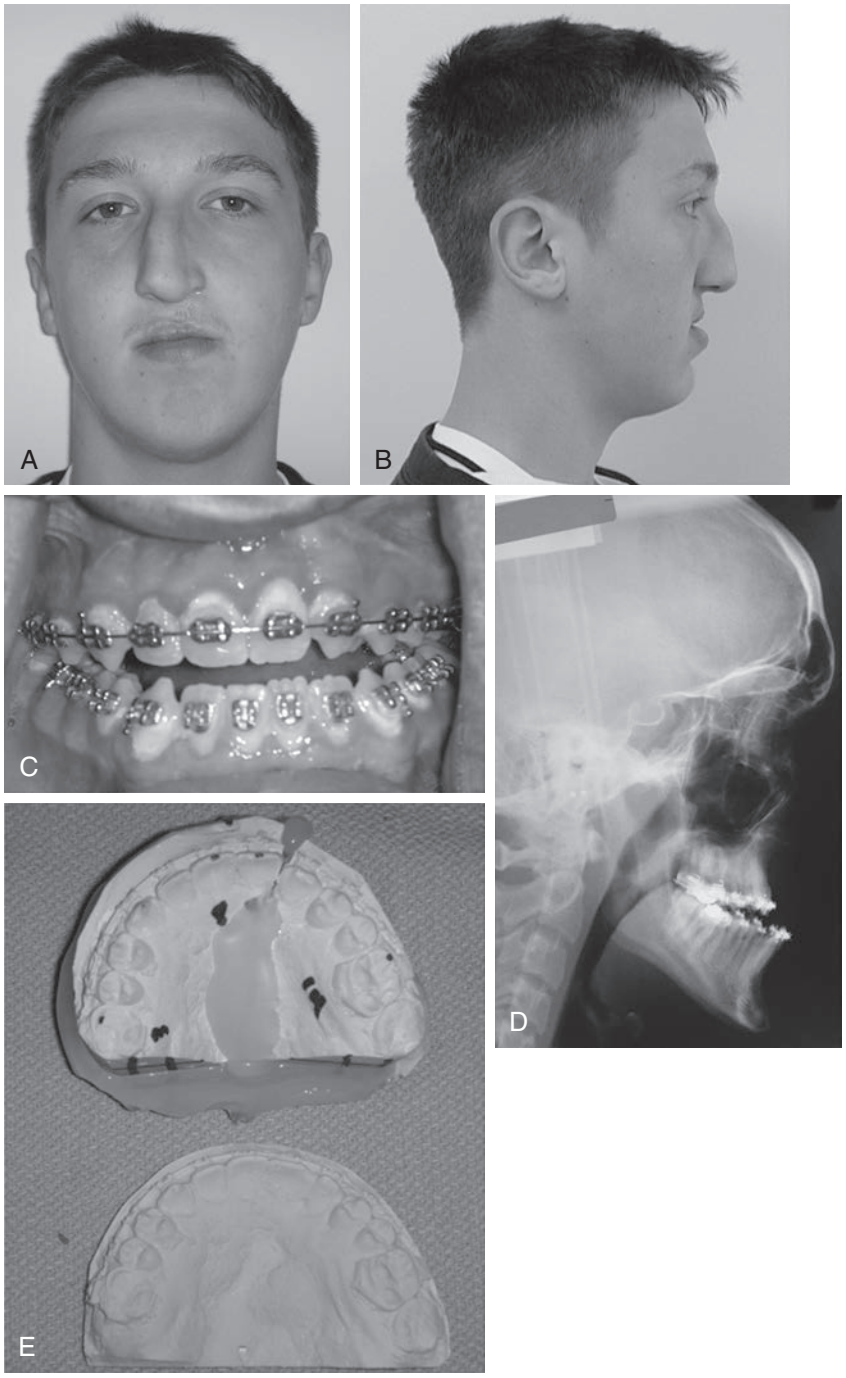
All children with facial deformities, congenital or acquired, can become victimized because of their facial differences. This may become more prevalent during the adolescent years. Enormous peer pressure is felt at this age, especially in the United States. Adolescents with cleft lip and palate are often ridiculed during this period in their lives, and low self-esteem with social withdrawal can follow. Although counseling can help, the patient must also learn to cope with the problem, which may be improved with corrective skeletal surgery.

Surgical Reconstruction

Surgeons who care for children with cleft lip and palate deformities must proceed with an understanding of the three-dimensional regional anatomy, the extent of hard and soft tissue defects present, and the complex interplay between surgery and subsequent maxillofacial growth. This understanding allows the clinician to formulate and sequence appropriately the staged surgical treatment of patients with cleft lip and palate from the initial consultation in infancy through adulthood. The goals of skeletal reconstruction include improvement of skeletal proportion and balance, correction of the occlusion, normalization of nasal breathing, closure of residual defects and fistulas, and improvement of the soft tissue position by providing a bony foundation for support.

Maxillary advancement in the patient with cleft lip and palate does not remove scarring of the lip or correct

anatomic soft tissue landmarks. It does, however, provide the best opportunity for skeletal foundation support of the soft tissue drape. Usually an improvement in lip and nasal asymmetry as well as further support for the nasal tip are seen postsurgery. By providing improved structural support, skeletal surgery may reduce the soft tissue stigma enough to diminish the need or desire for revisional procedures of the lip and nose. Advancement of the skeletal foundation changes the visual perception of the scar by altering the pattern of light reflection, thus making it less obvious. In addition, the common practice of placing the lip scar in the philtral column to diminish its prominence is often counteracted by the underlying deficiency of the maxillary skeletal base. This places the scar on the most flat, unsupported area of the lip, which is far more obvious. Advancement of the skeletal base not only improves the soft tissue drape but also moves the scar to an area of greater curvature on the lip, making it less conspicuous. Patients should be counseled that mid-face advancement sets the stage for definitive lip and nasal revisions in the future (Figure 34-1).



• **Figure 34-1** **A** to **D,** Preoperative facial, occlusal, and cephalometric views of 17-year-old with repaired unilateral cleft lip and palate and associated with severe mid-face deficiency and 13-mm anteroposterior discrepancy. **E,** Model surgery planning demonstrating narrowing of maxilla through the cleft site.

The residual skeletal dysmorphologies that can be present in patients with unilateral cleft lip and palate are numerous and often found in combination (Box 34-1). Reconstruction of these defects and deformities requires accurate diagnosis, thoughtful treatment planning, and precise surgical execution of the defined treatment plan. This reconstructive effort typically involves multiple clinicians who have varying degrees of involvement based on the patient's stage of development and specific esthetic and functional demands.

In patients with bilateral cleft lip and palate, similar dysmorphologies are present; however, additional dental and skeletal discrepancies may also be present (Box 34-2). If successful bone grafting of the bilateral cleft maxilla has been performed, with elimination of fistulas and bony continuity is achieved, then conventional Le Fort I osteotomy may proceed (with or without concomitant mandibular surgery). Despite successful bone graft reconstruction of the bilateral cleft maxilla, segmental surgery can be more complicated because of palatal scarring, incomplete graft

• Box 34-1 Residual Dysmorphology in the Child and Adult Unilateral Cleft Lip and Palate Patient

Residual cleft lip and nasal scarring
Nasal cartilage distortion
Deviated septum
Hypertrophied nasal turbinates
Unrepaired or residual oronasal fistulas associated with the primary palate (cleft)
Cleft dental gap
Missing or malformed teeth
Dental crowding
Complex malocclusion
Periodontal disease
Inflammation of the soft tissue surrounding oronasal fistulas
Defects or hypoplasia involving the pyriform rim, nasal floor, and alveolus
Maxillary hypoplasia (anteroposterior, vertical, and transverse)
Maxillary canting and asymmetry
Compensatory mandibular asymmetry
Mandibular growth disturbance

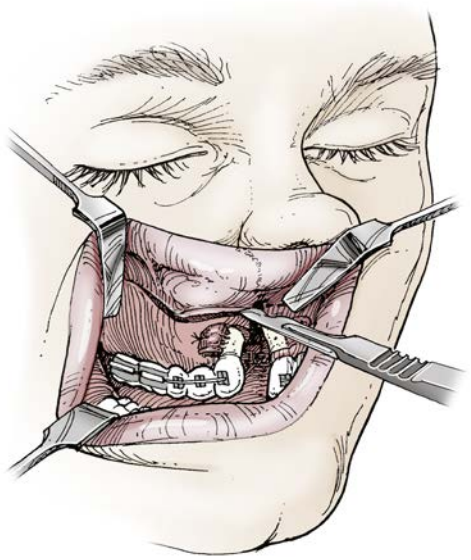
• Box 34-2 Additional Dysmorphology in the Child and Adult Bilateral Cleft Lip and Palate Patient

Ectopically positioned premaxilla
Continuous oronasal fistula from the incisive foramen forward to the maxillary clefts on both sides
Exaggerated curve of Spee and occlusal plane discrepancies
Reduced vascularity of the premaxillary segment requiring modified vestibular incision design and osteotomies through tunneling procedures

consolidation, and lack of an adequate vascular supply to the premaxilla. A thorough preoperative evaluation of the previous procedures and clinical and radiographic examinations is required before mid-face advancement is undertaken.[4,16,22,27,28]

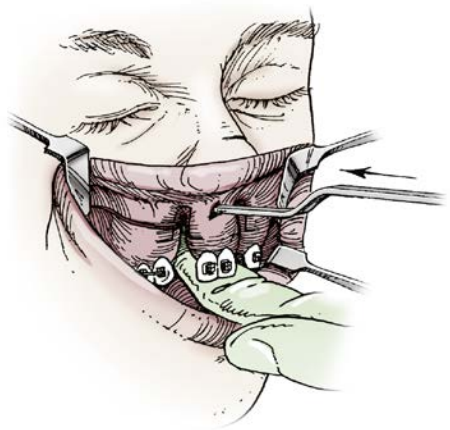
Technical Considerations

Contemporary cleft team–directed treatment protocols include maxillary bone graft reconstruction of the cleft maxilla and palate at developmentally appropriate times.[5-9] The benefits for the patient include provision of a bony matrix for eruption of the permanent dentition, establishment of continuity of the maxillary segments, elimination of residual oronasal fistulas, support for the alar base of the nose, and stabilization of the premaxilla in the bilateral cleft patient. If bone grafting is performed effectively, it can decrease the complexity and potential morbidity of future cleft-orthognathic surgery. Mid-face advancement in the patient with a properly grafted cleft then becomes relatively straightforward. If cleft maxillary grafting is not successful, residual fistulas and cleft dental gaps add to the complexity of the mid-face procedure. In patients who did not undergo grafting, the procedure becomes even more complex. In these two situations, surgical flap design must be altered to ensure adequate vascular perfusion. Maxillary advancement in the presence of cleft lip and palate is different from that in the noncleft patient because of the absence of tissues and the scarring of the soft tissue envelope. Vascular perfusion of the mobilized maxilla comes from the overlying soft tissues, with the palate being predominant. In the patient with cleft, this critical tissue overlying the palate is most often scarred and fibrotic and may have residual fistulas present. This possible compromise to the palatal soft tissue pedicle requires that the surgeon carefully determine the incision design for maxillary osteotomy. In most cases the traditional circumvestibular approach with maxillary down-fracture at the Le Fort I level can still be employed successfully (Figure 34-2). However, a modified incision preserving an anterior vascular pedicle is required when patients are undergoing cleft maxillary osteotomy and have bilateral clefts even if successfully bone grafted, have severe palatal scarring, or previously underwent palatal island flap repair of the palate (Figure 34-3). This technique should ensure adequate vascular supply to the premaxilla for uneventful healing postoperatively. However, the maintenance of an anterior vascular pedicle does increase the degree of technical complexity of the operative procedure.

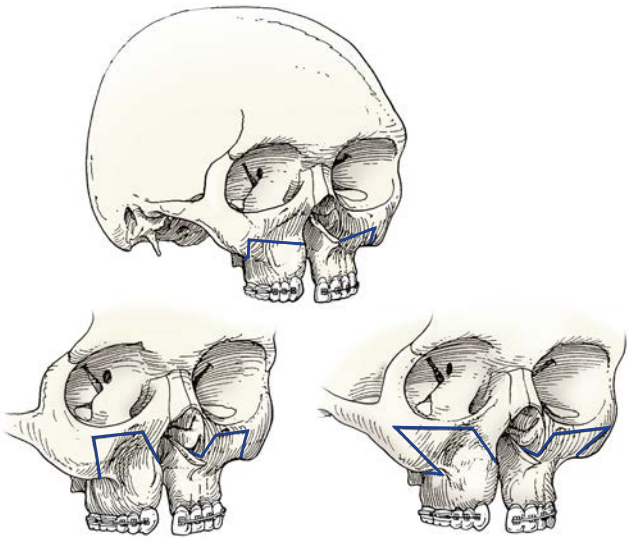


• Figure 34-2 The circumvestibular incision can be used in most patients with cleft and provides the best visualization for conducting the osteotomy. (From Turvey TA, Vig KWL, Fonseca RJ: Maxillary advancement and contouring in the presence of cleft lip and palate. In Turvey TA, Vig KWL, Fonseca RJ, editors: *Facial clefts and craniosynostosis: principles and management,* Philadelphia, 1996, Saunders.)

In the conventional approach to mid-face advancement at the Le Fort I level, a circumvestibular incision is created from the zygomaticomaxillary buttress to the opposite side high in the mucobuccal fold. Ensuing subperiosteal dissection exposes the entire lateral wall of the maxilla from the pyriform rim to the pterygomaxillary junction and superiorly to the inferior orbital rim above. Dissecting inferiorly toward the alveolus (e.g., dentoalveolar segment) is not



• **Figure 34-3** An anterior pedicle incision limits visualization and access but provides additional perfusion to the maxilla. It should be used in cleft patients with significant palatal scars and in patients with bilateral clefts. (From Turvey TA, Ruiz RL, Costello BJ: Surgical correction of midface deficiency in cleft lip and palate malformation, *Oral Maxillofac Surg Clin North Am* 14:491, 2002.)



• **Figure 34-4** Osteotomies for cleft patients should be designed to address the specific skeletal dysmorphology. (From Turvey TA, Ruiz RL, Costello BJ: Surgical correction of midface deficiency in cleft lip and palate malformation, *Oral Maxillofac Surg Clin North Am* 14:491, 2002.)

recommended because this reduces the perfusion coming from the buccal flap. This wide exposure permits excellent and safe visualization of the performance of Le Fort I osteotomy. During down-fracture of the maxilla, perfusion of the mobilized maxilla is provided by the lateral buccal soft tissue pedicles and the palate. This technique allows superior visualization of the operative field and permits the surgeon direct control of hemorrhage from the greater palatine vessels.

When performing mid-face advancement with an anterior pedicle for improved vascularity, visualization is reduced and mobilization by down-fracture is not possible. Mobilization is achieved through in-fracturing and anterior traction of the maxilla. In most cleft palate patients the area of greatest resistance to mobilization is the vertical portion of the palatine bone. The bone is located in the posterior medial aspect of the maxillary sinus. The bone is thick, and access is difficult at best, especially with maintenance of an anterior vascular pedicle. Adding to this difficulty are the greater palatine vessels, which descend from the sphenopalatine fossa to the posterior maxilla. These vessels run through a canal in this bone and are prone to injury during osteotomy or mobilization. Hemorrhage control is difficult because of the limited access and is usually limited to packing and/or the injection of local anesthetic with vasoconstrictor.

In the cleft patient who has not undergone maxillary bone graft construction, residual oral nasal fistulas are common. In addition, patients who underwent gingivoperiosteoplasty in infancy usually lack the bone volume necessary to support the dentition and may also have residual fistulas or skeletal gaps. Incision design in these patients must therefore also include consideration of the closure of residual oronasal fistulas and the necessary bone grafting. Of great importance is the reconstruction of the nasal floor, which is completed using the tissues lining the fistula.

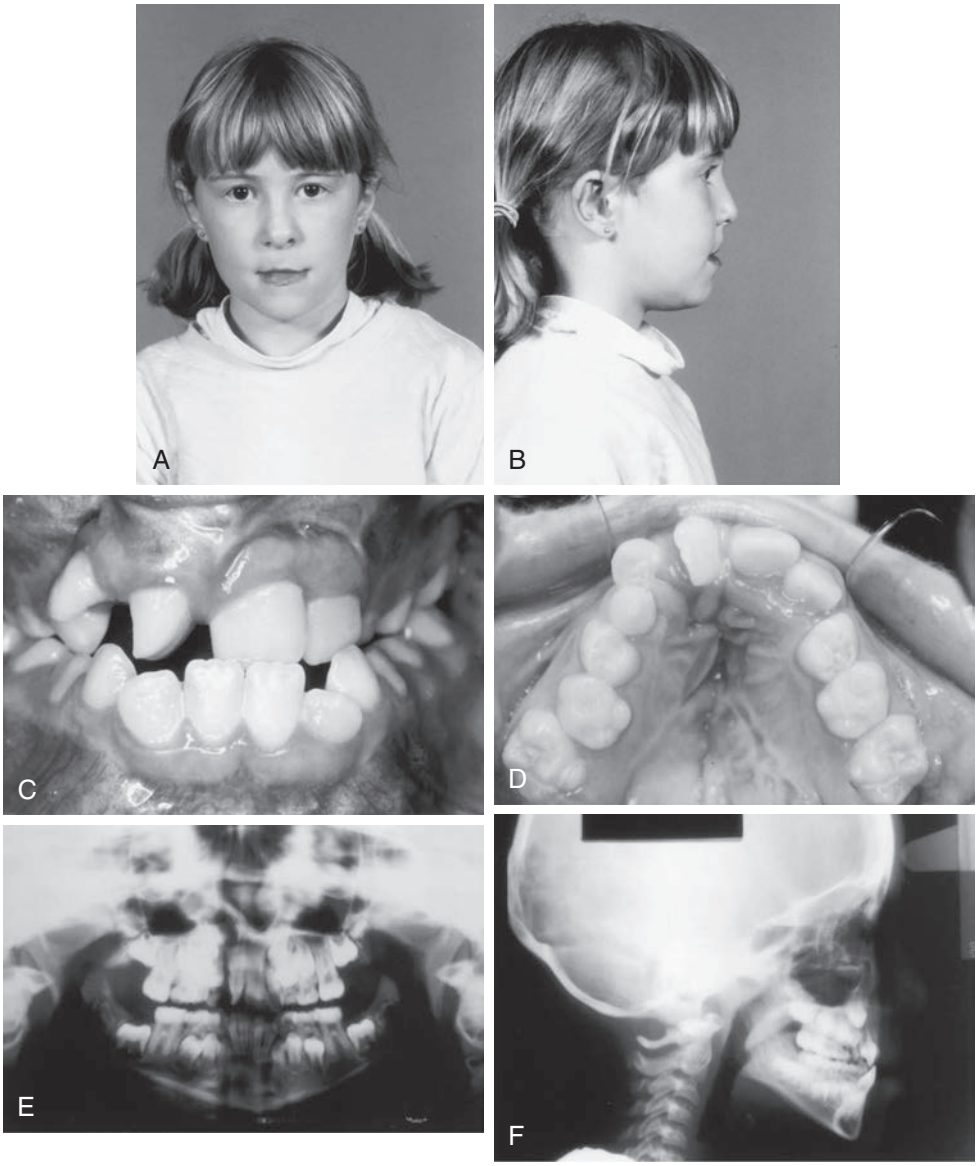
Osteotomy design in the patient with cleft should also be carefully planned (Figure 34-4). The cleft deformity extends from beyond the alveolus to involve the entire maxilla and adjacent bones. The deformity is rarely symmetric. As a result, the design of the osteotomy becomes very important for the improvement of soft tissue support and ultimately the esthetics of the mid-face. Even subtle differences in osteotomy design on the cleft side can have a noticeable impact on facial esthetics.

Adequate mobilization of the maxilla is a key to success in the cleft patient undergoing surgical correction of mid-face deficiency. This entails patience on the part of the surgeon not only to adequately mobilize the bony maxilla, but also to stretch the soft tissue envelope. As described previously, the area of greatest bony resistance in the cleft palate patient is the perpendicular portion of the palatine bone. Usually a small, guarded osteotome is used to weaken this area, permitting mobilization. However, care must be exercised by the surgeon to ensure that this area has been adequately weakened before mobilization. If the maxilla remains resistant to mobilization, excessive force may cause an unfavorable fracture extending to the skull base or orbit, potentially causing neurologic injury or blindness.[30,31] Prudent surgical technique would call for further weakening of this area by osteotome before attempting mobilization again.

Further segmentation of the cleft maxilla for the improvement of occlusal discrepancies should be approached cautiously. The vascular pedicle in these patients has often already been compromised, and further segmentation may lead to necrosis of the segment. It may be judicious to accept minor crossbites or other occlusal imperfections rather than risk necrosis of mobilized segments. If segmentation of the cleft maxilla is necessary, the use of the cleft itself as the area through which segmentation is performed is preferred.

Bone Grafting

There are several major reasons why fresh autogenous bone grafts are employed during mid-face advancement in the patient with cleft lip and palate. First, the bone grafts can be wedged between the osteotomy segments, increasing the stability of the advancement. Second, the autogenous grafts improve bone healing and decrease the chance of fibrous nonunion. Last, they provide an excellent opportunity to contour the facial skeleton for improved facial esthetics. In the cleft patient the mid-face is not only retruded but is also asymmetric and deformed (Figure 34-5). Alteration of the skeletal morphology therefore permits improvement of facial esthetics. Augmentation of malar projection, the infraorbital region, the paranasal regions, and the chin is easily and commonly performed during mid-face advancement in these patients. Commonly used bone harvest donor sources include the cranium and iliac crest. Autogenous grafting does require more time intraoperatively for graft harvest and has associated potential morbidity. However, the use of the bone and the predictability of the result justify its use. The advent of bone substitutes has not diminished the need for obtaining autogenous grafts. Allogeneic bone has yet to demonstrate the same level of success associated with autogenous grafting. Good surgical technique minimizes the morbidity of autogenous bone graft harvest and provides the patient with a compatible



• **Figure 34-5** **A-B,** An 8-year-old child with repaired cleft lip and palate who is already demonstrating maxillary deficiency. **C-D,** Anterior crossbite, malrotations, and ectopic eruption of teeth into the cleft. Oronasal fistulas are present on the buccal and palatal. **E,** The Panorex demonstrates a missing lateral incisor and developing cuspid on the cleft side with minimal periodontal support for the malrotated central incisor adjacent to the cleft. It is important that the orthodontist not attempt to rotate the tooth before placement of the bone graft. Once a periodontal defect occurs, as it most surely will if correction of the malrotation before grafting is undertaken, the bone graft cannot eliminate it. **F,** The cephalometric radiograph demonstrates maxillary deficiency, anterior crossbite, and the mixed dentition.

• **Figure 34-5, cont'd** **G,** The bone graft was placed at age 8, and a preliminary stage of orthodontics was initiated after the graft to level, align, and maintain adequate space for eruption of the cuspid adjacent to the central incisor. **H,** This radiograph taken at age 11 demonstrates eruption of the cuspid into the grafted bone. **I-J,** At age 14 the patient demonstrates progressive maxillary deficiency and a protrusive lower lip. The amorphous facial appearance results not only from maxillary deficiency but also from contour deficiencies of the cheeks and infraorbital regions. **K,** Anterior crossbite is present. A maxillary left premolar was removed to facilitate eruption of the left cuspid. Note the excellent periodontal health and absence of fistulas facilitated by the bone graft. **L,** The cephalometric radiograph confirms maxillary deficiency.

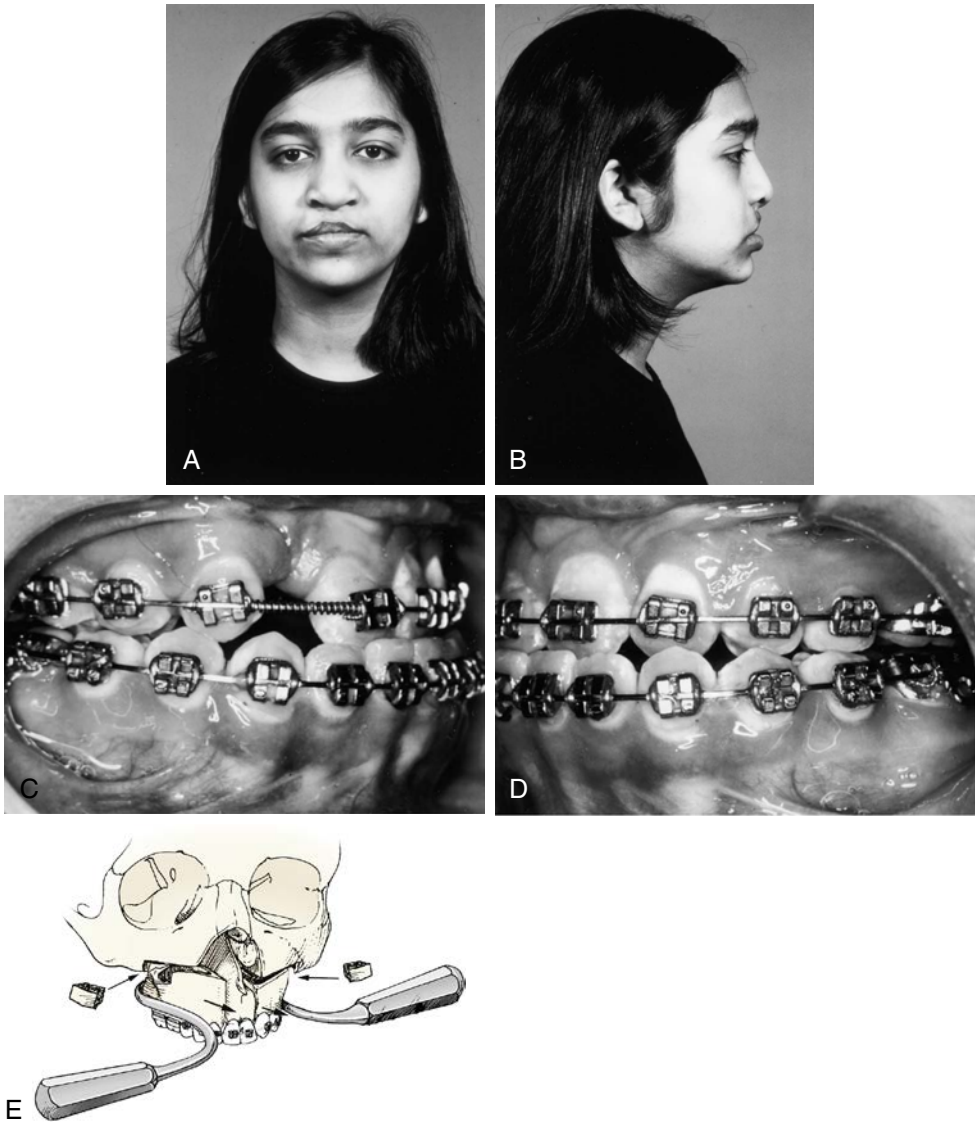
• **Figure 34-5, cont'd** **M,** At the time of surgery, split-thickness cranial bone grafts were to be placed in the osteotomy defects and support the cheek prominence and infraorbital regions. **N,** The surgery performed was maxillary advancement, mandibular setback, augmentation genioplasty, and bone grafts to contour the cheeks and maxilla. The genioplasty was performed to improve the balance. **O-P,** The postsurgical Panorex and cephalometric radiographs. **Q-R,** Postoperative facial views at age 15. **S-T,** Oral views at age 18 demonstrating cuspid substitutions for the lateral incisors and no need for prosthetic management. **U,** Demonstration of good stability of the result; no lip or nasal revisions have been performed. (From Turvey TA, Ruiz RL, Costello BJ: Surgical correction of midface deficiency in cleft lip and palate malformation, *Oral Maxillofac Surg Clin North Am* 14:491, 2002.)

and stable long-term solution. Fresh autogenous iliac bone is the most commonly harvested autogenous bone graft for the cleft patient. A large volume of cancellous or corticocancellous bone is available for use from this site. Cancellous bone is most often used for filling alveolar defects, whereas the cortical grafts can be used to stabilize the operated maxilla or augmentation of the facial skeleton. Our preference for contour augmentation of the middle face is split-thickness cranial bone. Block or onlay bone grafts should be rigidly fixated with screws to the facial skeleton to reduce infection, promote healing, and reduce resorption of the graft during incorporation into the facial skeleton (Figure 34-6).

Obstructed Nasal Breathing

Cleft patients often present with difficulty during nasal respiration. This is secondary to a number of anatomic causes including a deviated nasal septum, enlarged nasal turbinates, chronic tissue inflammation associated with residual fistulas, and scarring of the internal nose from previous reconstructive procedures. During mid-face advancement with down-fracture, the surgeon is afforded unparalleled surgical access to the structures of the internal nose. Undertaking concomitant septoplasty and/or inferior turbinectomy, where indicated, may significantly improve nasal breathing



• **Figure 34-6** **A-B,** A 16-year-old patient with bilateral cleft lip and palate who previously underwent bone grafting of the maxilla bilaterally. Note the deficient projection of the entire middle face, especially the paranasal regions. Also, note the relatively protrusive lower lip. **C-D,** Orthodontic preparation included advancing the cuspid on the left adjacent to the central. Attempts to open the space on the right for a prosthetic lateral incisor are in progress. **E,** The right posterior maxilla was mobilized independently, and an osteotomy at the right lateral incisor space was performed. The posterior segment was advanced a greater distance than the left, so the cuspid was placed adjacent to the central incisor. It is desirable to eliminate prosthetic treatment when possible. Feasibility model surgery demonstrated that closure of lateral incisor space on the right could be performed without compromise. The major advantages of this were eliminating prosthetic needs and improving occlusal symmetry.

• **Figure 34-6, cont'd** **F,** The segments were stabilized with bone plates and screws. **G,** Inlay and onlay cranial bone grafts were placed to facilitate bone consolidation and contouring of the midface. **H-I,** Improved skeletal support permitted soft tissue and nasal revisions 9 months after maxillary advancement and bone grafting. **J,** Final occlusion without the need for prosthetic care. (From Turvey TA, Ruiz RL, Costello BJ: Surgical correction of midface deficiency in cleft lip and palate malformation, *Oral Maxillofac Surg Clin North Am* 14:491, 2002.)

postoperatively and is important for not only function, but also quality of life. Excised septal cartilage should not be discarded if future rhinoplasty is anticipated. The harvested cartilage is easily banked in the vestibule under the mucosa or alternatively can be left between the nasal septum and mucosa, obviating the need for harvest during subsequent rhinoplasty.

Stabilization of the Mobilized Cleft Maxilla

The revolution in the development of rigid internal fixation systems has seen the field of cranio-maxillofacial surgery develop from the placement of wire fixation, through stainless and alloy metal plates, to titanium fixation and now resorbable fixation systems. The use of rigid internal fixation has many benefits, including allowing limited function during convalescence and an improvement in the stability of the repositioned facial bones during healing.[12] The use of bone plates and screws may improve long-term stability, although a true comparison study has not been published to date.[15,32,33] Perhaps more important than just the use of plates and screws is an understanding by the surgeon of the importance of not inappropriately altering the position of the envelope of the major muscles of mastication during repositioning of the osteotomized facial skeleton. A disadvantage of rigid fixation is the inability to use elastic traction to manipulate tooth-bearing segments.

Biodegradable bone plates and screw systems have been available for several years now and are approved for use in both the mid-face and the mandible. When evaluating the use of these systems, the surgeon must be aware that the polymer combinations are different in each product and can have an impact on the rigidity and degradation of the material. Our experience is that with a self-reinforced polylactate system, acceptable characteristics and high patient appeal can result. Investigations of the stability of these systems continue to be promising, and they represent an alternative method of fixation for the patient and surgeon to consider.[34]

Velopharyngeal Considerations

One concern associated with advancement of the cleft maxilla is the potential for deterioration of speech in the postoperative period. The velopharyngeal sphincter is a complex mechanism that, under normal conditions, functions to close off the nasal cavity from the oral cavity through elevation of the soft palate and contraction of the lateral pharyngeal walls.[35] In many patients with repaired cleft lip and palate, the apparatus is altered and the patient has learned to overcome a short or scarred palate that does not move well by recruiting adjacent soft tissue structures. An example of one such anatomic adaptation includes Passavant's ridge (hypertrophy of tissue in the posterior pharyngeal wall), which is noted in many patients with cleft and aids in overcoming the insufficiency of velar stretch and movement.

Some patients require surgical assistance in obtaining velopharyngeal competence. This can be accomplished through a number of different procedures but is most commonly and effectively managed with the superiorly based pharyngeal flap. A patient with a short, scarred soft palate that does not move well may not tolerate the change in position of the soft palate associated with maxillary advancement, and velopharyngeal function may deteriorate.[36,37] Some patients develop compensatory reserve to overcome the change in position of the soft palate after mid-face advancement. A few cleft patients who demonstrate borderline velopharyngeal closure preoperatively may be unable to tolerate even a small degree of maxillary advancement. This potential should not be overlooked, and all cleft patients undergoing maxillary advancement should be counseled appropriately. Although routinely done in the cleft team setting, all patients should have a complete speech evaluation by a speech pathologist familiar with cleft patients before mid-face advancement surgery.

Almost all cleft patients have some degree of hypernasality after maxillary advancement. Among the patients who develop significant hypernasality after maxillary advancement, however, the number of persons who require surgical correction (e.g., pharyngeal flap, sphincteroplasty) is low. Fortunately, resolution gradually occurs with time so that, for most patients, returning to baseline speech by 6 months after surgery is typical. Any consideration for surgical intervention for relief of velopharyngeal incompetence in the postmaxillary advancement cleft patient should therefore be delayed at least 6 months before proceeding. This time period allows for natural neuromuscular adaptation to occur and permits bone healing to proceed without introducing more scarring, which may contribute to relapse.

In some patients with pharyngeal flaps in place who did not have velopharyngeal competence before mid-face advancement surgery, it has been noted that hypernasality improved postsurgery. Although sibilant distortion errors and articulation is expected to improve in the patient who has surgical correction of malocclusion, reduction of hypernasality after maxillary advancement is a paradox. This finding is explained by the altered dynamics of the sphincter that result from maxillary advancement surgery. Stretching of the marginally functional pharyngeal flap may improve the velopharyngeal mechanism enough to allow for improved speech in some patients. However, this observation is not predictable, and patients must be cautioned appropriately.

The surgeon should always be cognizant of the implications of the pharyngeal flap intraoperatively as well. Its presence should be communicated to the anesthesiologist before intubation is attempted to prevent injury to the flap and significant hemorrhage in the airway during intubation. The assistance of nasal-endoscopic–guided intubation can be invaluable to a smooth and safe induction of the required general anesthesia.[38] When a pharyngeal flap is in place and maxillary advancement is attempted, the flap should be divided only if it does not permit adequate mobilization of the maxilla. In our experience this situation is rare.

Summary

The surgeon who manages mid-face deficiency in the presence of cleft lip and palate must carefully consider the treatment objectives, the history, the clinical examination findings, and the patient's wishes to render appropriate treatment. Close cooperation with specialists in other disciplines such as orthodontists and speech pathologists who are familiar with cleft patients is a necessity. Attention to detail during treatment planning and meticulous surgical technique, modified where necessary to accommodate the patient with cleft lip and palate, lead to safe and predictable correction of mid-face deficiency in this group of patients.

Revision Surgery for Cleft Malformations

NATASHA FÜRCHTGOTT, RAMON L. RUIZ, BERNARD J. COSTELLO

Clefting of the lip and palate represents a complex malformation of both the hard and soft tissues of the face. Children who are born with a cleft of the lip and/or palate experience several unique functional and esthetic challenges requiring an interdisciplinary approach.[1-6] To achieve the best outcomes, clinicians must take into consideration each child's speech, occlusion, facial appearance, self-esteem, and a number of other complex issues that arise during the child's growth and development. Successful reconstruction requires multiple surgical phases. Consequently, treatment that takes place during growth and development must be carried out with concern for the long-term biologic consequences. Thoughtful planning is formulated in order to provide the maximum long-term functional and esthetic benefit.[1,2] Surgeons caring for children with clefts must maintain a firm cognitive understanding of the three-dimensional anatomy of the cleft lip and palate malformation and the complex interplay that exists between surgical intervention and ongoing facial growth.

Various surgical procedures involved in staged reconstruction of cleft lip and palate have been described extensively in the literature. The American Cleft Palate–Craniofacial Association (ACPA) has developed parameters of care to facilitate the coordinated interdisciplinary treatment of individuals affected with cleft lip and palate deformities.[7] The ACPA document summarizes a management protocol that is centered on thoughtful timing of specific interventions based on the patient's dental, skeletal, speech, and psychologic development. Contemporary management involves several phases of surgery during infancy (cleft lip and palate repair) and early childhood (bone graft reconstruction of the cleft maxilla and alveolus) that are considered required operations in all cases of complete unilateral or bilateral cleft lip and palate. In addition to those primary stages of repair, most children will require additional procedures for treatment of secondary issues. Secondary reconstruction of cleft lip and palate may involve surgery for treatment of velopharyngeal dysfunction, bone graft reconstruction of clefts of the maxilla, treatment of residual skeletal disproportion and malocclusion, closure of palatal fistula, normalization of lip and nasal form, and prosthetic rehabilitation of the cleft dental gap. Although indications for each of the primary and secondary surgical undertakings are specific to each child, they must not be viewed as isolated events. Ongoing growth and development in concert with the secondary surgical effects must be considered. This chapter reviews aspects of secondary cleft lip and palate reconstruction that may be required after primary cleft lip and palate repair. The chapter provides a description of the contemporary philosophy based on the most current outcome data, and how this relates to the specific timing controversies of surgical intervention (Table 35-1).

Fistula Closure

A child born with cleft palate has as part of the congenital deformity a communication between the oral and nasal cavities. Successful surgical repair requires separation of the oral and nasal side soft tissues followed by reconstruction of the soft palate musculature and establishment of separate nasal and oral mucosal linings. The result is two-layer closure of the hard palate (nasal mucosa and oral mucosa) and three-layer closure of the soft palate (nasal mucosa, levator musculature, and oral mucosa). A residual abnormal oronasal communication, or fistula, after initial repair is a relatively frequent issue with many types of palate repair. Before deciding on a specific management approach to the residual fistula, it is important to define the clinical situation based on the patient's age, previous surgical history, functional impact, and exact location of the fistula.

The extent to which the cleft defect involves the primary and secondary palate must be determined. The primary palate consists of the anatomic structures anterior to the incisive foramen. The secondary palate consists of the anatomic structures between the incisive foramen and uvula. It follows that a complete cleft of the primary and secondary palate would therefore involve the maxilla, alveolus, hard palate, and soft palate. An isolated cleft palate involves the hard and

TABLE 35-1 Stages of Cleft Lip and Palate Reconstruction: Infancy Through Adolescence

Surgical Treatment	Age	Timing Considerations
Cleft lip repair	10-12 weeks	
Cleft palate repair	9-18 months	Exact timing of repair is based on child's speech-language age
Secondary palate surgery for velopharyngeal insufficiency	3-5 years	
Bone graft reconstruction of cleft maxilla and alveolus	6-9 years	Based on dental development
Orthognathic surgery	14-16 years for girls, 16-18 years for boys	
Dental implant placement	16-18 years	
Lip and nasal revision	After 5 years	Varies widely depending on clinical findings and psychosocial concerns; definitive nasal surgery usually delayed until adolescence

soft palates without affecting the alveolus (i.e., a complete cleft of the secondary palate). A cleft involving only the soft palate, and not the hard palate or alveolus is described as an incomplete cleft of the secondary palate. Even when a child is born with a complete cleft palate, affecting the primary and secondary palates, the primary palate repair involves closure of the secondary palate, or only those structures posterior to the incisive foramen. As such, the alveolus remains unrepaired in the traditional sequence, and this area is not referred to as a fistula, but rather unrepaired alveolus. Those patients that undergo gingivoperiosteoplasty have this area repaired at some point during the primary repairs—usually during the lip repair.

The goals of cleft palate repair during infancy are twofold: first, to establish complete "watertight" closure of the secondary palate for separation of the oral and nasal cavities, and, second, to repair the levator musculature to allow for optimal speech production. Repair of the skeletal maxillary alveolar cleft defect and its associated oronasal communication is not generally attempted at this stage. Many surgeons consider this alveolar defect part of the original cleft deformity that has been purposely left and therefore not a true fistula. Definitive repair of the anterior alveolar aspect of the cleft is instead incorporated into the bone graft reconstruction performed during midchildhood based on dental development.[5,6,8,9] Ideally, a child with a complete cleft palate will undergo palate repair (successful closure of the hard and soft palates) during infancy, followed by bone graft reconstruction of the maxilla and alveolus (or primary palate) with closure of the residual nasolabial fistula during the mixed dentition.

Unfortunately, residual palatal fistulas are occasionally encountered after the initial palate repair. The incidence of palatal fistula after single-stage palatoplasty varies greatly, with the reported rates from 0 to over 60%. The risk of fistula formation seems to be associated with the size (width) of the original cleft defect and the experience of the surgeon.[10-14] The type of repair used by the surgeon may also affect the fistula rate. Recent reports indicate that a two-flap palatoplasty technique is associated with the lowest rate (3.4%) of palatal fistula formation.[13] The Furlow double-opposing Z-plasty is, in most studies, associated with a significantly higher incidence of oronasal fistula.[5,12]

Overall fistula rate of 4.9% has been reported recently in a prospective, randomized, controlled clinical trial comparing outcomes of two different palatoplasty techniques.[12] However, most of these studies involved non-syndromic children and often have a number of selection criteria that do not represent the entire challenging population. Compliance with the postoperative restrictions is also a key factor. The most common location of residual palatal fistula occurrence after cleft palate repair is the junction of the hard and soft palates. This is followed by the anterior hard palate and incisive foramen region.[5,6,11,14] Understanding their functional impact is a key to understanding whether or not a repair will be necessary upon their presentation.

Indications for Fistula Repair and Timing of Surgery

Most fistulas are noted early in the postsurgical period after palate repair. Most are the result of local wound breakdown secondary to tension because of inadequate medial mobilization, vascular compromise, wound healing problems, trauma to the palatal flaps, inadequate suturing technique, hematoma formation leading to flap necrosis, patient/parent compliance, or other factors. Another time period when a palatal fistula may be encountered is during phase I (before bone graft) orthodontic treatment, especially if maxillary expansion is undertaken. There is disagreement about the causal relationship of orthodontic expansion and development of palatal fistula. Most experienced cleft surgeons believe that fistula defects discovered during maxillary expansion are small, preexisting oronasal communications and are not caused by orthodontic treatment. Small fistulas

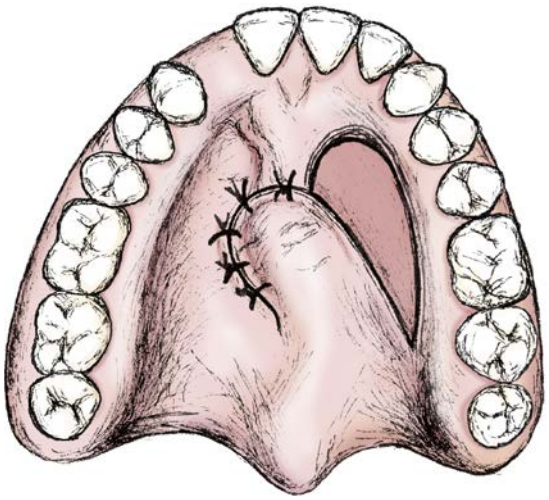
present since infancy can be hidden within a narrow palate by collapsed maxillary segments and then become "uncovered" as the maxillary arch form is expanded by orthodontic or orthopedic means. Most are not major functional concerns, and can be addressed at the time of bone grafting or later.

The recommended timing of fistula closure may vary significantly and remains a controversial topic. Although early intervention is uncommon, some surgeons and cleft teams may advocate aggressive management with early closure of any fistula present after initial palate repair. We prefer to take a more long-range view of these problems and delay surgery for several years when possible (e.g., no functional speech and/or feeding-related issues). In infants the closure of a small (up to 4 mm), nonfunctional fistula can generally be deferred until later in childhood. In such cases fistula repair may be incorporated into future procedures such as pharyngeal surgery for velopharyngeal insufficiency (VPI) or bone graft reconstruction of the cleft maxilla and alveolus.

When a larger (>5 mm) fistula is present, there is a greater likelihood that functional concerns will be encountered, such as nasal air escape affecting speech, nasal reflux of food and liquids, and hygiene difficulties. When significant functional issues exist, earlier closure of the persistent fistula is indicated. As part of the decision-making process, surgeons must weigh the benefits of fistula repair against the negative effects of a second palatal surgery (involving stripping of mucoperiosteum) on maxillary growth. Another consideration in timing of fistula closure is the type of repair technique selected for repair. Attempts to close a fistula with local flaps or repeat palatoplasty may be undertaken during infancy and early childhood. On the other hand, in cases in which the use of a regional (e.g., tongue) flap may be preferable, the child must be old enough to cooperate with the perioperative regimen.

Operative Techniques for Closure of Palatal Fistulas

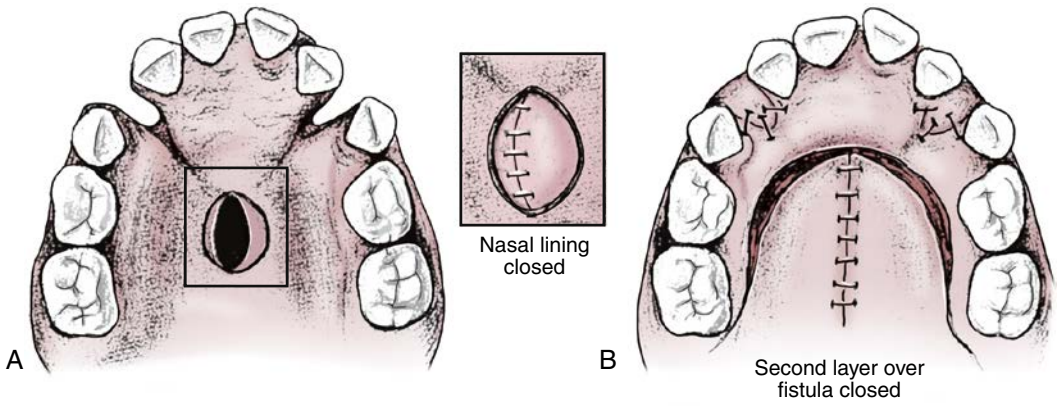
Repair of residual palatal fistulas using a number of different techniques after cleft palate repair has been described.[5,10,15-17] Current techniques used for fistula repair include local palatal flaps, modifications of the von Langenbeck and two-flap palatoplasty techniques, palatoplasty with incorporation of a pharyngeal flap, and the use of a tongue flap. Other regional flaps, including the buccal mucosal, buccinator myomucosal, temporalis muscle, and vascularized tissue transfers are less frequently used but have been described.[15,18-22] Recently, the use of acellular dermal matrix (ADM) as an interpositional barrier has been used as an adjunct to repairing fistulas under the premise that this material can aid in wound closure where there is extensive preexisting scarring and lack of healthy surrounding tissue. At this time, there is only Level III evidence that suggests that ADM use could prevent the formation or aid in the permanent repair of palatal fistulas.[23,24]



• **Figure 35-1** The use of a small, rotational flap for closure of a residual palatal fistula. This type of repair can have a high failure rate. Turnover flaps or sliding flaps are used to establish a nasal side closure, and a palatal mucosal flap is outlined. The random pattern, full-thickness mucoperiosteal flap is elevated and mobilized for coverage of defect. (From Ogle OE: The management of oronasal fistulas in the cleft palate patient, *Oral Maxillofac Surg Clin North Am* 14:553, 2002.)

One of the most frequently described procedures for closure of residual fistulas is the use of local soft tissue flaps created within the palatal mucosa and rotated over the defect for closure (Figure 35-1). The components of this approach are the creation of turnover flaps around the defect for nasal side closure, elevation of a palatal finger flap, and rotation of the flap for coverage of the defect. A significant area of exposed bone is left at the donor site, and this is allowed to heal by secondary intention. Unfortunately, this type of repair is useful only for very small palatal defects and is associated with a relatively high failure rate.[15] Small rotational flaps within palatal tissues that contain extensive scarring from prior surgical procedures are difficult to mobilize without residual tension and may have diminished blood supply, resulting in a less-than-ideal healing capacity and a potentially greater chance of wound breakdown. Our preferred approach to residual palatal fistulas involves the modification of one of the primary palate repair techniques, namely the Bardach (two-flap) or von Langenbeck procedure in conjunction with the use of acellular dermal matrix as an interpositional graft material.[5,25] These approaches allow adequate coverage of even large defects with the use of bulky soft tissue flaps, a layered repair of the nasal and oral sides, and a tension-free line of closure (Figure 35-2).

In addition, the amount of bone that is left exposed after the repair is minimal to none. This is because the vertical depth of the palatal vault translates into soft tissue extension medially, and the result is palatal soft tissue flaps that adequately cover the underlying bone with a layer of dead space between the palatal shelves and the oral mucosa lining. The Bardach palatoplasty is the authors' preferred method. The primary advantage of this approach is the ability to raise large soft tissue flaps, which can be mobilized easily and allow for visualization and tension-free closure of the nasal



• **Figure 35-2** Modification of the two-flap palatoplasty technique for closure of a residual palatal fistula. **A,** Two large mucoperiosteal flaps are developed with dissection extended to a point posterior of the fistula defect. The nasal mucosa is repaired as a separate layer. **B,** Closure of the oral side. The midline is closed first using multiple sutures, and then the lateral incisions are reapproximated. (From Bardach J, Morris HL, eds: *Multidisciplinary management of cleft lip and palate,* Philadelphia, 1985, Saunders.)

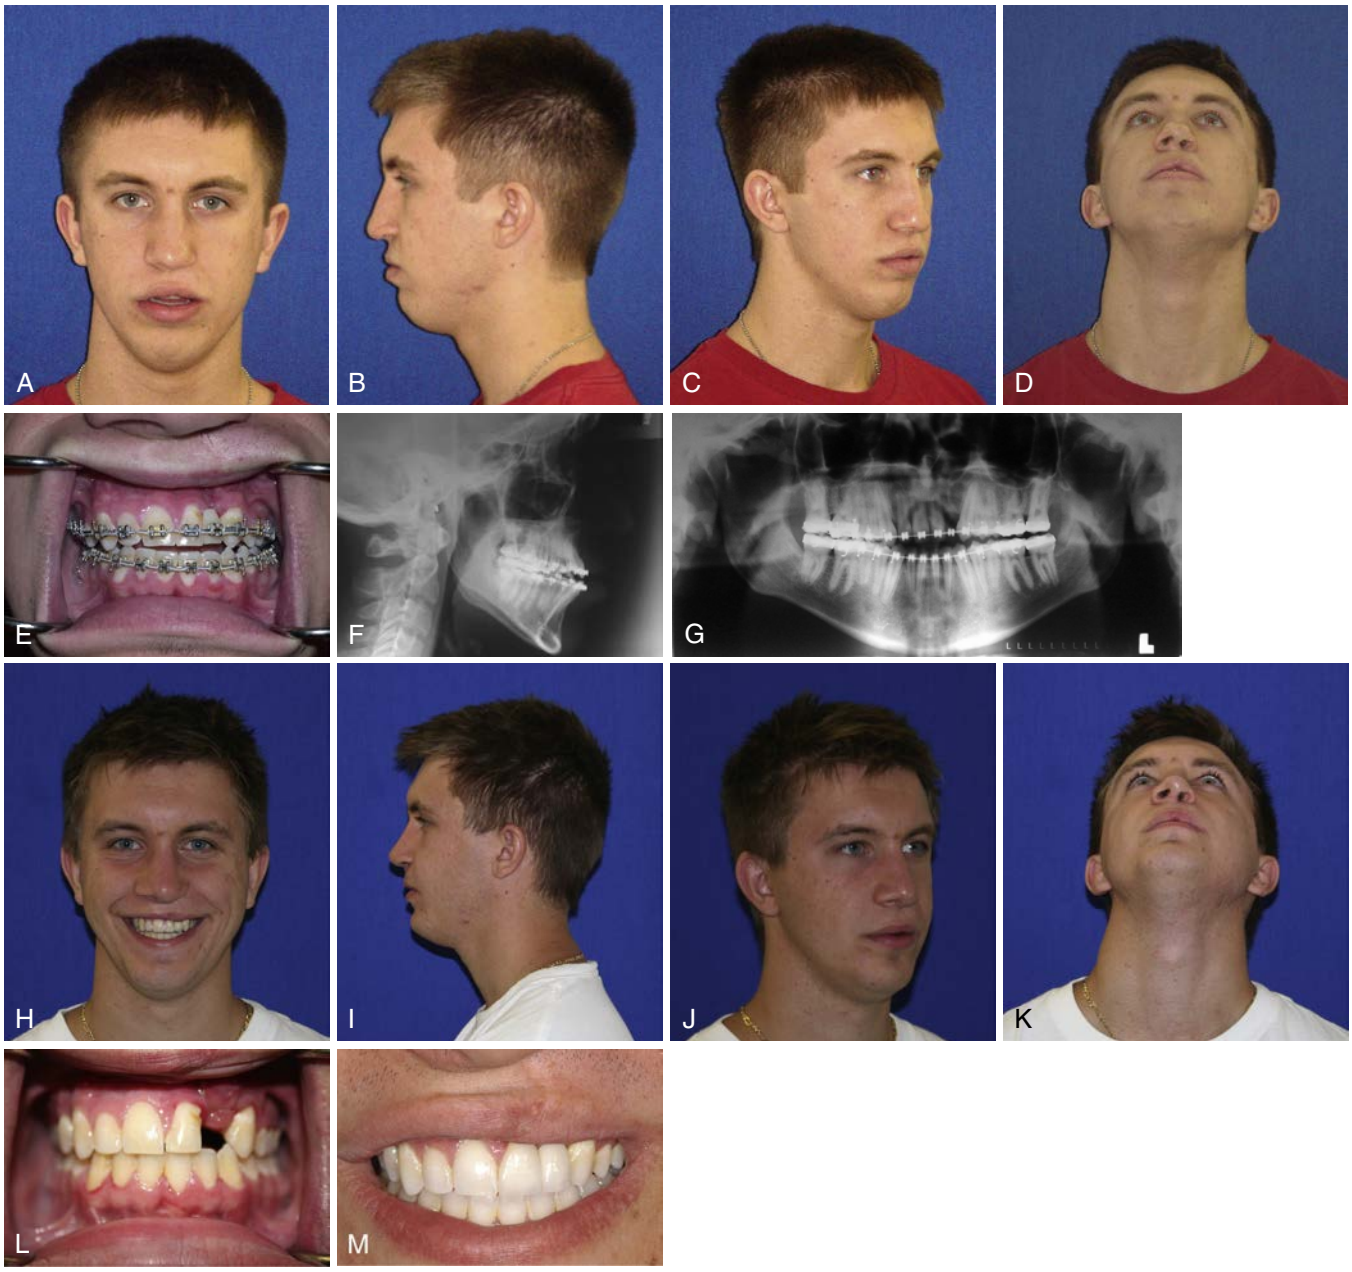
mucosa. By comparison, one of the theoretic advantages of the von Langenbeck procedure is the creation of bipedicled flaps that maintain anterior and posterior blood supplies. Although the anterior pedicles do provide additional perfusion, they also result in less freely movable flaps with limited access and visualization of the nasal side tissues. When there is a much larger (>1.5 cm) defect, successful closure may dictate that the surgeon recruit additional soft tissue using a regional flap, such as a pharyngeal flap, facial artery myomucosal flap (FAMM), pedicled buccal fat or other local tissues.

Fistula defects within the posterior hard palate or soft palate may be addressed with the use of a modified palatoplasty procedure, as described earlier, in combination with a superiorly based pharyngeal flap. After the palatal flaps are developed and the nasal side dissection is complete, a pharyngeal flap is harvested. The pharyngeal flap soft tissue is then incorporated into the nasal side closure of the area where the fistula was present. With this technique a substantial amount of additional soft tissue can be recruited for tension-free repair of a large palatal defect. When the fistula is located within the anterior two-thirds of the hard palate and cannot be closed using local tissue with acellular dermal matrix interposed, then the procedure of choice for recruitment of additional soft tissue may be the anteriorly based dorsal tongue flap (Figure 35-3). First, the nasal side closure of the palatal defect is performed using turnover flaps with multiple interrupted sutures, if possible. Next the surgeon develops an anteriorly based tongue flap that is approximately 5 cm in length and approximately two-thirds the width of the tongue. The tongue flap is elevated along the underlying musculature and then inset using multiple mattress sutures for closure of the oral side approximately four-fifths of the way around the defect. The recipient bed within the tongue is closed primarily. After the initial surgery, the tongue flap is allowed to heal and primarily vascularize for approximately 2 weeks. Nasal fiberoptic intubation may be indicated for the second-stage procedure because the tongue is still sutured to the palate, restricting normal visualization of the airway. The flap is sectioned and the stump at the donor site is freshened and inset. The use of laterally or posteriorly based tongue flaps has also been presented in the literature.[26,27] In our opinion, an anteriorly based flap is better tolerated by most patients and allows for the greatest degree of tongue mobility, decreasing risk of tearing the flap from its palatal insertion.

Most fistulas can be closed with a modified palatoplasty technique and the use of ADM with or without the use of local flaps. However, the tongue flap can be of use for larger fistulas. It is particularly useful in those that are anterior as is the case in patients with a premaxilla that has been lost due to surgical misadventure or other issues. Another option is vascularized tissue using a microvascular flap. However, pedicle management in the mid-face is technique sensitive, and requires a microvascular surgeon with regular experience in this area for a successful survival of the flap.

Secondary Cleft Palate Surgery for Management of Velopharyngeal Dysfunction

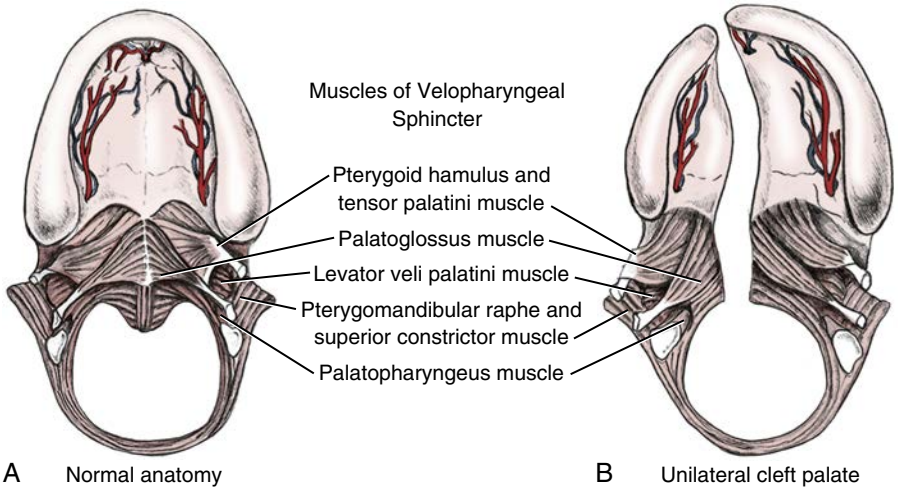
The secondary palate is composed of a hard (bony) palate anteriorly and a soft palate or "velum" posteriorly. Within the soft palate the levator veli palatini muscle forms a dynamic sling that elevates the velum toward the posterior pharyngeal wall during the production of certain sounds. Other muscle groups within the velum, the tonsillar pillar region, and the pharyngeal walls also affect resonance quality during speech formation (Table 35-2). The combination of the soft palate and pharyngeal wall musculature jointly form what is described as the velopharyngeal mechanism (Figure 35-4, *A*). The velopharyngeal mechanism functions as a complex sphincter valve to regulate airflow between the oral and nasal cavities and create a combination of orally based and nasally based sounds. Children born with a cleft



• **Figure 35-3** An 18-year-old male born with a left-sided unilateral cleft lip and palate is shown before and after a number of revision procedures just before completion of his treatment. **A-G,** Multiple views with the typical imbalances seen from both congenital malformation and iatrogenic growth deformity. He exhibits maxillary hypoplasia, mild mandibular asymmetry, retrogenia, notching of the vermilion, asymmetry of the dorsum of the nose and cartilaginous nasal tip, asymmetry of the nares, poor nasal base support, and septal deviation. He lacks a left maxillary lateral incisor and is planning to have an implant placed at this site. His preoperative lateral cephalometric radiograph and panoramic tomogram show rather mild, but significant, skeletal discrepancies in the sagittal plane and a lack of bone at the maxillary/alveolar cleft site. **H-M,** He underwent orthognathic surgery to address multiple planes of occlusion and an anterior open bite, including a Le Fort I osteotomy in three pieces, inferior turbinate reductions, and a genioplasty. He also underwent a complex secondary rhinoplasty, which includes nasal bone osteotomies, septoplasty, sculpting of the upper and lower lateral cartilages, and a columellar strut graft for improved projection and support. His postoperative views show the results shortly following additional bone grafting for implant reconstruction at the cleft site.

TABLE 35-2 Muscle Groups Contributing to the Velopharyngeal Mechanism

Muscle	Insertion	Origin	Function
Musculus uvulus	Mucous membrane of soft palate	Palatal aponeurosis	Velar extension
Tensor veli palatini	Soft and hard palates	Medial pterygoid plate	Opens auditory tube
Salpingopharyngeus	Palatopharyngeal aponeurosis	Torus tubarius	Motion of the lateral walls
Superior constrictor	Medial pharyngeal raphe	Velum; medial pterygoid plate	Posterior and lateral wall sphincteration
Levator veli palatini	Soft palate	Temporal bone	Elevation of the velum
Palatopharyngeus	Soft palate aponeurosis	Pharyngeal wall	Adduction of posterior pillars; sphincteration of velum
Palatoglossus	Tongue	Tongue	Retract tongue; antagonistic to the levator during speech



• **Figure 35-4** Anatomy of the velopharyngeal mechanism. **A,** Normal anatomy. **B,** Anatomic distortions associated with complete cleft of the primary and secondary palate. Note abnormal insertions of levator veli palatini muscle along the posterior edge of the hard palate.

palate have, by definition, a malformation that dramatically affects the anatomic components of the velopharyngeal mechanism. Clefting of the secondary palate causes division of the musculature of the velum into separate muscle bellies with abnormal insertions along the posterior edge of the hard palate (Figure 39-4, *B*). The initial palatoplasty is, as described earlier, not simply carried out for closure of the palatal defect (oronasal communication) itself, but is aimed at addressing the underlying muscular anatomic deformity. During two-flap palatoplasty, care must be taken to sharply separate the levator muscle bellies off the palatal shelves, realign them, and establish continuity in order to create a functioning palatal-levator muscle sling. Some describe this primary repair of the palatal musculature as an "intravelar veloplasty." Although this description helps to articulate the importance of addressing the levator muscle, it may confuse some clinicians by suggesting that muscle repair or "intravelar veloplasty" is a separate procedure. The degree of aggressive retropositioning of the levator musculature can be variable among surgeons. Irrespective of the type of cleft palate repair technique employed (e.g., von Langenbeck, Bardach, Furlow), meticulous release of abnormal levator muscle insertions with velar muscle reconstruction must be incorporated as a critical element of the surgical procedure. Most children who undergo successful cleft palate repair during infancy (9 to 18 months) will go on to develop speech that is normal or demonstrate minor speech abnormalities that are amenable to speech therapy. In a smaller segment of this patient population, the velopharyngeal mechanism will not demonstrate normal function despite surgical closure of the palate. [28] VPI is defined as inadequate closure of the nasopharyngeal airway port during speech production. The exact cause of VPI after "successful" cleft palate repair is a complex problem that remains difficult to define and quantify. Inadequate surgical repair of the musculature is one potential cause of VPI. The role of postsurgical scarring and its impact on muscle function and palatal motion is poorly understood. The theoretic advantages of using a Furlow double-opposing Z-plasty procedure for the initial palate repair include better realignment of the palatal

muscles and lengthening of the soft palate. These benefits may be negatively balanced by a velum that demonstrates less mobility secondary to scarring associated with two separate Z-plasty incisions. Even muscles that are appropriately realigned and reconstructed may fail to heal normally and function properly because of congenital defects having to do with their innervation.

In addition, a repaired cleft palate is only one factor contributing to velopharyngeal function. Nasal airway dynamics and abnormalities related to vocal tract morphology and lateral and posterior pharyngeal wall motion may contribute to velopharyngeal dysfunction. Certainly, these other structures may also play a positive role in compensating for palatal deformity. For example, a short, scarred soft palate that does not elevate very well may be compensated for by recruitment and hypertrophy of muscular tissue within the posterior pharyngeal wall ("activation of Passavant's ridge").[29-31] The audible nasal air escape that results in hypernasal speech associated with VPI is perhaps the most debilitating consequence of the cleft palate malformation. A variable number of children with VPI after palatoplasty will go on to require management involving additional palatal and pharyngeal surgery.[28] The percentage is quite variable and not universally agreed upon, but generally is approximately 20% to 40% for non-syndromic patients. Patients with syndromes do have higher rates of VPI, but these are generally due to other contributing factors such as cognitive status or neural innervation. Other studies claim much lower rates of VPI, but the measurement and reporting is not uniform or validated in these published studies. Without a truly objective measure of speech in this patient population, it is difficult to know the true incidence of VPI after primary palate repair.

Left untreated, nasal air escape—related resonance problems will lead to compensatory speech abnormalities and articulation errors. Warren's elegant aerodynamic demands theory provides the best explanation of what occurs with severe VPI. [32] His theory states that nasal air escape due to inadequate velopharyngeal closure will cause the patient to articulate pressure consonants at the level of the larynx or pharynx instead of within the oral cavity. These abnormal, compensatory misarticulations further complicate problems with speech formation and decrease speech intelligibility in patients with cleft palate–related VPI.

Timing and Indications for Surgery

After the initial cleft palate repair, periodic evaluations are critical to assess the speech and language development of each child. Typically this involves a standardized screening examination performed by a speech and language pathologist as part of a visit to the cleft palate team. In patients with VPI, more detailed studies including the use of videofluoroscopy and nasopharyngoscopy may be indicated. Videofluoroscopic studies are used to radiographically examine the upper airway with the aid of an oral contrast material. These techniques allow dynamic testing of the velopharyngeal mechanism with views of the musculature in action. In addition, details of the upper airway anatomy including residual palatal fistulas can be visualized and their contribution to speech dysfunction evaluated. For a videofluoroscopy study to be of diagnostic value, it must include multiple views of the velopharyngeal mechanism. The speech pathologist should be present to verbally test the patient in the radiology suite.

Nasopharyngoscopy using a small, flexible, fiberoptic endoscope is routinely used for the evaluation of patients with VPI. Nasopharyngoscopy allows for direct visualization of the upper airway, and specifically the velopharyngeal mechanism, from the nasopharynx. This technique avoids radiation exposure associated with videofluoroscopy but requires preparation of the nose with a topical anesthetic, skillful maneuvering of the scope, and a compliant patient. Once the endoscope is inserted, observations of palatal function, airway morphology, and pharyngeal wall motion are made while the patient is verbally tested by the speech pathologist.[5] The opportunity for direct visualization of the velopharyngeal mechanism in action during speech formation provides information that is critical to clinical decision-making related to secondary palatal surgery in cases of confirmed or suspected VPI. The pattern of closure and the characteristics of any abnormal closure patterns during certain speech sounds may help tailor treatment, and tends to be valuable information to optimize speech.

Secondary palatal surgery in young children is indicated when VPI causes hypernasal speech on a consistent basis and is related to a defined anatomic problem.[33-35] The timing of surgery for VPI remains controversial. Recommendations typically range from 3 to 5 years of age at the earliest. In young children, obtaining enough diagnostic information to make a definitive decision regarding treatment is often difficult. In such a young age group, variables such as the child's language and articulation development and a lack of compliance during the speech evaluation compromise the diagnostic accuracy of preoperative assessments.[36-38]

By the time a child reaches 5 years of age, compliance with nasopharyngoscopy is better, and there is enough language development to allow for a more thorough perceptual speech evaluation. These factors allow for more definitive conclusions regarding the status of velopharyngeal function or dysfunction in the child with a repaired cleft palate. It is also important to note that decisions regarding advisability of surgery for VPI are usually made after close collaboration with an experienced speech and language pathologist. The surgeon and speech pathologist should make this decision together and try to tailor the treatment to that particular child's needs.

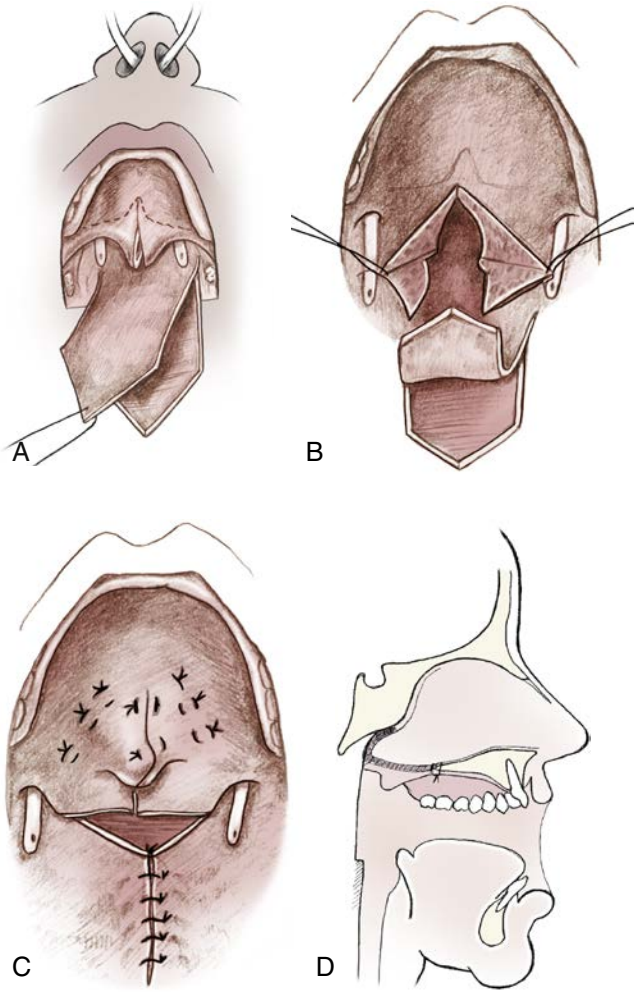
VPI and hypernasal speech may also be encountered in older patients at the time of orthognathic surgery for treatment of cleft-related maxillary deformity. Approximately 25% of patients who have undergone cleft palate repair during infancy will require additional surgery for treatment of mid-facial deficiency during adolescence when they are nearing skeletal maturity.[39] This usually involves mid-face

advancement at the Le Fort I level with or without mandibular surgery to restore skeletal proportions, treat malocclusion, and improve facial balance. Advancements of the maxilla in patients with a repaired cleft palate may worsen existing VPI or may be the cause of new-onset VPI.[40-42] A minority of patients with borderline velopharyngeal closure preoperatively will develop hypernasal speech even after relatively small degrees of maxillary advancement. Because predicting exactly how each patient will respond to maxillary advancement is difficult, formal speech assessment and detailed counseling of the patient and family regarding the possibility for development of postoperative VPI before any cleft orthognathic surgery is undertaken is recommended. Fortunately, most patients who develop VPI after maxillary advancement will recover adequate velopharyngeal closure without the need for additional palatal surgery within approximately 6 months. It is important to note that no significant difference has been convincingly documented when one looks at the speech outcomes after use of distraction osteogenesis techniques for mid-face advancement versus conventional orthognathic surgery.

In a study by Turvey and Frost, pressure-flow studies were used to examine velopharyngeal function after maxillary advancement in patients with repaired cleft palate.[43] In their study group, patients with adequate velopharyngeal closure before surgery demonstrated three differing responses after mid-facial advancement: (1) adequate velopharyngeal closure after surgery, (2) deterioration with inadequate velopharyngeal function after surgery followed by a gradual improvement and recovery of normal closure over a 6-month period, and (3) inadequate velopharyngeal closure after surgery without improvement, necessitating pharyngeal flap surgery. When maxillary advancement does result in clinically significant VPI, additional corrective surgery should be delayed at least 6 months. In most cases postoperative neuromuscular adaptation allows the velopharyngeal mechanism to recover, and the patient returns to a baseline level of function with resolution of hypernasal speech without the need for additional operative intervention.

Operative Techniques

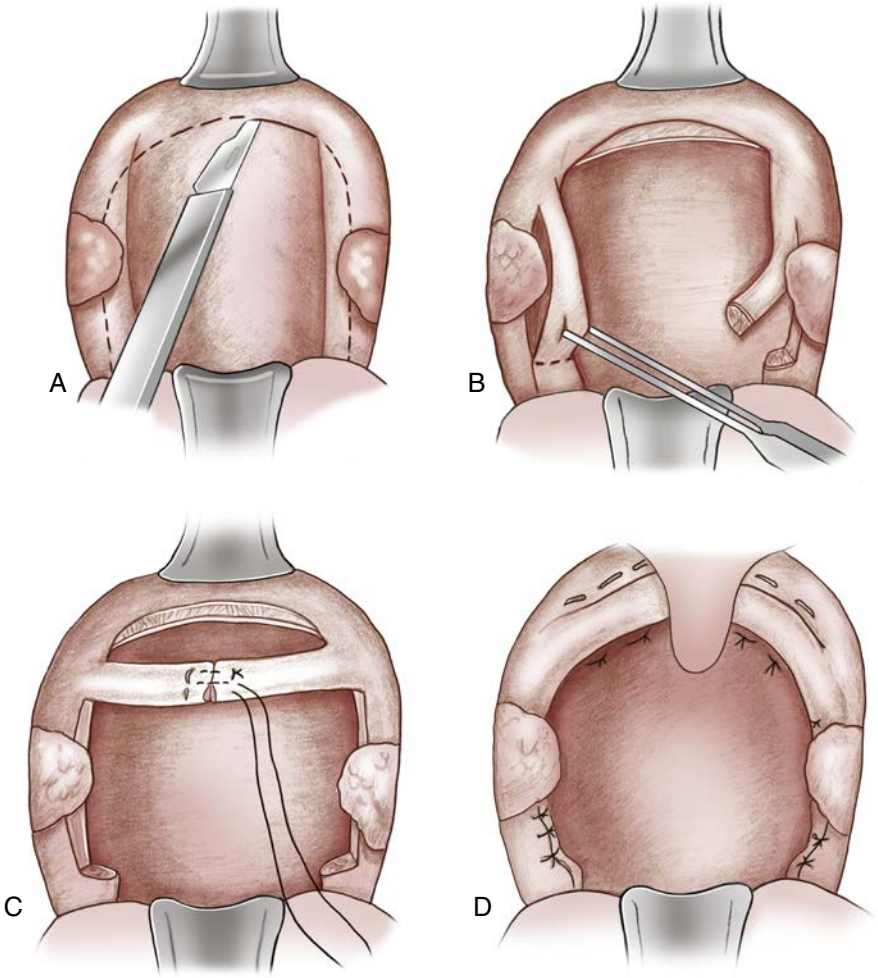
Contemporary surgical management of VPI generally involves one of three types of procedures: (1) the superiorly based pharyngeal flap, (2) palate rerepair, and (3) the sphincter pharyngoplasty. The use of autogenous and alloplastic implants for augmentation of the posterior pharyngeal wall has been described but is not a commonly used procedure today. A resurgence of posterior wall augmentation has been attempted by some utilizing fat grafting with the Colemen technique, but comparative data are lacking. Some surgeons have advocated the use of a second palatoplasty operation as an attempt at palatal lengthening in the patient with VPI; however, limited data exist to broadly support this as a preferred technique. The superiorly based pharyngeal flap remains the standard approach for surgical management of VPI after palate repair. The procedure was initially described by Schoenborn in 1876.[44-46] Surgical maneuvers are directed at recruiting tissue by developing a superiorly based soft tissue flap from the posterior pharyngeal wall (Figure 35-5). The soft palate is then divided along the midsagittal plane from the junction of the hard and soft palates to the uvula, and the flap from the posterior pharyngeal wall is inset within the nasal layer of the soft palate. As a result, a large nasopharyngeal opening that cannot be completely closed by the patient's velopharyngeal mechanism is converted into two (right and left) lateral pharyngeal ports. Closure of these ports is easier for the patient to accomplish as long as adequate lateral pharyngeal wall motion is present. When randomly applied to patients with VPI, the superiorly based pharyngeal flap procedure is effective 80% of the time.[47] When the flap is applied using careful



• **Figure 35-5** Illustration of superiorly based pharyngeal flap operative procedure. **A,** Creation of superiorly based flap of posterior pharyngeal wall soft tissues. The pharyngeal flap is developed and elevated off the prevertebral fascia. The soft palate is divided with a midline incision from the uvula to the junction of the hard and soft palates. **B,** Soft palate oral, nasal, and muscle layer dissection in preparation for flap inset. Nasopharyngeal airways are placed to help size each lateral pharyngeal port. **C,** The flap is sutured into the nasal side of the soft palate before the nasal side is repaired and the oral mucosa and underlying musculature are repaired. **D,** Sagittal view demonstrating appropriate vertical level of flap inset.

preoperative objective evaluations, success rates as high as 95% to 97% have been reported.[48,49] Shprintzen and colleagues have advocated custom tailoring of the pharyngeal flap width and position based on the particular characteristics of each patient as seen on nasopharyngoscopy.[47,50] The high overall success rate and the flexibility to design the dimensions and position of the flap itself are advantages of the superiorly based pharyngeal flap procedure. The disadvantages of the pharyngeal flap procedure are primarily related to the possibility of nasal obstruction resulting in mucous trapping and postoperative obstructive sleep apnea (OSA). Inferiorly based pharyngeal flaps for management of VPI are rarely used. Previous reports have documented increased morbidity without better speech outcomes associated with inferiorly based flaps.[51] In addition, inferiorly based flaps tend to cause downward pull on the soft palate after healing and contracture of the flap. The result may be a tethered palate with decreased ability to elevate during the formation of speech sounds.

The dynamic sphincter pharyngoplasty is another option for the surgical management of VPI. This procedure was described by Hynes in 1951 and since has been modified by a number of other authors.[52-57] The operative procedure involves the creation of two superiorly based myomucosal flaps created within each posterior tonsillar pillar (Figure 35-6). Each flap is elevated, with care taken to include as much of the palatopharyngeal muscle as possible. The flaps are then attached and inset within a horizontal incision made high on the posterior pharyngeal wall. The goal of this procedure is the creation of a single nasopharyngeal port (instead of the two ports of the superiorly based pharyngeal flap) that has a contractile ridge posteriorly to improve velopharyngeal valve function. The main advantage of the sphincter pharyngoplasty over the superiorly based flap is the perceived lower rate of complications related to nasal airway obstruction as described earlier.[58-60] Despite this perceived advantage, there is no evidence that



• **Figure 35-6** Pharyngoplasty procedure. **A,** Incision of the posterior pharyngeal wall and the posterior tonsillar pillars. **B,** Elevation of bilateral myomucosal flaps within the tonsillar pillars. Care is taken to include palatopharyngeus muscle. **C,** The mobilized flaps are then sutured to each other at the midline. **D,** Closure is then achieved by insetting the joined flaps within the posterior pharyngeal wall incision. The donor site of each flap is also closed with interrupted sutures.

pharyngoplasty procedures achieve superior outcomes in the resolution of VPI or decreased complications. Also, the use of a sphincter pharyngoplasty technique may be associated with increased scarring along the tonsillar pillar region. Some advocate its use to avoid the uncommon complication of OSA, but few studies exist examining the true incidence of this complication.

In the past, augmentation of the posterior pharyngeal wall has been attempted to facilitate closure of the nasal airway. Various autogenous and alloplastic materials have been used, including local tissue, rib cartilage, injections of Teflon, silicon, Silastic, Proplast, fat, and collagen.[61,62] Improvement in speech after augmentation of the posterior pharyngeal wall is unpredictable. Problems with migration or extrusion of the implanted material and an increased rate of infection add to the problems with these techniques. For these reasons, pharyngeal wall implants or augmentation techniques are rarely used today.

Some surgeons advocate the use of a revisional palatoplasty instead of a pharyngeal flap or pharyngoplasty procedure in the management of patients with VPI after cleft palate repair in infancy.[63] Some experience has shown this to be effective in a select group of patients who may have had incomplete or less aggressive muscular repairs. The technique can be performed using either a double-opposing Z-plasty or a two-flap palatoplasty with radical retropositioning of the levator musculature. Unfortunately, the anticipated benefits of these second palatoplasties have not, as of yet, been objectively established in broad populations. The clinician must consider the disadvantages of this type of surgical procedure and weigh them against potential benefits. The double-opposing Z-plasty procedure requires a more aggressive dismantling of the palate than what is required during a conventional pharyngeal flap procedure. The result may be a slightly longer palate but one with more extensive scarring and less physiologic movement. Another consideration is the significantly higher rate of fistula formation associated with this type of repair. This can be alleviated with the use of acellular dermal matrix as an interpositional graft material. Comparative studies with high levels of evidence are still lacking.

Complications Related to Surgical Procedures for Velopharyngeal Insufficiency

Surgery involving airway structures is always associated with the potential for complications related to postoperative hemorrhage and edema. As a result, patients who undergo attachment of a pharyngeal flap benefit from admission to the surgical intensive care unit or other observation setting with continuous airway monitoring during the first 24 hours after surgery. This type of setting permits the rapid recognition and prompt management of any complication that may lead to airway compromise. Of all the procedures related to cleft care, the pharyngeal flap and sphincteroplasty operations carry the greatest risk for early airway compromise. Airway compromise is not common but requires swift management to avoid life-threatening consequences.

Long-term postoperative complications related to the superiorly based pharyngeal flap are frequently associated with problems related to increased airway resistance. Insertion of a pharyngeal flap is designed to decrease the size of the nasopharyngeal airway, facilitate velopharyngeal closure, decrease nasal air escape, and make speech more intelligible. At the same time the procedure may create a pathologic level of upper airway obstruction that leads to new problems. Patients who undergo pharyngeal flap surgery may start snoring. Snoring itself does not represent any significant pathophysiology but may concern parents or significant others who observe the patient during sleep. When the degree of upper airway resistance is more severe, the result may be postoperative OSA. OSA is defined as cessation of breathing during sleep secondary to upper airway obstruction. OSA disrupts the sleep cycle, compromises effective oxygenation, and can cause behavioral changes and daytime somnolence in affected individuals. Left untreated, OSA is associated with severe cardiac and pulmonary consequences.

When OSA is suspected in a child who has previously undergone a pharyngeal flap procedure, a formal workup including nasopharyngoscopy and a sleep study (polysomnography) is indicated. Care should be taken to evaluate the entire airway in order to determine the level of the obstruction. Surgeons may initially assume that the airway obstruction is related to the flap only to discover that a more significant issue exists somewhere else in the airway. Often a thorough clinical evaluation yields abnormal findings that contribute to the problem of OSA at multiple levels of the upper airway. Because of the potential complexity of the clinical problem, the decision to modify or take down a pharyngeal flap in a child with OSA must be made only after discussions among the surgeon, sleep specialist (e.g., pediatric otolaryngologist, neurologist, or pulmonologist), and speech and language pathologist. Of interest, many adolescent or adult patients who have had pharyngeal flap placement during childhood will tolerate surgical division of the flap without a recurrence of severe VPI or hypernasal speech. On the rare occasion when VPI does recur after flap take-down, interval treatment with a prosthetic device such as a palatal lift appliance for a minimum of 6 months should be considered before one embarks on any further palatal surgery. Palate rerepair may be an option in this patient population, but the incidence of sleep apnea after this procedure is not well documented as of yet.

Management of the Submucous Cleft Palate

A submucous cleft palate (SMCP) is another form of the congenital cleft palate malformation in which the overlying mucosal layer is intact but the underlying soft palate musculature is divided. As described by Calnan, the classic clinical

findings with an SMCP are a triad of bifid uvula, hard palate bony notch, and separation along the median raphe of the soft palate especially during elevation of the velum.[64] Presentations with less than this classic triad can be considered occult forms of SMCP. When an SMCP is present, as in a complete cleft of the secondary palate, the levator muscle is clefted in the midline and abnormally inserts into the posterior edge of the hard palate. The primary functional concern related to SMCP is the possibility that the patient will develop VPI and resultant hypernasal speech. Despite this concern, the majority of patients with an SMCP will not require surgical intervention. In fact, less than 44% of patients will actually remain completely asymptomatic until later in childhood.[65] The bifid uvula is the most easily detected feature of the SMCP triad of clinical findings. However, a bifid uvula may also be observed in the absence of other features of submucous clefting (e.g., notched hard palate, velar separation, hypernasality). In fact, the incidence of bifid uvula is approximately 1:80, whereas the incidence of SMCP is 1:280.[66] Previous investigation has suggested a connection between the isolated finding of a bifid uvula and velopharyngeal dysfunction when otherwise asymptomatic patients were evaluated using a nasopharyngoscopy.[67] As a result, the clinical finding of an isolated bifid uvula may be considered an indicator of increased risk for VPI in a patient who is to undergo adenoidectomy. This underscores the value of a thorough clinical evaluation and the importance of presurgical speech evaluation and family counseling regarding the potential risks of postsurgical VPI. A smaller percentage of children have an occult SMCP. Surgical consultation is often requested once VPI-related speech difficulties are noted during childhood speech development or after surgical intervention (e.g., adenoidectomy).

Prior reports have attempted to describe characteristic facial features, cephalometric findings, and speech studies that lead to a presumptive diagnosis of SMCP.[68] The vast majority of patients with an SMCP will require either no treatment or speech therapy only. Surgical intervention is not undertaken simply because the diagnosis of SMCP is made. Speech is closely monitored during childhood with interval speech evaluations, and surgery is reserved only for those cases with VPI not amenable to speech therapy. The specific surgical procedure used to manage submucous cleft–related VPI varies depending on the preference of the surgeon and speech pathologist. Several early procedures emphasized exploration of the soft palate through a limited midline incision with repair of the levator muscle. Contemporary methods primarily involve the use of a standard palatoplasty (e.g., two-flap, pushback, or Furlow) and repair of the velar musculature, with or without a simultaneous pharyngeal flap procedure, or the use of a sphincter pharyngoplasty. Controversy exists regarding which procedure results in the best outcome. It has been suggested that correcting the anatomic deformity associated with SMCP with a palatoplasty should be reserved for patients with a small gap between the velum and posterior pharyngeal wall. Those patients with a larger gap would theoretically benefit from mobilization of a posterior pharyngeal flap or augmenting the posterior pharyngeal wall via a sphincter pharyngoplasty in an attempt to eradicate hypernasality in a single operation. Due to significant variability in methods of speech outcome assessment, there is not enough evidence to support one technique over the other.[69]

Bone Graft Reconstruction of the Cleft Maxilla and Palate

Approximately 75% of all orofacial clefts will involve the maxilla.[5] Despite successful lip repair and closure of the hard and soft palates during infancy, a residual nasolabial fistula and bony cleft defect that involves the alveolar ridge, maxilla, and piriform rim will remain. These residual deformities are addressed by secondary bone grafting performed during the mixed dentition stage of middle childhood (6 to 9 years of age). The objectives of bone graft reconstruction of the cleft maxilla are to establish adequate bony matrix for eruption of the permanent cuspid tooth, close any residual alveolar oronasal communication, establish bony continuity of the maxillary ridge, and improve the underlying bony support of the nasal base. In the case of bilateral cleft lip and palate, an added benefit of bone graft reconstruction is stabilization of a mobile premaxillary segment. The details and technical considerations of these procedures are discussed in detail separately within this volume. Occasionally, additional bone may be helpful for dental implant reconstruction and/or esthetic considerations in the mid-face. Bone can be obtained from the ramus, chin, zygoma, rib, iliac crest, or other sources. Bone morphogenic protein has also been utilized to facilitate these reconstructions, but is not approved for children by the FDA.

Orthognathic Surgery for Treatment of Mid-facial Deficiency

Patients who underwent cleft palate repair during infancy often exhibit some degree of maxillary growth restriction. This disproportionate jaw growth is the biologic consequence of prior surgical intervention and is not related to the congenital cleft deformity in most cases. Previous authors have reported a 25% incidence of maxillary hypoplasia that is severe enough to produce a clinically significant dentofacial deformity with negative effects on speech and occlusion.[5,6,18,39] The successful treatment of these secondary skeletal deformities frequently requires protocols that include orthognathic surgery in conjunction with a final phase of orthodontic mechanics. Simultaneous bone grafting can be used for contouring the dysmorphic skeletal structures. Additionally, the coordinated closure of cleft dental gaps or fistulas in the maxilla can sometimes be coordinated with the orthognathic surgical procedures. The details of these procedures are discussed in detail in the chapter dealing with orthognathic surgery for patients with clefts.

Revision Surgery for Cleft Lip and Nasal Deformities

Reconstruction of the Cleft Nasal Deformity

Congenital clefts that involve the lip, nose, and underlying cartilaginous and skeletal structure will result in a complex three-dimensional deformity of the nasal complex that affects both form and function.[70,71] In the case of a complete unilateral cleft, the typical nasal deformity is characterized by splaying of the alar base, unilateral inferior displacement of the alar base, deviation of the nasal tip, and irregularity of the caudal nasal septum. Abnormal fibrous insertions and relationships exist between the lateral crus of the lower lateral cartilage and the lateral piriform rim on the cleft side. At the time of the initial lip repair, nasal deformity can be addressed through primary nasal reconstruction. The approach includes dissection along the lower lateral cartilage separating the cartilage from overlying skin and sharp release of fibrous insertions along the piriform rim so that the nares can be repositioned in an attempt to restore symmetry. Despite effective primary cleft lip and nasal repair during infancy, most patients will demonstrate enough residual nasal dysmorphology and/or chronic obstructive nasal breathing to require secondary surgery for treatment of the cleft-associated nasal deformity. The timing of cleft nasal revision also remains somewhat controversial. Some surgeons take a more aggressive approach and undertake extensive nasal reconstruction during early childhood. The authors' philosophy is to delay the definitive cleft rhinoplasty when possible until the nasal complex has nearly achieved its mature size.

If the patient's reconstructive treatment plan also requires maxillary advancement, then nasal surgery is usually delayed until at least 6 months after the orthognathic procedure. This allows for a more predictable outcome and long-lasting improvement in nasal function and facial esthetics. Early surgery is reserved for individuals with severe airway or nasal airflow problems. An additional consideration must be potential psychosocial consequences and self-esteem issues that arise (e.g., teasing at school). When indicated, early nasal surgery can go forward after bone graft reconstruction of the maxilla so that a stable bony foundation along the piriform rim and nasal base exists first.

Secondary cleft-nasal reconstruction will often require dorsal reduction, upper and lower lateral cartilage sculpting, columellar strut grafting, and lateral nasal osteotomies. Cartilage grafting is a critical component of the final nasal reconstruction and is used for augmentation of the dysmorphic lower lateral cartilage as well as improvement of nasal tip projection.[5,72,73] Several donor sites may be considered including auricular cartilage, nasal septum, and rib cartilage. Ear cartilage is useful when augmentation of hypoplastic cleft-side lower lateral cartilage is required. Septal cartilage is most easily accessible and provides an excellent scaffold for repositioning of the lower lateral cartilages and for improvement of nasal tip symmetry and projection. Unfortunately, many patients seeking definitive nasal reconstruction have undergone previous septal cartilage harvests. In many of these patients, insufficient quality and quantity exist for a second septal cartilage graft. In these cases the use of costochondral cartilage is preferred. Rib cartilage provides adequate amounts of graft material but requires a distant donor surgical site with potential morbidity. We have found this type of cartilage graft to provide excellent strength for straightening the nasal tip and alar complex. Several key enhancements include improvement of the supratip break with increased tip definition and better symmetry. These techniques are best carried out through an open rhinoplasty.[5] A transcolumellar incision is combined with marginal incisions to provide wide access and direct visualization of the nasal dorsum, upper and lower lateral cartilages, and nasal septum.

A similar rationale is applied when considering the timing of secondary nasal reconstruction in the bilateral cleft lip patient, but the specific dysmorphology addressed is somewhat different. Generally, nasal asymmetry is less problematic, and the dysmorphology is characterized by deficient columella length. Previous literature has focused on the lengthening of the columella through the use of banked forked flaps or primary columella lengthening using soft tissue flaps from the floor of the nose and with alar flaps.[74,75] Unfortunately, these types of surgical procedures often result in a distorted columellar-labial angle, excessive scars that may extend onto the nasal tip, and additional distortion of the broad nasal tip. We find that the approach described by Posnick using septal cartilage or costochondral strut grafts attached to the caudal nasal septum and lower lateral cartilages yields the most natural-looking results.[5,6] The objective is treatment of the underlying cartilaginous anatomy with stretching of the overlying soft tissue envelope, instead of direct surgical manipulation of the columella skin (Figure 35-7).

Secondary Surgery for Cleft Lip Scar Revision

Even when the initial cleft lip repair procedure is considered successful, the majority of children will benefit from an additional lip revision at some point.[4,76] The majority of publications are retrospective cohort studies or case series. Although revision procedures are often viewed as optional phases of cleft lip reconstruction, surgeons should advise families of this likelihood. As a child grows, the hard and soft tissues of the maxillofacial complex grow and change, and the repaired lip is affected. Ongoing growth often makes it difficult to predict which children will benefit from additional lip surgery. A child's lip may initially look satisfactory and over time demonstrate unfavorable changes necessitating revision. On the other hand, favorable changes may occur during the healing process that actually improve the appearance of the repaired cleft lip. At approximately 8 to 10 weeks after surgery, significant lip contracture may be seen during the fibroblastic phase

of healing. The result may be vertical shortening of the repaired cleft side that will seemingly require further surgery. Often, if the same child is reevaluated after 6 months or later, after additional wound maturation, they will demonstrate very good lip esthetics and not be considered a candidate for revision.

It can be very challenging to address some of these postoperative deformities. Clinically, the consequences of poor technique or abnormal wound healing can be seen as cutaneous roll and vermilion discontinuities with medial notching, a vertically short or elongated cleft-side lip element, hypertrophic scarring, transverse hatch marks from sutures, shifting of the Cupid's bow, abnormal upper lip animation, or an asymmetric fullness (muscle bulge) indicating an inadequate reapproximation of the muscular layer during the initial repair.[77] Esthetic goals for lip repairs include symmetry, muscular continuity, philtral length and shape, presence of a medial tubercle, fullness of the vermillion, and continuity of the white roll. Lip scar revisions may consist of small "touchups" or require total reconstruction of the lip deformity.

Ideally, only one lip scar revision is undertaken, when the child is between the ages of 5 and 15 years. The procedure is staged for as late in childhood as possible. When a severe deformity persists or psychosocial concerns arise, lip revision may be carried out earlier in life. The surgical objectives of cleft lip revision include excision of residual scar and any remaining hypoplastic tissue with reapproximation of key anatomic landmarks—vermilion-cutaneous junction and vermilion-mucosal junction—along with leveling of vertical lip lengths (i.e., philtral columns). Critical to an acceptable outcome is the meticulous repair of the orbicularis oris muscle as a distinct layer, and some surgeons will pay particular attention to the perinasal muscular

• **Figure 35-7** A 52-year-old man born with a bilateral cleft lip and palate is shown before and after his lip revision and dental reconstruction with bone grafting and implants. His whistle deformity is resolved with an appropriately sized philtrum. The dental reconstructive plan allowed for esthetic teeth to be present throughout the healing phase of each aspect of the reconstruction.

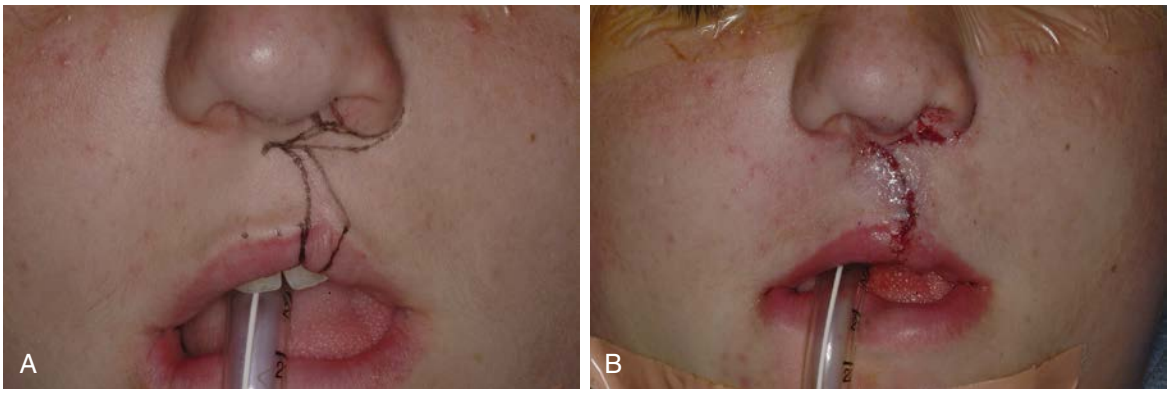
Figure 35-7, cont'd.

reconstruction as well. The cleft surgeon should typically dissect and repair all layers (skin or vermilion, muscle, and oral mucosa) in order to establish improved lip form and normalize function and animation (Figure 35-8). Often this requires complete takedown of the lip and recreation of the full-thickness defect.

Comprehensive Dental and Prosthetic Rehabilitation

In general in patients with a cleft of the primary palate (maxilla and alveolus), three possibilities exist with regard to the status of the permanent lateral incisor: (1) the lateral incisor is present and erupts normally, (2) the lateral incisor is congenitally missing, or (3) the lateral incisor is present but is dysmorphic and not a restorable tooth. When the lateral incisor is hypoplastic, extraction is typically performed before or at the time of bone graft reconstruction. In those cases in which a lateral incisor is missing, management of the residual dental gap will eventually be required. Treatment options include the placement of a three-unit fixed prosthesis, replacement of the missing tooth with an endosseous dental implant, or orthodontic substitution of the ipsilateral cuspid tooth for the lateral incisor. Cleft-orthognathic surgery designed to differentially reposition the segments and close the cleft dental graft can also be considered. Additional bone grafting is often performed at the time of cleft-orthognathic surgery in these cases to ensure stable results and closure of a residual oronasal fistula. In contemporary practice the use of a three-unit bridge for replacement of a congenitally missing incisor may generally be avoided. This prosthetic option has several disadvantages: it usually requires preparation of two otherwise perfectly healthy teeth (central and cuspid), hygiene is more difficult around the pontic, and even in the best of circumstances the prosthetic restoration will require replacement several times during the patient's lifetime. In reality, many of the adjacent abutments are compromised and most of these patients will require comprehensive reconstructions (e.g., hybrid prostheses) that can be rather expensive. In North America, most of these types of reconstructions are not covered



• **Figure 35-8** Unilateral cleft lip revision. Preoperative and postoperative photographs of a patient undergoing revision of a unilateral cleft lip. The full-thickness cleft defect is recreated with care taken to reconstitute the orbicularis oris muscle. The scar and residual hypoplastic tissue were excised, and anatomic landmarks including the vermilion border, white roll, wet-dry line, and nasal sill are reapproximated.

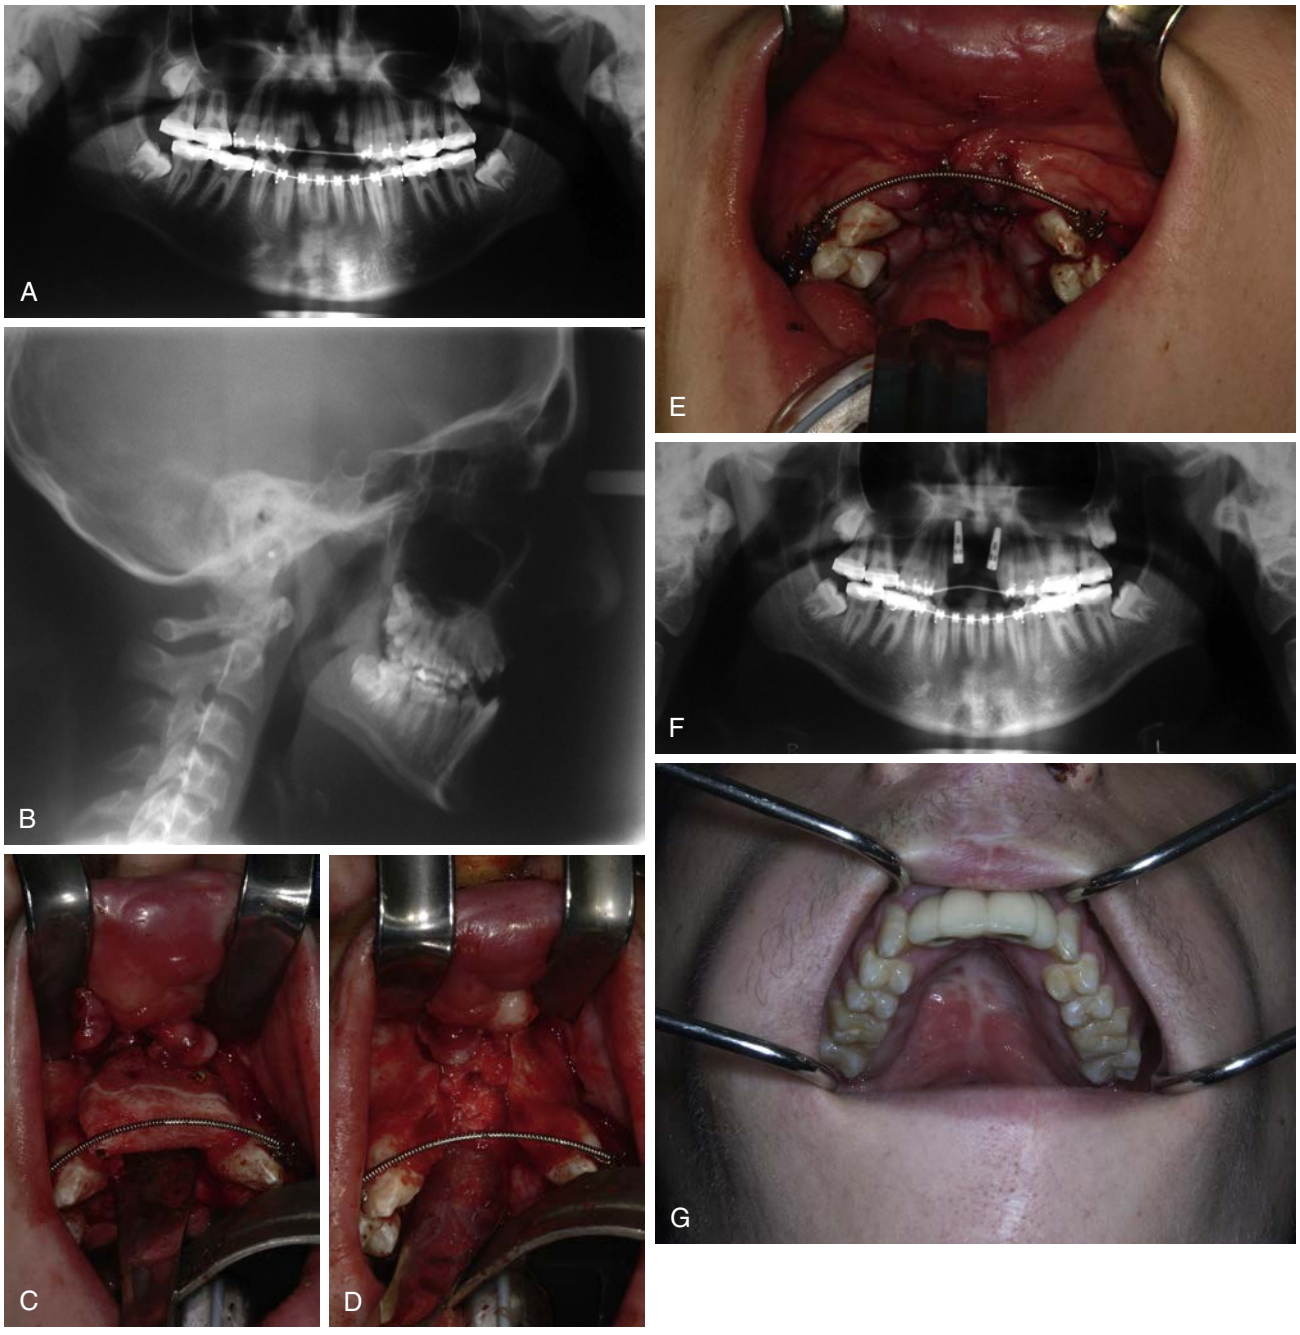
by most insurance plans in a meaningful way. Patients will benefit from understanding the long-term consequences of their reconstructive choices, and the dental reconstructive costs that are often be incurred.

Over the course of the past two decades the use of dental implants has revolutionized the prosthetic rehabilitation of patients with missing teeth. This technology has also been applied to patients born with cleft lip and palate (Figure 35-9).[78-80] Use of an implant-supported crown provides a natural-looking restoration with excellent long-term viability and obviates the need for instrumentation of the surrounding teeth. When a dental implant is being considered, pertinent treatment-planning concerns include an evaluation of bone quality and quantity and the maintenance of adequate space for the implant and restoration. Our preferred approach involves the preservation of a minimum of 7 mm of interdental space to allow for placement of a small diameter dental implant with appropriate emergence profile and adjacent space between roots for esthetic reconstruction. Secondary soft tissue procedures may be beneficial to further optimize the attached tissue in this region. In many instances other areas require extensive reconstruction as well, necessitating a long-term treatment plan that anticipates the health of surrounding teeth as well. Periodontally involved teeth should be evaluated very carefully to anticipate the need for extraction and plan the most long-lasting reconstruction possible.

In most patients who have undergone previous "successful" bone grafting, the vertical dimension of the alveolar ridge seems to be well maintained until the time of implant placement. Facial-palatal width of the ridge, however, may be more problematic, and a significant number of patients may require additional minor bone grafting approximately 3 to 5 months before implant surgery. In most cases the width of the alveolus can be nicely augmented with bone harvested as a cortical block from the mandibular symphysis or ramus. Implant placement requires that the patient be at or near skeletal maturity. Another option for management of the cleft dental gap and missing lateral incisor is orthodontic management designed to substitute the ipsilateral cuspid for the missing lateral incisor. Frequently the result is very acceptable dental esthetics even if prosthetic modification of the cuspid is not undertaken. As with dental implant rehabilitation, this treatment option obviates the need for preparation of the adjacent healthy tooth structure. Another advantage of this treatment option is that it may be undertaken at a younger age than the other prosthetic options. Limiting factors related to this option are primarily due to orthodontic anchorage. Consideration can be given to using skeletal anchorage devices if this becomes problematic.

Summary

Orofacial clefts are complex malformations that affect the three-dimensional anatomy of the maxillofacial hard and soft tissues. Successful reconstruction of these defects involves multiple stages of surgical intervention. Primary surgery achieves the initial closure of the lip and palate defects at age-appropriate intervals based on form and functional concerns. Secondary surgical procedures are subsequently carried out as indicated to close residual oronasal communication, address VPI, reconstruct the bony maxillary cleft, restore maxillary skeletal and facial proportions and occlusion, improve lip esthetics and nasal form and function, and facilitate the dental prosthetic rehabilitation of the patient. Because the multiple, separate surgical interventions that are carried out during active growth have profound functional and esthetic consequences, thoughtful planning of each stage of reconstruction is critical to maximize the benefit for the patient and mitigate the potentially negative biologic consequences related to surgery and growth. Surgeons must maintain a thorough understanding of the anatomy, the intricacies of the cleft malformation, and the underlying patterns of growth and development of the cranio-maxillofacial region.



• **Figure 35-9** Prosthetic rehabilitation of a 17-year-old patient with previously unrepaired bilateral maxillary alveolar clefts. He had undergone primary lip and palate repair during infancy but did not achieve successful bone graft reconstruction. Ultimately he lost the premaxillary segment. Treatment consisted of bone graft reconstruction of the bony clefts and large central defect with closure of the oral-nasal fistula. This was performed using autogenous corticocancellous bone graft obtained from the anterior iliac crest followed by dental implant placement 6 months later. **A,** Preoperative panoramic radiograph and **B,** lateral cephalometric radiograph reveal cleft defects and the central defect from the missing premaxilla. **C,** Intraoperative closure of the nasal-side fistula. **D,** Intraoperative insetting of the bone graft. **E,** Clinical closure of the defect with advancement flaps. **F,** Panoramic radiograph after bone graft reconstruction and implant placement. **G,** The prosthetic hybrid prosthesis restoration.

Craniomaxillofacial Surgery in the Pediatric Patient: Growth and Development Considerations

BERNARD J. COSTELLO, MARK P. MOONEY, JOCELYN M. SHAND

The goals of craniomaxillofacial surgery include establishing a stable morphology and improving facial esthetics. Surgical treatment may necessitate manipulation of the soft tissues or bony structures based on the particular dysmorphology, defect, or injury. For example, the failure of fusion that creates facial clefting is usually repaired in infancy during the growth phase. Just repairing these soft tissues in key growth areas may have negative consequences later in life. This interplay highlights the possible biologic consequences of early intervention during the growth phase.

When skeletal discrepancies exceed the envelope of those that can be appropriately treated with orthopedic growth modification and/or orthodontic compensation techniques, surgical repositioning of the craniofacial structures may be indicated.[1] In many instances, patients with skeletal deformities benefit from surgical treatment following the completion of facial growth. This approach allows for a definitive treatment that is highly predictable and stable in the majority of cases.[2] In contrast, surgical treatment performed before skeletal maturity is less predictable and may require reoperation following skeletal maturation. However, early intervention may be warranted for functional or esthetic reasons. Unfortunately, the hoped-for advantage of early surgical interventions to "unlock growth" has not been realized, and in most cases, there are no clear benefits to early operative intervention, which is partially due to the associated drawbacks.[3,4] These common issues emphasize the importance of considering growth when planning treatment for surgical reconstruction.

This chapter reviews the concepts of development and growth in the craniomaxillofacial skeleton as they relate to the treatment of soft tissue and skeletal dysmorphologies. The basic principles of craniofacial growth are reviewed, and the specific patterns of craniofacial dysmorphologies are discussed with regard to potential early and/or staged intervention. A balanced approach to treatment planning is presented with growth as the center of discussion. However, functional aspects of the airway and occlusion are of considerable importance in some patients. Certain clinical situations require intervention even at the cost of harming growth potential when there is a significant benefit perceived. Additionally, esthetic concerns in patients with severe deformity require careful consideration for psychosocial reasons.

Growth Discrepancy and the Craniofacial Skeleton

Growth discrepancies involving the craniofacial skeleton are common, and many of these discrepancies can be managed with orthopedic growth modification and/or orthodontics alone if they are not severe.[1] In particular, congenital craniofacial malformations, deformities, and disruptions may have severe skeletal dysmorphologies and discrepancies. For example, deformational plagiocephaly causes cranial and possibly orbital asymmetry that when diagnosed early is treated with a form of growth modification using custom-molding helmets or bands. In instances when the discrepancy is particularly large or other deformities of the cranio-orbital region are encountered, surgery may be helpful to dismantle the craniofacial components and reposition them in a more normal conformation. There are a number of examples of these skeletal and soft tissue discrepancies that occur in childhood requiring treatment. Deciding when to intervene is important to optimize the long-term results for these clinical challenges.

Growth abnormalities and dysmorphology of the lower face are the most commonly encountered clinical problems for the craniomaxillofacial surgeon. When these discrepancies involve the teeth, most minor discrepancies are treated

with orthodontic compensation. However, some are beyond the envelope of orthodontic compensation techniques and may benefit from surgical repositioning of skeletal components. Orthognathic surgery for the treatment of skeletal discrepancy and malocclusion has traditionally been undertaken following the completion of growth, and there is considerable contemporary literature regarding the effects and stability of these procedures. However, there are only a limited number of studies that have investigated the outcome following orthognathic, craniofacial, or other types of maxillofacial surgery performed in the growing child.[5-12] The supposition that surgical intervention before skeletal maturation may "inhibit" the future growth potential of the involved bone is long standing, especially if a growth center is involved. This concept is in part based on the findings obtained from studies of patients with cleft lip and palate deformities, Robin sequence, craniofacial microsomia, Treacher Collins syndrome, and a range of other conditions in those who had undergone surgical procedures during growth.[13] The results and observations from these studies do provide information about growth potential; however, is it imperative to recognize that these patients also have an underlying dysmorphology that may influence facial growth independent of surgical treatment. In the assessment of subsequent facial growth problems, it is difficult to delineate between that related to the preexisting condition with its aberrant growth pattern and that potentially caused by the surgical osteotomy or other manipulations. Early surgery has usually been reserved for individuals with marked skeletal dysmorphologies and/or severe functional concerns (e.g., intracranial pressure increases, choanal atresia, or severe obstructive sleep apnea). The presence of severe functional problems or implications for the psychosocial development of the child may become important when considering early surgery. A firm understanding of the patterns of facial growth is essential when planning surgical reconstruction.[14]

There is some predictability to the growth of the cranium and face, but individual variation and pathologic conditions must be considered.[15,16] Common growth variations (e.g., vertical maxillary excess with mandibular hypoplasia) and pathologic clinical situations (e.g., maxillary hypoplasia in the patient with a cleft palate) should be recognized, treatment planned, and staged with these issues in mind. Clinicians must be aware of these early discrepancies, not to force early intervention in most cases, but to develop a diagnosis and stage the reconstruction for the most predictable result. Treatment plans can then be formulated based on the best estimation of the expected pattern of growth.

Concepts of Craniofacial Skeletal Growth and Development

Craniofacial development, growth, and remodeling are a complex interplay of structure and function beginning in the embryo and continuing throughout adult life. The delicate equilibrium that exists between various parts of the craniofacial skeleton is stimulated by genes and local function and coordinates complex biomechanical and molecular signaling to yield a composite skeletal form.[17] Problems can occur at any time during this process and negatively impact the growth and development process. Understanding the basic biology of craniomaxillofacial development and growth is essential when planning treatment for malformations, disruptions, and deformities. The basic definitions are important to understand when discussing the biology of growth and development (Table 36-1).

TABLE 36-1 Definitions

Term	Definition
Dysmorphology	Abnormal morphology of tissues
Malformation	Formation of tissue is poor as a result of an intrinsic problem with development
Disruption	A breakdown in normal tissue development causing abnormal morphology
Deformation	Changes in morphology caused by external forces on normal tissue
Growth	Increase in cell size (plasia) or cell number (trophy)
Remodeling	Compensatory or adaptive changes of tissue
Development	Increase in complexity
Hyperplasia	Increase in the size and number of cells

In general, there is a cephalocaudal growth vector that occurs throughout early life and facial development that is thought to be closely linked to the functional demands of each region (Figure 36-1). Enlow[18,19] has discussed the concepts of growth in detail and outlines the two main morphologic events that direct craniofacial growth. These include (1) basal cranium growth and (2) development of the pharyngeal and facial airway structures. This vector of cephalocaudal growth is directly related to the changes seen in the proportions of the head and face during early life. In the early phase, this is reflected in the relative importance of cranial growth as a response to the rapid growth of the brain tissues. This occurs in the neurocranium, which houses the structures of the brain, orbits, and olfactory system, and this region comprises the cranium and upper third of the face. The remainder of the facial tissue accelerates their growth at a later phase as the airway and muscles of mastication increase their function. This represents the viscerocranium (Table 36-2).

The bones of the craniofacial skeleton grow and develop by remodeling and displacement throughout young life. Remodeling occurs as a result of local factors that result in the change in the size and shape of various components of the facial skeleton. Displacement occurs by bones that move apart at the joint, suture, or articular regions.[18,19] This

• **Figure 36.1** Multiple views of skulls from infancy through adolescence show the progression of craniofacial bone growth. The general progression is from superior to inferior with a downward and forward growth vector.

TABLE 36-2 Average Percent Growth Completion of Various Craniofacial Dimensions

	Average Adult % Completed by Age 1	Average Adult % Completed by Age 5	Average Age at Maturity
Cranium	84%-86%	90%-94%	Males: 14 yr Females: 16 yr
Orbits	84%-86%	88%-93%	Variable
Zygoma	72%	83%	Males: 15 yr Females: 13 yr
Maxilla	75%-80%	85%	Males: 15 yr Females: 14 yr
Mandible	60%-70%	74%-85%	Males: 16 yr Females: 14 yr

From References 18-23.

displacement occurs away from the articular surfaces (i.e., cranial sutures, temporomandibular joints, or maxillary sutures). Bone growth is modulated through this process by augmenting or diminishing various regions in response to the functional needs and the timing of gene expression. The two processes of remodeling and displacement should occur in a coordinated and interdependent fashion. If the processes are balanced, the skeleton develops appropriately. In contrast, if the balance is disturbed (i.e., nasal obstruction or prenatal cranial suture fusion), the skeleton develops outside the envelope of equilibrium resulting in a skeletal discrepancy.[1]

Local signaling appears to occur between the bony components of the face to develop each area in response to the increasing functional demands of mastication and breathing. The orbits, maxillae, and mandible are each dependent upon one another early in this phase, whereas the cranial base has a more intrinsic or genetically based control mechanism.[18,19] The cranium and orbits will develop in response to the rapid growth of the brain and globes, which occurs during the first year of life, and hence the cranio-orbital complex is comparatively much larger than the maxillomandibular complex in infancy. The early developing neurocranial complex creates a craniocaudal growth vector that is clockwise in direction when viewing the right lateral skull. Later, the functional demands of mastication and deglutition on the mandible become prominent, and the nature of the equilibrium balance with the maxilla is also altered in response to the growth and development of the airway and the functional needs of mastication and speech development. Constant modifications to this process are made throughout growth and development to obtain a functional state of equilibrium.

The equilibrium of the craniofacial complex is altered following a series of normal developmental events. These include:

1. Central neurologic development
2. Optic pathway development
3. Speech and swallowing development
4. Airway and pharyngeal development
5. Facial expression and muscular changes
6. Tooth development and exfoliation

Each region has a unique growth curve, and there are various peaks of growth velocity that alter craniofacial equilibrium resulting in skeletal growth changes to restore this equilibrium. It is essential to have an understanding of each region when deciding the timing of various reconstructive efforts. In general, more definitive corrections are performed later in the growth phase and ideally should be undertaken at the completion of growth because earlier intervention may alter the growth curve and disrupt the equilibrium. Relapse toward the original dysmorphology is more likely to occur when the body attempts to restore the balance that has been altered by surgical intervention performed before skeletal maturation.[18,19]

Regions of Craniofacial Growth and Development

Cranium

The cranium is made up of the chondrocranium and the neurocranium. The chondrocranium, or cranial base, develops initially in cartilage derived from occipital somites and then becomes bone by endochondral ossification. These ossification centers form the bones of the base of the skull

(i.e., the occipital, sphenoid, temporal, and ethmoid bones). Growth of the cranial base bones occurs interstitially at articulations called synchondroses. Whereas the majority of the growth is occurring at the synchondroses, once ossified, the inner and outer surfaces of each bone can also remodel via appositional growth.

The neurocranium, or cranial vault, is made up of large and small curved, flat bones that are formed intramembranously, the majority of which are derived from neural crest cells. The growth of these bones occurs interstitially at the fibrous articulations (i.e., the sutures) and appositionally on the endocortical and ectocortical surfaces. The cranial vault grows rapidly in the first year of life, and the velocity of growth plateaus in the following 5 years. A diploic space is present between two clear cortices of bone in most children between the ages of 2 and 5 years. The vast majority of growth in this area is complete by ages 5 to 7 years.[3,4] At 1 year of age, the width of the head is 84% of its adult size, and at 5 years of age, the head width increases to 93%.[20-23] Head circumference is similar with 86% of the growth complete by 1 year of age and 94% of growth completed by 5 years of age. The maturation age of the cranium width is 14 years in females and 15 in males. The incredible amount of growth within the first 5 years of life is reflective of the neurodevelopment that occurs during this time.[20-23]

Craniosynostosis is the premature fusion of cranial vault sutures, which is generally an antenatal event that causes growth restriction perpendicular to the affected suture. Craniosynostosis is most often seen with only one suture. However, craniofacial dysostosis syndromes occur when the cranial base synchondroses (primarily the presphenoethmoid synchondroses) and, to a lesser extent, the cranial vault sutures are affected to varying degrees. The alteration of the mid-face occurs in craniofacial dysostosis syndromes, such as Apert's, Pfeiffer, and Crouzon's syndromes. These syndromes are characterized by a restriction of growth in the anterior cranial vault and cranial base that results in severe orbital and mid-facial hypoplasia and Class III malocclusion. In addition, when the brain and cranial base components do not form in their normal fashion (i.e., Binder sequence and Down syndrome), the development of the mid-facial complex and the balance is also distorted.[24-26]

In many cases, treatment of dysmorphology in the cranial vault and orbits is more definitive after 1 year of age because the vast majority of growth in the cranium is complete at this time. In the case of craniosynostosis, surgical correction is necessary earlier to allow appropriate volume for brain growth. For patients with craniofacial dysostosis in which skull base fusion has also affected the orbits and mid-face, this is corrected at a later stage (Figure 36-2).

Orbits

The orbits consist of bones from the cranio-orbital and nasomaxillary complexes, and most of the growth in the orbit region occurs at the sutures between these bones. The orbits grow rapidly in the first year of life in association with the globe, optic nerves, and neurocranial development, and the velocity decreases over the next 5 years. The vast majority of growth in this area is completed by 5 years of age.[3,4] The intercanthal width at age 5 is on average 30 mm, which is approximately 93% of the adult value (33 mm). Intercanthal width is fully mature in males at 11 years of age and in females at 8. Orbital height grows at a more gradual rate in comparison with the other orbital dimensions. The impressive growth of this region before 5 years of age is a result of the rapidly developing globes and optic neurologic system.[3,4]

Orbital dysmorphology is seen in unicoronal craniosynostosis, the craniofacial dysostosis syndromes, and also in patients who fail to obliterate the foramen cecum during development with midline lesions, such as encephaloceles, dermoids, or gliomas. The delicate balance is disturbed, and the tissues adapt based on the pathologic condition that is present. Most treatments are best performed after the age of 5 years (Figure 36-3).

Zygoma

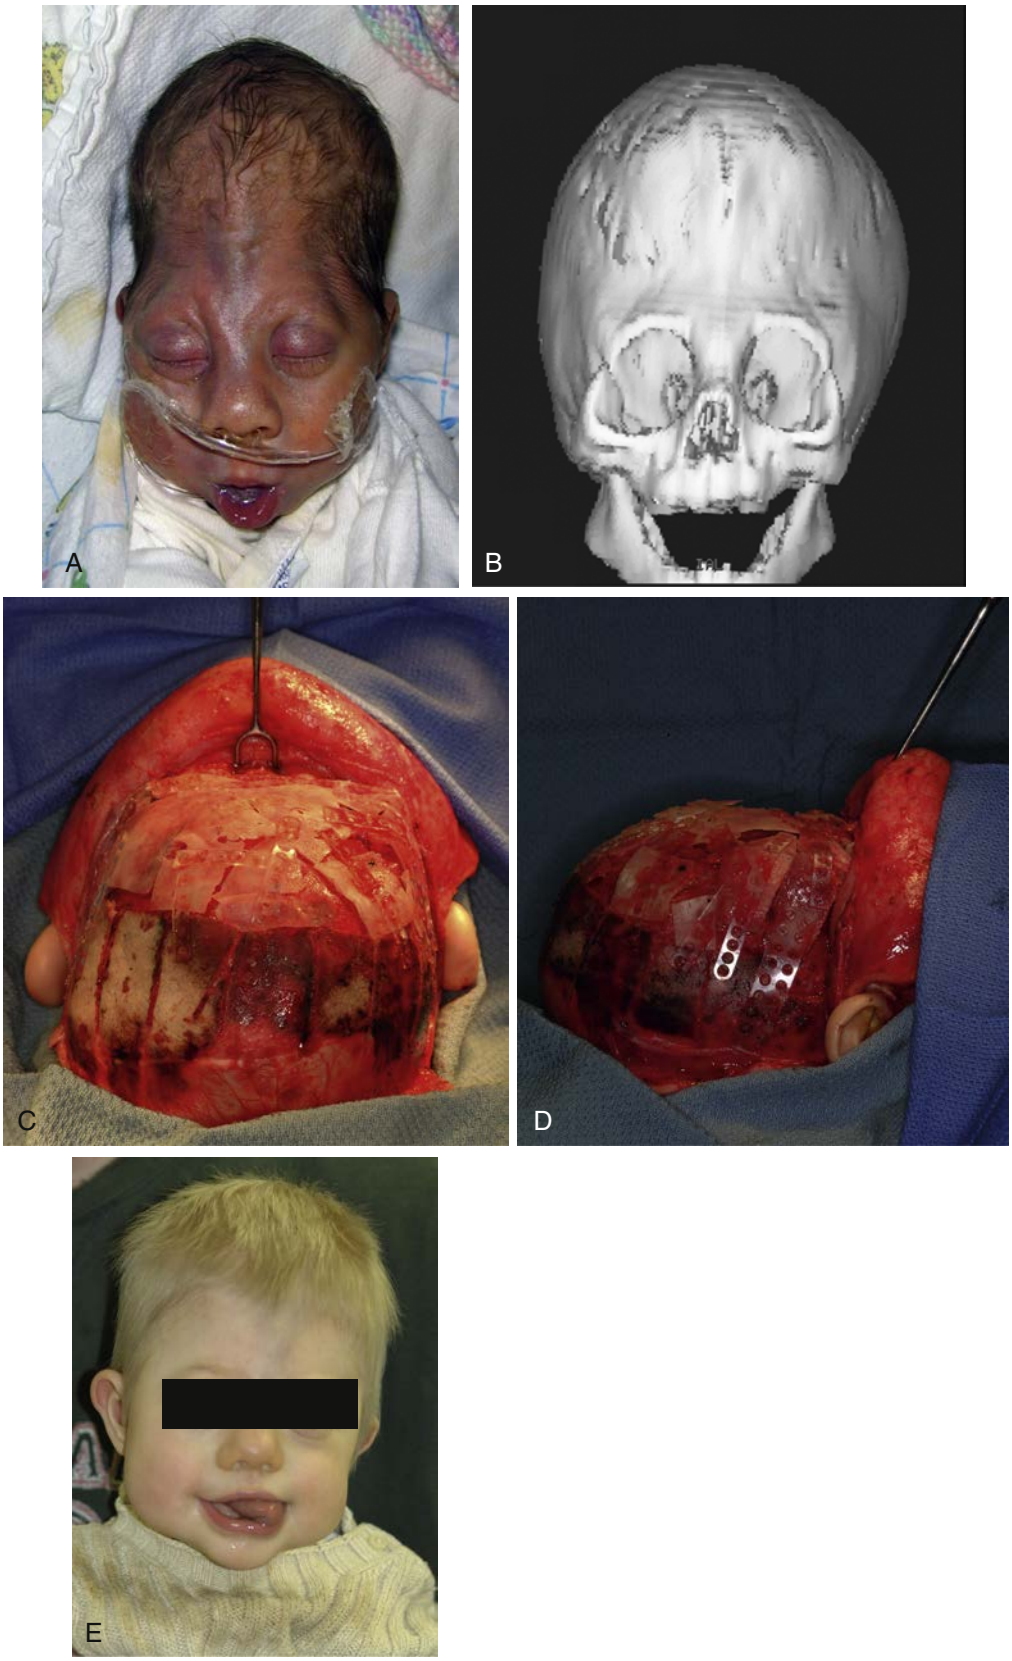
The zygomatic bones grow rapidly in the first year of life and level off in velocity over the next 5 to 7 years. Growth in this area is initially somewhat more gradual when compared with the cranium and orbits, but the vast majority of growth in this area is similarly complete by age 5 to 7. The bizygomatic width is 83% of the mature adult size by the age of 5 years, and the width of the face is mature at 15 years in males and 13 in females.[3,4]

Zygomatic deformities are seen in Treacher Collins syndrome, craniofacial dysostosis syndromes, Down syndrome, achondroplasia, cretinism, and other growth restrictions of the cranial base. The hypoplasia is also evident in the maxilla and nasal complex. Definitive correction in this area can usually be performed after the age of 5 years (Figure 36-4).

Maxilla

Much like the cranium, the maxilla develops by intramembranous ossification of neural crest cells. Maxillary enlargement is a result of early nasal septal growth and later by sutural growth and surface remodeling with a forward and downward displacement relative to the cranial base. Mid-facial height (nasion to gnathion) reaches maturity at 13 years in females and 15 years in males.[3,4] The most active times of growth are between the ages of 1 to 2 years and 3 to 5 years. The height of the mid-face (nasion to stomion) matures slightly earlier in males at 14 years and 12 in females. Mid-facial projection (tragus to stomion) reaches maturity at 14 years in males and 13 in females.[3,4]

The mid-facial hypoplasia seen in patients in craniofacial dysostosis syndromes, achondroplasia, and other disorders is quite impressive, often in all three dimensions.[27] Patients may develop severe anterior-posterior maxillary hypoplasia, transverse discrepancies, and anterior open bites. For these reasons, definitive correction of maxillary dysmorphology



• **Figure 36-2 A,** A newborn with bicoronal and metopic craniosynostosis and Saethre-Chotzen syndrome. Constriction of growth perpendicular to the sutures is evident with the resultant dysmorphology and small cranial vault requiring expansion. **B,** Three-dimensional CT scan showing the cranial vault constriction associated with craniosynostosis. **C** and **D,** Cranial vault reshaping has been performed by disassembling the dysmorphic bones, advancing the cranio-orbital complex, and reshaping the bones to a more normal conformation and expanded volume to accommodate the brain at this critical time of growth. **E,** Postoperative result showing improved cranial vault and orbital morphology.

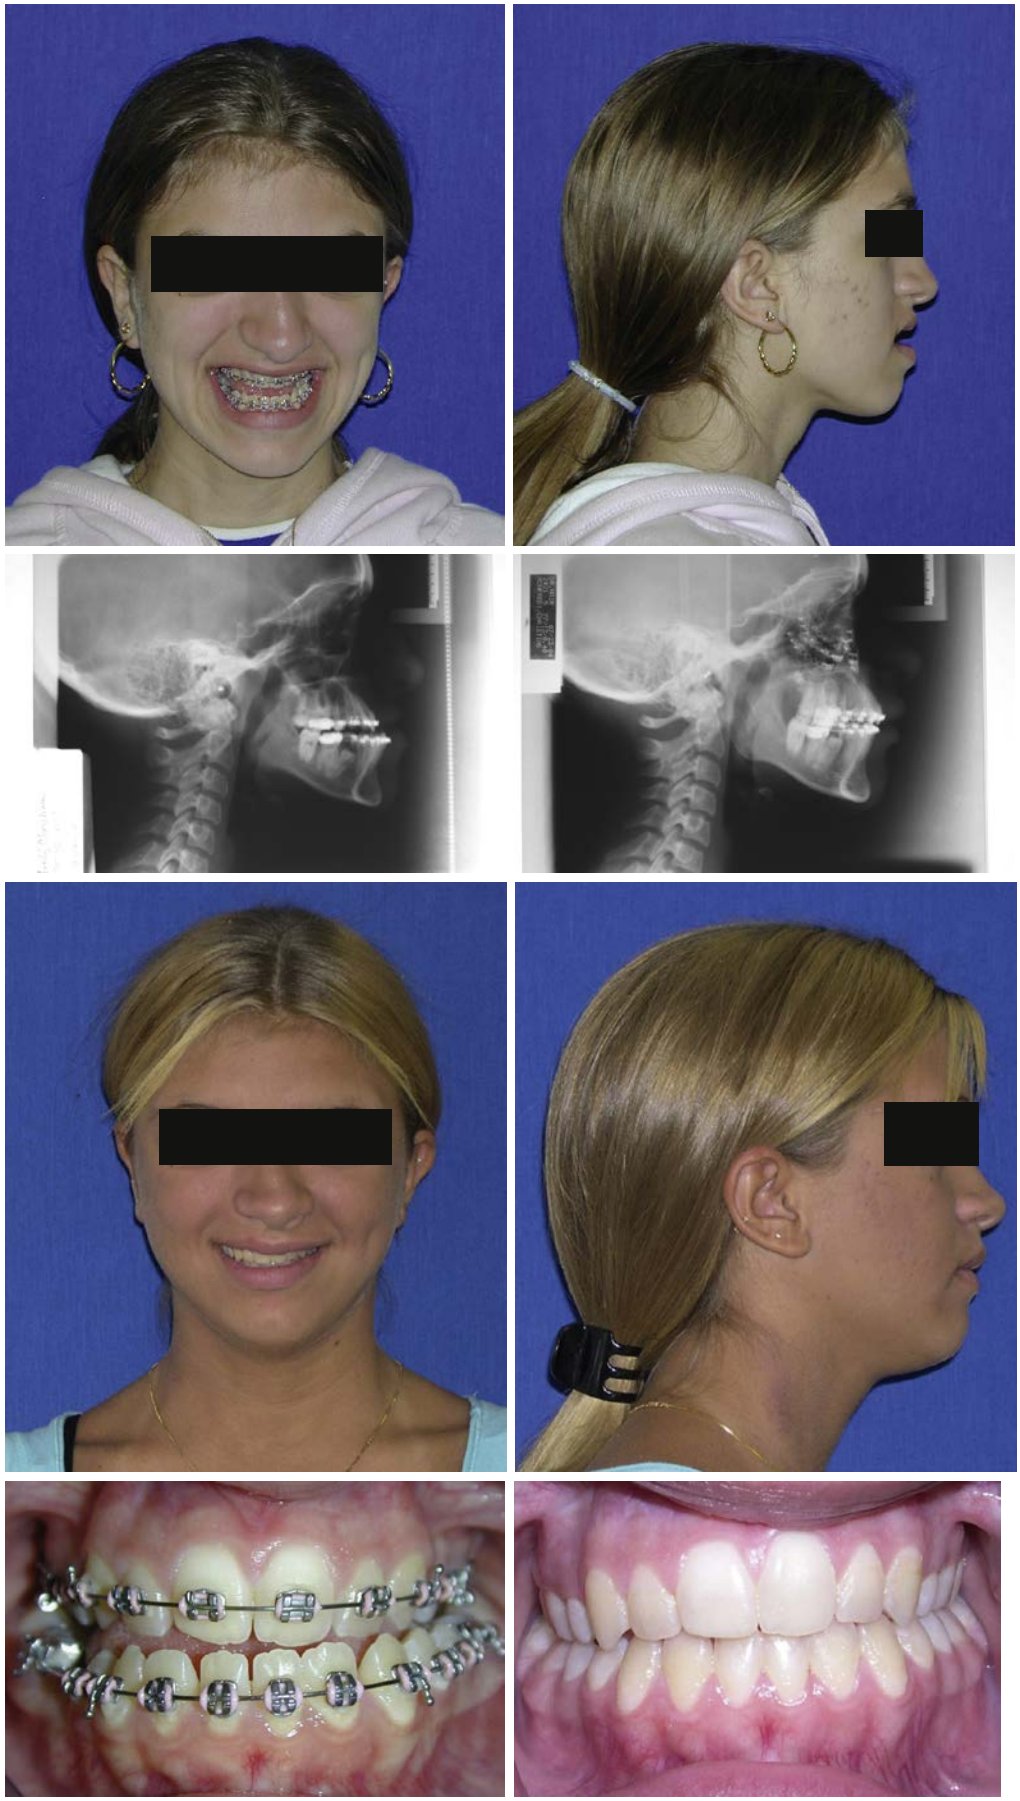
• **Figure 36-3** A young girl with a history of long-standing torticollis that exhibits facial asymmetry and cranial asymmetry. The cranial vault asymmetry has the typical conformation associated with skull molding or positional plagiocephaly. The compensatory changes in the orbit and lower face can be addressed at different times based on their growth velocities and presumed completion of growth.

• **Figure 36-4** This young boy had a facial translocation procedure in infancy for a skull base tumor and postoperative radiation therapy to the left orbit, zygoma, and skull base. At the original procedure, symmetry was quite good, but as the child grew during the following decade, facial asymmetry developed including lower orbital and zygomatic hypoplasia.

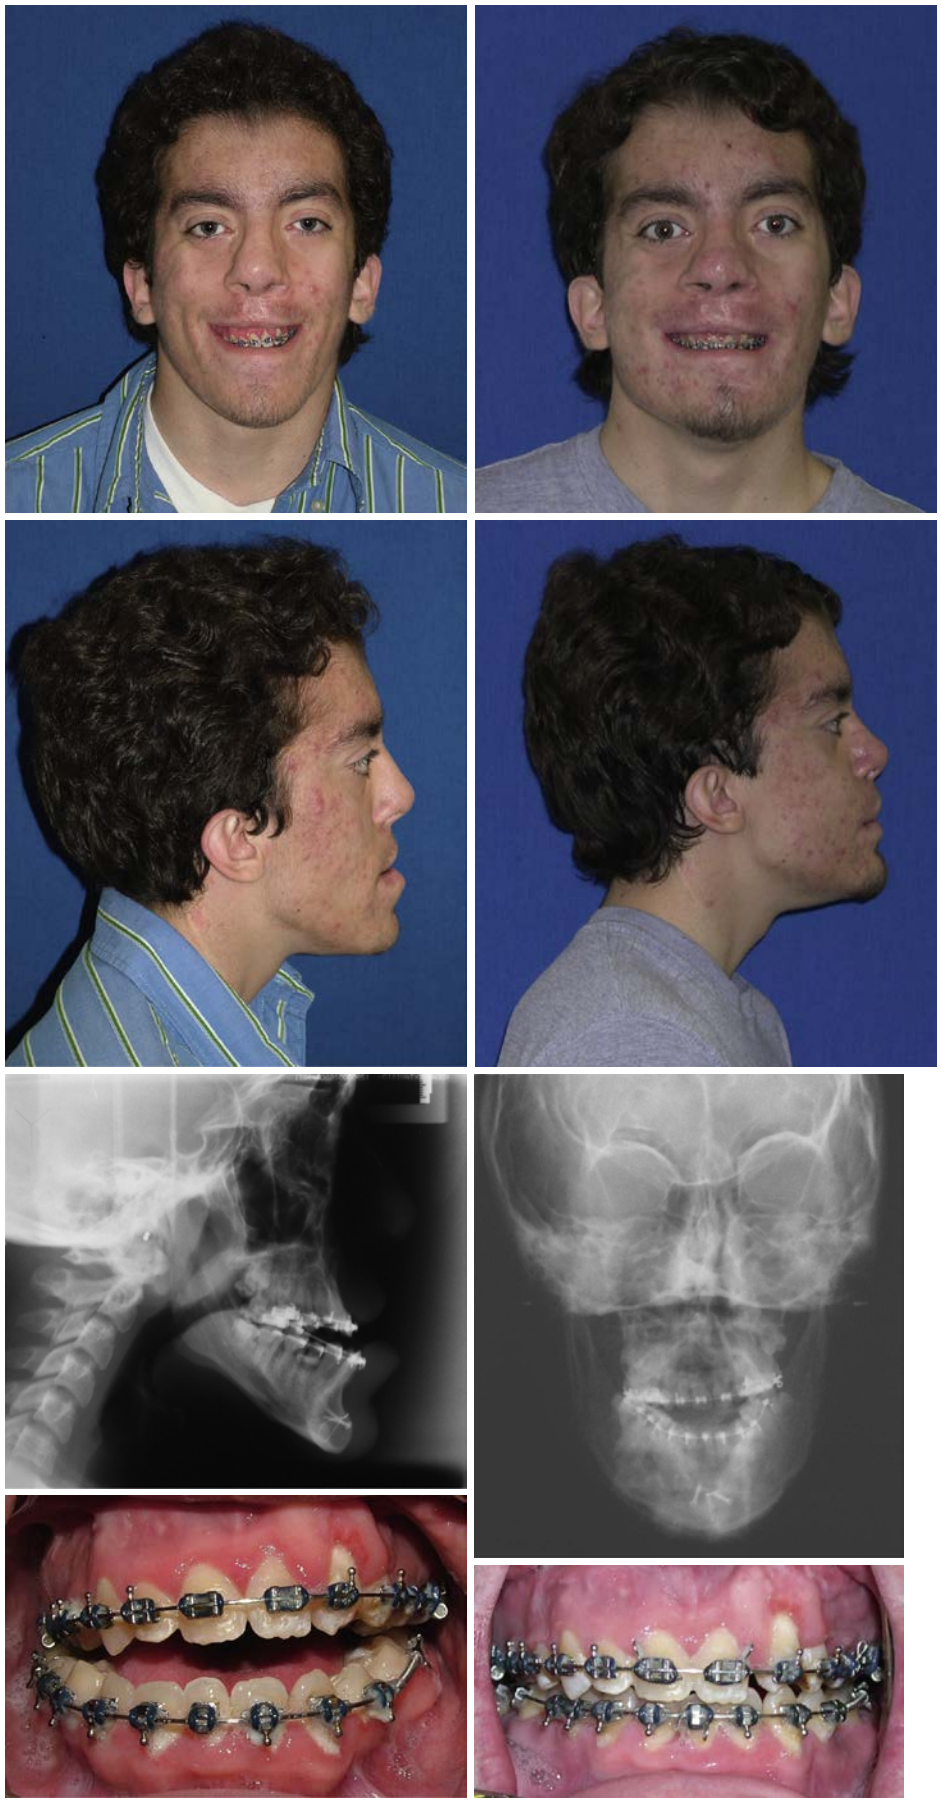
is usually reserved for after the age of 14 in girls and 16 in boys once skeletal maturity has been achieved. When these deformities are particularly severe, early intervention is often entertained. This may include attempts at growth modification (i.e., reverse-pull headgear) or early mid-facial advancement with osteotomies (Figures 36-5 and 36-6).

Mandible

There is a classic notion that the condyle is the independent growth center of the mandible. Although the condyle is relatively important in the growth and development equilibrium, the mandible develops by displacement and remodeling in all regions, not just the condyle. Periosteal apposition (e.g., posterior ramus region), resorption (e.g., anterior coronoid and ramus), and endochondral growth occur in the mandible. The coordinated apposition and resorption results in an inferior and anterior displacement of the mandible throughout the growth phase. Mandibular width is nearly 93% complete by the age of 5 years; however, it does not mature until 13 years in males and 12 in females.[3,4] Mandibular depth (tragus to gnathion) is 85% complete at age 5; however, it does not reach the mature dimension until 15 years in males and 13 in females. Mandibular height is 67% complete by 1 year and 88% complete by 5 years. Mandibular height is mature at 12 years in females and 15 in males.[3,4,28]



• **Figure 36-5** Thirteen-year-old female with Crouzon's syndrome and the typical orbital and mid-face hypoplasia resulting in a Class III skeletal-dental relationship. She underwent a modified Le Fort III procedure advancing her zygomas and maxilla to provide her with positive overbite and overjet. Because the procedure was performed at the near completion of growth, her result has remained stable without a recurrent Class III relationship.



• **Figure 36-6** This young man underwent distraction osteogenesis advancement via a Le Fort I osteotomy with a genioplasty setback by another surgeon when he was 9 years of age. The treatment was complicated by difficulty with vector control and an anterior open bite postoperatively. He subsequently underwent traditional orthognathic surgery repositioning the maxilla and mandible at skeletal maturity for his definitive treatment. He underwent a Le Fort I advancement at skeletal maturity to ensure the most stable result.

Marked alterations in the development of the mandible are found in Cornelia de Lange's syndrome, Nager syndrome, Treacher Collins syndrome, and craniofacial microsomia (Figures 36-7 and 36-8). There is frequently severe mandibular hypoplasia yielding a Class II malocclusion and a high mandibular plane angle, and there may be anomalies of the temporomandibular joint complex. Correction of mandibular deformities is usually reserved until after the age of 16 in girls and 18 in boys. Early intervention for severe deformities may include either growth modification devices or early osteotomies for mandibular advancement.

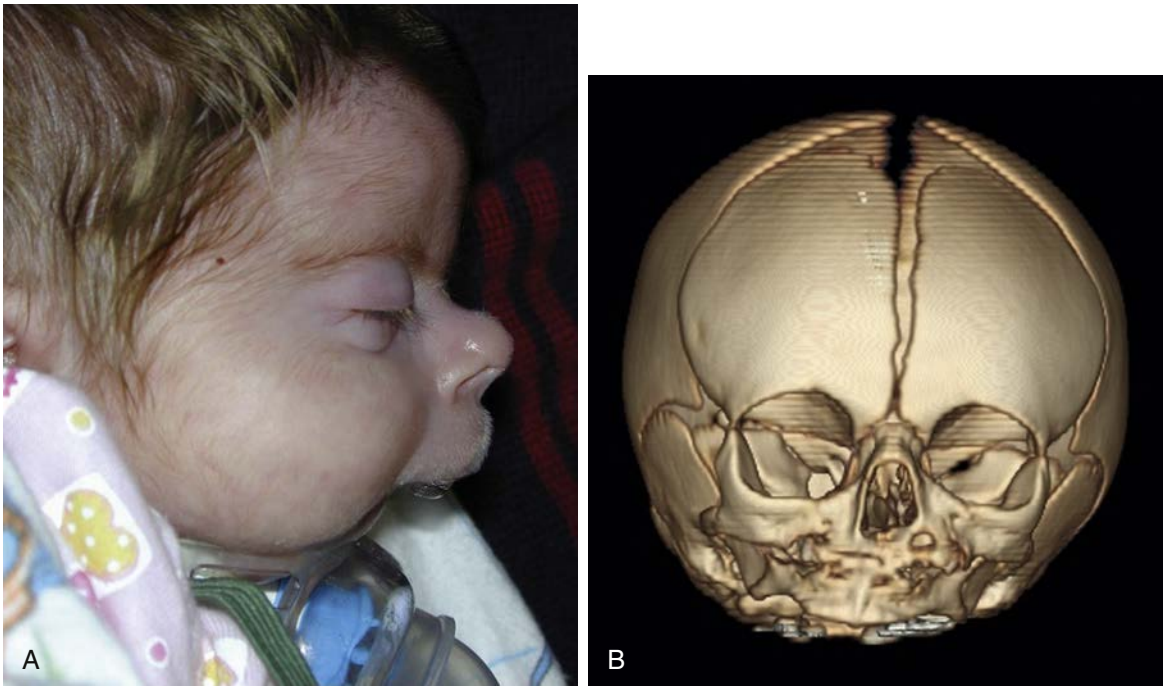
Clinical Evaluation of Craniofacial Growth

There is considerable individual variation seen in the growth of the craniofacial skeleton, and many methods have been developed to assess the individual growth of patients considered for surgical correction of a craniofacial dysmorphology. The evaluation of the craniofacial skeleton can be performed by a number of simple methods based upon both expected norms and concepts of growth and development. There are considerable data on the growth of the facial skeleton in patients without significant deformity or growth discrepancy.[15,16,28] Individual measurements can be made and compared with existing age-matched control data to gain some information about the extent of the deformity. In comparison, there is a limited amount of data available on the various anomalies, and therefore only generalizations can be made with respect to the differences observed with the abnormal relationships.

Anthropometric measurements can be performed on individuals with calipers and correlated with normative data sets.[20-23] This data can be helpful in determining either the amount of correction to be undertaken or in evaluating the success of treatment.[29] Posnick and others[3,4,30] have evaluated individual types of deformities and the success of various surgical corrections using this type of approach, in addition to data generated from measurements performed on computed tomography (CT) scans. Whereas the measurements on CT are generally not practical for clinical practice, they are helpful in the outcome assessment of the surgical correction.[3,4,30]

Hand-wrist plain films have been used for many years to assess skeletal growth and to predict the maturation point of the craniofacial skeleton.[31] The same process can be performed by analyzing the maturation of the cervical spine, and the predictive value of the cervical spine analysis has been purported to be similar to the hand-wrist technique.[32]

One of the best methods to ascertain an individual's craniofacial growth is to evaluate serial cephalometric radiographs. Minimal or no change in velocity of the maxillofacial growth during adolescence is a good indicator of skeletal maturation. Cephalometric radiographs from the same machine using the same technique can be compared 6 or 12 months apart to evaluate for any significant change indicating growth.[16,33]



• **Figure 36-7 A,** A newborn with Cornelia de Lange syndrome who was diagnosed with mandibular hypoplasia as a fetus with ultrasound techniques. She underwent an EXIT procedure with a tracheostomy performed using maternal circulation for a brief period of time to establish an airway. The typical mandibular hypoplasia of this disorder is evident on the lateral view. **B,** Mandibular hypoplasia is evident in another patient with a physical impediment to growth of the mandible. This child has congenitally fused maxilla to the mandible, or syngnathia. The inability of the mandible to function will contribute to hypoplasia over time.

• **Figure 36-8** **A-C,** A teenager with craniofacial microsomia who was born with a Tessier #7 right lateral commissure cleft. The cleft was repaired in infancy by another surgeon, but she retains the right-sided hypoplasia seen with this disorder. **D-F,** A Le Fort I osteotomy, bilateral sagittal split osteotomies, and a genioplasty provide improved facial balance and occlusion in the postoperative views.

Surgical Management Considerations

Cranio-orbital Dysmorphology

Dysmorphology of the craniofacial skeleton is seen in patients with craniosynostosis of various types, including coronal, sagittal, metopic, and the various combinations of multiple-suture craniosynostosis. Craniosynostosis is an excellent example of the balance that is required when considering early correction of a dysmorphology.

By definition, craniosynostosis is the early fusion of one or multiple sutures of the cranial vault. This causes both a telltale dysmorphology and a concern that the intracranial volume is less than the amount required for the rapidly developing brain. This mismatch can cause issues with brain growth, optic nerve function, and overall neurologic development. For this reason, expansion of the cranial vault is considered for some children with this disorder in an attempt to both increase the volume available to the brain for growth and improve the dysmorphology caused by the restriction of cranial vault growth in the affected area.

The importance of brain growth requires that the surgeon consider the treatment of craniosynostosis before the ultimate maturity of the skull, but very early correction is associated with marked relapse and the need for reoperation. For this reason, most surgeons tend to surgically dismantle the cranial vault before 1 year of age but after some growth has occurred; typically, this is beyond the 6-month time period. In cases where multiple sutures are involved, the need for treatment is more urgent, and even earlier treatment is considered knowing that additional cranial vault expansions will likely be required.

The need for revision surgery is higher in patients who have undergone very early correction of cranio-orbital dysmorphology. The concept that early surgery may "unlock" growth has not proven to be sound based on the current understanding of craniofacial growth. However, delaying

the surgical correction significantly may have adverse effects on brain development and optic nerve function. The exact timing remains controversial because no predictable and repeatable measure of either brain growth velocity or intracranial pressure is easily obtainable to allow the clinician to better judge the timing of surgical expansion.

Mandibular Hypoplasia

Mandibular deficiency, with Class II malocclusion, is one of the most common patterns of facial deformity and presents in a variety of expressions. When the mandible is particularly hypoplastic, early surgery in this group is often considered for airway concerns, such as obstructive sleep apnea or tracheostomy dependence. Contrasting results have been reported in the literature pertaining to the outcome of mandibular advancement before skeletal maturation.[7,10-12,34] Direct comparison between these studies is not possible because of the heterogeneity of a number of factors: variation in age, number of patients, presence of associated craniofacial deformities, and osteotomy and fixation techniques. Huang et al[12] reviewed the outcomes of mandibular advancement in 22 growing children and found a variation of response, which appeared to be influenced by the amount of advancement. In those who underwent advancement of 10 mm or more, significant condylar remodeling and/or resorption was demonstrated, with remodeling in the posterior symphyseal region also observed in some cases. These patients had significant "relapse" that continued over several years after the operation. In contrast, the group that underwent advancements of 9 mm or less demonstrated a milder degree of relapse. They found that no significant mandibular growth occurred after 11 years of age, and the mandible returned to its preoperative growth direction within 2 years following surgery. Their patient sample was mixed with the inclusion of four patients with recognized craniofacial syndromes and two with juvenile rheumatoid arthritis. These associated features are significant confounding factors when attempting to analyze the outcomes.

In contrast, a number of authors have reported favorable results following mandibular advancement.[7,10,11,34] An early study by Schendel et al[10] examined the results of sagittal split mandibular advancement, with nonrigid fixation, in 12 growing patients. They demonstrated minimal skeletal relapse and the maintenance of harmonious growth between the mandible and maxilla. In a group of 12 patients, Snow et al[34] demonstrated postoperative mandibular growth in the vertical dimension following sagittal split advancement in 11 of the patients. Vertical maxillary growth was found in a number of cases, and a concurrent vertical lengthening of the ramus was observed, which resulted in the maintenance of the chin position in the horizontal plane and harmonious facial balance. In addition, the occlusion was maintained, in a Class I relationship, over a 5-year period postoperatively in the 12 cases.

The risk factors for relapse in following mandibular advancement appear to be similar to those seen in the skeletally mature patients. Although the number of patients in the studies in growing children is limited, they appear to indicate that preexisting condylar pathologic conditions, high mandibular plane angles, and large mandibular advancements of greater than 10 mm are potential factors for significant relapse and concur with the findings from adult studies.[35-38]

Since the advent of mandibular distraction osteogenesis techniques, there have been numerous reports of mandibular lengthening in the growing child for treatment of facial deformity or obstructive sleep apnea. There are some short-term follow-up reports on growth and development following the distraction procedure; however, at present there are no convincing, published, long-term prospective studies examining subsequent facial growth patterns and outcomes through to skeletal maturation.[39,40] It is not possible to extrapolate the early results and attempt to draw conclusions about long-term outcomes. A recent study by Hopper et al[41] retrospectively assessed mandibular stability in seven cases following advancement with an external distraction appliance at 12 months after the operation. During the consolidation phase, relapse of the mandible was demonstrated with variable amounts of change. Cephalometric analysis revealed clockwise rotation of the mandible with relapse of advancement and posterior movement of the pogonion. Interestingly, the amount of mandibular relapse during the consolidation phase was demonstrated to be greater than that which occurred between the postconsolidation phase and the subsequent 12-month follow-up in some cases. They found an average relapse of 22% during the consolidation phase (range 4% to 41%), and from the period following the end of the consolidation phase to a 12-month follow-up, there was an additional mean relapse of 28% (range 7% to 58%). This degree of relapse asks the question of what the benefit is from early osteotomy in this patient population. Long-term, longitudinal studies are needed to further evaluate the success of these procedures.

Surgery in the small child or infant is potentially challenging for a number of reasons. The performance of sagittal split osteotomies in the growing child can be technically interesting by virtue of the small amount of cancellous bone and increased pliability of the bone, in conjunction with the presence of second molar and impacted third molar teeth. There is a paucity of literature describing the complications that are seen after early osteotomy with or without the use of distraction osteogenesis. Complications include traumatic injury to tooth buds, nerve injury, malunion, nonunion, trismus, ankylosis of the temporomandibular joint, and intraoral and extraoral scarring. For a number of patients, the hoped-for advantages are outweighed by the number of complications seen. As with most complicated procedures in surgery, patient selection is paramount (Figure 36-9).

Despite these concerns, early advancement of the mandible can have a number of advantages for patients who are approaching skeletal maturity, but have significant deformity. For this population, the risk is relatively low, and the benefit is potentially significant (see Figure 36-7). Even very small children with serious functional concerns (i.e., severe obstructive sleep apnea) may benefit from early advancement of the facial structures even knowing that revision surgery is likely or even

• **Figure 36-9** **A** and **B,** A child born with hemifacial microsomia at age 6 who was previously distracted by another surgeon at an earlier age to improve symmetry and occlusion. The previous asymmetry has recurred, and relapse is evident with crossbites and three-dimensional hypoplasia on the affected side. Early surgery can be helpful in many cases for psychosocial or functional reasons, but may require revision osteotomies and additional procedures that may have a higher degree of complexity in the secondary phase. **C,** The patient is now at skeletal maturity with a more complex deformity than the original asymmetry, and is still in need of maxillary and mandibular orthognathic surgery. The three-dimensional deformities are rarely, if ever, completely addressed with either early distraction or growth modification attempts.

certain. In these cases, the benefits may be so great that they outweigh the possible need for additional procedures.

Mandibular Hyperplasia

For skeletally mature patients who undergo the surgical treatment of mandibular prognathism, long-term stability remains a problem, and the nature of the "relapse" appears to be multifactorial. It is recognized that postpubertal mandibular growth is common, and it is unpredictable in its potential for occurrence in individual patients and the degree of growth. The positioning of the proximal segments following mandibular setback and seating of the condyle can be technically difficult, resulting in subsequent forward movement of the mandible post-surgically. These factors combine to make the correction of mandibular prognathism during growth extremely challenging with difficulty in predicting the final position of the mandible. The risk of relapse of this procedure in the growing child is significant. Because it is not possible to predict the amount of future mandibular growth and accommodation for this growth with "surgical overcorrection" at the time of the setback, the procedure itself does not guarantee a successful outcome. For similar reasons in the growing child, orthopedic correction with functional appliances of skeletal Class III patients with mandibular excess and/or vertical excess are poor candidates for growth modification.[42] Buschang et al,[43] demonstrated a worsening of the horizontal relationship between the anterior nasal spine and pogonion positions during adolescence as a result of the differential growth movements of the mandible. It was not unusual for the anterior-posterior relationship to worsen by greater than 4 mm during adolescence. These results concur with the findings of Harris et al who also observed a progressive worsening of dental relationships in Class III cases.[44]

There is a paucity of literature on the effect of surgical mandibular setback in the growing child because the procedure is rarely undertaken before skeletal maturity. Wolford et al have some experience with the early management of this deformity.[45,46] They performed bilateral high condylectomies with articular disc repositioning, either simultaneously with mandibular setback or as a staged procedure, with condylectomies followed by orthognathic surgery for the management of condylar hyperplasia. The concept of this combined approach is to remove the active "growth center" and therefore retard further mandibular growth potential. They reported stable long-term outcomes, with predictable results of the mandibular position, in 25 patients managed with concomitant high condylectomy and mandibular reduction, with a mean age of 16.7 years and range of 13 to 24 years. There are few published reports examining this combined approach for comparison. In general, the procedure of high condylectomy has been reserved for severe cases of condylar hyperplasia during growth, with the correction of the skeletal malocclusion performed after puberty and following the stabilization of the condylar growth pattern (Figures 36-10 and 36-11).

Maxillary Hypoplasia

In the adult patient, the Le Fort I maxillary advancement has been shown to be a relatively stable procedure, and

• **Figure 36-10** Two patients with varying degrees of maxillary hypoplasia associated with unilateral cleft lip and palate. **A,** This patient exhibits a degree of mandibular hyperplasia and maxillary hypoplasia. **B,** The second patient displays a large degree of discrepancy, but a greater degree of maxillary hypoplasia without the severe mandibular hyperplasia.

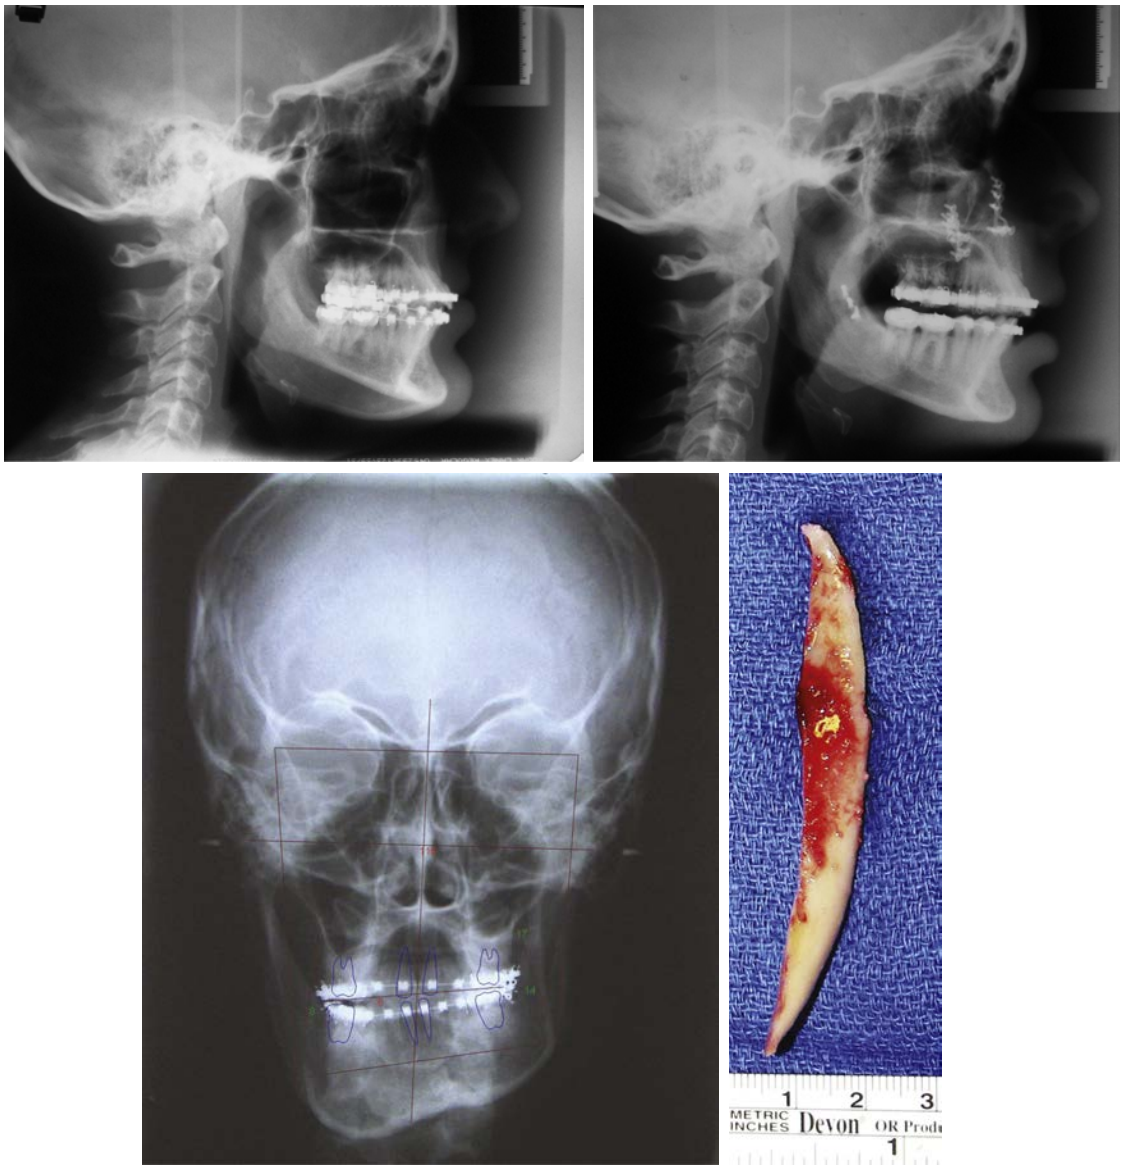
in patients undergoing large maxillary advancements, the stability has been found to be improved by the use of interpositional grafting and rigid fixation.[2,13,47] In the consideration of performing maxillary advancement before the completion of growth, it is imperative to assess the nature of the associated skeletal Class III malocclusion. This may be a consequence of isolated maxillary hypoplasia, mandibular hyperplasia, or a combination of both. As previously discussed, mandibular growth commonly occurs through puberty and can influence the outcome of a surgical result leading to a degree of relapse of the Class III malocclusion. If the maxillary deficiency is the underlying cause of the Class III malocclusion, potentially it may be possible to overcorrect the maxillary position at the time of advancement; however, the planning of the amount of "overcorrection" is an empirical decision by the clinician because there are no predictive guidelines for mandibular growth potential. In the presence of mandibular hyperplasia, the surgical correction of the skeletal deformity in the maxilla and/or mandible before the completion of growth can be undertaken with the proviso that a second surgical procedure may be required in the future to compensate for any significant malocclusion.[14]

In patients with a cleft lip and palate or other craniofacial anomalies associated with significant maxillary hypoplasia, there are potential indications for undertaking maxillary advancement during growth. In patients with skeletal Class III discrepancies of greater than 15 mm, there may be consideration for performing two-stage surgical procedures: (1) maxillary advancement during growth to reduce the degree of deformity and improve facial esthetics followed by (2) definitive orthognathic surgery at skeletal maturity. Correction of these large skeletal discrepancies as a single-jaw procedure is associated with significant relapse and may be detrimental to facial balance and esthetics.[13] Undertaking these large movements even as an early single-stage bimaxillary procedure may still demonstrate significant relapse in some cases.[13,14,48,49] The first-stage procedure of maxillary advancement can be performed either by conventional advancement osteotomy or by the technique of distraction osteogenesis, although in some cases distraction osteogenesis may permit larger advancements to be performed.[48,49]

Whether conventional orthognathic or distraction techniques are used for mid-facial or maxillary advancement, the underlying restriction of maxillary growth remains unchanged. Disproportionate maxillary growth in relationship to the mandible following staged advancement will continue (see Figure 36-6). The control of the vector of movement and the maintenance of proportionate bilateral movement in distraction osteogenesis is technically more difficult. The best occlusal and esthetic outcomes post-growth are obtained by experienced orthognathic surgeons using standard techniques of advancement. There have been a number of reported complications using the technique of distraction, especially if there is inadequate mobilization of the maxilla at the time of surgery, which may result in the unfavorable propagation of forces in the mid-facial complex.[50-52]

The maxillary hypoplasia present in craniofacial dysostosis cases, such as Apert's and Crouzon's syndromes, is often severe and occurs concomitantly with fronto-orbital hypoplasia and exophthalmus. The correction of the position of

• **Figure 36-11** A 19-year-old female with hemimandibular hyperplasia that is now stable based on sequential radiographic reviews and a quiescent bone scan. Preoperative views show the significant degree of three-dimensional asymmetry caused by the growth disturbance. Postoperative views show the balanced facial thirds and optimized occlusion.



• **Figure 36-11, cont'd**

the fronto-orbital complex is usually undertaken between the ages of 5 to 7 years, when approximately 85% of orbital and zygomatic growth has been completed.[20-22,29] The surgical technique undertaken is based on the amount of movement desired at levels of both the frontal bone and orbital complex, and differential movement may be required. The fronto-orbital advancement can be achieved by either a monobloc procedure or by a staged approach with frontal advancement followed by Le Fort III maxillary advancement. The surgery at this stage is undertaken to correct the fronto-orbital complex position and is not based on the occlusion. The Le Fort III advancement can also be performed by conventional osteotomy or distraction osteogenesis techniques[53,54] (see Figure 36-5). At the completion of skeletal growth, the patient will require definitive orthognathic surgery for management of the malocclusion, which is typically a Class III pattern with or without an anterior open bite.

In addition, there are several technical considerations and aspects of performing maxillary osteotomies in the growing patient. The positioning of the second and third molars and the canines are of importance in the patients undergoing early maxillary osteotomies. Performance of the osteotomy cut with the provision of sufficient space above the apices of the permanent dentition is critical. These teeth may still be unerupted or partially erupted. Failing to provide sufficient space at the osteotomy may result in potentially adverse outcomes for the tooth: ankylosis, impairment of root growth, or devitalization. Due consideration for the location of the tooth roots is also imperative during the placement of plates and screws.

Vertical Maxillary Excess

Vertical maxillary excess (VME) has a well-recognized pattern of facial growth and characteristics. There is characteristic elongation of the maxilla vertically and differential lengthening of the maxilla which result in the development of an anterior open bite in some patients. The VME influences the position of the mandible, with the clockwise rotation of the mandible posterior and inferior, and results in an increase in the mandibular plane angle and increased lower facial height. Early animal experiments appeared to indicate a beneficial response to maxillary impaction during growth, with a 50% to 70% reduction in vertical growth postoperatively.[55] However, these experiments were performed in animals with a "normal" maxillary position without the underlying predisposition for the development of VME. An early report by Freihofer[7] in 1977 found that three growing patients who underwent maxillary impaction for correction of anterior open bite deformities showed marked relapse with continued downward movement of the maxillary molars with growth. Subsequent studies have concurred with the findings of the Freihofer[7] study and contrasted with the results of the animal investigations. Mojdehi et al[56] examined the outcome of maxillary impaction in VME in a series of 15 growing patients, with a mean age of 12.8 years, and found that maxillary repositioning did not change the vertical growth pattern of the maxilla. The growth was not normalized nor retarded by early surgical impaction of the maxilla. In addition, they found that there was evidence of adaptive changes in the mandible with postoperative mandibular and condylar remodeling and repositioning. Washburn et al.[8] reviewed the subsequent growth of the maxilla in 16 patients following maxillary impaction undertaken between 10 to 16 years of age. In the group of patients with bimaxillary protrusion preoperatively, counterclockwise mandibular rotation with growth downward and forward of the mandible was observed, with a mild degree of increase in the height of the lower face.

Continued vertical growth of the maxilla can be anticipated despite early maxillary impaction, and this vertical growth rate will be similar to that observed preoperatively, resulting in relapse and recurrence of the VME. The additional feature of differential maxillary or mandibular growth and the development of an anterior open bite tendency further complicate the potential for undertaking surgery before skeletal maturation (Figure 36-12).

If the patient would benefit from early surgical intervention for psychosocial reasons, adequate warnings regarding the propensity for relapse and the necessity for an additional surgical procedure at the completion of growth are required. To attempt to reduce the chance of development of an open bite postoperatively, it is advisable to maximize the overbite at the time of surgery.

• **Figure 36-12** This adult patient exhibited VME and some mandibular hypoplasia early in life, but developed a late growth phase open bite in her teen years as a result of disproportionate growth of the posterior maxilla. She reports not having an open bite in the younger years of her childhood. She has a long history of obstructive nasal breathing, tonsil hypertrophy, and loud snoring.

Summary

The aims of craniomaxillofacial surgery are to improve function, occlusion, craniofacial balance, and esthetics. Accurate diagnosis, assessment, and careful treatment planning are essential in achieving a successful outcome, and an understanding of the pattern of facial growth is integral in this process.[14,57] Particular attention to the perioperative airway concerns is warranted in these patients, especially when associated with a syndrome or limited temporomandibular joint movement.

The psychological implications of dentofacial deformity have been investigated in a number of studies.[13,58,59] Psychological parameters, such as self-confidence, self-esteem, insecurity, and identification with body image, are intrinsically related to the patient's perception of their facial appearance. A self-perception of an abnormal facial appearance may affect an individual's psychosocial development and interactions. This is especially true during adolescence, which may have important longer-term ramifications. Whereas a single-definitive operation performed at skeletal maturity is preferable for patients who have a significant deformity, psychological implications may present a compelling reason to consider early orthognathic surgery.

The decision to proceed with surgery before the completion of growth is complex and should not be made lightly. Comprehensive understanding of the development of the facial skeleton is critical in this decision process. The patient and his or her family must be fully apprised of all the implications and involved in the decision process. When early surgery is considered, the risk of relapse following surgery during growth necessitating a further surgical procedure at maturity should be discussed in detail with the patient and family. In some cases, such as in the presence of severe maxillary hypoplasia, a two-stage surgical approach may be part of the overall treatment plan.

There are a number of patients who benefit from early surgical intervention before maturation, and careful diagnosis and treatment planning and full consultation with the patient and family are vital when considering craniofacial surgery in the growing patient.

Nonsyndromic Craniosynostosis: Diagnosis and Contemporary Surgical Management

RAMON L. RUIZ, MICHAEL JASKOLKA, ANN M. RITTER, TIMOTHY A. TURVEY, BERNARD J. COSTELLO

Introduction

Cranial sutures represent a form of articulation in which the margins of the bones of the cranial vault are connected by a dense layer of fibrous tissue. The cranial vault is composed of six major (Figure 37-1) and several minor sutures. Initially, the sutures allow head deformation during vaginal delivery as part of the birthing process. Later, during an infant's postnatal development, cranial vault sutures facilitate head expansion to accommodate propulsive brain growth.[1] Only small amounts of pressure (5 mm Hg) from the growing brain are required to stimulate bone deposition at the margins of a cranial bone.[2,3] Under normal conditions, the brain volume will triple within the first year of life, and by age 2, the cranial capacity is four times that at birth.[4]

The term *craniosynostosis* is defined as the *premature fusion* of one or more of the cranial vault sutures. With rare exception, this is an intrauterine event so that a more accurate description of craniosynostosis may be a *congenital absence* of the cranial vault suture(s). The result is fusion of the bones at the suture and arrested growth. The classic theory expressed by Virchow states that premature fusion of a cranial vault suture results in limited development of the skull perpendicular to the fused suture and a compensatory "overgrowth" through the sutures that remain open.[5] This concept was further extended by Delashaw to more completely explain the characteristic dysmorphology that occurs depending upon which of the cranial sutures is affected.[6]

In general, most forms of nonsyndromic craniosynostosis are thought to represent sporadic events. Even though a positive family history may be found in 2% to 10% of cases a clear etiologic explanation is usually absent.[7] This implies a combination of genetic promoters and impact of epigenetic and environmental factors, such as maternal thyroid disease.[8] Advances in molecular and cytogenetic testing as well as large population-based studies such as the U.S. National Birth Defects Prevention Study will continue to further explain the etiology of nonsyndromic craniosynostosis.

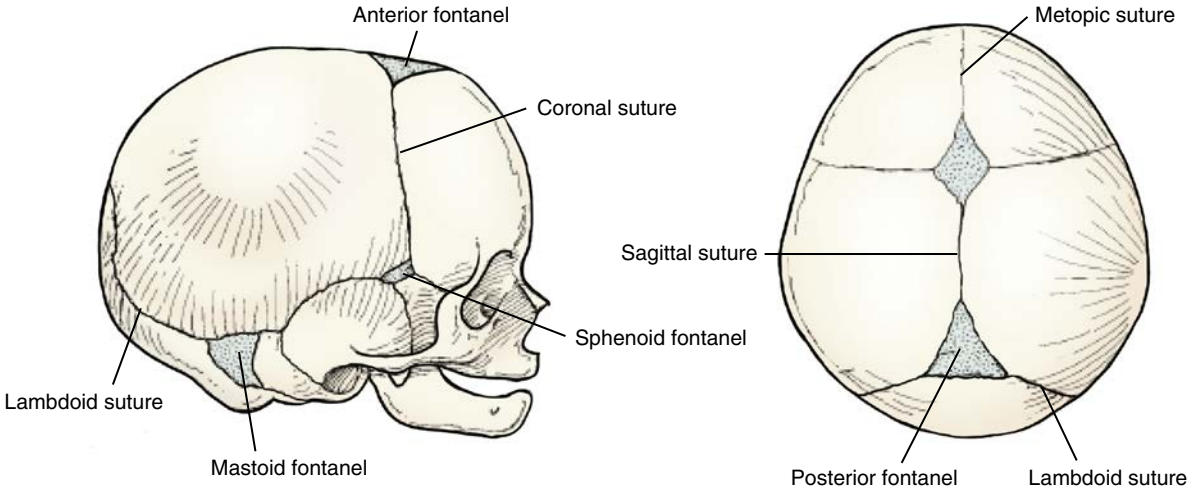
Malformations resulting from craniosynostosis affect the cranial vault and orbital regions. Management typically requires a combined neurosurgical and craniofacial approach for release of the involved suture so that unrestricted brain growth and reshaping of the dysmorphic skeletal components can occur.

Functional Consequences of Craniosynostosis

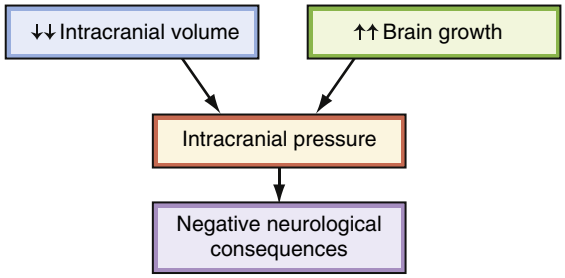
Brain volume expansion occurs at a rapid rate during the first 2 years of life. During this time, it is growth of the visceral structures (i.e., brain and eyes) that drives the growth of the skeletal structures (i.e., cranial vault and orbits). Patent cranial vault sutures create a flexible complex of cranial bones that allow the growing brain to push them outward. Cranial growth occurs both at these open regions in a direction that is perpendicular to each suture and through endocranial resorption in combination with ectocranial deposition of bone.

Intracranial Pressure

The congenital absence of a cranial vault suture results in fusion of the adjacent bone plates with arrested growth along that suture. Although compensatory growth occurs at the uninvolved sutures, it is hypothesized that a reduction in cranial volume ensues. The combination of a rapidly expanding brain and diminished cranial volume secondary to the restricted cranial growth may result in increased intracranial pressure (ICP), greater than 15 mm H_2o, with negative neurologic consequences.



• **Figure 37-1** During infancy, the cranial vault sutures remain open to allow for normal brain growth. Major cranial vault sutures include the metopic, right and left coronal, sagittal, and right and left lambdoid. (From Ruiz RL, et al: Nonsyndromic craniosynostosis: diagnosis and contemporary surgical management, *Oral Maxillofacial Surg Clin North Am* 16:447-463, 2004.)



• **Figure 37-2** The relationship between diminished bony growth caused by craniosynostosis and increased ICP with resultant neurologic damage. Although this description of events is incomplete, it represents one of the basic considerations upon which surgical management is based. (From Ruiz RL, et al: Nonsyndromic craniosynostosis: diagnosis and contemporary surgical management, *Oral Maxillofacial Surg Clin North Am* 16:447-463, 2004.)

This sequence of events (Figure 37-2) is often used to explain the theoretic relationship between craniosynostosis and brain insult, but it does not adequately explain why some patients will develop elevated ICP and others will not. Not all patients with craniosynostosis demonstrate reduced intracranial volume.[9-11] Additional factors may include localized areas of pressure secondary to abnormal morphology, variations in CSF production, flow and absorption, increased venous resistance, anomalous venous drainage, and airway obstruction. In the classic study published in 1982 by Renier and colleagues, increased ICP was recorded in 14% of children with untreated single-suture craniosynostosis. When two or more sutures were fused, the likelihood of elevated ICP increased to 47%.[2,12] Other investigations have more recently reported a range of increased ICP in 4.5% to 44% of similar patients continuing to support raised ICP as a pathologic finding in patients with nonsyndromic craniosynostosis.[13,14]

Children with untreated craniosynostosis who go on to develop increased ICP may exhibit a number of neurologic changes, including headaches, vomiting, sleep disturbances, feeding difficulties, behavioral changes, and diminished cognitive functioning.[2,12,15,16] Symptoms related to increased ICP are rarely encountered before 1 year of age and frequently have a slow, gradual onset. In the pediatric patient, these are difficult to detect and, left untreated, may be irreversible.[16] Recognition of these neurologic signs and symptoms is further complicated by the young age of the patients with craniosynostosis who cannot yet communicate these physical findings to alert parents and examiners.

Hydrocephalus

Hydrocephalus is not usually observed in patients with nonsyndromic single-suture craniosynostosis, but it may occur independently and not necessarily as a consequence of this condition. In contrast, hydrocephalus is encountered in approximately 10% of children with multiple-suture craniosynostosis and may be seen in the craniofacial dysostosis syndromes.[17-19] The correct diagnosis may require serial neurosurgical evaluations, computed tomography (CT) scan, magnetic resonance imaging (MRI), and cerebrospinal fluid (CSF) flow studies.

In cases where the infant has both hydrocephalus and craniosynostosis, careful consideration must be given to the exact timing and sequence of the cranial vault reshaping and ventriculoperitoneal (VP) shunt placement. Although the final decision is a neurosurgical one based on the child's neurologic condition, placement of the VP shunt should be performed as a separate surgery after the cranial vault reconstruction when possible. The presence of a VP shunt at the time of synostosis repair may decrease brain expansion in the postoperative period, thus reducing physical support to the bone segments and delaying the elimination of extradural dead space.[16]

Ophthalmologic Effects

In patients with craniosynostosis and associated elevated ICP, the optic nerve is at risk. Prolonged, untreated ICP elevations can produce papilledema, optic nerve atrophy, and eventual loss of vision, which may be complete. With this in mind, pre- and postoperative dilated ophthalmologic examinations are often undertaken to help screen for the presence or recurrence of increased ICP. Although they may be used to support the diagnosis of elevated ICP, the absence of papilledema is not necessarily effective at excluding its presence in an infant.[20]

When the specific form of craniosynostosis produces orbital deformity or asymmetry, negative impact on visual function may be realized. For example, orbital dystopia secondary to unilateral coronal synostosis can result in disturbances of extraocular muscle movement (i.e., strabismus), upper eyelid ptosis, and poor binocular vision. In cases of syndromic or nonsyndromic bilateral coronal suture craniosynostosis, decreased orbital volume will cause proptosis with an increased risk of direct trauma to the eye and corneal exposure or ulceration.

Neurodevelopmental Considerations

Nonsyndromic craniosynostosis is associated with a risk of neurodevelopmental impairment. This has been documented in treated and untreated patients in terms of cognitive, language, and psychomotor abilities.[21,22] Hypothesized mechanisms include elevated ICP, localized areas of intracranial pressure and reduced cerebral blood flow, and abnormal cerebral shape due to abnormal cranial and skull base morphology. The use of MRI has helped to elucidate other intracranial abnormalities including those in the cortical and subcortical structures.[23,24]

It is hypothesized that suture release and cranial vault remodeling is beneficial in limiting the severity or progression of delay, but this has yet to be proven. Many questions remain regarding the impact of timing and surgical procedure on neurodevelopmental outcomes. Ongoing studies are attempting to more clearly define the incidence and severity of impairment and their association with the different types of nonsyndromic craniosynostosis and their treatment.[25] Regardless of the hoped for impact of surgery, this is a patient population that is at high risk for developmental delay.[22] The most recent multidisciplinary practice parameters for care of the patient with single-suture craniosynostosis recommend perioperative neurodevelopmental screening and referral for early intervention therapy.[26]

Diagnostic Approach to Abnormal Head Shape

When an infant has a cranial vault asymmetry, the examiner must be alert to the possibility of prematurely fused sutures. However, abnormal head shape may be produced by various causes that must be distinguished from craniosynostosis. Most commonly, external forces applied to a flexible cranium with open sutures cause a "deformation" of the skull. In newborns, this deformational plagiocephaly is often the direct result of the head passing through the birth canal or the baby's early descent into the true pelvis and may involve the anterior and posterior cranial vaults.[27,28] Another common cause of deformational plagiocephaly are the postnatal external forces that result from repetitive sleep positioning. In 1992 the American Academy of Pediatrics made the recommendation that infants be placed on their backs during sleep, which has lead to an approximate 40% reduction in the risk of sudden infant death syndrome (SIDS).[29] However, associated with the "Back to Sleep" campaign came an increased awareness of cranial vault deformities within the pediatric community; an increased number of referrals for management of nonsynostotic posterior plagiocephaly has resulted.[30,31]

Accurately differentiating which cranial vault deformities are the result of nonsynostotic causes (i.e., positional plagiocephaly) and which are associated with a true absence of a cranial vault suture (i.e., craniosynostosis) is critical to establishing a diagnosis and formulating the appropriate treatment plan. The importance of a correct diagnosis is underscored by the dramatically different treatment approach to each condition. Craniosynostosis requires surgical treatment, whereas benign positional skull molding (positional plagiocephaly) is not associated with any neurologic consequences and typically requires conservative nonsurgical management. These techniques include patient counter positioning, the selective use of custom-made cranial orthotic devices, and in the case of torticollis, neck physical therapy.

A careful history and clinical examination are the primary basis upon which the diagnosis of craniosynostosis is made. As craniosynostosis is an intrauterine event, parents will often report that the deformity was noted immediately after birth and never improved after that time. In contrast, the typical history provided in cases of positional plagiocephaly is that the child's head was well rounded at the time of birth and the asymmetry was noted 3 to 6 months later, suggesting postnatal deformation of a flexible cranial vault.

Clinical examination of the infant with craniosynostosis is a key element in establishing the diagnosis. Craniosynostosis leads to arrested skeletal growth perpendicular to the affected suture through continued or compensatory growth at the sutures that remain open. This combination of arrested growth in one region and additional growth in others explains how unilateral sutural involvement results in a bilateral deformity and how fusion of one suture within the posterior cranial vault produces a deformity that affects the entire anteroposterior (AP) dimension of the cranium. An examiner familiar with these aberrant growth patterns and the characteristic dysmorphologies specific to each type of synostosis will be able to consistently establish an accurate clinical diagnosis. Following clinical evaluation by a pediatric craniofacial surgeon and/or pediatric neurosurgeon, radiographic imaging

is indicated for confirmation of the diagnosis. A complete skull series of plain radiographs may be used to evaluate the cranial vault sutures. In cases where all of the sutures cannot be adequately visualized using plain films, additional imaging with the use of a computed tomography (CT) scan of the craniofacial region is indicated. In addition to confirming the diagnosis, high-resolution craniofacial CT scans provide detailed three-dimensional morphologic information, which is useful during the surgical planning phase. High-resolution CT scans with 0.6 millimeter axial and coronal cuts with overlap and 3D reconstructions of the cranial vault, cranial base, orbits, and maxillofacial skeleton are recommended. Precise patient positioning is important in obtaining a diagnostic scan. In the past, infants may have required sedation or general anesthesia for appropriate image acquisition, but modern day rapid multislice scanners have largely made this less frequent.

Although technologic advancements have dramatically increased the accuracy of standard radiographic imaging, incorrect and outdated terminology is still occasionally used in describing cranial vault sutures. At some medical centers, radiologists and surgeons continue to use terms such as "fibrous synostosis," "suture dysfunction," and "impending synostosis" when describing cranial vault sutures that otherwise appear open. We now know that craniosynostosis is in the vast majority of cases an intrauterine event that is either present at birth or not at all.[16,31] Therefore if a suture appears patent on a radiographic study that is of diagnostic quality, the diagnosis of craniosynostosis is ruled out. Although the pathologic postnatal fusion of cranial vault sutures has been described in the scientific literature, it is considered an extremely rare event that is specifically related to specific clinical and syndromic conditions. The use of the terms described earlier is not consistent with contemporary knowledge about craniosynostosis, may be confusing to parents and health care providers, and may even result in inappropriate surgical treatment for patients who do not truly have craniosynostosis.

When reviewing radiographic imaging of the infant cranial vault, an additional important consideration is the metopic suture. Normal (e.g., physiologic) closure of the metopic suture occurs between 3 and 8 months of life, starting at the nasion and progressing towards the anterior fontanelle.[36,37] Therefore, radiographic absence of the metopic suture in an older infant with no craniofacial dysmorphology (e.g., trigonocephaly, hypotelorism, horizontally retrusive lateral orbital rims) is not craniosynostosis and rather a physiologic, appropriate, closure of the metopic suture.

Treatment of Nonsyndromic Craniosynostosis

General Considerations

There are two primary objectives in the contemporary surgical management of nonsyndromic craniosynostosis: first, the release of the involved (i.e., fused) suture so that brain growth can proceed in an unrestricted fashion and second, the reconstruction of all dysmorphic skeletal components so that a more anatomically correct shape is achieved. The best results are achieved with collaboration between a pediatric craniofacial surgeon and pediatric neurosurgeon.

Surgical techniques historically used to treat craniosynostosis involved only the removal of the involved suture via a "strip craniectomy."[38,39] Generally, these limited craniectomy procedures would be performed by a neurosurgeon working independently. The theory behind this approach was that release of the suture would allow unrestricted brain growth and that the expanding brain would adequately recontour the bones, prior to refusion, without the need for formal craniofacial reconstruction. Although this approach may allow for some cerebral decompression, the reality is that a dysmorphic skull will not reshape itself, even in the presence of an expanding brain, and the result is a residual bony deformity.

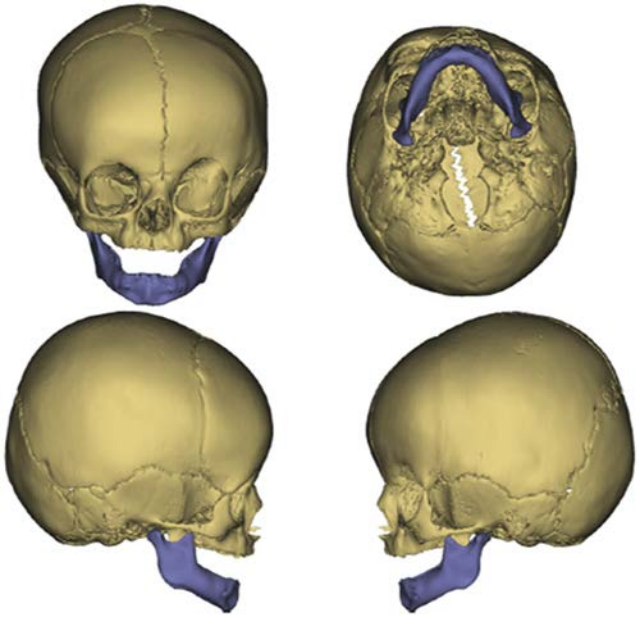
Modern surgical management of craniosynostosis involves release of the involved suture(s) with a formal craniotomy performed by a neurosurgeon. At the same time, reconstruction requires the removal, dismantling, and reassembly of all dysmorphic skeletal components into a more anatomically correct position. Depending upon which specific cranial vault suture is affected, the reconstruction may also involve the orbits. The exact surgical plan is formulated based on the extent of the skeletal deformity, the suture or sutures involved, and the age of the patient at the time of diagnosis. In most cases of nonsyndromic, single-suture craniosynostosis, one operation to simultaneously release the suture and reshape the affected skeletal parts will adequately address the problems definitively. This is more likely when the surgical procedure is carried out during the first year of life and the patient has normal brain growth. In addition to a combined craniofacial and neurosurgical approach, involvement of a number of other pediatric subspecialists, including pediatric anesthesiologists and pediatric intensivists, is required.

In recent years, there has been resurgence in strip craniectomy procedures with the recognition that adjunctive interventions must also be used to improve the dysmorphology. The most popular of these approaches are endoscopic assisted suturectomy with postoperative cranial orthotic molding. The endoscopically assisted approach includes a strip craniectomy for the release of the involved suture(s) and the creation of multiple "barrel-stave" osteotomies within the cranial vault.[40-45] The primary advantage of this technique is a smaller surgical incision. Other theoretical advantages include shorter operative times, reduced need for blood transfusions, less morbidity and shorter length of hospitalization. The main disadvantage encountered with the use of an endoscopic procedure is that the surgical maneuvers performed do not address the cranial and/or orbital dysmorphology and residual

deformity, which remains following the surgical procedure. The child's cranial vault dysmorphology is treated with the use of a postoperative custom molding helmet (i.e., cranial orthotic). Full-time orthotic wear often begins 7 to 10 days following surgery and may be required for 9 to 12 months with an average use of 3 helmets.[45] There is theoretical concern over the extended use of a device with the potential to restrict growth of the brain and skull, and so close supervision and adjustments of the device by an orthoptist is necessary. Application of this technique is most predictable in patients with cranial deformities that are mildly dysmorphic. Because the successful use of custom-made cranial orthotic devices (e.g., bands or helmets) is largely dependent upon ongoing rapid brain growth for reshaping, children diagnosed with craniosynostosis after 6 months of age are not considered good candidates for endoscopic treatment. A final concern is the representation of endoscopic surgery as "nonsurgical" or "minimally invasive." Although the length of the incision used is decreased, significant complications including hemorrhage, laceration of the sagittal sinus, the need for blood transfusion, dural tears, and brain injury are possible. Blood transfusion is required in a portion of children undergoing the operation. Surgeons contemplating an endoscopically assisted procedure must be aware of these potential problems and make standard preparations (e.g., type and cross blood, secure neurosurgical support) to deal with them as necessary. A less commonly discussed procedure is spring assisted cranioplasty. This technique involves a similar craniectomy for release of the fused suture and placement of a spring, which provides continuous force across the sutural area in order to facilitate expansion of the cranial vault.[46] The hoped for advantage is a limited procedure (e.g., isolated craniectomy) with expansion provided by the spring device following the procedure. Disadvantages include a surgical procedure that is limited to suture release with no reshaping of the dysmorphic skeletal components and spring devices, which in their current stage of technical refinement, are only unidirectional and provide no three-dimensional control. Another disadvantage is the requirement of a second surgical procedure and general anesthetic for device removal.

Surgical Planning

One of the primary goals of surgical treatment of nonsyndromic craniosynostosis is the normalization of the dysmorphic cranium and orbits. To achieve this goal, careful preoperative planning is a necessity. The ubiquitous use of CT scans for the diagnosis of craniosynostosis has combined with the mainstream availability of software-based computer systems to make 3D virtual manipulation an increasingly accessible option. In general, following CT acquisition, DICOM data is segmented and a virtual model constructed (Figure 37-3). Osteotomies are then designed and the resulting bone segments repositioned. Multiple iterations of the surgical simulation can be developed (Figures 37-4). The application of normative data sets[47,48] allow for quantification of the presenting deformity as well as idealization of the final result. After the simulated treatment plan has been finalized, transfer of this information to the patient during surgery can be facilitated with the use of rapid prototyped templates (Figures 37-5).



• **Figure 37-3** Preoperative virtual model of a patient with left sided unilateral coronal craniosynostosis.

Increased cost is always a concern when adopting new technology and should be offset by improved patient outcomes. The virtual surgical planning process described above has been shown to be accurate when applied in the clinical setting, and it is postulated that there is a reduction in operative time and improved skeletal repositioning. This has been demonstrated in the orthognathic surgery literature,[49] but has yet to be definitely proven in the realm of craniosynostosis reconstruction.

Another consideration must weigh the benefit of virtual surgical planning with the potential negative impact of radiation exposure from the CT scan. If CT is used in the diagnostic workup, the scan can be used for virtual planning as long as a minimum axial slice thickness of 1.0 mm is acquired and stored. If the CT dataset is acquired with a significant interval prior to surgery, the fit of the CAD/CAM templates may be poor due to the interval growth of the skull. Although an additional CT scan may be considered, modification of the original CT scan based upon head circumference change has shown to be an accurate method to account for skull growth in this scenario.[50]

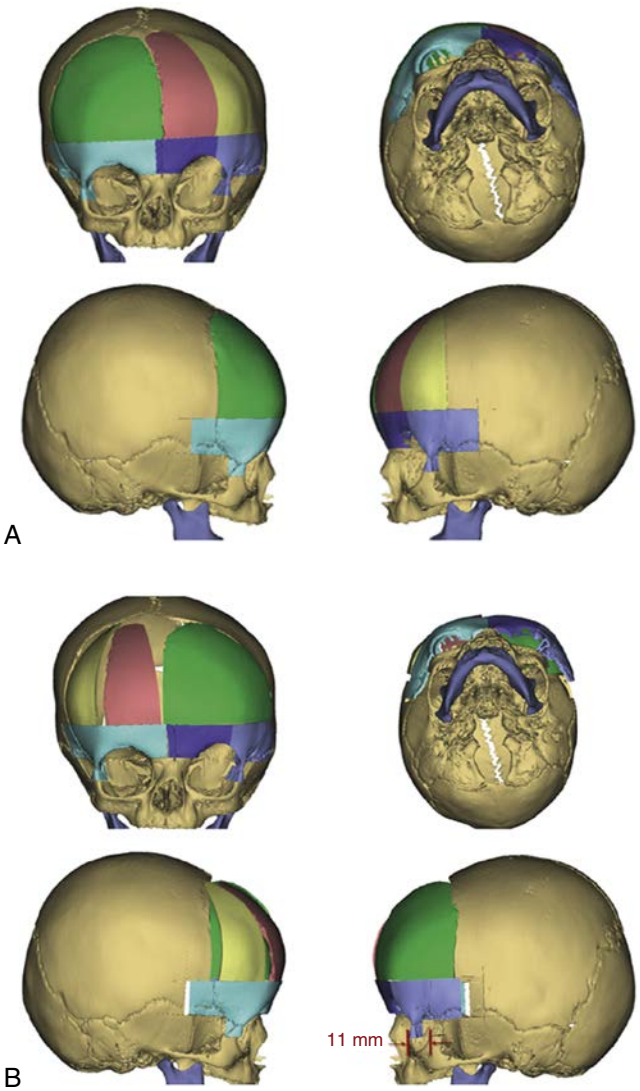
Timing of Surgery

In almost all patients with single-suture craniosynostosis, elevated ICP is not encountered before 1 year of life. A

diagnosis of craniosynostosis made before 12 months of age does not represent a "surgical urgency" because the risk for the child of developing increased ICP is minimal during this time period. The fused suture and cranial vault dysmorphology can be safely addressed at some point during the first year before the possibility of elevated ICP increases.

The specific, ideal age at which to proceed with craniosynostosis repair is a subject that remains controversial. A wide range of recommended ages exists among pediatric craniofacial and neurologic surgeons who routinely perform these procedures. Some surgeons advocate for a relatively "early" repair carried out at approximately 3 to 6 months of age, whereas others postpone surgery until after age 9 to 11 months.[16,51] There are theoretic advantages and potential negative consequences associated with each approach.

Early surgical correction carried out when the child is 3 to 6 months of age is often suggested by surgeons who believe that releasing the suture early will "unlock" normal growth and allow the brain to perform most of the bony reshaping as it expands, thus reducing the degree of bony remodeling required at the time of surgery. This theoretic advantage, however, does not obviate the need for formal skeletal reconstruction to establish the desired anatomic configuration of the cranium. Bone segments in younger infants are more malleable, which permits easier reshaping, and the growing brain does provide rapid elimination of extradural dead space and support for the newly constructed bony framework.



• **Figure 37-4** **A,** Osteotomies completed on the virtual skull model. **B,** Repositioning of the osteotomized bone segments

Delaying the surgical procedure until approximately 9 to 11 months of age permits a greater proportion of the child's cranial vault growth to occur before correction. This may translate into a more stable skeletal result with fewer postsurgical distortions related to subsequent growth. At this age, the bones are better ossified and more cortical, which results in less separation at sutural lines (e.g., frontozygomatic suture) and easier placement of rigid internal fixation devices.

Irrespective of the timing, careful dismantling of the dysmorphic skeletal components and reshaping with some degree of overcorrection is advocated as continued growth is likely to be abnormal and trend toward recapitulation of the original presentation.[52]

When craniofacial reconstructive surgery is carried out during infancy, complete healing of relatively large (1.5 cm) bony defects will occur without the need for additional bone grafting. This is due to the combined bony healing capacity of the pericranium and the dura, which is highly osteogenic during infancy. Most residual cranial vault defects will heal completely when the surgery is performed during the first 2 years of life. When cranial vault surgery is undertaken between 2 and 4 years of life, complete healing of residual full-thickness defects is less predictable and either immediate grafting or a secondary procedure for repair may be indicated. After age 4, it is unlikely that even small full-thickness cranial vault defects will resolve without deliberate reconstruction or grafting at the time of the initial surgery.

Complications and Transfusion Management Strategies

Isolated suture craniosynostosis reconstruction has demonstrated a high level of overall safety as confirmed by a recent single center review of 746 patients with a reported complication rate of 4.6% and mortality of 0.1%.[53] Although safe, these procedures are associated with significant blood loss. A prior review and survey of 8101 craniofacial procedures reported a similarly low rate of mortality, but attributed 50% of cases to blood loss.[54] Thoughtful transfusion protocols must be employed. Controlled hypotensive anesthesia protocols are generally avoided because of the potential adverse impact on cerebral perfusion.[55] A number of protocols have been described for the management of intraoperative blood

loss during craniosynostosis procedures including the use of intraoperative blood salvage, preoperative erythropoietin (EPO) administration, iron supplementation, standardized transfusion guidelines, and intraoperative tranexamic acid.[56-60]

Special Considerations Related to Delayed Diagnosis

Despite an awareness of abnormal head shape–related problems within the pediatric medical community, the diagnosis of craniosynostosis may not be established until later in infancy or childhood. The definitive diagnosis may be delayed by an atypical morphologic presentation, health care providers that are not familiar with the different head-shape patterns, nondiagnostic imaging, or a lack of access to craniofacial subspecialists for timely consultation. Another scenario is the delay of a diagnosis or of definitive surgical treatment in a child born with multiple congenital deformities. It may be that initial attention is directed at resolving other medical (e.g., cardiac) problems that are a more immediate threat to the child's health and the issue of abnormal head shape is addressed later in life. Children who have untreated craniosynostosis after 3 years of life may represent a unique diagnostic challenge to craniofacial and neurologic surgeons. This is especially true if the child has minimal craniofacial dysmorphology. In such cases, the primary consideration in deciding whether or not to pursue surgical intervention is the presence of any evidence of increased ICP. Initial workup includes imaging studies and a formal pediatric ophthalmologic evaluation. When a comprehensive neurologic examination is not conclusive, the use of additional surgical and/or diagnostic measures may be useful. Invasive monitoring of ICP may be accomplished using an epidural sensor.[12,51,61] The procedure requires a burr-hole craniotomy to place an intracranial wire transducer, which is left in place for 24 to 48 hours. Measurements of the patient's ICP are made on an hourly basis and at different activity levels (e.g., sleeping, playing, crying) during this time interval. This form of monitoring may provide valuable information useful in the decision-making process in a case where there is little or no indication to pursue surgery for morphologic reasons. Another method of documenting increased ICP involves a direct lumbar puncture.[51]

Forms of Nonsyndromic Craniosynostosis

Sagittal Suture Craniosynostosis (Scaphocephaly)

Sagittal suture craniosynostosis is the most common form of nonsyndromic single-suture synostosis with a prevalence of approximately 1 in 5000 live births.[62] More male children are typically affected with a male to female ratio of 3 : 1 reported.[62]

When the sagittal suture is prematurely fused, the result is a scaphocephalic skull deformity. Absence of the sagittal suture results in arrested development of the two parietal bone plates with no growth perpendicular to the suture and a narrow bitemporal and biparietal dimension. At the same time, the brain continues to expand, and there is compensatory growth at the major sutures that remain open (i.e., lambdoid, coronal, and metopic). The overgrowth perpendicular to the coronal and lambdoid sutures causes an abnormal elongation of the cranial vault in the AP dimension, and patients will demonstrate frontal and occipital bossing as a result. This abnormal head shape is often described as "keel-like." The exact dysmorphology varies greatly depending on whether there is fusion of the entire sagittal suture, fusion of the anterior portion of the suture, or fusion of the posterior portion of the suture.

Surgical management of sagittal suture craniosynostosis requires biparietal craniotomy for release of the fused suture in combination with posterior two-thirds cranial vault reshaping (Figure 37-6).[63,64] The dysmorphic skeletal components of the cranium are dismantled and reassembled to establish an anatomically correct head shape.

When the posterior region of the sagittal suture is absent, our approach is to reshape the posterior two thirds of the cranial vault. This is done with the patient in the prone position. A postauricular coronal scalp incision is made, and the initial dissection is carried posteriorly within the supraperiosteal plane. Once the coronal scalp flap is developed, additional incisions are created through the periosteum and it is elevated as three separate flaps: right and left parietal and occipital. The coronal and lambdoid sutures are identified, and burr-hole and osteotomy placement is marked with a sterile marker or pencil. Formal biparietal and occipital craniotomy is then performed by the pediatric neurosurgeon, and the dysmorphic bones are removed. Reshaping of the bone flaps is carried out through the creation of additional osteotomies and use of bone-bending instruments on a sterile back table. The goal of these maneuvers is to increase bitemporal and biparietal width and reduce the AP length of the cranial vault. The reshaped skeletal segments are then reinserted and secured with biodegradeable fixation consisting of bone plates secured with monocortical screws. The pericranium is loosely approximated with interrupted sutures and the coronal scalp flap is closed in layers with inverted interrupted sutures for approximation of the galea and subcutaneous tissues and a running resorbable suture for skin closure. The authors do not use drains routinely.

If only the anterior portion of the sagittal suture is involved, the dysmorphology may be characterized primarily by frontal bossing with less impact on the posterior cranium. In those cases, craniotomy and reshaping of the anterior cranial vault is carried out with the patient in the supine position.

Some surgeons advocate a more aggressive total cranial vault reconstruction that is performed as a single-stage operation for patients who have fusion of the entire sagittal suture. Such extensive cranial reshaping is associated with disadvantages, including increased morbidity and blood loss, difficult intraoperative access to the entire cranial vault, and fewer points for anchorage of rigid internal fixation appliances. In our experience, the use of total cranial vault reshaping procedures is rarely necessary as surgical treatment of the middle and posterior cranium generally results in resolution of frontal bossing over time.[65] We prefer to manage patients who have complete sagittal suture involvement with an initial surgical procedure in which only the posterior two thirds of the cranium is reshaped as previously

described. If necessary, additional reshaping of the anterior cranial vault is then undertaken as a second phase of surgical treatment approximately 6 to 12 months later.

Coronal Suture Craniosynostosis (Anterior Plagiocephaly)

Craniosynostosis involving one of the coronal sutures is the second most common type of sporadic, nonsyndromic synostosis with a relative prevalence of approximately 1 in 10,000 children.[66,67] Although the exact cause of coronal craniosynostosis remains unknown, recent work has suggested that a mutation within the fibroblast growth factor receptor 3 gene is implicated in certain individuals.[51,68]

The congenital absence of the coronal suture results in the arrested development of the frontal and parietal bones. Clinically, there is anterior plagiocephaly with flattening of the forehead on the affected side. Other characteristic abnormal physical findings include orbital dystopia with the orbit on the affected side positioned superiorly and posteriorly, nasal asymmetry, and ipsilateral zygomatic hypoplasia. At the same time, there is compensatory overgrowth along the cranial vault sutures that remain open, including the contralateral coronal suture. The result is flattening of the forehead on the affected (i.e., fused) side and frontal bossing on the unaffected (i.e., patent) side of the anterior cranial vault. In this manner, a unilateral coronal synostosis produces a bilateral skull deformity.

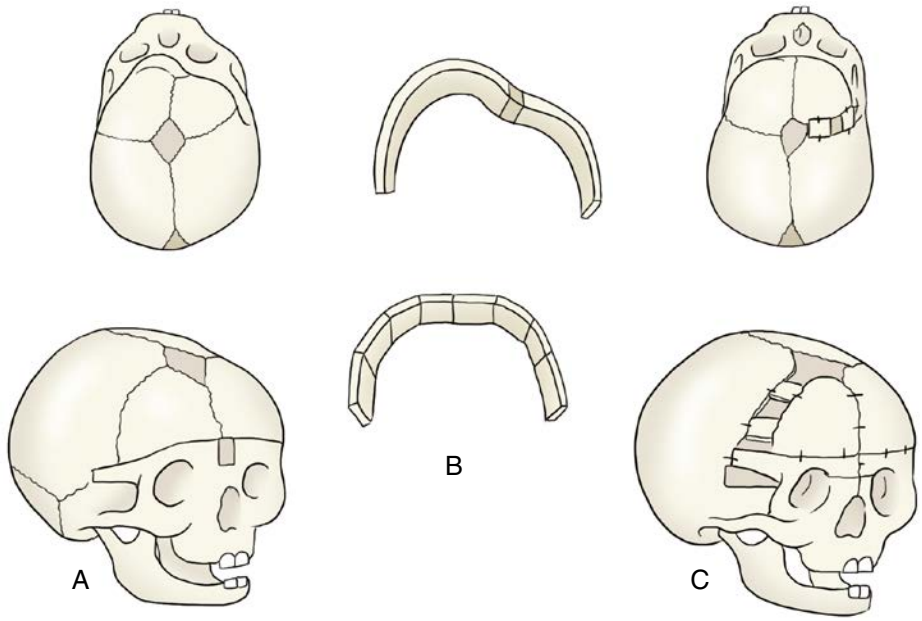
In patients with coronal suture synostosis, the anterior skull base demonstrates shortening on the affected side and elevation of the sphenoid wing.[69] This is due to involvement of the frontoethmoid, frontosphenoid, and sphenoethmoid sutures, termed the "coronal ring." A plain AP skull radiograph of a patient with unilateral coronal synostosis will demonstrate a characteristic "Harlequin-eye" deformity created by the skull base distortion and superiorly malpositioned orbital rim. Asymmetry of the entire cranial base is also common with a shift in the anterior and posterior cranial base to midsagittal plane angles of greater than 7 degrees as a consistent finding on CT scan evaluation.[70] Cranial base involvement also frequently produces some level of mandibular deviation leading to lower facial asymmetry.

The contemporary surgical treatment of unilateral coronal suture synostosis consists of bifrontal craniotomy, orbital osteotomies with creation of an orbital bandeau, frontoorbital advancement, and anterior cranial vault reshaping (Figures 37-7 and 37-8). A postauricular coronal scalp incision is created, and dissection is carried out in the supraperiosteal plane. The pericranium and temporalis muscles are elevated separately. Bilateral circumferential periorbital dissection is then carried out with complete exposure of the orbits to the level of the inferior orbital rim and zygoma. This requires release of the lateral canthal ligaments. Care is taken to preserve the medial canthal attachments and nasolacrimal apparatus. We outline the orbital bandeau including the tenon extensions within the temporal bones bilaterally using a sterile pencil or marking pen before deciding on burr-hole placement. Typically a bifrontal craniotomy is created by the pediatric neurosurgeon with removal of the frontal bone unit.

Next, the dura is dissected free of the inner table of the cranial vault and along the anterior skull base. A reciprocating saw with a small blade is used for the creation of osteotomies along the lateral orbital wall and/or rim, orbital roof, and superior-medial aspect of the orbital wall on each



• **Figure 37-7** Illustration of reconstructive procedure used to address the dysmorphology associated with unilateral coronal suture craniosynostosis. **A,** Outline of the bifrontal craniotomy and orbital osteotomies. **B,** The dysmorphic orbital bandeau is removed, and vertical osteotomies are used for reshaping. **C,** The reconstructed orbital bandeau is reinserted, and anterior cranial vault reconstruction is carried out. side of the bandeau. Care is taken to prevent injury to the temporal lobe of the brain during the sectioning of pterion bilaterally. The orbital osteotomies are carried one half to three quarters of the length of the orbit on each side. The final osteotomy cut is across the nasofrontal region joining both orbital osteotomies and allowing for mobilization of the orbital bandeau. Once the bandeau is removed, it is taken to the sterile back table where reshaping is carried out. Recontouring frequently involves the creation of a vertical osteotomy in the midline to allow for advancement of the affected orbital segment. Additional osteotomies between the lateral orbital region and tenon extension may be used for additional reshaping of the bandeau. The newly constructed orbital unit is then inserted and secured to the temporoparietal bones bilaterally using bone plates and screws. We add a third point of fixation at the nasofrontal junction and lateral orbital rims using 2-0 PDS suture to prevent upward displacement of the bandeau when the coronal flap is repositioned. In cases where severe flattening of the superior orbit is present, onlay bone grafts may be added on the affected side of the bandeau for additional contouring. The frontal bones are then osteotomized and used to reconstruct the anterior cranial vault region with reshaping as necessary. Closure begins with lateral canthopexies performed through the coronal access and proceeds as previously described.

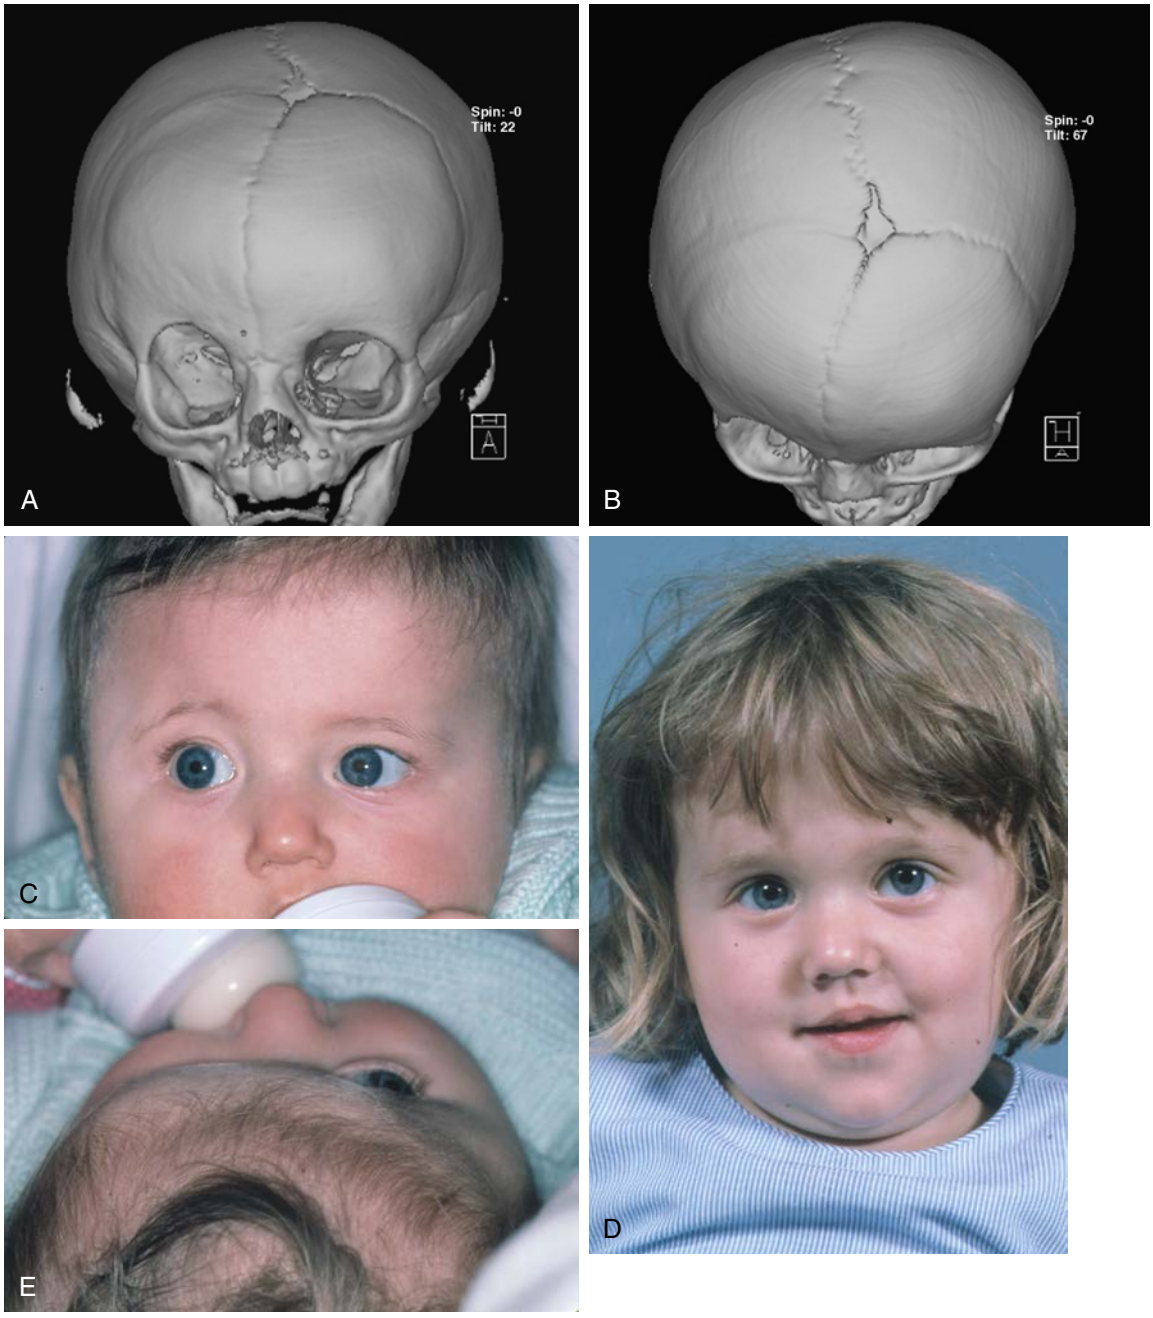
Metopic Suture Craniosynostosis (Trigonocephaly)

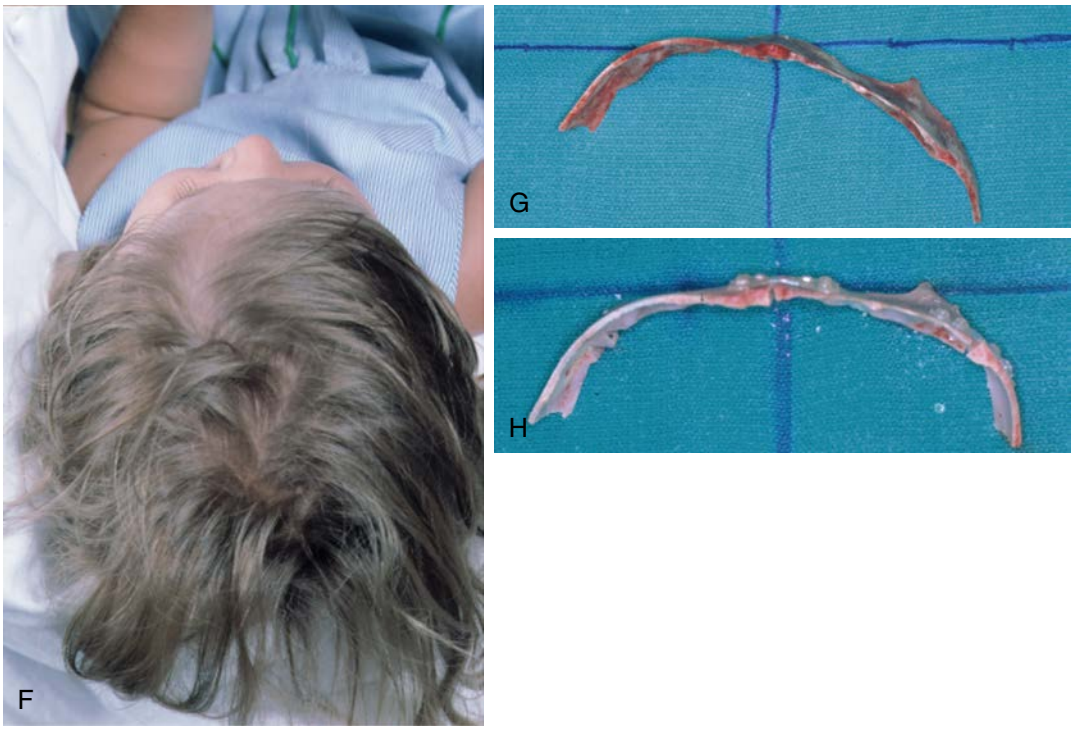
Metopic suture craniosynostosis has a traditionally reported prevalence of 1 in 15,000 children.[71] Recent reports have indicated an increase in prevalence to approximately 1:5,000 children.[72] An increased proportion of male children are affected. Unlike other forms of isolated, single-suture craniosynostosis, approximately 5% of patients with metopic fusion will have a positive family history.[71,73]

Premature fusion of the metopic suture may be seen in nonsyndromic, otherwise healthy infants or as part of an identified syndrome. Previous reports have suggested that a third group of infants born with metopic synostosis will demonstrate other congenital malformations, neuromuscular dysfunction, and/or neurodevelopmental delay but without the delineation of a syndromic diagnosis.[71,73-75] This observation is consistent with our experience. At the University of North Carolina, a review of patients with metopic suture involvement, treated by the senior author (RLR), revealed a high rate of associated congenital malformations.[76] Forty-three percent of patients seen with a diagnosis of metopic suture synostosis over the course of a 4-year period had associated malformations, but no clear syndromic diagnosis. Malformations not previously described in association with metopic synostosis were observed, including three patients with a tethered spinal cord. Whether the combination of metopic synostosis and associated anomalies represents an unknown syndrome remains unclear. Thorough medical and genetic evaluation of infants born with metopic craniosynostosis is indicated to prepare these children for craniofacial surgery, counsel parents, and determine long-term neurodevelopmental prognosis.

The combination of arrested growth of the frontal bones perpendicular to the midline (metopic) suture and continued growth at the coronal sutures creates a trigonocephalic



• **Figure 37-8** Nine-month-old child with right-sided unilateral coronal suture craniosynostosis and anterior plagiocephaly. Surgical reconstruction consisted of bifrontal craniotomy, fronto-orbital advancement, and anterior cranial vault reshaping. **A** and **B,** 3D craniofacial CT scan reveals absence of the right coronal suture. Note the degree of cranio-orbital dysmorphology on the affected side. **C,** Preoperative frontal view demonstrates a skeletal deformity characterized by flattening of the forehead on the affected side, orbital dystopia, and nasal asymmetry. **D,** Postoperative frontal view 15 months following the surgical procedure. **E,** Bird's-eye view preoperatively.



• **Figure 37-8, cont'd** **F,** Bird's-eye view postoperatively. **G,** Intraoperative view of the orbital bandeau before reshaping. **H,** Intraoperative view of orbital bandeau after osteotomies, reshaping, and reassembly using resorbable bone plates and screws. (From Ruiz RL, et al: Nonsyndromic craniosynostosis: diagnosis and contemporary surgical management, *Oral Maxillofacial Surg Clin North Am* 16:447-463, 2004.)

(i.e., triangle-skull) skull deformity. The associated dysmorphology is characterized by a triangular-shaped forehead, orbital hypotelorism, and horizontally retrusive lateral orbital rims. Other findings that may be noted during clinical examination include a narrow forehead, epicanthal folds, biparietal widening, elevated brow position, and lateral orbitozygomatic hypoplasia. Radiographic features of metopic synostosis described in the literature include the absence of the suture, pulled anterior fontanelle, straight lateral frontal bone, posteriorly displaced lateral frontal bone, frontal bone tangent to mid-orbit, up-sloping lateral orbital rims, interorbital narrowing, narrowing of the upper orbital width, and presence of an "omega" sign deformity along the endocranial surface of the metopic ridge. All of these clinical and radiographic features may be helpful in differentiating the physiologic metopic suture closure from true, pathologic synostosis.[77]

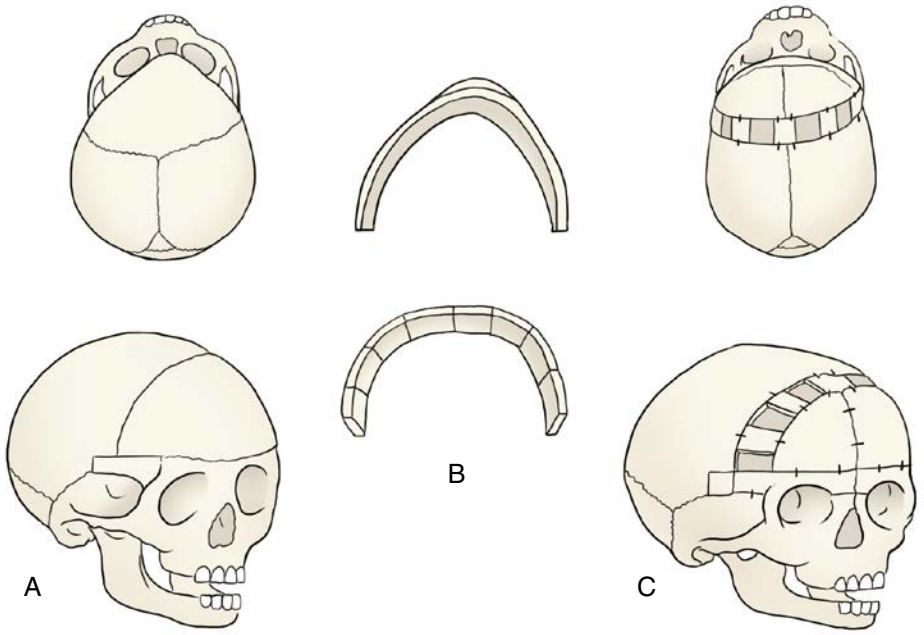
In addition to the other characteristic findings of metopic synostosis, patients will often present with a pronounced vertical bony ridge within the center of the forehead along the metopic region. It is important to note, however, that patients with normal physiologic closure of the metopic suture, and no synostosis, also frequently develop a ridge along the metopic suture region. As a result, surgeons must be mindful that the isolated finding of a metopic bony ridge, without other dysmorphic features, does not represent craniosynostosis.

The severity of clinical expression of metopic synostosis is extremely variable making clinical decision making about surgical intervention uniquely problematic. In the opinion of the authors, surgical intervention for metopic suture craniosynostosis is indicated in cases where clinically significant dysmorphology is present. Not all patients will require surgical intervention since some have only minimal morphologic deformity. This is especially true because the likelihood of a child developing increased ICP secondary to metopic synostosis is quite low.[73]

The surgical approach to reconstruction of the trigonocephalic skull deformity associated with metopic synostosis is similar to the surgical procedure described for coronal synostosis. Bifrontal craniotomy is carried out in conjunction with fronto-orbital advancement and anterior cranial vault reshaping (Figures 37-9 and 37-10). Reshaping of the orbital bandeau is carried out to advance the lateral orbital segments and create a more rounded forehead with improved anatomic contour. The creation of a gap at the vertical midline osteotomy within the bandeau and placement of an autogenous bone graft may be performed in an effort to widen the orbits and address the orbital hypotelorism. Although this is a reasonable surgical maneuver, it has minimal impact on the hypotelorism as it does not address the patient's medial orbital wall to medial orbital wall distance.

Lambdoid Suture Craniosynostosis (Posterior Plagiocephaly)

Posterior plagiocephaly secondary to true lambdoid suture craniosynostosis is a rare event with a prevalence of



• **Figure 37-9** Illustration of reconstructive procedure used to address the trigonocephalic skull deformity associated with metopic suture craniosynostosis. **A,** Outline of the bifrontal craniotomy and orbital osteotomies. **B,** The dysmorphic orbital bandeau is removed, and vertical osteotomies are created for reshaping. **C,** The reconstructed orbital bandeau is reinserted, and anterior cranial vault reconstruction is completed. (From Ruiz RL et al: Nonsyndromic craniosynostosis: diagnosis and contemporary surgical management, *Oral Maxillofac Surg Clin North Am* 16:447-463, 2004.)

approximately 1 in 150,000 live births.[78-80] Because posterior plagiocephaly as a result of synostosis is so uncommon and it may be confused with positional plagiocephaly, the diagnosis must be definitively confirmed with radiographic imaging before any surgical intervention is undertaken (Figures 37-11, 37-12, and 37-13).

When premature fusion of one lambdoid suture occurs, the most noticeable finding is often a severe flattening of the occipitoparietal region. Restricted growth of the ipsilateral parietal bone also produces retraction of the forehead on the affected side, inferior-posterior displacement of the ear and shortening of the affected side of the skull. By contrast, posterior positional plagiocephaly has a distinct morphologic pattern characterized by occipitoparietal flattening, ipsilateral frontal bossing, and forward displacement of the ear on the affected side.

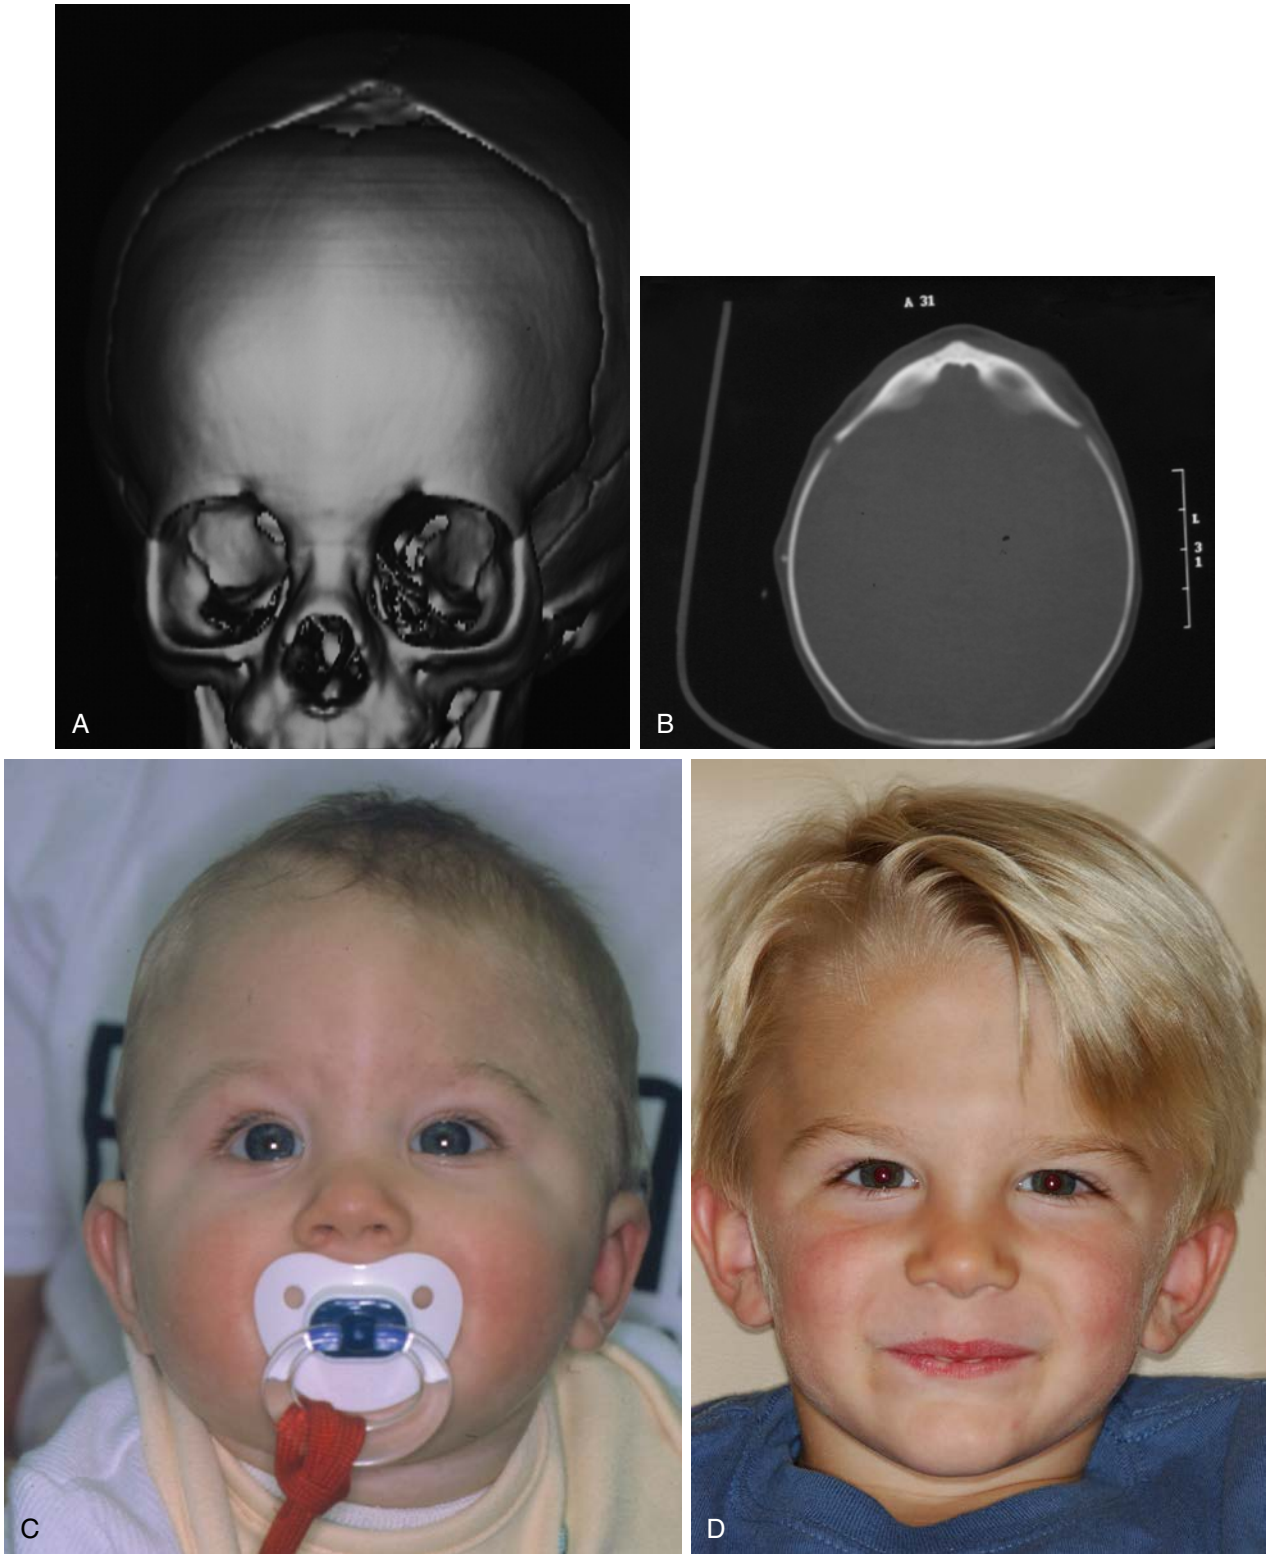
Although surgeons may be tempted to perform a more limited procedure, such as strip craniectomy to address unilateral lambdoid craniosynostosis, a combined craniofacial and neurosurgical approach remains the most appropriate treatment. Our preference is to carry out a formal craniotomy with reshaping of the involved portions of the posterior cranium based upon the extent of the dysmorphology.

Bilateral Coronal Suture Craniosynostosis (Brachycephaly)

When bilateral coronal craniosynostosis is seen in conjunction with mid-face deficiency, the possibility of a craniofacial dysostosis syndrome (e.g., Apert, Crouzon, Pfeiffer, Saethre-Chotzen, etc.) must be considered.[81] However, the congenital absence of both coronal sutures is known to occur in patients without mid-face deficiency or a syndromic diagnosis.[82] Although these patients demonstrate what is thought to be a "nonsyndromic" form of bilateral coronal craniosynostosis, recent advances in molecular testing suggest that there may be some familial pattern with implication of mutations within the fibroblast growth factor receptor (1, 2, and 3) genes.[83]

Bilateral coronal suture fusion results in a characteristic craniofacial dysmorphology described as brachycephaly. This deformity includes shortening of the anterior skull base bilaterally resulting in a decreased AP cranial dimension, widening of the skull secondary to compensatory growth at the sagittal suture, and horizontal deficiency of the lateral orbital rims. In addition, some patients will exhibit significant vertical elongation of the anterior cranial vault.

Because two cranial vault sutures are involved, the incidence of increased ICP rises to approximately 42%.[2,12] Surgical intervention is undertaken to increase intracranial and orbital volume and establish a more anatomic position and contour of the orbits and forehead. The standard surgical approach for the repair of the deformity associated with bilateral coronal synostosis includes a more extensive bifrontal craniotomy than used in unilateral cases, fronto-orbital advancement, and anterior cranial vault reconstruction.



• **Figure 37-10** A 7-month-old child with metopic suture craniosynostosis and trigonocephaly. He underwent craniofacial reconstruction via bifrontal craniotomy approach, fronto-orbital advancement, and anterior cranial vault reshaping. **A,** 3D craniofacial CT scan reveals absence of the metopic suture with trigonocephalic skull deformity. **B,** Axial view CT scan reveals the triangular-shaped frontal bone complex with a prominent bony ridge in the region of the metopic suture. **C,** In addition to the triangular-shaped forehead, the preoperative frontal view demonstrates hypotelorism and horizontal retrusion of the lateral orbital rims. **D,** Postoperative frontal view 2 years after the surgical procedure.

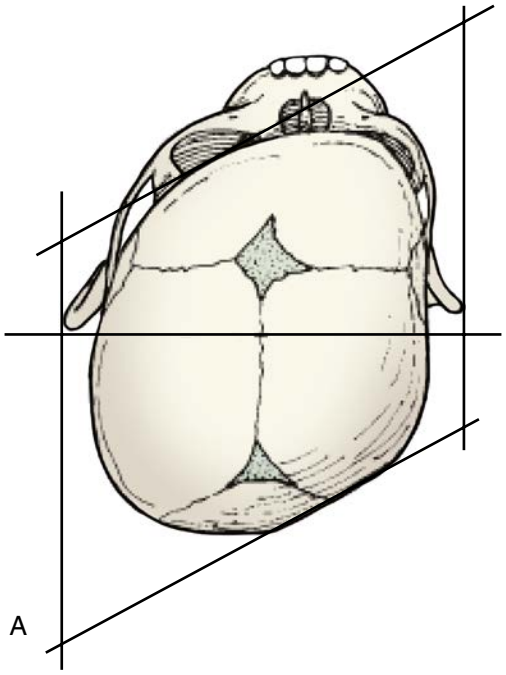
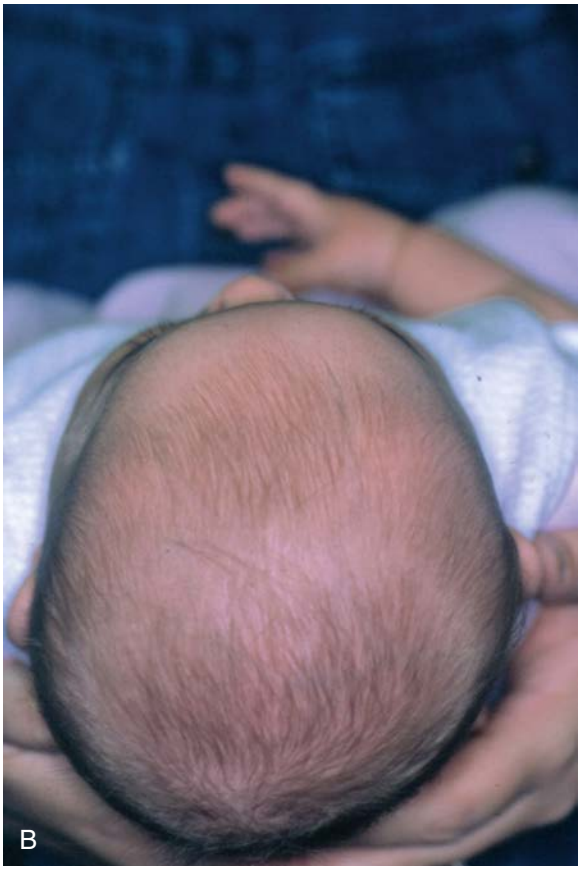
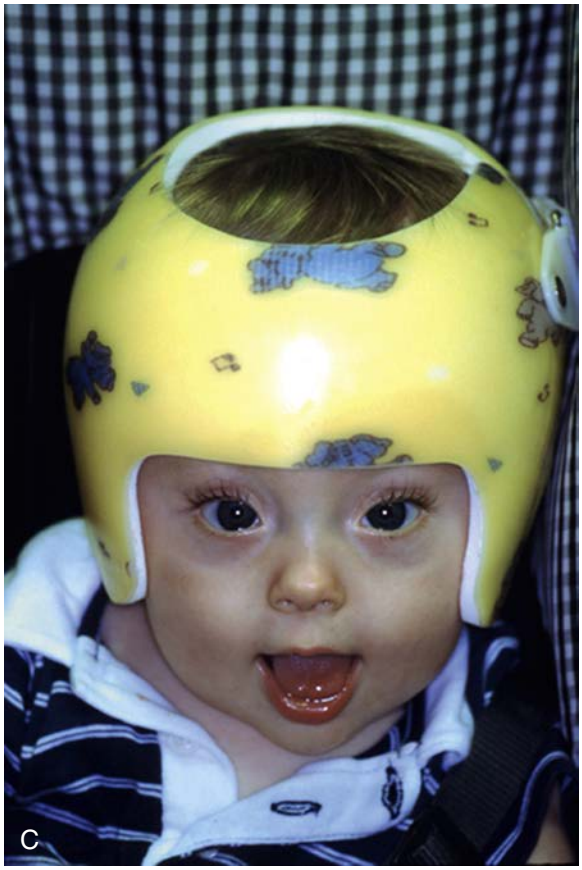
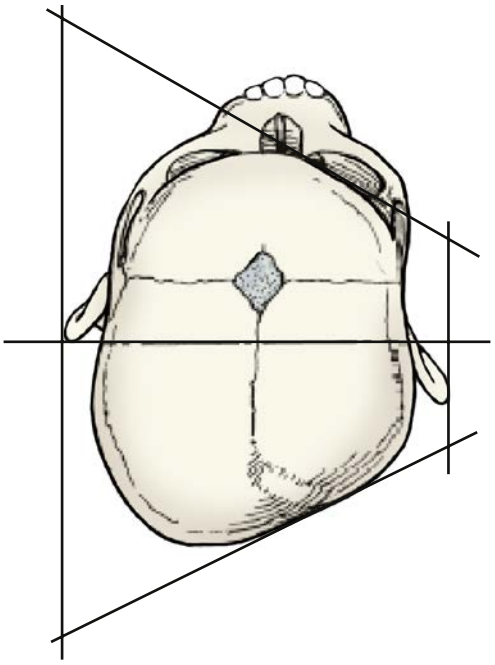
• **Figure 37-10, cont'd** **E,** Bird's-eye view preoperatively. **F,** Bird's-eye view postoperatively. **G,** Intraoperative view of the orbital bandeau before reshaping. **H,** Intraoperative view of orbital bandeau after osteotomies, reshaping, and reassembly using resorbable bone plates and screws. (From Ruiz RL et al: Nonsyndromic craniosynostosis: diagnosis and contemporary surgical management, *Oral Maxillofacial Surg Clin North Am* 16:447-463, 2004.)



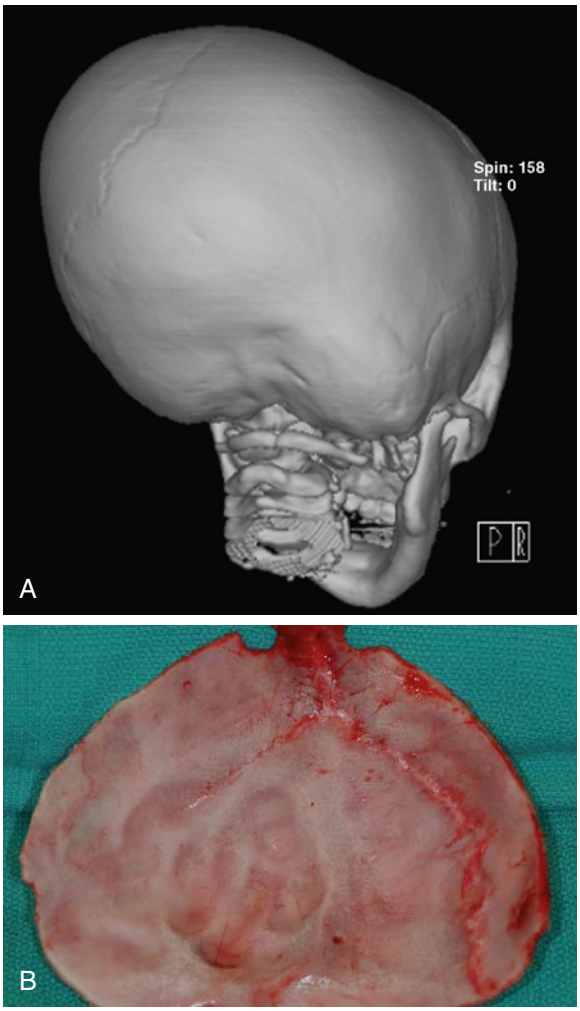




• **Figure 37-11** **A,** Illustration of cranial vault dysmorphology characteristic of benign deformational plagiocephaly. Postnatal external forces, such as repetitive sleep positioning, cause unilateral occipitoparietal flattening. Because the sutures are open and the cranial vault complex is flexible, all of the structures on the affected side are displaced anteriorly. Additional clinical findings include ipsilateral frontal bossing and forward displacement of the ear on the affected side. The outline of the cranial vault as viewed from above develops a form that resembles a parallelogram. **B,** Bird's-eye view of a child with deformational (positional) plagiocephaly. This is a nonsurgical condition. **C,** Custom cranial orthotic band used to correct deformational plagiocephaly. (From Caccamese J et al: Positional plagiocephaly: evaluation and management, *Oral Maxillofacial Surg Clin North Am* 16:439-446, 2004.)



• **Figure 37-12** Illustration of cranial vault dysmorphology characteristic of posterior plagiocephaly secondary to unilateral lambdoid suture craniosynostosis. In this example, arrested development across the right lambdoid suture causes flattening of the occipital and parietal bones. The lack of cranial growth on the affected side also produces retraction of the forehead on the right (ipsilateral) side, and the right ear is displaced posteriorly and inferiorly when compared with the left. Compensatory overgrowth also occurs at the sutures that remain open, which causes contralateral frontal bossing. From a bird's-eye view, the cranial vault may take on the shape of a trapezoid. (From Ruiz RL, et al: Nonsyndromic craniosynostosis: diagnosis and contemporary surgical management, *Oral Maxillofacial Surg Clin North Am* 16:447-463, 2004.)



• **Figure 37-13** **A,** 3D CT scan of a patient with right-sided unilateral lambdoid suture synostosis. **B,** Intraoperative view of the occipital bone reveals conspicuous absence of the lambdoid suture on the affected side. (From Ruiz RL, et al: Nonsyndromic craniosynostosis: diagnosis and contemporary surgical management, *Oral Maxillofacial Surg Clin North Am* 16:447-463, 2004.)

Summary

Contemporary surgical management of nonsyndromic craniosynostosis requires the combined expertise of a pediatric craniofacial surgeon and pediatric neurosurgeon. The goals of surgical intervention are the release of the affected suture allowing for unrestricted development of the visceral components (e.g., brain, eyes) and 3D reconstruction of the skeletal components establishing a more normal anatomic position and contour.[84] Surgeons caring for infants with these cranial and orbital malformations must maintain a thorough understanding of the 3D anatomy, characteristic dysmorphology associated with the different types of synostosis, and the complex interplay that exists between surgical intervention and ongoing skeletal growth.

Syndromes with Craniosynostosis: Evaluation and Reconstruction

BRENT GOLDEN, CAROLYN DICUS BROOKES, TIMOTHY A. TURVEY

Introduction

Craniosynostosis, or premature fusion of cranial sutures, is a congenital abnormality that occurs in roughly 1:2000 to 1:2500 live births.[1,2] To date more than 150 syndromes with craniosynostosis as a component have been identified[2]; these are seen in 1:25,000 to 1:100,000 live births.[3,4] The term *craniofacial dysostosis* (CFD) has been used historically to describe the syndromic forms of craniosynostosis that exhibit sutural and enchondrosal pathology of the cranial vault and cranial base with associated craniofacial deformity. These syndromes typically manifest with some degree of characteristic exorbitism, hypertelorism, and multidimensional mid-face deficiency.

The most common phenotypic variants of this sort have been described by Carpenter,[5] Apert,[6] Crouzon,[7] Saethre-Chotzen,[8,9] Pfeiffer,[10] and Muenke.[11] Historically, the craniosynostosis syndromes were distinguished from one another primarily based on limb and visceral involvement, although some aspects of the craniofacial manifestations also were more typical within each. Today genotypic characterization of the syndromes can define the diagnosis or contribute to classification.[2]

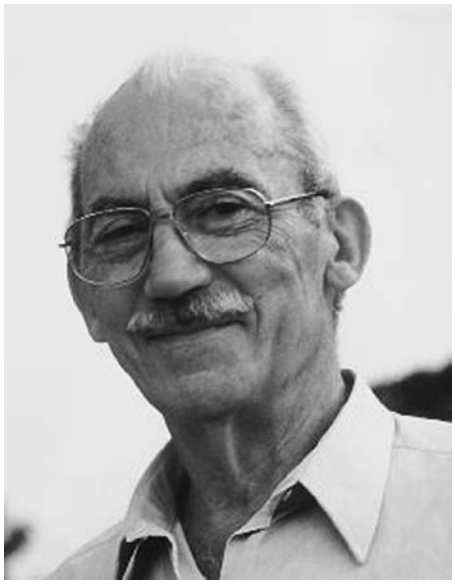
Surgical management of the craniomaxillofacial skeleton has its distant history in the care of tumors and traumatic injuries. Elective osteotomies to reconstruct the maxillofacial region for deformities can be traced back to Gillies in England and Auxhausen and Wassmund in Germany during the early part of the twentieth century. However, it was Tessier in France during the second half of the twentieth century who pioneered modern craniofacial techniques and principles not only for management of the orbital region, but also for combined craniofacial and maxillofacial reconstruction (Figure 38-1). His influence on the surgical algorithms that follow cannot be overstated.

The goal of this chapter is to review our current understanding of the specific genetics and dysmorphology of the most commonly encountered syndromes, to describe the craniofacial implications of the craniosynostosis syndromes, and to describe a general framework from which to approach surgical care of these anomalies.

Genetic Understanding and Syndrome-Specific Traits

Broadly speaking, the craniosynostosis syndromes are predominantly autosomal dominant in their transmission and penetrance is often complete.[2] Genotype characterization is now possible for many of the mutations associated with craniosynostosis syndromes. The fibroblast growth factor receptor (FGFR) and TWIST genes are most often affected with over 90% of syndromic craniosynostoses caused by mutations in the FGFR2 locus.[12] The FGFs are involved in skeletogenesis and limb development, among other processes. Gain of function mutations in FGFR 1, 2, and 3 cause a family of eight craniosynostosis syndromes:[13] Crouzon syndrome, Crouzon syndrome with acanthosis nigricans, Apert syndrome, Pfieffer syndrome, Muenke syndrome, Beare-Stevenson syndrome, Jackson-Weiss syndrome, and FGFR-2 related isolated coronal synostosis.[2] Loss-of-function mutations in the TWIST gene also result in premature suture fusion, presumably through upregulation of the FGRFs and Runx, which is a transcription factor for osteogenesis.[14,15]

Genotype-phenotype correlations have now been described; however, there is much that remains uncharacterized about genotype-phenotype relationships. Patients with similar phenotype may have different genetic diagnoses while identical mutations have been found in patients carrying different clinical diagnoses.[2,13,16-19] At present, the eponymic phenotypic descriptions remain necessary.



• **Figure 38-1** Paul Tessier, MD.

Muenke Syndrome

Muenke syndrome is characterized by bilateral or, less commonly, unilateral coronal suture synostosis with minor anomalies of the hands and feet such as broad great toes, brachydactyly, or clinodactyly.[2,11] It is linked to a specific mutation in *FGFR3* and is inherited in an autosomal dominant fashion with incomplete penetrance and variable expressivity.[11] It has been noted to be the most common genetic cause of a craniosynostosis syndrome.[20]

Variability of clinical features is notable. Additional cranial sutures may be involved or patients may simply be macrocephalic.[11,21,22] Ventriculomegaly and hydrocephalus are rare.[23] Patients may exhibit mild mid-facial hypoplasia, mild ptosis, and a high arched palate.[21] Mild to moderate sensorineural hearing loss is extremely common (in contrast to the conductive loss seen in most other craniosynostosis syndromes).[22] Though normal intellect is the rule, developmental delay is seen in about one third of patients.[24] Because diagnosis allows early assessment and intervention to address hearing loss and developmental delay and because those with Muenke syndrome are more likely to require reoperation after cranial vault remodeling, it is prudent to obtain genetic testing for all patients with any variant of coronal synostosis.[11,21,22]

Crouzon Syndrome

Crouzon syndrome is a relatively frequent form of syndromic craniosynostosis characterized by multiple anomalies of the craniofacial skeleton with an autosomal dominant inheritance pattern, complete penetrance, and variable expressivity[25-67]; it accounts for roughly 4.5% of all cases of syndromic craniosynostosis.[2,4]

Mutations in *FGFR2* cause Crouzon syndrome while a specific mutation in the *FGFR3* gene causes the related Crouzon syndrome with acanthosis nigricans, which is most often sporadic.[2] This related syndrome has craniofacial findings similar to those that characterize Crouzon syndrome as well as acanthosis nigricans, often not seen until childhood, and sometimes additional skeletal anomalies such as choanal atresia and short vertebral bodies.[68,69] Some of the mutations in the *FGFR2* gene seen in Crouzon syndrome are identical to those seen in Pfeiffer and Jackson-Weiss syndromes[2,70-75]; it is likely that in the past many of these individuals have been clinically diagnosed with Crouzon syndrome.[76]

Though the craniofacial manifestations of Crouzon syndrome are marked, they are generally less severe than those of Apert syndrome and malformations of the extremities are classically absent. Premature synostosis of the coronal ring including both coronal sutures, the frontosphenoid suture, and the sphenoethmoidal synchondrosis results in brachycephaly, a short and wide anterior cranial base, and a total mid-face hypoplasia. Additional cranial sutures may be involved.[50] The lambdoid sutures can experience early closure more frequently than in Apert syndrome, and patients experience more significant posterior fossa pathology; chronic tonsillar herniation may be found in more than 70% of Crouzon patients,[2,77-79] and as many as 30% of patients have progressive hydrocephalus.[23]

The orbits are hypoplastic, especially laterally and inferiorly, resulting in characteristic exorbitism.[80] Orbital hypertelorism is usually moderate, and many patients exhibit exotropia.[50] Optic atrophy may be seen in roughly 20% of patients.[80] Conductive hearing loss is common.[24,81] Normal intellect is expected.[2]

Apert Syndrome

Apert syndrome is another relatively common craniosynostosis syndrome, accounting for 4% to 5% of craniosynostosis cases.[3,82] In addition to craniosynostosis with turribrachycephaly and mid-face hypoplasia, a hallmark of the syndrome is symmetric, four-limb syndactyly involving at least the second through fourth digits (Figure 38-2). Inheritance is autosomal dominant with complete penetrance, though the majority of cases are sporadic.[2] *FGFR2* mutations cause Apert syndrome and specific mutations have phenotypic links, such as more severe craniofacial involvement and cleft palate.[83]

At birth patients have bicoronal synostosis and often present with a wide midline calvarial defect that predictably obliterates over time; the metopic suture may close quite early or in a more delayed fashion. Asymmetry of the cranial base, orbits, and mid-face is more common than in Crouzon syndrome.[84,85] Proptosis and hypertelorism are always present. Exotropia and strabismus are common, though optic atrophy is seen less often than in Crouzon syndrome.[80,86,87] The nose is short with a depressed bridge and a rounded tip.[85] Though ventriculomegaly is common, progressive hydrocephalus is less frequent than in Crouzon syndrome.[88-90] The lambdoid sutures tend to close later than in Crouzon patients with posterior fossa dysmorphology

• **Figure 38-2** A typical appearance of the complex compound syndactyly seen in Apert syndrome. (From Gilbert-Barness E, editor: *Potter's pathology of the fetus, infant and child,* ed 2, Philadelphia, 2007, Mosby.)

that is only infrequently associated with chronic tonsillar herniation.[77]

Ears tend to be large and low set; acquired, conductive hearing loss may be observed.[85,91-93] Lateral palatal swellings containing mucopolysaccharides appear early and grow with age, and dental eruption is often delayed. A long soft palate can contribute to airway obstruction. Cardiovascular and genitourinary anomalies are found in about 10% of patients.[94] Fused cervical vertebrae are seen in the majority.[95] The periorbital findings also vary from those in Crouzon syndrome, with a greater downward slant to the lateral canthi and a distinctive, S-shaped upper eyelid ptosis. The quality of the skin often varies from normal, with acne and hyperhidrosis being prominent features.[2,85,96,97]

Saethre-Chotzen Syndrome

Saethre-Chotzen syndrome has an autosomal dominant inheritance pattern with variable penetrance and expressivity[2,16] and is caused by loss-of-function *TWIST* mutations. Its pattern of malformations may include craniosynostosis, low-set frontal hairline, ptosis of the upper eyelids, small ears with prominent crura, facial asymmetry, and limb anomalies such as brachydactyly, partial cutaneous syndactyly, and clinodactyly. Patients with Saethre-Chotzen rarely exhibit ventriculomegaly or require shunting.[23] Strabismus and hypertelorism are common.

Pfeiffer Syndrome

Pfeiffer syndrome consists of craniosynostosis, broad thumbs and great toes, and variable partial soft-tissue syndactyly.[10] The syndrome has been subdivided into three types.[98] Current thinking suggests that Pfeiffer syndrome is heterogeneous because it may be caused by different genetic abnormalities; either a single recurring mutation (Pro252Arg) of *FGFR1* or by several different mutations affecting *FGFR2.*[99-104] Type 1 exhibits autosomal dominant inheritance with complete penetrance and variable expressivity, though it may be sporadic. Types 2 and 3 are usually de novo.[98,105,106]

Type 1 Pfeiffer syndrome corresponds to the classic Pfeiffer syndrome and is associated with a satisfactory prognosis. Turribrachycephaly, mid-face retrusion, proptosis, hypertelorism, and a depressed nasal bridge are frequently noted. Type 2 Pfeiffer syndrome is associated with cloverleaf skull, neurologic impairment, and variable elbow ankylosis or synostosis. Choanal atresia and cleft palate may be seen. Patients are at risk for early death.[2,98,107] Type 3 Pfeiffer syndrome patients lack cloverleaf skull but have a more severe phenotype than Type 1 patients; elbow ankylosis may be seen. Early death is common.[98] Conductive hearing loss is common in all subtypes.[24] Hydrocephalus is also very common, and has been reported in the majority of Type 1 and most or all Type 3 patients.[108] Cervical fusions are seen more commonly in Types 2 and 3.[109,110]

Although some authors have found similarities between certain patients with Pfeiffer, Crouzon, and Jackson-Weiss syndromes, the three disorders are nosologically distinct. According to Cohen, the phenotypes of the three conditions do not correlate well with the known molecular findings.[27,111,112] Patients with these three syndromes may have similar or even identical mutations in exon B of *FGFR2,* yet the phenotypes are inherited consistently within families, an observation that is as yet unexplained by the molecular findings.[71,99]

Kleeblattschädel or Cloverleaf Skull

Kleeblattschädel anomaly (cloverleaf skull) is a phenotypic description of a trilobular-shaped skull, usually secondary to pansynostosis of the coronal, lambdoidal, metopic, and sagittal sutures. In this situation the brain protrudes through the open anterior and parietal fontanelles giving the characteristic "cloverleaf skull" appearance. The cloverleaf skull anomaly is known to be both etiologically and pathogenetically heterogeneous; it may occur as an isolated anomaly or together with other malformations, making up various syndromes (i.e., Apert, Crouzon, Carpenter, Pfeiffer, and Saethre-Chotzen). The deformity commonly requires shunting for progressive hydrocephalus,[23] and chronic tonsillar herniation develops almost universally.[117] Because of the significant variation in associated deformities, the extent and timing of reconstructive surgery is highly patient-specific.[31,113-116]

Craniofacial Management

Basic principles of craniofacial surgery as developed by Tessier are as valid today as when he described them, and current techniques remain largely aligned with his original ideas. The principles that follow are directly traceable back to him and those who advanced his work.

Patient-Specific Planning

The care of patients with craniosynostosis syndromes follows certain timelines that have been supported by recent Parameters of Care.[118] The suggested timing of interventions is based on the balance between functional and psychosocial concerns and expected patterns of growth. Even so, every patient should be treated based on a unique, patient-specific diagnostic problem list. Developmental and neurocognitive assessments should be performed at regular intervals. Clinical craniomaxillofacial evaluation combined with anthropomorphic analysis and comparison to normative data is useful for characterizing the pattern and severity of craniofacial deformity. Radiographic evaluation with computed tomography with or without lateral cephalometry is a necessary adjunct to quantify and qualify the skeletal dysmorphism; MR imaging of the brain and spine is frequently indicated.

Timing of Surgical Care

The timing of any operative intervention is a major factor when planning for craniofacial reconstructive surgery in the growing child. Goals of surgical management in this group include minimizing surgical burden (number of operations, length of treatment periods); limiting operative risk; and eliminating long-term, adverse health sequelae (increased intracranial pressure, vision loss, hearing loss, chronic or acute obstructive airway events, severe psychosocial detriment). In general this means that surgery will be staged and interventions will proceed in a craniocaudal direction. Surgery cannot be expected to change abnormal growth patterns, and therefore the most definitive reconstruction can only be completed once structures can be treated to their adult size and position. Of course, functional and developmental concerns may require earlier intervention, but always with the understanding that additional operations for definitive reconstruction are a distinct likelihood.

Placement of Incisions

Incisions should be designed to minimize visible scars. The combined use of bicoronal and intraoral incisions provide substantial access to the cranium and face with minimal esthetic compromise and are preferred. A bicoronal incision allows access to all aspects of the cranial vault as well as the superior orbits, nasoorbitoethmoidal region, zygomas, and pterygomaxillary junction. A layered closure of the coronal incision (galea and skin) optimizes healing and limits scar widening. Resuspension of the mid-facial periosteum to the temporalis fascia may facilitate redraping of the soft tissues. When detached, each lateral canthus should be reattached in a superior-posterior direction with overcorrection. Intraoral incisions provide access to the infraorbital regions, nasomaxillary base, and pterygomaxillary junction as well as the mandibular ramus, body, and symphysis.

Subperiosteal Dissection and Osteotomies Under Direct Visualization

Dissection is safely and preferentially performed in a subperiosteal plane with wide exposure to provide clear and direct visualization for any osteotomy procedure. One of Tessier's original concepts was that careful dissection of the pericranium and periorbita would allow all osteotomies and reconstruction without interfering with ocular, oculomotor, palpebral, or lacrimal functions.[119] In addition, wide release allows for flap relaxation and placement of onlay or inlay bone grafts to improve stability.

Overcorrection, Stabilization/Fixation, and Grafting

Relapse is an expected component of healing for patients who undergo moderate to large movements of the craniofacial skeleton, especially before skeletal maturity. Causes of relapse may include normal biology of healing, inadequate surgical mobilization of hard or soft tissue structures, or ongoing aberrant growth. Because of these factors and in anticipation of the tendency to return to the natural deformity, overcorrection at the time of bony construction is often prudent.

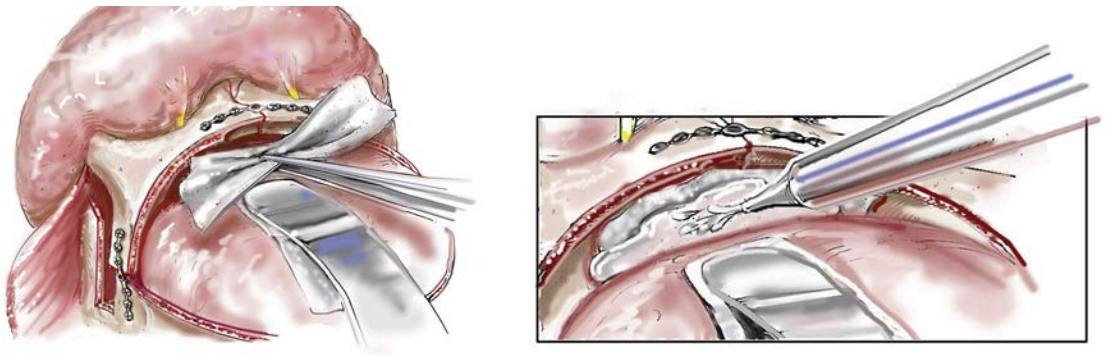
Stabilization of reconstructed skeletal structures using bone plates and screws (titanium or resorbable) further promotes maintenance of the surgical result. Fresh, autogenous bone grafts should be used to fill all possible defects to promote healing and stability with open reconstructive procedures.

Management of Intracranial Dead Space

Due diligence in eliminating or minimizing dead space is critical when increasing the dimensions of the cranium, especially retrofrontal intracranial dead space. Since the retrofrontal dead space is expected to dissipate predictably and relatively quickly in infants, conservative management is appropriate in this group.[120] As age increases, greater difficulty exists in predicting the timing and completeness of brain expansion to fill the intracranial cavity, and greater care must be taken relative to extent of surgical expansion and expectation of risk.

Management of Intracranial-Aerodigestive Communication

Of particular importance is the management of any cranial base communication between the sterile intracranial compartment and the bacteria-rich aerodigestive tract when



• **Figure 38-3** Basic operative principles to use in managing the cranial base defect include primary repair of dural tears when possible, dural grafting when needed, and re-creation of a tissue layer across the cranial base using some combination of bone grafts, tissue sealants, and/or pericranial flaps.

performing combined intracranial and extracranial surgery (monobloc advancement, facial bipartition, intracranial Le Fort III).[121,122] Optimally, no open communication should be left between the sino-nasal cavity and the anterior cranial fossa, and this seal should be protected during the early postoperative period. Basic operative principles to use in managing the cranial base defect include primary repair of dural tears when possible, dural grafting when needed, and re-creation of a tissue layer across the cranial base by way of bone grafts, tissue sealants, and pericranial flaps (Figure 38-3).[123,124] It is possible that distraction techniques offer advantages in protecting this barrier as well.[125] If working in the teenager or adult, frontal sinuses are often present and must be cranialized.

Postoperatively, care must be taken to allow sufficient time and immobilization of the local and grafted tissues to minimize risk of wound breakdown (fistula formation) and infection or loss of grafted material. Means to achieve this may include a period of extended postoperative intubation for 3 to 5 days and/or bilateral nasopharyngeal airways maintained after extubation. Additionally, after extubation care must be taken to avoid increasing nasal pressures by instituting mechanical sinus precautions and avoiding CPAP or positive pressure ventilation. When ventricular shunts are present management is significantly more complex, and great care must be taken in close coordination with the neurosurgical team to avoid overshunting (and prolongation or prevention of dead space elimination) or undershunting.

Algorithm of Care

Care of the child with syndromic craniosynostosis is based on understanding that form and function in the human condition are intimately linked. The natural shape, size, and proportions of the craniofacial region are finely tuned to provide and protect a multitude of functions including breathing, feeding, cognition, vision, hearing, smell, communication, and socialization. Because the design of the head and face is so well suited to these roles, any alteration in the form tends to cause deterioration in one or more of these functions. Because no one specialist can possibly evaluate and manage all the different concerns related to the health and well-being of a child with a craniosynostosis syndrome, care should take place in a center that is familiar with the management of these syndromes and that offers support from the many surgical, medical, and psychosocial disciplines required to yield optimal outcomes. Although each syndrome and indeed each patient has unique considerations, a guiding surgical framework can be conceptualized based on anticipated growth and development.

Infants and Toddlers (Birth to 4 Years)

Standard evaluation of the patient with syndromic craniosynostosis always begins with a thorough history and physical examination.

Airway

Of primary importance for the newborn with syndromic craniosynostosis is the patency and stability of the airway. Newborn infants are obligate nasal breathers for the first few months of life, making deficiency of the mid-face and nasal passages particularly problematic during this early stage.[126] The characteristic total mid-face deficiency seen in syndromic craniosynostosis frequently leads to diminished nasal and nasopharyngeal volumes and increased nasal airway resistance (obstruction) and these patients may be more prone to acute or prolonged obstructive problems.[127,128] A thickened velum (most frequently seen in Apert syndrome), choanal stenosis/atresia, and laryngotracheal anomalies can further contribute to structural airway obstruction.[128-131] Central apneas and hypopneas may also be present.[130,132,133]

Monitoring in a neonatal intensive care unit (NICU) is prudent, and interventions may be necessary to ensure the airway remains patent. Medical or surgical therapies to stabilize the airway may include positioning, nasopharyngeal intubation,[134] repair of choanal atresia, positive airway pressure,[135-137] or tracheostomy.[135,138,139] After the first year of life, adenotonsillectomy is an additional first-line treatment.[140-142] As with each functional concern, ongoing evaluation of the airway is required throughout growth and development, ideally at a multidisciplinary craniofacial center with airway expertise.[143-145] Strong consideration should

be given to baseline and regular polysomnography to screen for obstructive sleep apnea.

Feeding

Feeding is critical to maintain an anabolic balance. During the first months of life, the coordination of oral feeding with limited nasal airflow can lead to inadequate caloric intake, excessive caloric expenditure, or both. When the upper airway is sufficiently inhibited, an infant or child can fail to thrive even when capable of feeding orally for limited periods. Short-term nasogastric tube feeding or longer-term feeding gastrostomy tube placement can help overcome these challenges. The determination of when and how to pursue non-oral feeding should be made with appropriate input from the pediatrician/neonatologist, therapist with feeding expertise, and pediatric otolaryngologist after a consensus is reached about the etiology of the failure to thrive. In children with Apert or Pfeiffer syndrome screening imaging of the gastrointestinal system to evaluate for intestinal malrotation or esophageal atresia is often prudent.[2]

Vision

Protection of the ocular globes can be an urgent need soon after birth in the most severe phenotypes of syndromic craniosynostosis. When anterior cranial base and orbital hypoplasia is marked, exorbitism (shallow orbits) and exophthalmos (proptosis) can reach levels resulting in prolonged corneal exposure or even globe herniation. Persistent corneal exposure risks exposure keratopathy, abrasions, or ulcerations eventually threatening loss of vision. A pediatric ophthalmologist should participate in evaluation and planning, and artificial ocular lubrication may need to be meticulously maintained. In extreme circumstances, subluxation of the globe may even begin to occur chronically, requiring immediate and constant reduction. For the child with marked exorbitism and proptosis experiencing any of these vision-threatening complications, urgent cranio-orbital decompression with or without temporary tarsorrhaphies will be needed, and timing should be determined with the pediatric ophthalmologist's input.

The development of visual impairment over time in craniosynostosis syndromes is multifactorial and the incidence varies by diagnosis. Using a visual acuity cut-off that would allow one to get a driver's license, Khan found that 40% of this group had limiting visual impairment in their best eye.[146] Amblyogenic factors such as strabismus and refractive errors contribute to most cases of visual impairment with contemporarily managed patients. Importantly, these conditions are treatable with timely provision of eyeglasses for refractive errors, patching for amblyopia, or surgery for strabismus correction—all underscoring the importance of early involvement of the pediatric ophthalmologist.[87,146-148] Timing of strabismus correction as it relates to craniofacial procedures remains complex since cranio-orbital procedures are required early in life and may impact the multiple inciting factors.[149] Deferring strabismus surgery until after cranio-orbital reconstruction is often considered.

Hearing

Hearing deficits occur with increased frequency in children with craniofacial syndromes. The different syndromes vary in the types of audiologic problems that present, but conductive problems related to middle ear disease predominate.[24,81] Suboptimal hearing can contribute to impairment in speech and language development, and routine audiologic monitoring serves to promote early intervention in order to limit disability and maximize developmental progress. The field of amplification is rapidly advancing, and the oversight of a pediatric otolaryngologist is necessary.

Associated Anomalies of the Spine and Extremities

The limb defects found in some syndromic craniosynostosis patients require the involvement of orthopedic or plastic surgery specialists to assess and treat as appropriate. The first surgery for syndactyly is not urgent at birth.

The risk of spinal congenital anomalies noted previously necessitates radiographic screening of the spine early in life for specific syndromes, as well.[2]

Hydrocephalus

Nonsyndromic craniosynostosis rarely results in hydrocephalus. Within the syndromic group there are some syndromes that are particularly predisposed. This ventriculomegaly may and often does behave in a nonprogressive way as a benign or compensated finding that does not require shunting. Distinguishing between progressive hydrocephalus and nonprogressive ventriculomegaly is a difficult but important component of the neurosurgical care requiring experienced judgment.[23,89,90,150] Collman reports that ventricular dilation of either sort has been reported in between 30% and 70% of patients with Crouzon and Pfeiffer syndrome and 40% to 90% of patients with Apert syndrome.[23]

Progressive enlargement requiring shunting is more common in the Crouzon and Pfeiffer groups while those with Apert syndrome generally remain nonprogressive.[23,151,152] Difference in the timing of lambdoid synostosis has been hypothesized to explain these differences.[78]

Early on, patent fontanelles or sutures may allow for compensation of abnormal ventricular enlargement through increases in intracranial volume. As these mechanisms for compensation disappear, more vigilance is needed to prevent the development of aberrant pressures or to treat quickly once identified. Postulated causes of progressive hydrocephalus include mechanical obstruction to CSF outflow or impaired venous drainage based on skeletal changes in the posterior fossa leading to diminished CSF reabsorption.[23,153] When progressive enlargement is evident, shunting or endoscopic third ventriculostomy may be required. With evidence of increased intracranial pressure (ICP) in the absence of markedly expanding ventricles, cranial vault expansion is likely the best first course of action with close surveillance thereafter; this is discussed in the following section.[23]

Craniocerebral Disproportion

The goals of craniofacial reconstruction in the infant and toddler are to promote the protection, growth, and development of the brain and eyes and to normalize the cranial and upper orbital morphology. The cranial malformations associated with congenital absence of one or more of the cranial vault sutures may have negative neurologic effects in a subset of patients over time; this may be related to brain dysmorphology, altered regional blood flow, and/or inhibited cerebrospinal fluid dynamics. As more cranial sutures are involved, the risk for pathologic intracranial pressure rises markedly.[49-52] Thresholds for how high and how long intracranial pressure must be elevated to be classified as pathologic at any given age are not delineated by current evidence, but prolonged or repeated elevations are thought to contribute to the deleterious cognitive, behavioral, and visual effects of untreated disease.[154-171]

When the cranial vault is severely affected at birth by multisuture synostosis leading to profound constriction and concern for markedly elevated ICPs and exophthalmos, treatment with craniectomy over the sagittal suture with parietal and frontal outfracture as early as 12 to 16 weeks of life may be necessary for purely decompressive purposes. The decision to proceed in this urgent fashion is based on neurosurgical and ophthalmologic concerns and has very limited reconstructive goals.

It is commonly accepted that cranial vault expansion is the treatment of choice for syndromic synostosis with craniocerebral disproportion. Notably, there is significant center-to-center variation in preferences for region of the cranium and orbits to address first (i.e., posterior, anterior, total vault), techniques utilized (i.e., distraction, formal open reconstruction), and timing of surgery (i.e., less than 6 months, 6 to 9 months, older than 9 months). Endoscopic-assisted craniectomy of the coronal synostosis bilaterally with postoperative helmet therapy is a promising treatment that has been described, but is not yet widespread in application.[172,173]

In planning for nonurgent combined craniofacial and neurosurgical intervention with more complex reconstructive goals, consideration must be given to the distinct impact of the dysmorphology on the anterior cranial base, orbits, and the posterior cranial fossa. The anterior cranial base deformity has a significant negative impact on frontofacial esthetics and orbital position while the posterior fossa constriction may have implications for venous congestion, CSF hydrodynamics, and chronic tonsillar herniation. Clinical examination of the remaining open sutures, intracranial fullness, and orbital coverage is an invaluable guide to timing the first cranial intervention and to determining the first site of intervention; for instance, when the posterior deformity is not severe, anterior vault reconstruction may be the first stage of treatment. Dedicated, high-resolution CT evaluation of the craniofacial structures further characterizes the bony abnormality and assists with surgical planning. Brain MR imaging is indicated in specific patients who are predisposed to progressive hydrocephalus or who have marked posterior fossa deformity.[23,79,174,175]

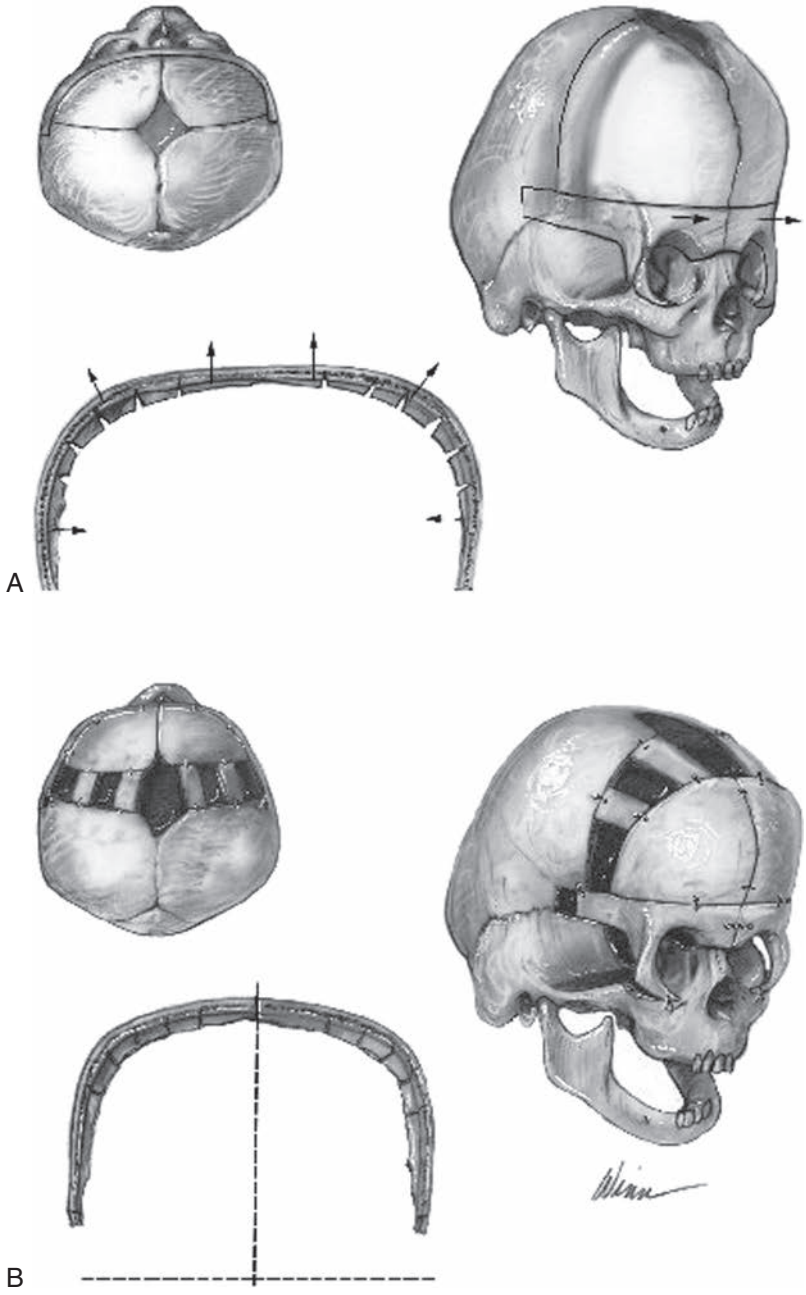
In the absence of acute functional disturbance, there are data to support the first stage of cranial vault expansion after 6 months of age and before 18 months.[176-178] This time frame has been shown to minimize the need for reoperation while still being mindful of the possible neurologic implications of waiting. After 9 to 12 months of life the reconstructed cranial structures may better maintain their shape and relative position, which should translate to fewer repeat procedures later in life.[159-161,179]

Standard treatment of the anterior cranio-orbital dysmorphology involves release of the affected cranial vault sutures with simultaneous anterior cranial vault and upper orbital decompression and recontouring (Figure 38-4).[73,126,127,178,180,181,184,185] Few advocate for distraction of the anterior cranial vault because of the complex reshaping that is usually required.[186] The goals of treatment include decreasing the bitemporal and anterior cranial base width at the level of the supraorbital bandeau while advancing the superior bony orbit. This should serve to ameliorate proptosis and allow for better periorbital coverage of the globe. Concurrently, the frontoforehead unit is advanced in the sagittal plane and recontoured.

When brachycephaly is combined with marked posterior occipital flattening (often leading to turricephaly), surgery to expand and reshape the posterior vault can be considered as a first stage (Figure 38-5). Children with brachyturricephaly generally need marked expansion, and greater magnitudes can be accomplished with posterior vault reconstruction than with fronto-orbital advancement.[187-189] Posterior vault expansion can be done by direct reconstruction as a single stage or by using distraction osteogenesis techniques.[187,189-196] The proposed advantages of posterior vault distraction include possible greater volume increases relative to conventional open reconstruction or anterior vault expansion and shorter operative time in some series.[191,196-198] Disadvantages include the inability to expand in three dimensions, a required second-stage operation to remove the distraction devices, and the increased risk of complications related to the mechanical distractor devices (infection, failure, scarring). Reported complication rates currently range from 12.5% to 100% and average 35.5%; device failure and infection are the most common.[188,189,191,192,194,196,199,200]

Treatment of the entire cranial vault in a single stage must take into consideration the increased risks involved, including a more complex anesthetic and positioning considerations. As such, total vault reconstruction remains infrequent.

Concurrent suboccipital decompression for chronic tonsillar herniation has been described, but is not routine practice.[117,201] Persistent, progressive or symptomatic chronic tonsillar herniation may be treated by a second stage of posterior cranial vault expansion. Staging the initial posterior vault expansion for a second cranial procedure may allow for more meaningful long-term posterior fossa expansion and treatment of chronic tonsillar herniation.[202] Standard suboccipital decompression may also be utilized.

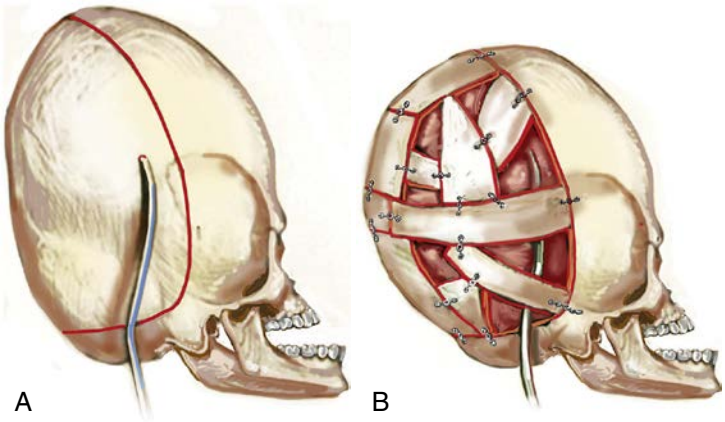


• **Figure 38-4** Illustration of the craniofacial skeleton of a child with bilateral coronal synostosis before and after anterior cranial vault and three-quarter orbital osteotomies with reshaping as described. **A,** Site of osteotomies as indicated. **B,** After osteotomies and reshaping and fixation of the cranio-orbital regions.

Recurrent Intracranial Hypertension

Throughout infancy and the toddler years, children must be followed in an interdisciplinary fashion. Venous obstruction, progressive hydrocephalus, and hypercarbia due to apneas may all contribute to intracranial hypertension. Importantly, it should be remembered that cranial vault expansion incompletely addresses venous obstructive problems—particularly with unaddressed posterior fossa deformity—and does not address airway concerns at all.[153] Clinical signs and symptoms of increased intracranial pressures may include irritability, papilledema, or a bulging fontanelle; however, these may be subtle and nonspecific in the pediatric population. To complicate matters, the majority of patients have no signs or symptoms until irreversible negative effects have accumulated.[174,203,204]

Routine screening for children with syndromic craniosynostosis should include regular craniofacial and neurosurgical evaluation, regular ophthalmologic evaluation, regular screening for sleep disordered breathing, and imaging as needed. Ophthalmologic evaluation is very useful to assess the optic disc since papilledema in this young age is quite specific for an increase in ICP. Importantly, absence of papilledema has low sensitivity for ruling out the condition.[204-207] Radiographic assessments may provide findings



• **Figure 38-5** **A,** Illustration of flattened posterior cranial vault with a ventriculoperitoneal shunt in place. **B,** Illustration after posterior cranial vault shaping is also shown.

that are supportive of persistent craniocerebral disproportion, including the thinning and patterning of the internal skull known as a "copper-beaten" appearance or the loss of brain cisternae observed on a computed tomography (CT) scan.[168-171] Intracranial monitors are indicated in equivocal circumstances to provide more information about ICP, but this too requires judgment as no clear normative data is available for children.[153]

Ideally, because of the implications of apneas on ICP, level I polysomnography would be obtained for any patients with symptoms of OSA.[208] If OSA is identified and considered a contributor, interventions to maintain airway patency are considered as described previously. In general, mid-face advancement should be avoided in this young age group because of the predictably poor maintenance of any improvements in the airway with additional growth.

If concerns arise regarding increased ICPs, further treatment with cranial vault decompression may be required.[113,168,180-182,209] In these circumstances the particulars of the surgical intervention should be dictated by the patient's presentation, and clinical judgment dictates what type of expansion is most prudent. When the determination is made that the greatest benefit can be obtained from treating the anterior cranial vault and orbits, surgical planning and execution similar to the original reconstruction is repeated. If there is greater concern about posterior shape and constriction as is more common in Apert syndrome and the more severe phenotypes of the craniosynostosis syndromes, expansion of the posterior cranial vault is performed.

When a repeat craniotomy is required, it is important to anticipate the increased technical challenges and attendant morbidity that must be expected. Simply turning a coronal flap will require more time and greater care to identify full-thickness calvarial defects and avoid dural tears. The bone may be more brittle and jagged than in the unoperated child, and dissection of the dura from the bone can be more challenging.[210,211] Dealing with these issues will lead to a longer operating time and increase expected blood loss.

The Young Child (4 to 13 Years)

Multidisciplinary coordination of care should continue throughout childhood with regular neurosurgical, craniofacial, ophthalmologic, audiologic, speech, psychological, airway, and genetic specialty surveillance and care.[212]

In the early school age years, the dysmorphology of the subfrontal facial mass and orbits takes priority. The deformity is a complex three-dimensional problem that requires a patient-specific approach. There is always some degree of sagittal underprojection of the upper mid-face and maxilla, but also vertical deficiency with telescoping of the nose upwards and variable degrees of transverse variance with facial widening and orbital hypertelorism superiorly and maxillary constriction inferiorly.[213-216]

Treatment is indicated based on the related functional, morphologic, and psychosocial implications of this deformity. The most significant functional problem is related to airway obstruction. Obstructive sleep apnea is a frequent finding with reports of between 40% and 80% of children being affected.[126,135,144,208,217-220] In symptomatic patients this percentage rises to between 68% and 74%. It is worth noting that relief of airway obstruction following monobloc or Le Fort III advancements has been unpredictable in some studies[221,222] and associated with recurrence in others.[223] Comprehensive airway evaluation in children with OSA should include preoperative nasal and endoscopic pharyngeal evaluation by an airway surgeon to fully characterize the level(s) of obstruction. Adenotonsillectomy should be considered prior to mid-face advancement when indicated.

Multiple surgical approaches are available to address this region, and the selected approach is based on the patient's individual needs. The goals of reconstruction with frontofacial advancement are to achieve acceptable forehead projection and symmetry when forehead and supraorbital projection remains deficient, minimize abnormalities in orbital depth and position, and improve the arc of rotation of the face with the aim of opening the airway. It is the exception to the rule that deficiency of projection along the cranium, zygomas, orbits, and upper jaw is uniform.

Fronto-orbital dysmorphology and not malocclusion should determine reconstructive goals at this stage because if a Le Fort I separation of the "total mid-face" complex is not carried out and the surgeon attempts to achieve a balanced occlusion, an overadvancement of the orbits with enophthalmos will typically occur. Normalizing the occlusion during the preadolescent years does not provide a maintainable outcome as remaining mandibular growth makes long-term stability unlikely. Generally, the Le Fort I osteotomy is thus *not* performed at the time of the "total mid-face" procedure. This will await skeletal maturity and then be combined with orthodontic treatment for stability purposes; until then a malocclusion may remain. Of course, in the teenager or adult who requires both total mid-face and orthognathic management, these procedures may be carried out simultaneously.

Additional functional concerns indicating the need for frontofacial advancement may include increased intracranial pressure as frontofacial advancement can provide anterior cranial expansion to increase intracranial volume.

Increased osseous protection of the vulnerable globe is also achieved with desirable esthetic improvements. With distraction procedures particularly, it is important that families anticipate some degree of overcorrection and esthetic compromise in the short term with the understanding that form will improve with ongoing lower facial growth.[223]

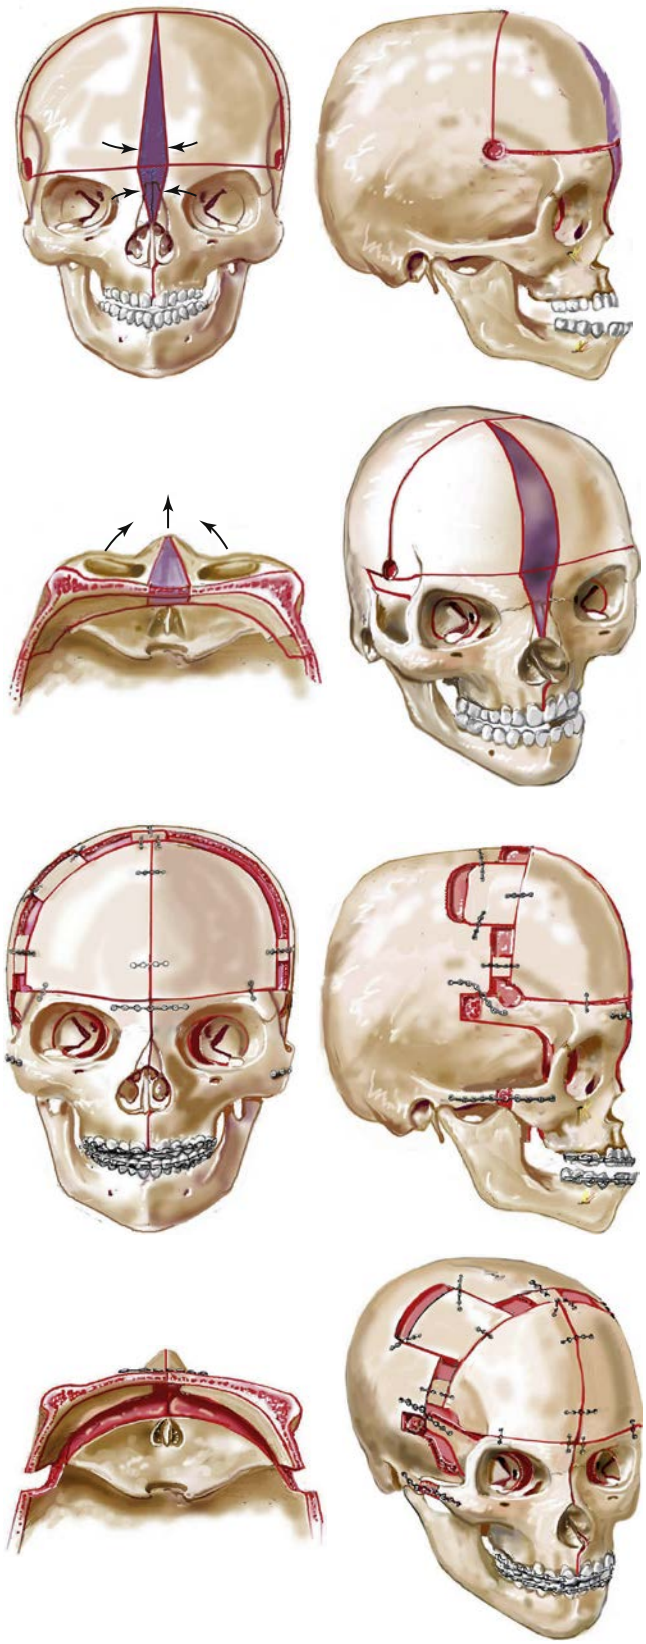
Definitive reconstruction of the orbital and upper mid-facial structures with or without readdressing the fronto-forehead unit in syndromic craniosynostosis for these goals is reasonable by 6 to 9 years of age since the cranial vault and orbits have attained approximately 85% to 90% of their adult size.[180,181,224-226] Although a recent assessment of centers treating Apert children found that first advancement took place at an average age of 5 years old, later treatment (after 8 years of age) has been shown to decrease the risk of additional surgery and should be considered when possible.[176,223] In addition, allowing time for the first molar teeth to erupt into occlusion can help with control of the advancement at the occlusal plane. Furthermore, this time frame coincides with early socialization in school, and there are psychosocial benefits to improving facial proportions and appearance during this stage.[227-230] A growing awareness of the negative implications of chronic airway obstruction and sleep disordered breathing is increasingly used as an indication for surgical intervention at the mid-face level at an earlier age, but this remains to be justified in light of the risk of recurrent obstruction and need for additional mid-facial advancement later in childhood.

The observed dysmorphology is dependent on the original malformation, the previous procedures carried out, and the effects of ongoing growth. If the supraorbital region, anterior cranial base, zygomas, nose, lower orbits, and maxilla all remain deficient and/or deformed in the sagittal plane (horizontal retrusion), a monobloc osteotomy is indicated. In these patients, the forehead is generally flat and retruded and will also require reshaping and advancement. If upper mid-face hypertelorism (increased transverse width) and mid-face flattening (horizontal retrusion) with abnormal facial curvature (concave arc) are also present, then the monobloc unit is split vertically in the midline (facial bipartition), a wedge of interorbital (nasal and ethmoid) bone is removed, and the orbits and zygomas are repositioned medially while the maxillary posterior arch is widened (Figure 38-6). When a monobloc or facial bipartition osteotomy is carried out as the "total mid-face" procedure, additional segmentation of the upper and lateral orbits for reconstruction may also be required to normalize the morphology of the orbital esthetic units.

Frontofacial advancement and/or cranial vault expansion procedures should be carefully staged with ventriculoperitoneal (VP) shunting procedures because the potential for morbidity is increased. In a patient with a VP shunt in place before the surgery, an experienced neurosurgical evaluation, including CT scanning of the ventricular system, is carried out to confirm physiologic shunt function. Surgery should be undertaken with extreme caution in the patient with a limited ability to eliminate the retrofrontal dead space.

If the supraorbital ridge is in good position when viewed from the sagittal plane (the depth of the upper orbits is adequate), the mid-face and forehead have a normal arc of rotation in the transverse plane (not concave), and the root of the nose is of normal width (minimal orbital hypertelorism), there is no need to further reconstruct this region (the forehead and upper orbits). In such patients, the basic residual mid-face deficiency and/or deformity is in the lower half of the orbits, zygomatic buttress, and maxilla. If so, the orbital-midface deformity may be effectively managed using an extracranial Le Fort III osteotomy (Figure 38-7).

Distraction osteogenesis as an alternative method to advance the frontofacial mass was described as early as 1995.[231] Using both external and internal types of devices, numerous centers today have adopted distraction osteogenesis techniques to facilitate advancement of the frontofacial mass while hoping to minimize complications and increase stability.[232-245] A proposed, theoretical advantage of distraction techniques is that it limits retrofrontal dead space and improves the seal across the cranial base, which may decrease the rate of meningitis, osteomyelitis, and loss of bone flaps.[125] In addition, multiple studies have suggested an ability to advance the mid-face with greater stability using distraction techniques as compared to single stage surgery.[243,246-248] It must be noted that relapse given in percentages is less useful than absolute values in this setting. The difference between 12% relapse (typical for conventional Le Fort III) and 5% relapse (typical for Le Fort III distraction osteogenesis) for a 15-mm advancement is 1 mm,[249] which is of questionable clinical significance and may not be a sole justification for distraction. In addition, no correlation has been shown between number of millimeters of advancement at



• **Figure 38-6** Overview of the skeletal morphology before and after facial bipartition osteotomy with repositioning and stabilization.

the frontofacial osteotomies and either greater functional gains or enhanced facial esthetics, so ability to further advance the mid-face with distractors has not yet been shown to have clear benefit.

A significant potential limitation of distraction techniques includes greater challenges in achieving the above mentioned key technical and esthetic reconstructive aspects in all three planes of space given the linear mode of operation. Emerging adaptations to address these limitations include bipartition prior to activation or combined monobloc with Le Fort II distraction.[190,250-253] Other disadvantages of distraction techniques for mid-face advancement include additional chances for morbidity as a result of pin tract infection, scarring, and/or device loosening requiring reapplication.[232-236,238-242,254-260] In all cases, there is the need for an additional surgical procedure and anesthetic for device removal. Distraction techniques are not immune to mechanical complications including pin migration, secondary trauma, CSF leakage, loss of bone flaps, or mortality. Dependence on a patient's, family's, and clinician's continued commitment to staying the course for necessary outpatient procedures or adjustments to achieve an acceptable result must also be factored into the decision-making process.

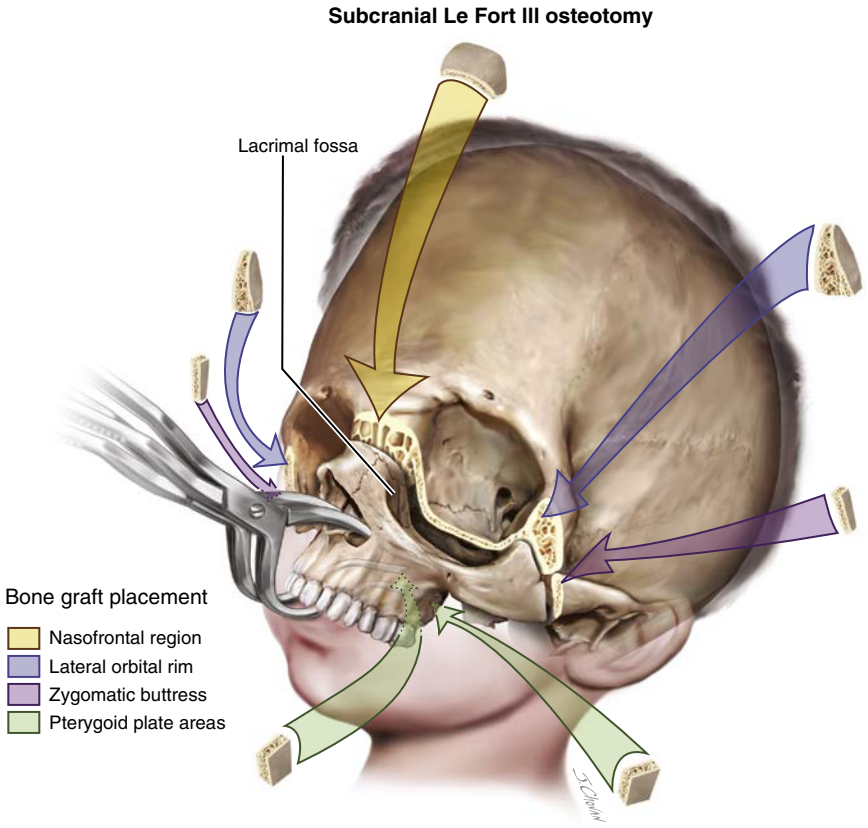
How the severity and frequency of complications compares between distraction and single-stage monobloc procedures remains a matter of debate to be settled; some centers continue to advocate for frontofacial distraction as superior,[243] some favor single-stage reconstruction,[261] and others promote predominantly subcranial treatment.[210] Surgeon expertise, clinical factors, and family input must all be considered when choosing the appropriate modality.

The Adolescent (13+ Years)

In the craniosynostosis syndrome patient with a mid-face deficiency, hypoplasia exists in all three planes of space. The upper anterior face is both vertically short (nasion to maxillary incisor) and there is a lack of horizontal (AP) projection of the mid-face. In addition, the width of the maxilla in the dentoalveolar region is generally constricted with a high arched palate. The mandible and chin may become secondarily deformed and benefit from surgical repositioning as part of orthognathic correction.

An Angle class III malocclusion is the expected maxillomandibular relationship secondary to the marked mid-face deficiency in most cases. This has deleterious functional implications for mastication, speech, dental health, and possibly temporomandibular joint function. Dental crowding is frequent as a result of maxillary hypoplasia, even though it is common to be missing teeth in syndromic synostosis.[262]

Normalization of the lower face and occlusion is most predictably accomplished through combined orthodontics and orthognathic surgery. In the syndromic craniosynostosis patient the lower jaw is expected to grow throughout skeletal maturity, therefore operative intervention with the



• **Figure 38-7** The subcranial Le Fort III osteotomy.

aim of normalizing the occlusion should be performed no sooner than the time of early skeletal maturity (approximately 13 to 15 years in girls and 14 to 16 years in boys) for optimum long-term stability. Ever since Obwegeser's innovative approach to osteotomies of the upper and lower jaws, the overwhelming majority of patients can be treated appropriately using some combination of standard orthognathic surgical techniques of Le Fort I level maxillary osteotomy, bilateral sagittal split mandibular osteotomies, and/or osseous sliding genioplasty. Further advantages of the Le Fort I osteotomy include the ability to address septal deviations and inferior turbinate hypertrophy concurrently with maxillary repositioning.[263]

Clinical assessment of the facial components in three planes of space along with the occlusal plane orientation drives treatment decisions. Cephalometrics and study models augment the clinical exam. Vertical proportions are assessed and compared to expected facial height and width with maxillary incisor display factoring into the assessment. Transverse asymmetry is determined by clinical exam and can be augmented by CBCT data. The maxillary width is assessed from soft tissue relationships and using dental casts. Canting and vertical asymmetry are noted on clinical exam. Sagittal projection is assessed using a natural head position and looking for balance between the forehead, nose, lips, and chin. These techniques are covered in more detail elsewhere in this textbook and may be referenced there.

Adjunctive Procedures: Rhinoplasty, Cranioplasty, Ptosis

Final reconstruction often requires soft tissue nasal and periocular procedures. Periocular considerations include variable lateral canthal malposition and upper lid ptosis in Apert patients, frequently with asymmetry.[119] Ptosis repair or lateral canthopexies may be needed at the surgeon's discretion. Secondary rhinoplasty will benefit many patients, especially those with Apert syndrome. Further detail of these procedures is beyond the scope of this chapter, but should be considered a necessary component of care in the syndromic craniosynostosis population.

Conclusion

The preferred approach to the management of a patient with syndromic craniosynostosis is to stage reconstruction based on craniofacial growth patterns, functional demands (cognition, vision, breathing, swallowing, speech, chewing, hearing), and psychosocial effects. Recognition of the need for a staged reconstructive approach allows clarification of the objectives of each phase of craniofacial treatment for the surgeons, craniofacial team, and family. By continuing to define our rationale for the timing, techniques, and extent of intervention and to objectively evaluate functional and morphologic (esthetic) outcomes, the quality of life for children born with a craniosynostosis syndrome will be further improved.

Acknowledgment

The authors would like to thank and recognize the previous authors of this text, Jeffrey Posnick and John Amato, whose expertise and contributions regarding the evaluation and management of these patients are maintained throughout the content of this chapter.

Oculoauriculovertebral Spectrum: Staged Reconstruction

BERNARD J. COSTELLO, RAMON L. RUIZ, JOHN F. CACCAMESE, JR.

Oculoauriculovertebral spectrum (OAVS) is a complex, three-dimensional hypoplasia that results from disruption of the development of the first and second branchial arches. This hypoplasia produces challenging reconstructive needs in the areas of the cranio-orbital complex, zygoma, maxilla, mandible, peri-orbital soft tissues, and ear. The variability of phenotype is impressive, ranging from minimal asymmetries and ear anomalies to complex lateral facial clefting with significant functional concerns and disrupted development of the lateral facial structures (Figures 39-1 and 39-2).

Because of the multifaceted aspects of the functional and esthetic challenges faced by patients with OAVS, a number of specialists are typically involved in the patient's care at multiple stages. Surgeons must understand the biologic basis for the deformity, as well as the expected esthetic and functional issues that may arise throughout the child's stages of growth. A thoughtful, staged reconstructive approach that respects the growth of these structures is best suited to address the complex needs of patients with OAVS. This chapter reviews some of the most important concepts of care for patients with OAVS and presents a staged, interdisciplinary reconstructive approach for dealing with the multiple dysmorphologies.

History

Goldenhar syndrome, which is often considered a variant of hemifacial microsomia, was initially described in the 1950s and was redefined by Gorlin in the 1960s.[1,2] This syndrome includes the characteristic hypoplastic mandible (often asymmetric), along with epibulbar dermoids and vertebral anomalies. By 1976, so much overlap with hemifacial microsomia had been reported that a clear distinction could no longer be made. The condition is now known to be extremely heterogeneous and complex; therefore, the term *oculoauriculovertebral spectrum (OAVS)* has been used.[3] Those at the Goldenhar syndrome end of the spectrum likely account for only about 10% of cases.[4]

Dysmorphology

The extent of dysmorphology in OAVS is considerably variable. Although no minimal diagnostic criteria have been set forth, many believe that the mildest form of this spectrum is expressed as microtia or preauricular or auricular abnormalities.[3] Patients may exhibit severe underdevelopment or lack of development of a number of structures, including the mandible, temporomandibular joint, orbit, ophthalmic structures, zygoma, maxilla, external ear, internal ear, and surrounding soft tissues. Involvement is not limited to facial structures, however, because renal, genitourinary, cardiac, and skeletal anomalies have been reported to occur with variable frequency.[3,5,6] Features of OAVS are listed in Box 39-1. Few patients exhibit all or even most of these findings. Patients with multiple congenital anomalies often are classified as patients with Goldenhar syndrome. The incidence of OAVS in the general population has been estimated at anywhere from 1:3500 to 1:26,500 live births; however, the generally accepted frequency is approximately 1:5600.[3,7]

Pathogenesis

OAVS has remarkable heterogeneity, and there are multiple etiologies.[3,8-11] Multiple chromosomal anomalies have been linked to this complex, the most significant of which are deletion 5q, trisomy 18, and duplication 7q. OAVS has also been observed in the children of diabetic mothers and in those exposed to retinoic acid, thalidomide, and primidone.[4] Additionally, a gene locus at 14q32 has been linked to OAVS and similarly has been linked to microphthalmia.[12]

• **Figure 39-1** **A** and **B,** An infant female is shown with minimal features of oculoauriculovertebral spectrum (OAVS), including external ear abnormalities. **C** through **E,** A young child with OAVS that is more significant, including external ear atresia, Kaban type IIB mandible hypoplasia, soft tissue hypoplasia, and asymmetries of the orbit, zygoma, and maxilla. She has already undergone distraction osteogenesis prior to age 5 by another surgeon but retains significant asymmetries throughout the anatomic regions, including the mandible.

Discordance is the rule among monozygotic twins, although infrequent concordance with variable expression has been documented.[6] Most cases of OAVS are sporadic, but familial instances have been reported with autosomal dominant, recessive, and x-linked inheritance patterns.[3,4] When an inheritance pattern is noted, there tends to be more dramatic dysmorphology and bilateral cases tend to be more common. Wieczorek and colleagues found an association between assistive reproductive technologies and OAVS.[11]

Poswillo was able to reproduce a hemifacial microsomia phenotype in an animal model by using maternal thalidomide exposure. He suggested that the pathogenesis was due to in utero vascular disruption of the stapedial artery anastomosis.[13,14] Resultant anomalies were found to depend on the extent of the hematoma, with large hematomas taking more time to resolve and thus resulting in more local tissue damage.

The constellation of anomalies seen in human OAVS (and associated conditions) suggests origin at about 30 to 45 days' gestation.[15] Hematoma itself has many causes, including maternal-fetal hypoxia, hypertension, and anticoagulants. It should be noted that even though hematoma

• **Figure 39-2 A** through **D,** This young boy with Goldenhar syndrome has a left-sided Tessier no. 7 cleft (macrostomia), left-sided hypoplasia in multiple anatomic units, and bilateral conductive hearing loss. Postoperative results show good healing of the commissure with minimal scarring. (The patient is also seen wearing a conductive hearing aid headband in **C**.)

Head and Neck

- Maxillary and mandibular asymmetry with hypoplasia on the affected side
- Microphthalmia
- Hypoplastic adnexal structures
- Coloboma
- Zygomatic hypoplasia
- External ear abnormalities or atresia
- Internal ear abnormalities
- Temporomandibular joint hypoplasia or absence
- Hypoplastic dentition or oligodontia
- Parotid hypoplasia or agenesis
- Plagiocephaly
- Torticollis

Associated Congenital Anomalies

- Cardiac defects (tetralogy of Fallot, ventricular septal defect, aortic coarctation, patent ductus arteriosus)
- Lung hypoplasia
- Renal agenesis, ectopic kidney, multicystic dysplastic kidney, vesicoureteral reflux, or ureteropelvic junction obstruction
- Vertebral anomalies
- Mental retardation, Arnold-Chiari malformation, encephalocele[20,23-28]

formation may explain the OAVS phenotype in some sporadic cases, it does not explain familial inheritance or the multiple malformations associated with OAVS.

In contrast, Johnston and Bronsky suggested that OAVS may represent a malformation sequence with major primary neural crest cell involvement in all or most cases.[16,17] These authors point out that hemorrhages produced in the Poswillo animal model occurred 2 days after thalidomide treatment, which is an unusually long delay for a primary developmental alteration.[13-17] Although late mandibular abnormalities were considered related to the hemorrhages, the cerebral hemispheres and mandibular arches were already severely underdeveloped at the time the hemorrhage occurred. These findings suggest that thalidomide-induced hemorrhage may not be the disruptive pathogenic mechanism for hemifacial microsomia, but instead that thalidomide may have had a teratogenic effect on second arch neural crest cells. Johnston and Bronsky point out a number of common characteristics of other otofacial malformations (i.e., retinoic acid syndrome, DiGeorge syndrome, Down syndrome, and Treacher Collins syndrome [TCS]) with hemifacial microsomia, which include mandibular, auricular, and conotruncal cardiovascular malformations (except in TCS).[16,17] The pathogenesis of these conditions involves the death of neural crest and adjacent cell populations of the second arch and retarded neural crest cell migration, possibly related to an altered retinoic acid (RA) and cellular retinoic acid binding protein (CRABPI) sensitivity in these cell populations.[16,17]

This complex sequence of variable expression typically is viewed as a heterogeneous complex rather than a distinct entity.[18] It is unclear why some patients exhibit more severe forms of hypoplasia and asymmetry. Patients with multiple congenital anomalies typically present with more severe dysmorphologies and a greater degree of asymmetry when compared with most sporadic cases. Patients who are believed to have Goldenhar syndrome typically exhibit bilateral hypoplastic tissues, but these are asymmetric in nature, unlike those seen with Nager syndrome or TCS. Patients with Nager syndrome or TCS typically exhibit more symmetry but also have severe hypoplasia of the same group of tissues derived from the first or second branchial arches.

Classification

In addition to the wide variety of terms applied to this complex, systems of classification have been identified to describe various aspects of the multiple malformations.[19-25] Mandibular morphology in OAVS is well described and has been well classified by Pruzansky, Kaban and others.[20,25-28] The extent of the temporomandibular joint (TMJ) dysmorphology is a principal factor when the timing of and techniques for mandibular reconstruction are considered.[15] Kaban's classification successfully defines the degree of TMJ deficiency, providing the diagnostic framework for a functional reconstruction.[15,20,21,27-29] Imprecise characterization of the extent of TMJ deficiency can result in misguided and inappropriately timed reconstruction.

The system of classification used most often describes deformities of the TMJ and ramus unit.[20,21,26-28] Type I skeletal defects involve mild, three-dimensional hypoplasia of the TMJ complex. Significant functional consequences are not usually associated with the deformity. Patients with type II OAVS have more moderate hypoplasia and are subdivided by IIA and IIB deformities. Type IIA deformities are those with relatively mild hypoplasia (but better than type I) and good function of the mandible. Type IIB deformities are those with more significant hypoplasia and an impaired TMJ complex, but one that still exhibits a posterior "stop" or articulation of the pseudocondyle with the cranial base. Patients usually have some limitation of function at the TMJ. Type III deformities are those characterized by absence of the functional unit (condyle and ramus). Additionally, the glenoid fossa may be poorly formed or absent with a smooth/hypoplastic cranial base. Patients with IIB and III deformities usually benefit from reconstruction of the ramus/condyle unit. Kaban type I and type II deformities can largely be managed by a variety of traditional orthognathic techniques at skeletal maturity, and some type IIB or type III deformities have been reconstructed with replacement of the vertical ramus with the use of rib, free fibula, or free metatarsal flaps.[30-32]

Another classification system has been described by Vento et al.[23] This system borrows from the tumor-node-metastasis (TNM) system used for clinical staging of tumors in the head and neck. The OMENS system (O for orbital distortion; M for mandibular hypoplasia; E for ear anomaly; N for nerve involvement; and S for soft tissue deficiency) breaks

• BOX 39-2 OMENS Classification System for Oculoauriculovertebral Spectrum

1. Orbit
   0 = normal
   1 = small size
   2 = poor position
   3 = both small size and poor position
2. Mandible
   Type I
   Type IIA
   Type IIB
   Type III
3. Ear
   Type I = small ear but most of the normal structure
   Type II = severely affected external anatomy with rudimentary auricle present
   Type III = external ear is only a small rudiment with no pinna
   Type IV = anotia
4. Nerve (cranial nerve VII)
   0 = normal
   1 = upper branches impaired
   2 = lower branches impaired
   3 = upper and lower branches impaired
5. Soft tissue
   0 = normal
   1 = mild hypoplasia
   2 = moderate hypoplasia
   3 = severe hypoplasia

out the deformities by anatomic structure and discusses the more complete picture of the deformity (Box 39-2). Each region is given a numeric and/or letter designation based on the anatomic components that are affected. An amendment to this approach has been proposed to indicate the presence of anomalies in other systems outside of the craniomaxillofacial complex.[24,25] Although the OMENS and OMENS-plus systems are more cumbersome to use clinically, they do encourage complete evaluation of the deformity and prompt thoughts regarding reconstruction of each region.[24,25] Once the complete deformity has been realized, a thoughtful, staged reconstruction can be formulated that plans for esthetics and function and respects growth potential in each area.[15,18,29]

Staged Reconstruction

The deformities of OAVS require a staged approach, tailored to meet the functional and esthetic needs of each patient. The following sections discuss the important aspects of each area typically affected by OAVS and the authors' preferred approach to the reconstruction. In general, those areas that have a functional concern are addressed in a standard, timely fashion to provide functional units during development when necessary. Timing is further based on maturity of the area of concern, such that reconstruction is provided once most growth velocity for that region is complete. However, functional concerns may supersede these growth concerns. For example, if a cleft palate is present, this is typically addressed at a time that respects growth concerns but provides for functional speech. Orthognathic surgery is typically performed during the teen years, when the vast majority of growth is complete, such that a stable and predictable result is achieved without the need for additional revisions. Some deformities are reconstructed in a way that is custom-tailored to the patient's needs when necessary. For example, esthetic concerns that become psychosocial problems for a child may be addressed earlier than at full maturity if the reasons are compelling. The overall approach is outlined in Table 39-1. Although considerable controversy surrounds the timing of these procedures, the authors prefer this approach, which respects growth potential when possible (see Table 39-1).

One important consideration is the nature of the deformity itself and whether or not it is progressive in most patients. This is a point of contention for many, and opinions on this fundamental aspect directly affect the thought process of how clinicians approach treatment planning for OAVS. Many believe that OAVS is a stable dysmorphology, which means that the deformity does not worsen over time.[28,29] Therefore, the degree of hypoplasia is similar if not identical at a young age to that seen when the patient grows to the teen years. For those who believe this to be the case, staging of orthognathic procedures is done in a fashion similar to that used in patients who do not have congenital deformities. Thus, waiting until the teen years to address maxillomandibular discrepancies allows the patient to grow to maturity and permits the surgeon to provide a stable and predictable result that is not likely to require revision surgery because of additional growth. Subscribers to this philosophy accept that the deformity does not worsen over time; therefore, there is no compelling reason to address asymmetries earlier for most patients.[15,29]

On the other side are those who believe that OAVS is a progressive deformity that should be addressed earlier to avoid additional asymmetry that might occur if one waits until skeletal maturity is reached. This is a primary argument for early distraction procedures aimed at lengthening the mandible at a young age to provide better symmetry at that time. Those who subscribe to this philosophy believe that leaving the deformity until the teen years will result in worsening asymmetry with time. Some data support this finding, although other data argue against it.[26-29] Several studies have evaluated patients in a longitudinal fashion and found that the deformity is not progressive in these cohorts.[15,29,33] Studies that previously had supported the idea that OAVS is a progressive deformity were not longitudinal and therefore may exhibit statistical and conceptual flaws that negate the concept of progressive deformity.[26-28,33]

Published outcomes of both of these approaches are good, and both techniques have been used with success. Although the early intervention approach has shown considerable merit, in the opinion of the authors, definitive operations performed in minimal stages offer the most predictable and long-lasting result with minimal intervention. This decreases the burden on the child, family, and health

TABLE 39-1 Authors' Approach to Treatment of Oculoauriculovertebral Spectrum

Deformity	Typical Age of Reconstruction
Cleft lip	3 months or later
Cleft palate	9-14 months Note: Submucous cleft repaired only if speech is affected once a complete speech evaluation is performed.
Cranio-orbital asymmetry	2-5 years or later
Oribital hypoplasia/ microphthalmia	5 years or later
Zygomatic hypoplasia	5 years or later
Kaban type III TMJ (atretic TMJ/ramus)	5 years or later
Maxillomandibular asymmetry	14-16 years or later in females 16-18 years or later in males
Soft tissue deficiency, lateral face	After orthognathic procedures
External ear	5 years of age or later

care system, while also providing the most accurate and definitive result.

Airway Management

Ensuring a stable airway is a primary concern. In some instances, OAVS may be diagnosed during fetal evaluation, and approximately half of these patients exhibit oligohydramnios or polyhydramnios, indicating possible fetal swallowing issues that may manifest as airway difficulty at birth.[34] In these settings, it may be important to consider airway management at the time of birth. Although an ex utero intrapartum treatment (EXIT) procedure or tracheostomy is rarely required immediately at birth for patients with OAVs, it is advantageous for the clinician to be prepared for a difficult intubation and management of the airway. In most instances, positioning the child lateral or prone may assist in improving airway dynamics. In some instances, a temporary nasal trumpet or stent may be helpful in the intermediate management of obstruction.[35,36] Clinicians should consider a pneumogram or formal sleep study if consistent obstruction is witnessed. In some cases of more severe obstruction, tracheostomy is helpful for optimizing the airway. Most children can be decannulated once coordination has improved. Lengthening of the mandible through distraction osteogenesis techniques can be considered in an attempt to decannulate the child prior to the development of speech, although poor outcomes are often seen with neonatal distraction, multiple anomalies in other systems, multiple airway abnormalities (e.g., tracheomalacia, laryngomalacia), or Kaban type III anomalies.

Cleft Lip and Palate and Velopharyngeal Insufficiency

One of the first features of OAVS that should be addressed is the presence of clefting. Cleft lips most often are present in the form of a lateral facial or Tessier no. 7 or macrostomia.[15,18] These types of clefts are present in at least 35% of patients with OAVS.[3] Unilateral or bilateral clefts of the lip and palate are present in approximately 7% to 15% of cases.[3] Failure of fusion of the lateral commissure may contribute to feeding difficulties if the cleft is large enough, and repair during the early months of life may be indicated for functional and esthetic reasons. Reconstruction involves repairing the orbicularis oris and associated musculature of the commissure with accurate approximation of the vermilion and oral mucosal tissues. In most instances, the repair is highly esthetic and functions well with minimal asymmetry (see Figure 16-2). Revision may be helpful at some point once additional growth has occurred in the area.

Isolated cleft palate is present in approximately 30% of patients with OAVS, but usually not in its overt form.[3] More often, patients with OAVS exhibit a submucous cleft palate (SMCP). Repair of the SMCP usually is deferred until a speech evaluation can be performed because many patients do not have significant speech issues with only an SMCP. A consistent and detailed speech evaluation typically is not possible until 3 to 5 years of age in the normally developing child. A significant percentage of patients will not require repair of the SMCP because the velum works well despite the minor clefting. However, this is not the case for patients who exhibit velopharyngeal dysfunction and who have hypernasality that affects intelligibility of speech. Patients with consistent velopharyngeal insufficiency that is due to the anatomic abnormalities associated with the SMCP or with occult SMCP (usually without the bifid uvula) should be considered for palate repair or a pharyngeal procedure to improve function (pharyngeal flap or pharyngoplasty).

It is also important to evaluate the patient for possible neurogenic causes of poor palatal motion. In some patients with OAVs, the reason for the velopharyngeal insufficiency is related to poor innervation of the palate on the affected side. Approximately 35% of patients with OAVS will exhibit velopharyngeal dysfunction, and most cases are not due to clefting.[37] Patients usually benefit from a tailored pharyngeal flap rather than from primary repair of the palate or a double-opposing z-plasty.[15,38] A detailed speech evaluation that includes a perceptual speech exam, nasendoscopy, and/or videofluoroscopy is helpful in determining the cause of velopharyngeal insufficiency.

Temporomandibular Joint and Ramus Reconstruction

Patients with OAVS exhibit abnormalities of the TMJ, including hypoplasia and occasionally absence. Those with mild to moderate hypoplasia who can function well rarely

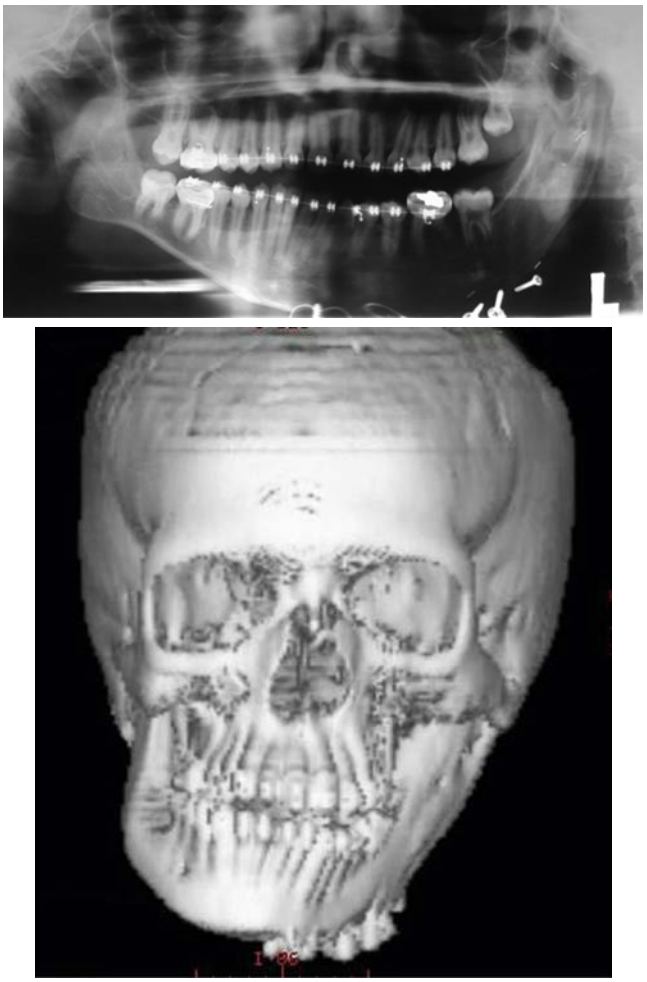
seem to have internal derangements or degenerative joint disease that affects function over the long term. Rarely do these patients require significant intervention regarding their TMJ. Those who have not developed a ramus/condyle/fossa unit benefit from reconstruction of the TMJ at some point. Some surgeons prefer to delay this process until growth has essentially been completed if the patient can function well (speech and mastication). It is interesting to note that most patients can function quite well when the condyle/fossa unit is not intact. For those who have psychosocial issues with the deformity or compelling functional reasons to perform a reconstruction earlier, a costochondral rib graft can provide a condyle and ramus unit.[15,29,39] Patients who exhibit obstructive sleep apnea and those with mastication difficulty may benefit from this approach at age 5 or later. Some patients will not have a fossa to accept the rib, in which case one may be reshaped and reconstructed within the skull base.[15,29] Grafts placed earlier than 5 years of age tend to resorb and lack significant size to allow for stability and fixation. Rib grafts placed early may grow unpredictably (Figure 39-3).

One of the main issues with early rib grafting is the unpredictable nature of growth once the graft has been placed. Rib grafts may undergrow, overgrow, or theoretically grow to "perfect" size, although this is rarely the case.[15,29,39] If ribs overgrow, then a significant issue may arise at the time of adolescence when a malocclusion is typically treated with orthognathic surgery (see Figure 39-3). The complex asymmetry that results may be more difficult to treat than the deformity that would have resulted if the graft had not been performed. Thus, the decision of whether to perform early grafting of the TMJ must be made carefully (see Figure 39-3).

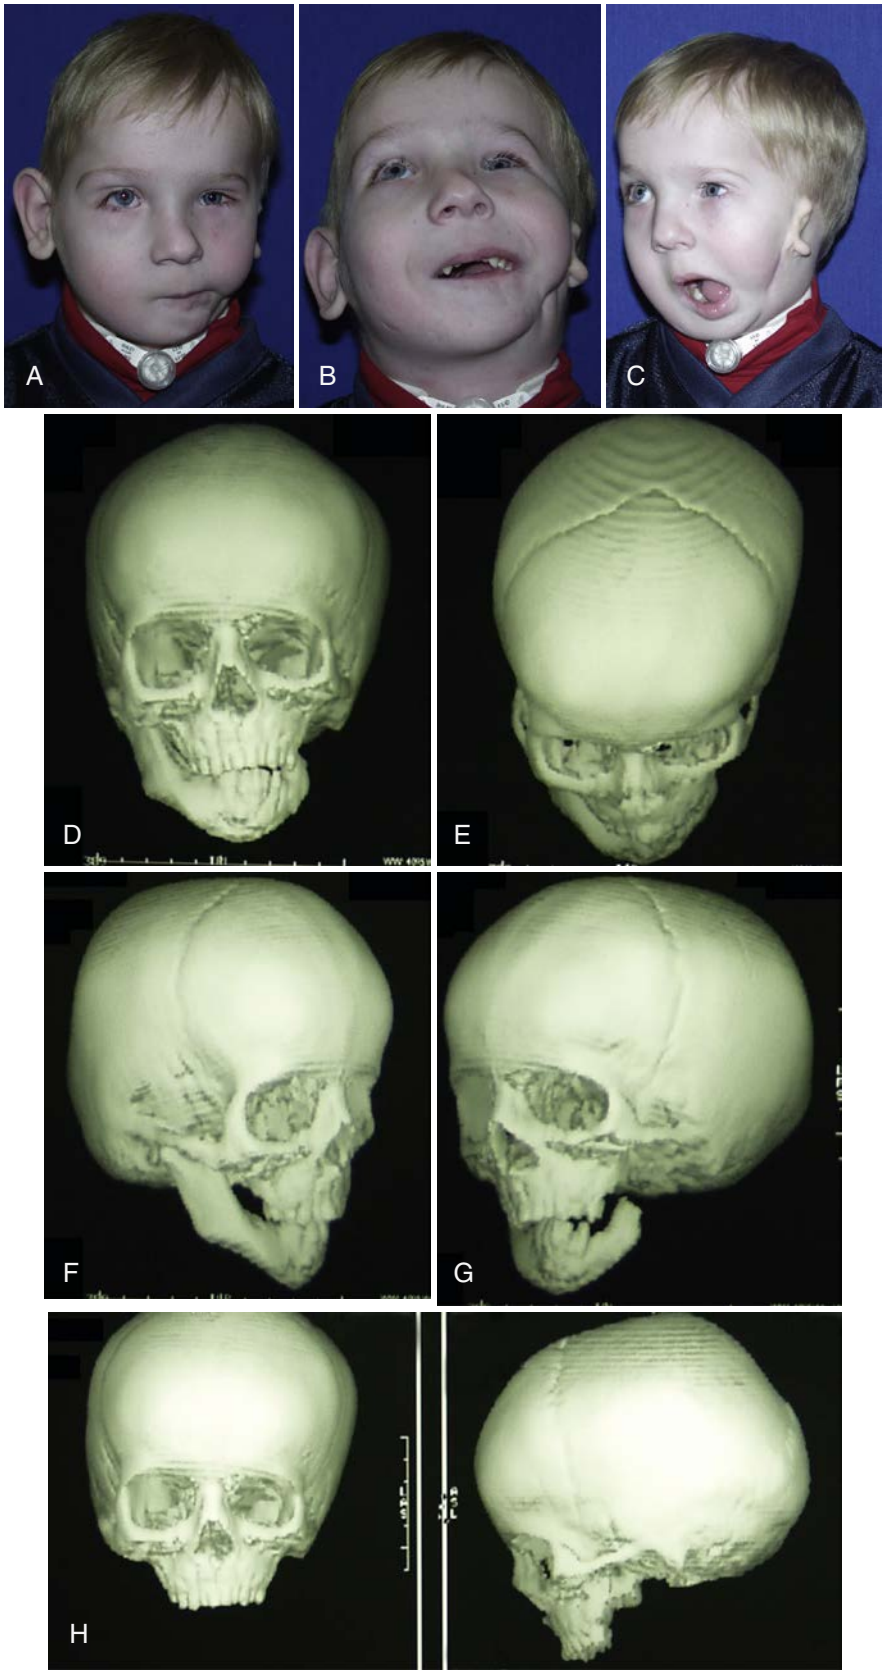
If costochondral grafting is not an option in patients, either because cartilage has already been harvested to construct ears because the surgical scar will be unacceptable, or because chest wall anomalies have occurred, the microvascular fibula remains an option. It has the additional advantage of providing subcutaneous tissue and/or fascia to provide additional soft tissue volume to the lateral face. The results for condylar replacement in the rapidly growing child can be poor, as the fibula fails to grow. However, this technique is a reasonable option in the skeletally mature patient with complex hard and soft tissue deficiencies.

In some instances, the option of a prosthetic TMJ replacement can be considered as a revision procedure after a rib graft, or as a primary reconstruction. Historically, this option has not been entertained in children because of concerns that the prosthesis would not grow. Given the issues associated with unpredictable growth of a rib graft, consideration can be given to this option, particularly in the older child. A custom prosthesis usually is best suited for those patients who lack a portion of the ramus. If a large area is deficient, then grafting with autogenous materials may be the best choice. This is usually performed with costochondral rib, vascularized fibula, and/or iliac crest graft.

Transport distraction osteogenesis has been described and used by some to reconstruct a ramus/TMJ unit in patients with Kaban type III OAV, but only limited success has been reported in the literature.[40-47] It is quite difficult to transport a distraction disc of bone to the exact point of articulation at the base of the skull and provide the level of symmetry that can be achieved with the other aforementioned techniques. Some initial descriptions mentioned the possibility of neocondylar genesis, but no long-term outcomes of these procedures have been published.[40-47] The technique has mostly fallen out of favor. Many patients who have undergone this procedure require revision surgery with costochondral reconstruction or other techniques that are more difficult to perform after the area has developed additional scarring (Figure 39-4). Another drawback is the growth restriction that occurs in this area, particularly if the surgery is performed at a young age. This transforms a stable deformity into a progressive one and potentially makes later reconstructions more difficult from a technical standpoint. Even after several decades of experience, no substantial functional outcomes of this technique have been reported in



• **Figure 39-3** A panoramic tomogram and three-dimensional computed tomography image show a teenager who was born with Kaban type III, left-sided oculoauriculovertebral spectrum (OAVS). She had a rib graft placed prior to age 5 by another surgeon, which has now overgrown, and this has resulted in a significant asymmetry toward the unaffected side. She also exhibits a class III relationship rather than the typical class II seen with OAVS.



• **Figure 39-4** **A** through **C,** A young boy with Goldenhar syndrome is shown with a right side that is classified as type IIA and a left side classified as type III. He has undergone a number of distraction procedures with external devices performed by another surgeon in an attempt to lengthen the right side and create a neocondyle through a transport distraction technique. Trismus may occur. Three-dimensional computed tomography scans show the postoperative anatomy (**D** through **H**). Vector control can be difficult and may alter the bone at previous distraction sites in a manner that makes conventional osteotomy or reconstructive techniques difficult.

a clinical trial or case series; therefore, this technique is not advocated by the authors. More predictable techniques such as costochondral rib grafting offer more predictable results.

Current translational research using regenerative medicine is aimed at engineering a construct of the TMJ ex vivo and integrating a multitissue graft such that a donor site can be avoided. Although these concepts are still years from clinical trials, we may be able to provide a more tailored graft that fulfills the patient's needs much better than what surgeons currently can offer.[48]

Mandibular Lengthening with Distraction Osteogenesis

Some surgeons believe that mandible lengthening and repositioning in the early years through distraction osteogenesis can improve symmetry and esthetics. If a distraction procedure or an early graft can eliminate tracheotomy dependence, early value can be derived from these methods. Although initial approaches involved intervening at an early age to improve symmetry, form, occlusion, and overall function, many of these approaches were hampered by difficulty controlling vectors and the bone growth impairment that may result from early surgery. Early intervention via distraction does not improve bone growth, and no current evidence suggests that an improved outcome results from this approach rather than from orthognathic surgery during the teen years. As a result, patients who typically have a deformity that is not progressive can be converted to a deformity that is progressive due to growth restriction from early surgical intervention. This is particularly true for patients who exhibit minimal asymmetry but have had distraction techniques performed at an earlier age. These issues are best addressed during the teen years with the use of standard orthognathic surgical techniques with which reconstruction is as definitive as possible with minimal stress on the patient, family, and health care system (see Figure 39-1, *C* through *E*).

Although they exhibit benefit in select patients, distraction techniques can be associated with a higher degree of infection, nonunion, and other complications that may increase the complexity of definitive reconstruction at skeletal maturity. This may produce a more difficult clinical scenario for standard orthognathic surgery approaches because bone quality and surrounding soft tissue may be affected by scarring and by hypovascularity (see Figure 39-4).

Zygoma and Orbit Reconstruction

Patients with significant hypoplasia of the zygoma may benefit from procedures designed to augment the region or formal osteotomy with bone graft reconstruction of the zygomatic complex. This is best performed once most growth is complete at this site. After age 5 to 7, most upper facial bone growth is complete, but this reconstructive effort may be delayed if no significant functional issues are present.

The zygoma can be created or augmented with onlay bone grafts or porous polyethylene implants. Onlay grafts or implants can be custom-fit to the patient's needs. Minor asymmetries are best approached via these methods. More severe hypoplasia of the zygoma usually requires formal osteotomies in the orbit and reconstruction of the orbit/zygoma complex with split-thickness cranial vault. The hypoplastic zygoma may be repositioned with an osteotomy, but this usually requires additional grafting to improve symmetry significantly. The graft usually is procured from the cranial vault because of its proximity during the surgical approach with a coronal incision.

These procedures can be performed earlier if function can be improved from an ophthalmologic standpoint through positioning of the globe. Occasionally, supporting the orbit floor with cranial bone or porous polyethylene implants is helpful for treating enophthalmos associated with orbital and zygomatic hypoplasia. A complete ophthalmologic examination is routinely performed from birth. Additional ophthalmologic issues such as epibulbar dermoids, coloboma, blepharophimosis, and strabismus may require the attention of a skilled pediatric ophthalmologist.[3]

Ear Reconstruction

Ear deformities are a hallmark of OAVS and may be the only initial finding of significance (see Figure 39-1). The deformity may be seen as mild as preauricular sinuses or tags, but more commonly, significant asymmetry and malformation of the external ear are present.[49-51] Deformities of the external helix, malposition of the ear complex, microtia, or anotia may occur. Minor deformities may benefit from simple excision of ear remnants or otoplasty of the malrotated ear. Other patients require much more extensive reconstruction. Three options are currently available for patients who wish to replace an external ear construct: (1) staged reconstruction with an autogenous cartilage rib graft, (2) placement of craniofacial implants to support a prosthesis, and (3) use of a porous polyethylene construct under a skin flap. Each approach has its advantages and drawbacks. With chondral grafts, a number of procedures are required to reconstruct the ear, and considerable experience of the clinician is important in achieving an ear that approaches normal.[50,51] However, this approach provides patients with an ear that is not removable and represents their own tissue. A well-made prosthesis provides excellent esthetics but is removable. Implants can cause chronic irritation around the skin overlying the temporal bone if they are not cleaned diligently. The use of porous polyethylene constructs provides a very nice shape and form that can be easily implanted, but a lifetime infection risk may require removal at some point and leaves significant scar tissue that renders the other options less attractive. Some patients have aberrant blood flow to the auricular area and may not be able to accept these options. Before considering these options, some surgeons perform preoperative angiography to evaluate blood flow to the site.

In some instances, patients may exhibit conductive or sensorineural hearing loss. Depending on the condition, patients may be candidates for a banded conductive hearing device to improve hearing on the affected side. Occasionally, this is required bilaterally in patients with bilateral deformity (see Figure 39-2). A bone-anchored hearing appliance may be used for patients with only conductive hearing loss, but this usually is delayed until 5 years of age. Some surgeons prefer to attempt this earlier, but the cranial vault in this area is not typically mature (diploic) until additional growth is complete.

Rarely, some patients may be candidates for additional middle ear surgery, including surgical treatment of auditory canal stenosis or atresia. Some patients may be candidates for cochlear implants, but this is rarely the case. If these types of surgical procedures are entertained, they should be performed prior to external reconstruction to ensure that the ear is in the optimal position for functional surgical reconstruction (i.e., the external ear is placed properly when compared with a reconstructed internal auditory meatus). Most patients with more severe deformity do not achieve bilateral hearing that is meaningful.[15] Select patients may benefit from these endeavors, and a thorough evaluation by a skilled pediatric otolaryngologist and an audiologist is helpful from the time of birth.

Orthognathic Surgery

Staged reconstruction of OAVS and related dysmorphologies has been discussed by many.[15,18,26-29,52] Posnick states that the most favorable functional and esthetic results are obtained when surgery is performed at or close to skeletal maturity, ideally when carried out with coordinated orthodontic therapy.[15,29] The complex three-dimensional deformity of OAVS usually is best approached with a Le Fort I osteotomy, bilateral sagittal split osteotomies, and a genioplasty (Figure 39-5).

Other osteotomy techniques can be used if the ramus component of the affected side is severely dysmorphic, or if previous distraction techniques have yielded a segment that is difficult to separate in the conventional manner. Other osteotomies commonly used in these situations include inverted L osteotomy, vertical ramus osteotomy with interpositional bone grafts, and other straight osteotomies with interpositional bone grafts. Mandibular reconstruction of severe type IIb deformities sometimes is considered when the child is still in the mixed dentition. For the type III deformity, first-stage reconstruction with a costochondral graft remains a popular choice and for most, the best alternative.[15,28,29] This may have to be performed in combination with a contralateral ramus osteotomy for more controlled positioning of the distal mandible. When first-stage procedures such as these are carried out at ages 5 to 12 for functional reasons, the need for additional maxillomandibular reconstruction at the time of skeletal maturity can be anticipated (Figures 39-6 and 39-7). Combined maxillomandibular surgery and costochondral rib reconstruction can be performed definitively at skeletal maturity if no major functional concerns are present at a younger age. Composite microvascular free fibula transfer can also be utilized for vertical ramus reconstruction. The option of recruiting muscle, fascia, or a de-epithelialized skin paddle can be useful to provide bulk to the lateral facial soft tissue while reconstructing the skeleton. Lastly, simultaneous total joint reconstruction with orthognathic surgery can be performed at skeletal maturity with a high degree of precision using virtual surgical planning. Both the fabrication of the TMJ device and the three-dimensional positioning of the Le Fort and mandibular osteotomies should be planned together. The advent of virtual surgical planning has greatly improved the ability for the surgeon to accurately improve symmetry well beyond other techniques such as gradual distraction.

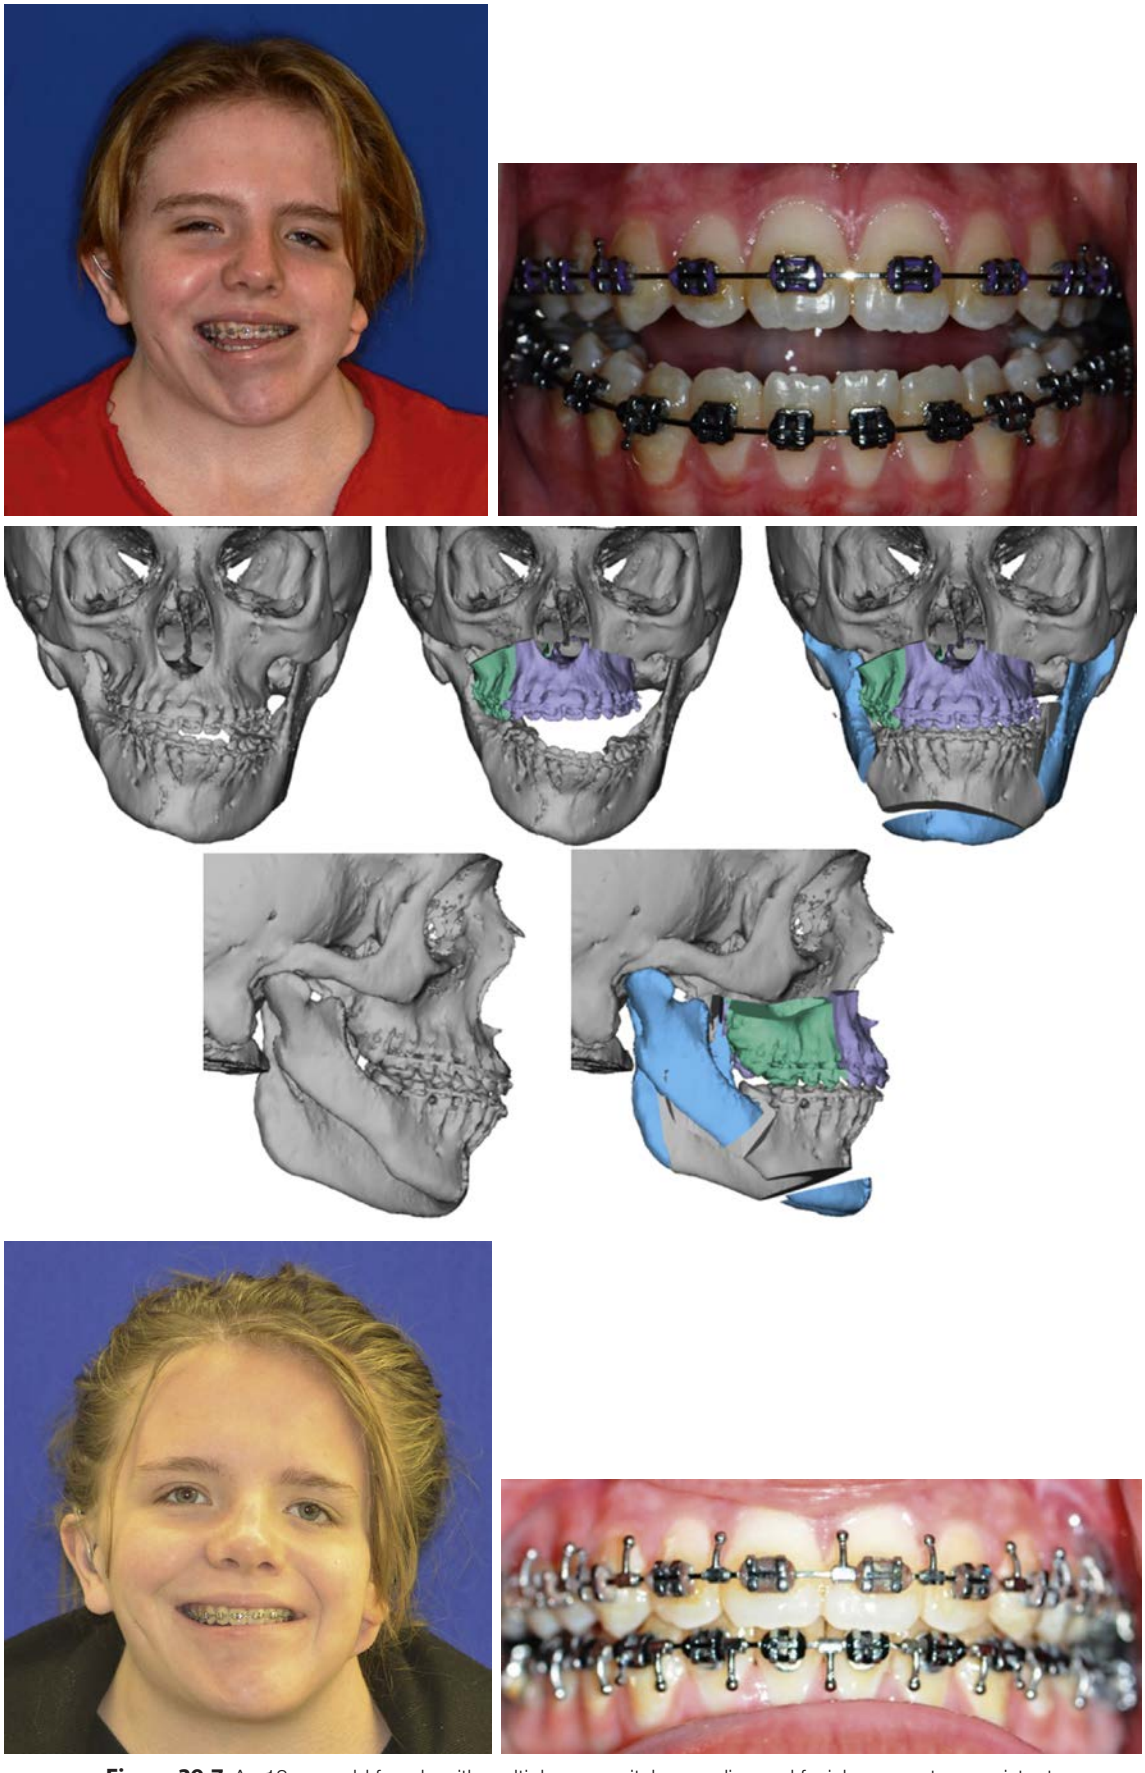
Because of the complexity of the asymmetry, the precision, control, and stability offered by orthognathic surgical techniques are almost always preferable when compared with techniques based on distraction osteogenesis. Distraction osteogenesis techniques used in the mature patient do not afford the control and precision that can be achieved with conventional orthognathic techniques and thus offer little or no advantage for the treatment of deformities associated with OAVS. It can be helpful to use both three-dimensional computed tomography images and stereolithographic models and virtual surgical planning to precisely plan treatment for complex three-dimensional asymmetry (see Figure 39-6). Use of only a lateral cephalometric radiograph and a posterior-anterior cephalometric radiograph underestimates the degree of asymmetry and the three-dimensional complexity. This is particularly the case for patients in whom previous ill timed reconstruction or distraction techniques have been performed and who still have significant asymmetry. These patients may be excessively long in the vertical dimension but still hypoplastic in the transverse and sagittal dimensions, making the postoperative deformity more difficult to reconstruct than the original problem.

Asymmetry is the result of a hypoplastic underlying facial skeleton and an overlying soft tissue envelope. Therefore, in addition to requiring extensive craniofacial surgery to construct a functional skeleton over which the soft tissue will drape normally, OAVS occasionally requires the augmentation of overlying soft tissues. The parascapular microvascular flap has been used with some success in this arena. When a fibula is used for reconstruction of the ramus, additional lateral bulk can be obtained by harvesting an osseo-septocutaneous flap with the de-epithelializing skin paddle buried to add bulk to the lateral face. Additional augmentation of the ramus and body of the mandible may be helpful for enhancing symmetry. Typically, this is done with onlay grafting or alloplastic implants. Alloplastic implants provide an easy way to improve symmetry but may be associated with a risk of long-term infection. Fat transfer techniques or a de-epithelialized scapula free flap may be used to further enhance the soft tissue once orthognathic surgery is complete. Techniques based on fat transfer may not provide a long-lasting and stable result because the fat transplant tends to resorb over time.[53-55] Very nice results have been achieved when the free-flap technique is used, and these tend to provide long-lasting improvements in facial symmetry. Combinations of these therapies can provide a refined approach that can be customized to the patient's needs.

• **Figure 39-5** A teenage girl with type IIA oculoauriculovertebral spectrum (OAVS) and a Tessier No. 7 cleft (repaired by another surgeon) is seen preoperatively and postoperatively. She underwent Le Fort I osteotomy, bilateral sagittal split osteotomies, and a double-stack genioplasty.

• **Figure 39-6** A teenage girl is shown preoperatively and postoperatively after treatment for type III oculo-auriculo-vertebral spectrum (OAVS). She had a rib graft at an early age and then distraction of the rib graft site on several occasions during childhood, performed by another surgeon. During the teen years, she underwent Le Fort I osteotomy, left-sided sagittal split osteotomy, and right-sided modified sagittal osteotomy through the previous distraction site with removal of an impacted tooth, as well as asymmetric genioplasty with bone grafting. A stereolithographic model can be helpful for analyzing asymmetry in patients who have complex three-dimensional deformities.

• Figure 39-6, cont'd



• **Figure 39-7** An 18-year-old female with multiple congenital anomalies and facial asymmetry consistent with OAVS. Virtual surgical planning was utilized to address her very complex asymmetries that are affected by her natural head position and orbital asymmetry. The family elected to not treat the orbital asymmetry. As such, her natural head position and orbits were used to guide the planes of symmetry for positioning of the maxilla and mandible for optimal symmetry without normal reference planes. Preoperative and post-operative views are shown in conjunction with her virtual surgical plan, including the intermediate steps.

Summary

OAVS is a complex, multidimensional congenital deformity that results from disruption of the tissues associated with the first and second branchial arches and neural crest cell migration. Resultant deformities of the cranio-orbital tissues, zygoma, ear, lip, palate, maxilla, mandible, and airway require a thoughtful staged reconstruction that is interdisciplinary. Clinicians should approach these deformities with techniques that have the best outcome data and a proven track record. Unfortunately, little comparative level I evidence exists to guide clear choices between treatments because of the long-term follow-up required to adequately assess outcomes. Orthognathic surgery remains the most predictable option for addressing the skeletal deformities associated with OAVS.

Treacher Collins Syndrome: Evaluation and Treatment

JEFFREY C. POSNICK, PAUL S. TIWANA, NEERAJ H. PANCHAL

Introduction

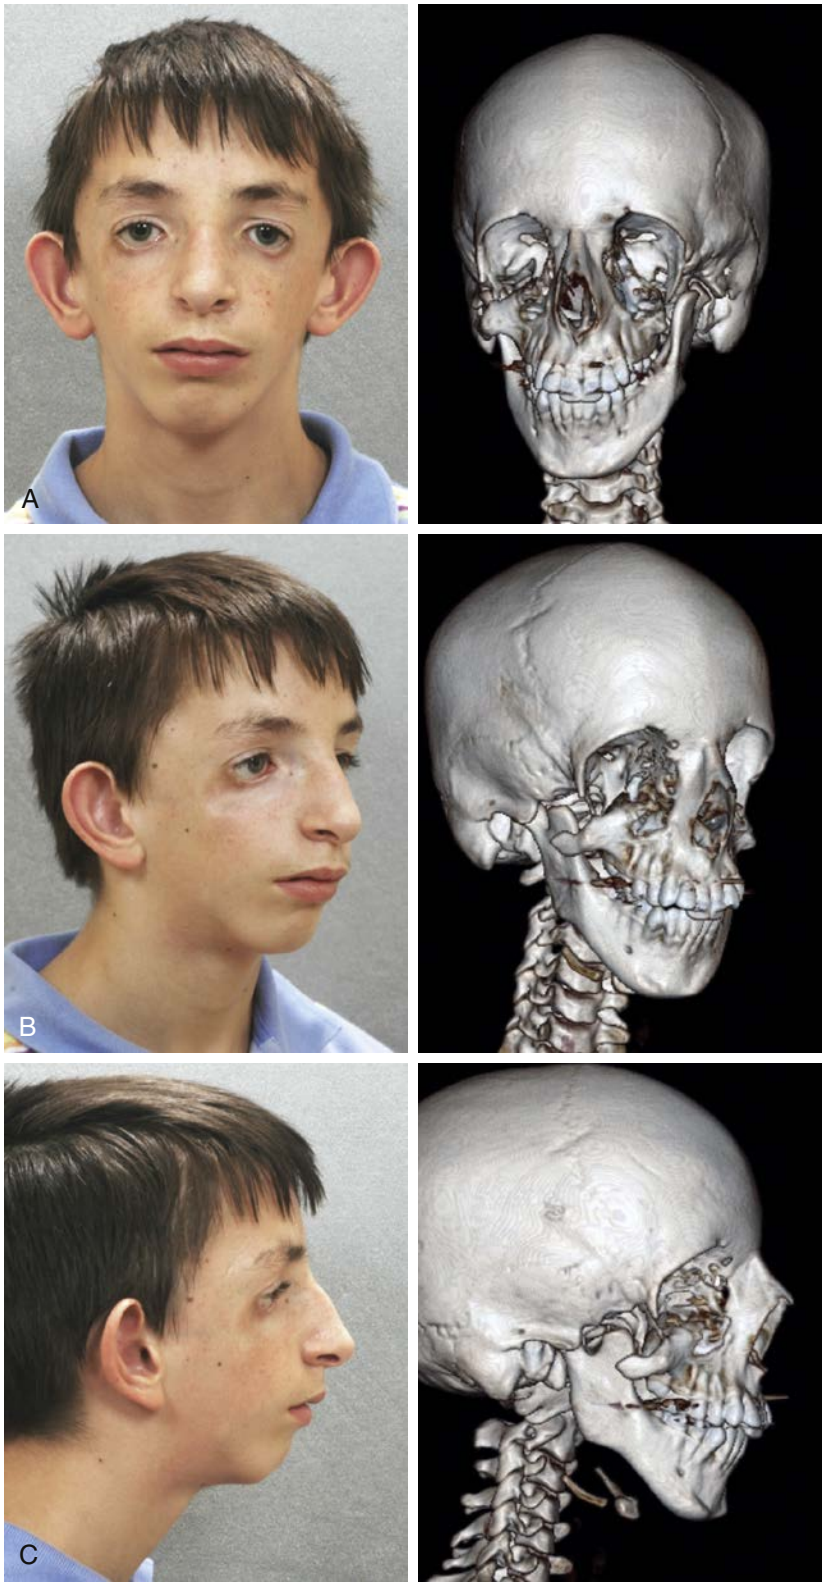
Treacher Collins syndrome (TCS), which is also known as *mandibulofacial dysostosis,* is an autosomal dominant condition with variable expressivity.[1-25] It is generally characterized by bilaterally symmetric abnormalities of the structures within the first and second branchial arches. Early descriptions are attributed to Berry,[26] Treacher Collins,[12] and Franceschetti and Klein.[8] To date, the physical findings of many hundreds of individuals and families with TCS have been published in the world literature.

The adult patient with fully expressed TCS has a convex horizontally deficient facial profile with a prominent nasal dorsum above a retrusive lower jaw and chin (Figure 40-1). The eye region is characterized by an antimongoloid slant of the palpebral fissure as a result of colobomata and hypoplasia of the lower lids and the lateral canthi, including the partial absence of the eyelid cilia and inferolateral orbital hypoplasia and dystopia. Tongue-shaped processes of hair frequently extend into the preauricular region. The external ears are absent, malformed, or malposed and hearing is impaired as a result of variable degrees of hypoplasia of the external auditory canals and the ossicles of the middle ears. A characteristic finding is hypoplasia of the malar bones, often with clefting through the arches and limited formation of the residual zygomas, including the glenoid fossa component. The maxilla and mandible bones are also characteristically hypoplastic, with variable effects on the temporomandibular joints (TMJs), the muscles of mastication, and the muscles of facial expression. Interestingly, hypoplasia of the centrally located soft tissues of the face is not seen with TCS. In general, there is an Angle class II anterior open-bite malocclusion and a steep clockwise-rotated maxillomandibular complex. The posterior facial height is short, and the anterior lower facial height is long. The A-point–to–B-point relationship in profile is consistent with the clockwise rotation of the jaws. The presence of cleft palate (with or without cleft lip and choanal atresia of the nasal cavity) is variable. Dental anomalies are present in 60% of individuals; these include tooth agenesis (33.3%), enamel opacities (20%), and the ectopic eruption of the maxillary first molars (13.3%).

Individuals with TCS have a reduced cranial base angle (i.e., basilar kyphosis). Craniosynostosis is not a feature of TCS, but the neurocranium may have an abnormal shape (i.e., decreased anteroposterior length and diminished bitemporal width) that is evident during childhood and remains through adulthood.[27] The degree of craniofacial malformation present at birth is believed to be relatively stable and nonprogressive with age (this is discussed in more detail later in this chapter). TCS should not be confused with similar entities such as oculo–auriculo–vertebral dysplasia or Goldenhar syndrome. Distinguishing facial features of patients with TCS often include coloboma of the lower eyelids; the upper eyelids are more likely affected among patients with Goldenhar syndrome.

Inheritance, Genetic Markers, and Testing

The occurrence of TCS is in the range of 1 in 25,000 to 1 in 50,000 live births. Inheritance is autosomal dominant, and male and female individuals are equally affected.[12] About 60% of probands with TCS have the disorder as the result of a de novo gene mutation. Each child of an individual with TCS has a 50% chance of inheriting the mutation (Figure 40-2). Teber and colleagues identified TCOF1 mutations in 28 out of 36 (78%) individuals with a clinically unequivocal diagnosis of TCS.[28] The most frequent clinical findings were downward-slanting palpebral fissures, hypoplasia of the zygomatic complex, hypoplasia of the mandible, conductive deafness, any degree of microtia, and atresia of the external ear canal. Although there were interfamilial and



• **Figure 40-1** An 11-year-old boy with fully expressed Treacher Collins syndrome. His eyes are characterized by an antimongoloid slant of the palpebral fissures as a result of colobomata and hypoplasia of the lower lids and the lateral canthi, including the partial absence of the eyelid cilia and inferolateral orbital dystopia. The appearance of the malpositioned adnexal structures is a reflection of both zygomatic–orbital dystopia and hypoplasia of the soft tissues. The maxilla and the mandible are also deficient and malformed. The patient demonstrates a type IIA mandibular malformation. The external ears are malformed and lack antihelical folds. **A,** Frontal facial and three-dimensional computed tomography scan views. **B,** Oblique facial and three-dimensional computed tomography scan views. **C,** Profile facial and three-dimensional computed tomography scan views.

• **Figure 40-2** This mother **(A)** and daughter **(B)** demonstrate the extent of variation in the expression of Treacher Collins syndrome within a family. The mother was not aware that she carried the Treacher Collins gene until after the birth of her daughter. (From Posnick JC: Treacher Collins syndrome: perspectives in evaluation and treatment, *J Oral Maxillofac Surg* 55:1120, 1997.)

intrafamilial variations that ranged from mild to severe, there were no genotype or phenotype correlations. Four clinically unaffected parents were heterozygous for the TCOF1 mutation. The authors concluded that modifying factors are important for phenotypic expression.

Genetic counseling for TCS is the process of providing individuals and families with information about the nature, inheritance, and implications of the syndrome to help them make informed medical and personal decisions. Molecular testing should be considered for any individual who presents with at least two major features or three minor features of TCS.[29-40] Until recently, penetrance in TCS was believed to be complete. Marres and colleagues[35] confirmed the absence of clinical and radiographic findings in an individual with a pathogenic TCOF1 mutation. For this reason, testing is acceptable for individuals with any degree of severity of TCS features to confirm or refute the diagnosis.

Prenatal diagnosis for pregnancies that are at increased risk for TCS is possible via the analysis of DNA extracted from fetal cells obtained by amniocentesis; this is usually performed at about 15 to 18 weeks' gestation. Chorionic villus sampling can also be used for diagnosis at about 10 to 12 weeks' gestation. The malformation-causing allele of an affected family member must be identified before prenatal testing can be performed.

Considerations During Infancy and into Early Childhood

At the time of the birth of a child with TCS, concerns will center on the adequacy of the airway, swallowing, feeding, hearing, vision (corneal protection), the presence of cleft palate (with or without cleft lip), any other associated malformations, and the psychosocial well-being of the family.[5,41-51] The airway may be compromised as a result of multiple factors. The first is maxillary hypoplasia, which occurs with a degree of choanal stenosis or atresia with the blockage of the nasal airway. Second, mandibular micrognathia with a retropositioned tongue that at least partially obstructs the oropharyngeal and hypopharyngeal spaces will be present. In addition, tracheomalacia, vocal cord anomalies, or neuromotor involvement may also negatively affect the upper airway. Depending on the severity of the anomalies, a spectrum of upper airway compromise may necessitate, at a minimum, special infant positioning, an extended hospital stay, and pulse oximetry monitoring. Surgical considerations for the management of airway compromise in the infant or young adult may include tongue–lip adhesion, the use of a custom-made oral appliance, immediate or delayed tracheostomy, or an urgent mandibular advancement procedure.

As a result of any compromise in nasal and oral breathing and associated musculoskeletal malformations, the newborn with TCS may also have difficulty with swallowing and with achieving an adequate lip seal to the extent that urgent gavage-assisted feedings or the placement of a gastrostomy tube may be required to ensure adequate nutrition.

When a cleft of the secondary palate is documented, potential additive effects on the airway before and after repair must be considered. When Nager syndrome is present, the soft palate is both clefted and severely hypoplastic to the extent that the achievement of a functioning palate is not feasible.[15,19] A primary pharyngeal flap—although helpful for velopharyngeal function—is rarely indicated, because further obstruction of the airway would likely result. Evaluation by a *medical geneticist* is indicated to clarify the diagnosis and all presenting anomalies, to discuss family planning issues, and to analyze chromosomal studies.

Within a few days of birth, the results of an examination by an experienced *pediatric otolaryngologist* in combination with formal *audiology testing* will clarify the extent of conductive hearing loss and allow for the early fitting of hearing aids to assist the infant with the acquisition of communication skills and encourage the normal bonding process with the family.

At some point early in life, a complete craniofacial *computed tomography (CT) scanning* from the top of the skull through the cervical spine with three-dimensional reformation will be useful to document the extent of craniofacial skeletal anomalies. Special *focused cuts through the petrous temporal bones* are also required to document external auditory canal and middle and inner ear anatomy. Appropriate craniofacial, maxillofacial, cleft lip and palate, and auricular reconstructive surgeons should also be consulted, as indicated.

An assessment by a *pediatric ophthalmologic* is necessary to determine associated eye anomalies, extraocular muscle function, corneal exposure difficulties, and visual acuity. Ophthalmologic issues may include vision loss (37%), amblyopia (33%), refractive errors (58%), anisometropia (17%), and strabismus (37%). Interestingly, it has been the impression of many clinicians and scientists that the individual with TCS has a tendency toward a short stature, at least early in life, and that above-average intelligence is generally observed.

Dysmorphology with Treacher Collins Syndrome

Cranio-orbito-zygomatic Region

In earlier published studies, 14 reproducible cranio-orbito-zygomatic measurements taken from each of 26 standard axial CT scans of individuals with symmetric forms of TCS who had not been operated on were compared with the measurements of age-matched controls.[27] The interorbital measurements (i.e., medial and lateral orbital wall separations) of the patients with TCS were at the mean when compared with their cohort group (i.e., no measurable orbital hypertelorism or hypotelorism), whereas the zygomatic measurements were significantly less than normal, thereby confirming the extent of malar hypoplasia. The congenitally deficient lateral aspect of the orbits in individuals with TCS was confirmed by the greater than normal values measured for globe protrusion and medial orbital wall protrusion in conjunction with diminished lateral orbital wall lengths. These measurements use the lateral orbital rim as a reference point and confirm the limited depth of the lateral orbits as a result of hypoplasia of the lateral orbital rims. The lateral orbital rims are components of the hypoplastic zygomatic complex. The abnormal shape of the anterior cranial vault in patients with TCS was documented as a diminished intercoronal (bitemporal) distance (width) and decreased cephalic length as compared with values for normal age-matched controls. In general, the CT measurements documented in the described study agree with the clinically observed morphology of TCS. The measurements carried out in the zygomatic structures confirmed the extent of hypoplasia of the zygomas for the group as a whole and in each individual patient; they also documented the extent of globe protrusion and decreased upper face width in patients with TCS. It appears as though the bones immediately adjacent to the involved zygomatic complex also experience a degree of hypoplasia or at least distortion.[6,27,52-60]

Maxillomandibular Region

In 1975, Roberts and colleagues completed a radiographic cephalometric study of TCS. Serial cephalometric radiographs were available for eight patients who presented with the full range of features that are characteristic of this syndrome.[61] The expected facial convexity in patients with TCS was substantiated by cephalometric measurements. The extent of convexity was attributed to the severity of mandibular retrognathia (i.e., a decreased sella–nasion–B-point angle). Interestingly, the horizontal projection of the maxilla to the cranial base (i.e., the sella–nasion–A-point angle) remained within normal limits in the patients that were measured. Over time and with growth, the facial convexity remained relatively constant, thus confirming that the facial profile morphology of the infant with TCS was remarkably similar to that of the adult. Anterior facial heights were measured as "upper facial height" (i.e., the nasion to the anterior nasal spine) and "total facial height" (i.e., the nasion to the menton). The upper facial height was found to be relatively normal, whereas the total facial height was often excessive. This is the result of a combination of anterior open-bite malocclusion, mandibular retrognathism, and chin dysplasia characterized by increased vertical length and horizontal retrusion. The angle between the sella–nasion plane and the mandibular plane was obtuse, which confirmed the steepness of the clockwise rotation of the mandibular plane. The angle between the sella–nasion plane and the palatal plane was also obtuse, thus confirming the steepness of the clockwise rotation of the maxillary plane. The posterior facial height was markedly shorter for patients with TCS, with values in five of the eight patients found to be a minimum of four standard deviations less than those of the normal cohort.

The effective horizontal length of the mandible was markedly reduced, with values in most of the patients falling below four standard deviations as compared with those in the normal cohort. The decreased mandible size was evident in both the ramus height and the body length. The gonial angle was confirmed to be obtuse, with values of two standard deviations from the mean as compared with control values. The extent of antegonial notching was also documented in patients with TCS and was found to be similar to that observed among patients with condylar arrest early during their lives (e.g., as a result of juvenile rheumatoid arthritis or TMJ trauma at a young age). The steepness of the clockwise rotation of the maxillary and mandibular planes combined with the anterior and posterior vertical height disproportions and severe horizontal deficiency of the mandible is also indirectly seen in the A-point–to–B-point discrepancy. All of these morphologic findings explain the observed facial dysmorphology.[16,17,52-54,62]

Facial Soft Tissues

Soft tissue anomalies in individuals with TCS are manifested primarily in four clinical regions: the external ears; the eyelid-adnexal structures; the preauricular-cheek skin;

and the temporal fossa (e.g., temporalis muscle hypoplasia).[26,63-74] The extent of deficiency within the soft tissue envelope is variable and, to large extent, reflective of the skeletal involvement. Each patient is unique and must be evaluated individually. The extent of soft-tissue anomalies continues to represent the most difficult obstacle to a favorable reconstruction.

External Auditory Canal, Middle and Inner Ear Structures, and Audiologic Findings

Relatively symmetric (i.e., from side to side) outer and middle ear malformations are characteristic of TCS. Middle ear abnormalities (e.g., hypoplastic or absent cavities and ossicles) are an almost universal finding.[75-79] The majority of patients have a unilateral or bilateral moderate or greater conductive hearing loss, with a flat or reverse sloping configuration on the audiogram. Most of the hearing loss in these patients is attributable to middle ear malformations. In 1993, Pron and colleagues reported the results of a detailed CT radiologic and audiologic investigation of a large series of pediatric patients with TCS.[79] The objectives of the study were (1) to determine the degree and symmetry of the external auditory canal and middle ear abnormalities and evaluate hearing loss; and (2) to explore the relationship between hearing loss and external auditory canal and middle ear abnormalities in patients with TCS. Data were available from 29 children who had not yet undergone any ear interventions and who had undergone audiometric testing and focused standardized petrous temporal bone CT scans. A review of the CT scans allowed for the evaluation of the external ear canal and the middle ear anatomy. The majority of patients (88%) had largely symmetric external auditory canal abnormalities that were either stenotic (31%), atretic (54%), or normal (15%). Middle ear cavity ossicular deformities were generally symmetric (96%), and cavities were either hypoplastic (85%) or missing (4%). Cavities that were hypoplastic were also deformed and assumed a rectangular rather than an oval shape. Ossicle deformities were generally completely symmetric and consisted largely of hypoplastic (46%) or missing (46%) ossicles. Ossicles (both the malleus and the incus) that were hypoplastic also tended to be ankylosed (82%) to either the lateral or medial wall of the tympanic recess. The structures of the external auditory canal and the middle ear are generally related. Increasing degrees of external ear canal malformations (i.e., normal, stenotic, or atretic) are directly associated with ossicle and cavity malformations. Of the patients with atretic canals, 67% had missing ossicles, and 33% had small or ankylosed ossicles. No abnormalities were noted in the inner ear structures (i.e., cochlea, vestibule, canals, and internal auditory meatus) in the patients with TCS who were studied. According to the study by Pron and colleagues, hearing loss for the patient with TCS ranges from mild to severe (average, 58 dB of hearing loss).[79] The majority of individuals (96%) have a moderate or greater degree of hearing loss.

Relationships exist between the external auditory canal, the middle ear ossicles, and the degree and configuration of hearing loss.[75-79] There is an association between the degree of external ear canal malformation and the degree of hearing loss in patients with TCS. In addition, hypoplastic, ankylosed, and missing ossicles appear to be associated with increasing levels of hearing loss; on average, the hearing loss is 52 dB, 56 dB, and 60 dB of hearing loss, respectively.

Facial Growth Potential with Treacher Collins Syndrome

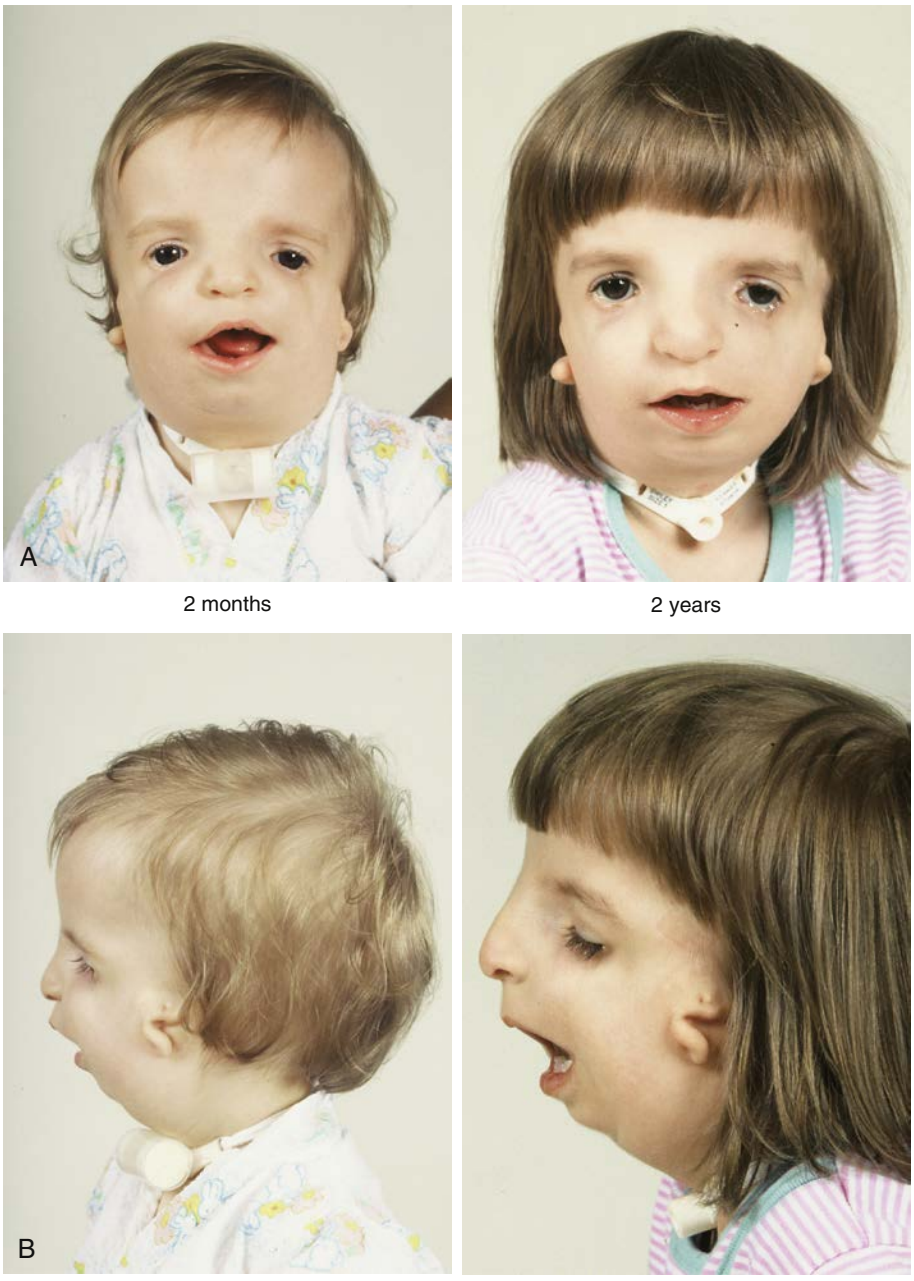
The degree of malformation present at the time of birth in a newborn with TCS is believed to be relatively stable and nonprogressive with age (Figures 40-3 through 40-6).[61,80-84] Roberts and associates reviewed serial cephalometric radiographs from individuals who were known to have TCS.[61] They documented the stability of the mandible, which continued to grow but not to catch up. Through independent research, Garner reported findings of the cephalometric analysis of three patients of varied ages who were confirmed to have TCS.[62] He also documented the relative stability of the anomalies without the progression of deformity at various ages.

To date, no convincing evidence demonstrates a clinically significant worsening of the TCS dysmorphology with facial growth. Early surgical interventions with mandibular osteotomies involving the use of either osteodistraction or standard orthognathic techniques are believed to adversely affect growth, thereby necessitating revision osteotomies at maturity. For this reason, waiting until the majority of jaw growth is complete before reconstructing the maxillomandibular components is recommended, if feasible. In any case, early mandibular surgery should not be expected to prevent the need for definitive maxillofacial reconstruction at maturity.

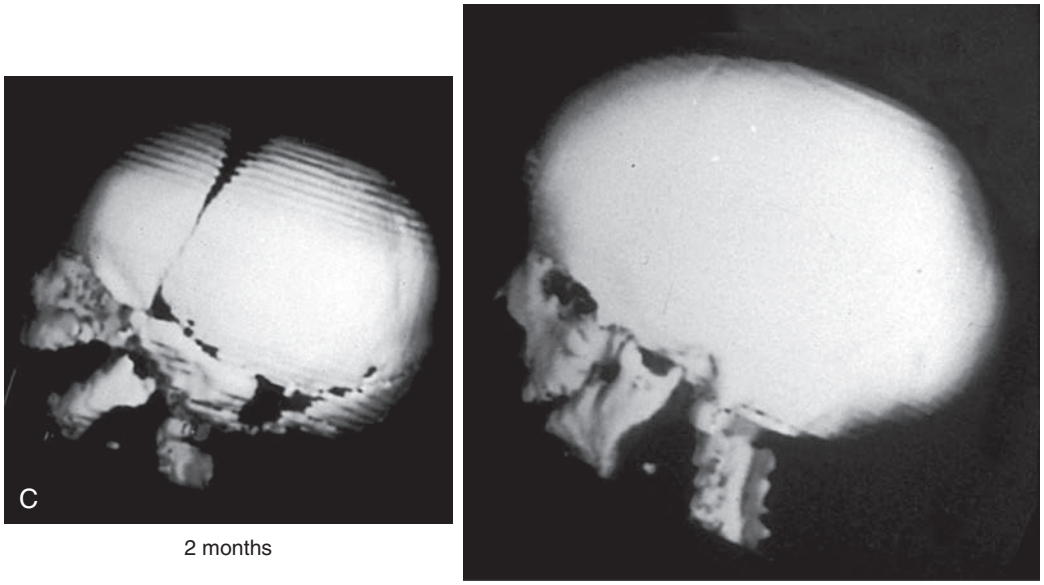
Classification of Temporomandibular Joint and Mandibular Malformation

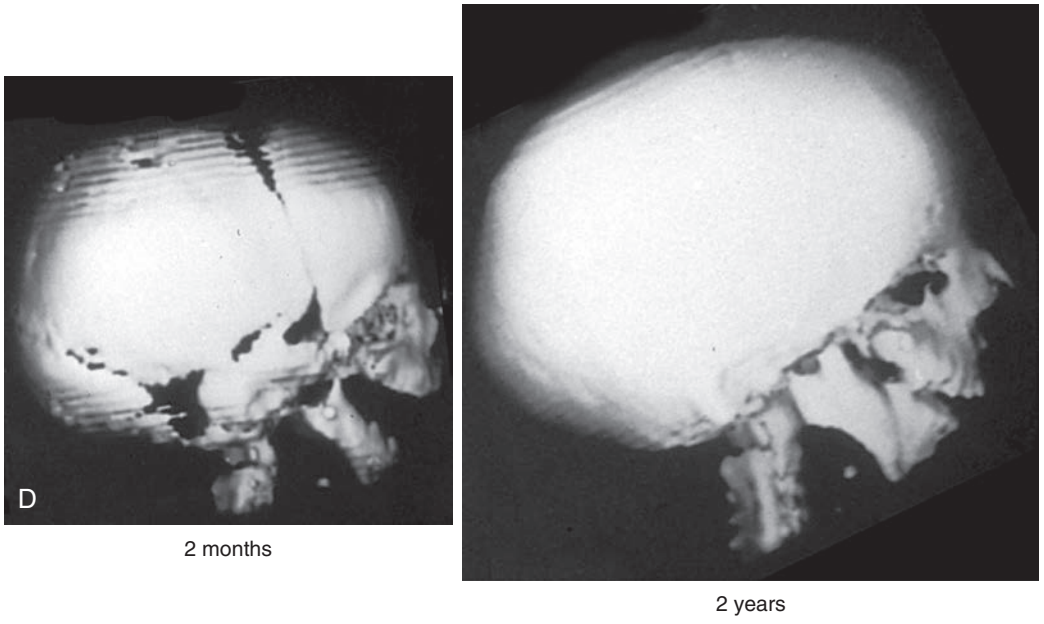
The extent of TMJ–mandibular malformation in patients with TCS will influence the timing and techniques of reconstruction.[85,86] A lack of clinically relevant definitions of the presenting glenoid fossa–condyle–ascending ramus malformations has resulted in confusion and miscommunication. Kaban and colleagues revised and clarified the previously described Pruzansky classification system for the degree of TMJ–mandibular malformation observed in patients with hemifacial microsomia.[85,87] This classification is also useful to define the presenting anomalies and then to direct reconstruction in the patient with TCS (Figure 40-7).

A type I TMJ–mandibular malformation involves minimal hypoplasia of the glenoid fossa and the condyle–ascending ramus on each side. All of the skeletal components are present (see Figure 40-7, *A*). Mandibular retrognathia and

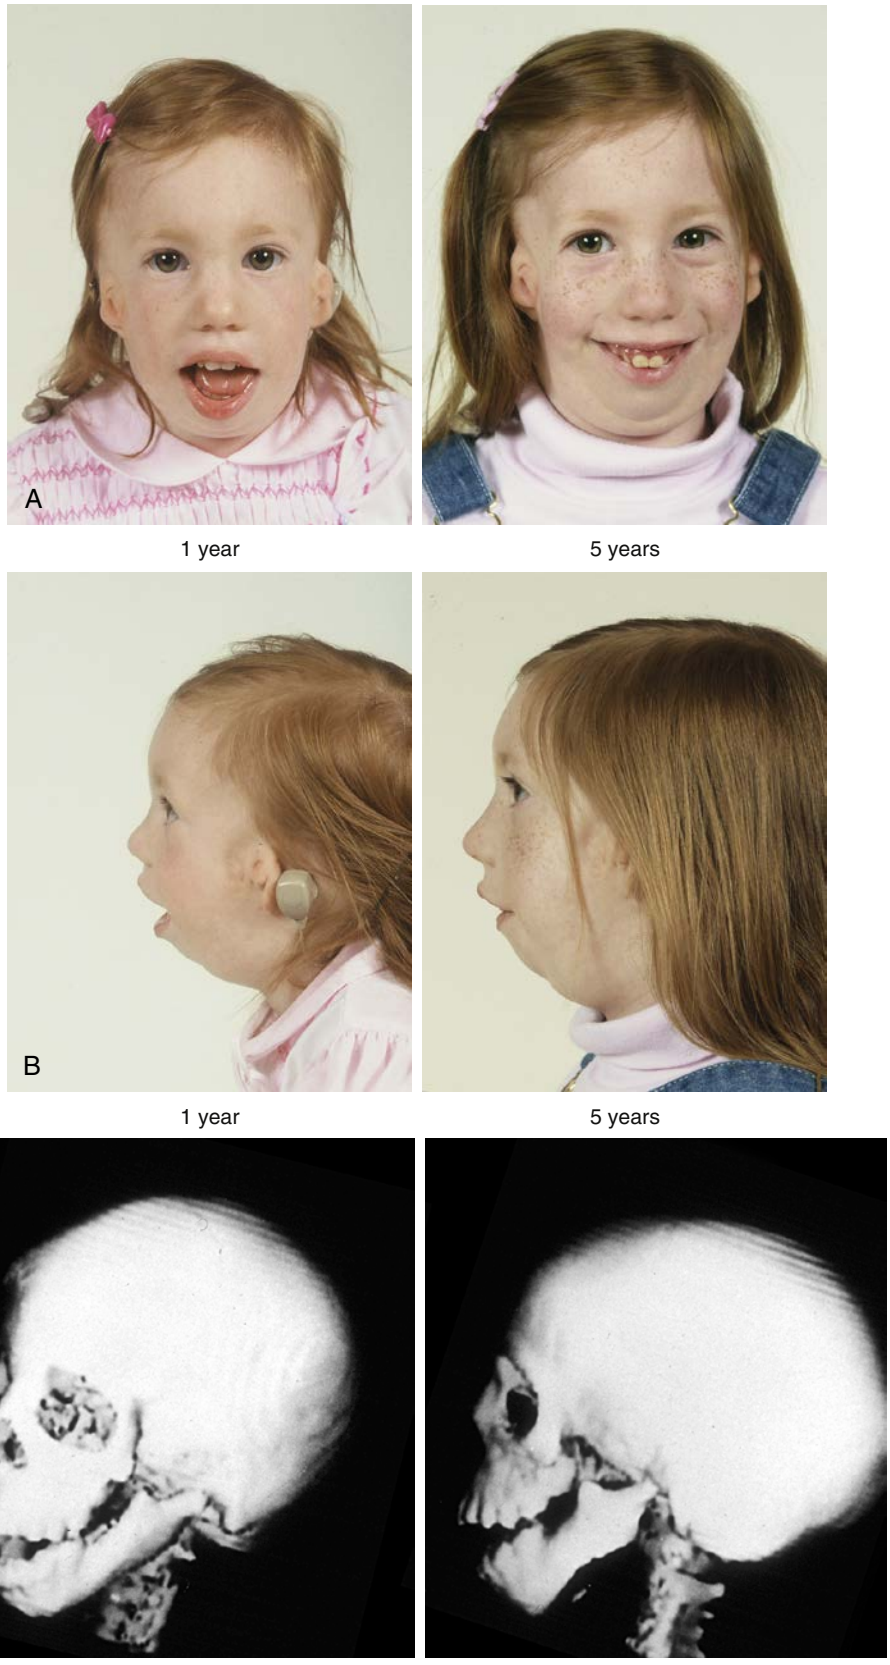


• **Figure 40-3** A child with a severe form of Treacher Collins syndrome was followed up longitudinally without treatment intervention. No progression of the deformity was seen during clinical or computed tomography scan examination. **A,** Frontal and **B,** profile views at 2 months and 2 years of age.





• **Figure 40-3, cont'd C and D,** Computed tomography scan views of the craniofacial region at 2 months and 2 years, respectively, demonstrating the consistent growth of the malformed condyles, the coronoid processes, and the ascending rami of the mandible. (From Posnick JC: Treacher Collins syndrome: perspectives in evaluation and treatment, *J Oral Maxillofac Surg* 55:1120, 1997.)



• **Figure 40-4** A girl who was born with Treacher Collins syndrome was followed up longitudinally at 1 and 5 years of age without treatment intervention. There is consistent growth of the craniofacial region without progression of the deformity. As a result of chronic nasal obstruction and an open-mouth posture, excess vertical facial growth can be seen. **A,** Frontal views at 1 and 5 years of age. **B,** Profile views at 1 and 5 years of age. **C,** Computed tomography scan views at 5 years of age. There is severe hypoplasia of the zygomatic complex with lateroinferior orbital deficiency. The mandible demonstrates a type IIA malformation.

• **Figure 40-5** A child who was born with Treacher Collins syndrome was followed up longitudinally without treatment intervention. No progression of the facial deformity occurred with growth. **A,** Frontal views at 10 months and 6 years of age. **B,** Profile views at 10 months and 6 years of age.

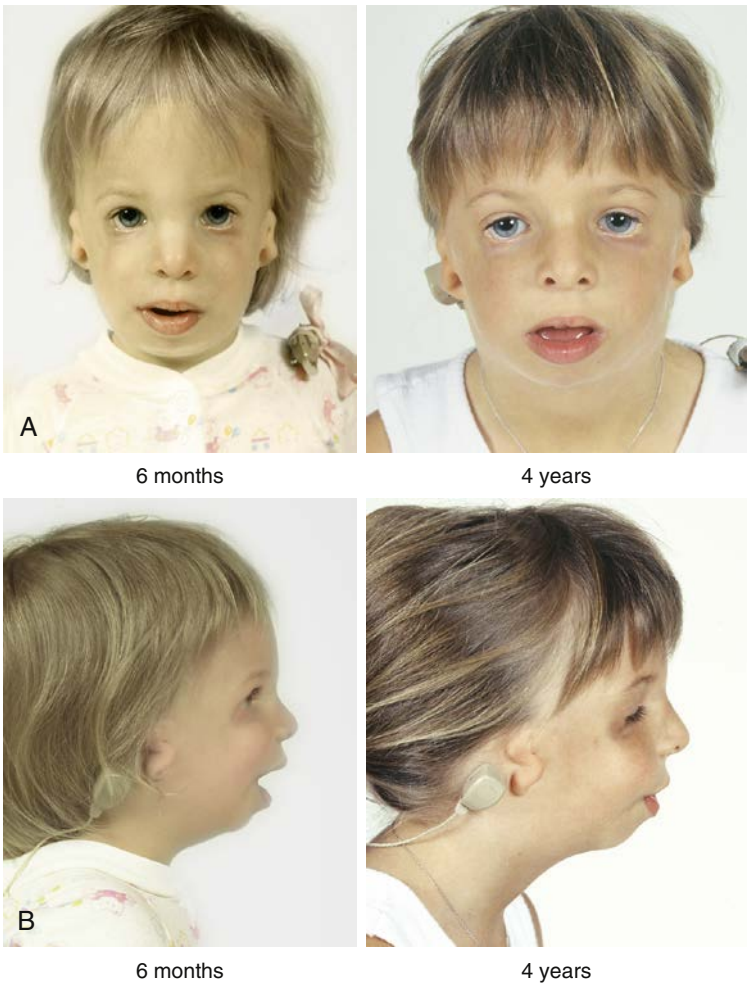
a mild anterior open bite are likely to be present, but TMJ function is essentially normal. The muscles of mastication are intact, and the condyle and the glenoid fossa are also fully intact. There is no need or advantage to constructing a neo-condyle or neo-glenoid fossa.

A type IIA TMJ–mandible malformation involves a moderate degree of glenoid fossa and condyle–ascending ramus hypoplasia (see Figure 40-7, *B-D*). The anatomic location of each joint is anterior and medial, but TMJ function remains satisfactory. One or more of the paired muscles of mastication are likely to be hypoplastic. By definition, in type IIA malformations, the condyle and the glenoid fossa have function that is at a level deemed better than could reliably be achieved through TMJ replacement. Even in patients with more severe type IIA malformations, when applying superior and posterior pressure to the chin, the condyles can be seated into a consistent location against the skull base–glenoid fossa. By completing ramus osteotomies, the proximal segments can be positioned into a stable location against the skull base, and the distal mandible can then be reoriented into the preferred location. This will avoid the need to construct neo-condyles (e.g., costochondral grafts). Coronoidectomies may be required to accommodate the short condyles.

The type IIB TMJ–mandibular malformation involves severe hypoplasia of the condyles. The mandible is without a stable centric relation. The glenoid fossa may be hypoplastic, but they are deemed functional. The hypoplastic condyles do not consistently seat in the glenoid fossa, and the mandible functions within a limited range of motion. The extent of mandibular retrognathia and anterior open bite is marked. With type IIB TMJ–mandibular malformations,



• **Figure 40-6** A child who was born with Treacher Collins syndrome was followed up longitudinally without treatment intervention. No progression of the craniofacial deformity has occurred. **A,** Frontal views at 6 months and 4 years of age. **B,** Profile views at 6 months and 4 years of age.

the rudimentary condyles are deemed too far medially and anteriorly displaced to be useful. The construction of a neo-condyle ascending ramus with the use of a bone graft is required (see discussion to follow). Coronoidectomies and recontouring of the surgically advanced mandible may be required. Fortunately, this pattern of malformation occurs in only a small percentage of patients with TCS.

The type III glenoid fossa–mandibular malformation involves deficiency to the extent that no posterior stop of the lower jaw against the cranial base is possible (see Figure 40-7, *E*). The condyles and the ascending rami are not present. The disc, the TMJ capsule, and the glenoid fossa on each side are also not developed. Severe mandibular dysmorphology is present, including horizontal retrognathia and decreased posterior ramus height. A tracheostomy is generally required shortly after birth to manage the airway. Eventual construction of both a neo-glenoid fossa and a neo-condyle ascending ramus will be required on each side. Reconstruction with bone grafts (e.g., cranial grafts for the zygomatic complex and either costochondral or a vascularized fibula flap for the mandible) will be required (see discussion to follow).

Staging of Skeletal Reconstruction: Timing and Techniques

The reconstruction and rehabilitation of the Treacher Collins malformation must address unique and specific components of the anomalies, including the following: (1) the zygomatic and orbital region; (2) the maxillomandibular region; (3) the nasal region; (4) the soft tissue envelope; (5) the external ears; (6) the external auditory canals; and (7) the middle ear structures (Figures 40-8 through 40-10).[27,82-84,88-108]

Zygomatic and Orbital Reconstruction

In previously published studies, we have documented the efficacy of reconstructing the malar and orbital deficiencies for moderate to severe forms of TCS with the use of full-thickness calvarial bone grafts that have been contoured three-dimensionally to form a new zygomatic complex (see Figures 40-8 and 40-9 through 40-13).[55] The neo-zygoma is then inset and stabilized with microplate and screw fixation. Exposure for the reconstruction is provided by a coronal scalp incision without the need for additional

• **Figure 40-7** Kaban and colleagues described a classification system to define the degree of temporomandibular joint–mandibular malformation observed in patients with hemifacial microsomia. By definition, a type IIB condylar deficiency will require the construction of a neo-condyle. The type III malformation will also require neo-glenoid fossa construction. The same classification system is used for Treacher Collins syndrome. Craniofacial computed tomography (CT) scans demonstrate the classification system. **A,** CT scan views of a type I mandibular malformation. **B, C,** and **D,** CT scan views of a type IIA mandibular malformation.

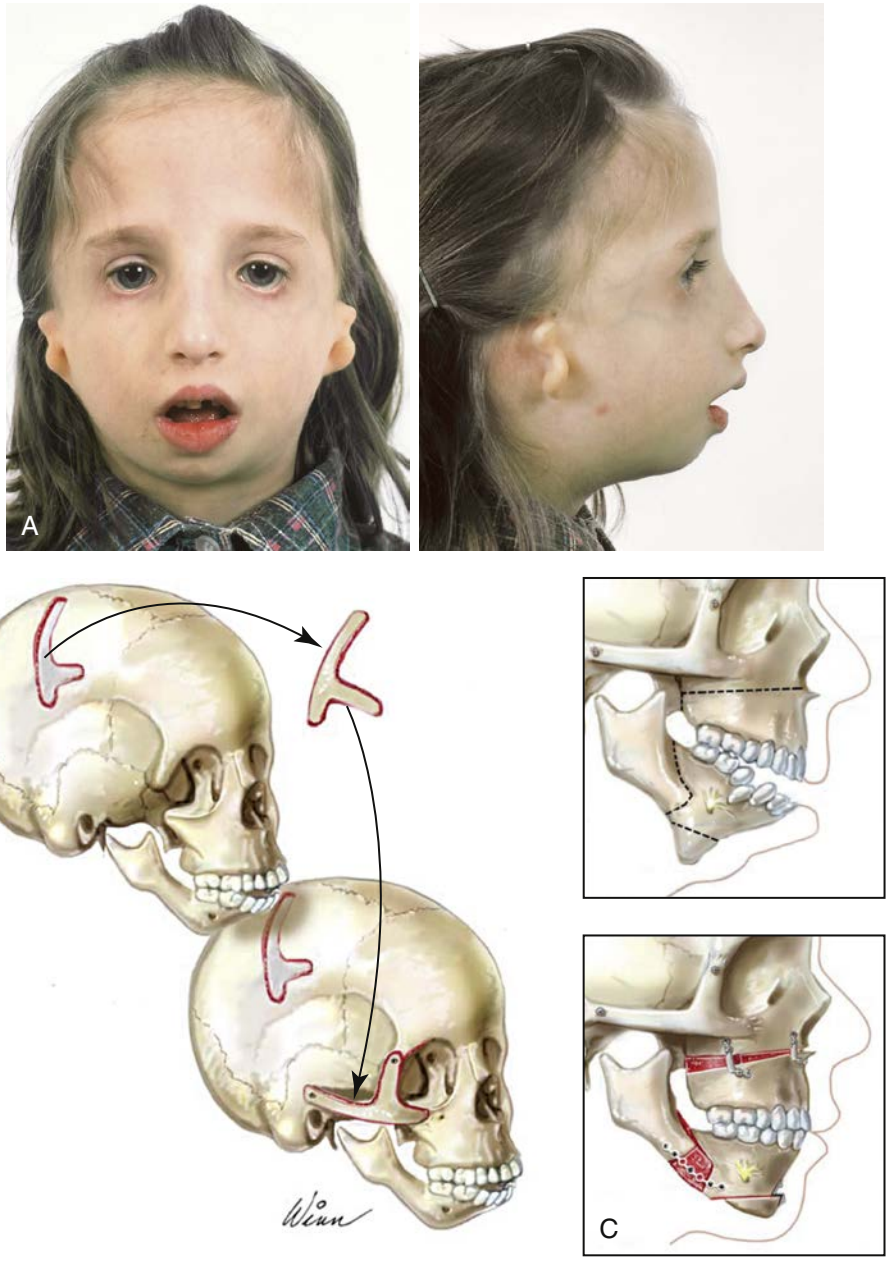
periorbital incisions. Orbital floor defects are reconstructed with fixed split-thickness autogenous cranial bone. Cranial vault donor sites are repaired either with autogenous split cranial grafts or artificial material. For nonautogenous reconstruction of the small skull donor sites, we prefer the use of a titanium mesh base fixed to the adjacent skull. The mesh is then filled in with a bone substitute. Lateral canthopexies are completed through the coronal scalp incision and secured to each new lateral orbital rim. In our study, computed tomography scanning that was performed before surgery and immediately afterward demonstrated significant increases in lateral orbital wall length (depth), lateral orbital (rim) width, interzygomatic arch width, and zygomatic arch length for patients with TCS. The late (i.e., ≥1 year) postoperative scans document that these changes were maintained. No complications occurred during surgery, and repaired skull donor sites healed without clinical defect. Zygomatic and orbital morphologic improvement was achieved in all patients, with follow-up intervals ranging from 24 to 50 months (mean, 35 months) at the close of the study. Unfortunately, over time, I have observed that partial resorption of the zygomatic complex graft occurs in some patients.

We believe that reconstructing the malar and orbital deficiencies before the patient is 7 years old is not advisable unless severe corneal exposure problems occur and skeletal deficiency is believed to be the cause. By this age, the cranio–orbito–zygomatic bony maturation is nearly complete. Therefore, adult-sized cheekbones may be constructed and placed with limited concern about how further growth will effect the initial result. In addition, skull donor-site reconstruction is simpler than it is at a younger age, because the presence of bicortical cranial bone in those who are more than 7 years old allows for the splitting of adjacent bone to assist with reconstruction (see Figures 40-11 and 40-12).

Other surgeons have recommended various methods and time frames for the zygomatic and orbital deformities associated with TCS.[55,56,59,60,109-114] We believe that the construction of the complete zygomatic complex from full-thickness autogenous cranial bone maintains volume and shape better than onlay grafts, which have been universally disappointing. Over time, onlay autogenesis bone grafts that have been placed in the craniofacial region (e.g., supraorbital ridge, zygoma, anterior maxilla, angle of mandible, chin) from all tried donor sites (e.g., skull, hip, rib) have demonstrated significant and unpredictable resorption. Furthermore, no commensurate growth (i.e., volume expansion) of the graft with the underlying bone (e.g., zygoma) should be expected. The belief that "even if the graft partially resorbs, at least something has been gained" should be abandoned; surface irregularities routinely result, which further detract from the baseline malformation.



• **Figure 40-8** **A,** A child who was born with Treacher Collins syndrome is shown during the mixed dentition. She has severe zygomatic complex and orbital deficiency as well as a type IIA condylar malformation. **B,** Illustration of the location of the full-thickness cranial bone graft donor site for zygomatic complex reconstruction. The zygomatic complex graft is also shown inset at the recipient site. **C,** Illustrations of a maxillofacial complex seen in a teenager with Treacher Collins syndrome (type IIA mandibular malformation). The cheekbone orbital reconstruction has previously been completed. The proposed maxillary, mandibular, and chin osteotomies are marked out and then completed. Counterclockwise rotation of the maxillomandibular complex is demonstrated as part of the reconstruction.

• **Figure 40-9** Additional images of the patient from Figure 40-8 showing the stigmata of Treacher Collins syndrome. At the age of 17 years, the patient was referred to this surgeon and agreed to a staged reconstruction that included three operations. The initial preoperative orthodontic treatment included the extraction of mandibular first premolars with the retraction of the anterior dentition to remove compensations. Orthognathic surgery included a Le Fort I osteotomy (counterclockwise rotation and anterior maxillary intrusion); bilateral sagittal split ramus osteotomies (advancement and counterclockwise rotation); and an osseous genioplasty (vertical reduction and advancement). During a second operation, the patient underwent zygomatic complex reconstruction with fixed full-thickness autogenous cranial bone grafts as described in this chapter and as illustrated in Figure 40-8. This was followed by a third operation: septorhinoplasty (open approach) to in-fracture the nasal bones, reduce the dorsal hump (bone and cartilage), and reshape the tip, including septal (caudal strut) grafting (see Chapter 38). **A,** Right profile views before and after reconstruction. **B,** Left profile views before and after reconstruction.

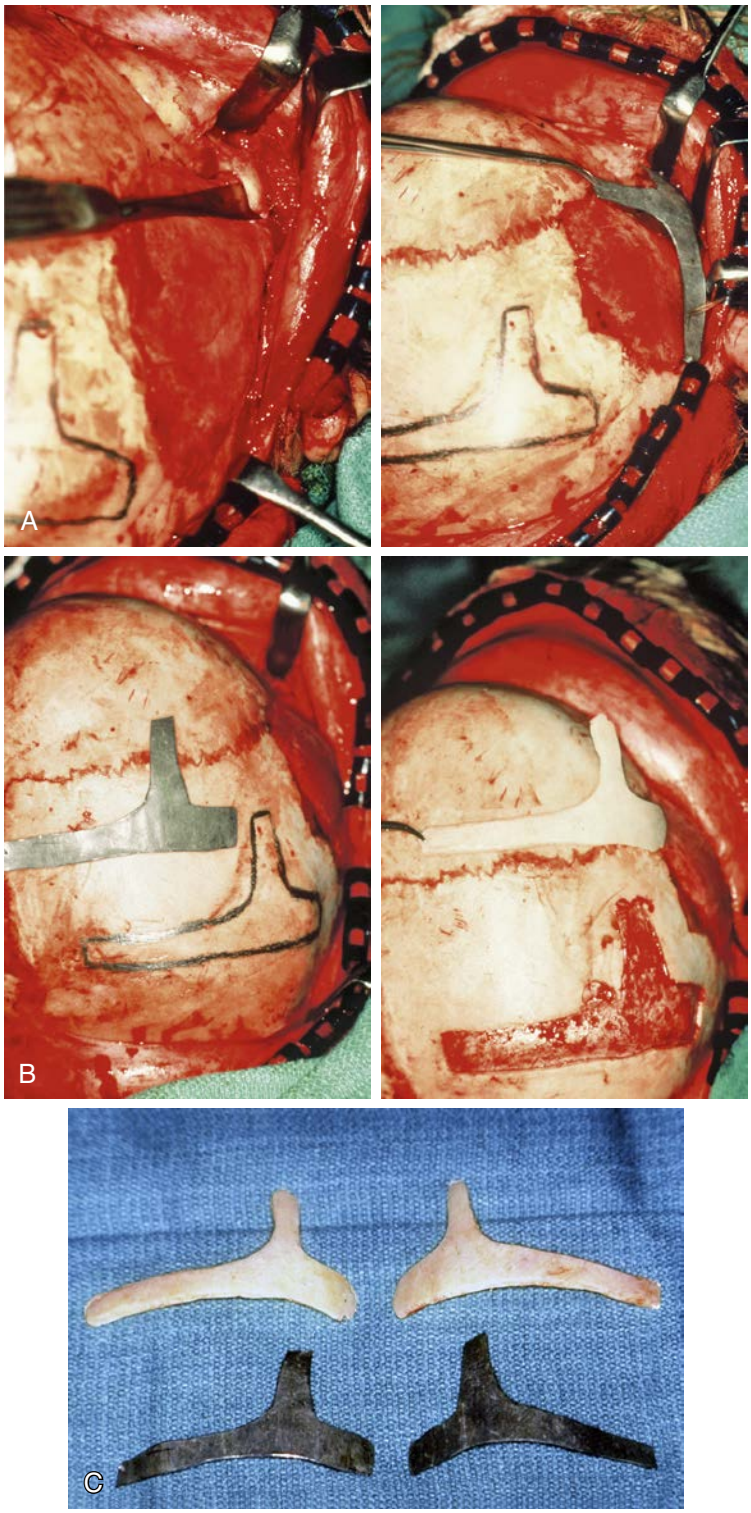
Maxillomandibular Reconstruction

A primary consideration for the timing and technique of jaw reconstruction is to clarify any special airway needs. This will influence whether or not first-stage early mandibular reconstruction is necessary prior to growth maturity. The second consideration is to define the extent of TMJ–mandibular malformation. With type I and IIA malformations, there is no need for glenoid fossa or condyle construction. In patients with these conditions, adequate TMJ anatomy is present so that mandibular reconstruction can be achieved through ramus osteotomies (e.g., sagittal split, inverted L, distraction [DO]) with the preservation of the working TMJ.

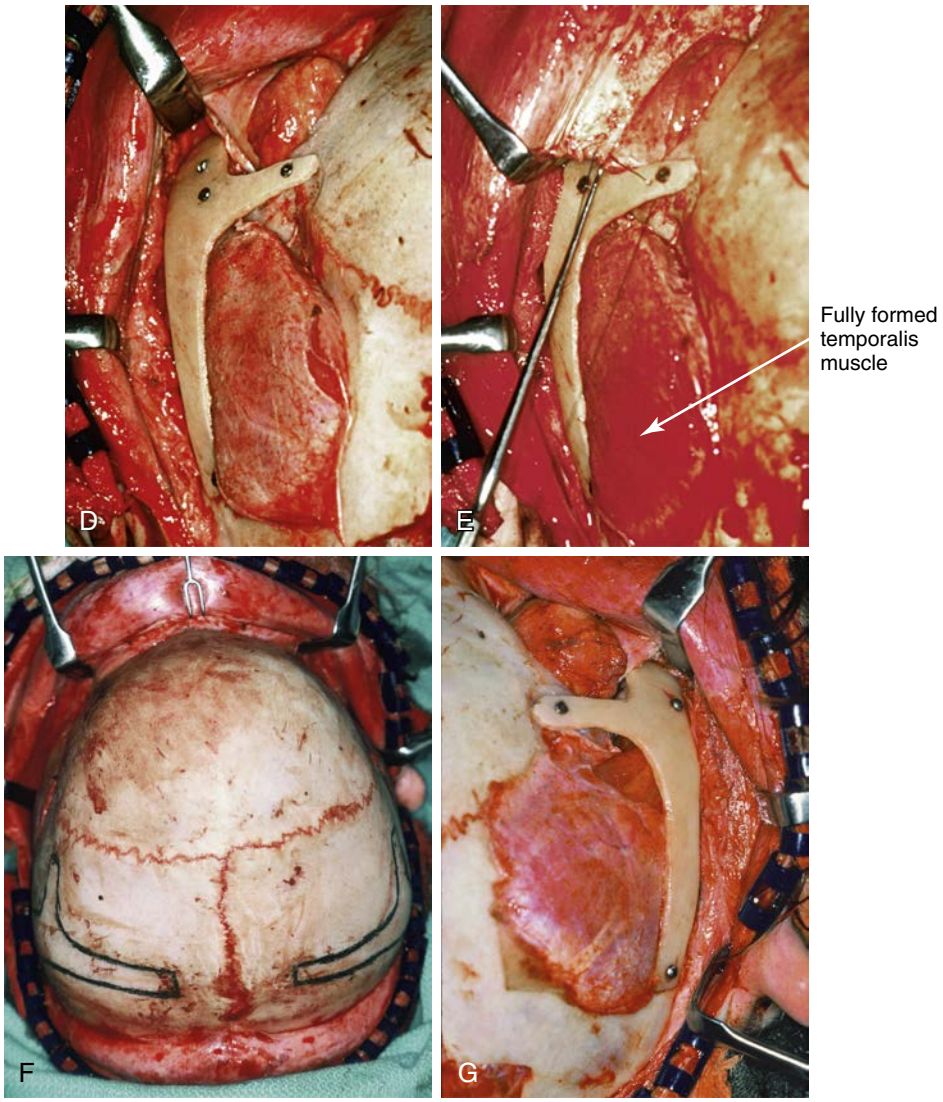
The basic dysmorphologies of the maxillomandibular complex that require reconstruction in patients with TCS are as follows: (1) altered facial heights (increased anterior lower facial height and decreased posterior facial height); (2) horizontal jaw deficiency (primarily in the mandible but also in the maxilla); and (3) chin dysplasia (increased vertical length and horizontal retrusion).[113-121] These malformations result in an excessive clockwise rotation of the maxillomandibular complex and an unfavorable A-point–to–B-point relationship when viewed in profile. In general, there is an Angle class II anterior open-bite malocclusion. Interestingly, some individuals will present with either a class I or class III relationship. These aspects must be addressed with the incorporation of counterclockwise rotation of the maxillomandibular complex to increase the posterior airway space, to correct the malocclusion, and to restore facial balance.

The most favorable esthetic results are generally achieved in patients who undergo definitive reconstructive jaw surgery only after early maxillofacial skeletal maturity (i.e., after the age of 13 to 15 years) and when these procedures are carried out in combination with effective definitive orthodontic treatment during the permanent dentition (see Figures 40-8 through 40-10). Mandibular and possibly maxillary premolar extractions are often required to orthodontically unravel dental root crowding, to normalize the inclination of the anterior teeth, and to fully decompensate the occlusion in preparation for the effective esthetic and airway repositioning of the jaws (see Figures 40-7, *A-D*). The surgical technique involves sagittal ramus osteotomies of the mandible in combination with a Le Fort I (maxillary) osteotomy and an oblique osteotomy of the chin. The incorporation of counterclockwise rotation of the maxillomandibular complex is generally required to successfully accomplish certain objectives. Any intranasal airway



• **Figure 40-12** Intraoperative views demonstrate the technique for zygomatico–orbital reconstruction in a 5-year-old child as it would be carried out for a patient with Treacher Collins syndrome. Working through a coronal (scalp) incision, the rudimentary zygomatic and orbital structures are exposed. Full-thickness cranial bone grafts are harvested, and each zygoma is crafted from such a graft. Each zygoma graft is inset and stabilized with microplates and screws. The orbital defects are reconstructed with cranial bone graft, and the orbital rims are reshaped with a rotary drill. Lateral canthopexies are completed through the coronal scalp incision and fixed to the new frontozygomatic suture regions. **A,** A view of the dissected rudimentary zygomatic remnant; the periosteal elevation is deep to the remnant. A template of the proposed zygomatic complex has been made. **B,** The template is taken to the mid-skull region, and its outline is marked out for craniotomy. The location for graft harvesting is posterior to the coronal suture, lateral to the sagittal suture, and anterior to the lambdoid suture. Through a craniotomy, the full-thickness cranial bone graft is harvested for zygomatic complex reconstruction. The exact same procedure is completed on the contralateral side. **C,** The two full-thickness cranial bone grafts are then crafted. The two templates and the two full-thickness crafted cranial bone graft–zygomatic complexes are shown.

Continued

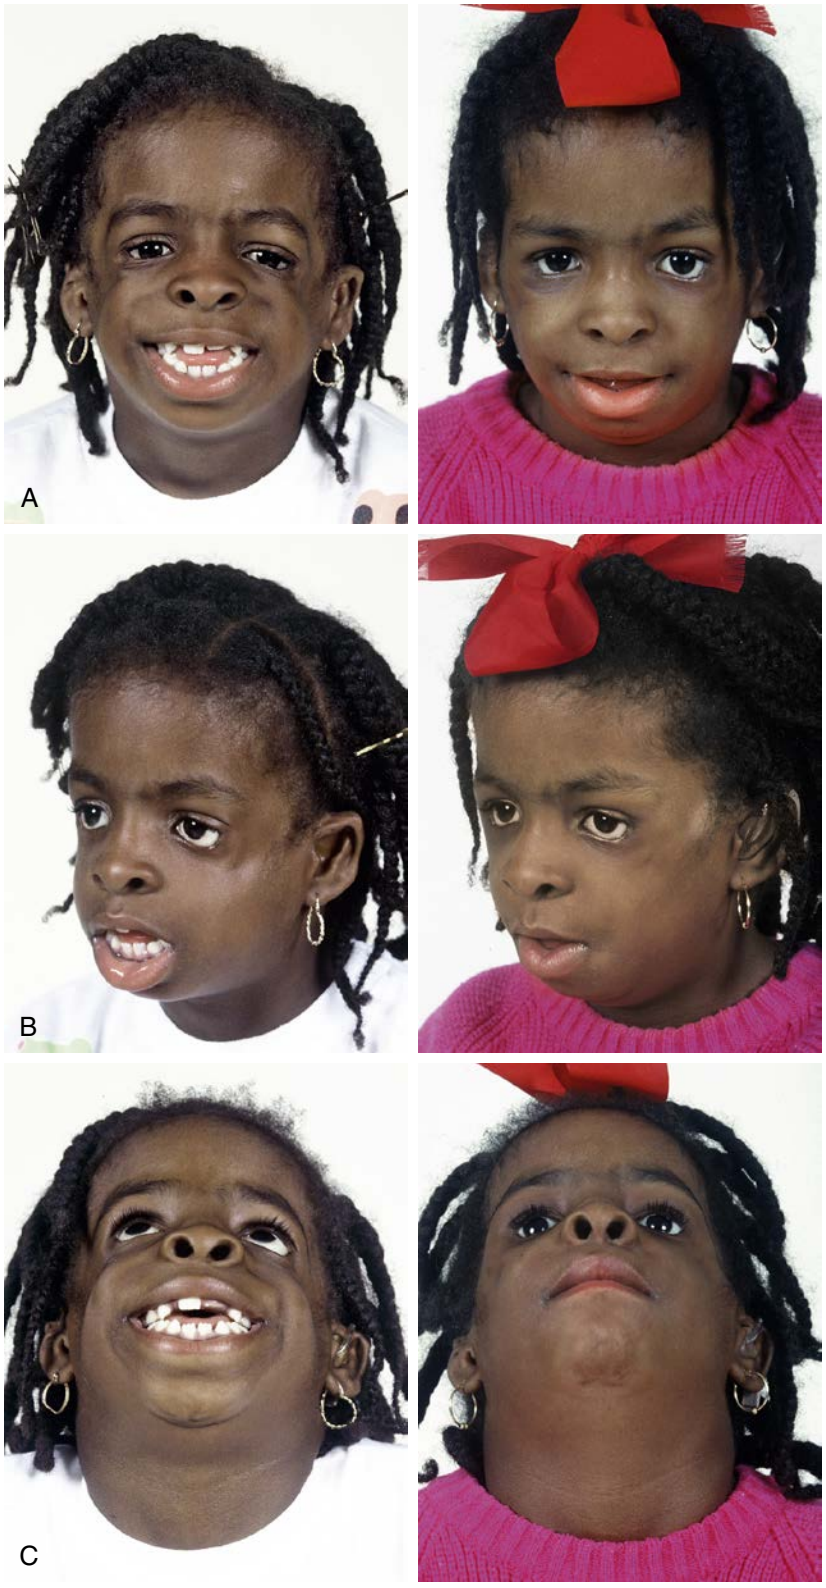


• **Figure 40-12, cont'd** **D,** The full-thickness cranial bone graft is fixed in place with microscrews. **E,** The lateral canthus is identified through the coronal incision and a 28-gauge stainless steel wire is passed through. In the patient shown here, the temporalis muscle has minimal hypoplasia. Thus, minimal temporal hollowing is expected after zygomatic reconstruction. The lateral canthus is pexed to the new frontozygomatic region. **F,** The locations for graft harvesting are outlined. **G,** The right side cranial graft is shown in place. (**A, B,** From Posnick JC, Goldstein JA, Waitzman A: Surgical correction of Treacher Collins malar deficiency: quantitative CT scan analysis of long-term results. *Plast Reconstr Surg* 92:12, 1993.)

obstructions are simultaneously managed (e.g., septoplasty, inferior turbinate reduction, recontouring of the nasal floor, widening of the aperture).

Type IIB mandibular malformations will require surgical construction of the congenitally missing condyle. Osteotomies alone—with the immediate repositioning or gradual DO of skeletal segments—will not be adequate. For the type IIB malformation, despite inherent limitations, mandibular reconstruction with a costochondral graft remains the preferred alternative when feasible (this will avoid the need to harvest fibula composite flaps). The incorporation of the counterclockwise rotation of the entire maxillomandibular complex will also be required to achieve facial balance and an adequate airway. Effective reconstruction can only be predictably carried out with neo-condylar construction followed by maxillary and mandibular osteotomies at or near skeletal maturity. Intranasal procedures to open the airway (i.e., septoplasty, inferior turbinate reduction, recontouring of the nasal floor and walls) are also carried out at the time of definitive jaw reconstruction.

The type III TMJ–mandibular malformation will require surgical construction of the congenitally missing glenoid fossa and condyle on each side (see Figure 40-7, *E*). Construction of the neo-glenoid fossa is required and best carried out as part of the zygomatic and orbital reconstruction (see the discussion of zygomatic–orbital reconstruction earlier in this chapter). For the type III condyle-ascending ramus malformation, construction of a neo-condyle on each side is also required. Mandibular osteotomies alone, with the immediate repositioning or gradual distraction



• **Figure 40-13** A 7-year-old girl who was born with Treacher Collins syndrome is shown before and after zygomatico–orbital reconstruction that was carried out via the technique described in this chapter. **A,** Frontal views before and after reconstruction. **B,** Oblique views before and after reconstruction. **C,** Worm's-eye views before and after reconstruction.

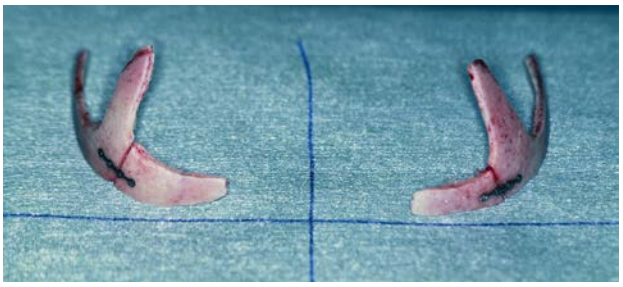
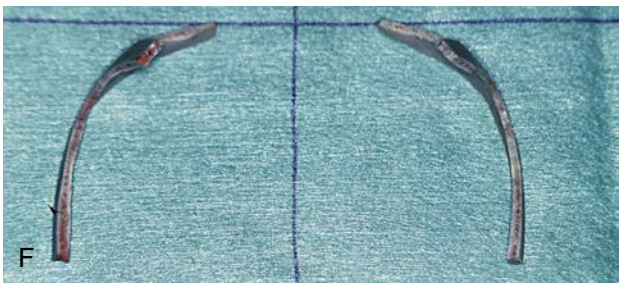
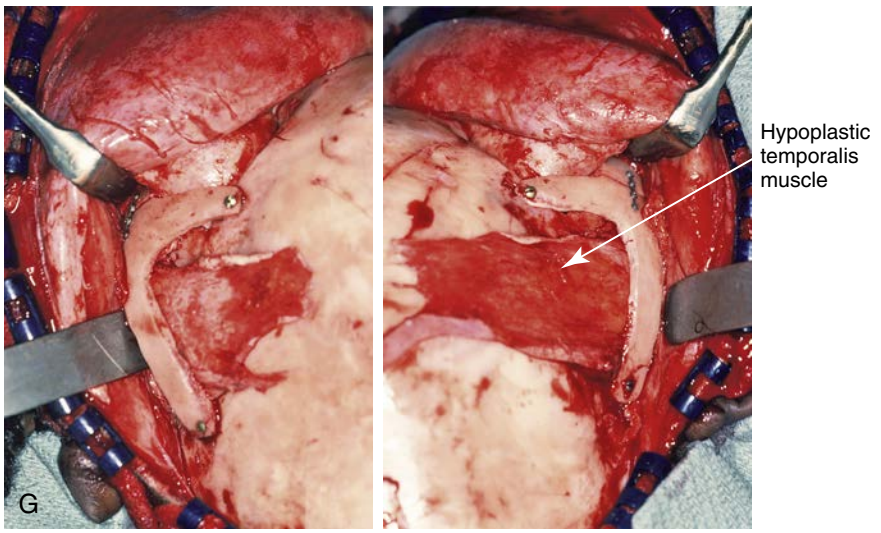
• **Figure 40-13, cont'd** **D,** Computed tomography scan views before and after zygomatico–orbital reconstruction. **E,** Axial computed tomography scan views through the mid orbits before and after cranial graft reconstruction.







• **Figure 40-13, cont'd** **F,** Intraoperative views of full-thickness crafted zygomatic complex before inset. **G,** Left and right intraoperative views of zygomatic complex reconstruction fixed with microplates and screws. The hypoplastic temporalis muscles will be rotated anteriorly as part of the reconstruction. A degree of temporal hollowing is to be expected as a result of the congenital soft tissue hypoplasia. It is important to not over-correct the zygomatic–orbital reconstruction, because this would accentuate the soft tissue deficiency. (**A-C** *(left),* From Posnick JC, Treacher Collins syndrome: perspectives in evaluation and treatment, *J Oral Maxillofac Surg* 55:1120, 1997. **A-C** *(right),* From Posnick JC, Goldstein JA, Waitzman A: Surgical correction of Treacher Collins malar deficiency: quantitative CT scan analysis of long-term results, *Plast Reconstr Surg* 92:12, 1993.)

of skeletal segments, will not be adequate. Despite limitations, neo-condylar construction with a costochondral graft remains the preferred alternative when feasible. Occasionally the combined extent of the deficiency of the skeleton and the soft tissues will require the microvascular transfer of a crafted fibula composite flap for each side (i.e., bone and soft tissue). The advantages of a vascularized fibular composite flap are obvious but the donor site morbidity (i.e., need for bilateral lower extremity harvesting) and recipient site requirements (e.g., need for bilateral neck microvascular anastomosis) are significant. In either case, at operation, the distal mandible is repositioned anteriorly to the preferred position of the maxilla. This is assisted by a prefabricated interocclusal acrylic splint, with the distal mandible secured by intermaxillary fixation. The proximal mandible on each side is then constructed with an autogenous costochondral graft or a fibula composite microvascular flap. Contouring of the native mandible with a rotary drill before placing the rib or fibula graft on the lateral side of or adjacent to the edge of the distal mandible is generally required to avoid lateral flaring. Fixation of the graft to the native distal mandible is done with an extended titanium plate from the graft forward along the inferior border of the body of the distal mandible on each side. Graft placement and fixation are generally carried out through an extraoral neck incision. The limited use of intraoral incisions in the ramus regions

during this procedure is preferred to minimize the incidence of infection and wound breakdown with subsequent graft loss or TMJ ankylosis.

Indications for First-stage Mandibular Reconstruction in the Newborn

TCS is a clefting syndrome that involves both sides of the face (i.e., the first and second branchial arches) in which upper airway anomalies occur with both regularity and variation. Hypoplasia of the mandible is one of the constant but variable components of the syndrome.[42,51, 80,93,119,120,122-137] Individuals with TCS are known to be at risk for sleep apnea, which has been reported to occur in more than 25% of affected individuals. For those with OSA who are tracheostomy dependent, an alternative method of treatment may include the sagittal advancement of the mandible to bring the tongue forward, to create space in the oral cavity, and to open up the retromandibular airway. DO techniques to gradually advance and then hold the mandibular segments until consolidation occurs have been used to improve the airway for almost two decades. The use of this technique has been reported by several authors as an effective method of decannulating otherwise tracheostomy-dependent individuals with TCS. The implications of this early mandibular advancement approach for long-term airway success and as a definitive jaw reconstruction option for patients with TCS have undergone little critical analysis.[138]

Anderson and colleagues reported the long-term results of mandibular lengthening with a DO approach that was carried out during the patient's childhood for the management of airway obstruction in an individual with TCS.[89] They documented that the airway improved in a 6-year-old patient with TCS after DO of the mandible to the extent that decannulation and the early resolution of airway obstruction were achieved. They showed that the minimum cross-sectional airway in this patient increased during the period of distraction but did not reach age-adjusted normal values. Subsequent serial scans over 10 progressive years of growth demonstrated that the minimal cross-sectional airway did not increase further. Specifically, measurements of the cross-sectional area that were taken at a fixed point of the upper airway (i.e., the base of the C2 vertebral body) demonstrated no increase in the cross-sectional area during growth. The published longitudinal case study from these authors demonstrates a failure of a sustained satisfactory cross-sectional area of the upper airway with chronologic age. They also used three-dimensional CT scans to document that mandibular growth continued in the same dysmorphic TCS pattern as it had before the distraction intervention. This resulted in an abnormally steep (clockwise rotated) mandibular plane angle. The combination of an increasingly steep mandibular plane angle and the failure of the distraction procedure to produce long-term positive horizontal projection was believed to have created the skeletal basis for ongoing upper airway obstruction. The authors conclude that a mandibular DO procedure carried out in a child with TCS who is experiencing OSA may be useful for opening the retromandibular airway. However, the initial improvement in the upper airway did not continue during chronologic growth. The clinical consequences were the reemergence of the symptoms of OSA that required further treatment (i.e., continuous positive pressure airway mask at night or tracheostomy). It is also known that a mandibular lengthening procedure carried out during early childhood will have other detrimental effects, including injury to the developing teeth; deformational growth of the mandible; facial soft-tissue scarring; injury to the inferior alveolar nerve; a significant incidence of TMJ ankylosis (both bony and fibrous); perioperative cardiovascular and respiratory complications in some patients; expense to the family and medical health care system; and the need for definitive jaw reconstruction at maturity.[139] Despite almost two decades of accumulated worldwide experience, the role of mandibular DO in the treatment protocol for infants and children with TCS remains to be determined through long-term outcome studies. In the absence of sound data, the use of mandibular osteotomies and lengthening procedures—by whatever means—during infancy and childhood should be used cautiously and selectively.

Indications for First-stage Mandibular Reconstruction During the Mixed Dentition

When a first-stage mandibular reconstruction during the mixed dentition for the type IIB condylar malformation is felt to be indicated, it is preferably carried out after the child is 7 to 10 years old and only after the eruption of the mandibular permanent first molars.[27,82-84,100-103,140] Unfortunately, a first-stage early mandibular reconstruction will not provide a long-term resolution of the mandibular and other maxillofacial deformities.[7,45,80,88,89,92,115,119,120,122,123,125-131,133-136,140-143] Problems with costochondral graft overgrowth, undergrowth, and asymmetric growth as well as with infection and TMJ ankylosis continue to plague the reconstructive surgeon (see Chapter 26). The final orthognathic correction of the upper jaw, the lower jaw, and the chin region will be required later, after early skeletal maturity (i.e., after 13 to 15 years of age).

The rationale for postponing the correction of the maxillomandibular deformity until the time of early skeletal maturity (i.e., 13 to 15 years of age) is the same as that for patients with standard dentofacial deformities, for those with other associated syndromes, and for those with a cleft lip and palate jaw deformity. The reasons that mandibular surgery during the mixed dentition is generally not preferred include the following: (1) to avoid injury to the developing permanent dentition and the inferior alveolar nerves[139,142]; (2) to avoid soft tissue (cutaneous) scarring; (3) to limit perioperative airway and infection complications; (4) to limit the patient's negative psychosocial memories; and (5)

to avoid any iatrogenic deformity of the TMJs and the mandible that may add difficulty to the achievement of a long-term favorable reconstruction.

In addition, safe and effective osteotomies in the malformed upper jaw and chin are not carried out during childhood as a result of the position of the developing teeth and the expected induced growth restrictions that would occur. The literature now confirms a lack of continued horizontal maxillary growth after early Le Fort I osteotomy. In addition, the favorable surgical placement of the jaws during the mixed dentition to ensure long-term functional occlusion and enhanced esthetics is not realistic.

In individuals with TCS, a Le Fort I osteotomy will be required to correct vertical, horizontal, and transverse maxillary deformities. The maxillomandibular complex invariably benefits from counterclockwise rotation for the correction of pitch orientation. Intrusion of the anterior maxilla is generally needed to establish a more normal upper-lip–to–tooth relationship during smile and in repose. The posterior maxillary height may require lengthening, but more frequently it can remain close to a neutral position. The planned maxillary plane change (i.e., pitch orientation) is carried out to achieve appropriate counterclockwise rotation of the mandible and the chin. The objectives are (1) to normalize the anterior facial height; (2) to open the upper airway; and (3) to establish an esthetically improved A-point–to–B-point relationship when the patient is viewed in profile. In 1993, Rosen documented the long-term stability of the counterclockwise rotation of the lower jaw when this is required to improve function and enhance the facial esthetics in patients with mandibular micrognathia. Others have carried out similar clinical studies that have confirmed the long-term skeletal stability of mandibular counterclockwise rotation as part of an orthognathic correction.[106,121]

For the type I and IIA mandibular malformations, bilateral intraoral sagittal split osteotomies are generally the preferred ramus procedures, because they allow for effective horizontal advancement, counterclockwise rotation of the mandible (without the need to actually lengthen the posterior facial height); and sufficient bone contact across each osteotomy site (see Figure 40-8, *C*). Stabilization at each mandibular osteotomy site is accomplished with titanium plates and screws as needed. Interposed (e.g., autogenous iliac) corticocancellous bone graft is used when required.

For the type IIB and type III rib or fibula graft-constructed mandible that was created earlier during the patient's life, splitting in the ramus region at the time of definitive reconstruction is preferred when feasible. The degree of bone contact across the osteotomy site after the advancement of the distal mandible is generally limited in these circumstances. The need for an interpositioned corticocancellous bone graft (e.g., autogenous iliac) should be anticipated (see Chapter 28).

For most patients with TCS, DO osteogenesis techniques have failed to demonstrate lower morbidity or improved soft tissue response as compared with standard osteotomies.[7,45,80,88,89,92,115,119,120,122,123,125-131,133-136,140,141,143-145] Data have indicated significant relapse during the consolidation phase of DO techniques and no ongoing jaw growth when the procedure is carried out during childhood. Kaban and colleagues and others continue to refine the application of curvilinear DO for the correction of the complex mandibular deformities of severe forms of TCS.[85] Despite their best efforts when using DO techniques, reliable three-dimensional vector control to achieve preferred proportions and symmetry of the osteotomized skeletal segments remains a work in progress. For these reasons, until DO technology and its clinical applications improve, we prefer the standard orthognathic correction of the maxillomandibular imbalance in patients with TCS when feasible.

Nasal Reconstruction

The bridge of the nose in the adult with TCS often has mild to moderate increased width, and a mid-dorsal hump is always present. The length of the nose is usually normal, but it seems long as a result of the imbalance with the upper and lower skeletal thirds of the face; also, the tip often droops and lacks the preferred projection. Most patients benefit from a rhinoplasty that includes osteotomies with in-fracture; the conservative reduction of the skeletal and cartilaginous dorsal hump; the removal of the cephalic portions of the lower lateral cartilages; and septal cartilage grafting (i.e., a caudal strut) sutured to the anterior septum to improve tip projection and definition. To achieve the most favorable esthetic results, it is best to postpone the rhinoplasty until after effective orthognathic procedures have been performed. Exposure is provided through an open (i.e., columella-splitting incision) technique (see Chapter 38 and Figure 40-9).

Facial Soft Tissue Reconstruction

Despite several decades of well-intentioned surgical attempts to improve the soft tissue deficiencies of the eyelid–adnexal regions, few esthetically pleasing soft tissue eyelid reconstructive results in patients with TCS have been reported.[67,72-74,146-149] The transposition of pedicled upper-eyelid-skin–muscle flaps to deficient regions of the lower eyelid is not technically difficult; unfortunately, the adnexal scarring that inevitably occurs often results in an "operated" look that generally detracts from any positive advantages of the procedure. The placement of full-thickness skin grafts to the lower eyelids is another frequently mentioned option. It predictably leaves a "patchy" look, and it should be reserved only for patients with recalcitrant corneal exposure problems. The lateral canthi are inferiorly displaced as a result of both orbital dystopia and hypoplasia of the lateral canthi and other components of the eyelid structures. Although the correction of the orbital dystopia and direct lateral canthopexies are helpful and should be carried out, they rarely normalize the multilevel soft-tissue hypoplasia of the specialized adnexal structures (i.e., skin, cartilage, eyelashes, ligament, fascia, and tendon). For these reasons, it is best to consult with an experienced oculoplastic surgeon when considering even minor eyelid procedures for patients with TCS.

The observed temporal fossa hollowing that is frequently encountered with TCS is also a reflection of multilevel hypoplasia that includes the skin, the temporoparietal fascia, the temporalis muscle, and the decreased bitemporal width of the anterior cranial vault. For this reason, transposing pericranial or temporoparietal congenital hypoplastic flaps will have limited utility for the management of either temporal or adnexal region subcutaneous deficiency.

When the procedure is meticulously designed and expertly executed, the transfer of soft-tissue flaps from other body regions, with microvascular reanastomosis, should be considered for reconstruction of TCS.[67,72-74,146-149] When this level of facial soft tissue replacement is required, parascapular free flaps have become the workhorse since they were first described by Dos Santos. Siebert and colleagues found that the parascapular flap allows for the reasonable correction of contour defects in the lateral aspects of the face; this yields improved esthetic results in selected patients with TCS by providing vascularized soft tissue in the subcutaneous plane while minimizing scarring.[149] Fortunately, hypoplasia of the centrally located soft tissues of the face (i.e., forehead, nose, upper and lower lips, chin, and submental region) is not seen in patients with TCS. Dermal fat grafts, autogenous fat injections, and other forms of soft tissue augmentation have gained popularity. The results of autogenous fat injection are variable and considered technique sensitive; they are generally not harmful, and they are clearly promising. Tanna and colleagues investigated the use of serial autologous fat grafting to restore soft tissue contour in patients with hemifacial microsomia.[150] Patients with moderate to severe hemifacial microsomia were divided into two groups: Group I included those undergoing microvascular free-flap reconstruction (i.e., inframammary extended circumflex scapular flaps; n = 10); Group II included those undergoing multiple staged autogenous fat grafting (n = 21). The two patient groups had similar OMENS scores (2.4 and 2.3, respectively) and similar pre-reconstruction facial symmetry scores (74% and 75%, respectively). At the final evaluation, facial symmetry scores were 121% for the microvascular free-flap group and 99% for the fat-grafting group. Furthermore, no statistically significant difference between the microvascular and fat-graft groups in either patient or physician rating of overall satisfaction was noted. The extrapolation of these study results to the individual with TCS is appropriate.[150-152]

External Ear Reconstruction

The surgical reconstruction of the auricle can be satisfactorily achieved through a staged approach in the hands of a few experts.[69,153-167] The methods described by Brent represent the reference standard for external ear reconstruction.[153-156] The successful grafting of a well-sculpted cartilage framework is the foundation for sound auricular repair. According to Brent, most children have adequate rib cartilage for the repair by 6 years of age. At that time, the synchondrotic region of ribs 6 and 7 will provide an ample cartilage block to form the framework of the ear; this is taken from the side contralateral to the ear being constructed. With the use of the preoperatively determined measurements and a prefabricated template, the position of the ear is determined, and a small preauricular incision is made. Unusable vestigial cartilage is excised. A thin-skinned pocket is developed, with the dissection carried beyond the marked auricular outline to recruit sufficient tension-free skin coverage. For patients with bilateral microtia, Brent prefers that the harvesting of cartilage grafts for each ear be separated by several months. Simultaneous bilateral auricular reconstruction would necessitate bilateral chest wounds with severe splinting and the potential for respiratory distress. Other stages of the auricular construction include lobule transposition, the detachment of the auricle with a skin graft, the management of the hairline, and tragus construction. Brent suggests that bilateral microtia repair be completed with five procedures that are carried out at 3-month intervals.

When completing microtia reconstruction in the patient with TCS, eventual external auditory canal and middle ear surgery must be considered. Auricular construction should precede any middle ear surgery because, after an attempt is made to open the canal, the chances of obtaining a satisfactory auricular repair are severely compromised as a result of the scarring of the skin envelope. When middle ear surgery is an option, Brent suggests that the cartilaginous framework be sculpted with a wider concha to accommodate a future surgically created canal.

Other options for external ear reconstruction include the use of alloplastic and homologous frameworks. Alloplastic materials that are currently in use include silicone and Medpor (Porex Surgical, Inc., College Park, GA). These foreign substances are more susceptible to infection, soft tissue wound dehiscence, and susceptibility to minor trauma, even decades after reconstruction. Innovative techniques of tissue engineering involving bovine cartilage cells that are grown in the laboratory and seeded on a synthetic biodegradable ear template that is then implanted beneath the skin of an immunocompetent mouse have shown promise for the future. Unfortunately, until tissue engineering evolves beyond the currently encountered immunogenic problems, sculpted autogenous rib cartilage will remain the material of choice for the surgical repair of the ear.

At the same time, unless the option of sculpted autogenous rib cartilage is carried out by an experienced auricular reconstructive surgeon, the chance of achieving an esthetically acceptable result is slim. For this reason, the use of a prosthetic external ear or no reconstruction at all in most individuals with TCS should not be discounted automatically.

External Auditory Canal and Middle Ear Reconstruction

Although some of the hearing loss in the patient with TCS is attributable to external auditory canal stenosis or atresia, most of the loss (i.e., an average of 44 dB) is attributable

to hypoplastic middle ear cavities and ankylotic or missing ossicles.[75,77,78] Ankylosed or nonfunctioning ossicles appear to limit hearing conduction to the same extent as if they were absent.[76] Attempting reconstruction of the middle ear in patients with TCS can be expected to result in gains in hearing. However, even if the ossicles are mobilized, middle ear dysmorphology remains; this results in residual hearing loss and leaves the patient dependent on some form of amplification. Jahrsdoerfer reported on a group of patients with TCS who underwent surgery for hearing rehabilitation.[78] He confirmed the generally unsuccessful attempts to satisfactorily improve "non-aided" long-term hearing. A form of bone conduction hearing aid is required for proper amplification in most patients, including those who have undergone reconstruction as well as those who have not. The bone conduction hearing aid may be a traditional unit, a modified amplification system, or a bone-anchored conduction unit.

According to Brent, for the gains from any middle ear surgery to outweigh the risks and complications of the procedure, it should be reserved for selected patients with bilateral and unilateral microtia in whom personal motivation is high, in whom the favorable radiologic evidence of middle ear development is present, and in whom a favorable outcome is expected according to an experienced otologist.[153-156] Furthermore, it must be planned through a team approach with an otologist and an auricular/reconstructive surgeon who are competent and experienced with ear-canal atresia, middle ear malformations, and microtia repair. At the time of middle ear surgery, the auricular/reconstructive surgeon initiates the procedure by lifting the reconstructed ear from its bed while carefully preserving both the connective tissue on the framework's undersurface and the overall circulation of the flap. The otologist proceeds by drilling a bony external auditory canal, completing ossiculoplasty, and then repairing the tympanum with a temporal fascia graft. The auricular/reconstructive surgeon then excises the soft tissues to exteriorize the meatus through the chondral region and harvests a skin graft that the otologist uses to line the new external auditory canal.

The Bone-anchored Hearing Aid Option

A bone-anchored hearing aid (BAHA) consists of a permanent titanium fixture that is surgically implanted into the skull bone behind the ear and a small detachable sound processor that clips onto the fixture. BAHAs are suitable for people with conductive or mixed hearing loss who cannot adequately benefit from or prefer not to use conventional hearing aids.

Colquitt and colleagues completed a systematic review and an economic evaluation of BAHAs for people who are bilaterally deaf.[168] Previous prospective studies of adults or children with bilateral hearing loss were eligible for review. Twelve studies were included; there were seven cohort pre-post studies and five cross-sectional audiologic comparison studies. Comparisons were made between BAHAs and the following: (1) conventional hearing aids, which are also known as air-conduction hearing aids (ACHAs); (2) bone conduction hearing aids (BCHAs); and (3) unaided hearing and ear surgery. The study also looked at (4) unilateral versus bilateral BAHAs. Outcomes reviewed included hearing measures, validated measures of quality of life, adverse events, and measures of cost-effectiveness.

There appeared to be some audiologic benefits of BAHAs for this group of patients, including improvements in speech as compared with BCHAs; and understanding and noise as compared with ACHAs (however, ACHAs may produce better audiologic results for other outcomes). In addition, hearing was found to be improved with the use of BAHAs as compared with unaided hearing, and studies that compared unilateral with bilateral BAHAs suggested the benefits of bilateral BAHAs in many situations. However, prospective case series of BAHAs reported rates of 6.1% to 19.4% for the loss of the implants over time. In addition, the financial analysis suggests that BAHAs are unlikely to be a cost-effective option in terms of hearing gain and probability of needing alternative aids. Interestingly, the greater the benefit from aided hearing and the greater the difference in the proportion of people using the hearing aid for more than 8 hours per day, the more likely the BAHAs were a cost-effective option.

Janssen and colleagues completed a systematic review of bilateral BAHAs for bilateral permanent conductive hearing loss.[169] This was a review of the literature from between 1977 and 2011, and it included studies in which subjects of any age had permanent conductive hearing loss and bilateral implanted BAHAs. Eleven studies met the criteria for data analysis. Bilateral BAHAs were found to provide audiologic benefit as compared with unilateral BAHAs (i.e., improved thresholds for tones, speech in quiet and in noise, improved localization/lateralization, and patient's perceived subjective benefit). Disadvantages of bilateral BAHAs included listening in noise in some condition, presumed additional cost, and presumed increasing adverse event risk. The authors concluded that bilateral BAHAs provided additional objective and subjective benefit as compared with unilateral BAHAs.

Conclusions

The current approach to the correction of malformations associated with TCS is to stage the reconstruction to coincide with facial growth patterns, visceral function (i.e., vision, breathing, chewing, swallowing, speech, hearing), and psychosocial needs. Precise morphologic analysis of each patient and the recognition of the need for a staged reconstructive approach serve to clarify the objectives at each interval for both the clinicians and the family. By continuing to define a rationale for the timing, methods, and extent of surgical, medical, and dental interventions and then objectively evaluating head and neck function, facial esthetics, and psychosocial outcomes, the outlook for individuals affected by TCS will be greatly improved.

The Management of Pediatric Craniomaxillofacial Pathology

JOHN F. CACCAMESE JR., ROBERT A. ORD, ANDREW R. SALAMA

Introduction

The term *pathology* can be all encompassing, and strictly speaking is defined as structural and functional deviations from normal that constitute disease or characterize a particular disease. In essence, this often refers to diseases that are aplastic, hypoplastic, neoplastic, traumatic, iatrogenic, or developmental in nature. For purposes of this chapter, we will limit our discussion to neoplastic and dysplastic diseases in children.

Although the origins of craniofacial surgery developed out of the need to comprehensively treat congenital pediatric deformities and traumatic injuries, the application of such principles to the treatment of neoplastic disease soon followed. Craniomaxillofacial (CMF) pathology presents the surgeon with the challenges of access, achieving oncologic margins, and preservation of vital structures, along with a functional and esthetic reconstruction. More specifically, tumors affecting the anterior cranial fossa, the anterior skull base, and the infratemporal fossa are often the domain of the maxillofacial surgeon and require the assistance of a neurosurgeon. Often more challenging than the approach to the tumor is the determination of resectability and whether the burden of morbidity outweighs the benefit of complete resection. Increasingly, there has been a role for endoscopic assisted, robotic, and image-guided resection of tumors, with the potential for improving both functional and esthetic outcomes.

Craniofacial Growth and Development

Cranial and facial growth and development results from complex interrelated and interdependent processes, with no single craniofacial component being self-contained or self-regulated.[1] Growth occurs as a result of a combination of remodeling and displacement. There are three primary fields of craniofacial growth and development; the brain and basicranium, the airway, and the oral region. The basicranium acts as a template to establish the shape and perimeter of facial form. The facial and pharyngeal airway space is determined largely by its surrounding parts. Enlow refers to the airway as the *keystone* for the face, whose growth is determined in part by both genetics and function, and acts to stabilize the remaining components of the face. The oral region either then assumes any basicranial asymmetry or compensates for the asymmetry by its own developmental process.[1] The effect of extirpative surgery or tumor treatment on facial growth and development may be significant though unavoidable if efforts are made to achieve a cure. One must consider these factors, not only when planning treatment, but also in long-term follow-up because subsequent deformity may have considerable psychosocial impact.

Imaging

Improvements in the quality of imaging and the ability to manipulate the images, whether it is to plan surgery, to guide the resection of a tumor in real time, or to fabricate a medical model, have had a profound impact in the treatment of CMF pathology. Imaging is particularly helpful because the full extent of the tumors often is not assessable by physical examination alone. The craniofacial region is relatively dense with vital structures, and appropriate preoperative images help to further elucidate their relationship to the pathologic process. This can be critical to determining resectability.

Typically, the imaging modalities used in the workup of CMF pathology include computed tomography (CT) and magnetic resonance imaging (MRI), with an increasing role for positron emission tomography (PET) and PET-CT. Occasionally, ultrasound, angiography, and bone scans have a role as well. At a minimum, a high-resolution CT or MRI is necessary for appropriate planning. The need for contrast is determined on a case-by-case basis. Software is

readily available for the surgeon to reformat images into the standard axial, coronal, and sagittal views as well as three-dimensional (3D) images for CT scans. In general, CT is less expensive and is preferred for detailing bony pathology and anatomy, tumor bulk, and node involvement. MRI is commonly considered to be superior for purely soft tissue lesions, detailed evaluation of nerves and vessels, and for lesions involving the brain or dura. With concerns over lifetime radiation exposure and the cumulative risk involved, the role of MRI is increasing, specifically in the pediatric population.

The use of PET scanning continues to grow rapidly in the field of oncology. It is often most useful in situations where conventional imaging yields equivocal results, as in the previously treated patient. PET scans help to differentiate surgical change from recurrence and reactive nodes from those with metastasis. Overall, PET has been found to be more sensitive and specific than conventional imaging in the evaluation of regional node disease. PET also has value in evaluating patients for unknown primary tumors, synchronous primaries, and distant metastasis.[2]

Angiography is routinely used for the evaluation of vascular lesions. Although MR angiography is becoming increasingly sophisticated in the diagnosis of such lesions, conventional angiography offers the benefit of interventional capability should the lesion mandate embolization. Angiography is also useful in determining the extent of carotid involvement of either direct tumor extension or metastatic disease. If carotid resection is deemed necessary, a carotid occlusion study can be performed to assess the patient's ability to function when reliant on the collateral circulation from the unaffected side via the circle of Willis.

With the continuous improvement of imaging techniques, the envelope of surgical possibility becomes increasingly limitless. By integrating surgery with the real-time manipulation and guidance of imaging, we are able to visualize various images simultaneously, see structures that are otherwise only visible through operative access, and improve the accuracy of surgery in difficult anatomic regions. Potential advantages might include smaller incisions, direct access to specific localized areas, and less morbid or invasive operations.[3]

Anatomic Classification

For the planning of craniofacial tumor surgery, Jackson classified the skull base into an anterior region and a posterior region to describe tumor location. The anterior region includes only the anterior cranial fossa. The posterior region was further broken down into anterior, central, and posterior segments relative to the petrous portion of the temporal bone.[4] Others have elaborated further on the site of origin (oral, nasal, cranial, etc.) and the direction of extension (craniofacial or faciocranial) and let this be their guide to approaching CMF tumors.[5] In this chapter, we will discuss pathology of the anterior fossa and anterior skull base, the infratemporal fossa, the mid-face, and the mandible.

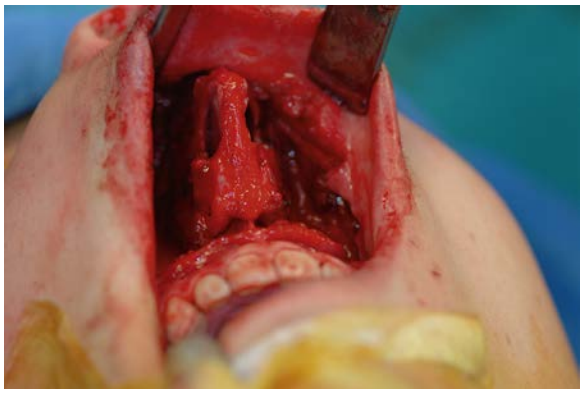
Within the facial skeleton, simple anatomic description modified by degree of extension helps one plan most accurately the surgical extirpation and the required reconstruction.

CMF Access

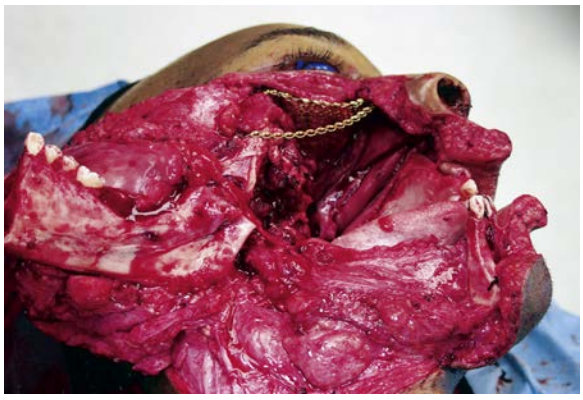
Many approaches to the facial skeleton have been advocated based on the location of the tumor, the necessity of safe resection margins, the proximity to vital anatomic structures, and the anticipated functional and esthetic outcome. Access surgery involves a multitude of osteotomies and facial incisions that can be tailored for specific purposes: when combined, these procedures produce acceptable safety for oncologic surgery. The craniofacial skeleton is rich in anatomic complexity. Surgery to the deep face, oropharynx, nasopharynx, and anterior skull base requires thoughtful planning. Although myriad approaches to the craniofacial skeleton and anatomic tumor classifications have been described, patients and their pathology should be evaluated on an individual basis. The goal of access surgery is to provide an operative environment in which the extirpative surgeon can safely remove tumor. This basic philosophy accounts for the protection of vital structures and maintenance of facial esthetics. The value of preoperative planning for access surgery cannot be overemphasized and should entail a comprehensive patient evaluation including high-resolution 3D imaging and a thorough review of the underlying pathology. Conceptualization of a tumor in space relative to surrounding structures is requisite to the operative phase of surgery.

Access to the superficial facial skeleton is relatively straightforward through a variety of common, well-described approaches. The workhorse incision of craniofacial surgery is the coronal incision. It provides broad access to the orbit and upper mid-face, and can be modified or combined with lateral orbital, oral, facial, and nasal incisions to provide near total access to the anterior or lateral cranial base and facial skeleton. The disadvantages include the potential for obvious scarring in patients with male pattern baldness, alopecia, and injury to the frontal branch of the facial nerve, which can be avoided with judicious tissue dissection beneath protective layers of the temporalis fascia and avoidance of monopolar cautery. Noticeable scarring can be addressed and somewhat obviated by the use of the stealth incision, which applies a zigzag incision rather than a straight line, eliminating the obvious part in the hair.[6]

Access to the anterior orbit, including the infraorbital rim and floor, can be obtained through cutaneous and conjunctival incisions. Skin incisions have the benefit of improved access in some situations and may be the most appropriate to achieve an oncologically sound resection. When managing benign pathology or performing a recontouring procedure (e.g., fibrous dysplasia), a transconjunctival approach



• **Figure 41-1** A mid-face degloving is performed using intercartilaginous incisions extended circumferentially within the nares and through the septum to liberate the nasal tip, upper lip, and oral mucosa from the underlying maxilla and nasal structures.



• **Figure 41-2** This patient required combined access for a large maxillary osteosarcoma involving the infratemporal fossa. A Weber-Ferguson incision was combined with a lip split and double mandibular osteotomy.

might provide a more esthetic outcome. Extension via lateral canthotomy/cantholysis or transcaruncular incision gives one near total access to the internal bony orbit and the lower half of the orbital rim. The medial orbital wall can also be approached by a subciliary lid incision, although the transcaruncular approach affords generous access behind the lacrimal system, all without a skin incision. Tumors in the paranasal sinuses that invade or abut the medial orbital wall typically require both a skin incision along the lateral nasal wall and a complementary osteotomy. The Weber-Ferguson approach, lateral rhinotomy, and medial maxillectomy are commonly employed in this circumstance.

Surgical access to the lower bony mid-face can be achieved by means of standard vestibular incisions. The mid-face degloving procedure extends exposure comfortably to the inferior orbital rim and nasal dorsum, and when combined with additional incisions and a craniotomy, this can be used to access the anterior skull base and sinonasal regions without the need for facial incisions. Fundamental knowledge of intranasal rhinoplasty techniques is applied, which includes intercartilaginous incisions extended circumferentially within the nares and through the membranous septum to liberate the nasal tip, upper lip, and oral mucosa from the underlying maxilla and nasal structures (Figure 41-1). More generous and direct access to the mid-face can be achieved with a Weber-Ferguson incision.

Access to the mandibular body and symphyseal regions can be achieved through mucosal and cervical incisions. Knowledge of the path of the facial nerve in the neck is essential to protect its marginal mandibular branch. The utility incision for mandibular access is an apron-style incision and is designed in a skin crease at least 2 cm below the inferior border of the mandible. Elevation of the facial vein at the mid to posterior lateral aspect of the submandibular gland, in the manner of Hayes Martin, generally affords protection of the marginal mandibular branch without the need for extensive nerve localization or dissection. Tumor in the mandibular angle, ascending ramus, and pterygomasseteric portion of the mandible requires more in-depth planning, depending on the extent of the tumor and need for appropriate surgical margins. Access to condyle for complete hemimandibulectomy can generally be achieved through a cervical incision. The preauricular approach and coronal approach can be used adjunctively with bulky tumors confined to the head of the condyle. An apron-style incision can be extended to include the lip-split modification and mandibulotomy, which affords direct visualization of the pterygoids and medial aspect of the condyle. Vertical compartment resection of the mandible enables en bloc removal of the vertical ramus and is reserved for tumors that infiltrate the muscle of the pterygomasseteric sling. It requires a subfascial parotid dissection in the plane of the masseter muscle or a standardized facial nerve dissection; both approaches carry risk of injury to the branches of the facial nerve.

Small tumors of the oral cavity (less than 4 cm) can generally be treated transorally. Larger tumors of the posterior tongue, tongue base, and retromolar fossa can be safely approached through an apron/lip-split incision and a paramedian mandibulotomy. The osteotomy can be performed in the midline, although lateral placement in the premolar region still preserves the mental nerve and is generally preferable. The inferior border of the mandible is exposed and miniplates are adapted, secured, and then removed. The osteotomy is then performed and the indexed hardware replaced in the reconstructive phase to restore the premorbid occlusion and mandibular continuity. A horizontal ramus osteotomy can be used adjunctively (double mandibular osteotomy) and can obviate the need for a lip-split incision (Figure 41-2).[7] The stability of rigid fixation is important, because many patients are subjected to external beam radiotherapy before bony healing is complete. The use of a bicortical mini-locking plate has a biomechanical advantage when used at the inferior border.[8] Mucosal incisions should be designed not to overlap the osteotomy. A variety of modifications have been suggested to enhance the stability of the reconstructed mandible, however they are largely unnecessary if AO principles of rigid fixation are applied. Disadvantages of these approaches include the added time in the operating room, potential for nonunion

in the face of radiation, malocclusion, and trismus. The visor approach entails the raising of bilateral apron-style incisions toward the inferior border of the mandible, which are then connected with sulcular or vestibular incisions. The mental nerves are identified and divided as part of the process. It provides broad access to the lateral tongue and floor of mouth. Access to the floor of mouth can be also achieved through a delivery/pull-through approach. Following exposure of the inferior border of the mandible, the geniohyoid, genioglossus, and mylohyoid muscles are divided at their insertions to the mandible. The lingual mucosa is then elevated in a sulcular or vestibular incision on the lingual aspect of the mandible. The entire tongue and floor of mouth can be safely "delivered" to the neck for tumor removal. The use of a sulcular incision in dentate patients facilitates easy closure.

Access to the central skull base and nasopharynx can be approached through the oral cavity through the use of a standard Le Fort I down-fracture. The lateral osteotomies of the Le Fort may need to be modified to maintain oncologic integrity of the approach, in the form of low osteotomies or limited use of pterygoid separation in the face of gross tumor infiltration. Removal of the posterior wall of the maxilla provides direct access to the nasopharynx. The use of indexed miniplates and/or occlusal splints is recommended to restore the occlusion in the reconstructive phase. A two-piece Le Fort I osteotomy broadens access, although the palatal mucosa must be incised to complete the exposure. The relationship of blood supply to the translocated structure(s) should be considered along with the planned resection to avoid ischemic complications.

Access to the anterior skull base usually entails a combination of surgical approaches rather than a single approach. Access to the paranasal sinuses and fronto-orbital regions typically involves a facial approach and either a cranial or subcranial approach (Figure 41-3). Each must be tailored to the patient and the location and extension of the tumor. Avoiding a craniotomy has intrinsic advantages, especially in patients with multiple medical comorbidities. The subcranial approach entails the use of custom osteotomies about the anterior craniofacial skeleton. A frontal sinusotomy without removal of the posterior wall allows safe access to the ethmoids and frontal sinus and obviates the need for a craniotomy. Tumors that approach the dura or invade the dura require a formal bifrontal craniotomy. The craniotomy should be planned keeping the both the extirpation and reconstruction in mind (Figure 41-4). The craniotomy can be extended caudally to include the superior and lateral orbital rims as necessitated for access. The bone flap not only provides access, but can also be split into calvarial grafts to facilitate bony reconstruction.

Craniofacial disassembly employs the concept of modular facial anatomic units, developmental embryology, and blood supply. Transfacial swing procedures in which the orbit, maxilla, and mandible are osteotomized in variable combinations allow exposure of the midline of the cranial base. Nasomaxillary translocation involves complete separation of the nasal skeleton and at least half of the maxilla. It is best suited for exposure of the lower clivus. The blood supply of the rotated unit is maintained and reconstruction is simplified with indexed microplating. Fronto-orbital osteotomies are utilized for large orbital tumors, internal carotid artery exposure, and orbital apex decompression.

Endoscopic Approaches

More and more, endoscopic approaches are being used for tumor resection or to assist in tumor removal along with conventional approaches. The clear advantage to this technique is the avoidance of facial incisions, which in and of themselves might result in permanent disfigurement. In addition, endoscopic approaches may obviate the need for wide periosteal dissections and osteotomies that could interfere with facial growth. In some cases the use of endoscopes allows the surgeon to "look around" the tumor, which is often not possible with conventional skull base access. Rapid healing and return to function as well as shortened hospital stays are further benefits of the technique.

In the hands of a skilled endoscopic surgeon, the potential advantages are clear. The learning curve is steep, however, and until one is facile with the technique, possible disadvantages include increased operative time, increased blood loss, decreased access to control hemorrhage, and incomplete tumor removal. One can always convert to an open procedure when appropriate to maximize the possibility of surgical success.

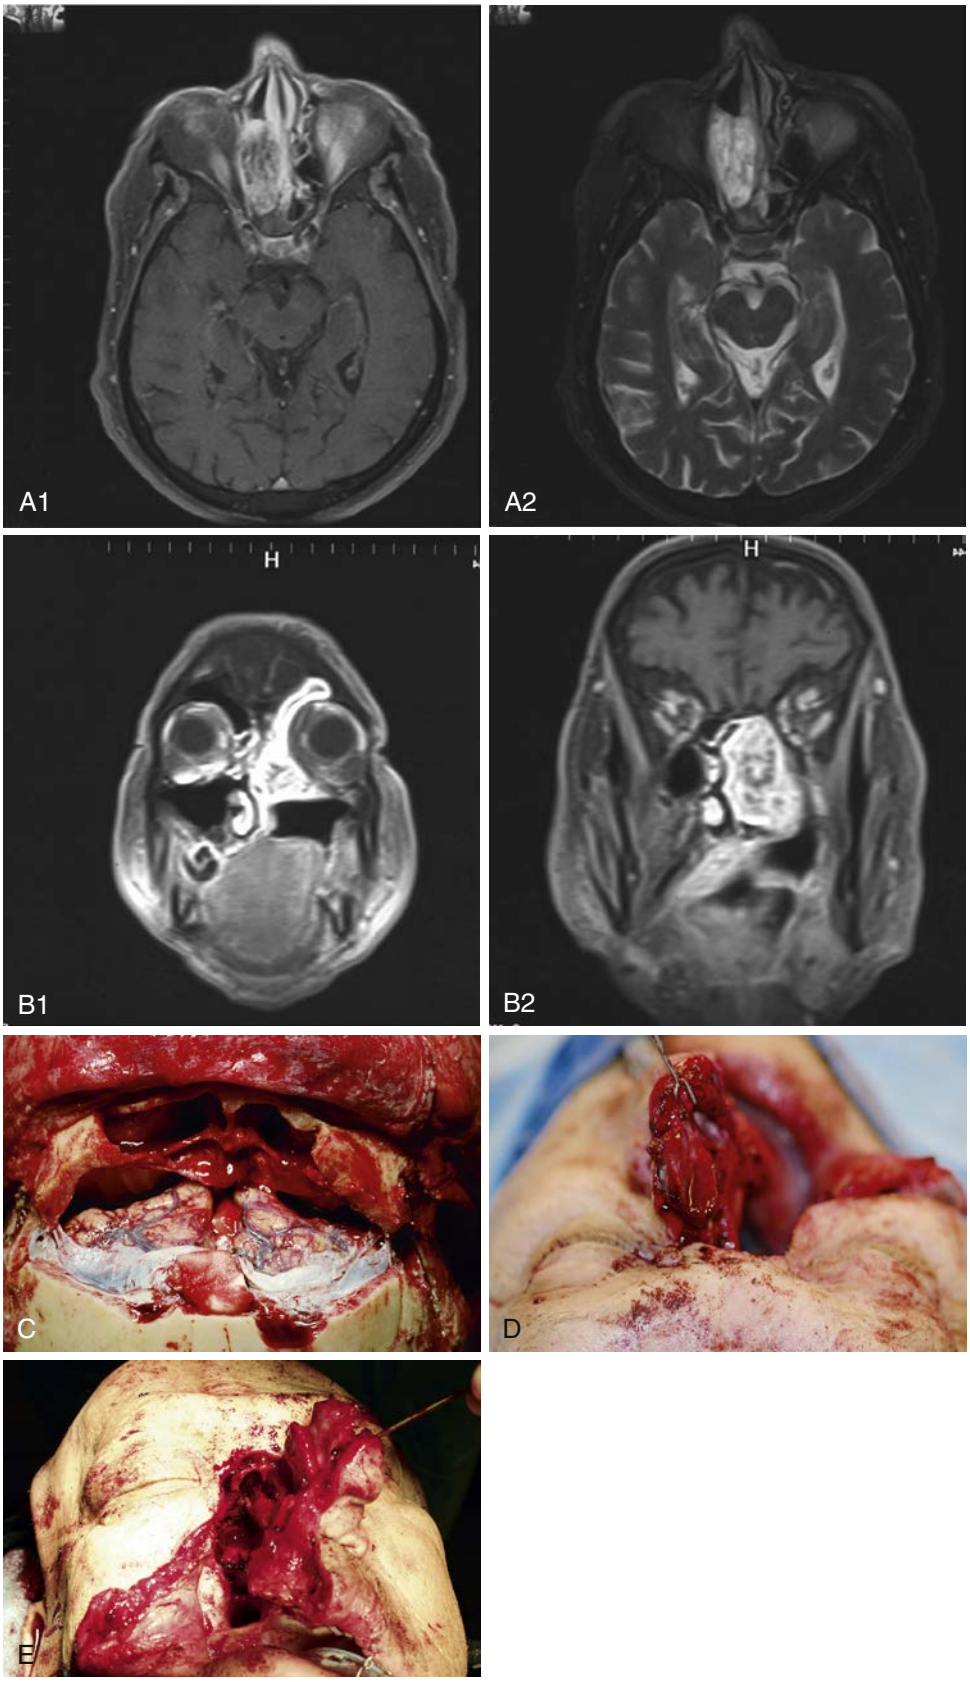
Pathology

Benign and malignant tumors involving the CMF structures are relatively rare occurrences in children.[9-12] The treatment of these tumors is based primarily on their biologic behavior, as well as location and size. Although cure is the ultimate goal, significant consideration must be given to the functional, developmental, esthetic, and psychosocial consequences of treatment, whether surgical or medical. For surgical disease, immediate reconstruction with grafting and free tissue transfer has become more readily accepted.

Benign disease of the jaws is generally classified into odontogenic and nonodontogenic tumors. With the exception of odontomas, odontogenic tumors are rare in children and are classified into epithelial, mesenchymal, and mixed tumors. Of these, the ameloblastoma is often considered to be the most aggressive.

Odontogenic Tumors

Odontogenic tumors are thought to arise from the cells that form teeth. They are usually classified into those arising from epithelial, mesenchymal, or mixed origin. Most are benign and, although they can be seen at any age, some have a higher incidence in children or behave differently in the pediatric patient; these tumors will be discussed in this section.



• **Figure 41-3** **A** and **B,** MRI demonstrating ameloblastoma involving paranasal sinuses and anterior skull base. **C,** Craniotomy to access anterior cranial base and frontal sinuses from above. **D** and **E,** Weber-Ferguson incision for access to medial maxilla and ethmoid sinuses.

• **Figure 41-5** A 19-year-old African American boy with "presumed" dentigerous cyst. However, note resorption of distal root of second molar. Histologically this is a unicystic ameloblastoma.

Ameloblastoma

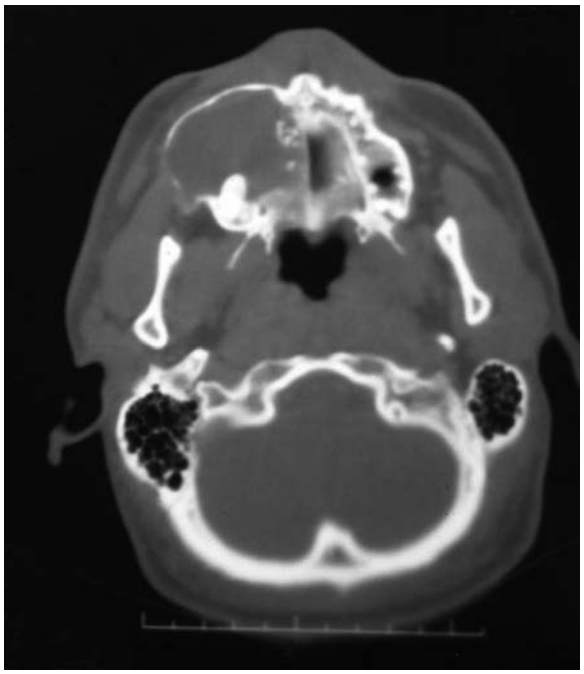
Ameloblastoma is the most common odontogenic jaw tumor and it is most commonly seen in the fourth decade. It is benign but aggressive and is divided into unicystic and multicystic/solid types. It is not common in the pediatric population, only comprising 12% to 15% of patients younger than 19 to 20 years old and very rare in children younger than 10 years.[13-15] In our original paper we found an incidence of 28.9% (11 of 38 cases), but we included adults with recurrent lesions who were originally treated as children.[16] Clinical presentation is usually of a painless swelling at the angle of the mandible which radiologically may be uni- or multilocular and may involve unerupted teeth, mimicking a dentigerous cyst, although root resorption may alert the clinician to a more aggressive lesion (Figure 41-5). There is usually buccal and lingual expansion of bone. Frequently the diagnosis is made as an asymptomatic incidental finding on a panoramic radiograph. However, the importance of recognizing pediatric ameloblastoma as an entity lies in the greatly increased percentage of lesions characterized as unicystic. Unicystic ameloblastomas comprise approximately 15% of all ameloblastomas, but represent 76.5% of pediatric cases reported in Europe and the United States.[16,17]

Unicystic ameloblastoma is a diagnosis that is based on the histologic characteristics, not the radiologic appearance. Ackermann et al classified these into four types: Type I and II are intraluminal or epithelial lining only while Type III and IV involve the capsule (mural types).[17] The clinical importance is that the solid/multicystic type is more aggressive and has higher recurrence rates when treated with modalities other than segmental resection. Resection is recommended for mural types to prevent recurrence with soft tissue invasion, while low recurrence rates (10% to 25%) from enucleation alone of unicystic ameloblastoma has classically been described.[18-20] Most papers group all unicystic ameloblastomas together and do not separate out those unicystic ameloblastomas with capsular involvement. Whether enucleation alone is sufficient in this group remains controversial. Involvement of the capsule in unicystic ameloblastoma has been reported to be as high as 49% to 81%.[17,19] It is not uncommon to experience sampling bias in unicystic ameloblastomas. Oral and maxillofacial pathologists may be reluctant to commit to or have insufficient tissue to assign a particular subtype to a unicystic ameloblastoma based on an incisional biopsy alone. Lower grade lesions that are enucleated with curative intent may require additional surgery if the final pathology report indicates a more aggressive subtype.

A recent report indicates recurrence rates of approximately 80% in unicystic ameloblastomas treated by enucleation, although numbers were small.[21] A systematic review to determine which modality of treatment resulted in the lowest recurrence rate showed a rate of 3.6% for resection, 30.5% for enucleation alone, 16% for enucleation and application of Carnoy's solution, and 18% for marsupialization. The authors concluded that there was only weak evidence to show that resection resulted in the lowest recurrence rate, with enucleation alone showing the highest recurrence rate. Marsupialization could not be evaluated.[22] In pediatric cases we undertake segmental resection with primary microvascular reconstruction for all multicystic/solid ameloblastomas and all unicystic ameloblastomas that are large enough to compromise mandibular integrity or involve soft tissue. Unicystic ameloblastomas with tumor involving just the lining or the lumen of the cyst are treated by enucleation, but we advocate resection for mural unicystic ameloblastomas.

Adenomatoid Odontogenic Tumor

Approximately 66% occur in patients aged 10 to 19 years. They are common in females and in the anterior maxilla. They present as a swelling in the canine, bicuspid region, and can have unerupted teeth involved. Frequently, they contain small calcifications that may be peripheral and give them a mixed radiolucent/radio-opaque appearance on x-ray. They are treated by enucleation, and recurrence is rare. The low recurrence rate may be due to these lesions being hamartomas rather than true tumors, or to their low proliferative



• **Figure 41-6** Large adenomatoid odontogenic tumor displacing alveolar ridge, palate, and displacing teeth.

rate seen with a Ki-67 marker.[23,24] They are usually small and removal is simple, but occasionally they may present as large lesions (Figure 41-6).

Odontogenic Myxoma

Odontogenic myxomas are most common in patients 20 to 30 years old, but are seen in children and only rarely in infants. They may appear as a painless swelling of the mandible or maxilla. Radiographically, they may be unilocular or multilocular; however, larger lesions are usually multilocular.[25] They may show root resorption, similar to the ameloblastoma. Often they contain thin bony trabeculae which classically show a step-ladder appearance, although they may show an expanded "soap bubble" appearance (Figure 41-7). CT may help to define soft tissue infiltration outside the cortical bone.[26] They are infiltrative and display many of the pathologic characteristics of ameloblastomas. Despite a pathobiology similar to solid ameloblastoma, some authorities have recommended enucleation/curettage for smaller lesions, which leads to recurrence in 25% of cases.[27] The authors believe in resection with 1 cm margins, especially for posterior maxillary lesions that can lead to recurrent tumors invading the pterygoids, orbit, and skull base if curetted. Some authors have advocated maxillectomy with narrow margins in pediatric maxillary myxomas.[28]

Ameloblastic Fibroma

This tumor contains neoplastic elements deriving from both epithelium and mesenchyme. Some of these lesions may be considered as early developing odontomas as opposed to true tumors. They are mostly seen in children less than 20 years of age, and the majority occur in the posterior mandible either as a swelling in larger cases or are noted incidentally on screening radiographs as a well-defined unilocular or multilocular lesion (Figure 41-8). Many reports suggest that recurrence following simple curettage is rare; however, recent reports have indicated recurrence rates of up to 20% and recommend complete surgical excision.[29,30] Although the malignant counterpart, ameloblastic fibrosarcoma, is rare, approximately 50% of cases have been reported as a recurrence in a previous benign ameloblastic fibroma. Although the ameloblastic fibroma is usually treated by curettage or simple excision, recurrent lesions may require resection. In cases of malignant ameloblastic fibroma, radical resection provides a greater opportunity for local control.

Ameloblastic Fibro-odontoma

Ameloblastic fibro-odontomas are frequently seen in children less than 10 years of age. Histologically, they resemble the ameloblastic fibroma, but contain enamel and dentin. Although this lesion again may represent a stage in odontoma formation, some lesions continue to grow and behave like a true neoplasm (Figure 41-9). Clinically, they occur as swellings of the maxilla or mandible. On radiographs they are radiolucent lesions containing differing amounts of calcifications and usually containing an unerupted tooth. Treatment is by curettage and recurrences are rare.

Odontoma

Odontomas are the most commonly seen odontogenic tumors; they are hamartomas that are subdivided into complex odontomas, which are masses of calcified tissue (dentin and enamel), and compound odontomas, which consist of multiple tooth-like structures. These lesions are seen most often in children and are frequently diagnosed as they interfere with normal tooth eruption. Radiologic features may show a few small tooth-like structures overlying an unerupted tooth or a large area of calcification with a radiolucent rim and sclerotic border, depending on the type and size of the lesion (Figure 41-10). Simple excision is curative but may be challenging in large cases.

Nonodontogenic Tumors

Juvenile Aggressive Fibromatosis

The fibromatoses arise from the superficial or deep musculoaponeuroses of regions of the body, most commonly the abdominal wall (desmoid tumor). However, they may arise in the head and neck, particularly in children younger than 10 years of age, and tend to be aggressively infiltrating in this location.[31] Gold describes three histologic types: desmoplastic, active, and sarcomatoid.[32] They may be found in bony, paragnathic, or soft tissue locations. Although these tumors destroy and infiltrate bone, there is often a marked proliferation of cortical bone in paragnathic cases in young patients (Figure 41-11). This is due to stimulation of the active periosteum in children. Although some

of these lesions are very indolent and slow growing, others infiltrate widely and can grow rapidly, behaving as low-grade sarcomas (Figure 41-12). Because of their poorly circumscribed margins, which are difficult to define clinically or radiographically, obtaining good surgical margins is frequently difficult and recurrence rates of 70% are reported.[33] In purely oral lesions, excluding neck lesions with brachial plexus involvement, recurrence rates of 23.8% have been achieved.[31] Interestingly, many authors have commented on the fact that complete excision with negative margins is not always essential to obtain local control, and long-term stability and even regression has been reported in incomplete

excision.[34,35] Sacrifice of essential nerves may therefore not be necessary.[34] In some head and neck sites such as the skull base, it may be impossible to obtain clear margins with this disease.[36] In unresectable cases with continuing growth, radiation therapy, chemotherapy, and hormonal therapy have all been attempted with varying success rates.[37-39] There are no good prospective trials to indicate what the current best management is for aggressive fibromatosis, and these lesions continue to remain a multidisciplinary challenge. Recently, a European consensus approach by the Sarcoma Patients EuroNet and European Organisation for Research and Treatment of Cancer/Soft Tissue and Bone Sarcoma Group initiative recommended that for head and neck sites there is clear consensus that medical therapy would be the first treatment choice. If there is progression or relapse, radiotherapy should be considered, though facial growth is still a concern. When surgery is opted for, additional radiotherapy can be considered to minimize the risk of local relapse.[40] The authors prefer surgery up front in cases of resectable disease when this can be accomplished with accepatble morbidity.

Central Giant Cell Lesions

The central giant cell granuloma is an osteolytic lesion of the jaws that is locally destructive and variably aggressive (Figure 41-13). The mean age of diagnosis is 20 years, and it is more common in females (3:2). The mandible is involved twice as often as the maxilla, and the lesions range from being asymptomatic swellings or incidental findings to being painful with associated paresthesias.[41] Chuong et al in 1986 classified giant cell lesions of the jaws as either aggressive or nonaggressive based on several criteria. Aggressive giant cell lesions were defined as having a size of greater than 5 cm, rapid growth, causing tooth root resorption or tooth displacement, cortical bone thinning or perforation, or recurrence after simple curettage. Findings that included a tumor >5 cm in size or tumors that recurred after curettage were considered aggressive tumors based solely on these features; otherwise, three of the other signs have to be present for a tumor to be classified as aggressive.[42]

Nonaggressive lesions in the jaws are amenable to simple curettage. Aggressive lesions have reported recurrence rates

as high as 70% after enucleation or curettage.[43] Multiple modalities have been used to treat giant cell lesions, including interferon, corticosteroids, calcitonin, or receptor activator of nuclear factor kappa-B ligand (RANKL) inhibitors, based on the assumption that the lesions are proliferative vascular lesions, inflammatory, or that the osteoclast is the predominant cell type. Results of these treatments when used alone have been mixed.[43-48] For now, the gold standard of therapy for aggressive lesions is en bloc resection, though Kaban has published promising results combining curettage of the aggressive variant with adjuvant interferon therapy.[43]

Aneurysmal Bone Cyst

The aneurysmal bone cyst (ABC) is a pseudocyst of bone filled with blood, and can occur as a primary lesion or secondarily as a component of another lesion such as fibrous dysplasia.[49-51] These "cysts" can be either unilocular or multilocular and can result in significant expansion of the affected jaw or bone. ABCs are more common in the mandible, but they occur in the maxilla and have been reported in other bones of the face, such as the zygoma, clivus, and cranial bones. They may occur in any age group, but are usually seen in patients less than 20 years of age. Sometimes there will be a history of trauma preceding the development of the lesion.

Aneurysmal bone cysts can be treated by curettage, but have a high incidence of local recurrence. ABCs are often multilocular and divided by multiple bony septae. This can interfere with curettage and explains the many treatment modalities reported in their management, which include no treatment, curettage, cryotherapy, excision, and resection. Marginal or en bloc resection should be curative, but necessitates future reconstruction (Figure 41-14).

Juvenile Nasopharyngeal Angiofibroma

Juvenile nasopharyngeal angiofibromas (JNA) are highly vascular, benign, aggressive tumors that occur in the region of the sphenopalatine foramen of adolescent male patients and account for 0.05% of head and neck tumors.[52] They are nonencapsulated and frequently extend beyond their site of origin to involve the nasal cavity, sphenopalatine fossa, orbit, sphenoid sinus, and middle cranial fossa.[53] The typical presentation is of painless unilateral nasal obstruction and epistaxis. Intracranial extension and bleeding may result in life-threatening complications.

Cure is achieved by complete surgical extirpation, and the approach to the tumor is tailored to the specific anatomic location. Many approaches have been used and advocated, including various facial incisions and skull base approaches. Recently, endoscopic approaches have gained favor as the procedure of choice when feasible. Carrau et al have had good success with endoscopic and endoscopically assisted approaches. Their recurrence rate compares favorably to what has been historically reported in the literature (13% vs. >20%) and their complications were few.[53-55] Regardless of the surgical approach chosen, most centers advocate preoperative angiography and embolization of the major feeding vessels to improve hemostasis at the time of removal.[56,57] The arterial sheath can then be left in place for assistance in managing difficult-to-control intraoperative bleeding.

Although the JNA is often within the realm of the ENT surgeon, the maxillofacial surgeon frequently contributes to the management of this pathology. Even though it is becoming more common for these tumors to be removed endoscopically, there is still a role for access osteotomies in the treatment of these benign but aggressive lesions (Figure 41-15).

Juvenile Ossifying Fibroma

Juvenile ossifying fibroma (JOF) is a fibro-osseous lesion that is histologically similar to ossifying fibroma and fibrous dysplasia. The lesions are more common in the maxilla than the mandible, and are most frequently encountered in the first and second decades of life (age <15 years). It is a variant of the ossifying fibroma and is characterized by rapid progression during childhood. JOF is alternatively known as the aggressive ossifying fibroma and is distinguished histologically from the more common ossifying fibromas by its cellular fibrous stroma with a network of osteoid rimmed by active osteoblasts.[58] Growth is rapid, occurring over weeks, rather than months to years (as seen in the nonaggressive form), and may cause erosion of the adjacent bone as well as significant facial deformity and functional impairment. Surgical resection has been advocated for these lesions because the recurrence rate is 30% to 56%.[59-61] Due to their rapid enlargement and often large size, facial incisions to improve access may be unavoidable to ensure complete tumor removal (Figure 41-16).

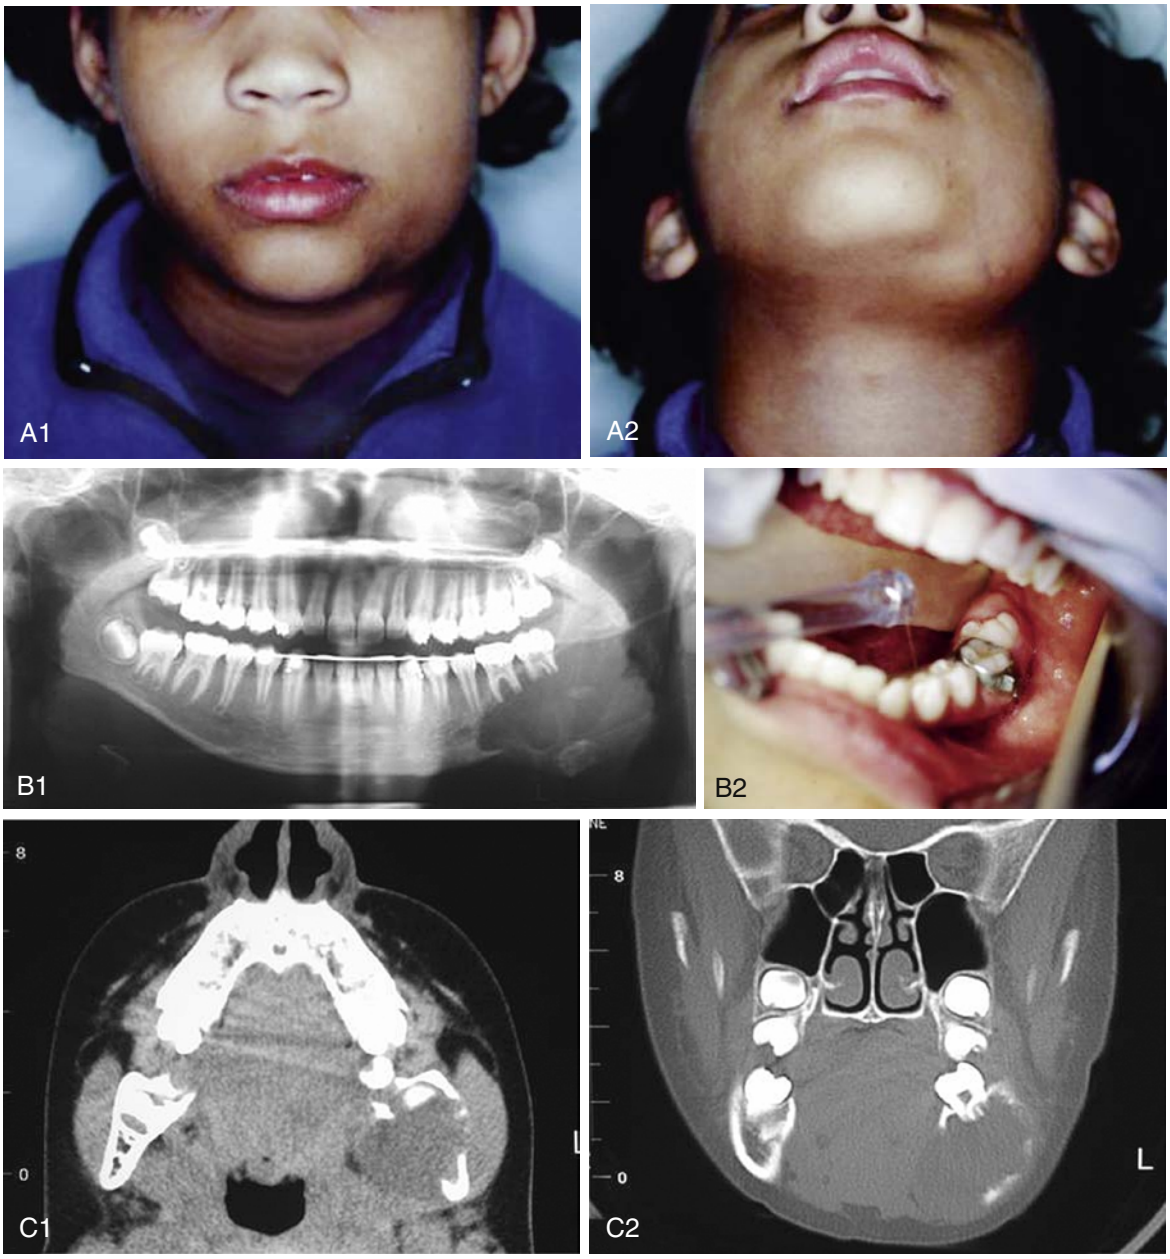
Craniofacial Fibrous Dysplasia

Fibrous dysplasia is a disease in which normal bone is replaced by abnormal but benign fibro-osseous tissue. It was initially described by von Recklinghausen in 1891, and further characterized by Jaffe and Lichtenstein.[62,63] It results from a mutation of the *GNAS1* gene leading to increased intracellular cyclic adenosine phosphate. It can occur as an isolated condition or as a component of McCune-Albright syndrome. The syndrome includes the findings of fibrous dysplasia and café au lait skin pigmentation, in addition to multiple endocrinopathies (Figure 41-17). Fibrous dysplasia can affect single (monostotic) or multiple (polyostotic) bones of the skeleton and commonly involves craniofacial structures. The disease manifests as slowly progressive and painless swellings of bone resulting in functional problems related to the area of growth. Though largely a benign disease, a low rate of malignant sarcomatous transformation has been reported (Figure 41-18).[58]

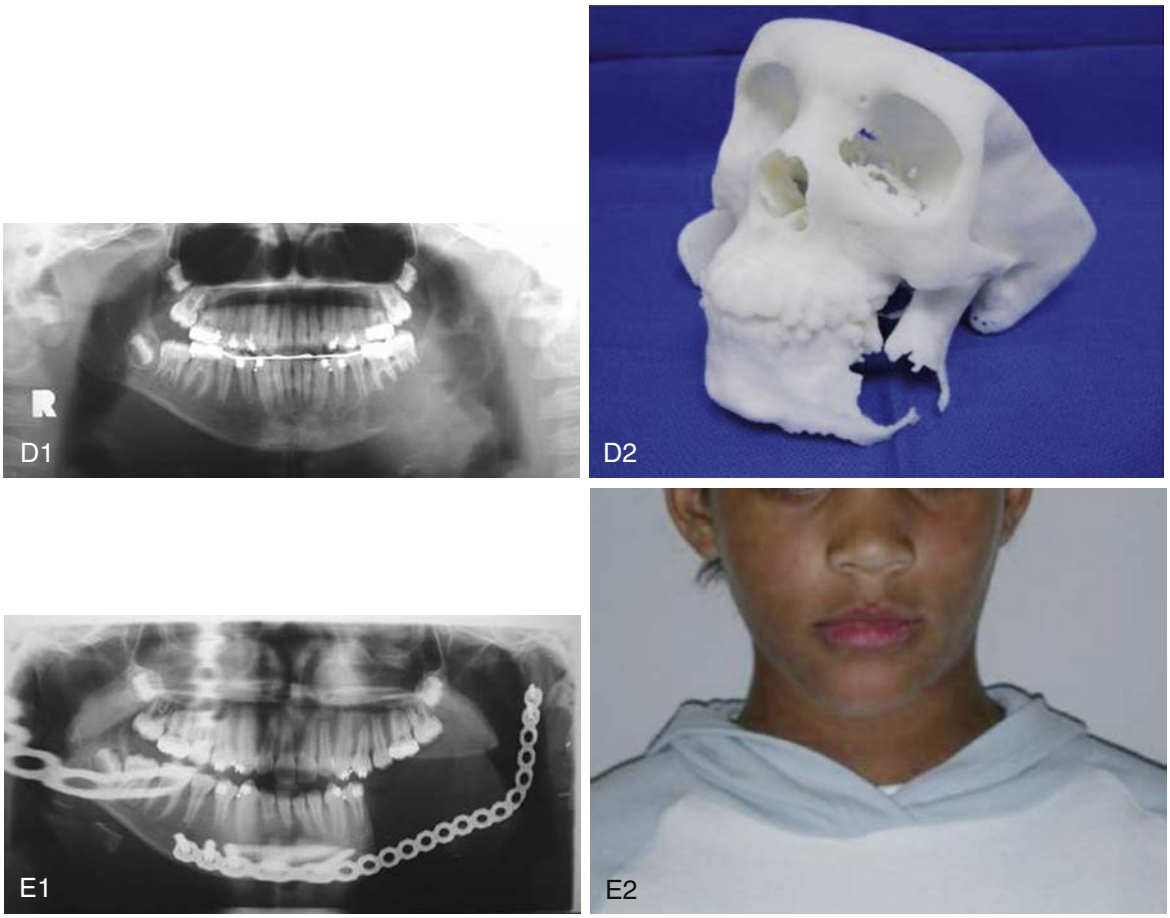
Craniofacial fibrous dysplasia (CFD) can result in severe deformity and significant functional impairment. Complications are generally the result of both the mass effect and the composition if the lesion. Ocular complications include diplopia, proptosis, blindness, epiphora, and exposure

keratitis. Loss of color vision often signifies impending visual loss, one of the more devastating consequences of the disease. At one time, prophylactic optic nerve decompression was advocated based on the appearance of CT scans[65]; however, Lee et al recommended close follow-up with symptomatic intervention only, citing a poor correlation between blindness and optic canal narrowing as viewed on diagnostic imaging.[64-66] Oral manifestations can include malocclusion, loose teeth, limited opening, and impaired mastication.[67] Nasal obstruction and obliteration of the sinuses are also common. Paresthesia and anesthesia can be the result of direct nerve compression, with central nervous system effects also having been documented when the neurocranium is involved.

The appearance of polyostotic CFD has been described as that of leonine facies. This is a result of both the broadening and lengthening of the face as a result of dysplastic bone growth. The dysplastic tissues do not grow symmetrically, further worsening the esthetic appearance. The effect, however, can be much more localized, affecting one or several bones of the face unilaterally, resulting in an obvious asymmetric swelling. Esthetic concerns can be of significant psychosocial impact in this patient population because the disease frequently manifests in the first and second decades. Because this is a benign condition with low malignant potential and because the affected areas are so diffusely involved, repositioning osteotomies and bony recontouring are the mainstay of surgical therapy



• **Figure 41-14** **A,** A 13-year-old girl with rapidly enlarging mass in the left mandible. **B,** Panorex shows radiolucency of left mandible with expansion and root destruction. **C,** CT showing radiolucency of the left mandible and root destruction. Biopsy shows central giant cell granuloma; the lesion was curetted.



• **Figure 41-14, cont'd D,** The lesion rapidly recurred and was resected. Pathology shows aneurysmal bone cyst. **E,** The hemimandibulectomy defect was temporarily reconstructed with a bar and subsequently grafted successfully.

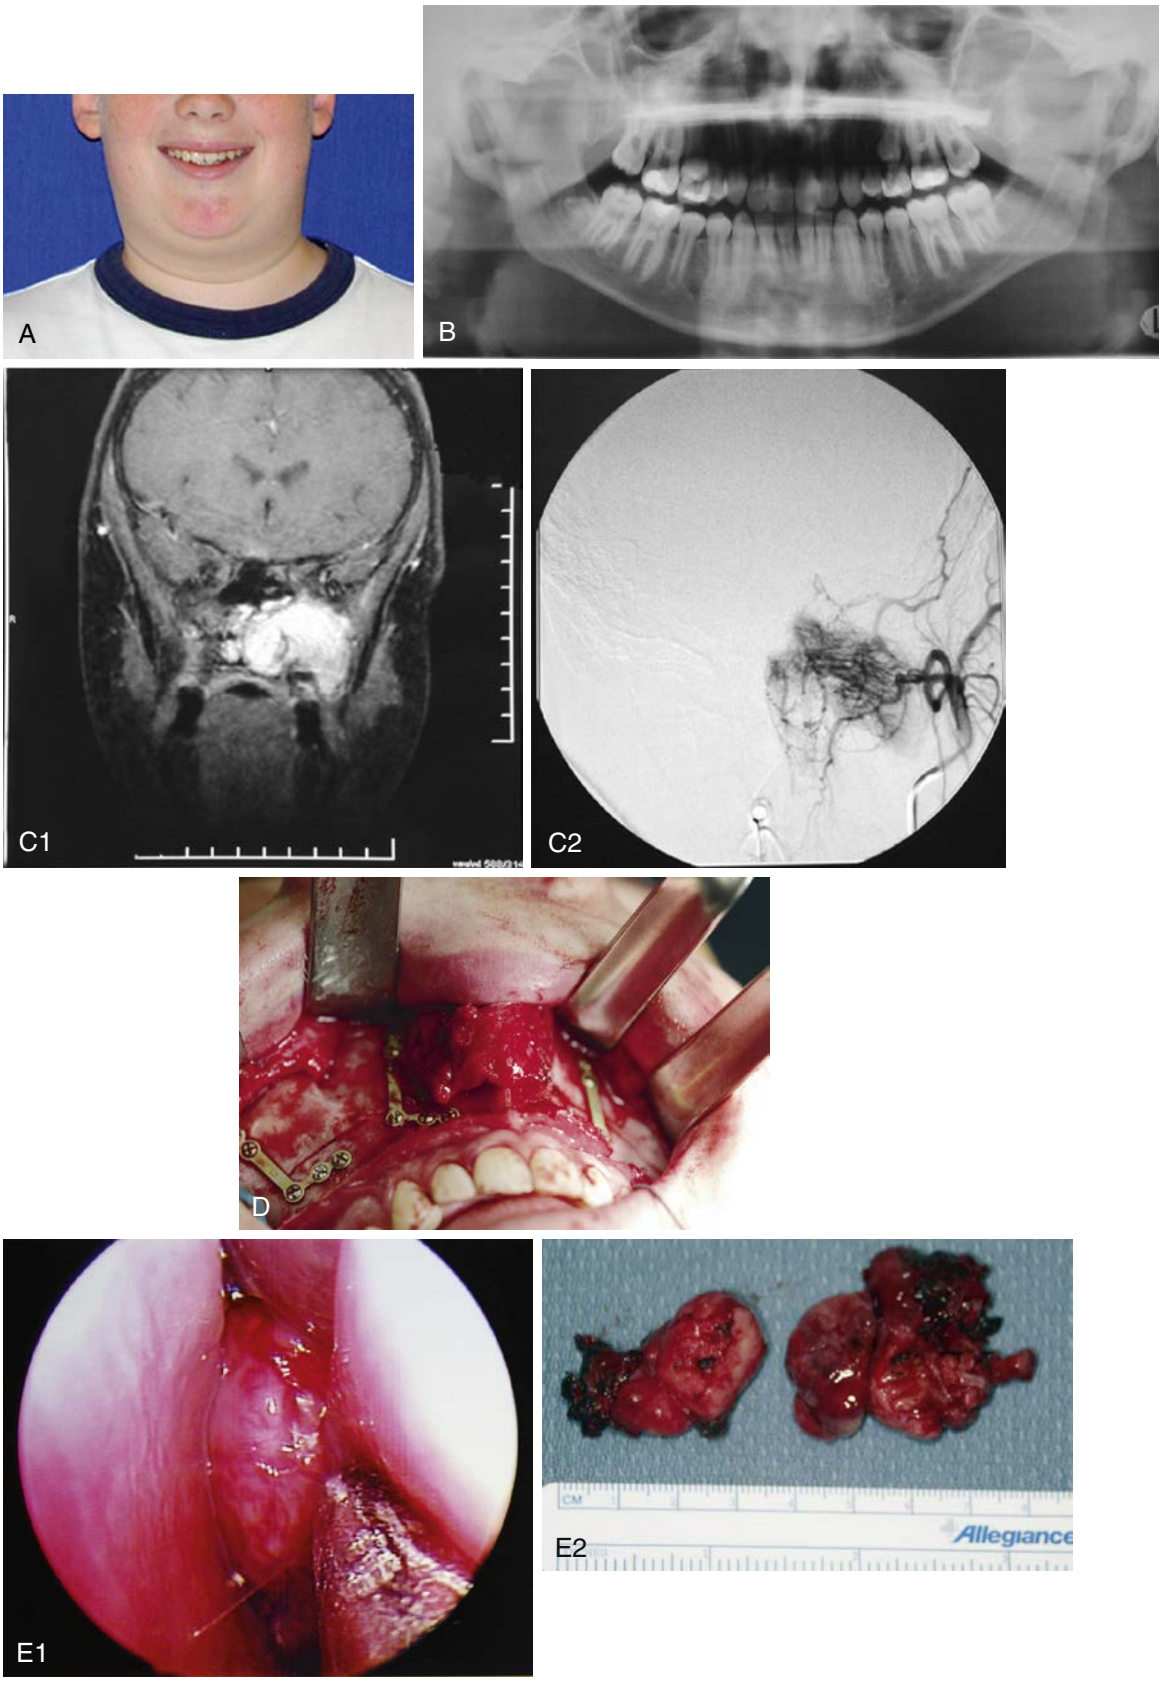
(Figure 41-19). Others have described resection and reconstruction with bone grafts, but the authors rarely find indication for this approach.[68] In general, recontouring procedures offer some esthetic and functional benefit without eradicating the disease. The authors' preference is to perform recontouring procedures definitively once growth has ceased; however, psychosocial and functional concerns often mandate earlier intervention with the understanding that revision may be necessary as growth of the lesion continues.

Many groups have documented the value of bisphosphonate therapy in small cohorts of patients with fibrous dysplasia and McCune-Albright syndrome. These studies have shown the beneficial effects of long-term bisphosphonate treatment on dysplastic lesions leading to reduced fracture rate and bone pain, and radiologic evidence of long bone lesion healing.[69-71] Further randomized controlled trials are needed, however, before their efficacy can be advocated.

Depending on the quality of the dysplastic tissue, recontouring of facial bones can be accomplished with rotary instrumentation, saw blades, and a variety of chisels and gouges. Osteotomies can be accomplished in the usual fashion and fixated with plates and screws. Sometimes, the soft fibrous nature of the bone can make fixation a challenge. It is also important to note that these lesions can be well vascularized and sometimes result in significant blood loss, so cross-matching of blood is indicated for larger procedures. Some dental complications have been described, including malocclusion and failed orthodontic therapy.[67] Because the application of orthodontics is often a necessary and useful adjunct to orthognathic procedures, definitive jaw surgery can be all the more challenging in this patient group. With the sometimes excess growth of the facial bones comes the slow expansion of the soft tissue envelope. This may take time to redrape following surgery and, despite aggressive recontouring, can give the appearance of residual deformity.

Neurofibromatosis

Neurofibromatosis (NF) is an autosomal dominant disorder that occurs as one of two genetic variants, NF1 (von Recklinghausen disease) or NF2 (central neurofibromatosis). NF1 occurs in approximately 1 in 4000 live births and is often the result of a spontaneous mutation.[72] Specific criteria have been determined that result in a diagnosis of NF1. These include two or more of the following signs: café-au-lait spots, multiple neurofibromas (or one of the plexiform type), axillary/groin freckling, optic glioma, Lisch nodules, dysplasia of the sphenoid or a long bone,



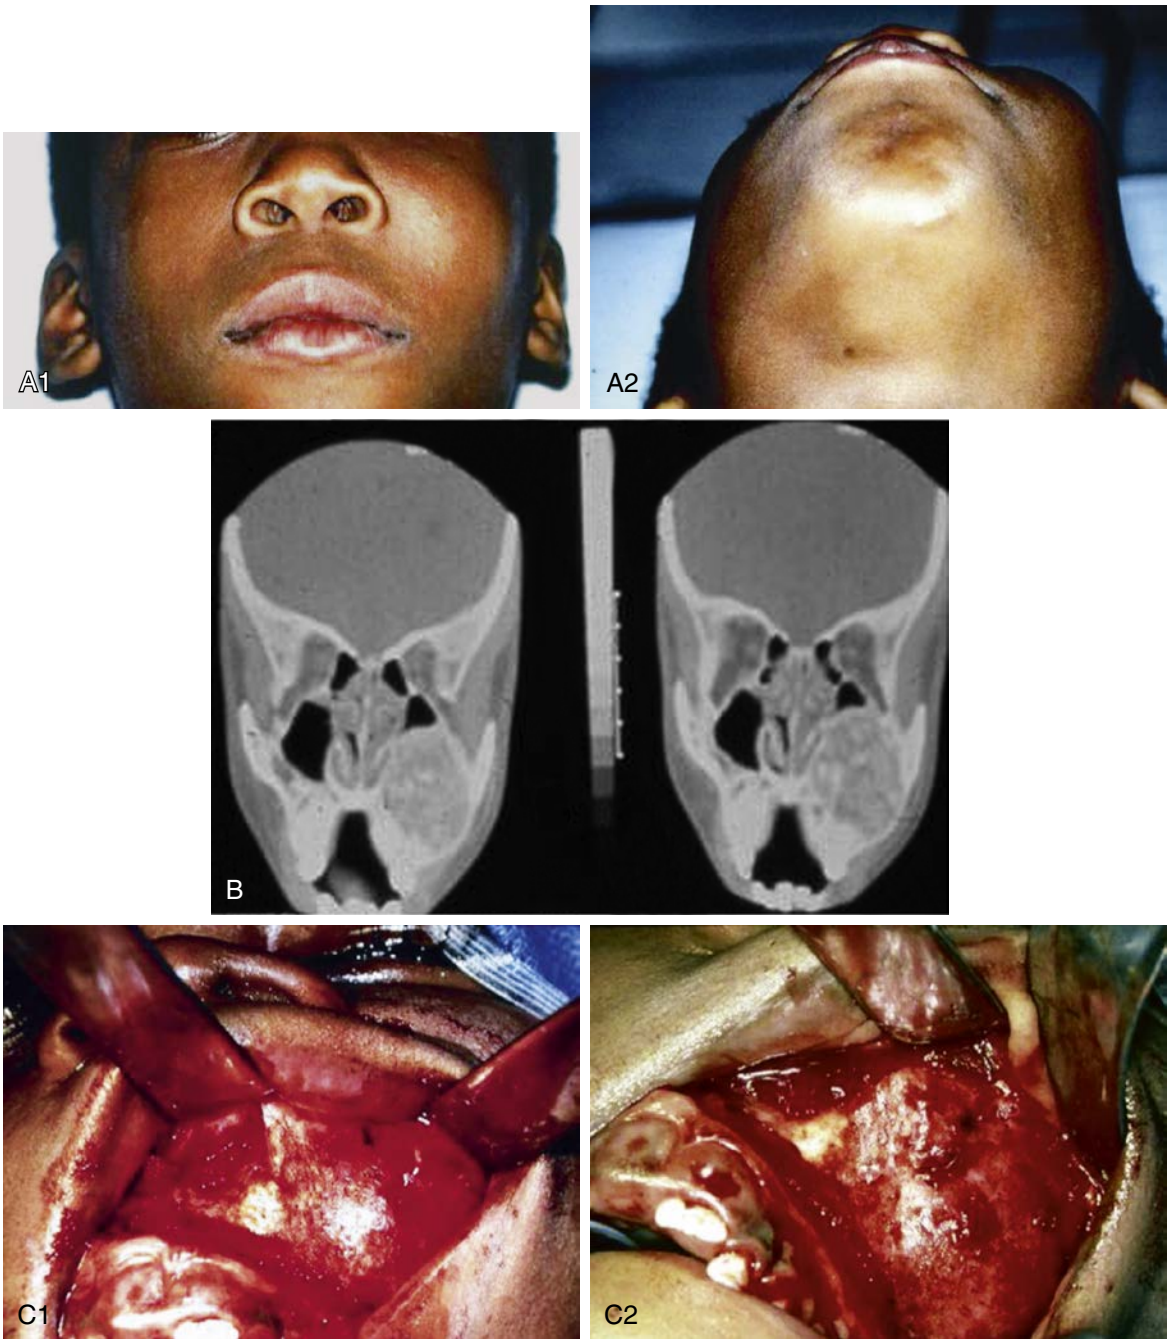
• **Figure 41-15** **A,** A 12-year-old male with left juvenile nasopharyngeal angiofibroma (JNA). **B,** Panorex shows radiolucent mass of left maxilla *(white circle)* with some bowing of posterior maxilla. **C,** JNA on MRI abutting the skull base and preoperative angiogram demonstrating vascularity. **D,** Le Fort I preplated and down-fractured for additional access. **E,** Endoscopic view of lesion and surgical specimen. The lesion was resected via Le Fort I access with endoscopic assistance.

and a first-degree relative with NF-1 (Figure 41-20). Centrally, tumors of the optic tracts are seen in up to 20% of patients, while the most common peripheral tumor is the plexiform neurofibroma.[73]

Plexiform neurofibromas are benign tumors that arise from Schwann cells, which extend across the length of a nerve and involve multiple fascicles.[74] The tumors are invasive, and despite surgical resection (often subtotal), regrowth following surgery is common. These tumors often result in significant functional and esthetic impairment, and craniofacial NF can be particularly disfiguring. Additionally, these lesions have the potential for malignant transformation, which can be difficult to discern, given the surrounding soft tissue mass of the tumor.

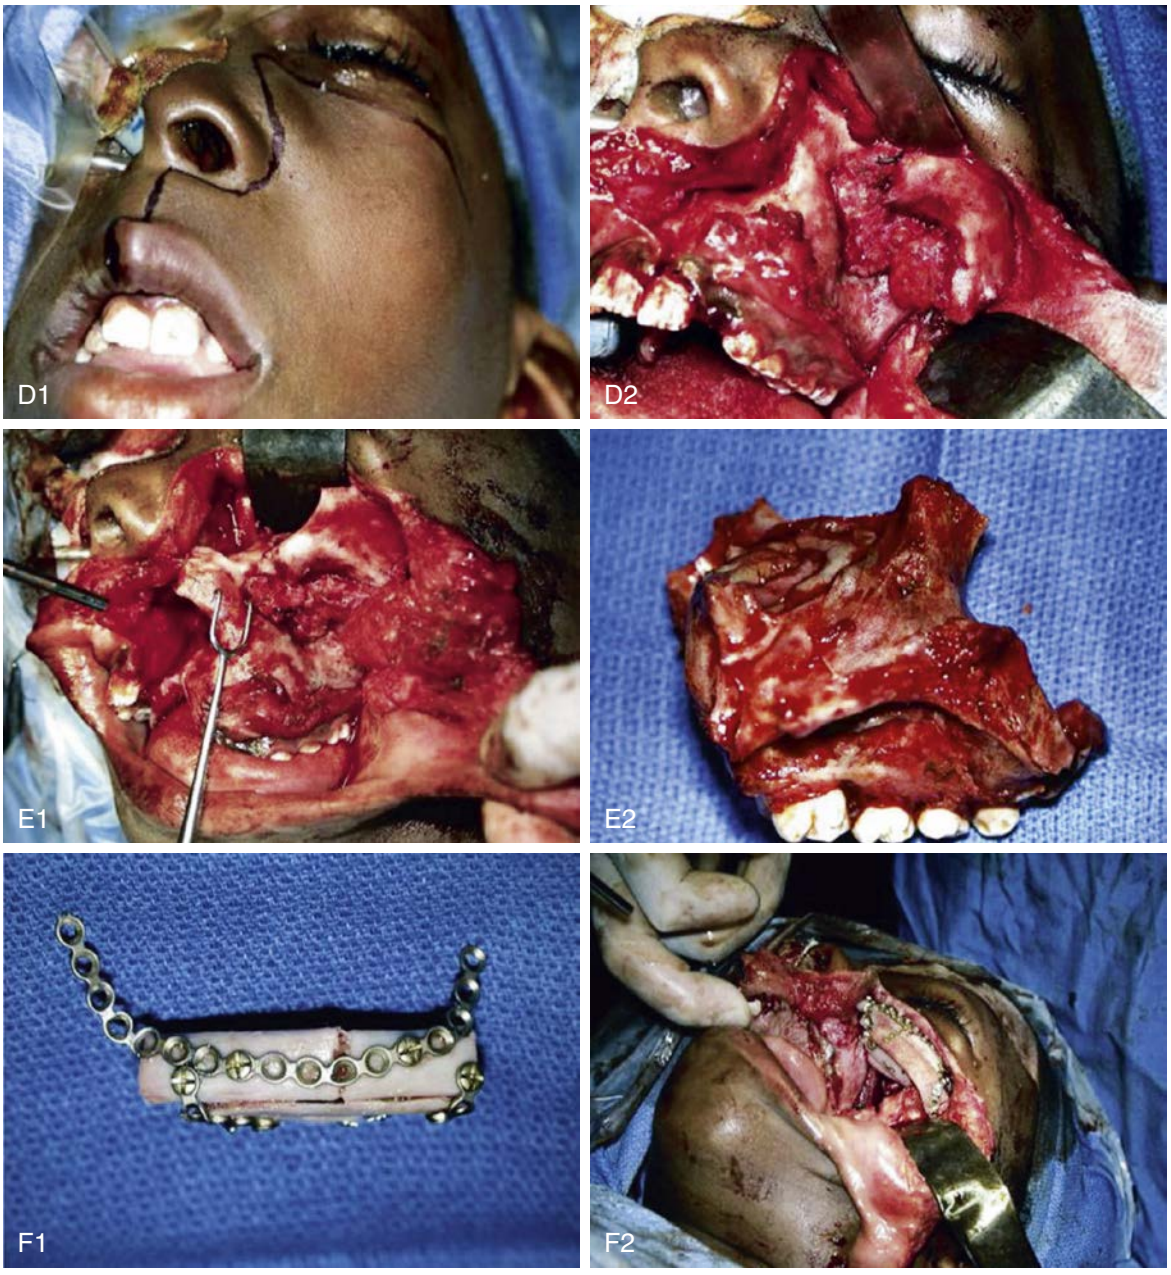
Plexiform neurofibromas of the head and neck can originate from cranial or upper cervical nerves. The trigeminal is the most frequently involved of the cranial nerves with orbital involvement being common. Resultant dysplasia of the sphenoid wing is often noted on imaging studies, as is "egg-shaped" enlargement of the anterior orbital rim.[75] Jackson classifies cranio-orbital neurofibromatosis for purposes of treatment planning into three groups:

- The soft tissue is significantly involved but bony involvement is minimal and vision is unaffected



• **Figure 41-16** **A,** A rapidly growing zygomaticomaxillary mass in a young boy. **B,** CT shows a mixed lesion of the left maxilla, histologically an aggressive juvenile ossifying fibroma. **C,** The lesion at initial surgery.

Continued



• **Figure 41-16, cont'd D,** The lesion rapidly recurs and requires reoperation and resection with access via Weber-Ferguson incision. **E,** Maxillectomy specimen. **F,** Reconstruction with rib grafts.

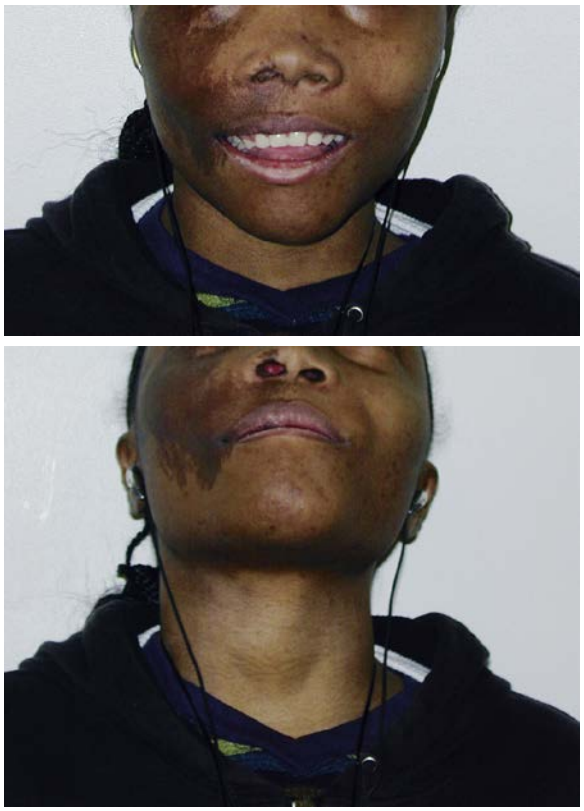
- Soft tissue and bone are involved and vision is unaffected (Figure 41-21)
- Soft tissue and bone are involved and the eye is blind or absent[76,77]

Treatment of these cranio-orbital neurofibromas is variable, involving simple excision in some cases and globe enucleation with extensive bone grafting in others. Otherwise, Jackson recommends excision and direct closure of other lesions of the head and neck, taking care to preserve vital structures at the expense of incomplete resection. Exposure is paramount in treating these lesions, both to obtain complete resection and to have optimal control of bleeding. Neurofibromas can be quite vascular, and in some instances, preoperative angiography and embolization is warranted.[78]

Although NF can be disfiguring, total resection of craniofacial neurofibromas often leaves the patient with equally problematic reconstructive defects, whether the orbital contents have been completely exenterated or the temporal lobe is prolapsing into the orbit. Careful consideration must be given to the reconstruction of these defects and they may warrant the use of prosthetic, microvascular, local flap, or free bone grafting techniques.

Congenital Epulis (Congenital Granular Cell Lesion)

The congenital epulis is a rare lesion that typically occurs on the alveolar ridge of the newborn and occasionally on the tongue. Despite the similar microscopic appearance



• **Figure 41-17** A 15-year-old girl with McCune Albright syndrome; note craniofacial bone involvement and the café au lait spot on the right cheek.

between the epulis and the granular cell tumor, there are distinct immunohistochemical differences between the two, and the histogenesis is still unknown.[79]

The lesion itself appears as a smooth pink to red mass of variable size emanating from the alveolar ridge, which can be attached by a smaller stalk. Lesions of up to 7.5 cm have been reported, though most are less than 2 cm in size. In some instances there can be multiple tumors, and occasionally they are detected in utero on ultrasound. They can be accompanied by polyhydramnios due to impaired fetal swallowing of amniotic fluid. When sizable lesions are noted on antenatal ultrasound, appropriate steps can be taken at the time of delivery to assure the airway of the infant is secured. Ex-utero intrapartum treatment (EXIT) procedures have been utilized for larger obstructing lesions.[80]

The lesion is more common in females (>85%) and is most often found in the para-midline area of the maxillary alveolar ridge, but can be seen on the mandible or as multiples involving both ridges. Some smaller lesions may regress spontaneously. Otherwise, the lesions are excised because they can impair feeding (Figure 41-22). Recurrence for the congenital epulis has not been reported, even in the event of incomplete excision.[79,80]

Epignathus (Oral Teratoma)

Epignathus is a rare form of organized teratoma that arises from the oropharynx or nasopharynx. These lesions contain tissue elements derived from the three primitive embryonal germ layers (endoderm, mesoderm, and ectoderm). Some cases have very well-differentiated organs, and might be the result of an abnormal multiple gestation or parasitic fetus rather than a true teratoma. Epignathi are most commonly benign, but malignant and aggressive variants exist. They can be associated with facial malformations such as cleft palate and branchial cleft cysts, as well as other anomalies such as congenital heart disease. Epignathi, like congenital epulis, can be associated with polyhydramnios due to impaired fetal swallowing. Fetal hydrops secondary to high-output cardiac failure can also occur. Securing an airway at the time of delivery is of critical importance when dealing with these lesions, and EXIT intubation or tracheostomy may be necessary.[80,81]

Melanotic Neuroectodermal Tumor of Infancy

The melanotic neuroectodermal tumor of infancy (MNTI) is a benign tumor of neural crest origin and most commonly appears within the first 12 months of life (>90%). It most often occurs in the maxilla, but also can be seen on the skull, the epididymis, the mandible, and the brain (Figure 41-23). It appears as a rapidly growing mass that is blue or black in color, and it will displace teeth and infiltrate bone. Clinically, malignancies such as rhabdomyosarcoma, Ewing's sarcoma, and neuroblastoma must be ruled out. Radiographically, it can be seen to destroy bone and may have a sun-ray appearance similar to that of an osteosarcoma.[79,82]

Some patients with melanotic neuroectodermal tumors may have high urinary vanillymandelic acid (VMA) levels, somewhat like those with a pheochromocytoma, retinoblastoma, or neuroblastoma. However, the VMA levels are unrelated to tumor behavior and will drop once the tumor has been removed. Treatment consists of resection or curettage. Some recommend a margin of 5 mm, given the destructive and infiltrative nature of the lesion and its propensity for recurrence (15% to 20%). Staining for synaptophysin, cytokeratin, and HMB-45 can help establish the diagnosis. In rare instances, the tumor behaves malignantly by metastasizing (3%), and in the skull and brain it can cause significant morbidity by local extension.[79,82,83]

Malignant Tumors

Malignant tumors are fortunately rare in children. The spectrum of disease is very different to that seen in adults. Leukemia and lymphomas of childhood are more prevalent than solid tumors, and the head and neck is a very uncommon site for cancer in the pediatric population. Cancers associated with tobacco and alcohol abuse such as squamous cell carcinoma, which comprises the majority of head and neck cancers in adults, are seldom seen in the pediatric population. Small blue round cell tumors such as rhabdomyosarcomas, Ewing's sarcoma, retinoblastoma, and lymphoma are seen most often in the pediatric head and neck region. Many of these neoplasms will require multimodality treatment, and the long-term effects of radiation therapy and chemotherapy on the growth and development of the face, jaws, and teeth as well as the potential for radiation induced

sarcomas many years later add to the complexity of patient management.

Rhabdomyosarcoma

This is the most common pediatric sarcoma; 35% to 40% occur in the head and neck. The site and histologic type is important in determining prognosis. The orbit (25%), parameningeal (50%), and other sites (oral cavity, scalp, etc.) (25%) are the major sites; the histologic types are botryoid, embryonal, alveolar, and pleomorphic. Orbital tumors metastasize infrequently and have the best prognosis with a 5-year survival rate greater than 85%, whereas parameningeal tumors (infratemporal, paranasal sinuses, nasopharyngeal, and middle ear) have the worst prognosis.[84,85] Parameningeal tumors are often diagnosed later as a result of nonspecific symptomatology; consequently, skull base and cranial nerve invasion has already occurred (Figure 41-24). Relapse-free survival is considerably less in this group at 57%.[86] The embryonic and botryoid types of rhabdomyosarcoma have the best cure rates, and they are the most common types in the youngest children. The foundation of treatment for pediatric rhabdomyosarcoma is chemotherapy. The overall prognosis is improved when complete surgical resection is achievable; however, this is not always feasible in the head and neck, particularly in parameningeal sites.[87] Radiation therapy is used for orbital tumors and in conjunction with chemotherapy. In parameningeal rhabdomyosarcomas, radiation to the spinal axis and intrathecal chemotherapy improves survival. Meazza et al. claimed that meningeal prophylaxis is not necessary due to improvements in radiotherapy techniques and chemotherapy.[88] They also claimed that hyperfractionated accelerated radiation therapy may be superior to conventional radiation, although severe radiation-related late sequelae were seen. This study is contradicted by the findings of Intergroup Rhabdomyosarcoma group IV which found no advantage to accelerated hyperfractionated radiation.[89] Prognosis is

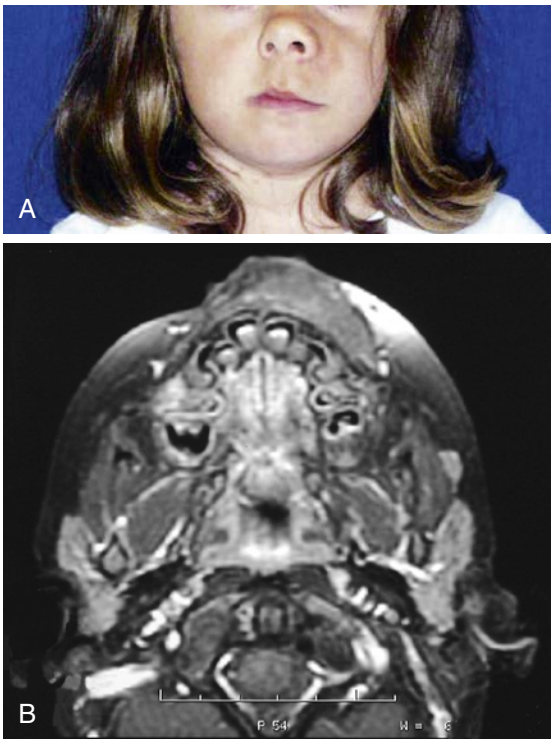
also dependent on stage, and in rhabdomyosarcoma both a surgical-pathologic clinical staging and TNM type of staging have been used. In a recent review of 49 head and neck cases, significant prognostic factors for survival included age <11 years and tumor size <5 cm as well as multimodality regimes.[90]

In patients who fail chemotherapy, a regime of ablative surgery with moulage technique and after-loaded brachytherapy and reconstructive surgery (the AMORE protocol) has been advocated with initial results of 11 of 15 patients tumor free after a mean follow-up of 2.8 years.[90] In a longer-term follow-up of this protocol with 22 patients, 7 had relapse which was largely ascribed by the authors to incomplete surgery or suboptimal positioning of the brachytherapy.[91,92]

Other Sarcomas

Most other sarcomas are rare except for retinoblastoma (Figure 41-25). Osteosarcoma and Ewing's sarcoma of the head and neck are very infrequent in children. In childhood bilateral hereditary retinoblastoma, children who have received radiation for retinoblastoma or for other tumors are at increased risk for developing osteosarcoma. There is some evidence that osteosarcoma arising in a previously irradiated patient is more aggressive in behavior.[93]



• **Figure 41-20** **A,** A 5-year-old girl with left facial swelling and café au lait spot on the left nose and cheek. **B,** MRI demonstrating soft tissue mass consistent with neurofibromatosis.

• **Figure 41-21** A 6-year-old boy with neurofibromatosis and significant cranio-orbital bone involvement and normal vision.

Best results are with primary radical surgery, and the value of radiation therapy or adjuvant/neoadjuvant chemotherapy is unclear in this group of patients.[94] In Ewing's sarcoma it is thought that 80% to 90% of patients have micrometastases at presentation and that this is a systemic disease. Therefore all patients receive chemotherapy, and radiation and/or surgery may be used in combination with the chemotherapy. The mandible appears to be the most common head and neck site.[95]

When malignancies in the growing patient are treated, both surgery and radiation can leave the patient with considerable secondary deformity of the facial skeleton (Figure 41-26). In addition, the pituitary, visual acuity, and tear production can be affected by radiation, and cataractogenesis can also be a problem.[96-98] Corrective efforts must be geared toward both soft and hard tissue correction, keeping in mind the vascular damage incurred from radiation therapy. Conventional jaw surgery alone might not be enough to address the global facial tissue hypoplasia and asymmetry. Free tissue transfer can be a valuable tool in correcting soft tissue disparities. The orbit can be a particularly vexing problem because the globe position might not be amenable to correction.

Salivary Gland Tumors

Head and neck cancer comprises only 2% to 3% of all cancers, and only 3% to 4% of these cancers are found in the salivary glands. Approximately 80% of salivary tumors are found in the parotid, and in adults 80% are benign. In children, although the majority of tumors are seen in the parotid, there is an increased rate of malignant tumors (42.9%).[99] The majority of these tumors are mucoepidermoid carcinomas and, fortunately, most are low grade, with survival rates of 97.3% reported.[100] In another series of major salivary gland tumors in children, 77% of which were mucoepidermoid carcinoma or acinic cell carcinoma, the 5-year survival was 94.2%.[101] In most cases, because malignancies are low grade, superficial parotidectomy is the treatment of choice with total parotidectomy for deep lobe tumors. The facial nerve will not be sacrificed unless there is infiltration by the cancer. Neck dissection is carried out for clinically node-positive necks or when there is a high-grade neoplasm. Radiation is usually indicated

• **Figure 41-22** Congenital epulis of the mandible in a neonate. This lesion interfered with feeding and was subsequently excised. (Photo courtesy Sean Edwards, DDS, MD.)

in high-grade tumors. It should be noted that there is an increased risk of developing a salivary gland malignancy in children who have had a previous cancer (e.g., leukemia) treated by radiation or chemotherapy.[100,102] Intraoral minor salivary gland tumors comprise approximately 10% of adult tumors. In a series from China, 23.5% of pediatric salivary tumors were found in the minor glands with 65% malignancy.[103] Again, most of these are low-grade mucoepidermoid carcinomas that can be managed with wide local excision.[104] In our own unpublished series of 160 cases of minor salivary gland tumors, only 9 were in children (5.6%) and 8 of these were cancers. Treatment is directed by the site, stage, and grade of tumor with neck dissection and radiation therapy used as they would be in adult patients.

Reconstruction

Reconstruction of postablative defects in children is a relatively uncommon problem, but the underlying principles are similar to those of the adult: timely restoration of form and function. Ideal reconstruction should also include adequate obturation of the surgical defect and structural support of external facial features.[105] Restoration of form and function in a growing patient should be viewed as a dynamic process and the effects of treatment on subsequent development should be considered. Growth of the orbital-craniofacial skeleton is a complex, coordinated process that depends on sequenced events that evolve among specific growth centers. Interruptions in this process such as surgery, radiation, and resultant scarring can result in significant changes in growth patterns. Active growth in the donor and recipient tissue sites are principal concerns in pediatric reconstruction. The presence of developing teeth within the structure of the jaws must also be considered. The management of the psychosocial aspects of prolonged hospitalizations and multiple surgeries in patients of this age should be integrated in the overall treatment strategy as well.

• **Figure 41-23** A 2-month-old male with an MNTI involving the right mandible. **A,** MNTIs are rapidly growing lesions—this one had doubled in size in 2 weeks. **B,** The defect after curettage, ostectomy, and extraction of involved teeth. Treatment planning constitutes the first phase of reconstruction in any patient, but is perhaps of greater importance in the young patient. Communication between the surgical teams (ablative and reconstructive) and facilitating medical specialties are paramount in presurgical evaluation and treatment planning. The specifics of the potential ablative defect should be reviewed at the initial consultation with emphasis on the anatomic regions and subunits involved. Qualitative and quantitative aspects of planned ablative defects must be taken into consideration in an effort to match the amount and likeness of the reconstruction. The degree of soft tissue required should be considered and decisions made about limitations on replacement of skin, mucosa, and dura, as well as general bulk and the potential of neural grafting. Linear defects of the bony craniofacial skeleton are relatively straightforward reconstructive problems; however, composite defects involving bone and soft tissue require a thorough comprehension of the defect in space prior to surgery.

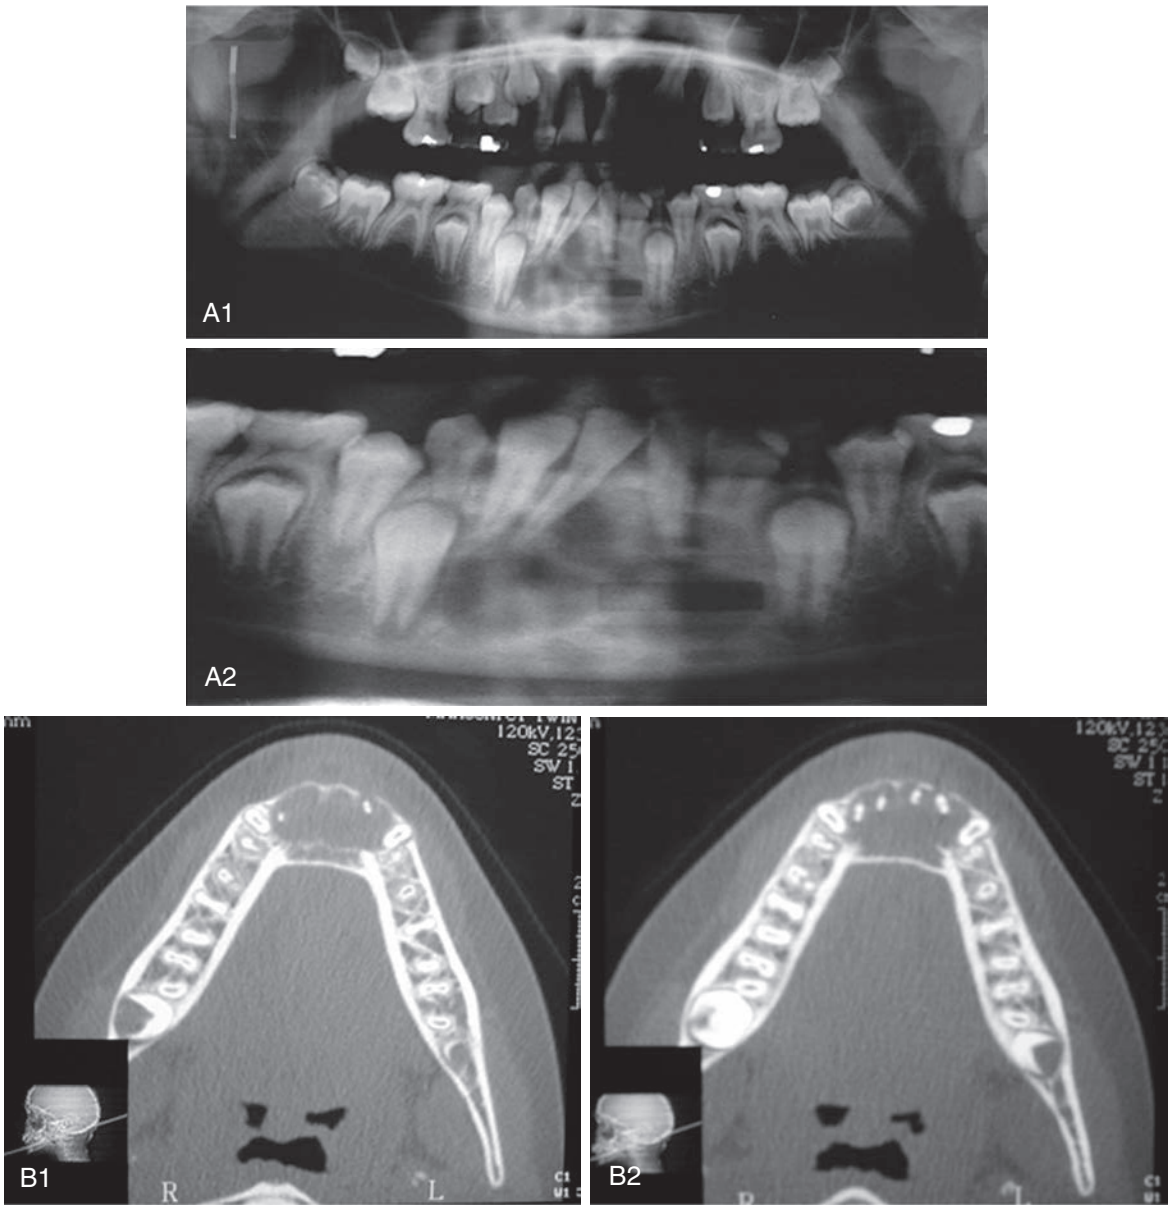
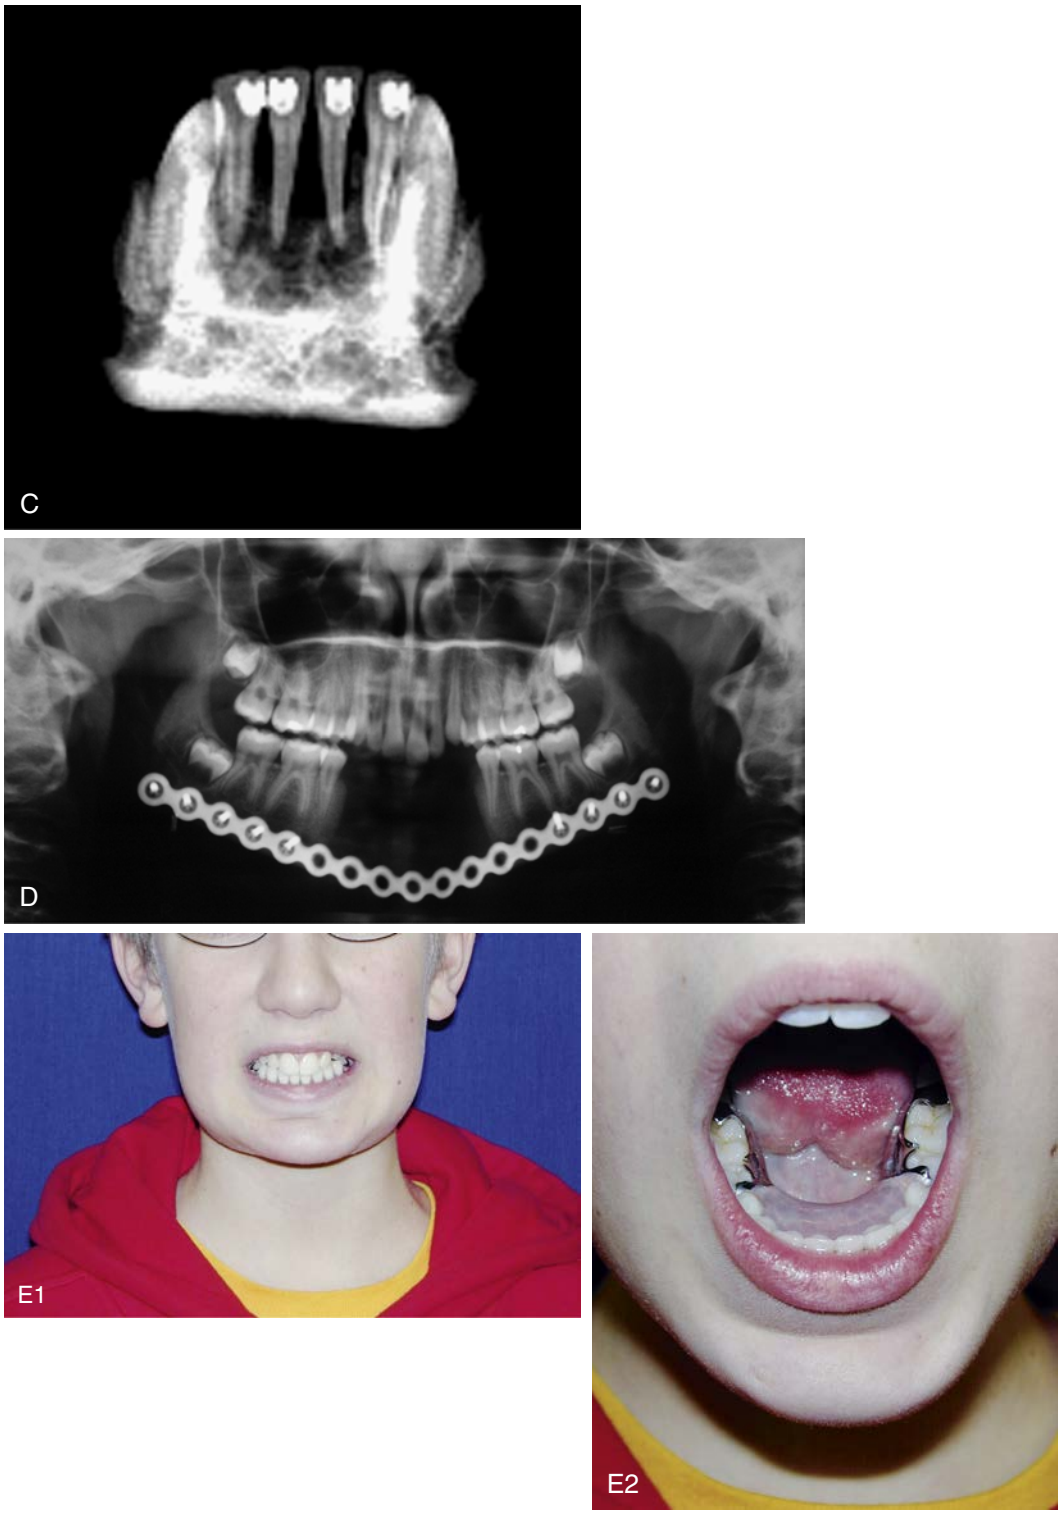
Primary reconstruction has intrinsic advantages over delayed or secondary procedures. It is generally advantageous to limit unnecessarily staged surgery, which equates to a more timely return to function and limited operating sessions. One benefit of immediate reconstruction is that it can allow more normal growth of the maxillomandibular complex because occlusion is maintained or restored sooner. The two-team approach of flap and graft harvesting conserves operating room time. Moreover, access and orientation of the surgical defect is often optimized at the time of the initial resection, prior to the effects of scarring and radiation in selected cases.

Reconstruction of the mandible can be performed with grafted bone or free tissue transfer. Iliac crest, ribs, and cranial grafts are suitable for replacement of segmental mandibular and orbitomaxillary defects. Iliac crest bone grafting is a reliable technique that can be performed primarily or secondarily to restore continuity defects. The limitations are somewhat dependent on the age of the patient, the length of the defect, the presence of intact periosteum, and the available bone stock that can be safely harvested. The placement of reconstructive hardware can be more complicated in the presence of the developing teeth and tooth buds. The infection rate may be higher in patients who are primarily reconstructed, where salivary contamination of the graft can result in graft failure.[106]

Costochondral rib grafts are suitable for short length replacement of the mandible, particularly the ascending ramus in which the condyle must be replaced. Ribs are soft, pliable, and demonstrate growth at the condylar head; however, the growth tends to be unpredictable, sometimes exceeding that of the nonoperated side. The natural anatomic curvature of the rib lends itself to replacement of the mandibular body and parasymphysis. Additionally, for infants and toddlers, the rib is one of very few suitable options. The bone stock of ribs, however, does not support placement of endosseous implants, and typically requires subsequent bone grafting upon completion of skeletal growth. The most important disadvantage is the

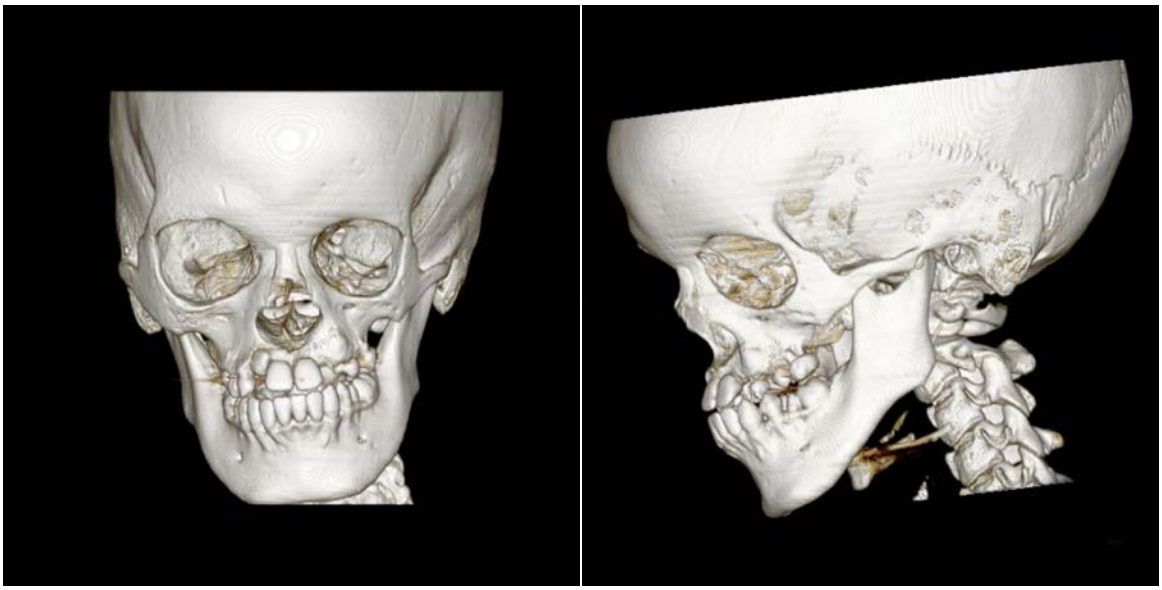


• **Figure 41-25** **A,** A 13-year-old male referred with swelling/cortical expansion of the anterior mandible after recurrence following multiple attempts at curettage by another surgeon. Initially diagnosed as hemangiopericytoma. **B,** CT shows radiolucent lesion with cortical expansion.



• **Figure 41-25, cont'd C,** The lesion was resected with margins due to its aggressive behavior and the identification of small round blue cells within the specimen. He underwent adjuvant chemotherapy. **E,** Patient with partial denture in place, definitive reconstruction is planned.

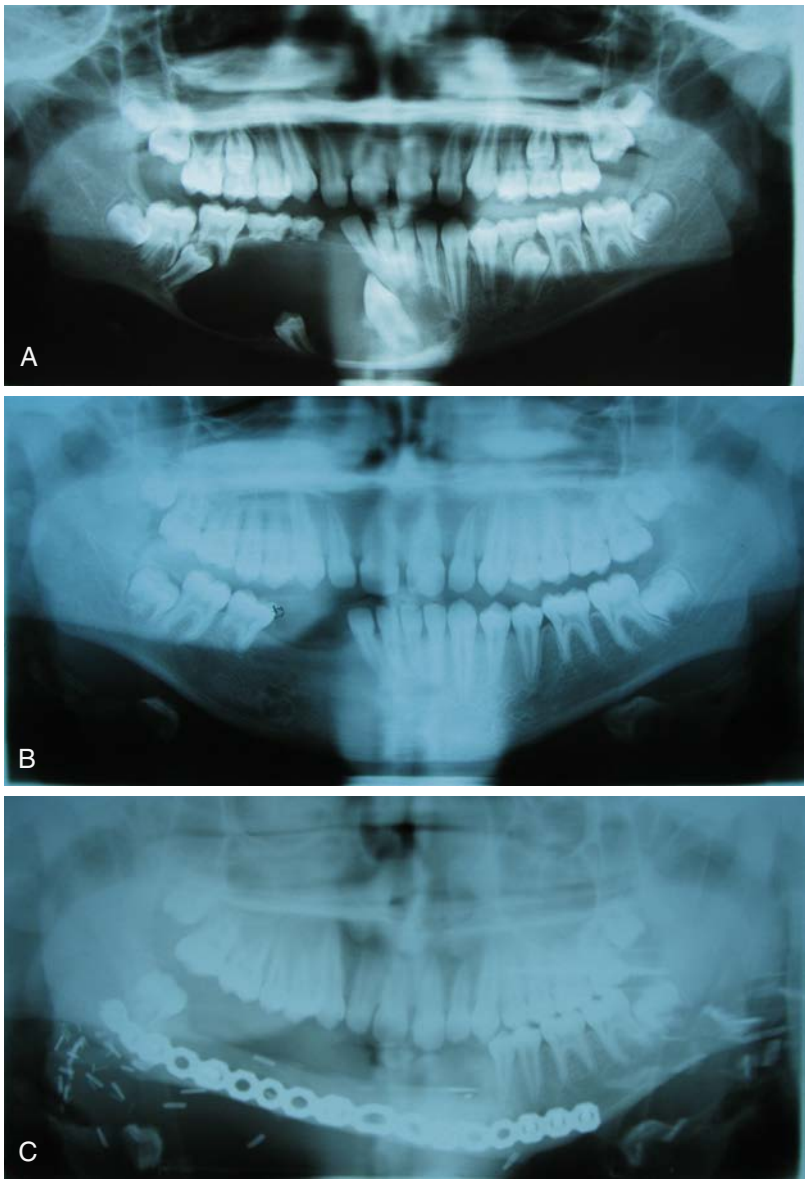
possibility of rib resorption, which can mandate additional reconstruction.[107] Some cases may be amenable to treatment with nonvascularized bone, distraction osteogenesis, or combination therapy. It has been suggested that adult patients with defects approaching 9 cm in length, with irradiated tissue fields, or with defects involving composite tissues are candidates for free flaps.[109] Guo et al propose that 6 cm defect length, compromised periosteum, and failed previous bone graft be further added to these indications for children.[109]



• **Figure 41-26** A 4-year-old boy who underwent chemotherapy and radiation for left orbital rhabdomyosarcoma. Note the affected hypoplastic orbit, maxilla, and mandible on the left side.

There are a number of suitable choices for free flap reconstruction in the maxillofacial region in children and adolescents. The utility of musculocutaneous and fasciocutaneous flaps (radial forearm, anterolateral thigh, rectus, etc.) approximates the range of that available in the adult, and flap selection is guided by area, volume, and tissue match. Bone-only and composite reconstruction can be achieved with the fibula, iliac crest, radius, and scapula free flaps. The scapula and fibula provide the best balance of adequate bone stock, limited morbidity and adequate pedicle length for microvascular anastomosis. Free fibula flaps provide the greatest amount of linear bone stock, although the height of the fibula may be limited in children under 13 years (Figure 41-27).[110] Multiplanar osteotomies provide great versatility in composite reconstruction in the maxillofacial skeleton. The fibula can be folded onto itself in a double-barrel fashion, facilitating the placement of endosseous implants. There is little evidence to show that free fibula harvest adversely affects limb development in children. Most growth occurs in the proximal epiphyseal plate, which is complete by 15 in girls and 17 in boys.[111] Experimental evidence suggests that both transplanted scapula and fibula exhibit growth following free tissue transfer in conjunction with the native mandible.[112] Transfer of the fibula, including the epiphyseal region of growth, has been suggested to support growth at the recipient site, however, growth occurs with the native mandible when this region is not included. Age of the patient does not appear to be a limiting factor; Warren et al encountered no problems with insufficient vessel caliber or unexpected vasospasm.[108] Because experience in free tissue replacement of the mandible is limited to published case series, the effects on growth are still unclear. Experimental evidence in animals suggests that free tissue transfer supports growth in the craniofacial skeleton, but this has not been substantiated in humans.[113] The scapula has been utilized in pediatric reconstruction, and lengths of up to 12 cm of bone have been reported.[108] The bone is relatively thin and may require supplemental bone grafting to accommodate endosseous implants. Growth of the scapula is affected by harvesting, but the functional consequences are limited.[110] Composite parascapular flaps including several soft tissue paddles, segments of free rib, and scapular bone are possible, enabling chimeric reconstruction of complex defects. Transfer of the deep circumflex iliac artery (DCIA) flap in the growing child is uncommon, and in older adolescents has been met with slightly greater postoperative gait disturbances than in adults, though it has not been intensively reviewed in the literature. The entirety of the iliac crest is composed of cartilage from early development and is an active growth center in the pelvis. Mechanical demands from muscle tension contribute to acetabular growth, which can be affected by surgery and subsequently affect gait.[110] Like the fibula, the DICA can be osteotomized to conform to a neomandible or maxilla, with or without a soft tissue muscle component from the internal oblique muscle, does well to receive endosseous implants (Figure 41-28), but has limited utility in the child.

Distraction osteogenesis (DO) does play a role in limited segmental defects of the mandible and is a viable alternative in linear defects of 3 cm or less, provided that there is no soft tissue defect and the wound bed has not been radiated. With the introduction of transport DO, longer spans including the curvature of the symphysis may be included in this reconstruction. The limitations to date include the paucity of well-documented case series, outcome measures for adequate rehabilitation in the pediatric patient, and the time required for placement and activation.



• **Figure 41-27** **A,** A 10-year-old boy with cystic lesion of the right mandible diagnosed as unicystic ameloblastoma. **B,** Recurred following enucleation and ostectomy. **C,** Resected and reconstructed with microvascular free fibula transfer.

Calvarial bone grafting is also an option in reconstruction of the orbit, maxilla, and cranium. Full-thickness, split, and vascularized calvarium are all viable choices, although split calvarium is technically challenging in patients younger than 12 years of age, when the diploic space is not well established. Inner table split calvarium is commonly used for reconstruction following craniotomy, and the outer table replaced without the need for donor site modification. Cranial bone can be modeled and shaped to suit specific anatomic demands. Pedicled transfer of the calvarium has been reported based on branches of the superficial temporal artery. Limited amounts of cancellous bone are available for harvesting. The relative thinness of the bone is well suited for use in the orbital floor, malar, and nasal bones. There is evidence to suggest that cranial bone undergoes less resorption than endochondral donor sites.[114]

Reconstruction of the maxillofacial region in the growing patient is uncommon and particularly challenging. Long-delayed reconstruction can significantly impact growth, appearance, and function. The choice of reconstruction should account for the potential consequences of both the donor and recipient sites and illustrates the need for well-developed treatment plans. Decisions on the traditional reconstructive ladder are less linear, and even when single-staged, simple reconstruction utilizing free tissue transfer may offer advantages over staged reconstruction, it is not uncommon that eventual skeletal and soft tissue augmentation or revision will be necessary.

Distraction Osteogenesis of the Craniomaxillofacial Skeleton

KEVIN S. SMITH

History

The technique of lengthening bone by gradual distraction has been used in a variety of specialties sporadically over the past century. Its application to the craniofacial skeleton is relatively recent, and its indications have been expanding over the past decade. Distraction osteogenesis (DO) was used by orthopedic surgeons during the first half of the 20th century. The concept of DO was formally introduced in 1969 by Gavriel A. Ilizarov, who together with Dr. L. M. Sojbelman published his first case series of distraction epiphysiolysis in the journal *Eksperimentalnaja Khirurgia Anestesia*.[1,4] After he graduated from medical school in 1943, the Russian government sent Ilizarov to work in the Kurgan district of western Siberia. In post–World War II Russia, thousands of wounded veterans were in need of multiple surgical procedures, many of which involved conditions such as fracture, pseudoarthrosis, and osteomyelitis. Ilizarov had been applying this method for multiple surgical applications for years before his case reports were published. After hearing of the "miracles" accomplished with his revolutionary surgical procedures in orthopedic surgery, people in Russia referred to him as the "magician from Kurgan." In 1951, Ilizarov started to use metal rings with transosseous wires to align and manipulate bone segments of complicated fractures in long bones, subsequently achieving bone healing after stabilizing the segments for a time. Early in the 1960s, Ilizarov distracted a short tibial stump with the intention of subsequently grafting the gap he had created. He was surprised to discover 1 month later on postoperative x-ray that he could not see a gap at all. At this point, he was able to identify technical aspects of the procedure that led to gradual successful lengthening of the tibia. The early concepts that he proved are still seminal today and are important in justifying these early concepts. Early postulates included (1) that corticotomy was safe with continued bone marrow viability, and (2) that combining corticotomy with slow distraction bone lengthening was possible. Ultimately, Ilizarov is recognized as one of the most important surgeons in the establishment of DO as a procedure with a large number of applications.[2,3,9]

From a maxillofacial perspective, dentofacial traction is a procedure that has been used since the 18th century. Fauchard in 1728 had started to practice dental arch expansion in the presence of dental crowding; this was done at the expense of tooth movement with little change in bone morphology. Westcott in 1859 reported correction of crossbite in a 15-year-old patient after a slow and tedious process that had lasted several months. Angell in 1860 achieved rapid palatal expansion over the course of 2 weeks at the expense of midpalatal suture separation. Thirty-three years later, in 1893, Goddard standardized the procedure by recognizing the need for a 3-week period of stabilization to allow for "osseous material" formation at the "created gap."[10] In 1937, Kazanjian achieved mandibular advancement by gradually applying traction rather than acute movement of an osteotomized mandible. The device used consisted of a wire hook attached to the symphysis, which was advanced with traction with the use of an elastic band. Anchorage was achieved with the aid of a facial appliance anchored to the maxillary teeth and stabilized against the patient's forehead, much like a phase I orthodontic appliance. Activation was started 3 days postoperatively when forward movement of the osteotomized mandibular segment was attained. Seventeen days later, traction was ended, and intermaxillary fixation was instituted for 11 weeks with the aid of occlusal splints. At this point, DO lacked recognition as a reliable method, in part because of lack of bone segment manipulation control, difficulty manipulating the custom appliances, and inadequate skeletal fixation methods used for stabilization after distraction.[10]

In 1973, Snyder reported the first successful mandibular DO in a canine model following the distraction principles previously established by Ilizarov for limb lengthening. Guerrero and McCarthy[20,21] were among

the first to report on the clinical feasibility of mandibular lengthening by gradual distraction in patients with craniofacial anomalies. Since the first reports, DO has been widely used in the treatment of patients with various cranio-maxillofacial deformities. Recently, there has been an explosion of reports in the literature regarding the use of DO on the cranio-maxillofacial skeleton, and much has been learned about the indications and usefulness of this technique.[21-26] Techniques and outcome expectations continue to be refined.

Biologic Basis of Distraction Osteogenesis

During the 1997 International Congress of Cranial and Facial Distraction Osteogenesis in Paris, France, Dr. Paul Tessier referred to DO as the "end of facial osteotomies as we know them."[69] Two decades have passed, and traditional osteotomies still are used much more frequently, but distraction has provided solutions to some very difficult problems that were challenging or impossible to address prior to its development. As with many new technologies, much excitement was generated early in the development of distraction devices and techniques. As more experience and data become available, the best indications and the limitations are becoming clearer. Distraction techniques appear to have great potential in addressing a number of difficult problems such as exceptionally large advancements and advancements required in very young patients.

DO offers several purported advantages to the clinician who is managing craniofacial anomalies. Its major advantage is that it provides the opportunity for lengthening of craniofacial bones to a degree not typically possible with traditional techniques. DO also eliminates donor site morbidity in cases in which bone grafting typically is used in combination with traditional advancement techniques. In addition, DO provides a method of lengthening the craniofacial skeleton while at the same time distracting the surrounding soft tissue matrix. Consequently, DO has gained popularity as a treatment modality and has opened new therapeutic opportunities for the treatment of patients with numerous congenital and acquired craniofacial skeletal anomalies.[27-31]

Established treatment parameters for DO as initially described by Ilizarov are important for a successful result and include the following[6]:

- Cortical osteotomy with minimal periosteal stripping
- Latency period ranging from 3 to 7 days, depending on the surgical site, and a potentially shorter duration for younger children[68]
- Distraction rate of 0.5 to 2.0 mm per day depending on the surgical site, usually 1.0 mm per day. Faster rates in children, especially neonates[68]
- Distraction with application of continuous force is ideal but activation of the device twice per day or three times per day is effective and practical for the patient.
- Consolidation period should be approximately 6 weeks or should last until cortical outlines are visible on radiograph.

The procedure entails performing an osteotomy of the cortical bone at the site of anticipated lengthening. Preservation of the periosteum and the surrounding vascular supply is an important factor in the success of DO.[5] The objective of DO will be to slowly separate the edges of the osteotomy to create a regenerative chamber that will give rise to bone. Depending on the distraction site, great variation is expected in the size and conformation of the osteotomy, and a regenerative chamber is possible (i.e., maxillary osteotomy, mandibular ramus osteotomy, fronto-orbital and mid-face osteotomy, or alveolar ridge osteotomy).

Once the corticotomies have been completed and the distractor device is in place, the latency period begins. The latency period ranges from 0 to 10 days, with the most common durations of 1 to 2 days in children and 5 days in adults. This allows for resolution of the inflammation resulting from the corticotomy and surgical placement of the device. The first phase of healing involves organization of the hematoma and induction of mesenchymal cells, as well as endosteal and periosteal cells, into osteoblasts and fibroblasts. Type I collagen is deposited and osteoid production takes place.

Once the distraction phase begins, this healing tissue is exploited by lengthening of the regenerate. Distraction of the regenerate tissue then can occur at a rate of approximately 1 mm per day. Although this process of regenerate lengthening is directed at providing bone, the surrounding soft tissue also is stretched during the lengthening procedure. This phenomenon of soft tissue expansion is referred to by some as *distraction histogenesis*. Skin, muscle, nerves, and vascular tissue purportedly have been generated, not stretched, but observation of many cases and conflicting literature make these concepts controversial.

In the young child, larger bones with a larger regenerate chamber site may be able to tolerate quicker distraction rates. Decreasing the rate is recommended for small areas such as the dentoalveolar ridge segments.[36] The initial process of bone formation involves a regenerate chamber that is filled with a fibrous matrix that will ossify at the periphery and then centrally over time. The regenerate area consolidates into bone once the distraction process is consolidated and the segments are rigidly fixed in place.[37] Distraction that moves too quickly will result in nonunion, and distraction that occurs too slowly will result in early healing without the potential to lengthen the segments.

The consolidation time in adults should be at least 3 months and can be as long as 6 months, depending on the magnitude of distraction, the type of deformity, and the patient's age. How the length of consolidation affects stability is unclear at this point, but it is clear that bone stability is very important during the consolidation phase. Once

consolidation has been confirmed, removal of the hardware can be performed with basic radiography or other imaging modalities such as computed tomography (CT) scan.[13,14]

In some cases, distraction osteogenesis offers several advantages over other techniques such as the following:

- Ability to accomplish large advancements
- Ability to expand soft tissue surrounding matrix
- Minimizes or eliminates the need for bone grafting
- Potentially less relapse than with traditional methods

However, when compared with traditional techniques, DO may have a number of disadvantages in certain situations, including those listed here:

- Higher postoperative infection rate at the osteotomy site
- Greater risk of hardware failure
- Difficulty with vector control with less precise positioning of segments when compared
- Risk of premature bone formation or nonunion

Relative contraindications to DO include the following[68]:

- Patient/family noncompliance regarding activation of distraction device
- Lack of adequate bone (class III hemifacial microsomia)
- Radiation therapy
- Bisphosphonate use

Mandibular Distraction Osteogenesis

Mandibular retrognathia is a congenital or acquired condition that can represent functional and esthetic problems.[7,8,14] Congenital abnormalities that may exhibit severe mandibular retrognathia include craniofacial anomalies such as hemifacial microsomia, Pierre Robin sequence, Treacher Collins syndrome, Nager syndrome, and a number of others. Acquired sources of origin include post-traumatic and iatrogenic post-surgical scar formation that may induce growth disturbances[32,38] (Figure 42-1). Mandibular growth may be adversely affected by condylar fractures that occur at an early age with formation of ankylosis at the temporomandibular joint and/or deficient mandibular growth.[11,12,14]

Obstructive apnea is a complicating factor that may be encountered in patients with mandibular hypoplasia. Repetitive obstruction can result in long-term health problems. In most instances, the diagnosis should be made after a formal sleep study has been conducted. In neonates, mandibular hypoplasia associated with obstruction may translate into feeding difficulties, as the coordination between breathing and swallowing is fairly delicate during the first months of life. The opportunity to provide lengthening of the mandible with potentially greater stability and less likelihood of relapse in challenging cases requiring exceptionally large advancements has made DO an attractive option for a subset of this population[15,39] (Figure 42-2).

Although several other options may be available for patients with obstruction at the tongue base, infants born with severe mandibular hypoplasia and difficulty maintaining a patent airway may benefit from DO.[40,41,68] Early lengthening of the body of the mandible bilaterally can produce volumetric expansion of the airway, which may lead to early decannulation or may even avoid the need for tracheostomy[42,43] (Figure 42-3). Most children who benefit from this technique have no other significant airway obstruction (e.g., laryngomalacia, choanal atresia, tracheomalacia). A careful interdisciplinary evaluation is helpful before this procedure is considered as an option. Also, although DO has been applied to other types of neonatal mandibular hypoplasia, unless condyle and fossa conformation proceeds relatively normally, rates of trismus or ankylosis of the temporomandibular joint may be high.

A critical part of achieving successful results with distraction osteogenesis involves presurgical planning, appropriate placement of the devices, and accurate determination of the correct vector of distraction. The use of a paralleling device can greatly enhance the proper alignment and provide positive vector control (Figure 42-4). Often, stereolithic models (Figure 42-5) are used to facilitate determination of the best site for placement of the devices.

This model is useful for the following:

- Determining adequacy of bone stock at areas of screw placement
- Determining the position of the inferior alveolar nerve and developing teeth
- Assessing the correct position of the appliance, so the mandible is advanced along the desired vector
- Pre-bending the appliance to conform to the anatomy of the skeleton

Indications for mandibular lengthening based on distraction osteogenesis include the following:

- Severe mandibular retrognathia associated with a syndrome, especially in infants and children who are not candidates for traditional osteotomy (Figure 42-6)
- Unilateral mandibular hypoplasia with asymmetry (hemifacial microsomia) with adequate bone structure
- Transverse deficiency of the mandible associated with malocclusion
- Nonsyndromic severe mandibular retrognathia associated with malocclusion
- Severe obstructive sleep apnea associated with mandibular hypoplasia
- Post-traumatic mandibular hypoplasia
- Post-surgical mandibular continuity defects in patients with history of tumor excision and/or aggressive developmental cysts (Figure 42-7)
- Alveolar bone vertical height deficiency[13]

A number of technical factors are important to consider when mandibular distraction procedures are performed. It is important to exercise caution during corticotomy and placement of the distractor device, to avoid injury to the inferior alveolar nerve. Reports of neurosensory changes in the inferior alveolar nerve after DO range from no neurosensory deficit[44,45] to deficits in

• **Figure 42-1** **A** and **B,** External distraction device on a patient with severe mandibular retrognathia and Pierre Robin sequence. **C,** Preoperative lateral profile view with mandibular retrognathia associated with Pierre Robin sequence. **D,** Postoperative lateral profile view after mandibular distraction osteogenesis with the use of an external distraction device. Patient shows well-balanced maxillomandibular relationships and improved mandibular projection.

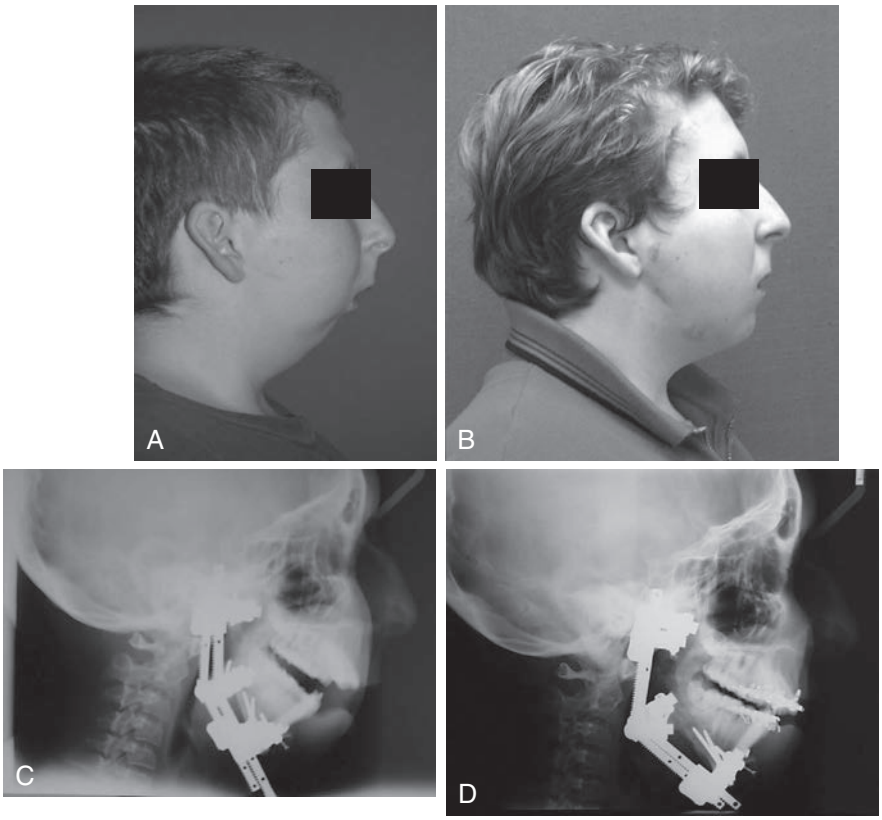
25% to 50% of reported cases.[46,47] In a study by Block, 10 mm of mandibular distraction in dogs with measurement of action potentials along the inferior alveolar nerve revealed minimal effect on the ability of the nerve to conduct.[48] Other studies showed similar results that at a rate of 1 mm per day had no deleterious effects on the inferior alveolar nerve. However, Hu reported that distraction rates of 2 mm per day may result in degenerative changes in the inferior alveolar nerve.[16]

Relapse with Mandibular Distraction Osteogenesis

In the past, bilateral sagittal split osteotomies with the use of wire fixation led to an average of 2 mm relapse[49] and up to 30% relapse in the sagittal plane.[50] This situation has been improved considerably by the advent of rigid fixation. However, when advancements must be greater than 10 to 12 mm, then the potential for relapse may be greater.[51] The use of distraction techniques may allow for more stable advancement in exceptionally large movements, although true comparative data are not yet available to strongly support this concept.

In the author's experience, distraction can provide 10 to 20 mm of lengthening with minimal or no relapse if an appropriate distraction protocol and consolidation periods have been followed.[52,53] It is important to note that early removal of fixation with a short consolidation phase may result in less desirable results. The recommended consolidation period for mandibular distraction should be at least 3 months after significant lengthening, and the decision to remove the appliance or consolidation fixation may be based on visualization of cortical bone formation on radiography.[14]

Relapse has been reported when the distraction technique is used, and the degree is often both case dependent and vector dependent. A paucity of convincing evidence favors one technique over another when one considers the options of traditional advancement versus that performed with distraction osteogenesis. Admittedly, the studies are difficult to perform because of the small numbers of patients with the need for exceptionally large advancements, but



• **Figure 42-2** **A,** A patient with branchial arch syndrome with obstructive sleep apnea. **B,** Postoperative profile view after mandibular distraction with an external distractor device and obstructive sleep apnea that is now resolved. **C,** Lateral cephalometric films with external distractor device in place preoperatively and postoperatively. **D,** After distraction of the mandible.

many clinicians believe that DO techniques are superior for cases requiring unusually large advancements. In some instances, it is not possible to use traditional techniques for exceptionally large advancements, but fortunately, this is an uncommon scenario. Ongoing technical refinements may produce more predictable distraction and consolidation phases, which may translate into more predictable outcomes.

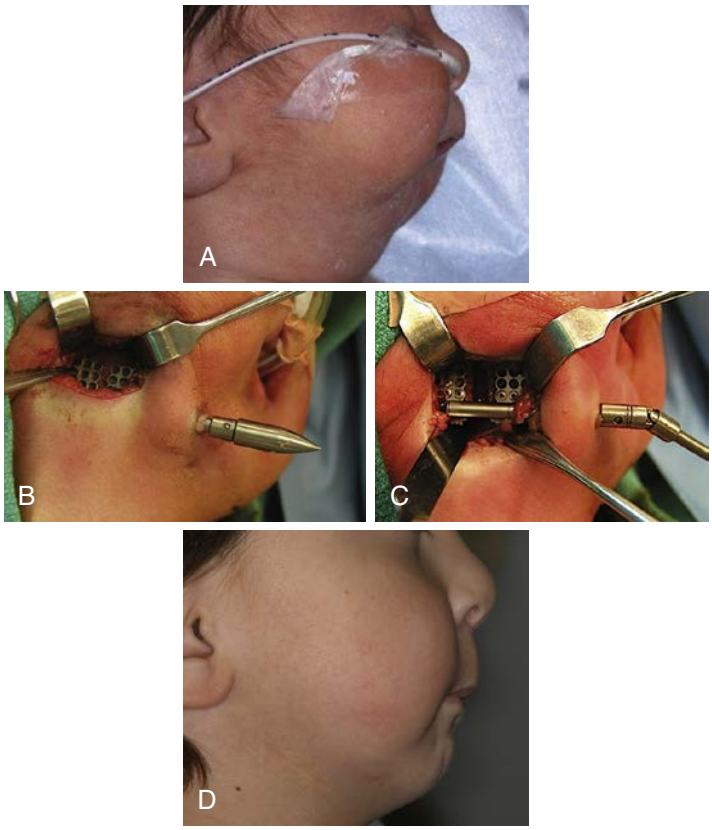
Maxillary Distraction Osteogenesis

In addition to mandibular lengthening with distraction techniques, one of the earliest applications of distraction was its use in mid-face advancement at the Le Fort I or III level. Maxillary hypoplasia is a skeletal abnormality that may occur as a manifestation of impaired maxillary growth, especially in patients with a history of previous surgery for treatment of conditions such as cleft lip and palate. Severe hypoplasia in this population usually is related to postoperative scar tissue formation, which is ideally suited for gradual distraction techniques.[17,54,55] In other instances, it is a dysplasia associated with underdevelopment of the mid-face, as occurs in Apert, Crouzon, or Pfeiffer syndrome.

One of the traditional treatment modalities used for maxillary hypoplasia is the Le Fort I osteotomy, with immediate advancement attained through rigid fixation with or without bone grafting.[56-58] However, the maxilla in these patients may prove to be difficult to mobilize because of scar tissue resulting from previous surgery. When orthognathic surgery is performed, a greater tendency for relapse may be noted in patients with clefts exhibiting maxillary hypoplasia, even with the use of skeletal fixation.[18,59,60]

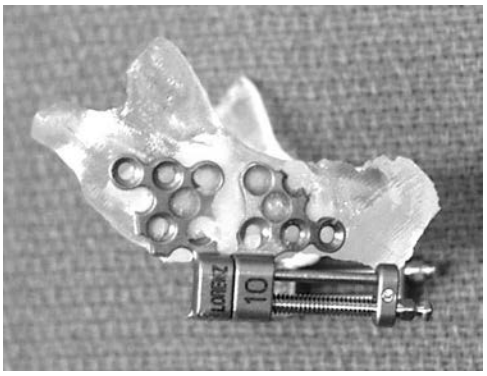
Maxillary Distraction in Mixed Dentition

While the craniomaxillofacial surgeon must always weight the benefits of surgical intervention in a growing child against the restrictions in growth the intervention may ultimately cause, occasionally, the significant psychosocial morbidity associated with dentofacial deformities may require surgical intervention prior to the completion of facial growth. As a result of the surgeries required to correct cleft lip and palate deformities, many of these patients develop significant mid-face hypoplasia. Inhibition of mid-face development may be seen as early as 4 to 6 years of age in the developing child. The results of this skeletal deformity



• **Figure 42-3** **A,** Neonate profile with severe respiratory distress secondary to Pierre Robin Sequence.**B,** Submandibular approach for mandibular internal distractor device placement, utilization of bullet shaped trocar helps placement of transcutaneous activation arm. Device also has antireversing gears to prevent accidental reversing of distraction. **C,** Distraction device in place and testing of distraction to ensure corticotomy is complete. **D,** Five year follow-up for distraction patient, note healing of submandibular scars and continued mandibular growth.

• **Figure 42-4** Paralleling device demonstrating use for neonatal DO. The device can be adjusted in all planes and allows for vector control and can be used for all applications. Adult and pediatric sizes are available.



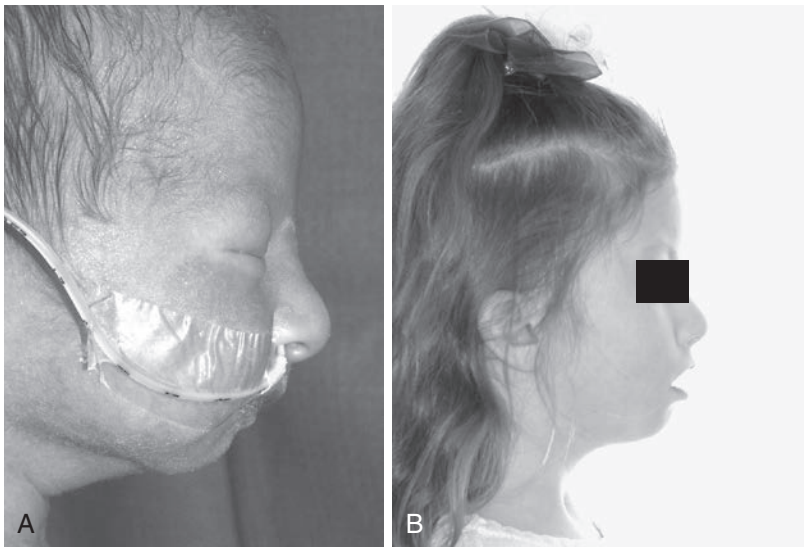
• **Figure 42-5** Treatment planning with the use of stereolithographic model of the mandible as an aid for assessment of mandibular and condylar anatomy.

can cause patients significant disturbance in psychosocial development.[60a]

Maxillary distraction in the mixed dentition can help alleviate the potentially difficult psychosocial issues during this stage of development.[60b]

While some surgeons consider distraction osteogenesis to enhance further development of the jaw,[60c,d] others have shown it early maxillary distraction can further limit mid-facial growth, and may require subsequent orthognathic surgery to correct their dentofacial deformities. Maxillary distraction can have a positive influence in decreasing or occasionally eliminating the amount of maxillary advancement needed at skeletal maturity.

Generally, the decision for distraction in the mixed dentition must involve the family. Frank discussions regarding the psychosocial issues regarding the child must take place



• **Figure 42-6** **A,** Preoperative profile view of neonate with mandibular hypoplasia. **B,** Postoperative profile view 6 years after distraction osteogenesis.

• **Figure 42-7** Intraoperative view of a mandibular transport distraction device used as a method of treatment for mandibular continuity defects.

as the probability of needing further orthognathic surgery is high[60e] once skeletal maturity is reached. The authors experience shows that children with social issues welcome this surgery as the influence on facial normalization is tremendous (Figure 42-8).

Maxillary DO techniques may offer a better option in some patients who require very large advancements. It has been reported that with the use of maxillary DO, it is possible to obtain up to 40 mm of maxillary advancement in patients with an approximated 7% relapse at 1-year follow-up.[19,61] Long-term comparative studies are currently under way for the purpose of more completely evaluating these concepts.

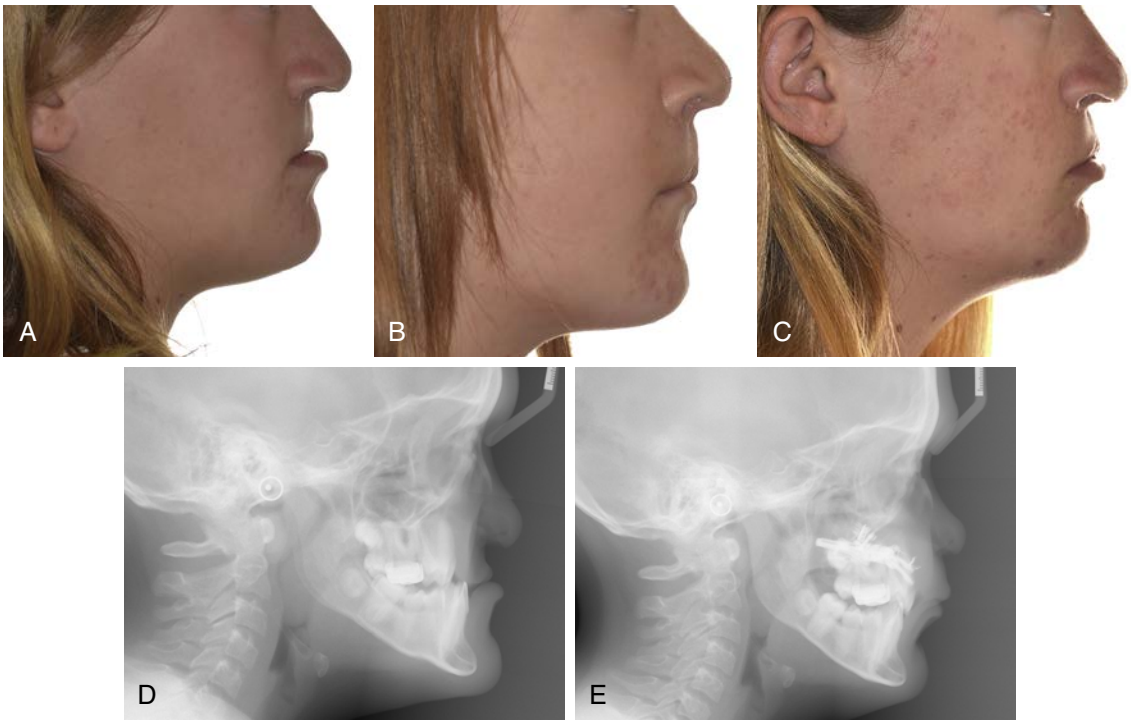
Indications for maxillary DO include the following:

- Craniofacial syndromes with mid-face hypoplasia (Figure 42-9)
- Maxillary hypoplasia associated with cleft lip and/or palate (Figure 42-10)
- Severe obstructive sleep apnea

Cranial Vault Distraction Osteogenesis

In recent years, DO has been used as a treatment modality for patients with craniosynostosis. Typically, cranial vault expansion and reshaping have been used to deal with the growth restriction seen with fused cranial vault sutures (Figure 42-11). This requires fairly aggressive dismantling of the cranial vault with a significant possibility of morbidity and even mortality. Recently, endoscopic techniques have been used to potentially minimize the aggressive nature of the procedure, with the hope of reducing complications. Other options recently considered include expansion of the cranial vault through corticotomy and expansion with the use of DO. When compared with the traditional methods of calvarial expansion and reshaping, DO is seen to offer some advantages such as potentially less hazardous complications, reduced scar tissue formation, and fewer residual bone defects.[62,63] Reported complications of cranial vault reshaping procedures include significant intraoperative blood loss and epidural dead space, which may lead to a higher risk of postoperative infection.[33,64] Additionally, the surgeon is sometimes limited to a certain amount of cranial vault expansion because of the soft tissue envelope and the need for closure of the scalp under tension. This contributes to postoperative relapse and incomplete expansion of cranial vault deformities in some cases. Craniectomy also temporarily renders calvarial bone free from vascular nutrients, which theoretically causes greater resorption of the reshaped cranium.[34,66] DO also offers the advantage that bone formation may be accompanied by gradual stretching of the soft tissue envelope and the possibility of histogenesis via simultaneous expansion of the functional matrix, including muscles, skin, mucosa, fascia, periosteum, blood vessels, and nerves.[35,65]

One of the limitations of distraction for the treatment of patients with craniosynostosis is the fact that it is currently



• **Figure 42-8** **A,** An 11-year-old female with severe maxillary hypoplasia secondary to cleft lip and palate surgery. Patient complained of social issues, after discussing possible secondary orthognathic surgery the family elected DO in mixed dentition. **B,** Patient 6 months post internal maxillary distraction. **C,** Patient 3 years post internal maxillary distraction. Patient elected to not have further orthognathic surgery despite end to end occlusion. Patient felt her facial form was acceptable. **D,** Cephalometic x-ray of 12-year-old with severe maxillary hypoplasia. **E,** Immediate post distraction phase showing adequate distraction of maxilla.

a unidirectional expansion that cannot effectively treat the 3D deformity as completely as cranial vault reshaping can. In brachycephaly, for example, vertical height and bitemporal distance are elongated and a narrow anterior-posterior dimension occurs as compensation for synostosis of the coronal suture. Consequently, the goals of cranial vault reshaping in those cases include reduced vertical height and bitemporal distance and the attainment of fronto-orbital advancement. When DO is applied in such cases, the fronto-orbital advancement achieved will not correct all of the dysmorphology that is present. A "masking" effect will occur, making the cranium appear to be closer to normal dimension in the vertical and horizontal planes. Similarly, in patients with scaphocephaly, vertical height will seem to be reduced after bitemporal distance has been widened. In patients with asymmetric deformity (plagiocephaly), traditional cranial vault reshaping should be the preferred technique because of the potential to perform more complete bone reshaping with minimal epidural dead space and tension during scalp closure.[67] These techniques continue to be refined and are used at a small number of centers. Long-term stability and the predictable nature of treatment continue to be evaluated and presented.

Resorbable Distraction

The use of resorbable distraction devices may play a role in future application of DO of the entire craniofacial complex.[70,71] Obvious advantages of resorbable devices include elimination for the need of secondary surgery for device removal. Disadvantages would be strength and rigidity concerns. Use of resorbable materials for plating is well documented so biocompatibility issues are not concerning (Figure 42-12).

Summary

The technique of DO for the craniofacial skeleton has undergone many changes and improvements. Advantages, disadvantages, and best indications have become more refined over time. When used well, the techniques provide the surgeon with the ability to lengthen bones to a greater extent than is possible with traditional techniques. Additionally, a number of challenging clinical situations seen by the cranio-maxillofacial surgeon, such as neonatal mandibular hypoplasia, may be best treated with these techniques. In some cases, these procedures may offer the only option for bone lengthening. Continued outcome research and technical refinements are likely to improve the decision-making process for surgeons while producing even better results for patients.

Complications: Maxilla

GABRIELE MILLESI

Introduction

Orthognathic surgery has become a routine procedure that is included in all resident programs and is practiced all over the globe. This is due to improvements in communication techniques, instruments, and perioperative management. The incidence of severe complications is low.[1-3] In a prospective study, Kramer published a complication rate of 6.4% in 1000 patients undergoing a Le Fort I procedure.[2] Nevertheless, the list of various complications is long. Knowledge of and respect for these complications are of paramount importance in reducing morbidity.

Le Fort I Osteotomy

Preoperative

Planning

Preoperative complications are mainly related to inadequate cooperation between the orthodontist and the surgeon, which is mirrored in a compromised or incorrect treatment plan. The crucial questions in orthodontics-first cases are the inclination of incisors, transverse compatibility of the arches, and the curves of Spee, independent of the skeletal deformity. In general, preoperative dental alignment by the orthodontist is desirable, but this varies with the skeletal deformity. In class III deformity for example, preoperative orthodontic decompensation in the maxilla often results in uprighting of the proclined incisors which is counterproductive in open-bite cases.

Dental widening of the maxillary arch to improve transverse relationships will result in relapse of an open bite or crossbite. The inclination of the incisors not only dictates the desired rotation of the maxilla but also the sagittal and vertical movement from an esthetic point of view. Any orthodontic closure of an open bite, done by extrusion and clockwise rotation of upper incisors, may result in a progression of dental show and alters the surgical treatment plan unfavorably (Figure 43-1) and with an unstable long-term outcome. Therefore it is important to discuss the combined treatment plan with the orthodontist at the very beginning, before orthodontic treatment is started.

Another aspect in planning in the contemporary setting must be whether the patient has already been treated with fillers or augmented with autologous fat in the lip and midface area. The treatment plan must not allow a transient situation in regard to show of teeth or maxillary soft tissue support to influence the determined posterior-anterior or vertical position of the maxilla. At the very least, it needs to be discussed with the patient (Figure 43-2).

Finally, before the start of treatment, the candidate should be screened to determine whether he or she belongs to the 10% of patients who suffer from body dysmorphic disorders. A patient seeking a surgical correction because of this psychiatric disease, with delusions of physical defects, is impossible to treat successfully.[4]

Intraoperative

Surgical Setting of Patient

Any pathologic pressure caused by malpositioned auxiliary anesthetic tools, such as ventilation filters on the head or electrocardiography (ECG) cables on the neck, should be avoided, as it may lead to pressure-derived alopecia (Figure 43-3) or localized necrosis (Figure 43-4).

An unfavorable positioning of the endotracheal tube with distortion of the normal symmetry of the entrance of the nose can result in loss of orientation of the midline as well as necrosis of the nasal tip (Figure 43-5).

Vascular Complications

Bleeding and Downfracture

Le Fort I osteotomy is a surgery with expected blood loss. Therefore, it should be performed under ideal conditions, including the correct surgical setting to optimize venous drainage by elevating the head (reverse Trendelenburg position) and under controlled hypotension. In this way the monitored arterial pressure correlates to the true intracerebral pressure. Our experience suggests and the literature indicates that no autologous blood transfusion is necessary[5-9] and is an avoidable expense, even though

• **Figure 43-1** **A**, Patient with maxillary excess, open bite deformity, transverse discrepancy, and severe crowding. Orthodontic treatment was started without consultation of an OMS and designing a conservative surgical treatment plan. **B**, Intraoral view of upper dental arch. **C**, Same patient after 3 years of orthodontic treatment, presenting with gummy smile and conservative closure of open bite but unsatisfying esthetic. **D**, Patient after orthodontic alignment of the upper dental arch with higher risk of dental relapse.

antithrombotic prophylaxis is administered starting preoperatively for a maximum of 3 days. To prevent any thromboembolic complications, it is further recommended to use venous compression stockings during surgery. To minimize blood loss, a preoperative vestibular injection of local anesthetic with vasoconstrictor is used to reduce oozing of the mucosa, meticulous subperiosteal dissection is performed, and packing with gauze or cauterization or ligation of bleeding vessels is also used.

If major bleeding occurs, it can be either arterial from the maxillary artery and its branches or venous from the pterygomaxillary plexus. In general the descending major palatine artery or the sphenopalatine artery is the origin, or more seldom the nasoethmoidal artery.

As Lanigan and colleagues[10] published in 1990, of 800 replies concerning complications in orthognathic surgery, only 30 instances of major bleeding were reported. An injury to the descending palatine artery may occur when dissecting or reducing the lateral wall of the nose (Figure 43-6), going too high and too far back (no more than 25 to 30 mm), or by separating the maxilla from the pterygoid process with the osteotome. The length of the medial

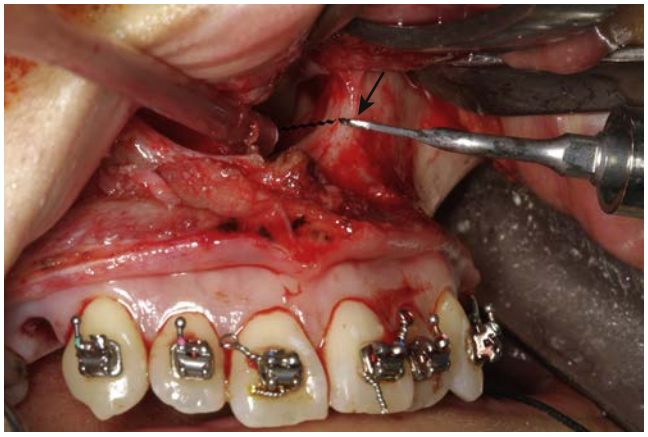
• **Figure 43-4** Skin ulceration caused by pressure of mislocated electrocardiography cable intraoperatively.

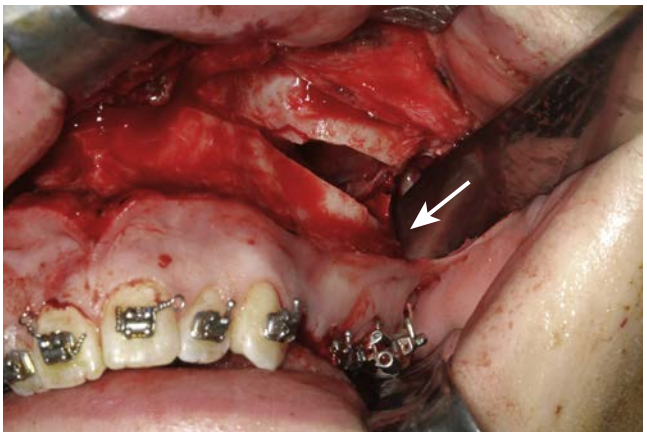
wall of the sinus from the piriform rim to the descending palatine artery is approximately 34 mm.[11] It is, however, essential that the dissection of the lateral nasal wall be done in such a way that any uncontrolled fracture of the pterygoid plate with disruption of the pterygopalatine fossa can be avoided. The basal, anteroposterior approach toward the canal of the descending palatine artery with the chisel can be detected by an obvious change of pitch. When it turns low, it is time to stop. Turvey and Fonseca[12] published the results of anatomic studies on cadaver dissections, on the position of the internal maxillary artery

• **Figure 43-5** Distortion of the symmetry of the nose and nostrils by nasal endotracheal tube under tension.



• **Figure 43-6** Dissection of the lateral wall of nose must be performed below the insertion of the inferior turbinate as marked with a *black line* and *arrow.*

entering the pterygopalatine fossa. They found that the mean height of the pterygomaxillary suture is 14.6 mm (range 11-18 mm) and that the mean distance from the inferior junction maxilla/pterygoid plate to the most inferior position of the internal maxillary artery, entering the pterygopalatine fossa, is 25 mm (range 23-28 mm). This is important to know if you use an osteotome, such as an Obwegeser or Kawamoto osteotome, with a width of 10 to 15 mm, for dissecting the pterygomaxillary junction.



• **Figure 43-7** When separating the pterygomaxillary junction, the osteotome must be guided downward *(arrow)*.

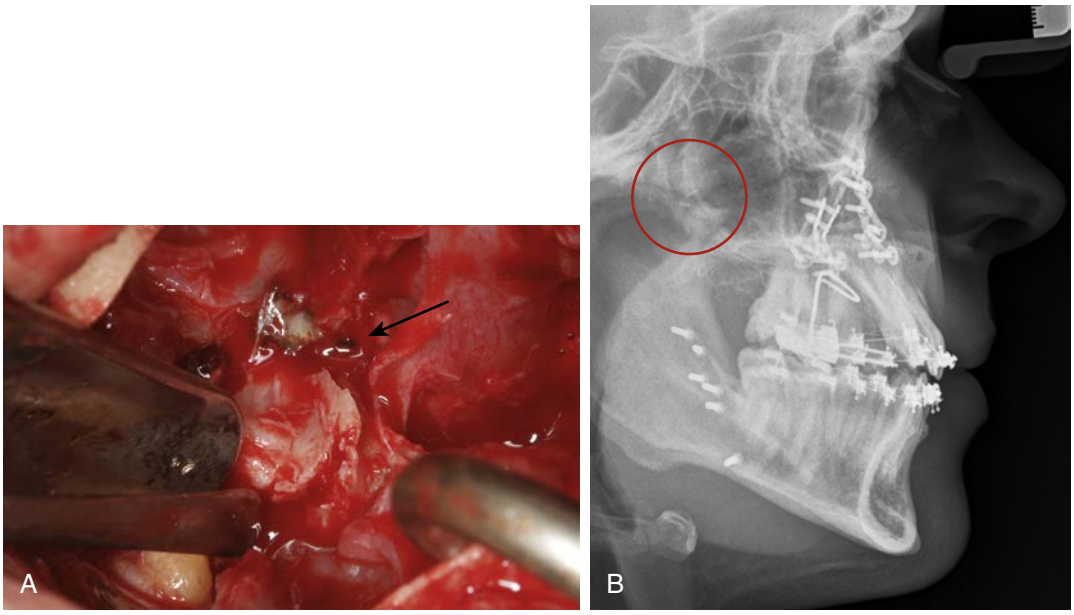
Downward direction of all instruments is crucial in this step (Figure 43-7). Any forceful, uncontrolled downfracture should be avoided. The phenomenon of bradycardia and even asystole, provoked by a trigemino-cardiac reflex, may need an anesthesiologic intervention. In cases of resistance, the dissections of the lateral nasal wall as well as the pterygomaxillary junction must be redone. Sometimes the reason for resistance is that the posterior aspect of the Le Fort I osteotomy is located too far rostral, through the sinus, or too far dorsal, through the pterygoid plates. The ideal position is the pterygomaxillary junction or the tuberosity. When visualization of the lacerated vessel is not possible, immediately packing and continuing the osteotomy until the downfracture has taken place is advised. In cases of direct access, clipping is the first choice (Figure 43-8). If the artery disappears in the canal, compression with a bone chip or resorbable hemostatic agent should be tried.

Cauterization and hemostatic agents are the therapy of choice for venous bleeding from the pterygoid plexus.

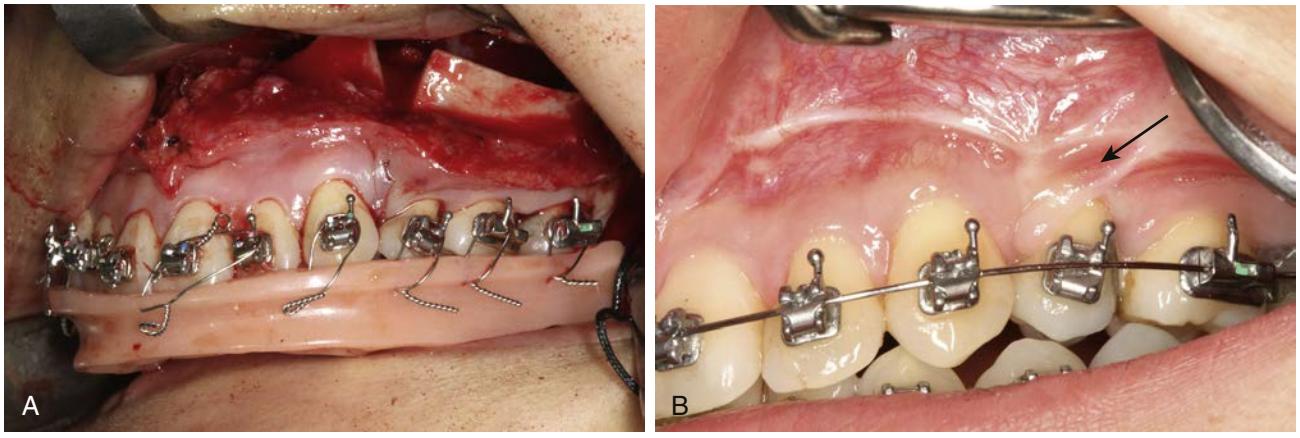
If severe arterial bleeding occurs and ligation and packing are unsuccessful, immediate angiography and embolization are unavoidable. In extreme situations, ligation of the external carotid artery is an option. If this is not done intermediately, a later risk of aseptic necrosis of the maxilla may arise.

Ischemia

The vascularization of the Le Fort I downfracture has been studied extensively by Bell and colleagues, with microangiographic and histologic techniques.[13] The principles indicate that the palatal mucosa is sacred and, if possible, the greater palatine vessel should be preserved. In case of laceration it can be sacrificed, although, as shown in studies by Nelson and co-workers,[14] the blood flow in the attached gingiva and alveolar bone will be decreased, as these areas are usually supplied by the superior alveolar artery, which is dissected by the buccal approach. Nevertheless, it is important to place the circumvestibular incision high above the mucogingival junction and to keep the attached gingiva in place



• **Figure 43-8** **A**, During cutting of the lateral wall of the nose, the roof of the canal of the descending palatine artery was opened in the posterior aspect and the artery injured *(arrow)*. Bleeding was managed by clipping the artery. **B**, Hemoclips are visible on the lateral cephalogram, marked with *circle*.

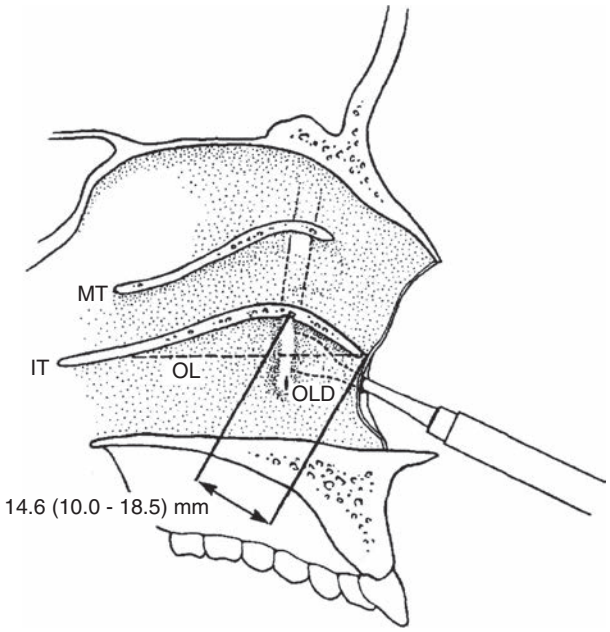


• **Figure 43-9** **A**, Unfavorable location of circumvestibular incision, too close to the mucogingival junction. **B**, Situation in **A** results in scarring, malnutrition, and recession of the gingiva.

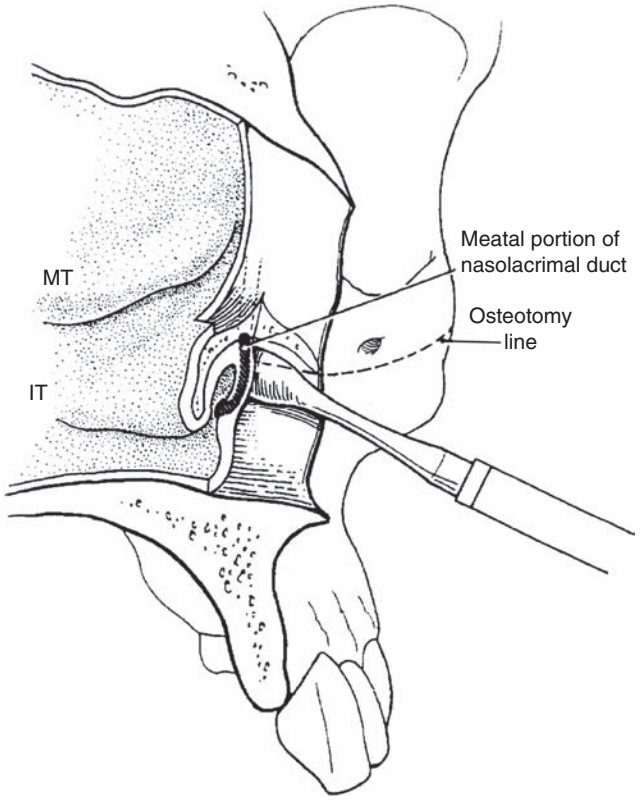
so that later recessions due to scarring can be prevented (Figure 43-9). No further extension than to the zygomatic buttress is also recommended to avoid prolapse of the buccal fat pad. The height of the incision might vary depending on the planned movement of the maxilla or if interpositional bone grafting is needed. The risk of postoperative ischemia increases with the amount of mobilization especially in anterior and downward direction. It further increases in patients with anatomic and iatrogenic irregularities such as cleft lip and palate or craniofacial dysplasia. The method of mobilization of the maxilla is also important. It must be done gently but forcefully, without too much compression of the palatal pedicle. Hugo Obwegeser[15] recommended maxillary advancement where the maxilla is moved steadily under control, millimeter by millimeter. If prolonged ischemia of the vestibular mucosa is observed, minimize the hypotensive anesthesia, inject anticoagulation agents, and do warm packing of the maxilla with gauze sponges. Gentle and careful wound closure without tension is indicated.

Laceration of the Lacrimal Duct

Laceration of the lacrimal duct may occur if the osteotomy through the piriform rim and the lateral nasal wall is designed too high. As noted by You and colleagues,[16] the nasolacrimal duct is located 10 to 14 mm posterior from the piriform aperture and approximately 15.5 mm above the nasal floor (Figure 43-10). Therefore it is advisable to place the osteotomy beneath the anterior attachment of the inferior turbinate and the infraorbital foramen, as well as to elevate the nasal mucoperiosteum where the meatus of the nasolacrimal duct ends, not to injure the ostium or the canal of the duct itself (Figure 43-11). If the nasolacrimal system is jeopardized postoperatively by edema, the obstruction of the passage of the tears will be transient and will recover in



• **Figure 43-10** Illustration of lateral nasal wall showing the distance from the anterior attachment of the inferior turbinate to the nasolacrimal canal orifice. *IT*, inferior turbinate; *MT*, medial turbinate; *OL*, high Le Fort I osteotomy; *OLD*, ostium of nasolacrimal duct. (From You ZH, Bell HW, Finn RA: Location of the nasolacrimal canal in relation to the high Le Fort I osteotomy, *J Oral Maxillofac Surg* 50:1075-1080, 1992.)



• **Figure 43-11** Diagram of the relationship between the high Le Fort I osteotomy and the meatal portion of the nasolacrimal duct. The meatal portion of the nasolacrimal duct can be protected by detaching the mucosa from the lateral nasal wall and placing a periosteal elevator between the mucosa and the lateral wall as the osteotomy is accomplished. *IT,* Inferior turbinate; *MT,* medial turbinate. (From You ZH, Bell HW, Finn RA: Location of the nasolacrimal canal in relation to the high Le Fort I osteotomy, *J Oral Maxillofac Surg* 50:1075-1080, 1992.)

general. If a disruption has occurred during osteotomy, a persistent epiphora and recurrent dacrocystitis may result. This may require surgical intervention by doing an endonasal endoscopic dacryocystorhinostomy.[17] Hemolacria, a retrograde hemorrhage, is another complication, but a rare one. This phenomenon describes retrograde blood flow via the lacrimal apparatus if the intranasal pressure is increased during blowing the nose or in combination with epistaxis.[18]

Tooth Damage

When performing a single-piece Le Fort I osteotomy, tooth injuries should be avoidable! A preoperative glance at the x-ray should give information on the length of the roots and should be a warning not to place the osteotomy cut too inferiorly. According to experimental studies by Bell,[19] a distance of approximately 5 mm above the apices should be respected. If root resection occurs, calyx or enamel matrix derivatives can be placed on the open canal. Periodic follow-up is necessary, including sensitivity testing and x-rays. As long as there are no clinical and radiologic symptoms, endodontic treatment can be postponed.

Nasal Airway

Prior to Le Fort I osteotomy, the patient's history of nasal airway and breathing habits should be elicited. If the patient reports nasal obstruction and breathing problems, a clinical and radiologic examination noting septal deviation and size of turbinates and nostrils should be performed (Figure 43-12). In cases of impaction of the maxilla, a generous reduction of the cartilaginous septum (Figure 43-13), vomer, and lateral nasal wall and contouring and widening of the aperture is necessary (Figure 43-14). This reshaping of the entrance of the nose is essential for improving airflow. Resection of the nasal cartilaginous septum must be limited to the basal horizontal portion and must not be extended to the anterior, columella aspect. This may provoke a dropping of the tip of the nose if over-resected (Figure 43-15). There are two philosophies on the reduction of the turbinates.[20] The resection may be done by cutting them off and coagulating the open wound; the second approach, submucous resection, is to preserve the mucosal coverage, reduce the bone, and close the mucosa (Figure 43-16). This may be more difficult sometimes, but from a physiologic standpoint, it is more plausible and with less risk of postoperative bleeding and rhinitis sicca. Care must be taken to avoid laceration of the ostium of the nasolacrimal duct. In some cases impaction of the maxilla is impaired because of the basal position of the intranasal endotracheal tube (Figure 43-17, *A*). This can be solved by grooving the palatal plate paraseptal with a pear burr (see Figure 43-17, *B*). Based on scientific studies,[21] superior repositioning of the maxilla, often combined with transversal expansion, results in an improvement of nasal breathing, most probably also due to the change of bony shape of the nasal valve and nostrils. Patients even report intensified smell sensations. All these changes may have an unfavorable esthetic aspect in patients with normal width of the alar base as described in the paragraph on esthetics.

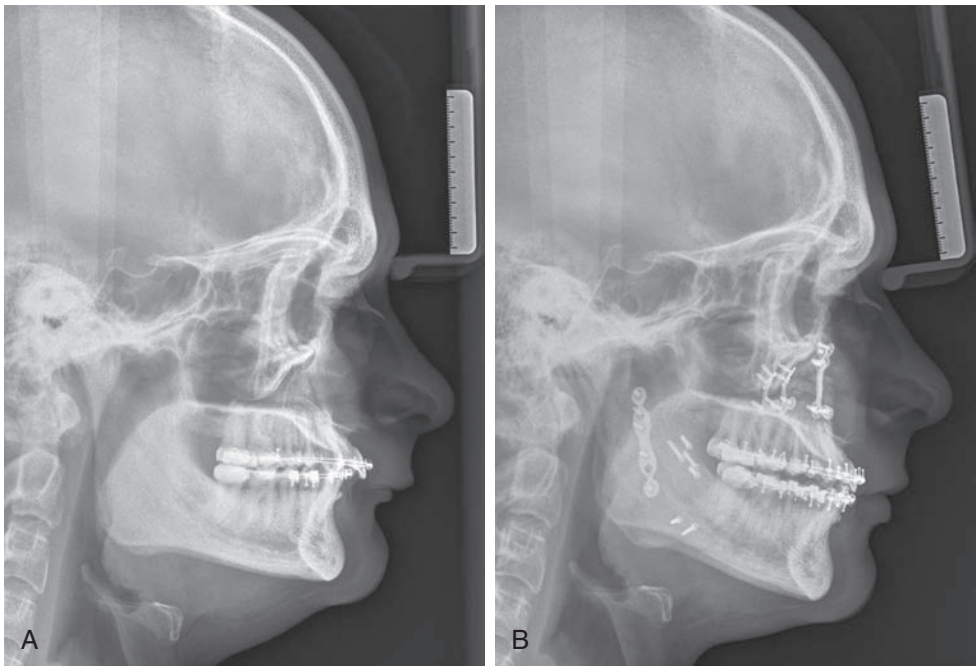
From Profitt WR, Turvey TA, Phillips C: Orthognathic surgery: a hierarchy of stability, *Int Adult Orthod Orthognath Surg* 3:191-204, 1996.

Stability and Early Relapse

The crucial points in stability include the means of internal fixation, changes of maxillary position, and quality of bone. There is no doubt that rigid internal fixation of the maxilla by either titanium or absorbable osteosynthesis material is the gold standard. Within 2 to 6 weeks, resorbable osteosynthetic material may show a higher incidence of slight mobility,[22,23] ending up with the same long-term stability as titanium plates. If guiding elastics are used postoperatively, the new position of the maxilla may be altered by loosening the screws. It depends on the quality of the bone whether movements are dentally derived or due to bony remodeling. Failure of osteosynthesis may occur in fragile structured maxilla independent of planned movement. As stated in the literature[24] (Table 43-1), the most unstable measurement of the maxilla is downward combined with advancement (Figure 43-18), independent of the degree of displacement. Inadequate maxillary mobilization during downfracture plays an important role in the successful outcome by Obwegeser; the maxilla should be directable into the new position using a forceps. Impaction of the maxilla is a stable procedure. If bony contact is still preserved in the posterior aspect of the maxilla, anterior downgrafting depends on the amount of dislocation. A critical size for bone grafting is between 3 and 5 mm, which also depends on the thickness of the maxillary bone.[25] Cortical bone harvested from the angle (Figure 43-19) of the mandible or chin, as well as calvarial bone, is



• **Figure 43-18** **A**, Patient with short alveolar process and hypoplastic maxilla and no show of upper teeth, as well as retroposition of mandible. **B**, Same patient after bimaxillary osteotomy with downgrafting of the maxilla and obvious change of occlusal inclination, a critical movement in regard to relapse. X-rays taken 8 months after surgery.

ideal for interpositioning in the osteotomy gap (Figure 43-20) or in the retromolar area. Stability of maxillary expansion and long-term relapse are discussed in the "Postoperative Complications" section.

Postoperative

Late Bleeding

Characteristically, if bleeding occurs after Le Fort I osteotomy, it is within a 2-week time frame. The patient should be advised about this possibility at the time of discharge from hospital. In general, anterior or posterior epistaxis may occur. The first step in treatment will be anterior and posterior nasal packing, as well as blood examination and a review of the patient's general health status. If blood loss is acute, it must be decided whether to reopen the operative site or, in cases of fulminant bleeding, to do a digital subtraction angiography followed by embolization. In rare situations, the source of bleeding may not be a disrupted or recanaliculated vessel, but a ruptured pseudoaneurysm of the maxillary artery or its terminal branches.[26,27]

Aseptic Necrosis

Studies performed by Bell,[13] Nelson,[14] and their colleagues have shown that the Le Fort I procedure is feasible and safe. Ischemic complications can appear to different degrees: loss of tooth vitality, periodontal defects, loss of tooth, and loss of segments up to the entire maxilla. Kramer and colleagues[2] reported on a postoperative study group of 1000 patients

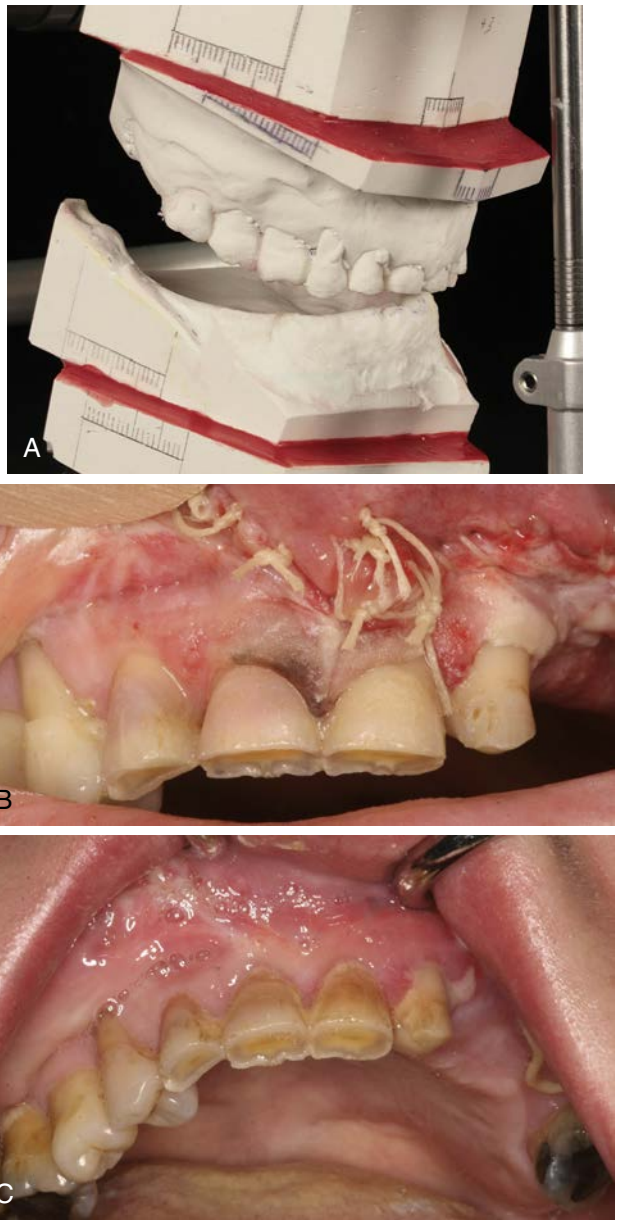
and found a 1% incidence of ischemic complications. The risk of partial aseptic necrosis of the maxilla rises with the degree to which vascular support has been jeopardized by extensive movements and segmentation, as described in the section "Segmented Le Fort I Procedures". In general, postoperative maxillary perfusion is judged clinically by the gingival and pulpal blood flow. A more scientific assessment, if uncertainty exists, would be either magnetic resonance angiography or laser Doppler flowmetry as described by Dodson and co-workers.[28] When the palatal tissue is the sole source of perfusion and the descending palatine arteries have been changed, transitory paleness of the anterior gingiva may occur, especially if movement has been significant (Figure 43-21). Time and patience are necessary before the epithelium will begin bleeding again. There are cases in literature where aseptic necrosis and even total loss of the maxilla occurred after dramatic bleeding, extensive hypotension, and ligation of the external carotid artery or embolization.[29]

Blindness and Other Ophthalmologic Complications

Blindness after Le Fort I osteotomy has been reported in very rare cases (0.25%) mainly associated with high Le Fort I osteotomies and in patients with malformations.[30] This fact may be misleading because the cause for this complication is the pterygoid maxillary disjunction, which should always be the same maneuver, independent of the height of the Le Fort I osteotomy. If this is done too forcefully it may result in uncontrolled fracture lines and bleeding. The combination of controlled hypotension and excessive hemorrhage is considered one of the risk factors of midface surgery. Compression in the pterygoid palatine fossa up to the superior orbital fissure and optic foramen is another risk. If optic nerve damage and its origin are diagnosed, instant decompression of the optic nerve and application of corticosteroids may help, but recovery rates are poor. Besides blindness, several other ophthalmologic complications are described in the literature,[31] such as a decrease in visual acuity, extraocular muscle dysfunction, neuroparalytic keratitis, and injuries of the lacrimal apparatus resulting in epiphora and keratitis sicca as described in the section "Laceration of the Lacrimal Duct". If ophthalmologic postoperative symptoms are detected, an ophthalmologic consultation, as well as an acute computed tomography (CT) scan, becomes urgent. All these symptoms may occur in the absence of direct trauma to neurovascular structures but are consequences of forces transmitted during pterygomaxillary separation. These indirect forces may be traction, compression, or contrecoup trauma to structures running through the superior orbital fissure and in the pterygopalatine fossa. In the worst case, the fracture lines can extend to the base of the middle cranial fossa, resulting in a pseudoaneurysm (false aneurysm),[26] an arteriovenous fistula, or sinus cavernosus thrombosis.

Infection

Septic complications in orthognathic surgery and in specific in maxillary surgery are extremely rare and more often seen in the mandible, which is less vascularized and is affected by the pooling effect of saliva.[32] Kramer and colleagues[2] described a 1.1% incidence of infection in a prospective evaluation of 1000 patients undergoing Le Fort I osteotomy. One reason for it may be that antibiotic prophylaxis is standard. In a prospective study, Danda and co-workers[33] indicated an incidence of infection under 9.3% if antibiotics were administered, in comparison to a rate of up to 25% if no antibiotics were prescribed. The only question is, which antibiotics, and how should they be administered? In 2011, Danda and Ravi[34] published a meta-analysis on this topic. It is essential to start intravenous antibiotics at the beginning of surgery; risk of infection rises with every hour of operating time.[35,36] After surgery, the regime may vary according to preference: 3



• **Figure 43-21** **A**, Major dislocations of the maxilla during Le Fort I osteotomy, especially anterior and downward, are risky for the vascular supply. **B**, Postoperative, day 3, after excessive anterior movement and downgrafting of the maxilla, obvious ischemia of the buccal gingiva of the incisors. **C**, Postoperative, day 8, recovery of blood supply of the papillae spontaneously.

to 5 days orally. In a prospective, randomized, double-blind, placebo-controlled clinical trial, Tan and associates observed no advantage in outcome if the antibiotics were administered orally or intravenously postoperatively for a period of 2 days. Intraoperative amoxicillin was given intravenously and from postoperative day 3 to 5 orally. In transoral surgery, infections are primarily induced by streptococci, anaerobic gram-positive cocci; *Bacteroides* species; and anaerobic gram-negative rods, which can be ideally treated with amoxicillin-clavulanic acid[34,37] or, in cases of allergic reactions, with clindamycin. In rare cases, with transcutaneous approaches for drainage or screws, staphylococci may play a role as well.

Patients who suffered from maxillary sinusitis before orthognathic surgery are in greater danger of developing an infection postoperatively. Retention of a hematoma, lack of vascularization, edema, and compromised nasal airflow are further causes.[38] Free autologous bone grafts or interpositions of hydroxyapatite blocks may be at higher risk of infection as well (Figure 43-22). In cases of sinusitis maxillaris postoperatively, vestibular draining and lavage are sufficient in general under antibiotic medication.

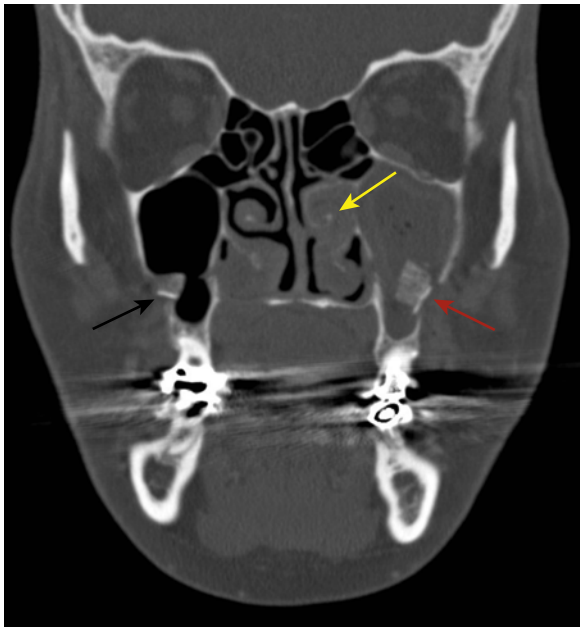
Local abscesses arising from sutures, such as alar cinch sutures with nonresorbable materials, are possible and must be excised.

Acne

In orthognathic surgery, it has become routine for patients to be given corticosteroids intraoperatively and perhaps a second time on the first or second postoperative day.[39] The expected result is not only a significant decrease in edema but also a decrease in pain. In rare cases, this may induce steroid acne. In contrast to acne vulgaris, the acneiform skin eruptions will disappear without scarring, but it will take some weeks in general, and eruptions can only be treated topically (5% benzyl peroxide) (Figure 43-23).

Stability

Long-term stability of the maxilla is the result of where the maxilla was moved, how it was stabilized, and whether an isolated or combined bimaxillary procedure was conducted. The hierarchy of stability by Proffit (see Table 43-1) indicates that the least stable surgical procedures are maxillary advancement and downward[40] movement without mandibular adaption, as well as transverse expansion. Any stretching of soft tissues and muscles, such as the pterygomasseteric muscle sling or the thick, inelastic palatal mucosa, is counterproductive. Neuromuscular adaption is also one of the critical elements of stability. Awareness of all these risk factors is important in designing treatment. Extreme changes in angulation of the occlusal and facial planes must be avoided. As Reyneke[41] described, only a change of the occlusal plane up to 9 degrees can be tolerated. Stabilization with rigid internal fixation has become state of the art, and bridging gaps on the Le Fort I level in vertical changes helps increase long-term stability of the maxilla (Figure 43-24). Nevertheless, it is very important that the mobilized maxilla be maneuvered into the new position without any traction or force, because under constant pressure, even stable screws can begin moving via resorption. Unbalanced and heavy occlusal forces may cause micromovements and overloading of the osteotomy gap. Clenching and bruxism are a problem and need special awareness, as well as restriction to soft diet immediately after surgery. Micromovement of healing sites may result in fibrous union and may require replacement of osteosynthesis and bone grafting. A postoperative evaluation of skeletal relapse is difficult because of identification of bony landmarks combined with orthodontic alterations.[42] If biodegradable bone plates and screws are used,



• **Figure 43-22** Patient with a severe retroposition of the maxilla and class III deformity had to be grafted with iliac crest in a second surgery because osteosynthesis was not stable for lack of solid bone. On the left side the patient developed a serious sinusitis, despite antibiotic application, mainly because of insufficient nasal circulation *(yellow arrow)* on that side. An endoscopic exploration and infundibulotomy, drainage, and partial removal of the displaced augmented bone *(red arrow)* had to be performed. On the right side the interpositioned bone healed without complications.

• **Figure 43-23** Patient suffering from a steroid acne after bimaxillary osteotomy for nearly 6 weeks, after application of 1g of Solu-Dacortin intraoperatively.

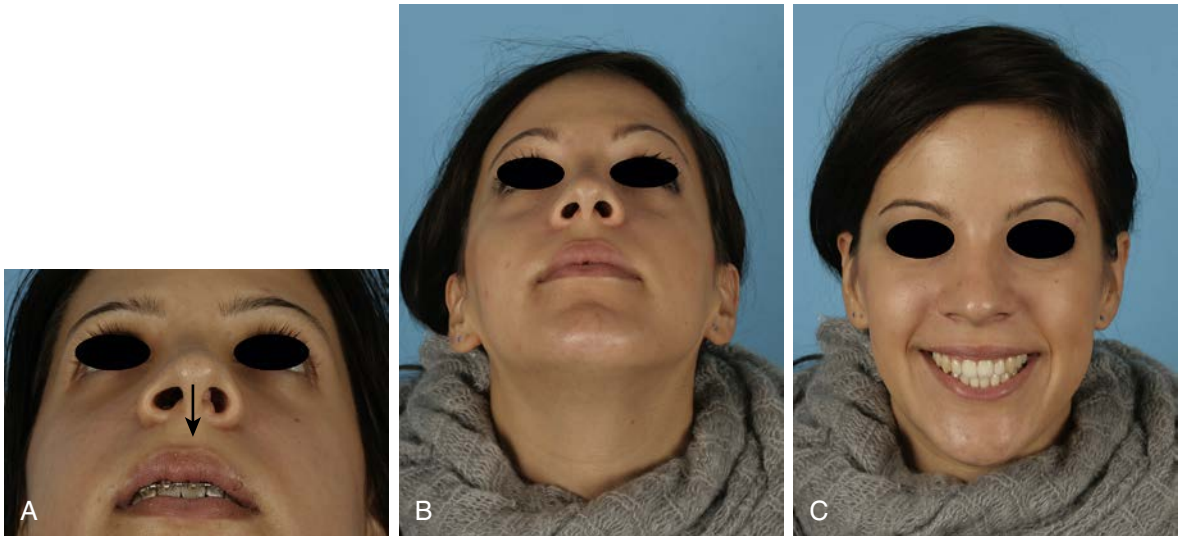
tracking degradation and ossification are even more difficult, because this is a process that lasts up to 3 years.[43]

Esthetics

The literature indicates that there has been a change in motivation to undergo orthognathic surgery.[44-46] Recently expectations of esthetic improvement have ranged higher than functional concerns. The most critical regions for esthetic complaints after maxillary surgery are the nose and the smile, as well as an increase of soft tissue in the midface. Any Le Fort I procedure carries the risk of altering the esthetic appearance of the nose in regard to broadening the base and changing the tip projection. Familiarity with the anatomy of the nose and its relationship to the maxilla is important. The primary tip projection is supported by the septum and the medial crura, both resting on the anterior nasal spine and crest. The dome of the alar cartilages creates the secondary tip projection. The alar cartilages have a fibromuscular attachment to the piriform rim, which is detached during Le Fort I osteotomy, as well as the septum base.

• **Figure 43-24** In case of fragile bony structures, osteosynthesis must be supported by bone grafts to achieve long-term stability.

Referring to the earlier section on nasal airway, it is mandatory to be guided by the principles of reducing the septum and removing any obstacle presenting repositioning of the maxilla to preserve a midline position for the septum and the nose itself (Figure 43-25). If asymmetry is noted postoperatively, revision becomes necessary, and the osteosynthesis must be opened to gain access to the septum. In rare cases only the base of the columella is displaced and can be corrected from a nasal approach. Care must be taken to ensure that the septum is not over-resectioned or reduced in the anterior part, because this portion plays a significant role in supporting the nasal tip. An alteration of the bony platform of the alae results in a flaring of the nostrils. In patients with narrow nostrils and nasal airway, this may be even a desired side effect, but often broadening of the nose is a disadvantage of Le Fort I osteotomy. The esthetic modifications of the nose depend on the direction in which the maxilla is repositioned.[40,47] A pronounced supratip depression and an increase of basal width are observed when advancing the maxilla. Using an alar cinch suture, the mobilized periosteum, paranasal musculature, and indirectly the crus laterale can be anchored to the area of the anterior nasal spine by nonresorbable suture. We have never faced complications such as fistulas or subcutaneous abscesses using a nonresorbable suture, which guarantees a long-term result. In some cases the patient might observe some paranasal tension, which decreases with time. The least risk of anatomic changes of tip projection can be observed by performing a subapical osteotomy where the piriform aperture remains untouched and the bony footplate of the alae stable (Figure 43-26). But this is only feasible in an extremely long maxilla. The role of the anterior nasal spine in altering the tip projection is overestimated; we always remove it to prevent



• **Figure 43-25** **A**, Buckling of the nasal septum and midline shift of the maxilla postoperatively after too little resection of the cartilaginous septum and the lateral wall of the nose. **B**, Same patient 1 year after bimaxillary osteotomy because of a class III deformity. Four days after primary surgery, a correction of the maxillary midline and a loosening of the buckled septum was done. **C**, Satisfying esthetic outcome (1 year after surgery) after reentry as described in **B**.

any interference with the septum. The advancement of the piriform aperture is more crucial.[48]

An inferior movement of the maxilla may result in a drop of the nasal tip (parrot beak), and eventually the bases of the alars may lie below the level of the columella. In contrast, if this exists before surgery, it can be corrected with impaction of the maxilla (Figure 43-27, *A-D*).

In maxillary excess with the phenomenon of the "frowning mouth," it is risky to do too much impaction because it will result in black triangles in the commissures instead of a harmonic show of teeth in repose and a broad smile. The movement of the cheilion in horizontal and vertical directions can be improved with an alar cinch using muco-musculo-periosteal V-Y sutures.[49] These sutures aim to reorient the dissected paranasal muscles to their original vector and have an influence on the length and volume of the upper lip. The angulation of the front teeth is crucial for creating a beautiful smile arch; more protrusion preoperatively (see Figure 43-27, *E, F*), combined with later impaction, may increase the beauty of the smile.[50]

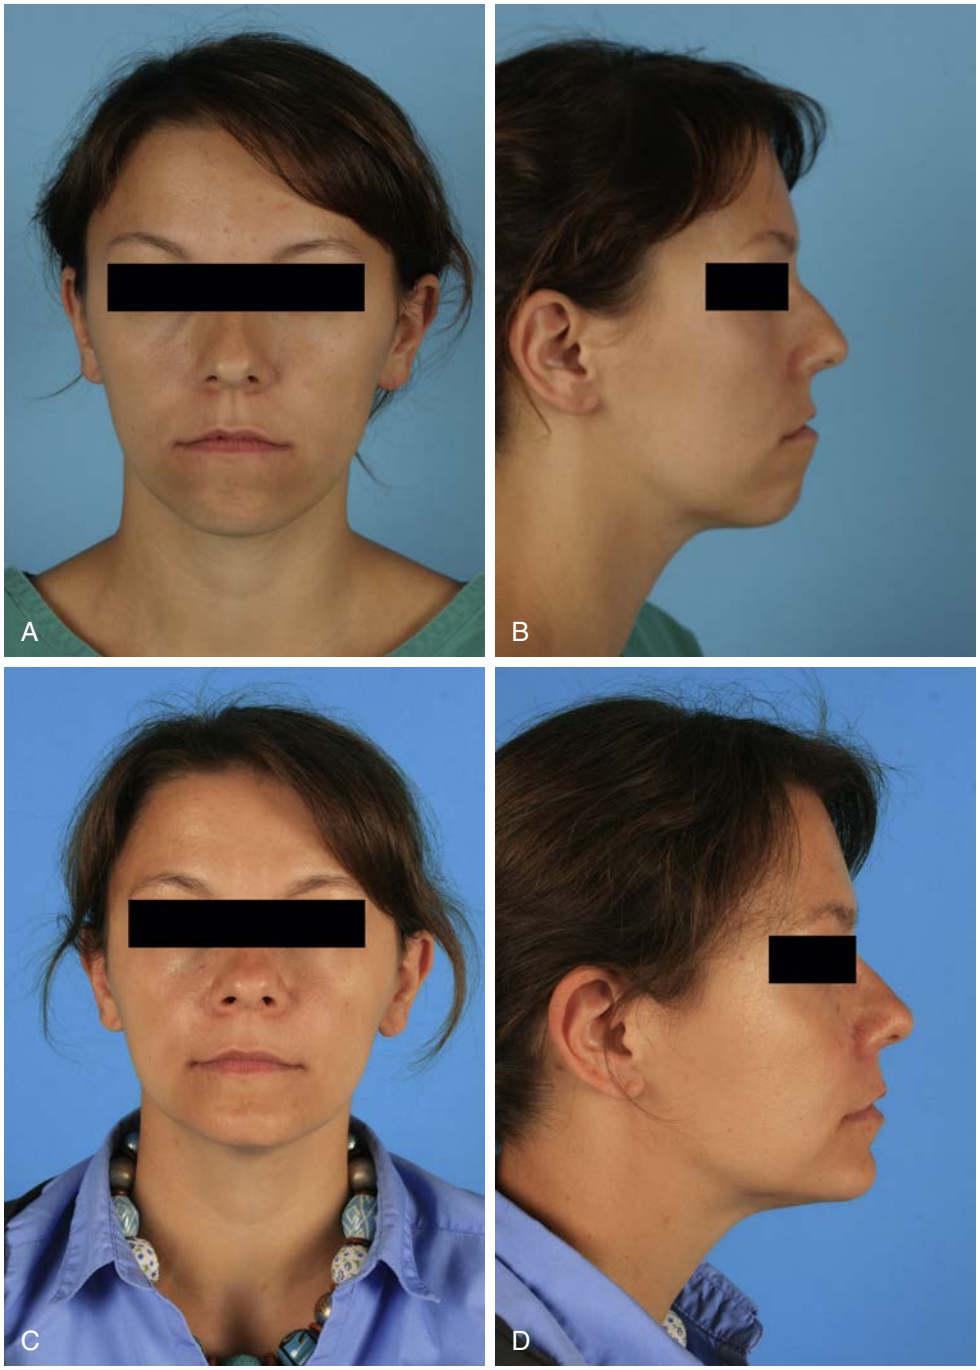
• **Figure 43-26** **A**, Patient with maxillary excess and aggravated closure of the lips. **B**, A subapical osteotomy was performed to preserve the piriform aperture and the nasal platform. The steep inclination of the incisors and the gummy smile could be corrected by tilting the segment. **C**, Postoperative cephalogram after subapical osteotomy, bilateral sagittal split osteotomy, and genioplasty. **D**, Esthetic outcome after harmonizing the vertical excess and preserving nasal appearance.

A major esthetic complication in Le Fort I osteotomy is if impaction of the maxilla is too generous, leading to cases of gummy smile. No show of upper incisors destroys a youthful appearance and may worsen with age as the upper lip elongates (Figure 43-28).

Performing high Le Fort I osteotomies may require contouring of bony steps (Figure 43-29). Generous mobilization of the periosteum to remove the visual tension and then smoothing by filling with crushed bone covered with a resorbable membrane can help this irregularity. In the infraorbital area, autologous fat grafting or lipofilling could also be an option to harmonize the contour.

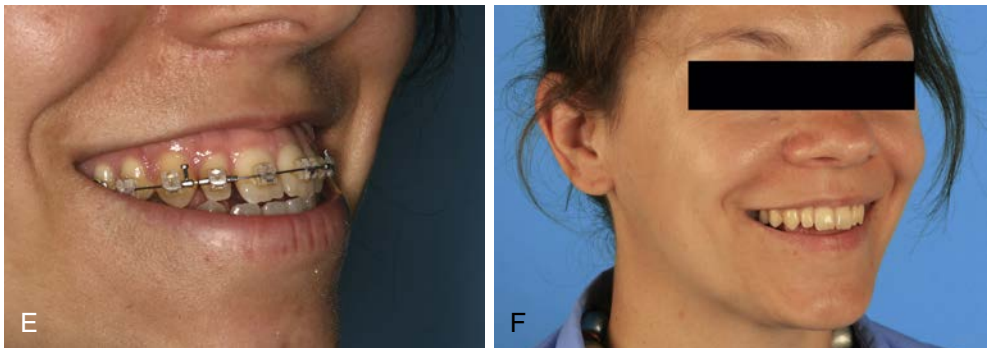
Disturbance of Somatosensory Function

Any preoperative discussion of risk factors of Le Fort I osteotomy must include the possibility of alterations in somatosensory



• **Figure 43-27** **A**, Patient with frowning mouth, midface deficiency, hypoplasia of the chin, dental edge-to-edge relation. **B**, Profile view, preoperative. **C**, Postoperative frontal view after Le Fort I osteotomy, bilateral sagittal split osteotomy, and genioplasty. By advancing and impaction of the maxilla in the molar area, the sad impression of the frowning mouth can be improved. **D**, Profile view, postoperative.

Continued



• **Figure 43-27, cont'd** **E**, Pronounced inclination of the frontal teeth in accordance with the orthodontist before surgery, so that after impaction in the molar area and advancement of the maxilla, sufficient lip projection still remains. **F**, Obvious improvement of smile arc after surgery.

function. During Le Fort I osteotomy, the posterior superior alveolar nerve, a branch of the maxillary nerve, as well as the middle and anterior superior alveolar nerves, branches of the infraorbital nerve, are in the operating field. The intraoral dissection results in a disturbance in sensitivity of the vestibular mucosa and the teeth, as well as the mucous membrane of the sinus. After emerging through the infraorbital foramen, the infraorbital nerve terminates in branches to the eye, the nose, the upper lip, the skin, and the vestibular mucosa and the gingiva. Disturbance may include changes in tactile perception, two-point discrimination, and sensitivity to heat on the skin in the mid-face area, the upper lip, the gingiva, and mucosa of the palate or vestibule as well as the sensitivity of the upper teeth. To avoid laceration of the infraorbital nerve, careful preparation and handling of retractors (Figure 43-30) is advised during surgery. As mentioned before, the horizontal bone cut should be done at least 5 mm above the apices in respect of vitality and sensitivity of the teeth.[13]

Ueki and colleagues studied the recovery from hypoesthesia of the upper lip using trigeminal somatosensory evoked potentials after Le Fort I osteotomy.[51] The average recovery time was 9.7 to 13.9 weeks. This outcome was independent of degree of movement of the maxilla,[52] fixation method, or surgical technique. Only in segmented Le Fort I osteotomies can a higher incidence of changed sensitivity on the palate and the gingiva be documented[52,53] in correlation with manipulation of the palatal nerve. Thygesen and associates[53] also evaluated subjective observations in their study. Patients reported being handicapped in their functional ability (lip movements, finding occlusion, increased tooth pulp sensation) because of changed sensation.

Interestingly, patients with persistent somatosensory disturbances, who are satisfied with the overall outcome of the surgery including esthetic and function, will tolerate the alteration much better than patients who are unhappy with the postoperative result. The highest risk of long-lasting disturbances in somatosensory function is described in pulp vitality, followed by gingiva and palate. Cutaneous numbness normally recovers within 6 months.

Postoperative pain control following Le Fort I osteotomy is essential to prevent centralization of the pain. The perception of pain is not only a physical phenomenon; it is also psychological and may provoke anxiety.[54] Appropriate management of pain results in a lower complication rate and enhances recovery.[55]

Segmented Le Fort I Procedures

Introduction

Segmental procedures in orthognathic surgery have a long history, mainly because orthodontic treatment in combination with orthognathic surgery was not standard from the very beginning. With the improvement and refinement of orthodontics, the need for a segmental approach has definitely decreased. However, there are still indications for it, such as severe discrepancies in dental arch width, vertical height of the alveolus and curve of Spee, or inclination of teeth. The decision to do segmental surgery arises from the wish to achieve perfect occlusion or for esthetic reasons.

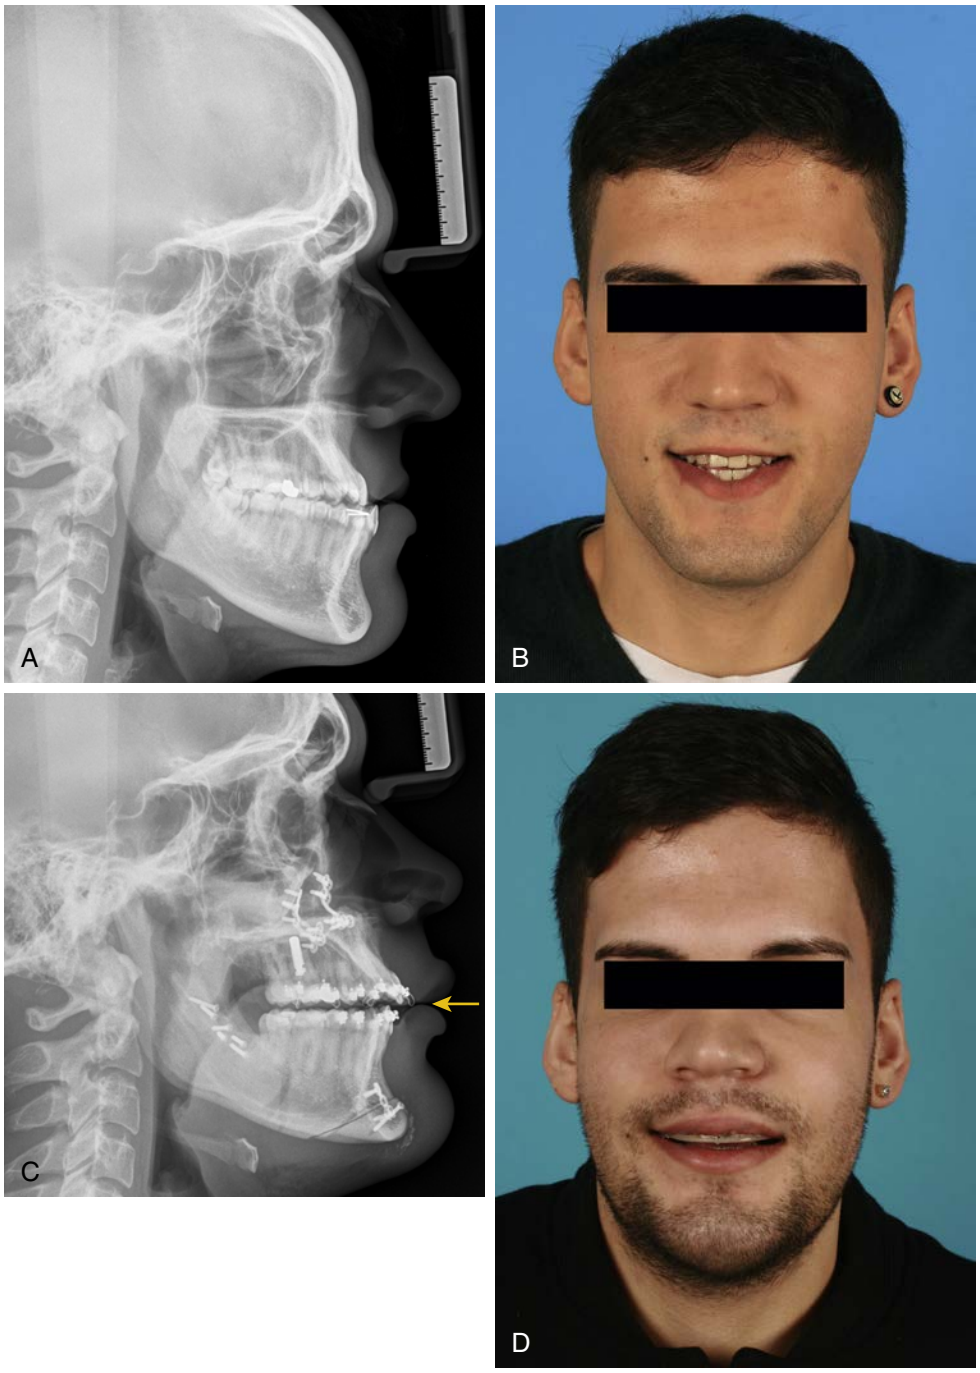
In cases of a surgery-first approach, where no preoperative orthodontic treatment is performed at all, the frequency of segmentation is high.

Preoperative Complications

Planning

Any segmental procedure is more challenging than a single-piece Le Fort I osteotomy; therefore it needs precise planning in two ways: vascular support of the segment, and a definition in advance of where to perform the cuts, prove the feasibility, and create the gap for movement either by cooperation with the orthodontist or by extraction. This is the first step toward a successful outcome, because root injuries rank highest on the list of complications in segmental procedures.

In the history of orthognathic surgery, before the era of the Le Fort I osteotomy, segmentation of the alveolar process was popular and often practiced. Independent of the design of the vascular pedicle of the segment, one can find techniques referring to their famous inventors such as Wassmund, Wunderer, Schuchard, Koele, Epker, and Cupar.[56] Preference for the one technique over another depends on the desired movement of the segments. Later, based on scientific research,[13,57] a segmented Le Fort I osteotomy and its vestibular incision became routine, and this is also practiced in isolated segments nowadays.



• **Figure 43-28** **A**, Lateral cephalogram of a patient with class III deformity and transversal discrepancy of the maxilla. **B**, Same patient with class III deformity, maxillary retrusion, and gummy smile. **C**, During surgery, maxillary impaction was performed too extensively *(arrow)* in the A-point. **D**, First day after surgery, a revision surgery was offered, but the patient was not willing to go through surgery again, although he was informed about a lack of show of teeth and some compression on the septum.

For esthetic planning, a point of reference, such as the upper incisal edge of the frontal teeth, has to be defined. This point of reference determines the midline shift, impaction, or setback.

Intraoperative Complications

Prolonged Operating Time, Blood Loss

The risk of intraoperative bleeding is subject to the same anatomic facts as in total Le Fort I procedures and is described at length in the later subsection on hemorrhage. Nevertheless segmental Le Fort I osteotomy is more challenging and more time consuming.[58] A long operating time correlates with increased blood loss. In 2000, Yu and colleagues[59] reported that blood loss in segmented procedures was 30% more than in total Le Fort I. Reduction of blood loss may occur until the use of a piezo scalpel for the segmentation (Figure 43-31). This was also studied by Landes and co-workers.[60] Blood loss

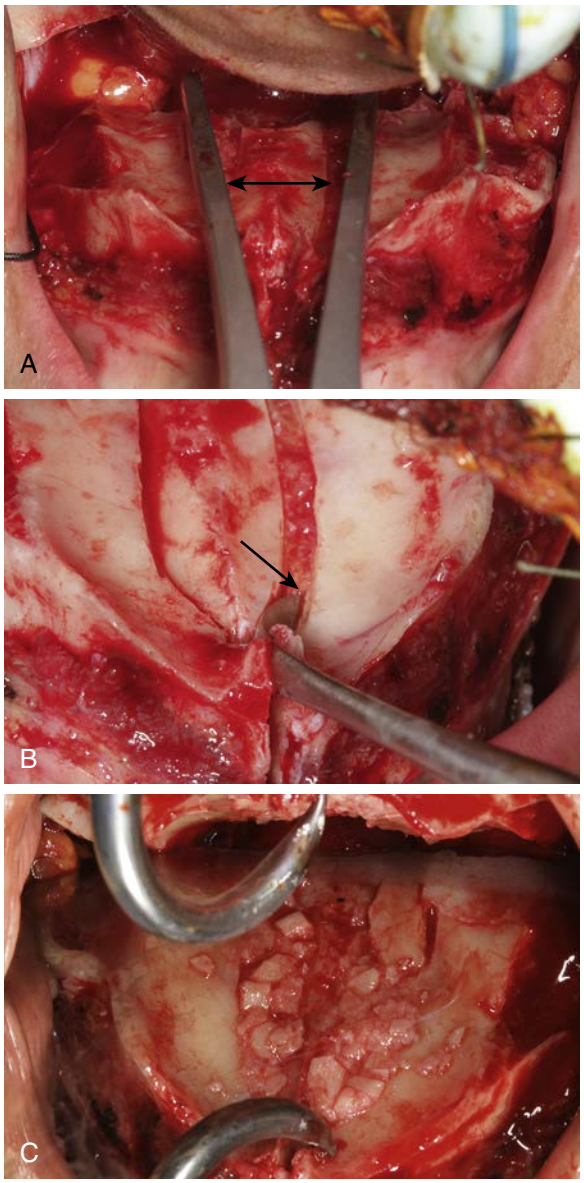
differed up to 230 mL in comparison to use of conventional instruments. The initial prolonged time of surgery using the piezo saw could be compensated soon through a learning curve.

Ischemia

The crucial question in segmentation is, where does the vascular support come from? Certainly, it is the palatal pedicle via the ascending palatine branch of the facial artery and the anterior branch of the ascending pharyngeal artery. If possible, the greater palatine artery, which is the blood supply for the palate and the palatal alveolus, should be preserved in segmental procedures as well. This is advantageous if laceration of the palatal mucosa occurs during segmentation (Figure 43-32). In critical segmental osteotomies, in cleft patients for example, a vestibulobuccal subperiosteal tunnel with vertical incisions is an option, instead of incising horizontally. The excellent visibility and accessibility to all areas of the maxilla makes the Le Fort I downfracture technique optimum for segmentation. Reliance on the reverse periosteal-endosteal blood flow[19] is necessary if the greater palatine artery is injured. If multiple segments are designed, it is advisable to check the color of the attached gingiva of the dento-osseous segments during surgery, and segmentation should occur from posterior to anterior, as the most critical blood supply will be in the gingiva of the frontal segment. The more extensive the mobilization and dislocation of the bony segments, the higher the risk that blood supply will be jeopardized by the tension of the soft tissue pedicle (Figure 43-33, *A*). The second consideration is the size of the segment, and if subperiostal undermining of the gingiva or periosteum for reasons of mobilization is necessary (see Figure 43-33, *B*), it has to be done adjacent to the osteotomy cut not touching the pedicle of the smaller segment. If obvious ischemia is observed intraoperatively, mobilization must be stopped, and the surgery must be aborted. Sometimes wrapping the segments in warm tissues and antithrombotic medication can help.

Dental Injuries and Periodontium

Dental injuries are by far the most common intraoperative complications in segmental maxillary surgeries.[61] Before performing a segmental procedure, it is absolutely mandatory to check the preoperative health status of the teeth, sensitivity, pocket probing, and evaluation of root resorptions. Schultes and colleagues[62] reported a high incidence of periodontal lesions in 35 teeth out of 74 osteotomies in a retrospective study. A strategy must be designed as to where to place the vertical incision. If it is planned well ahead, the orthodontist will open a space or do a tilting of the roots. If no orthodontic help is available, the anatomic situation of the roots should be explored by CT scan or digital volume tomography (DVT). If there is not at least a 3-mm working space interdentally, extraction should be considered. The surgical technique and the amount of displacement of the segments also play a role. The osteotomy cut should be performed with a thin chisel, or with a piezo scalpel. To



• **Figure 43-33** **A**, Spreading of the palatal mucosa *(arrow)* is done with controlled force so as not to jeopardize the vascular pedicle. **B**, The tension is released by a horseshoe cut, but undermining *(arrow)* of the palatal mucosa must be performed meticulously. **C**, The achieved gapping of the palatal plate is stabilized by packing the osteotomy sites with milled bone chips.

prevent mobilization of the attached gingiva, a penetration and weakening of the interdental bone with a l-mm transgingival Lindemann burr is recommended (Figure 43-34). Dependent on the pitch-roll movement of the segment, removal of interseptal and interradicular bony interferences may be necessary. A negative consequence of this maneuver may be damage to the alveolar socket caused by trying to position the segment, resulting in tension and destruction of the periodontium. In combination with unfavorable approximation of the bony margins, an angular loss of the interdental bone height is inevitable. Bridging the bony gap with milled bone chips (Figure 43-35) is helpful for stability, but survival and nutrition of the augmented bone then depends on sufficient interdental wound closure and blood supply of the papilla. If shaving of the root adjacent to the vertical osteotomy has occurred, the prognosis of the injured tooth depends on the level of the laceration (Figure 43-36). Application of an enamel matrix protein on the open root surface can help. In general there is a chance that injury in the final third of the root will be tolerated without symptoms.[63]

Postoperative Complications

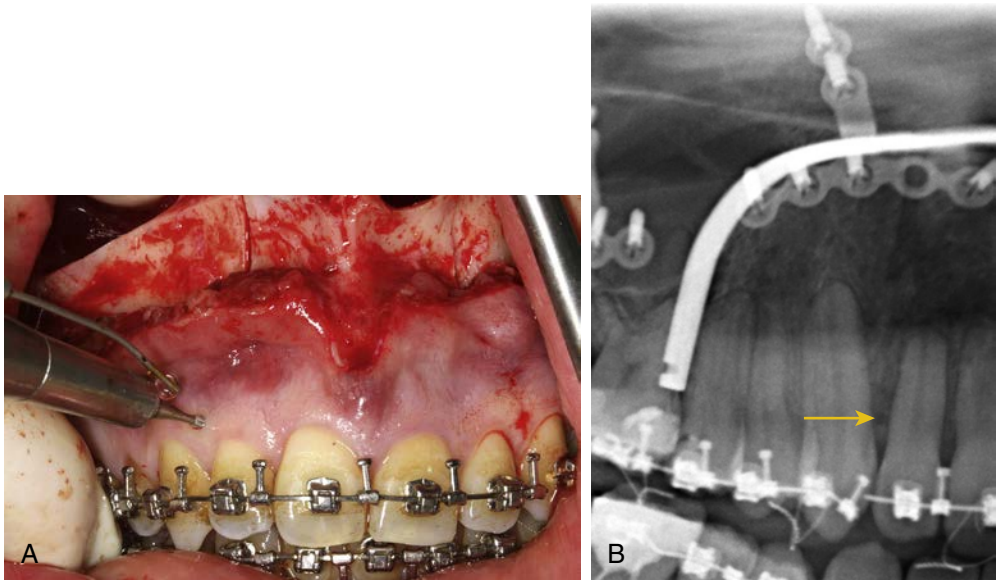
Stability, Fibrous Union

Stable maxillary expansion in a segmented Le Fort I osteotomy depends on the morphology of the palate, the surgical technique, and the retention. Successful widening is limited to 5 to 7 mm; in cases of a high-arched palate and of extraction with anterior movement of the molar segments, more expansion is feasible. To release tension, a bilateral, paranasal osteotomy on the floor of the nose should be performed (see Figure 43-33, *B*). This is the area of least bone but high thickness of the palatal mucosa, in contrast to a midline osteotomy where a perforation of the mucosa is a threat (Figure 43-37, *A*). Mobilization and undermining of the vascular pedicle must be done on the lateral aspect of the osteotomy site. Expansion must be executed in intervals with cautious force. Then the widening can be stabilized by either a resorbable miniplate (see Figure 43-37, *B*) or packing of the osteotomy sites with autologous bone chips (see Figure 43-33, *C*). Maxillary segments are kept in place with rigid osteosynthetic fixation and dental acrylic splints (Figure 43-38). These appliances have an integrated palatal arch bar and are wired to the surgical hooks for up to 6 weeks. After removal of the acrylic splint, a transpalatal arch wire must be worn for further retention up to 3 months. Most relapse in width is seen within the first year, and then it is necessary to distinguish between skeletal and dental relapse.[64] Skeletal relapse in a two-piece maxilla mainly occurs in the molar area and can be up to 47%[65] of the arch width in the first molar area. Overexpansion is recommended. Dental relapse can be avoided if the molars are kept upright instead of tilting and intrusion orthodontically preoperatively is avoided. Therefore it is also essential that the surgeon become acquainted with the original pretreatment occlusion before designing his or her treatment plan.

Fibrous union of segments of the dental arch derives from an unstable osteosynthesis in combination with insufficient bony structures and overloading. Micromovements of the interdental osteotomy gaps, filled with milled autologous bone chips, can prevent revascularization and stable healing. If nonunion exists, reosteosynthesis in combination with cortical bone grafting should be performed.

Infection, Periodontal Problems

Patients with a compromised periodontal health status are more at risk to develop an infection after segmental



• **Figure 43-34** **A**, The desired interdental osteotomy cut is defined by transgingival perforations with a Lindemann burr in the gingiva fixa. **B**, X-ray corresponding to the clinical picture in **A**. The interdental perforation is marked with an *arrow*.

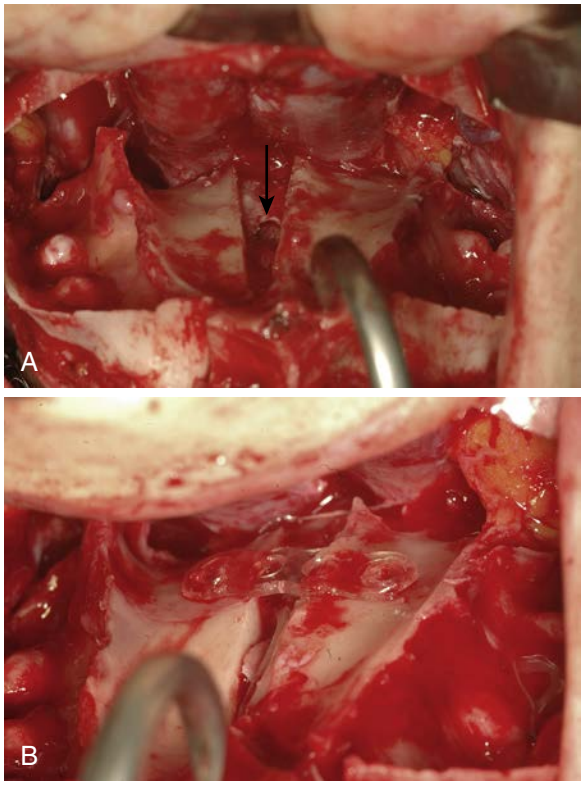
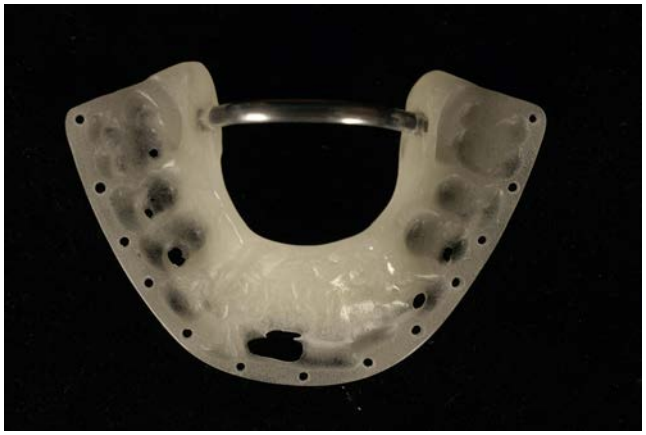
• **Figure 43-36** Shaving of the root of the first premolar in the upper third during segmentation.



• **Figure 43-37** **A**, Transversal widening was performed by a single midline osteotomy, in contrast to a horseshoe, bilateral paranasal osteotomy, which results in a perforation *(arrow)* of the thin palatal mucosa. **B**, Stabilization of the transversal widening by fixation with a resorbable plate.



• **Figure 43-38** Acrylic splint with an integrated palatal arch bar, which must be in place postoperatively up to 3 weeks and must be replaced by a transpalatal arch after removal.

Le Fort I osteotomies. A widened periodontal ligament space can be a first sign and the origin of osteolytic lesions and root resorption. If the infection is ascending from the periodontal pocket along the vertical osteotomy cut, osseointegration of the grafted bone chips will not succeed, and stable healing is in danger. In the worst scenario, the tooth will be lost and the segment remains mobile (Figure 43-39). Tooth loss is rare,[61] but an angular interdental bone loss occurs with greater frequency (Figure 43-40). One of the most difficult goals in segmental surgery is to achieve a salvage-proof interdental soft tissue seal. Any protrusive rotation of segments results in undesired tension of the interdental papillae, creating a periodontal pocket. In cases of extractions, closure of the extraction socket is the aim by sewing a subperiostal rotation flap into the defect (Figure 43-41).

Root Resorptions, Loss of Dental Vitality

As mentioned before, root injuries do not necessarily become symptomatic. As long as the patient is asymptomatic, observation and x-ray control are the treatments of choice before endodontic treatment is performed. Pepersack,[63] who studied tooth vitality and sensitivity in 429 segments operated by Hugo Obwegeser, came to the conclusion that return of sensitivity in the maxilla takes up to 1 year. Teeth adjacent to the vertical osteotomy in the mobilized fragment remain nonreacting at a higher percentage independent of vascularity. A 5-mm distance between the horizontal osteotomy and the root apices, as described by Bell,[19] is the general rule for the safe conduction of osteotomies. Normal vascularity is the crucial point of success, not a lack of sensitivity.

Oroantral or Oronasal Fistulas

Laceration of the palatal mucosa may happen during segmentation, whether it is conducted with a rotatory instrument or a piezo surgical scalpel (see Figure 43-32, *C*). To accelerate wound healing, meticulous closure of the nasal mucosa as well as the palatal defect, including coverage with a resorbable membrane on the floor of the nose, is recommended. In segmented Le Fort I surgery, an attempt should be made to preserve the greater palatine artery. Antibiotic prophylaxis (amoxicillin) is prescribed, and some ointment that enhances wound healing is applied intraorally. In the rare cases where persisting fistulas occur, secondary reconstructive interventions must be planned.

Aseptic Necrosis

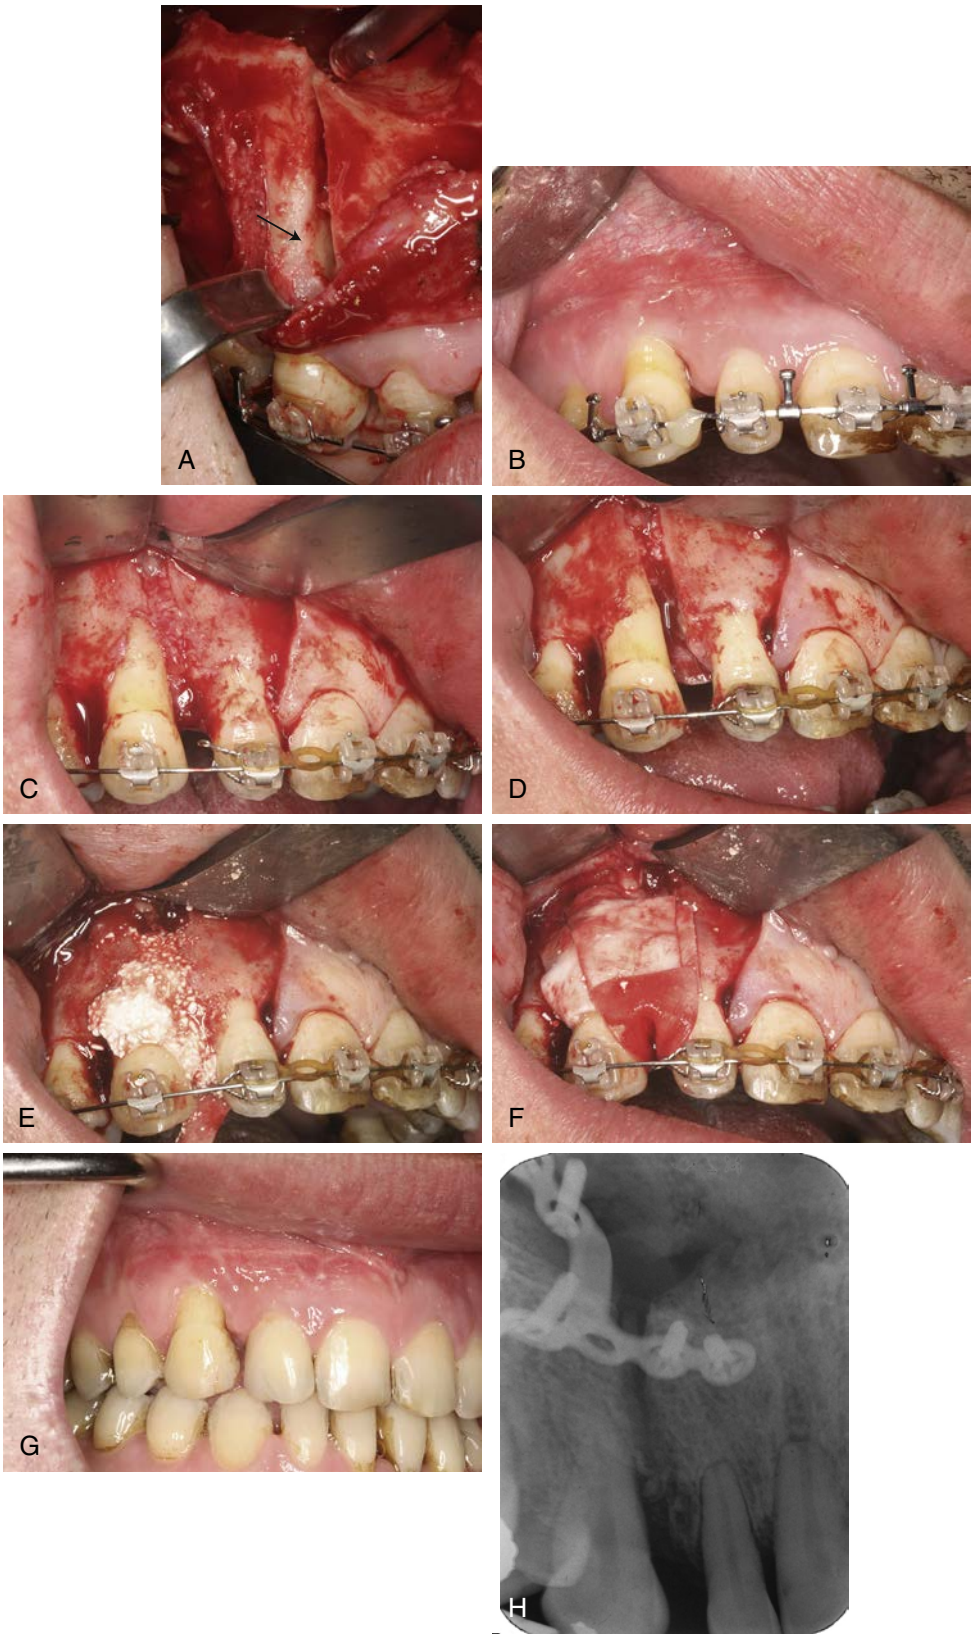
Because of the knowledge of vascularization of the maxilla based on the scientific studies by Bell and colleagues,[13,17,19,55] aseptic necrosis is a rare complication, but the risk increases in segmental procedures. Nevertheless, aseptic necrosis can also occur as a result of decreased blood flow triggered by excessive bleeding or hypotension, or extensive stretching (Figure 43-42) of the palatal vascular pedicle, for example. The most vulnerable structures are the buccal gingiva and the alveolar bone in the anterior maxilla. This has to be considered when segmentation of the front block of the anterior incisors is scheduled (Figure 43-43). In orthodontia-first cases, multiple segmentations should be prevented by good preoperative orthodontic treatment. Only in "surgery-first" cases, where overall treatment time is cut short, is there more dependence on multiple segments. Aseptic necrosis can present to different degrees, from loss of tooth vitality, to periodontal defects, loss of the bony socket, tooth loss, and loss of total segments up to the entire maxilla.[29] Pulpal necrosis is often camouflaged by an early hyposensitivity due to violation of the sensory fibers during surgery. Stripping of the palatal soft tissues adjacent to the osteotomy cut, or the periosteum in vertical incisions, for mobilization of the segments, has to be done very carefully, always starting on the side with the safer vascular pedicle. In cases of widening, a horseshoe-shaped palatal cut, dividing the tension on two locations, is recommended. An unfavorable compression of acrylic splints, used for retention, on the palatal mucosa or gingiva must also be taken into consideration.

Surgically Assisted Rapid Palatal Expansion

SARPE (surgically assisted rapid palatal expansion) or SARME (surgically assisted maxillary expansion) is the procedure of choice in adult patients with a maxillary transverse deficiency more than 5 mm, with periodontally compromised (Figure 43-44, *A*) and already elongated or tilted molars and premolars. Differentiation between absolute and relative width discrepancies is important. *Relative* implies a discrepancy between the maxilla and the mandible in sagittal relationship and does not necessarily require a surgical intervention. Complications can occur intraoperatively or postoperatively.

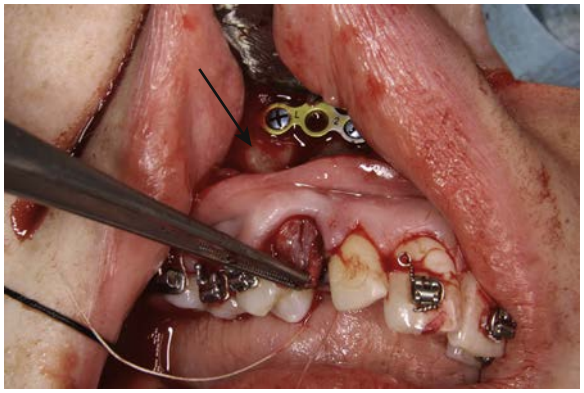
Intraoperative

Intraoperative complications depend on the technique performed. There is a wide range, from simple outpatient

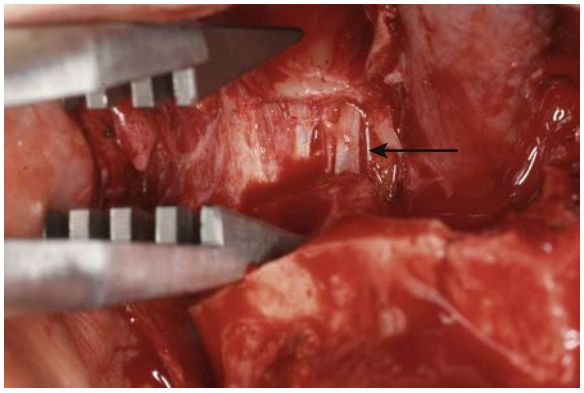


• **Figure 43-39** **A**, A patient, already periodontally compromised preoperatively, was undergoing a segmental Le Fort I osteotomy. Root shaving *(arrow)* of the canine occurred in the vertical osteotomy cut *(arrow)*. Intraoperatively, an enamel matrix protein was applied on the open root. **B**, Two months after surgery, the patient developed a periodontal pocket with a probing depth of 7 mm. **C**, Four months after surgery, an exploration of the osteotomy site was performed. There was fibrous tissue in the osteotomy gap and no bony regeneration. **D**, Infection and resorption had ascended to the middle third of the root, where shaving was diagnosed combined with a pseudoarthrosis of the segment. One of the reasons for the complication was that the patient was a heavy smoker and did not follow a soft diet after surgery. **E**, An attempt was started to save the canine by root planing and filling the gap with bone substitute biomaterial (hydroxyapatite, algae derived). **F**, The defect was covered with a resorbable membrane before wound closure. **G**, Clinical aspect 2 months after augmentation. **H**, X-ray 2 months after augmentation. Within 1 year the patient developed a recurrence of the infection, and the canine had to be removed.

• **Figure 43-40** Traumatized papilla and angular interdental bone loss at site of vertical osteotomy.

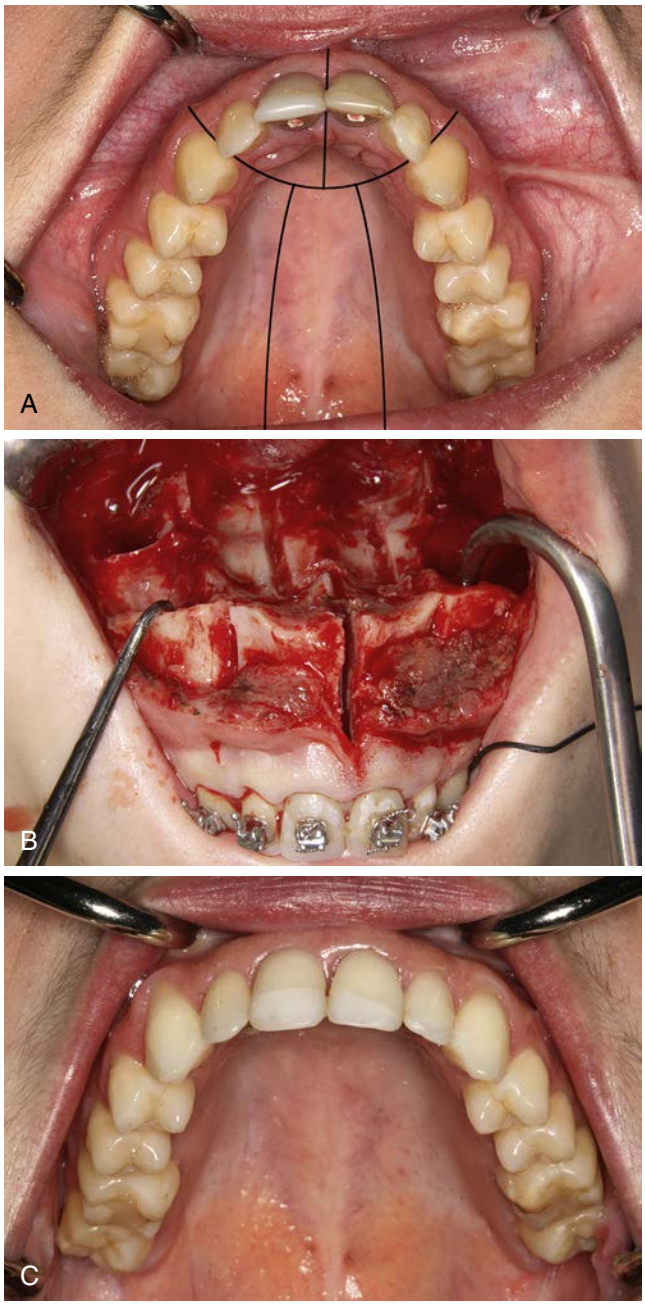


• **Figure 43-41** It is mandatory to achieve a salvage impermeable seal at the site of vertical osteotomy. A periosteal flap *(arrow)* is rotated from the vestibule into the extraction socket.



• **Figure 43-42** Extensive stretching of the vascular pedicle and mobilization of the maxilla enhances the risk of avascular necrosis. *Arrow* marks stretched and squeezed descending palatine artery.

procedures as described by Glassmann[66] or Pogrel and colleagues,[67] concentrating on sectioning the zygomatic buttresses, a midline palatal osteotomy, and a split of the alveolar bone between the incisors only, to a modified Le Fort I osteotomy including dissection of the posterior maxilla from the pterygoid plates. The second issue is the type of appliance used (bone-borne distractor or tooth-anchored device).

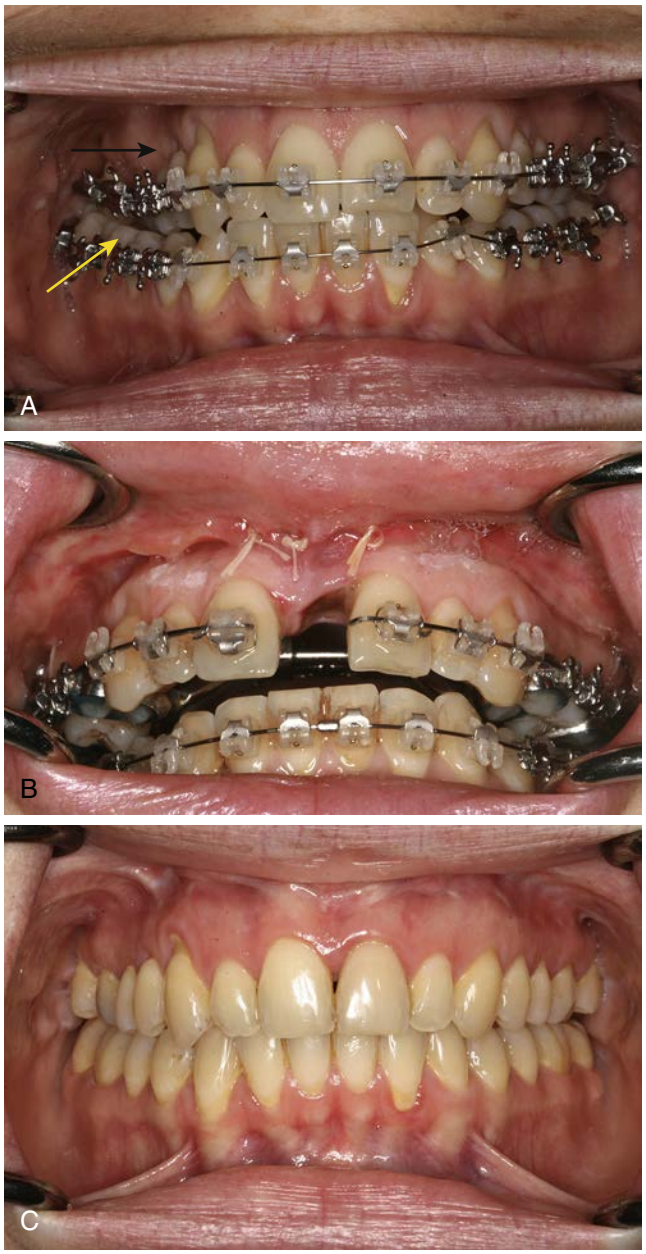


• **Figure 43-43** **A**, Dental arch of a "surgery first" patient with transversal deficiency and open bite deformity. *Black lines* mark the pattern of segmentation to achieve a harmonic dental arch. **B**, Intraoperative situation. **C**, Eight months post-surgery, dental alignment is finished orthodontically.

Hemorrhage

If a SARPE with a modified Le Fort I osteotomy is performed, except for the downfracture, risks of laceration of the descending palatine artery with the osteotome are similar to those during a regular downfracture procedure.

But in contrast to a Le Fort I osteotomy with downfracture, there is a lack of direct vision; therefore, packing is the treatment of choice in case of bleeding. If access allows it, the dissection can be achieved using an angulated, elongated tip of a piezo scalpel of the latest generation with less risk

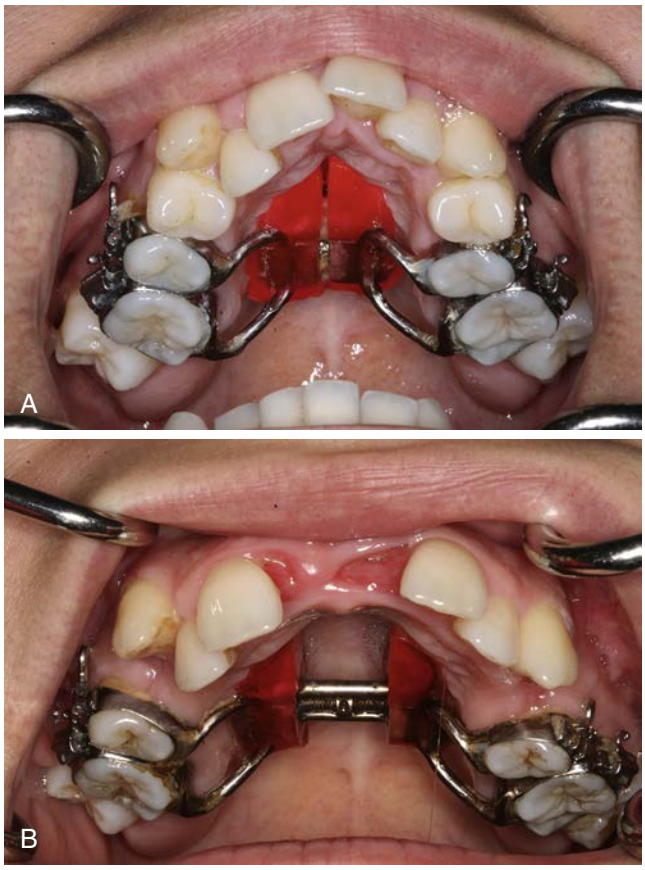


• **Figure 43-44** **A**, Patient with crossbite and multiple recessions buccally *(arrow)*, a contraindication for any conservative orthodontic expansion. **B**, Expansion after surgically assisted rapid palatal expansion was executed too quickly (0.5 mm per day), resulting in an exposure of alveolar bone. **C**, Same patient at the end of orthodontic treatment. Orthodontic movement of incisors and the attached gingiva may improve and create a papilla. A minor loss of papilla presenting in a black triangle will remain, however.

of soft tissue laceration. The risk of nasal bleeding is minor because in SARPE, only the anterior aspect of the lateral wall of the nose and the septum is osteotomized up to 1.5 cm. This is done to prevent broadening of the base of the nose as well as an asymmetric shift of the septum.[68]

Laceration of the Palatal Mucosa

When hyrax or Hass appliances are used (Figure 43-45, *A*), they are already put in place before the SARPE, and



• **Figure 43-45** **A**, Patient with transversal discrepancy with Haas appliance in situ. **B**, Tooth-borne anchorage combined with the palatal shields and a total release in performing a modified Le Fort I osteotomy, including a dissection of the pterygomaxillary junction, allows a symmetric, parallel expansion.

the patient is intubated orally. To minimize the tension on the palatal mucosa, two paranasal cuts are performed with the elongated piezo scalpel on the floor of the nose. Under digital palatal control, perforation of the mucosa can be avoided. Subperiosteal, interdental separation is performed using a piezotome, as well as in the area of attached gingiva; transmucosal perforation with a Lindemann burr is a good choice. In that way a path of the desired fracture line can be created when force is administered.

Other techniques, such as using a bone-borne distractor (Figure 43-46), may require a palatal incision for anchoring the device, which is tolerated as well. Even mucosal midline incisions[67] to perform paranasal palatinal bone cuts are feasible. Risk of infection or wound-healing problems such as an oronasal fistula exist but are rare. Latency up to 5 days before starting distraction should be considered. A distraction rate of not more than 0.25 mm per day should be achieved.

Dental Injuries

Treating the sensibility of the incisors is routine before the SARPE, and if they react negatively, an endodontic treatment must be done. While performing the median medial osteotomy, root shaving of the central incisors or substantial

injury to the alveolar socket can occur[69] (Figure 43-47, *A,B*). If there is severe crowding of the incisors with extreme proximity of the roots, the distraction design should be changed to two osteotomies, between the canine and the second incisor on both sides, if there is more space, or the orthodontist should be asked for root tipping before the surgical procedure.

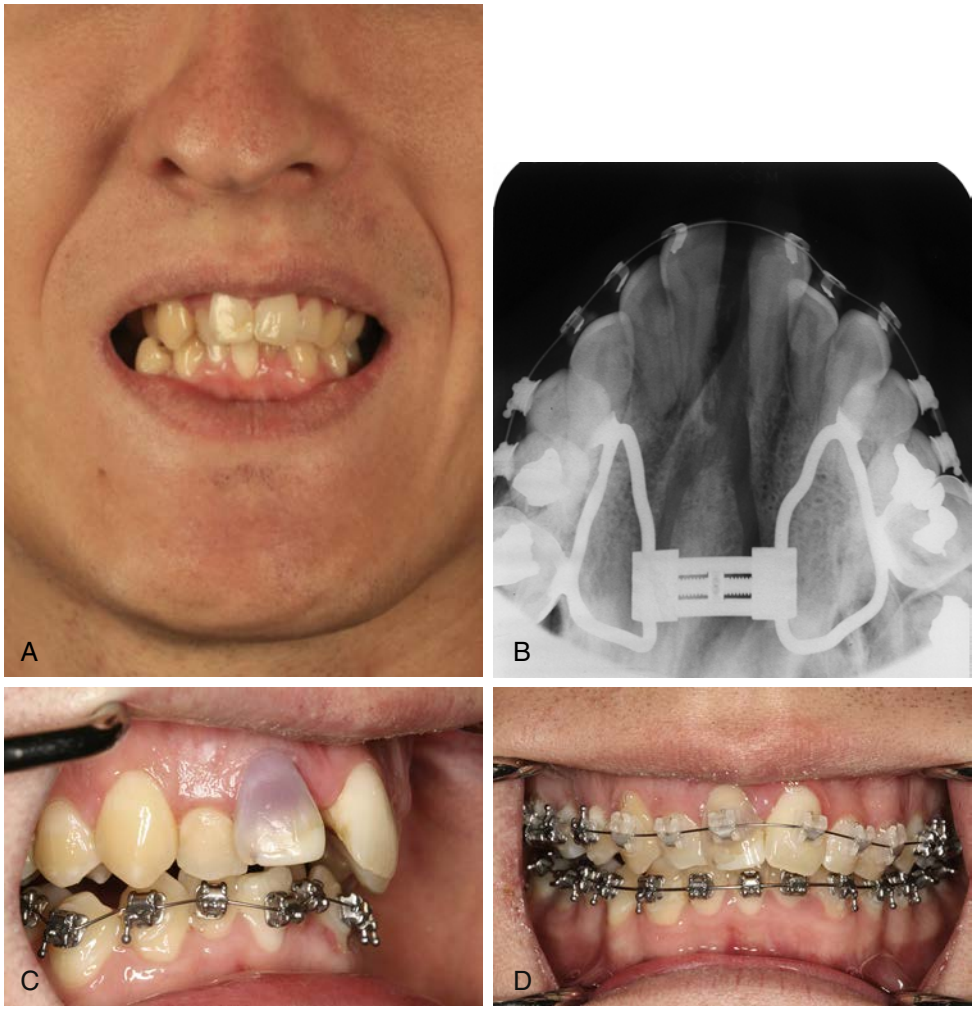
When the two halves of the maxilla are mobilized and expansion started intraoperatively, some enamel matrix derivative can be injected prophylactically under the expanded papilla between the incisors, to protect denuded root surface.[70]

• **Figure 43-46** Bone-borne distractor fixated via a palatine incision.

Postoperative

Late Bleeding

A release of the nasal septum and the lateral wall of the nose, to prevent broadening of the nose and a deviation of the septum during distraction, may increase the risk of postoperative nasal bleeding. Therefore, staying within a range of 1.5 cm anteroposterior separation is suggested. If epistaxis occurs, it can be easily treated by nasal packing. A higher risk of postoperative bleeding exists in cases where pterygomaxillary dissection and separation have



• **Figure 43-47** A, Patient with severe dental crowding and transversal discrepancy. **B**, Injury of the alveolar socket of the right incisor when performing the interdental osteotomy. **C**, Postoperative discoloration of right incisor. The patient had no symptoms, and the tooth was kept under observation. **D**, Three months postoperatively the discoloration had improved, sensitivity was still questionable, but x-ray was without findings. Further observation was the treatment of choice.

been done, and this requires reopening of the operation site.

Periodontal and Dental Problems

There is a high risk of necrosis of the interdental papilla between the upper incisors because of mobilization and tension. In general the distraction is begun intraoperatively, and then there is a latency period of approximately 4 days. The amount of distraction must be strictly kept to 0.25 mm per day or gapping between root surface and gingiva and necrosis of the exposed alveolar socket may occur. Recovery of the gingival tissue can be followed by the appearance of immature attached gingival tissue medial to the central incisors (see Figure 43-45, *B*). If distraction is done too fast and too aggressively, periodontal recession (Figure 43-48) can occur. Orthodontically achieved alignment of the front teeth may improve the esthetics later on (see Figure 43-44, *B,C*). If the recession is combined with an interdental bone loss (Miller class III), it can only be treated with a free full-thickness gingiva graft with an esthetically compromised outcome. Hypersensitivity as well as discoloration of incisors is observed (see Figure 43-47, *C*). Patience and observation are recommended. Without any clinical symptoms of inflammation or pain, root canal treatment should be postponed (see Figure 43-47, *D*), but close radiologic follow-up is necessary. Often root resorption of the incisors can be observed when closing the gap orthodontically. This was documented in 28.6% in the paper published by Verlinden and colleagues.[69]

If distraction is achieved by using a tooth-borne distractor, compression on the periodontal ligament may lead to resorption of the roots and buccal cortical bone of the anchor teeth.[71] Therefore controlled mobilization of the maxillary halves is essential to minimize the resistance.

Infection

Ulcerations and necrosis of the palatal mucosa can also be seen in combination with permucosal fixation of distractors[72] that may lead to loosening of the device and earlier removal. The patient is advised to clean the teeth and brush the distractor meticulously to prevent plaque retention. Otherwise gingivitis and mucositis are inevitable (Figure 43-49). A Haas-type expander with acrylic palatal flanges may cause some pressure-derived irritation of the mucosa. During distraction, an acute sinusitis maxillaris can occur as well. Therefore antibiotic prophylaxis should be applied during the active period until retention time.

Unfavorable Movement of Segments

Patients must be informed that asymmetric movement of the maxillary halves may happen, resulting in a loss of midline. If no further Le Fort I osteotomy is planned, another intervention with correction of symmetry is necessary. To avoid this complication, accurate mobilization of the locus of resistance must be performed and controlled intraoperatively. If the pterygomaxillary junction is not dissected, more distraction will be achieved in the canine-premolar area, in a V shape instead of parallel widening (Figure 43-50). The patient should not experience pain or pressure transmitted to the posterior orbit during distraction. Otherwise mobilization is insufficient. Precise identification of the width deficiency is mandatory. Distraction must be started

• **Figure 43-48** **A**, Expansion after surgically assisted rapid palatal expansion was executed too aggressively, resulting in an exposure of alveolar bone and a periodontal pocket. **B**, Partial restoration of the papilla by orthodontic movement of incisors, resulting in a recession.

• **Figure 43-49** Severe plaque and tartar retention on a bone-borne (Rotterdam) distractor in a patient who was not taking dental hygiene seriously.

• **Figure 43-50** **A**, Circular crossbite in a patient with transversal deficiency. **B**, Patient during distraction with a bone-borne distractor positioned in the premolar area. Expansion occurs in a V-shaped manner, with less expansion in the second molar area. The pterygomaxillary junction was not released in this case.

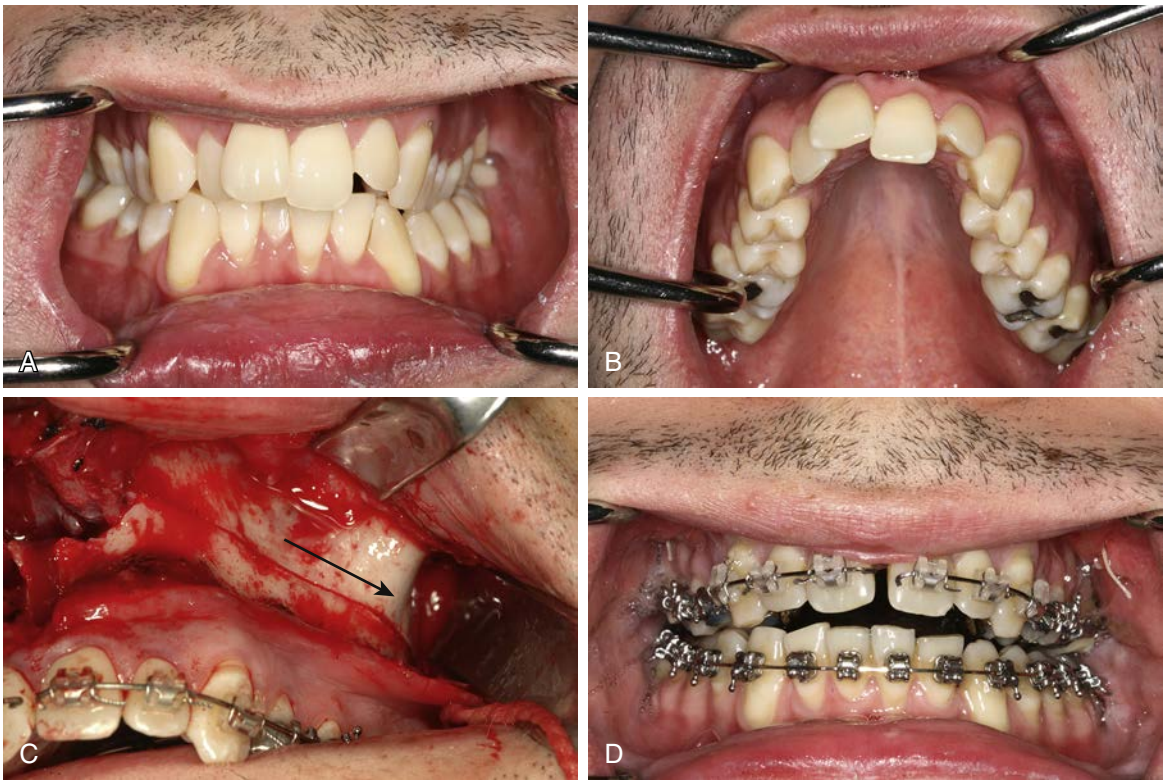
in the operating room, and in general minor widening (up to 1.5 mm) is preferable at the start. It is advisable to fill this gap with collected crushed bone mixed with enamel matrix protein.

If a palatal torus exists, this can be an obstacle in palatal expansion and needs to be removed before performing a SARPE.

Dislocation and widening of the base of the nose can be prevented by osteotomizing the nasal septum and the piriform rim and lateral nasal wall up to 1.5 cm. In cases without significant nasal stenosis, an alar cinch suture with nonresorbable material is advocated. If the design of the horizontal maxillary cut is done declining to the occlusal plane (ramped cut), the result will be a downward movement in the molar area while expanding (Figure 43-51). This will end with worsening or production of an open bite. To prevent such an adverse result, a wedge of bone in the zygomatic buttress area should be excised.[68]

Relapse

In maxillary transverse expansion, the number one complication is relapse. This is due to the poor quality and amount of bone in the midpalatal osteotomy site. It takes 6 to 12 months to achieve bony continuity; often it remains fibrous, as can be found after performing a Le Fort I osteotomy in a second step. Therefore a long-term retention up to 6 to 12 months is critical. Chamberland and Profitt[73] observed 57% relapse within the first 9 months and 43% in the following 6 months. Similar to other reports, the average expansion across the first molars was 7.6 ± 1.57 mm. Maxillary expansion with the SARME procedure is thought to be more stable than segmented Le Fort I osteotomy, but there are no clear data to support this contention. Average relapse rates in SARPE vary considerably among publications, from 5% to 25% and average 10% in the first maxillary molar.[67,74] The development of a diastema indicates that the hemimaxillae are separated and that it is not only a dental tipping. Symmetric, parallel expansion also depends on the type of distractor, bone borne or tooth borne, and if so, how and on which teeth the force is anchored (see Figure 43-45, *B*). In general, expansion is greater in the anterior than in the posterior in SARPE, correlating to the expected relapse.[75] There are multiple studies on stability after SARPE, but the data are inconsistent (age of patients, design of surgery and distraction, amount and where expansion was performed, distraction rates, points of measurements, length, and method of retention are difficult to compare).[72,76,77] Therefore it is very difficult to give a unique solution leading to success.



• **Figure 43-51** **A**, Patient with class II deformity and maxillary transversal deficiency. **B**, Collapse of dental arch in patient in **A**. **C**, A surgically assisted rapid palatal expansion is planned, and a modified Le Fort I osteotomy performed, but the osteotomy line in the anterior wall of the maxilla is cut in a ramplike way *(arrow)*. **D**, During expansion, a posterior movement of the segments is observed, with a front opening of the bite.

Zide Quick Analysis of the Chin, III-460t–461t
Zinc chloride, II-551
Zirconia
for abutment, I-636
disadvantages, I-600
framework with, I-599–601, I-600f–601f
for screw-retained restoration, I-627–628
for single anterior implant, I-630–631
Zoledronic acid (Zometa), II-508t, II-510
Zoloft. *See* Sertraline (Zoloft)
Zone of adherence, III-397–398, III-402–404
Zostrix. *See* Capsaicin (Zostrix)
Zygoma
anatomy, II-189–190, II-190f
growth rate, III-629t, III-630
malunion, II-204–205
Zygoma *(Continued)*
processes of, II-189
reconstruction
in oculoauriculovertebral spectrum, III-695
in Treacher Collins syndrome, III-713–715
zygomatic arch and, II-200
Zygoma complex, II-27t
anatomy, II-189–190
fracture, II-27t
Zygomatic arch, II-189
cross section, III-402f
fracture, II-200–207
surgical approaches, II-199–202
Zygomatic complex, surgery, II-193–194
Zygomatic fracture, II-22–24, II-25f, II-27t, II-189–210
Carroll-Girard screw, II-193–194
complications, II-202–207
diplopia caused by, II-203–204
enophthalmos caused by, II-205–206
fixation, II-200
malunion, II-204–205, II-226
management, II-189–210
patient history, II-190–191
pediatric, II-243
physical examination for, II-190–191
radiography for, II-191–193
retrobulbar hemorrhage caused by, II-206–207
soft tissue complications, II-203
surgery, II-191–194
coronal approach, II-199–200
eyebrow approach, II-195–196
Zygomatic fracture *(Continued)*
lower eyelid approach, II-196
subciliary approach, II-197–198
subtarsal approach, II-198–199
transconjunctival approach, II-196–197
upper eyelid approach, II-194–195, II-195f
vestibular approach, II-194
treatment, II-193
Zygomatic implant, I-569–583, I-678–679
axis, I-573f
deformation under function, I-571–573
design, I-573
historical perspective, I-569–570
occlusal loading, I-572f
patient selection, I-570
postoperative care, I-578
preoperative considerations, I-573
prosthesis fabrication, I-581–582
prosthetic conversion technique, I-577–578
radiographic evaluation, I-570–571
sinus infection associated with, I-579–581
stress under load, I-572, I-572f
surgical complications, I-579–581
surgical options, I-573
surgical protocol, I-574–577
trajectory, I-572–573, I-576–577
Zygomatico-orbital reconstruction, in Treacher Collins syndrome, III-725f–729f
Zygomaticofrontal region, surgical approaches, II-194–196
Zygomaticomaxillary buttress, II-211
Zygomaticomaxillary complex, II-192f
